Abstract

Nowadays, liver metastasis remains difficult to cure. When tumor cells escape and arrive in the liver sinusoids, they encounter the local defense mechanism specific to the liver. The sinusoidal cells have been widely described in physiologic conditions and in relation to metastasis during the past 30 years. This paper provides an "overview" of how these cells function in health and in diseases such as liver metastasis.

LIVER ARCHITECTURE

The liver is the largest organ of the body, constituting 2-5% of the adult body weight. It receives blood supply from two major blood vessels. The hepatic artery supplies oxygenated blood, whereas the portal vein, which provides 80% of the total blood supply, supplies nutrient-rich deoxygenated blood. The liver thus acts as a guard between the digestive tract and the rest of the body[1], transforming, detoxifying, and accumulating metabolites. The liver also produces different types of plasma proteins, such as albumin, which are delivered into the blood, as well as metabolites that are constituents of the bile[2,3].

The liver is surrounded by connective tissue, designated as Glisson's capsule. It is composed of polygonal lobules separated by connective tissue. At the periphery of the lobule, are regions that consist of bile ducts, lymphatics, nerves and branches of the hepatic artery and the portal vein. At the center of the lobule is the central vein. Hepatocytes (parenchymal cells) are the basic structural component of the liver, representing 60% of the total cell number and 80% of the total liver volume. They are arranged radially within the lobule to form cellular plates, between which the liver capillaries and the sinusoids are located.

Blood arriving through branches of the portal vein and the hepatic artery pass through the sinusoids, towards the central vein[1,4,5]. The liver sinusoids are lined with a discontinuous layer of fenestrated endothelial cells. Between the endothelial cells and the hepatocytes, is a discontinuous basal lamina and a subendothelial space named the space of Disse, through which exchange between the blood and the hepatocytes take place.

Various liver sinusoidal cells can be recognized within the sinusoids. These include, in addition to the sinusoidal endothelial cells, Kupffer cells, hepatic NK cells and stellate cells, which complement one another in performing their specialized functions.

LIVER SINUSOIDAL CELLS

The sinusoidal cells are the predominant non-parenchymal cells, comprising about 35% of the total cell number and about 17% of the total volume of the liver. These cells are divided into sinusoidal endothelial cells (44%), Kupffer cells (33%), stellate cells (10-25%) and hepatic NK cells (5%)[3,6-8].

Liver sinusoidal endothelial cells

The cells forming the sinusoidal wall (endothelium), the liver sinusoidal endothelial cells (LSECs), were first described at the electron microscopic level by Wisse[9]. They can be visualized by injection with fluorescent acetylated LDL (AcLDL)[15], latex beads of Ø 20 nm[16], or formaldehyde modified serum albumin (FSA)[17]. Katz *et al*.[18], mentioned that dendritic cells are also able to take up AcLDL; however, this cannot interfere upon injection of AcLDL in the blood, as dendritic cells are to be found within the tissue and not in the blood. The liver sieve plates are a group of open pores or fenestrae lacking a diaphragm and a basal lamina underneath the endothelium. They can be visualized by perfusion fixation of the liver. These fenestrae measured 150-175 nm in transmission electron microscopy[10]. It is assumed that the transport and exchange of fluid, solutes and particles between the space of Disse and the sinusoidal

blood occur through these open fenestrae[10,11].

A typical feature of endothelial cells is their high endocytic capacity[10]. This function is reflected in the presence of numerous endocytotic vesicles and in the effective uptake of a variety of substances from the blood by receptor-mediated endocytosis[10-13].

The typical LSECs phenotype, open fenestrae in sieve plates and lack of the basement membrane are maintained by paracrine and autocrine regulation[19]. CD31 has been mentioned as a de-differentiation and non-fenestration marker. In *in vitro* CD31 appears after 1 d monoculture; however, when co-culture with hepatocytes or stellate cells is performed, CD31 expression is prevented. This can be abolished by the addition of anti-VEGF. In accordance, VEGF stimulates the production of nitric oxide (NO)[19].

Kupffer cells

Kupffer cells are categorized as tissue macrophages and represent the largest population of their kind in the body[11]. Kupffer cells lay preferentially anchored to the periportal zone of the liver lobule[20].

Kupffer cells have irregular shapes with many cytoplasmic extensions and contain a large number of phagosomes and lysosomes that are associated with their endocytic function. Peculiarities of the ultrastructural morphology of Kupffer cells are fuzzy coat, worm-like structures, annulate lamellae and fuzzy-coated vacuoles[9,21]. Kupffer cells are scavengers that move along the sinusoids[22,23] and phagocytose foreign material present in the bloodstream; fusion of the phagosome with a lysosome leads to digestion of the ingested material. Different techniques are used to visualize these cells, such as staining for acid phosphatase activity[24] or peroxidase activity[25], and immunostaining for Fc receptors[26]. Due to their phagocytic activity, they can also be stained *in vivo* by injection with latex beads. Another option is staining for ED1, ED2, and ED3[27,28].

Hepatic NK cells

In 1976, 100 years after Kupffer cells were discovered, Wisse *et al*., described a new sinusoidal cell type[29]. These cells, designated as "Pit cells", are nowadays consideredas liver-specific natural killer cells[30] with a large granular morphology[31], and can be visualized using mAb 3.2.3 against NKR-P1A[32].

Hepatic NK cells are always in contact with LSECs, and frequently in contact with Kupffer cells[10]. There is an average of 1 NK cell per 10 Kupffer cells. Hepatic NK cells can be separated into low-density and high-density cells. The two subpopulations differ morphologically, immunophenotypically and functionally from each other and from blood NK cells, particularly in the higher toxicity of high-density Kupffer cells[10,33,34]. Morphologically, NK cells can be recognized by their electron-dense, azurophilic granules and rod-cored vesicles. Rod-cored vesicles are small inclusions found exclusively in NK cells. Each vesicle contains a straight rod structure that bridges its entire diameter[10]. Hepatic NK cells have the capacity to kill incoming malignant cells[35].

Stellate cells

Ito discovered the true function of stellate cells in 1952[36], followed by Wake[37,38]. These cells are located within the space of Disse. They contain lipid droplets rich in vitamin A, and they synthesize and secrete a variety of extra-cellular matrix proteins. The activation of stellate cells from a quiescent vitamin A storing cells to a proliferating, fibrogenic 'myofibroblast-like' phenotype is a main event following liver injury[39,40].

COLON CARCINOMA METASTASIS

The liver is the predominant site of recurrence of the disease following initial therapeutic colon surgery, mainly due to two factors. First, viable tumor cells can escape into the portal blood stream during surgical manipulation and invade the liver[41]. Second, major surgery causes a transient postoperative weakening of the immune system[42-44]. The temporary immunosuppression induced by surgery is therefore associated with enhanced risk of metastasis. When colon cancer spreads to the liver, ablation of metastasis by surgical resection, cryotherapy or radiofrequency is the only curative treatment[45]. Moreover, the vast majority of patients are not amenable to surgical resection, due to existence of multiple metastases. In order to develop new strategies aimed at preventing metastasis, it is crucial to understand the cellular defense mechanisms against tumor cells and the tumor escape mechanisms.

Cytotoxicity of sinusoidal cells towards tumor cells

When the tumor cells invade the vascular bed and metastasize into the liver, they encounter the defense mechanisms specific to the liver. Kupffer cells and hepatic NK cells are the main resident cells of immune surveillance, but sinusoidal endothelial cells also participate in this process.

Kupffer cells The most important function of Kupffer cells is defense against infections and tumor cells. Kupffer cells act as antigen presenting cells and as effector cells that act directly by phagocytosis, or indirectly by activation of other cells, e.g. NK cells[46,47]. Though Kupffer cells are constantly acting as scavengers, they can be activated through different pathways. Firstly, soluble mediators can trigger their activation. IFN-γ is the prototypical macrophage activating factor. It is central to the development of Th1-dominated immune responses, and it affects not only macrophages in an autocrine fashion, but other immune cells as well.

One of the key events during innate immune reactions is the production of IL-12, mainly by macrophages[48]. IL-12 induces NK cells to rapidly secrete IFN-γ, which then in turn activates macrophages early in the immune response. It also induces IFN-γ production by T cells. IL-18, which is produced by Kupffer cells and other cell types, is also involved in enhancing IFN-γ production by T cells[49,50]. Macrophages also secrete IFN-γ upon stimulation with IL-12 and IL-18 together. It is known that IFN-γ is a possible reducer of metastasis of colon cancer in the liver[51].

Macrophages can also be activated by direct interaction with micro-organisms or bacterial products such as lipopoly-saccharide, glucan, muramyl dipeptide and lipid A[52]. A pivotal role for IFN-γ in the clearance of various intracellular pathogens has been amply demonstrated[53,54]. It has been described that macrophages release the cytotoxic radical, NO[55,56]. *In vitro* studies suggested that NO induces mitochondrial dysfunction in tumor cells

followed by membrane barrier dysfunction in the liver sinusoid[57,58]. Another important cytotoxic factor released by activated macrophages is tumor necrosis factor alpha (TNF-α), which is produced in both soluble and membrane-bound forms. After binding to its receptor, apoptosis can be induced in the target cell[59].

Cytotoxicity of macrophages can be classified into antibody-dependent and antibody-independent cell-mediated cytotoxicity. Both pathways are contact dependent and induce tumor cell death after a number of hours. Antibody-dependent cell-mediated cytotoxicity is based on the recognition of an antibody-coated target by Fc receptors on the effector cells[60-62]. Upon cross-linking of the Fc receptor, secretion of cytotoxic mediators occurs. Secretion of reactive oxygen species, IL-1 and TNF-α are probably involved[63]. Antibody-independent cell-mediated cytotoxicity involves binding to the macrophage followed by translocation of the lysosomal organelles to the target[47]. Moreover, cytotoxicity towards tumor targets involves cytolysis and phagocytosis[64].

In certain pathophysiologic conditions, apoptosis is chaotic and non-selective, may be massive and occurs persistently over an extended period of time[65]. A large number of apoptotic bodies produced are phagocytosed by Kupffer cells. It has recently been reported that engulfment of apoptotic bodies results in the generation of death ligands, such as FasL and TNF-α on the membrane of the Kupffer cells, but engulfment of latex beads does not produce a similar response[59]. This means that uptake of apoptotic bodies induces an additional immunologic response involving liver inflammation and fibrosis[59,66].

Hepatic NK cells Cytotoxic lymphocytes (CTL) and NK cells induce target cell death by means of granules and by death receptor-mediated pathways. Apoptosis refers to orchestrated cell death that is indispensable for maintenance of homeostasis. Characteristics of apoptosis are chromatin condensation, nuclear fragmentation, membrane blebbing, cell shrinkage, protein degradation and internucleosomal DNA fragmentation. Most of the morphological changes are caused by a set of cysteine proteases that are activated specifically in apoptotic cells. These death proteases are homologous to each other and are members of a large protein family known as caspases[67]. Over a dozen caspases have been identified in humans, and it has been suggested that about two-thirds of them function in apoptosis[68,69]. Different pathways can induce apoptosis, of which the Fas/FasL pathway is the best known. This pathway is frequently used by cytotoxic T cells and other immunocompetent cells. Stimulation of the Fas receptor (CD95) with Fas ligand recruits the proform of the initiator caspase 8, by interaction with the adapter molecule Fas-associated death domain through death domains and death effector domains. This leads to the formation of a complex called the death inducing signaling complex. Subsequently, procaspase 8 is cleaved autocatalytically to yield the active initiator caspase 8. The consequences of the activation of caspase 8 depend on the cell type. In type 1 cells, the other members of the caspase family (such as caspase 3) are activated directly[70]. In type 2 cells, caspase 8 activation results in the cleavage of the pro-apoptotic Bcl-2 family member Bid. Subsequently Bid and Bax are translocated to the mitochondria to cause release of cytochrome *c*. This results in the activation of caspase 9 through interaction with the adapter molecule apoptotic protease-activating factor. Caspase 9 activates caspase 3, which can then perform its function[71,72].

The granules of CTL contain various proteins, some of which are known to be involved in target cell death, such as perforin and granzyme. Various isoforms of the granzymes have been described. After granzyme B enters the target cell, it can directly cleave procaspase 3, Bid and inhibitor of caspase-activated DNase, thereby inducing apoptosis[71,73-75]. Death induced by granzyme A appears to be independent of the pathways used by granzyme B[75,76]. Granzyme A does not activate caspases in target cells, nor does it induce cleavage of other granzyme B substrates. The functions of the other granzyme isoforms remain unclear[76]. Perforin forms transmembrane pores and is an essential enabler of granzyme-mediated apoptosis[77].

Liver sinusoidal endothelial cells LSECs, like Kupffer cells, express an Fc receptor that may be involved in immunological defense. FcR-mediated uptake of IgG-immune complex has been shown to enhance presentation of antigens by MHC class II[78]. This process might take place in a compartment reminiscent of the multi-vesicular compartments observed in the LSECs. It is therefore conceivable that these organelles are involved in processing and presentation of antigenic peptides. In contrast to Kupffer cells, however, the multi-vesicular compartments observed in LSECs are not rich in MHC class II, which might indicate that LSECs are not involved in antigen presentation[79-81]. Nevertheless, Knolle *et al*.[82,83], demonstrated that both Kupffer cells and LSEC have MHC class II, and that both of these cells are involved in antigen presentation. However, LSECs failed to induce differentiation towards inflammatory Th1[82]. Furthermore, antigen presentation of soluble blood-borne antigens leads primarily to tolerance, instead of immunosurveillance. LSECs are known to express CD80 and CD86, molecules that are present on professional antigen-presenting cells, such as dendritic cells[14]. In addition, LSECs play a key role in receptor-mediated uptake, in degradation of macromolecules from the sinusoidal blood[84-86] and in the clearance of circulating apoptotic bodies[83,84]. Katz *et al*.[18], reported about some conflicting data, low or absent MHC class II, CD86 and CD11c. However, they mentioned a high capacity for AG uptake *in vivo* and *in vitro*. According to Knolle *et al*.[14,83], LSECs were unable to stimulate allogeneic T cells.

LSECs are known to secrete NO and can induce apoptosis in different types of cancer cells, such as lymphoma and colorectal carcinoma[87,88]. NO has also been reported to function as a cytolytic factor in macrophage-mediated cancer cell cytotoxicity[89].

Seventeen days after injection of colon carcinoma cells CC531s into the mesenteric vein, metastases are observed as nodules of 1-3 mm diameter on the surface of the liver lobes. When the liver sinusoidal cells are stained *in vivo* with FSA, no staining can be detected in the center of the metastasis nodule (Figure 1). On the border of the tumor some positive staining can be seen, but of lower intensity than in normal tissue. It is known that nodules of 1-2 mm diameter have no internal vascularization, and that the cells

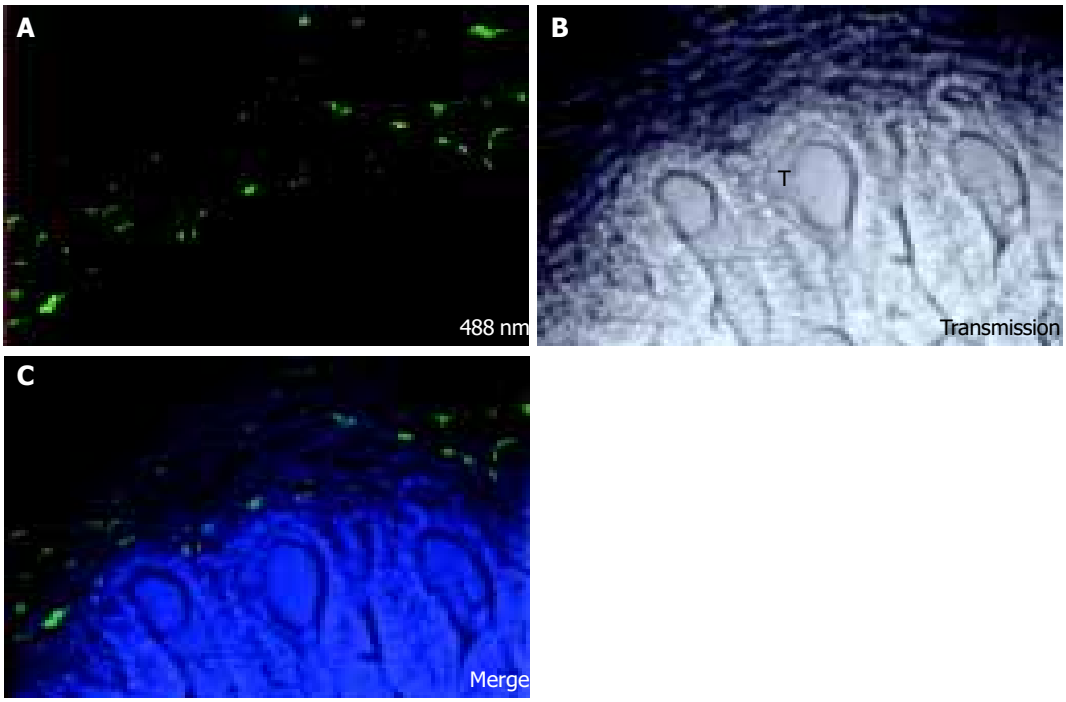

Figure 1 CC531s cells were injected into the mesenteric vein and were left in circulation for 17 d. One hour before perfusion fixation, FSA was injected into the penile vein. FSA stains only LSECs. Confocal microscopy was conducted and images were named after corresponding laser lines. **A**: FSA staining was measured with CLSM; fluorescence was observed only in part of the scanned field; **B**: Transmission image of the same field, with the tumor region in the lower part of the field. Formation of cryptae of the tumor (T) can be observed; **C**: After merging the two images, no staining was observed inside the tumor region. Image size: 500 μm×500 μm.

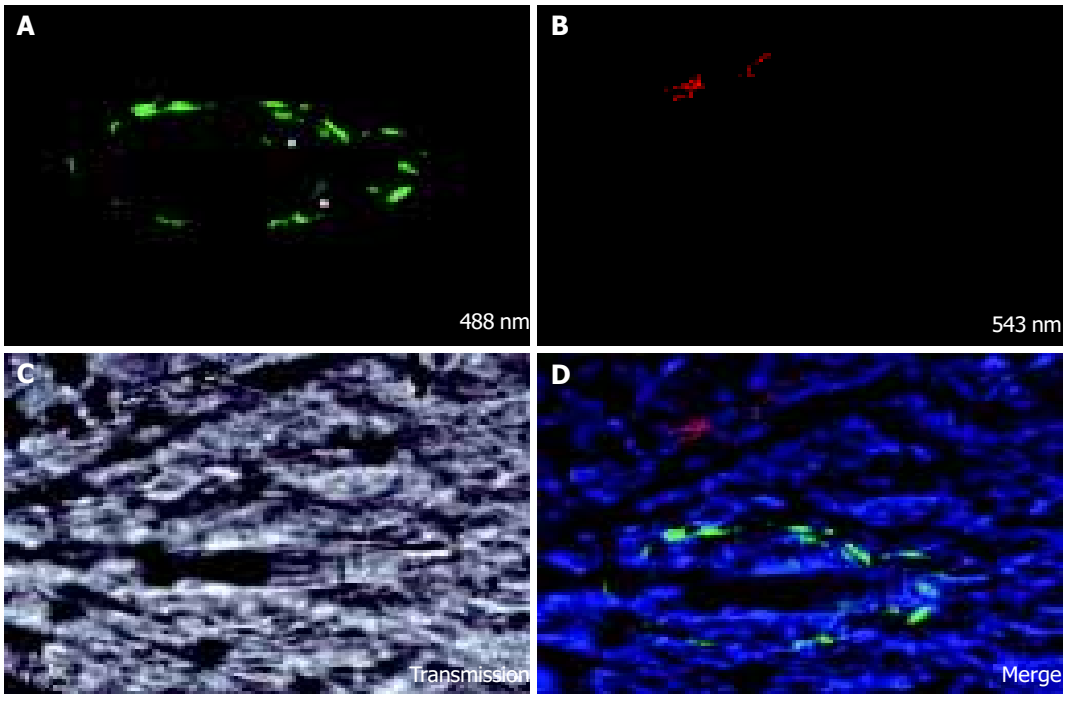

Figure 2 CC531s were labeled with DiO, injected into the mesenteric vein. After 24 h, Kupffer cells (KC) were stained *in vivo* with TRITC-labeled latex beads, and the liver was fixed by perfusion. Confocal microscopy was conducted and images were named after corresponding laser lines. **A**: Group of CC531s was visualized; **B**: KC was visualized by the up-take of fluorescent latex beads; **C**: The rest of the field was examined with the transmission function; **D**: CC531s proliferating inside the liver parenchyma and inside the group of CC531s cells, a vessel was seen. The vessel is much straighter than the normal liver sinusoids, indicating a newly formed vessel. Image size: 158.7 μm×158.7 μm.

receive nutrients and oxygen simply by diffusion (prevascular phase)[90]. Vessel formation, however, was observed with confocal microscopy in a cell cluster of 12 CC531s cells 24 h after injection of CC531s cells (Figure 2) and it is

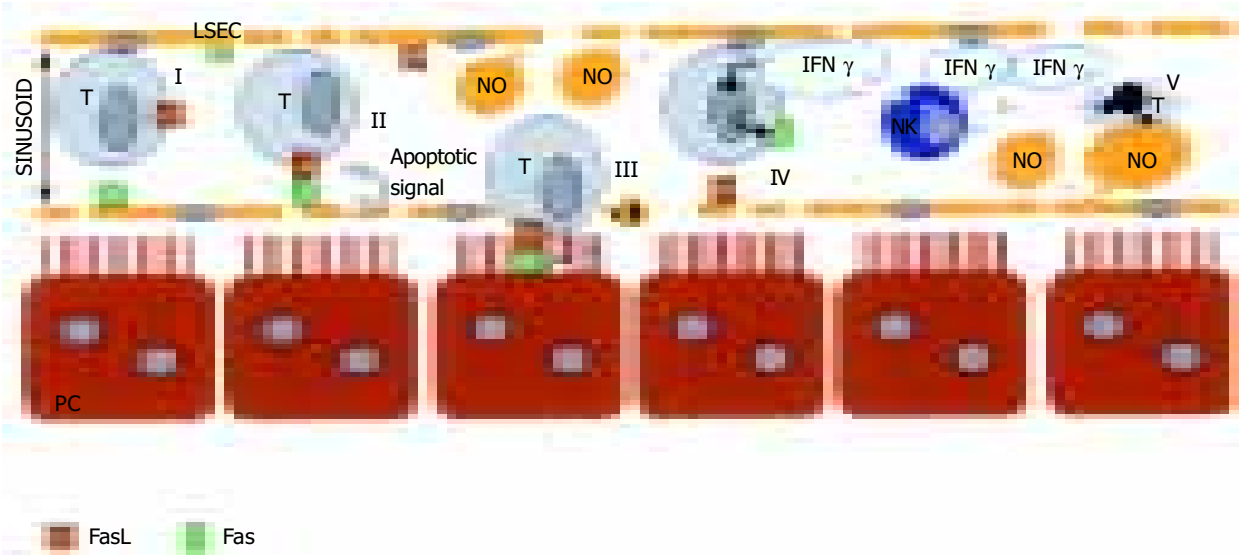

Figure 3 Schematic overview of the early metastatic events occurring along the liver sinusoid in which the LSECs and CC531s colon carcinoma cells (T) play a central role. Fas expressing LSECs (I) undergo apoptosis by FasL expressing CC531s (I and II). By doing so, the colon cancer cells provide themselves a gateway towards the liver parenchyma, as the LSECs retract and gaps are induced in the liver sinusoidal lining (III). Subsequently, the CC531s cells have free access to the hepatocytes, which expresses Fas (III). By this means, CC531s are able to invade in the liver parenchyma. LSECs express FasL and CC531s express Fas (IV). When IFN-γ is present in the sinusoid, Fas becomes active. NO produced by the LSECs induces apoptosis in CC531s cells only when IFN-γ is present (V). As a result the IFN-γ-activated pathway supports the immune system by killing tumor cells. Note: Parenchymal cell (PC). This figure is a compilation of the data reported in Refs. [93,94,96,97].

known that colon carcinoma cells produce angiogenic factors such as VEGF[91]. However, even though angiogenic factors permit formation of vessels in micro-metastases as shown in Figure 2, these vessels are incapable of extending to provide a blood supply within macro-metastasis nodules as shown in Figure 1.

CONCLUSION

In conclusion, with our published studies, we add these results that most of the CC531s cells trapped in the sinusoids get phagocytosed by the Kupffer cells and only 6% of the cells are living in the sinusoid or in the space of Disse[92]. Hepatic NK cells help in the removal of the CC531s. In NK cells, depleted rates up to 33% of the CC531s are free of interactions with Kupffer cells[92]. In order to understand the pathways involved, *in vitro* studies were conducted and the following conclusions were made. CC531s, colon carcinoma cells, are able to kill LSECs by usage of Fas/FasL pathway[94] (Figure 3). *In vivo*, destruction of the sinusoidal lining can be observed and is also confirmed by others[93-95]. However, when CC531s are pre-treated with IFN-γ, the outcome of apoptosis in cocultures is inversed. Then, LSECs are able to induce apoptosis in pre-treated CC531s by NO pathway[96,97] (Figure 3). Generally we state that Kupffer cells, NK cells, and LSECs orchestrate together in the removal of CC531s.

ACKNOWLEDGMENTS

We want to thank Mrs. C. Seynaeve, M. Baekeland, D. Blijweert, and Mrs. Chris Derom for excellent technical assistance. Also thanks to Dr. B. Smedsrød for giving the FSA. The members of the "Australian Key Center for Microscopy and Microanalysis" of The University of Sydney are gratefully acknowledged for excellent administrative, technical, and practical support.

Abstract

AIM: To investigate the association between the genetic polymorphisms of ADH2 and ALDH2, lifetime alcohol consumption and esophageal cancer risk in the Taiwanese men.

METHODS: Between August 2000 and June 2003, 134 pathologically-proven esophageal squamous cell carcinoma male patients and 237 male controls were recruited from Kaohsiung Medical University Hospital and Kaohsiung Veterans General Hospital in southern Taiwan. ADH2 and ALDH2 polymorphisms were genotyped using PCR-RFLP.

RESULTS: Compared to those with ADH2*2/*2, individuals with ADH2*1/*2 and ADH2*1/*1 had 2.28- and 7.14-fold, respectively, increased risk of developing esophageal cancer (95%CI = 1.11-4.68 and 2.76-18.46) after adjusting for alcohol consumption and other covariates. The significant increased risk was also noted among subjects with ALDH2*1/*2 (adjusted OR (AOR) = 5.25, 95%CI = 2.47-11.19), when compared to those with ALDH2*1/*1. The increased risk of esophageal cancer was made greater, when subjects carried both ADH2*1/*1 and ALDH2*1/*2, compared to those with ADH2*1/*2 or ADH2*2/*2 and ALDH2*1/*1 (AOR = 36.79, 95%CI = 9.36-144.65). Furthermore, we found a multiplicative effect of lifetime alcoholic consumption and genotypes (ADH2 and ALDH2) on esophageal cancer risk.

CONCLUSION: Our findings suggest that polymorphisms of ADH2 and ALDH2 can modify the influence of alcoholic consumption on esophageal cancer risk.

INTRODUCTION

Epidemiologic studies have demonstrated that drinking alcoholic beverages is associated with the development of cancers in the oral cavity, pharynx, larynx, and esophagus[1]. Our previous study also reported that, in addition to cigarette smoking and areca chewing, alcohol consumption is one of the leading risk factors for esophageal cancer in Taiwan[2]. In that study, we found that subjects who consumed more than 1 220 g/year of alcohol (about 4 cans of beer per day for 20 years) in a lifetime were found to have a 9.7-fold higher risk for esophageal cancer than those who did not drink (95%CI = 4.3-22.0).

When ethanol is consumed through drinking, it is metabolized primarily by class I alcohol dehydrogenase (ADH2) into acetaldehyde, an intermediate metabolite, and then it is metabolized by aldehyde dehydrogenase (ALDH2) into acetic acid in humans[3]. Acetaldehyde, a well-known carcinogen in animals, plays an important role in alcohol toxicity in humans[4].

Genetic variation in the ability to metabolize alcohol might be associated with esophageal cancer risk. ADH2 and ALDH2 genes are located on chromosomes 4q22 and 12q24, respectively. One amino acid has been found to change from arginine (CGC) (ADH2*1) to histidine (CAC) (ADH2*2) in ADH2 gene at codon 47 of exon 3[5]. Bosron and Li[3] has found ADH2*2/*2 to have about 40 times

higher V_{max} than ADH2*1/*1, because ADH2*2/*2 encodes a superactive subunit of ADH2 in the oxidation of ethanol, causing acetaldehyde to accumulate in the circulation. For ALDH2, a single nucleotide transition from glutamic acid to lysine (G→A) at codon 487 of exon 12 has also been reported[6]. The mutant allele of ALDH2*2 (A/A) has relatively lower ALDH2 activity than ALDH2*1 allele (G/G)[7] in the metabolization of acetaldehyde into acetic acid, leading to the accumulation of circulatory acetaldehyde[8].

Many studies from Japan have reported that subjects with ADH2*1/*1 or ALDH2*1/*2 genotypes were much more susceptible to esophageal cancer than those with the genotypes[9-15]. In Taiwan, however, only one study has reported the relationship between genetic polymorphisms of ADH2 and ALDH2 and esophageal cancer risk[16]. In that study, Chao and his colleagues[16], studying 59 esophageal cancer patients who were also alcoholics and 222 alcoholic controls, found the allele frequencies of ADH2*1 and ALDH2*2 in alcoholic cancer patients to be 51% and 31%, respectively, much higher frequencies than those found in alcoholics without cancer (39%; $P<0.025$ and 8%; $P<0.001$). In this study, we further investigated the independent or combined effects of the ADH2 and ALDH2 gene polymorphisms on esophageal cancer risks in the Taiwanese men. We also evaluated interaction of ADH2 and ALDH2 with alcohol consumption and study the interaction's relationship to esophageal cancer risk.

MATERIALS AND METHODS

Patients and controls

In this hospital-based case-control study, we recruited male case patients with new histological diagnosis of esophageal squamous cell carcinoma from Kaohsiung Medical University Hospital and Kaohsiung Veterans General Hospital in the southern Taiwan from August 2000 to June 2003. The Department of Preventive Medicine at each hospital chose 1-2 age-matched (±4 years) healthy male controls who had no malignancies to give blood specimens at the time as the cases. In total, 134 cases and 237 controls were interviewed and genotyped from peripheral blood specimens.

Using a standardized questionnaire, trained interviewers collected demographic characteristics and information about cigarette, alcohol and areca consumption from study subjects[2]. Information on habitual substance use included whether the subject had been a habitual areca chewer, cigarette smoker, or an alcoholic in his or her lifetime, what year the subject started and quitted, the duration of consumption and the daily amount consumed, and type of alcoholic beverage consumed. This study was approved by Kaohsiung Medical University Hospital's IRB. Informed consent was obtained from all subjects.

Genotyping

ADH2 polymorphisms at codon 47 were determined by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP)[17,18]. The two primers were 5'-AAT CTT TTC TGA ATC TGA ACA G-3' (upstream) and 5'-GAA GGG GGG TCA CCA GGT TGC-3' (downstream). The PCR was carried out with 100 ng/μL genomic DNA, 10× buffer, 2.5 mmol/L dNTP, 20 pmol/L of each primer, 50 mmol/L $MgCl_2$ and 5 U Taq polymerase in a 25 μL reaction mixture. The PCR condition was performed by initial denaturation at 95 ℃ for 5 min, followed by 40 cycles at 95 ℃ for 1 min, 55 ℃ for 57.5 s, 72 ℃ for 45 s and a final extension at 72 ℃ for 10 min. The final PCR product was digested with *Mae*III for 4 h at 55 ℃ and electrophoresed and viewed on a 3% agarose gel. When a *Mae*III restriction site was presented, the 94-bp fragment was digested into two fragments: lengths of 59 and 35 bp. Individuals with ADH2*2/*2 and ADH2*1/*2 had 59- and 35-bp fragments and 94-, 59- and 35-bp fragments, respectively, whereas those with ADH2*1/*1 had only a 94-bp fragment (Figure 1).

ALDH2 polymorphisms at codon 487 were also determined by PCR-RFLP[11,19]. The DNA sample was amplified with two primers: 5'-CAA ATT ACA GGG TCA ACT GCT-3' (upstream) and 5'-CCA CAC TCA CAG TTT TCT CTT-3' (downstream). The PCR was carried out with 100 ng/μL genomic DNA, 10× buffer, 2.5 mmol/L dNTP, 20 pmol/L of each primer, 50 mmol/L $MgCl_2$ and 5 U Taq polymerase in a 25 μL reaction mixture. The PCR condition was performed by initial denaturation at 95 ℃ for 5 min, followed by 35 cycles at 94 ℃ for 15 s, 58 ℃ for 1 min 30 s, 72 ℃ for 30 s and a final extension at 72 ℃ for 10 min. The final PCR product was digested with *Mbo*II for 16 h at 37 ℃ and electrophoresed and viewed on a 12% polyacrylamide gel. When a *Mbo*II restriction site was presented, the 135-bp fragment was digested into two fragments: lengths of 126 and 9 bp. Individuals with ALDH2*1/*1 and ALDH2*1/*2 had 126- and 9-bp fragments and 135-, 126- and 9-bp fragments, respectively, whereas those with ALDH2*2/*2 had only a 135-bp fragment (Figure 2).

In addition, 20 case patients provided paired samples of tumors and peripheral blood for genotyping. We found that the evidence for both genotypes for ADH2 and ALDH2 were exactly the same in each case patient.

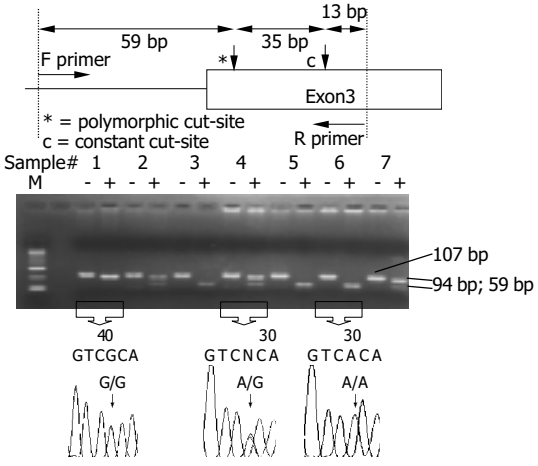

Figure 1 PCR-RFLP analyses of exon 3, codon 47 polymorphism of ADH2. M represents a size marker. Sample 1 is ADH2*1/*1; samples 2, 4, and 7 are ADH2*1/*2; samples 3, 5, and 6 are ADH2*2/*2. + and - represent the PCR product with and without restriction enzyme *Mae*III.

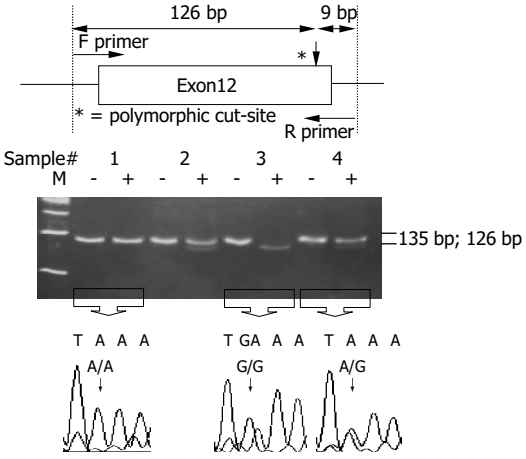

Figure 2 PCR-RFLP analyses of exon 12, codon 487 polymorphism of ALDH2. M represents a size marker. Sample 1 is ALDH2*2/*2; sample 3 is ALDH2*1/*1; samples 2 and 4 are ALDH2*1/*2. + and - represent the PCR product with and without restriction enzyme *Mbo*II.

Laboratory QA/QC

Three different genotypes of each ADH2 and ALDH2 were first sequenced to confirm the findings, then in each genotyping set (~10 samples), we included one positive control and one negative control sample. The positive control sample was included to ensure complete digestion of the PCR product by restriction enzymes. The negative control was placed with the same reagents as those used with actual samples, with the exception of DNA templates. In addition, about 3% of subjects (n = 12/378) were randomly selected for re-genotyping (the results were the same).

Statistical analysis

Hardy-Weinberg equilibrium statistic was calculated first. Genotype frequencies, demographic characteristics, and substance use (cigarette, alcohol, and areca) in cases and controls were compared by Student's t, χ^2, or Fisher's exact tests.

For substance use, subjects who reported smoking more than 10 cigarettes/week for at least 6 mo were defined as cigarette smokers, those who reported regularly chewing betel quid for at least 6 mo were defined as betel chewers, and those who reported drinking beer, wine, or distilled spirits more than one time per week for at least 6 mo were defined as alcoholics.

Using multiple logistic regression models, we determined the relationship of ADH2 and ALDH2 polymorphisms with esophageal cancer risk after adjusting for other covariates, including age (continuous variable), educational level (>high school, high school, and <high school), cigarette smoking (yes *vs* no), alcohol consumption (yes *vs* no) and areca chewing (yes *vs* no). Since the interactive effect between lifetime alcohol consumption and ADH2 and ALDH2 polymorphisms on esophageal cancer risk was also examined in this study, lifetime consumption of alcoholic beverage was calculated by multiplying the concentration of alcohol in the consumed beverage by the amount consumed per day by the number of years consumed, resulting in number designated as grams per year. The median cut-off point for lifetime alcohol consumption was 1 500 g/year, which equaled an average of five 300-350 cm^3 cans of beer (5% alcohol) per day for 20 consecutive years. Subjects were also classified as non-drinkers if they consumed ≤1 500 g/year, and those who consumed >1 500 g/year were used for the subsequent interaction analysis. The data were analyzed using the SAS 8.1 statistical package; all P-values were two-sided.

RESULTS

We found 231 pathology-proven cases of esophageal squamous cell carcinoma at Kaohsiung Medical University Hospital and Kaohsiung Veterans General Hospital between August 2000 and June 2003. Mean ages (±SD) of the recruited patients (n = 134) and non-recruited patients (n = 97) were 58.9±12.6 and 59.0±13.6 years, respectively, with no significant difference (P = 0.81).

Mean ages (range) of the 134 cases and 237 controls were 58.9 years (34-82 years) and 57.8 years (34-82 years), respectively, with no significant difference (Table 1). Educational level (P<0.0001) and the habitual use of cigarettes (P<0.0001), alcohol (P<0.0001), and areca (P<0.0001) were most significant predictors of esophageal cancer risk. We found cigarette smokers, alcoholics, and areca chewers had a 13.61-, 9.90-, and 13.33-fold higher risk, respectively, for developing esophageal cancer than non-smokers, non-drinkers, and non-chewers (95%CI = 6.81-27.21, 5.89-16.64, and 7.33-24.26, respectively) (data not shown).

The prevalence (number) of ADH2*1/*1, ADH2*1/*2, and ADH2*2/*2 in the controls was 6.8% (16/237), 38.4% (91/237), and 54.9% (130/237), respectively. The gene frequency of the ADH2*1 allele was 25.9%. The distribution of the different genotypes among the 237 controls closely conformed to expected Hardy-Weinberg frequencies (χ^2 = 0.00; df = 2; P = 1.00). The prevalence (number) of ALDH2*1/*1, ALDH2*1/*2, and ALDH2*2/*2 in the controls was 50.6% (120/237), 44.3% (105/237), and 5.1% (12/237), respectively. The gene frequency of the ALDH2*2 allele was 27.2%. The distribution of the different genotypes among the 237 controls also closely

conformed to expected Hardy-Weinberg frequencies (χ^2 = 1.95; df = 2; P = 0.38).

Table 2 shows the association of ADH2 and ALDH2 genotypes with esophageal cancer risk before and after adjusting for other covariates. Subjects with ADH2*1/*2 and ADH2*1/*1 had 2.28 (95%CI = 1.11-4.68)- and 7.14 (95%CI = 2.76-18.46)-fold, respectively, greater risk of developing esophageal cancer than the subjects with ADH2*2/*2, after adjusting for age, educational level, cigarette smoking, alcohol consumption, areca chewing, and ALDH2 polymorphism. In addition, the effect of ADH2*1/*1 was still significantly elevated (adjusted OR (AOR) = 4.80; 95%CI = 2.02-11.44), when compared to the combined ADH2*1/*2 and ADH2*2/*2 (data not shown).

For ALDH2 genotypes, subjects with ALDH2*1/*2 (AOR = 5.25, 95%CI = 2.47-11.19) were found to have a significantly more increased risk of esophageal cancer compared to those with ALDH2*1/*1 (Table 2). The risk for subjects with ALDH2*2/*2 was slight, but not significantly higher than those with ALDH2*1/*1 (AOR = 2.44; 95%CI = 0.44-13.55). However, compared to ALDH2*1/*1, the combined risk effect of ALDH2*1/*2 and ALDH2*2/*2 was significantly elevated (AOR = 5.20; 95%CI = 2.46-11.00) (data not shown).

Table 3 shows the joint effect of ADH2 and ALDH2 genotypes on esophageal cancer risk. The significantly increased trend for esophageal cancer risk was noted in subjects with ADH2*1/*2 or *2/*2 and ALDH2*1/*1, ADH2*1/*1 and ALDH2*1/*1, ADH2*1/*2 or *2/*2 and ALDH2*1/*2, to ADH2*1/*1 and ALDH2*1/*2. However, the increased risk was not pronounced in a group of ALDH2*2/*2, possibly because of small sample size.

Table 4 shows the effect of a lifetime interaction between alcohol consumption and ADH2 and ALDH2 genotypes on esophageal cancer risk. Using non-drinkers with ADH2*1/*2 or *2/*2 and ALDH2*1/*1 as a baseline, we found that the higher the lifetime consumption of alcohol, the greater the risk for esophageal cancer in each category of ADH2 and ALDH2 genotypes, except for a group of ALDH2*2/*2. When categorizing the subjects into amount of alcohol consumed in a lifetime (non-drinkers, drinkers with ≤1 500 g/year, or drinkers with >1 500 g/year), we found an increased trend for esophageal cancer risk in the more highly susceptible ADH2 and ALDH2 genotypes. Compared to baseline, the risk for developing esophageal cancer increased in subjects carrying ADH2*1/*1 and ALDH2*1/*2 and consuming more than 1 500 g/year of alcohol in a multiplicative fashion (AOR = 139.35, 95%CI = 10.05-∞, Table 5).

DISCUSSION

The present study finds alcohol consumption to be the major risk of esophageal cancer in the Taiwanese men. However, ethanol *per se* is not carcinogenic[1]. Researchers have paid much more attention to the relationship between acetaldehyde, the first metabolite of alcohol, and cancer risk, even though the detailed mechanisms of alcohol-associated cancers, such as esophageal cancer are still puzzling. Ethanol is metabolized mainly by ADH2 to become acetaldehyde and then further metabolized by ALDH2 to form acetic acid. Acetaldehyde is a very active intermediate able to attack DNA or protein to form adducts[20,21]. In addition, Yin and his colleagues[22] have reported the ADH activity in the 15 specimens of esophageal mucosa from the Chinese men to be about four-fold greater than that of gastric mucosa in the same population (n = 7). In contrast, the esophageal ALDH activity is only 20% of that in the stomach, suggesting that the concentration of acetaldehyde in esophagus is possibly much higher than that in the stomach after consuming the beverages.

Since the major metabolic pathway for ethanol is determined by ADH2 and ALDH2, polymorphisms on these two genes may affect the formation of acetaldehyde. For ALDH2 genotypes, Enomoto and his colleagues[23] reported that subjects with ALDH2*1/*2 had an average increase in peak blood acetaldehyde level that was five-fold higher than those with ALDH2*1/*1 after drinking a small amount of ethanol (0.1 g/kg of body weight), though this study did not investigate the effect of ADH2 genotypes on

acetaldehyde level. Another study done by Mizoi and his colleagues[24] found that, after consuming beverages, the blood acetaldehyde concentrations in those with ALDH2*2/*2 and ALDH2*1/*2 were 19- and 6-fold higher than in those with ALDH2*1/*1, respectively. The results of these studies suggest that subjects with ALDH2*2/*2 and ALDH2*1/*2 may have a higher risk of developing esophageal cancer than those with ALDH2*1/*1, which is consistent with our findings.

However, our study found no subjects with the highest susceptible genotype of ALDH2, ALDH2*2/*2, to be drinkers. Crabb *et al*.[8], and Thomasson *et al*.[25], found that individuals deficient in ALDH2 activity (ALDH2*2/*2 genotype) can develop intense facial flushing responses, because of high blood acetaldehyde levels, after drinking alcohol. This unpleasant discomfort may prevent people from consuming beverages and may keep them from developing alcoholism, which can explain our findings in this study.

In this study, we found subjects with ADH2*1 allele had a higher risk of developing esophageal cancer than those with ADH2*2 allele. Previous epidemiological studies from Japan also reported a significantly higher risk for esophageal cancer among Japanese drinkers with ADH2*1 allele, compared to those with ADH2*2 allele[10,15], which were consistent to our findings. In contrast, Mizoi and his colleagues[24] did not find any significant differences of blood acetaldehyde levels among the three ADH2 genotype groups. However, in an *in vitro* study done by Yin and his colleagues[26], the enzyme activity in ADH2*2 allele was reported to be much higher that that of ADH2*1, suggesting that ethanol is much easily metabolized by ADH2*2 allele to become acetaldehyde. This finding conflicts with the observations from epidemiological studies[10,12,13,15,16] and our study as well. Thus, the detailed mechanism of this ADH2 polymorphism, which may be involved in another metabolic pathway of ethanol or closely linked with other functional polymorphisms, on esophageal cancer risk deserves further examination.

The frequency of ADH2 and ALDH2 genotypes varies across different racial groups (Table 5). ADH2*1 allele is found to be predominant in Caucasians (~90%)[27], whereas most of the Asian people carry the ADH2*2 allele[25,28]. In addition, the frequency of ALDH2*1 allele is higher in Caucasian populations than in Asian populations. These differences in gene distributions, which affect the metabolism of ethanol, may explain why the Asian people experience facial flushing and other marked adverse reactions to drinking alcoholic beverages more easily than Caucasians[29].

Our study found 20 case patients with the paired DNA specimens of tumors and peripheral blood to have exactly the same genotypes of ADH2 and ALDH2 between them. Although the sample size is relatively small, it can be speculated that ADH2 and ALDH2 genes might be involved in an early rather than an advanced stage of esophageal tumorigenesis. This is a hospital-based case-control study, but it is unlikely that individuals carrying one particular genotype were recruited differently in the cases and controls. In addition, in this study, the genotype distribution among the controls closely conformed to Hardy-Weinberg expected frequencies. Information about the consumption of alcoholic beverages was collected from questionnaires, which may randomly misclassify the interest of exposure between the cases and controls and result in the underestimation of

our findings.

In conclusion, the present study found ADH2 and ALDH2 genotypes to be independently associated with esophageal cancer risk in the Taiwanese men. In addition, we have reported the interaction between the combined effect gene and environment on esophageal cancer risk. Subjects who consumed alcoholic beverages and carried susceptible genotypes of ADH2 and ALDH2 experienced a multiplicative increase in risk of developing esophageal cancer, much higher than those who were non-drinkers and did not carry susceptible genotypes of ADH2 and ALDH2. Our present findings can provide additional information about the role of alcohol on esophageal cancer risk in Taiwan.

Abstract

AIM: To explore the effect of six bile salts, including glycocholate (GC), glycochenodeoxycholate (GCDC), glycodeoxycholate (GDC), taurocholate (TC), taurochenodeoxycholate (TCDC), taurodeoxycholate (TDC), and two bile acids including cholic acid (CA) and deoxycholic acid (DCA) on esophageal cancer Eca109 cell line.

METHODS: Eca109 cells were exposed to six bile salts, two bile acids and the mixed bile salts at different concentrations for 24-72 h. 3-[4,5-Dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) assay was used to detect the cell proliferation. Apoptotic morphology was observed by phase-contrast video microscopy and deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) assay. Sub-G1 DNA fragmentations and early apoptosis cells were assayed by flow cytometry (FCM) with propidium iodide (PI) staining and annexin V-FITC conjugated with PI staining. Apoptosis DNA ladders on agarose were observed. Activation of caspase-3 was assayed by FCM with FITC-conjugated monoclonal rabbit anti-active caspase-3 antibody and expressions of Bcl-2 and Bax proteins were examined immunocytochemically in 500 μmol/L-TC-induced apoptosis cells.

RESULTS: Five bile salts except for GC, and two bile acids and the mixed bile salts could initiate growth inhibition of Eca109 cells in a dose- and time-dependent manner. TUNEL, FCM, and DNA ladder assays all demonstrated apoptosis induced by bile salts and bile acids at 500 μmol/L, except for GC. Early apoptosis cell percentages in Eca109 cells treated with GCDC, GDC, TC, TCDC, TDC, CA at 500 μmol/L for 12 h, DCA at 500 μmol/L for 6 h, and mixed bile salts at 1 000 μmol/L for 12 h were 7.5%, 8.7%, 14.8%, 8.9%, 7.8%, 9.3%, 22.6% and 12.5%, respectively, all were significantly higher than that in control (1.9%). About 22% of the cell population treated with TC at 500 μmol/L for 24 h had detectable active caspase-3, and were higher than that in the control (1%). Immunocytochemical assay suggested that TC down-regulated Bcl-2 protein level and up-regulated Bax protein level.

CONCLUSION: GCDC, GDC, TC, TCDC, TDC, CA and DCA, except for GC, can inhibit growth and induce apoptosis of esophageal cancer Eca109 cells. Activation of caspase-3, decreased Bcl-2 protein and increased Bax protein are involved in TC-induced apoptosis of Eca109 cells.

INTRODUCTION

Duodeno-gastro-esophageal reflux or bile reflux is involved in the pathogenesis of reflux esophagitis, Barrett's esophagus (BE), and esophageal adenocarcinoma. Recent studies have shown that bile acids and bile salts present frequently in the refluxate of BE patients, and influence the development and persistence of metaplasia[1-3]. Bile salts can enter mucosal cells in their non-ionized lipophilic form, cause injuries to cell membranes and tight junctions, and cell necrosis[4]. However, studies have shown that different bile salts induce cell apoptosis[5-7]. Whether different bile salts induce apoptosis of esophageal cancer cells remains unknown. Therefore, it is necessary to identify the effect of bile salts on esophageal cancer cells.

Glycine-conjugated bile acids such as glycocholic (GC) and glycochenodeoxycholic acids (GCDC) induce hepatocyte apoptosis *in vitro*[8], whereas taurine-conjugated bile acids such as taurocholic (TC) and taurochenodeoxycholic acids (TCDC) are well tolerated by hepatocytes[9,10]. Cell apoptosis is specifically induced by hydrophobic bile salts such as deoxycholate (DC) and dihydroxy bile salt, whereas conjugated bile salt glycodeoxycholate (GDC) and trihydroxy bile salt (TDC) and its conjugate glycocholate (GC) do not induce apoptosis in colorectal cancer cell lines[6]. Caspase cleavage and activation occur as early as 30 min after the

addition of DC to cells[6]. In a recent report, direct oligomerization of the Fas receptor (CD95/Apo-1) has been suggested as the primary causative mechanism of bile salt-mediated hepatocyte apoptosis[11-13]. However, CD95 is not involved in DC-induced apoptosis, but bile salt-mediated induction of mitochondrial permeability transition has been seen in colorectal cancer cell lines[6,14].

In the present study, we observed whether six bile salts and two bile acids could inhibit cell proliferation and induce apoptosis of human esophageal cancer Eca109 cells. We characterized the kinetics of bile salt-induced apoptosis of esophageal cancer cells. The difference in effects of different bile salts and bile acids on esophageal cancer cells was demonstrated. Activation of caspase-3 and expression of Bcl-2 and Bax proteins, as the key components in mitochondrial apoptosis "death-signal transduction" pathway[15-18], were described in bile salt-mediated apoptotic esophageal cancer cells.

MATERIALS AND METHODS

Materials

DMEM was purchased from Hyclone and trypsin was from Sigma. Fetal bovine serum (FBS) was from Hangzhou Jiangbin Biotechnology Co., Ltd. GC, GCDC, GDC, TC, TCDC, TDC, CA, and DCA were from Sigma. SP Histostain™-Plus kits and deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) kits were purchased from Beijing Zhongshan Golden Bridge Biotechnology Co., Ltd. Mouse mAbs to Bcl-2 and Bax were from Antibody Diagnostica Inc. Annexin V-FITC apoptosis detection kit I and FITC-conjugated monoclonal active caspase-3 antibody apoptosis kit I were from BD Biosciences.

Cell lines

Eca109 cell lines were obtained from the Fourth Military Medical University. Cells were cultured in DMEM plus 10% FBS. All cell lines were cultured under standard tissue culture conditions.

Methods

Assessment of cell proliferation MTT assay was conducted to determine the cell proliferation[19]. Eight bile salts at concentrations of 500, 250, and 50 μmol/L, and mixed bile salts at concentrations of 1 500, 1 000, 500, and 250 μmol/L, including GC, GCDC, GDC, TC, TCDC, and TDC at the ratio of 2:2:1:2:2:1, were observed in MTT assay.

Eca109 cells were seeded in a 96-well plate (4 to 6×10^4 cells/well). After 24 h of post seeding, cells were treated with different bile salts for 3 d, and untreated cells served as a control. Prior to the determination, 10 μL of the 2.5 g/L stock solution of MTT was added to each well. After 4 h of incubation, the culture media were discarded, and then 100 mL of DMSO was added to each well and vibrated for 10 min. The absorbance (*A*) was measured at 492 nm with a microplate reader. The percentage of viable cells was calculated as follows: (*A* of experimental group/*A* of control group)×100%.

TUNEL assay

Cell apoptosis was analyzed using *in situ* cell death detection kit based on the terminal TUNEL technique. Cells were grown on chamber glass culture slides and treated with bile salts. To avoid disadherence of apoptotic cells, the slides were coated with poly-lysine. In brief, after the cells were treated with or without bile salts for the indicated time, they were fixed overnight in 100 g/L formaldehyde, and then treated with proteinase K and H_2O_2, labeled with dUTP in a humid box at 37 ℃ for 1 h. The cells without addition of TdT enzyme were used as negative control.

Flow cytometry by PI staining

Cells from the medium supernatant and adherent cells treated with bile salts were collected and pelleted at 1 200 U/min. The harvested cells were fixed with 1 mL of 75% cold ethanol at -20 ℃ for a night, and then washed with PBS. Cell pellets were incubated with 10 μg/mL RNase and stained with 50 μg/mL propidium iodide (PI) for 30 min in the dark. Samples were analyzed by FACSCalibur FCM at excitation wavelength of 488 nm. In the assay, 10 000 cells were detected by FCM. The resulting histograms were analyzed by the program CELLQuest.

Flow cytometry by annexin V-FITC conjugated with PI staining[20]

Cells from the medium supernatant and adherent cells treated with bile salts were collected and pelleted at 1 200 U/min. Pellets were washed twice with cold PBS and then resuspended in a binding buffer at a concentration of 1×10^6 cells/mL, and 100 μL of the solution (1×10^5 cells) was transferred to each of two 5-mL culture tubes. Five microliters of annexin V-FITC and 5 μL of PI were added into each 100 μL solution, the cells were gently vortexed and incubated for 15 min at RT in the dark. Four hundred microliters of 1´binding buffer was added to the sample and analyzed by FACSCalibur FCM within 1 h.

DNA fragmentation

A total of 10^6-10^7 cells treated with bile salts were collected and low molecular weight DNA was extracted using cell apoptosis DNA ladder extraction kit (Beijing Dingguo Biotechnology Co., Ltd). Standard loading buffer was added, 20 μL DNA samples was run on an 1% agarose gel containing 0.1% ethidium bromide in TAE buffer (Tris 40 mmol/L, sodium acetate 20 mmol/L, and 1 mmol/L EDTA, pH 8.0).

Caspase-3 assay

Caspase-3 was analyzed by FCM using FITC-conjugated monoclonal active caspase-3 antibody apoptosis kit I. Cells were collected and washed with cold PBS, then resuspended in Cytofix/Cytoperm™ solution at a concentration of 1×10^6 cells/0.5 mL and incubated for 20 min on ice. Samples were washed twice with Perm/wash™ buffer, and then FITC-conjugated monoclonal rabbit anti-active caspase-3 antibody was added and incubated for 30 min at room temperature. The marked samples were analyzed by FACSCalibur FCM.

Immunocytochemical assay of Bcl-2 and Bax

Cells were grown on chamber glass culture slides and treated with TC at 500 μmol/L. To avoid disadherence of apoptotic cells, the slides were coated with poly-lysine. Slides with cells

were fixed in 65% cold acetone for 20 min. Bcl-2 and Bax were stained with the mAb using standard immunocytochemical techniques. Positive-staining-area percentages were calculated using a cell image analysis system (Qwin550CW). A mean of 20 adjacent fields, at a magnification of ×400, was analyzed for each section[21].

Statistical analysis

All values were expressed as mean±SD. Statistical differences between means were calculated by Student's *t*-test and χ^2 test. $P<0.05$ was considered statistically significant.

RESULTS

Morphological changes

The influence of different bile salts on the apoptosis of Eca109 cells was established. Morphological criteria of cell apoptosis, such as membrane blebbing, cell shrinkage, nuclear conden-sation and fragmentation, were assessed by phase-contrast video microscopy. Morphological changes were observed 3 h after the addition of DCA at 500 μmol/L, and 24 h after the addition of the other bile salts at 500 μmol/L, except for GC.

Inhibition of Eca109 cell proliferation by some bile salts

The experimental Eca109 cells were treated with eight kinds of bile salts and mixed bile salts at different concentrations as described above. The cell viability was determined by MTT assay (Figure 1). Except for GC, the other bile salts or bile acids inhibited the growth of esophageal cancer cells in a dose- and time-dependent manner. Cell growth was suppressed by 85% after 24 h treatment with DCA at 500 μmol/L, higher than that after treatment with other bile salts and bile acid at the same concentration ($P<0.01$). Cell growth was suppressed by 65% and 95% after 24- and 72-h treatment with mixed bile salts at 1 000 μmol/L, by 59% and 94% after 24- and 72-h treatment with TC at 500 μmol/L, which were higher than those after treatment with the other five kinds of bile salts.

TUNEL assay

TUNEL assay revealed that bile salts, except for GC, induced apoptosis of Eca109 cells. When treated with GC, GCDC, GDC, TC, TCDC, TDC, CA at 500 μmol/L for 24 h, DCA at 500 μmol/L for 12 h, and mixed bile salts at 100 μmol/L for 24 h, the positive-cell percentages were 2%, 11%, 9%, 25%, 11%, 12%, 15%, 43% and 30%, respectively. Compared to 2% in control, the percentages were higher in the cells treated with bile salts ($P<0.05$) except for GC. Figure 2 shows the image of cells treated with 500 μmol/L TC for 24 h.

FCM by PI staining

Eca109 cells treated with bile salts and bile acids at 500 μmol/L and mixed bile salts at 1 000 μmol/L were stained with PI and analyzed by FCM. Except for GC, the bile salts induced cell apoptosis in a time-dependent manner (Figure 3A). When treated with DCA at 500 μmol/L, the apoptotic cell percentage reached 44.9% after 12 h and 80.5% after 24 h (Figure 3B). After 24 and 72 h, the percentages were 27.7% and 72.4% after being treated with mixed bile salts at 1 000 μmol/L, and 19.7% and 75.5% after being treated with TC at 500 μmol/L, respectively.

FCM by annexin V-FITC conjugated with PI staining

Early apoptotic cells were annexin V-FITC-positive and PI-negative[20]. Early apoptotic cells increased in the cells treated with bile salts except for GC. The percentages of early apoptotic cells of Eca109 cells treated with GC, GCDC, GDC, TC, TCDC, TDC, CA at 500 μmol/L for 12 h, DCA at 500 μmol/L for 6 h, and mixed bile salts at 100 μmol/L for 12 h were 1.9%, 7.5%, 8.7%, 14.8%, 8.9%, 7.8%, 9.3%, 22.6%, and 12.5%, respectively. Some of them are shown in Figure 4. Compared to 1.9% in control, the percentages were higher in the cells treated with bile salts ($P<0.05$) except for GC.

DNA fragmentation

In this study, we observed DNA ladder formation in cells treated with GC, TC, and DCA at 500 μmol/L for 24 h, and mixed bile salts at 1 000 μmol/L for 24 and 48 h (Figure 5).

Caspase-3 assay

We analyzed active caspase-3 in Eca109 cells treated with TC and GC at 500 μmol/L for 24 h by FCM with FITC-conjugated monoclonal active caspase-3 antibody (Figure 6). In control and cells treated with GC at 500 μmol/L, 1% was found to be primarily active caspase-3 cells, and there was no difference between the two groups ($P>0.05$). But about 22% of the cells treated with TC at 500 μmol/L for 24 h had detectable active caspase-3, being higher than that in the control ($P<0.01$).

Expressions of Bcl-2 and Bax proteins

Figure 7 shows the morphologic images of cells with immunocytochemical staining of Bcl-2 and Bax proteins. Bcl-2 protein staining was weaker than Bax because the positive staining was weaker. Expression of Bcl-2 protein was reduced in 500-μmol/L-TC-treated Eca109 cells, while expression of Bax protein was increased (Table 1), suggesting that TC could down regulate Bcl-2 protein level and up-regulate Bax protein level.

Table 1 TC's effects on the expression of Bcl-2 and Bax in Eca109 cells (mean±SD)

Positive-area-percentage (%)	Bcl-2	Bax
Control	45±3	22±4
500 μmol/L TC, 24 h	26±4[a]	47±6[b]
500 μmol/L TC, 48 h	24±5[a]	71±4[b]

[a]$P<0.05$, [b]$P<0.01$ *vs* control.

DISCUSSION

Bile salts and bile acids are likely to influence the development and persistence of esophageal mucosal cell metaplasia[1-3]. It is necessary to investigate the effect of bile salts on esophageal mucosal cancer cells. In our studies, we have demonstrated

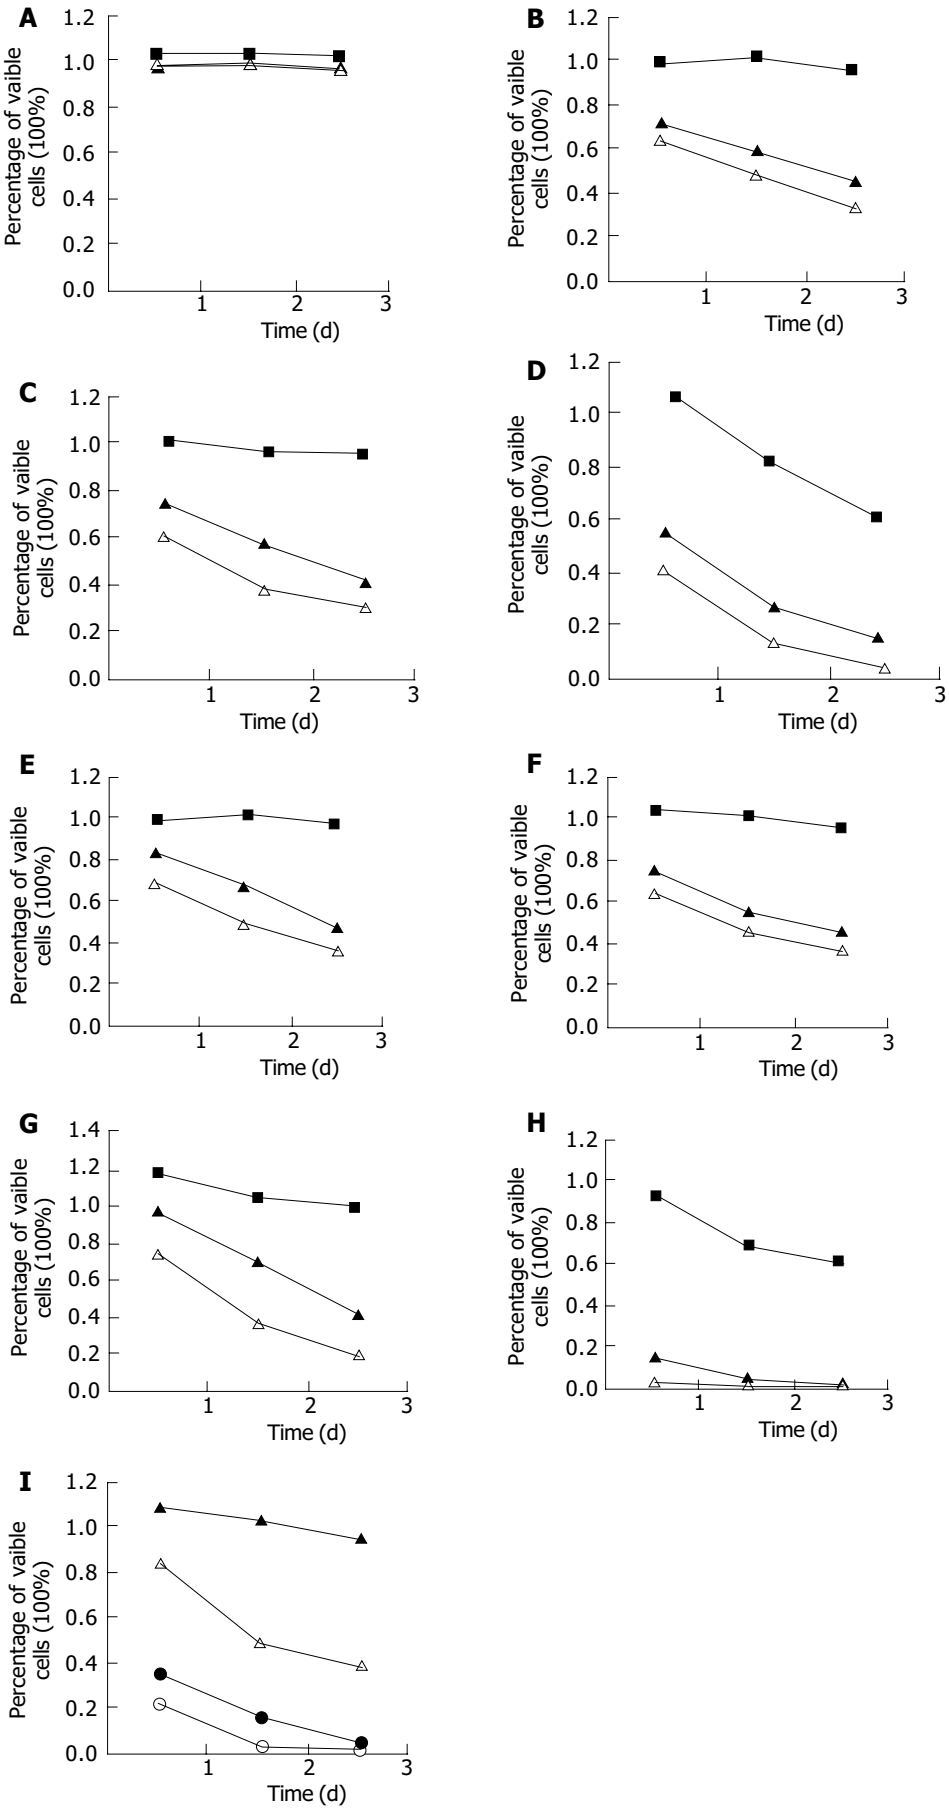

Figure 1 Effect of bile salts on Eca109 cell growth. ■ (at 50 μmol/L), ▲ (at 250 μmol/L), △ (at 500 μmol/L), ● (1 000 μmol/L), ○ (1 500 μmol/L). **A**: Glycocholate; **B**: Glycochenodeoxycholate; **C**: Glycodeoxycholate; **D**: Taurocholate; **E**: Taurochenodeoxychoate; **F**: Taurodeoxycholate; **G**: Cholic acid; **H**: Deoxycholic acid; **I**: Mixed bile salts.

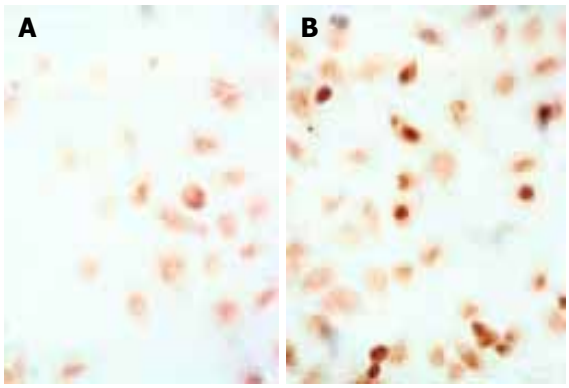

Figure 2 TC-induced apoptosis of control (**A**) and cells treated with TC (**B**) ×400.

that specific bile salts and bile acids at 50-500 μmol/L could inhibit growth and induce apoptosis of Eca109 cells.

Bile acids constitute 67% of normal bile, and are conjugated with glycine or taurine in normal human bile. Bile acids consisted of 40% CA, 40% CDCA, and 20% DCA. Lithocholic acid (LCA) and ursodeoxycholic acid (UDCA) is less than 5% respectively[22]. We selected GC, GCDC, GDC, TC, TCDC, and TDC, and CA and DCA in this study. The concentrations of bile salts in our study were from 25 to 500 μmol/L and those of mixed bile salts were 50 to 1 500 μmol/L, because the total bile acid concentration in esophagus of patients suffering from bile reflux is 0.89 mg/mL[23]. Six bile salts at concentration of less than 500 μmol/L are all water-soluble sodium salts in pH 7.1-7.5. Because of its hydrophobicity, the largest portion of DCA is not soluble in water, but a considerable amount of 700 μmol/L DCA is detectable in fecal water[24,25]. As this portion, at least theoretically, can get into contact with colonic epithelial cells, we selected the concentration at 25-500 μmol/L to investigate the effect of DCA on esophageal cancer cells. Our study demonstrated that less than 500 μmol/L DCA and CA could be dissolved thoroughly

in the media. Based on the components of normal bile, the mixed bile salts in our study comprised GC, GCDC, GDC, TC, TCDC, and TDC at 2:2:1:2:2:1.

The present study demonstrated that five bile salts, two bile acids and the mixed bile salts except for GC, could inhibit the growth of human esophageal cancer Eca109 cells in a dose- and time-dependent manner. Our results also showed that the induced-cell death was a major reason for the cell growth inhibition. Necrosis is the major effect of bile salts on esophageal mucosal cells, by entering mucosal cells and causing injuries to cell membranes and tight junctions[4]. However, the effects of five bile salts, two bile acids and the mixed bile salts except for GC, on apoptosis-inducing activity in esophageal cancer cells were examined in our study. They caused typical apoptotic alterations including morphological changes assessed by phase-contrast video microscopy and TUNEL assay, positive annexin V staining by FCM, apoptotic sub-G_1 peak by FCM with PI staining, and DNA fragmentation by gel electrophoresis.

Seven bile salts or acids and mixed bile salts have different effects between Eca109 cells and hepatocytes[8-10] and colon cancer cell lines[6]. They could induce apoptosis of esophageal cancer cells in a dose- and time-dependent manner. Conversely, hepatocyte-cytotoxic glycine-conjugated bile acids such as GC induce hepatocyte apoptosis *in vitro*[8], but not apoptosis of esophageal cancer cells, whereas hepatocyte-tolerated TC and TCDC[9] induce apoptosis of esophageal cancer cells. Our results also showed that TC was more toxic to esophageal cancer cells than other bile salts, suggesting that apoptosis-induced effect is correlative with the conjugated forms or structures of bile acids in esophageal cancer cells. In hepatocytes, the effect of bile salts is based on the glycine- or taurine-conjugated structure. It was reported that some hydrophobic bile acids such as TC activate PI3K-dependent survival pathways, which prevent their inherent toxicity[5]. But it seemed that PI3K was not activated by TC in esophageal cancer cells. The different mechanism of different bile salts needs to be defined by further studies.

The apoptosis "death-signal transduction" pathway is currently classified into the Fas/FasL pathway[26-28], the

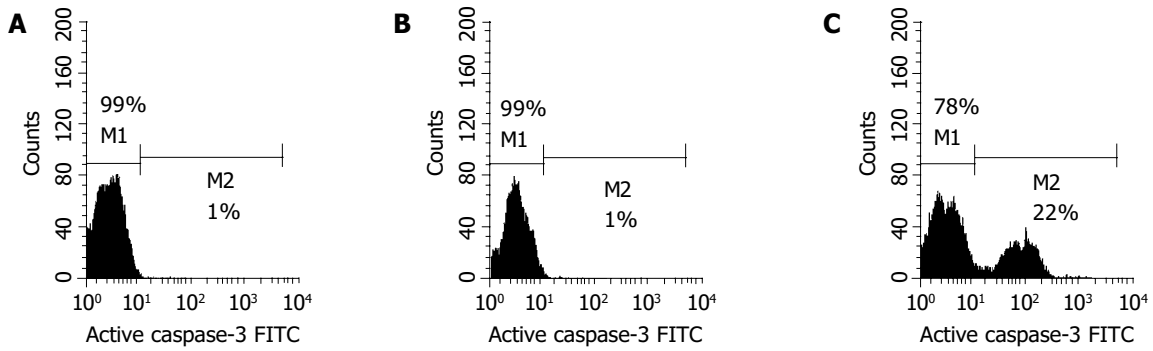

Figure 6 Active caspase-3 in the control (**A**) and cells treated with GC (**B**) and TC (**C**).

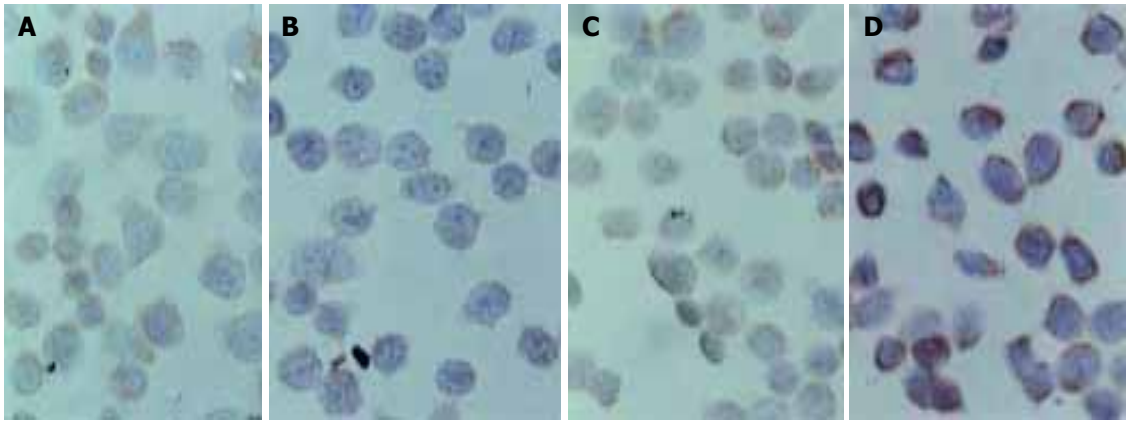

Figure 7 Expression of Bcl-2 (**B**) and Bax proteins (**D**) and controls (**A:** Bcl-2 and **C:** Bax) ×400.

mitochondrial pathway[16,29], and the endoplasmic reticulum-stress activated pathway[30,31]. It was reported that direct oligomerization of the Fas receptor is the primary causative mechanism of bile salt-mediated hepatocyte apoptosis[11-13]. The signal transduction of bile salt-mediated apoptosis of esophageal cancer cells was also investigated in our study. The data demonstrate that caspase-3 is activated in TC-induced cells. Activation of caspase-3 occurs as a consequence of TC-induced apoptosis. However, caspase-3 plays a pivotal role in the three apoptosis pathways[32-34]. We further observed the expression of Bcl-2 and Bax protein. Members of the Bcl-2 family, as the key components in the mitochondrial apoptosis "death-signal transduction" pathway, are important regulators in the apoptotic pathway[15,16]. As an oncogene-derived protein, Bcl-2 confers a negative control in the pathway of cellular suicide, whereas Bax, a Bcl-2-homologous protein, promotes cell death by competing with Bcl-2[17,18]. Reduced expression of Bcl-2 protein and increased expression of Bax protein in Eca109 cells treated with TC demonstrated in this study, suggest that TC-induced apoptosis is relative with the mitochondrial death-signal pathway in Eca109 cells. As opposed to hepatocyte death mediated by bile acids, CD95 is not involved in deoxycholate-induced apoptosis of colon cancer cell lines[6]. Because the changes of CD95 were not observed in our study, our results cannot prove that Fas receptor (CD95) is not involved in TC-induced esophageal cancer cell apoptosis. Toxic bile acids may be capable of stimulating multiple pathways to initiate cell death, but further studies are needed.

In conclusion, GCDC, GDC, TC, TCDC, TDC, CA, and DCA, except for GC, inhibit growth and induce apoptosis of Eca109 cells in a dose- and time-dependent manner *in vitro*. Activation of caspase-3, decreased Bcl-2 protein, and increased Bax protein are involved in TC-induced apoptosis of esophageal cancer cells.

Abstract

AIM: To study the different gene expression profiles in rats with Barrett's esophagus (BE) and esophageal adenocarcinoma (EA) induced by gastro-duodeno-esophageal reflux.

METHODS: Esophagoduodenostomy was performed in 8-wk old Sprague-Dawley rats to induce gastro-duodeno-esophageal reflux, and a group of rats that received sham operation served as control. Esophageal epithelial pathological tissues were dissected and frozen in liquid nitrogen immediately. The expression profiles of 4 096 genes in EA and BE tissues were compared to normal esophagus epithelium in normal control (NC) by cDNA microarray.

RESULTS: Four hundred and forty-eight genes in BE were more than three times different from those in NC, including 312 upregulated and 136 downregulated genes. Three hundred and seventy-seven genes in EA were more than three times different from those in NC, including 255 upregulated and 142 downregulated genes. Compared to BE, there were 122 upregulated and 156 downregulated genes in EA. In the present study, the interested genes were those involved in carcinogenesis. Among them, the upregulated genes included cathepsin C, aminopeptidase M, arachidonic acid epoxygenase, tryptophan-2,3-dioxygenase, ubiquitin-conjugating enzyme, cyclic GMP-stimulated phosphodiesterase, tissue inhibitor of metalloproteinase-1, betaine-homocysteine methyltransferase, lysozyme, complement 4b binding protein, complement 9 protein, insulin-like growth factor binding protein, UDP-glucuronosyltransferase, tissue inhibitor of metalloproteinase-3, aldolase B, retinoid X receptor gamma, carboxylesterase and testicular cell adhesion molecule 1. The downregulated genes included glutathione synthetase, lecithin-cholesterol acyltransferase, p55CDC, heart fatty acid binding protein, cell adhesion regulator and endothelial cell selectin ligand.

CONCLUSION: Esophageal epithelium exposed excessively to harmful ingredients of duodenal and gastric reflux may develop into BE and even EA gradually. The gene expression level is different between EA and BE, and may be related to the occurrence and progression of EA.

INTRODUCTION

The incidence of esophageal adenocarcinoma (EA) has increased considerably in the past few years and has already exceeded any other kind of malignant tumor in USA and the incidence of EA in Caucasians has exceeded squamous carcinoma[1]. A Dundee inquisition discovered that the incidence of EA has increased 49% in the last few years[2]. No detailed clinical epidemiological data in this respect can be acquired in Asia. However, some gastroenterology specialists also thought that the incidence of EA has increased in their country[3]. This may be related to the increasing incidence of gastro-esophageal reflux diseases, especially Barrett's esophagus (BE)[4,5]. Gastro-esophageal reflux diseases are caused by mucosa exposed excessively to harmful ingredients of duodenal and gastric reflux. It is usually considered that gastro-esophageal reflux can lead to esophagitis, BE and even EA. However, the exact mechanism especially the molecular biological mechanism of EA is unknown. In the present study, the same surgical procedures were performed in Sprague-Dawley rats to induce gastro-duodeno-esophageal reflux and the difference in gene expression profiles between BE and EA was investigated by cDNA microarray.

MATERIALS AND METHODS

Experimental animal and animal model

One hundred and twenty healthy Sprague-Dawley rats weighing 200-250 g were purchased from the Experimental Animal Center of Xi'an Jiaotong University. The rats were housed in rat cages at 22-25 ℃ with free access to standard

rat pellet food and water for 40 wk. Rats were treated following the Guidelines for the Care and Use of Laboratory Animals of National Animal Welfare Committee. The male pairing female rats were divided into two groups. Esophago-duodenostomy was performed on 90 rats to produce gastro-duodeno-esophageal reflux, and sham operation was performed on 30 rats[6]. The animals were fed with a standard chow.

Tissues and specimens

All the tissue specimens including BE and EA were taken from animals 40 wk after esophago-duodenostomy, by which gastro-duodeno-esophageal reflux animal model was induced. Normal esophageal epithelium at the same anatomical site served as normal control (NC). Inner part of each sample was cut, frozen in liquid nitrogen immediately after surgical resection, at the same time about 0.2 cm×0.2 cm×0.2 cm tissue of outer marginal part was used for histopathological examination to ensure all the frozen tissue specimens and their corresponding histological morphology.

Chip preparation

Four thousand and ninety-six target cDNA clones were used in cDNA microarray (United Gene Ltd). These genes were amplified by PCR, using universal primers and then purified by standard method. The quality of PCR was monitored by agarose gel electrophoresis. The obtained genes were dissolved in 3×SSC spotting solution and then spotted on silylated slides (Telechem Inc.) by Cartesian 7500 spotting robotics (Cartesian, Inc.). Each target gene was dotted twice. After spotting, the slides were hydrated (2 h) and dried (0.5 h, room temperature). The samples were cross-linked with UV light and treated with 0.2% SDS, H_2O and 0.2% NaNBH4 for 10 min respectively. Then the slides were dried in cold condition for use.

Probe preparation

Total sample RNA was extracted by single step method. Briefly, after being taken out from liquid nitrogen, specimens were ground completely into tiny powders, while liquid nitrogen was added in ceramic mortar and then the powders were homogenized in D solution plus 1% mercaptoethanol. After centrifugation, the supernatant was extracted with phenol:chloroform (1∶1), NaAC and acidic phenol: chloroform (5∶1), respectively. The aqueous phase was precipitated by an equal volume of isopropanol and centrifuged. The precipitates were dissolved with Millie-Q H_2O. After further purification by LiCl precipitating method, RNA was obtained by UV analysis and electrophoresis. mRNA was isolated and purified with Oligotex mRNA Midi kit (Qiagen, Inc.). The fluorescent-labeled cDNA probe was prepared through retro-transcription as previously described[7]. The probes from NC were labeled with Cy3-dUTP, while those from BE and EA with Cy5-dUTP respectively. The probes were mixed (Cy3-dUTP NC+Cy5-dUTP BE and Cy3-dUTP NC+ Cy5-dUTP EA respectively) and precipitated by ethanol, and then resolved in 20 mL hybridization solution (5×SSC+0.2% SDS).

Hybridization and washing

Probes and the chip were denatured respectively in 95 ℃ bath for 5 min, and then the probes were added onto the chip. They were hybridized in a sealed chamber at 60 ℃ for 15-17 h and washed in turn with solutions of 2×SSC+0.2% SDS, 0.1×SSC+0.2% SDS and 0.1% SSC for 10 min each, then dried at room temperature.

Fluorescent scanning and result analysis

The chip was read by a Scan Array 3000 Scanner (General Scanning Inc.). The overall intensities of Cy3 and Cy5 were normalized and corrected by a coefficient, according to the ratios of the located 40 h keeping genes. Cy3 was normalized as Cy3*. The acquired image was further analyzed by Gene Pix Pro 3.0 software with digital computer to obtain the intensities of fluorescent signals and the Cy5/Cy3* ratio. The data were an average of the two repeated spots. The differentially expressed genes were defined as the absolute value of the Cy5/Cy3* natural logarithm being more than 1.10 (the variation of gene expression was more than threefold); either Cy3 or Cy5 signal value required being more than 800, or both signal values being more than 200, or else being thought as an ineffective gene dot; PCR results being satisfactory.

RESULTS

Features of esophagus pathological changes

Sixty-nine rats survived in animal model group in the end and all animals that had undergone sham operation survived. Incidences of BE and EA in esophago-duodenostomy animal group were 37.5% and 2.8% respectively, significantly higher than that in the sham operation group.

Total sample RNA extraction

Total sample RNA from normal esophagus epithelium, BE and EA was extracted and the A_{260}/A_{280} was 2-2.6, indicating that pure mRNA was acquired.

Scatter spots of hybridization signals on gene chip

The scatter spots plotted with Cy3 and Cy5 fluorescent signal values displayed quite a disperse pattern in distribution. Most spots gathered around a 45 angle diagonal line, in which blue spots represented the area, where the signal intensities ranged 0.33-3-folds compared to those of the control. Some yellow spots distributed beyond or far from 45 angle diagonal line, indicating the existence of abnormal gene expression in BE or EA and their signal intensities were three times more or less than those in NC (Figures 1A and B).

Results and gene expression pattern by scanning analysis

In BE epithelia, 448 genes exhibited expression variations more than three times compared to the control, the up- and down-regulated genes were 312 and 136 respectively. In EA, 377 genes showed expression variations more than three times compared to NC, the up- and down-regulated genes were 255 and 122 respectively. Difference in gene expression between EA and BE was acquired by subtracting genes in common from total genes expressed differently in EA and BE compared to NC (any ineffective dot of hybridization was excluded from analysis). A total of 268 genes expressed

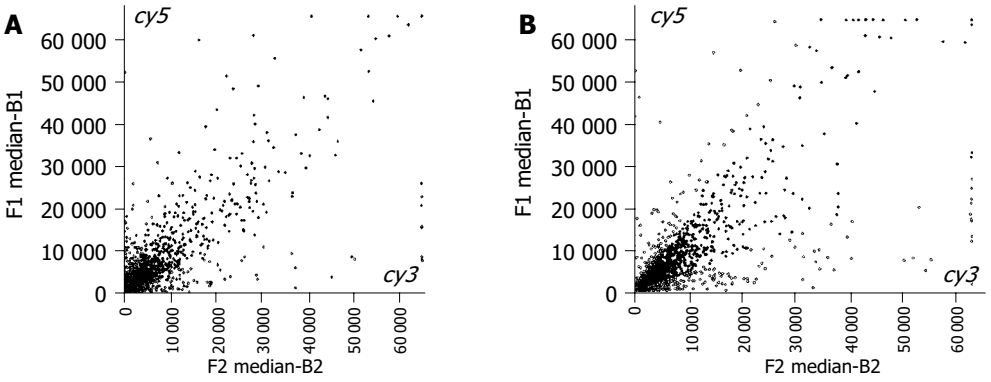

Figure 1 Scatter spots of hybridization signals on gene chip. **A**: Esophagus adenocarcinoma and normal control; **B**: Barrett's esophagus and normal control.

differently in BE compared to those in EA, the up- and down-regulated genes were 112 and 156 respectively. These genes might be divided into 12 groups (Table 1) according to their functions. Some genes involved in carcinogenesis are listed in Table 2.

Table 1 Different expressions of functional genes in BE and EA

Functional genes	Number	Upregulated	Downregulated
Oncogenes and tumor suppression genes	23	13	10
Ion channel and transporters	26	13	13
Cell cycle proteins	13	4	9
Extra-pressure reaction proteins	20	8	12
Cell regulatory proteins	15	5	10
Cell apoptosis-related proteins	19	11	8
DNA synthesis, repair, recombinant factors	20	6	14
DNA binding, transcription factors	23	7	16
Cell receptors	23	7	16
Immunity-related proteins	29	12	17
Cell signal transducing proteins	28	9	19
Metabolism-related proteins	29	17	12
Total	268	112	156

Table 2 Different expressions of some genes in BE and EA

Upregulated	Downregulated
Cathepsin C	Glutathione synthetase
Aminopeptidase M	Lecithin-cholesterol acyltransferase
Arachidonic acid epoxygenase	p55CDC
Tryptophan-2,3-dioxygenase	Heart fatty acid binding protein
Ubiquitin conjugating enzyme	Cell adhesion regulator
Cyclic GMP-stimulated phosphodiesterase	Selectin, endothelial cell, ligand
Tissue inhibitor of metalloproteinase 1	
Betaine-homocysteine methyltransferase	
Lysozyme	
Complement 4 binding protein, alpha	
Insulin-like growth factor binding protein	
UDP-glucuronosyltransferase	
Tissue inhibitor of metalloproteinase 3	
Rat liver aldolase B	
Retinoid X receptor gamma	
Complement component 9	
Rat liver carboxylesterase	
Testicular cell adhesion molecule 1	

DISCUSSION

Research has confirmed that BE is closely related to EA, every year the danger of BE developing into EA increases by 0.5% and the former is regarded as precancerous of the latter[5]. However, adenocarcinoma in the gastro-esophageal junction is thought as EA and its diagnosis can be made according to the fact that more than 50% carcinomas are situated in the esophageal lateral, mixing up the tissue origin of EA. Some clinical epidemiologic data on cardiac adenocarcinoma and EA indicate that the two diseases are similar in respects of age, sex, clinical, and pathological characteristics so that the origin of the two diseases is thought as the same tissue[8] and the two diseases are known as adenocarcinoma at the gastro-esophageal junction[9].

Miwa *et al*.[6], reported that EA arises from BE, which is induced by the contents of gastro-duodeno-esophageal reflux. The role of single genes in esophageal adenocarcinogenesis is reported[10]. However, the exact mechanism especially the molecular biological mechanism of EA is unknown. The carcinogenesis involved in more steps and more factors is caused by abnormal expression of tumor-associated genes including activation of oncogenes or inactivation of tumor suppression genes or both. Elucidation of the gene expression differences in malignant, precancerous and normal tissue is a crucial procedure for cancer control study. It is generally accepted that although the number of genes with mutation is limited in cancer, a large number of genes in related pathways may be affected at the expression level, and this aberrant gene transcriptional expression network plays an essential role in the initiation/maintenance of the malignant phenotype. With the advances in molecular biological techniques, cDNA microarray has been used to detect gene expression difference in various specimens by parallel analysis on a large scale[11]. In this research, animal model of gastro-duodeno-esophageal reflux was made and the difference in gene expression profiles between BE and EA was investigated by cDNA microarray. In the present study, we were interested in a group of genes involved in carcinogenesis.

Among the upregulated genes in EA, 18 genes were involved in carcinogenesis and carcinomatous progression including cathepsin C, aminopeptidase M, arachidonic acid epoxygenase, tryptophan-2,3-dioxygenase, ubiquitin-conjugating enzyme, cyclic GMP-stimulated phosphodiesterase,

tissue inhibitor of metalloproteinase-1, tissue inhibitor of metalloproteinase-3, betaine-homocysteine methyltransferase, lysozyme, complement 4b binding protein, complement 9 protein, insulin-like growth factor (IGF) binding protein, UDP-glucuronosyltransferase, aldolase B, retinoid X receptor gamma, carboxylesterase and testicular cell adhesion molecule-1. These genes might participate in carcinogenesis and carcinomatous progression of EA by various mechanisms.

Cathepsin C is a kind of cysteine protease. Cysteine proteases are negatively correlated with those inhibitors in effect and there is a balance in effect between them in normal tissues. However, in tumor tissue, genes expressing cysteine proteases are upregulated and inhibitors of cysteine protease are downregulated, thus breaking the balance in normal tissue and leading to extracellular matrix proteins decompounding, which might be related to invasion and metastasis of tumor[12]. Aminopeptidase M causes conversion of angiotensin III into angiotensin IV[13], which might be related to lesions of gastrointestinal tract mucosa[14]. The 5×-upstream region of the arachidonic acid epoxygenase gene was isolated by amplification of a 2 341-bp fragment and putative regulatory elements that resembled activator protein-1-like sequences were identified. Activator protein-1 as a nucleolus transcription factor, combined DNA by leucine zipper, is a pivotal factor of cellular malignant transformation in various oncogene signal-transducing pathways[15]. T lymphocytes undergo proliferation arrest when exposed to tryptophan shortage, which can be provoked by tryptophan 2,3-dioxygenase, an enzyme that catalyzes tryptophan degradation and is expressed in most human tumors and normal placenta[16]. Ubiquitin-conjugating enzyme is a key component of ubiquitin-proteasome-proteolytic pathway that is associated with tumorous cachexia and upregulated expression in some tumor tissues[17]. The cGMP phosphodiesterase decreases cGMP in SW480 and HT29 colon tumor cells, which inhibit apoptosis[18]. Tissue inhibitor of metalloproteinase inhibits the activity of metalloprotease and the latter is associated with tumor invasion and metastasis. In common, the former is downregulated and the latter is upregulated in tumor tissue. However, some researches indicate that some tissue inhibitor of metalloproteinase can also stimulate cell proliferation and angiogenesis, thus leading to tumorigenesis[19]. For example, overexpression of tissue inhibitor of metalloproteinase-1 is associated with poor prognosis and relapse in patients with tumor[19]. New data suggest that high levels of tissue inhibitor of metalloproteinase-3 mRNA in human breast tumors are associated with successful adjuvant endocrine therapy[20]. Betaine-homocysteine-methyltransferases catalyze synthesis of methionine from homocysteine, which provides methyl for DNA synthesis. Methionine, obtained in the diet and synthesized by several reactions in the body, is the sole precursor of *S*-adenosylmethionine, the primary methyl donor in the body. Enzymatic DNA methylation is an important component of gene control and may serve as a silencing mechanism for gene function. Disruption in methionine metabolism and methylation reactions may be involved in cancer process[21]. Lysozyme is an innate non-immunologic antibacterial enzyme produced by the Paneth cells of the upper intestinal tract. Lysozyme is not normally secreted in the alimentary tract without Paneth cells, where intense lysozyme production might herald a possible dysplastic evolution and even neoplasia[22]. Complement 4b binding protein and complement 9 are crucial ingredients of complement immune system and multi-complement 9 unites into a polymer as formation of the membrane attack complex, which mediates tumor cell lysis[23]. IGF-I and its main binding protein modulate cell growth and survival, and are important in tumor development and progression. Circulating concentrations of IGF and its binding protein are associated with an increased risk for common cancers, but the association is modest and varies between sites[24]. Uridine diphospho-glucuronosyltransferases are a family of drug metabolizing enzymes contributing to hepatic drug metabolism and protection against environmental toxins. They are involved in catalyzing estrogen, which may be associated with an increased risk for breast cancer[25]. Aldolase B is a kind of glycolytic enzyme. There is a direct relationship between the proliferation of tumor cells and the activities of glycolytic and gluconeogenic enzymes. A significant rise in glycolytic enzyme activities and a simultaneous fall in gluconeogenic enzyme activities are found in mammary carcinoma[26]. Retinoids are natural and synthetic compounds related to retinoic acid, that act through interaction with two basic types of nuclear receptors: retinoic acid receptors and retinoid X receptors (RXR alpha, RXR beta, and RXR gamma) as retinoid-inducible transcription factors. Thus, retinoid receptors are considered to be ligand-activated, DNA-binding, trans-acting, transcription-modulating proteins involved in a general molecular mechanism responsible for transcriptional responses in target genes. They exert both beneficial and detrimental activity related to the selective receptors[27]. Haugen *et al*.[28], reported that differential tumor expression of RAR beta and RXR gamma and lack of the RXR gamma isoform are found in normal thyroid tissue. Cell lines expressing both RAR beta and RXR gamma demonstrate significant growth suppression when treated with retinoids, whereas cell lines lacking these isoforms are unaffected. Carboxylesterase isoenzyme RL2 shows hydrolyzing activity towards activators of protein kinase C. Since protein kinase C is involved in carcinogenesis and cell proliferation, up-regulated carboxylesterase in adenocarcinoma might be involved in carcinogenesis[29]. Testicular cellular adhesion molecule is a cellular adhesion molecule expressed normally in testicle, which plays a role in cancer angiogenesis, progression, and metastasis[30].

Among the downregulated genes in EA, the downregulated genes involved in carcinogenesis include glutathione synthetase, lecithin-cholesterol acyltransferase, p55CDC, heart fatty acid binding protein, cell adhesion regulator and endothelial cell selectin ligand. The cellular defense system (including glutathione and glutathione-related enzymes) plays a crucial role in cell survival and growth. Glutathione and glutathione synthetase are associated with tumorigenesis and apoptosis[31]. An important factor that determines the movement of cholesterol in and out of the cells is the free cholesterol/esterified cholesterol ratio in plasma. The ratio

increases in several types of malignancies both in humans and in experimental animals, which might be related to decreased activity of lecithin-cholesterol acyltransferase[32]. p55CDC, a mitotic checkpoint protein, plays a crucial role in carcinogenesis and decreased expression of the proteins is associated with progression of some cancers[33]. Heart fatty acid binding protein is also known as a mammary-derived growth inhibitor, which is a tumor growth suppressor gene capable of inhibiting tumor cell proliferation[34]. Cell adhesion regulator can inhibit tumor cellular growth and regulate tumor angiogenesis. Its expression in some tumor tissues is downregulated and associated with progression of tumor[35]. Endothelial cell selectin ligand mediates lymphocytes interacting with endothelial cells or tumor cells and plays an important role in the metastasis of carcinoma[36], indicating that the ability to protect against esophagus tumorigenesis, decreases with the development of normal esophageal epithelium into BE, by overexposure to contents of gastric and duodenal reflux.

Many up- or down-regulated genes in EA compared to BE indicate that many genes in related pathways may affect development of BE into carcinoma and its molecular mechanism is very complex. The difference in gene expression between BE and EA indicates the molecular characteristics of the onset and promotion of BE and its progression into EA. The exact pathogenesis of EA and the relationship between EA and differently expressed genes need further study.

Abstract

AIM: To analyze retrospectively, our results about patients who underwent surgical treatment for adenocarcinoma of the cardia in relation to age, in order to evaluate surgical problems and prognostic factors.

METHODS: From January 1987 to March 2003, 140 patients with adenocarcinoma of the cardia underwent resection in the authors' institution. They were divided into three groups with regard to age. Patients <70 and > 60 year old (31) were excluded; we also excluded 18 out of 109 patients with poor general status or systemic metastases. So, we compared 51 elderly ($\geqslant$ 70 year old) and 58 younger patients ($\leqslant$ 60 year old). The treatment was esophagectomy for type I tumors, and extended gastrectomy and distal esophagectomy for type II and III lesions.

RESULTS: Laparotomy was carried out in 91 patients (83.4%), 38 in the elderly (74.5%) and 53 in younger patients (91.3%, P<0.05). Primary resection was performed in 81 cases (89%) without significant differences between the two groups. Postoperative death was higher in the elderly (12.1%) than the other group (4.1%, P<0.05), while morbidity was similar in both groups. A curative resection (R0) was performed in 59 patients (72.8%), 69.6% in the elderly and 75% in the younger group (P>0.05). The overall 3- and 5-year survival rates were 26.7% and 17.8% respectively for the elderly and 40.7% and 35.1% respectively for younger patients (P = 0.1544). Survival rates were significantly associated with R0 resection, pathological node-positive category and tumor differentiation in both groups.

CONCLUSION: As the age of the general population increases, more elderly patients with gastric cardia cancer will be candidates for surgical resection. Age alone should not preclude surgical treatment in elderly patients with gastric cardia cancer and a tumor resection can be carried out safely. Certainly, we should take care in defining the surgical treatment in elderly patients, particularly as regarding the surgical approach; although the surgical approach does not influence the survival rate, the transhiatal way still remains the best one due, to the lower incidence of respiratory morbidity and thoracic pain.

INTRODUCTION

In the Western world, we observe a lower incidence of gastric and esophageal cancer in contrast with the annual increase in the adenocarcinoma of the esophagogastric junction (EGJ) equal to 5-10%[1-10]. Both for gastric adenocarcinoma and cardia cancer, we notice an increasing number of elderly patients[11-14]. Anyway, with regard to clinicopathological features of the adenocarcinoma of the EGJ in the elderly and its surgical problems in relation to age, few data have been published in the international literature. Adenocarcinoma of the EGJ has been defined as a tumor whose center is within 5 cm proximal and distal of the anatomical cardia, and today this tumor is considered as a separate neoplasm because of its distinctive prognostic and pathological features[4-6]. However, the surgical treatment of the cardia is still controversial, mainly regarding the extent of gastric and esophageal resection, the limphadenectomy, the surgical approach and the importance of adjuvant chemotherapy[4,5,15-17]. These themes are very important in order to define the treatment of old patients, especially for the increasing number of over 70 year old suffering from this neoplasm as well as from other comorbidities peculiar to old age.

The aim of this study is to analyze retrospectively, our results about patients who underwent surgical treatment for adenocarcinoma of the EGJ in relation to age, in order to

evaluate surgical problems and prognostic factors, in particular in patients over 70 year old.

MATERIALS AND METHODS

Between January 1987 and February 2003, in our Institute, we observed 140 patients with adenocarcinoma of the EGJ. They were divided retrospectively into three groups with regard to age: (1) Group A: age $\geqslant$ 70 years old; (2) Group B: age $\leqslant$ 60 years old; (3) Group C: age < 70- and > 60-years old.

The 31 patients of group C were excluded in order to characterize better the other two groups. Group A consists of 51 patients (44 male, 7 female), and group B 58 patients (50 male, 8 female, Table 1). A retrospective study was done on these two groups of patients.

The surgical risk has been evaluated preoperatively with ASA score[18]. Eighteen out of 109 patients were excluded, 10 for poor general status with ASA score >3 (nine in group A, one in group B) and 8 for systemic metastases on preoperative staging (four in group A, four in group B). So, a total of 91 patients with gastric cardia cancer underwent laparotomy and only 81 underwent surgical resection. The surgical procedure was considered curative (R0), if gross tumor tissue including the metastatic lymph nodes were removed completely and the microscopic examination revealed no cancer cells at both proximal and distal margins. The procedure was considered palliative (R1), if microscopic disease was left behind. Resection specimens were assessed by an experienced pathologist. Staging is reported according to the most recent version of the UICC/AJCC guidelines for esophageal cancer (type I tumors) or gastric cancer (type II and III tumors)[19,20].

A particular effort has been made to identify areas with intestinal metaplasia in the distal esophagus and in the region of the cardia in all resection specimens. The retrospectively collected data included demographic parameters, histomorphologic tumor characteristics, the presence of associated intestinal metaplasia in the distal esophagus (Barrett's esophagus), the type of resection, post-operative 30-d death rate, morbidity, the depth of tumor invasion (pT), the pN category, the presence of residual disease on intraoperative assessment and histopathologic analysis of the removed specimen.

Surgical approach

The choice of surgical approach was based on the tumor type and on the goal of achieving a complete macroscopic and microscopic tumor resection, both in elderly and younger patients. Regardless of the surgical approach, we have recently believed in the transhiatal approach according to Pinotti's technique as a more valid alternative than the transthoracic approach. In general, a radical transmediastinal or transthoracic en bloc esophagectomy with resection of the proximal stomach has been the procedure of choice in 14 patients with type I tumors (seven in group A, seven in group B). Radical transmediastinal esophagectomy and resection of the proximal stomach was performed by a laparotomy and wide exposure of the lower posterior mediastinum by anterior splitting of the diaphragmatic hiatus and a left cervical incision. Extended esophagectomy was associated with proximal gastric resection in nine patients and with total gastrectomy in 5 cases. An extended total gastrectomy with transhiatal resection of the distal esophagus according to Pinotti's technique was performed in 42 patients with type III tumors. In 25 patients with type II tumors, an attempt was usually made to achieve a complete tumor resection by means of an extended gastrectomy with transhiatal resection of the distal esophagus according to Pinotti's technique. Lymphadenectomy comprised an en bloc removal of all lymphatic tissue in the lower posterior mediastinum, along the cardia, proximal two-thirds of the lesser curvature, and the fundus, and along the common hepatic and splenic artery toward the celiac axis. A transthoracic en bloc esophagectomy with resection of the proximal stomach was performed using a right posterolateral thoracotomy and laparotomy and included an extended en bloc mediastinal lymphadenectomy and an abdominal lymphadenectomy (two-field lymphadenectomy), as described above. The reconstruction after transmediastinal or transthoracic esophagectomy was performed with a narrow gastric tube or colon interposition and a cervical or high intrathoracic anastomosis. The extended total gastrectomy has always included a wide splitting of the diaphragmatic hiatus, transhiatal resection of the distal esophagus, and en bloc lymphadenectomy of the lower posterior mediastinum, in addition to a formal D2 lymphadenectomy (i.e., lymph node stations 1-11 of the Japanese classification)[21]. A mediastinal Roux-en-Y end-to-side esophago-jejunostomy performed with a circular stapler, was the reconstruction procedure of choice, after extended total gastrectomy and distal esophagectomy.

Statistical analysis

The survival status of our patients was ascertained between January and February 2003 and the follow-up was completed.

Data are shown as prevalence or mean±SD. Continuous data were compared by the Mann-Whitney test, ordinal data by the χ^2-test. Survival rate was analyzed by the Kaplan-Meier method and log-rank test. Prognostic factors were assessed by means of Cox regression analyses. $P<0.05$ was considered significant.

RESULTS

Regarding demographic data, both groups showed a preponderance of the male sex (Group A: M/F 4.8:1; Group B: M/F 6.2:1), but the male to female ratio was higher in the younger group than in the older group ($P<0.05$). Median age was 75.4±3.1; (range 70-84) for over 70 year old patients and 53.7±5.6; (range 32-60) in the other group (Table 1). The most common comorbidities in both groups were diabetes mellitus, coronary artery disease, hypertension and chronic obstructive pulmonary disease. Patients were divided into three types of tumor according to Siewert's classification (Figure 1). Laparotomy was carried out in 91 patients (83.4%), 38 in group A (74.5%) and 53 in group B (91.3%) ($P<0.05$). Primary resection was performed in 81 cases (89%), 33 in group A (86.8%) and 48 in group B (90.5%) (Table 1). There were no differences between the two groups regarding tumor stage.

Table 1 Demographic and surgical data in 109 patients with adenocarcinoma of the EGJ

	Group A (51)[1]	Group B (58)[1]	*P*	Total (109)
Median age (±SD)	75.4±3.1	53.7±5.6	*P*<0.05	62.6±13.8
Sex ratio (M / F)	4.8 / 1	6.2 / 1	*P*<0.05	5.5 / 1
Operability (%)	38 (74.5)	53 (91.3)	*P*<0.05	91 (83.4)
Primary resection (%)	33 (86.8)	48 (90.5)	NS	81 (89)
Postoperative death (%)	4 (12.1)	2 (4.1)	*P*<0.05	6 (7.4)
Morbidity (%)	16 (48.4)	16 (33.3)	NS	32 (39.5)
Mean hospital stay (±SD)	19.3±7.1 d	18.1±6.3 d	NS	19±6.9 d

[1]Group A: ⩾70 years old; group B: ⩽60 years old.

In type I tumor, we observed a prevalence (71.4%) of associated intestinal metaplasia in the distal esophagus (Barrett's esophagus) of elderly patients; rarely it was noticed in type II (10% *vs* 13.3%; *P*>0.05) or in type III (11.7% *vs* 3.8%; *P*>0.05, Table 2). In types II and III, there was a prevalence of grading G2 (*P*<0.05) compared to type I, independent of the age.

A curative resection (R0) was performed in 59 patients (72.8%), 69.6% in group A and 75% in group B respectively (Table 2). Three out of 59 patients treated with resection of the distal esophagus had tumor infiltration of resection margins. Fifty patients (61.7%) had positive lymph nodes, 20 in group A (60.6%) and 30 (62.5%) in group B, respectively (Table 3). Analysis of the pattern of lymphatic spread showed a most important metastatic involvement of lower posterior mediastinum and paracardial stations for type I and abdominal lymph node stations for types II and III, without significant differences between the two groups (A *vs* B: *P*>0.05). A greater percentage of positive lymph nodes was noticed in elderly patients (25% *vs* 17.6%), but it was statistically insignificant.

Postoperative death was 12.1% (4/33) in elderly patients and 4.1% (2/48) in the other group (*P*<0.05), without any correlation with sex, type of tumor, extent of resection and stage. Regardless of morbidity, there are no significant differences between the two groups. The most frequent complications were respiratory insufficiency and anastomotic leakage. The mean hospital stay (SD) was 19.3±7.1 d for group A and 18.1±6.3 d for group B (*P*>0.05, Table 1).

The overall 3- and 5-year survival rates were 26.7% and 17.8% respectively for group A and 40.7% and 35.1% respectively for group B (*P* = 0.1544, Figure 2). The worst results were observed for type I in both groups (Figures 3A and B). We noticed a difference in survival rate for types I and II between group A and B, but not significantly. As regards the type III survival rates were similar in both groups (Figures 4A-C).

Analysis of prognostic factors showed significant differences in both groups regarding: (1) tumor resection (R0 *vs* R1-2, *P*<0.05); (2) lymph node involvement (N0 *vs* N+, *P*<0.05); (3) pT categories (*P*<0.05);

Statistical analysis showed that elderly patients had lower

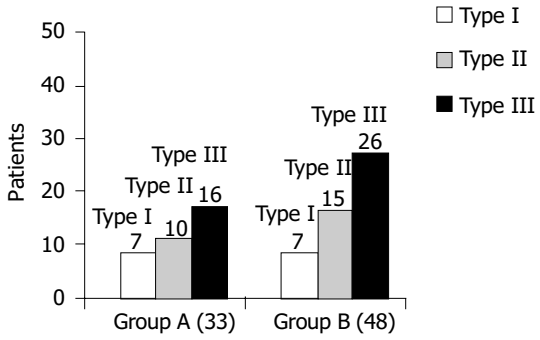

Figure 1 Subdivision of the 81 patients with adenocarcinoma of the EGJ, according to Siewert' Classification. Group A: ⩾70 years old; group B: ⩽ 60 years old. Type I A *vs* Type I B *P*>0.05; Type II A *vs* Type II B *P*>0.05; Type III A *vs* Type III B *P*>0.05.

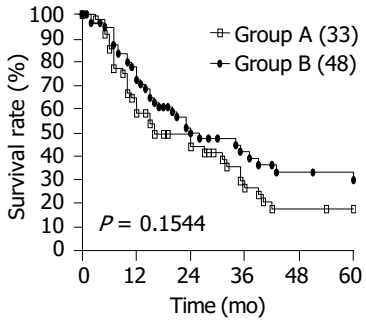

Figure 2 The 5-year survival rates of 113 patients with adenocarcinoma of the EGJ. The younger patients showed a better survival rate than the elderly (*P* = 0.1544). Group A: ⩾70 years old; group B: ⩽60 years old. Kaplan-Meier and log-rank test.

Table 2 Histopathologic data in 81 patients that underwent surgical resection for adenocarcinoma of the EGJ

	Group A (33, %)[1]	Group B (48, %)[1]	*P*
Intestinal metaplasia	71.4	71.4	NS
Curative resection (R0)	69.6	75	NS
Tumor involvement of resection margin	3	4.1	NS
Lymph nodes involvement (N+)	60.6	62.5	NS

[1]Group A: ⩾70-years old; group B: ⩽60-years old.

Table 3 Histopathologic data regarding pN category in 81 patients that underwent surgical resection for adenocarcinoma of the EGJ

pN category	Group A (33)[1]	Group B (48)[1]	*P*
Patients N0	13 (39.3)[2]	18 (37.5)[2]	NS
Patients N+	20 (60.6)[2]	30 (62.5)[2]	NS
Assessed lymph nodes	436	511	NS
Positive lymph nodes	109 (25)[2]	90 (17.6)[2]	NS

[1]Group A: ⩾70 years old; group B: ⩽60 years old. [2]Percentage in parenthesis.

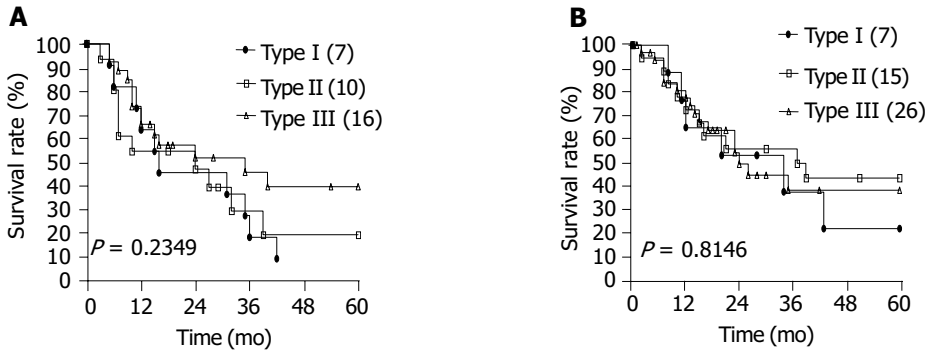

Figure 3 Survival curves according to Siewert's classification in the elderly (**A**) and in the younger group (**B**). In both groups the worst survival rate regarding type I. Group A: ⩾70 years old; group B: ⩽60 years old. Kaplan-Meier and log-rank test.

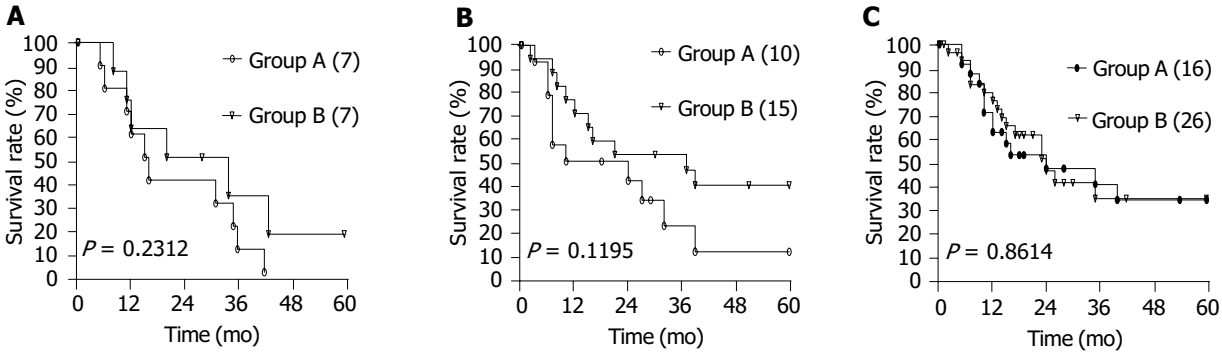

Figure 4 Survival curves according to Siewert's classification for type I (**A**), type II (**B**) and type III (**C**), respectively. There is a difference in survival rate only for types I and II between groups A and B, but not of much significance. Group A: ⩾70 years old; group B: ⩽60 years old. Kaplan-Meier and log-rank test.

5-year survival rate both into R0 (21% *vs* 49.9%) and N0 (24.1% *vs* 70%) category ($P<0.0001$) (Figures 5A and B). Differently, surgical approach and extent of esophago-gastric resection does not influence significantly the survival rates, both in the elderly and in the other group. The extent of esophago-gastric resection for type II tumor still remains a subject of controversy and debate. Regarding this type of tumor, we did not observe any significant improvement in patients that underwent total esophagectomy (Figure 6).

DISCUSSION

There are no major controversies in the surgical therapy of patients with esophageal and gastric cancer, but the management of patients with adenocarcinoma of the EGJ continues to be a matter of debate. Despite their rising incidence, there are marked discrepancies in the definition of such tumors, the selection of the surgical approach, and the outcome of surgical therapy[4,6,7,15]. The classification of Siewert, based purely on anatomical/topographic parameters, is needed for a valid comparison of data from various centers and assessment of different diagnostic and therapeutic approaches[4-6].

Anyway, the evaluation of our surgical results in relation with age was very difficult because not much information was available in the international literature. By comparison of two groups of patients that underwent surgical resection for adenocarc-inoma of the EGJ, we did not observe significant differences as regarding demographic data and survival rates. Younger patients showed a better but not a significant overall survival rate than the elderly people. In our study, this result is independent of the type of tumors, but the worst survival rate regarding type I, probably due to the inefficacious endoscopic screening in patients with EG chronic reflux disease. In elderly patients, we also observed that operability was significantly lower ($P<0.05$) while post-operative death was higher ($P<0.05$) than in the other group. Probably, both operability and primary

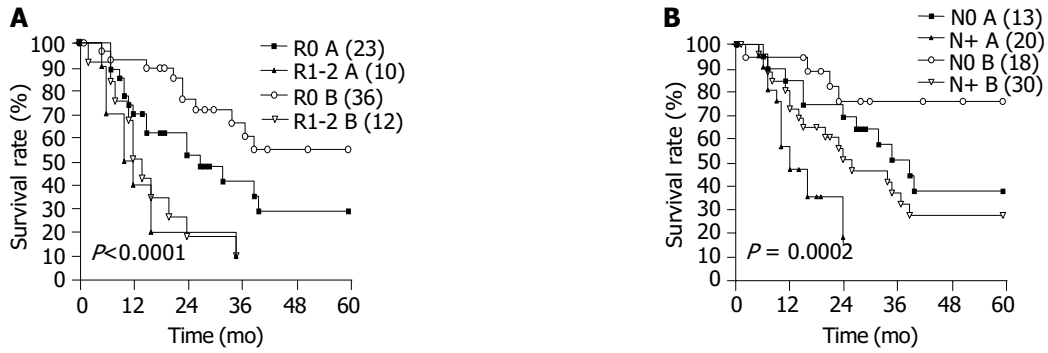

Figure 5 Overall 5-year survival rates of 81 patients with resected adenocarcinoma of the EGJ regarding type of resection (R0 *vs* R1-2) (**A**) and pN category (**B**). Elderly patients showed a lower 5-year survival rate than that of younger patients, both for pN0 category and curative resection (R0). Group A: ⩾70 years old; group B: ⩽60 years old. Kaplan-Meier and log-rank test.

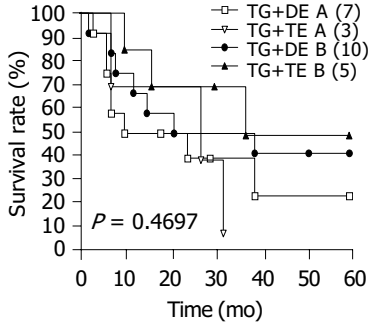

Figure 6 Survival rates of elderly and younger patients regarding the extent of esophagogastric resection for type II tumor: total gastrectomy with distal esophagectomy (TG+DE) *vs* total gastrectomy with total esophagectomy (TG+TE) (P = 0.4697). Both in the elderly and younger patients with type II tumor, total esophagectomy did not improve survival rates significantly. Group A: ⩾70 years old; group B: ⩽60 years old. Kaplan-Meier and log-rank test.

resection are lower in elderly patients due to their age-related comorbidity. Morbidity was higher but not significant in elderly patients[11,22]. Unlike other authors[11], R0 and N0 categories had significantly lower survival rates in the elderly group. It is very difficult to interpret these results, so further studies are needed. There were no differences between the two groups regarding other parameters. Moreover, in patients with type II tumor total esophagectomy did not improve survival rates[4,5].

A radical surgery is also necessary in distal esophagectomy through a safety margin of 3 cm according to some authors or 10 cm according to others[4,5,9,23-25]. In our experience, it is enough to have a safety distance of 5 cm from the upper margin of the tumor to ensure R0 resection. Therefore, the aim of the surgical treatment of the adenocarcinoma of the EGJ is to get a radical oncological resection, taking care of achieving R0 resection.

In conclusion, gastric cardia cancer is usually diagnosed in an advanced stage and is still associated with poor prognosis, particularly in elderly patients. As the age of the general population increases, more elderly patients with gastric cardia cancer will be candidates for surgical resection. In our study, as also observed by other authors for gastric cancer[26], the overall survival data were similar in both groups. Survival rate is strongly linked to curative resection (R0), lymph nodes involvement and stage of disease, which is advanced in more than half of patients. In our experience, unlike other authors, worst results regarding type I, is due to the inefficacious endoscopic screening in patients with EG chronic reflux disease which is correlated to intestinal metaplasia, independent of age. However, just like other authors[3], we observed a high percentage of Barrett's esophagus in elderly patients over 70 years. So, endoscopic secondary prevention should be enhanced in patients with EG reflux disease and particularly in the elderly.

Other authors just observed that an oncologically correct surgical procedure can safely be prosecuted, because age alone should not preclude gastric resection in elderly patients suffering from gastric cancer[26,27]. Regarding the adenocarcinoma of the EGJ, the extent of distal esophagectomy for type II tumor does not influence survival rates on the condition that it achieves a curative resection (R0). The role of lymphadenectomy continues to be a matter of debate. We agree with the necessity of extended lymphadenectomy by transthoracic[28,29] approach but, its potential benefits may be nullified by an associated increase in post-operative morbidity, particularly in over 70-year-old patients. However, we believe that the transhiatal approach according to Pinotti's technique is a more valid alternative than the transthoracic approach, due to the lower incidence of respiratory morbidity and thoracic pain[7,9,30-32]. According to some authors, in selected cases, it is also possible to perform a distal esophagectomy entirely by laparoscopy, without the need for any thoracic or cervical access[33].

In conclusion, age alone should not preclude surgical treatment in elderly patients with gastric cardia cancer and a tumor resection can be carried out safely. Certainly, further studies are needed to confirm the peculiarities observed in elderly patients, just like lower operability and survival rates for type I-II tumors and R0-N0 categories, higher post-operative death and morbidity after thoracotomy. If these data should be confirmed, we should take care in defining the surgical treatment in elderly patients, particularly as regarding the surgical approach.

Abstract

AIM: To identify chromosomal translocations specific to gastric cancer (GC), spectral karyotyping (SKY) analysis was performed on established cell lines and cancerous ascitic fluids.

METHODS: SKY analysis of 10 established cell lines and seven cancerous ascitic fluid samples identified recurrent chromosomal breakpoints and translocations in GC, several of which involved chromosomal loci of oncogenes or tumor suppressor genes.

RESULTS: A total of 630 chromosomal breaks were identified. Chromosome no.8 was the most frequently involved in rearrangements (65 breaks), followed by chromosomes no.11 (53), no. 1 (49), no. 7 (46), no. 13 (37), no. 3 (36), no. 17 (33), and no. 20 (29). Frequent breakpoints were detected in 8q24.1 (30 breaks), 11q13 (29), 13q14 (16), 20q11.2 (14), 7q32 (13), 17q11.2 (13), 18q21 (12), 17q23 (9), 18q11.2 (9). SKY analysis identified a total of 242 chromosomal rearrangements including 190 reciprocal and non-reciprocal translocations. The recurrent combinations of chromosomal bands involved in translocations were 8q24.1 and 13q14 (3 cases), 8q24.1 and 11q13 (3), 11q13 and 17q11.2 (2), and 18q11.2 and 20q11.2 (2). Our study validated the ability of SKY to characterize in detail the chromosomal rearrangements in solid tumors and derived cell lines. Moreover, fluorescence *in situ* hybridization helped to identify the insertions, translocations, and homogeneously staining regions of *MYC* and *CCND1* gene loci.

CONCLUSION: The non-random co-localization of certain cytogenetic bands suggests the importance of chromosomal translocations in gastric carcinogenesis, by serving as landmarks for the cloning of GC causing genes.

INTRODUCTION

Chromosomal aberrations are fundamental to cancer formation because they interfere with the function of oncogenes and tumor suppressor genes. Identification of recurrent chromosomal translocation may thus contribute to the cloning of cancer causing genes. Several genetic alterations associated with gastric cancer (GC) have been reported: (1) amplifications of *MYC, HST1/FGF4*, *INT2/FGF3*, *ERBB2*, *MET*, and *KSAM/FGFR2* genes[1-3], and (2) mutations of *APC*, *KRAS*, *TP53*, E-cadherin (*CDH1*), β-catenin (*CTNNB1*) and *RUNX3/PEBP2* genes[3-5]. These specific alterations have been implicated in multi-stage carcinogenesis of GC.

At the same time, previous cytogenetic studies of GC have demonstrated frequent aberrations of chromosome nos. 1, 3, 6, 7, 8, 13, 17, 20 and Y[6-9], while other chromosomes have also been found to be repeatedly involved in cytogenetic aberrations as demonstrated by recent comparative genomic hybridization (CGH) studies[10-13]. The chromosomal breakpoints identified were 1p22, 3p21, 3q23, 11p13-15, and 19p13 on primary gastric tumors[6,7,14], and 1q32, 5q11-22, 14q22, and 15q15 on human GC cell lines[15]. However, specific chromosomal translocations have not yet been identified in GC, because complete karyotypic analysis

was precluded by the complicated and cryptic nature of the rearrangements as well as the poor banding of condensed chromosomes. To overcome these limitations, multiplex fluorescence *in situ* hybridization (FISH) has been successfully used for two patients with GC[16].

To identify chromosomal translocations specific to human GC, we used multicolor spectral karyotyping (SKY) to analyze established cell lines and cancerous ascitic fluid samples and were able to identify and characterize recurrent chromosomal breakpoints and translocations in GC, several of which involved chromosomal loci of oncogenes or tumor suppressor genes.

MATERIALS AND METHODS

Cell lines and patient samples

Ten GC cell lines (KMK2, KHM14K, MKN1, MKN28, MKN45, MKN74, GT3TKB, SNU1, SNU5, and SNU16) and seven cancerous ascitic fluid samples from advanced GC (patient nos. 1-7) were the subjects of our study. SNU1, SNU5, and SNU16 were obtained from the Korean Research Institute of Bioscience and Biotechnology (Taejon, South Korea), and MKN1, MKN28, MKN45, MKN74, and GT3TKB from the RIKEN Cell Bank (Tsukuba, Japan). Two cell lines, KMK2 and KHM14K, were established at the Kumamoto University School of Medicine (Kumamoto, Japan) and their clinico-pathological features are summarized in Tables 1 and 2. Six cell lines were derived from poorly differentiated adenocarcinoma (MKN45, SNU1, SNU5, SNU16, KMK2, and KHM14K), two from moderately differentiated adenocarcinoma (MKN28 and MKN74), one from undifferentiated mucin-producing adenocarcinoma (GT3TKB), and one from adenosquamous cell carcinoma (MKN1). According to Lauren's classifications[17], seven cell lines (MKN45, SNU1, SNU5, SNU16, KMK2, KHM14K, and GT3TKB) were categorized as diffuse type, and two cell lines (MKN28 and MKN74) as intestinal type.

Primary tumors associated with carcinomatous peritonitis were histopathologically diagnosed as poorly differentiated adenocarcinoma in three patients, signet-ring cell carcinoma in two, and coexisting poorly differentiated adenocarcinoma and signet-ring cell carcinoma in two. These diagnoses indicated that all these tumors were diffuse type GC according to Lauren's classification. Ascitic fluid was aspirated with a syringe and the addition of heparin from the peritoneal cavities of seven patients with carcinomatous peritonitis. Informed consent in accordance with the institutional guidelines was obtained, for using the diagnostic material for research purposes.

Cell cultures and chromosome preparations

G-banding studies were performed as described previously[18]. Briefly, ascitic fluid was diluted in 10 mL of RPMI 1640 medium supplemented with 10% fetal calf serum at a final concentration of 1×10^6 cells/mL. The cells were cultured at 37 ℃ for 24-48 h in humidified air with 50 mL/L CO_2, exposed to colcemid (0.05 μg/mL) for 60 min, processed in 0.075 mol/L potassium chloride for 20 min, and fixed with methanol/glacial acetate (3:1). Chromosomes were stained with a Giemsa solution pretreated with trypsin, and karyotyped according to the International System for Human Cytogenetic Nomenclature (ISCN 1995)[19]. The remaining chromosome pellets were stored at -20 ℃ for SKY and FISH analyses.

SKY studies

Chromosomes prepared on a slide glass were denatured and hybridized with a cocktail probe mixture for 2 d at 37 ℃. The SKY probe mixture and hybridization reagents were purchased from Applied Spectral Imaging Inc. (Carlsbad, CA, USA) and signal detection was performed according to the manufacturer's protocol. Chromosomes were counterstained with 4', 6-diaminido-2-phenylindole dihydrochloride (DAPI) combined with an anti-fade solution (Vectaschield; Vector Laboratories, Burlingame, CA, USA). Images were acquired by means of an SD200 Spectracube (Applied Spectral Imaging) mounted on an Olympus BX50-RF (Olympus, Tokyo, Japan) using a custom-designed optical filter (SKY-1; Chroma Technology, Brattleboro, VT). With another special optical filter, the inverted DAPI images were captured in conjunction with spectral classifications as QFH band patterns for the identification of chromosomal breakpoints[20,21]. For each case, 10-20 metaphase spreads were analyzed, and karyotypes were described according to the ISCN 1995.

Double-color fluorescence in situ hybridization (DC-FISH)

Two cell lines, SNU16 and KMK2, were studied by means of DC-FISH using an oncogene and whole chromosome painting (WCP) probes. DC-FISH was performed as described previously[18]. The oncogene probe consisted of an I2 yeast artificial chromosome (YAC) clone containing *MYC* on 8q24.1 and a CPP29 cosmid containing *CCND1* on 11q13.3[22,23]. Human-specific DNA sequences were amplified from YAC by means of Alu-polymerase chain reaction[24], DNA probes were labeled by biotin-16-dUTP and digoxigenin-16-dUTP (Boehringer Mannheim Biochemicals, Mannheim, Germany). Metaphase spreads were counterstained with 0.04 μg/mL of DAPI, mounted in an anti-fade solution (Vectaschield), and observed with a BX40-RF fluorescence microscope (Olympus). Images were captured with a CCD camera (SenSys0400-G1; Photometrics Ltd, Tucson, AZ, USA).

RESULTS

Cytogenetic and SKY analysis

All established cell lines and patients with GC showed clonal karyotypic abnormalities. The modal chromosome number varied from 39 to 89. SKY detected chromosomal deletions, translocations (mainly unbalanced), inversions, insertions, dicentrics, duplication, ring chromosomes, isochromosomes, double minute chromosomes (DMs), and homogeneously staining regions (HSRs). Complex rearrangements involving more than three chromosomes were frequently encountered (Figure 1). Polysomy of chromosomes no. 16 (8 cases), no. 20 (8), no. 11 (7), and no. 9, no. 15, and no. 22 (5 each), and monosomy of chromosomes no. 5 (5 cases), and no. 4, no. 6, no. 13, no. 14, no. 15, no. 21, and no. 22 (4 each) were frequently observed. Structural rearrangements most

frequently involved chromosome no.8 (65 breaks), followed by chromosomes no. 11 (53), no. 1 (49), no. 7 (46), no. 13 (37), no. 3 (36), no. 17 (33), and no. 20 (29) (Figure 2). Chromosomal segments and bands were identified by combining SKY with DAPI banding (Figure 1). Representative karyotypes are listed in Tables 1 and 2.

A total of 630 chromosomal breaks that occurred in 177 breakpoints were identified by means of SKY analysis as shown in Figure 2 with several breakpoints highlighted: 8q24.1 (30 breaks), 11q13 (29), 13q14 (16), 20q11.2 (14), 7q32 (13), 17q11.2 (13), 18q21 (12), 17q23 (9), 18q11.2 (9), 1p22 (8), 1q32 (8), 7q22 (8), 8p11.2 (8), 8q22 (8), 9q22 (8), 10q22 (8), 20q13 (8), Xq22 (8), 7q11.2 (7), 11q23 (7), 22q11.2 (7), 3p13 (6), 3p21 (6), 3q21 (6), 4q12 (6), 9q13 (6), 13q12 (6), and 14p11.2 (6).

DC-FISH using YAC I2 and applied to two cell lines (SNU16 and KMK2) demonstrated that the chromosomal locus of the *MYC* gene (8q24.1) was involved in various types of chromosomal rearrangements including translocation, HSRs, and frequent insertion, thus resulting in gain and amplification of the gene (Figure 3). FISH using the MYC probe showed a periodic staining pattern, although we initially defined HSRs as abnormalities of chromosome no. 2 based on its SKY staining property as shown in Figure 3.

In KMK2, DC FISH with WCP 11 and cosmid CPP29 demonstrated that the chromosomal locus of the *CCND1* gene (11q13) was involved in translocations, resulting in increased copy number of the gene (Figure 4).

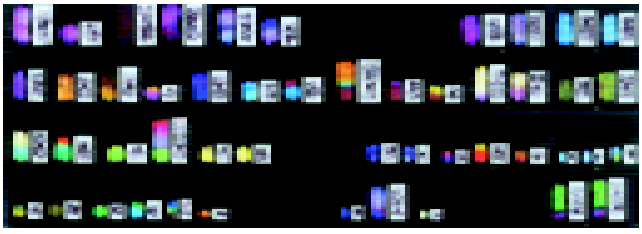

Figure 1 SKY analysis in GT3TKB. Color images are shown alongside inverted DAPI banding images.

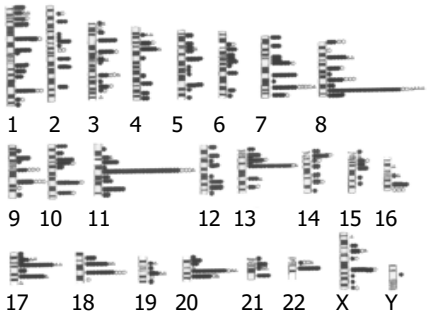

Figure 2 Assignment of breaks in 7 patients with GC and 10 established cell lines. A total of 630 breaks were identified by SKY. Closed and open circles represent diffuse type and intestinal type, respectively. Open triangle represents the breakpoints obtained from one cell line MKN1 established from a GC patient with adenosquamous cell carcinoma. Mapping analysis of breaks to the ideograms delineated two outstanding loci, 8q24.1 and 11q13. The other breakpoints highlighted are 13q14, 17q11.2, 18q21, and 20q11.2.

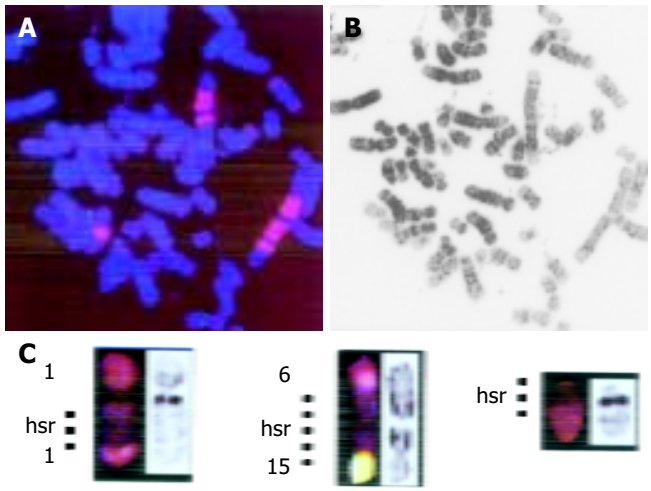

Figure 3 FISH and SKY analysis on SNU16. **A**: DC-FISH using YAC probe I2 (8q24.1, red) and cosmid probe CPP29 (11q13.3, green). I2 probe shows periodic staining pattern on HSRs, indicating amplification of *MYC* gene on HSRs but not double minute chromosomes (DMs). Three copies of *CCDN1* gene are detected; **B**: Inverted DAPI band image of the same metaphase plate shown in A; **C**: SKY findings of HSRs found in SNU16. Three HSRs were initially identified as originating from chromosome no. 2 based on their fluorescence color.

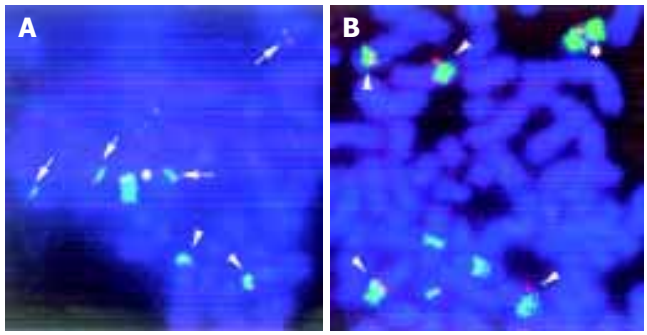

Figure 4 FISH analysis on KMK2. **A**: DC-FISH using YAC probe I2 (8q24.1, red) and WCP probe for chromosome 8 (green) demonstrates multiple insertions (arrows) and translocations (arrowheads) of *MYC* locus. Asterisk indicates a normal chromosome 8. **B**: DC-FISH using cosmid probe CPP29 (red) and WCP probe for chromosome 11 (green) demonstrates multiple translocations (arrowheads) at *CCND1* locus. Asterisk indicates a normal chromosome 11.

Identification of recurrent chromosomal translocations

A total of 242 chromosomal rearrangements including 190 translocations were identified. The four combinations of chromosomal bands repeatedly involved in translocations comprised 8q24.1 and 13q14 (SNU5, KMK2, and patient no. 6), 8q24.1 and 11q13 (SNU16, KMK2, and patient no. 1), 11q13 and 17q11.2 (KMK2 and MKN1), and 18q11.2 and 20q11.2 (GT3TKB and patient no. 7) as shown in Figure 5. Table 3 shows common translocation partners,

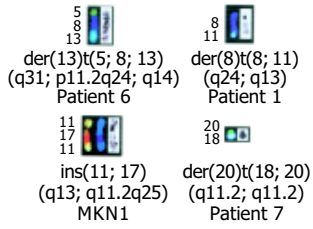

Figure 5 Partial karyotypes of recurrent translocations.

[1]The number of breaks are indicated.

some of which were previously undetectable because of the structurally complicated chromosomal rearrangements. The same der(20)t(18;20)(q11.2;q11.2) was found in two cases (GT3TKB and patient no. 7; Figure 3), and chromosome deletions of del(7)(q32), del(10)(q22), del(11)(q13), and del (18)(q11.2) were detected in two cases each.

DISCUSSION

SKY analysis proved to be capable of identifying 630 breaks and 242 rearrangements of chromosomes in 10 established cell lines and seven cancerous ascitic fluid samples of GC, as well as of identifying recurrent breakpoints. Chromosomal rearrangements frequently involved well-known oncogene and tumor suppressor gene loci that may be associated with gastric carcinogenesis, such as 8q24.1 (*MYC*), 11q13 (*HST1/FGF4, INT2/FGF3, and CCND1*), 7q32 (*MET*), 13q14 (*RB*), 17q11.2 (adjacent to the *ERBB2* locus), 18q21 (*DCC* and *BCL2*), 7q22 (*MET*), 3p21 (*CTNNB1*), and 16q22 (*CDH1*). The other breakpoints that were detected more than eight times were 20q11.2 (14 breaks), 17q23 (9), 18q11.2 (9), 1p22 (8), 1q32 (8), 8p11.2 (8), 8q22 (8), 9q22 (8), 10q22 (8), 20q13 (8), and Xq22 (8). However, it is not clear which breakpoints represent key genes during the earlier stages of tumorigenesis in this lineage, because when the entire tumor was examined in our study, it was already highly progressed and in the case of cell lines, they were further selected for liver culture conditions.

Two distinct breakpoints, which were not noted as unique occurrences by G-banding, 8q24.1 (30 breaks, 4.8% of 630 breaks) and 11q13 (29, 4.6%), were identified by a combination of SKY and DAPI banding analysis. The currently most likely candidate at 8q24 is the *MYC* gene, because it was frequently amplified and overexpressed in advanced GC, particularly in patients with carcinomatous peritonitis or distant metastasis[25,26]. The DC-FISH analysis used in our study showed that the *MYC* locus was involved in amplification resulting from the HSR as well as in multiple chromosomal translocations, insertions, and duplications in KMK2 (Figures 3 and 4). However, in SNU16, the *MYC* locus was amplified in HSRs but not on DMs, suggesting that other genes, for example the *K-sam* gene, may be involved in DMs (Figure 3)[27].

The second common breakpoint of 11q13 contains a variety of genes associated with cell proliferation and differentiation such as *HST1/FGF4, INT2/FGF3, CCND1, SEA, MYEOV*, and *SPA1*[28,29]. It has been demonstrated that *HST1/FGF4* is co-amplified with *INT2/FGF3* in human GC, although amplification of *FGF4* and *FGF3* does not correlate with mRNA overexpression[30], while high-level amplification of 11q13 has been frequently detected in CGH analysis[12,13]. All these genes are assigned to band 11q13.3. Band 11q13 may thus span a region approximately 25 Mb in size as estimated from both the physical length of 11q (86 Mb) and the number and size of the bands, which are divided into five sub-bands including three light bands (q13.1, q13.3, and q13.5). Since it is difficult to distinguish these subregions in a karyotype of 400 bands, 11q13.1 and 11q13.5 also warrant molecular dissection for the identification of target genes.

Combining SKY and DAPI banding analysis led to the identification of recurrent co-localization of the chromosomal bands involved in translocations: 8q24.1 and 13q14 (3 cases), 8q24.1 and 11q13 (3), 11q13 and 17q11.2 (2), and 18q11.2 and 20q11.2 (2). These translocations used to be frequently undetectable because of the complicated rearrangements of chromosomes. In most cases, each co-localized breakpoint contains chromosomal segments to which oncogenes or tumor suppressor genes have been assigned.

In conclusion, SKY analysis identified the frequently occurring breakpoints 8q24.1, 11q13, 20q11.1-13.1, and 13q14 and the recurrent translocations 8q24.1 and 13q14, 8q24.1 and 11q13, 11q13 and 17q11.2, and 18q11.2 and 20q11.2. SKY thus proved to be extremely useful for a comprehensive analysis of chromosomal translocations in GC and derived cell lines. The chromosomal breakpoints defined in our study may well contain critical genes which are involved in multistage carcinogenesis of GC and thus can serve as landmarks for crucial regions that warrant molecular dissection.

ACKNOWLEDGMENTS

We are grateful to Professor Carlo M. Croce (Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA) for providing DNA probes I2 and P72 (*MYC*) and to Dr. Masao Seto (Aichi Cancer Center Research Institute, Nagoya) for providing CPP29 (*CCND1*). We also wish to thank Professor Takeshi Okanoue (Department of Gastroenterology and Hepatology, Kyoto Prefectural University of Medicine, Kyoto) for critical reading of the manuscript.

Abstract

AIM: To investigate the effects of chitosan nanoparticles on proliferation of human gastric carcinoma cell line MGC803 *in vitro* and the possible mechanisms involved.

METHODS: Chitosan nanoparticles were characterized by particle size, zeta potential, and morphology. After treatment with various concentrations of chitosan nanoparticles (25, 50, 75, 100 μg/mL) at various time intervals, cell proliferation, ultrastructural changes, DNA fragmentation, mitochondrial membrane potential (MMP), cell cycle phase distribution and apoptotic peaks of MGC803 cells were analyzed by MTT assay, electron microscopy, DNA agarose gel electrophoresis, and flow cytometry.

RESULTS: Chitosan nanoparticles exhibited a small particle size as 65 nm and a high surface charge as 52 mV. Chitosan nanoparticles markedly inhibited cell proliferation of MGC803 cells with an IC_{50} value of 5.3 μg/mL 48 h after treatment. After treatment with chitosan nanoparticles, the typical necrotic cell morphology was observed by electron microscopy, a typical DNA degradation associated with necrosis was determined by DNA agarose electrophoresis. Flow cytometry showed the loss of MMP and occurrence of apoptosis in chitosan nanoparticles-treated cells.

CONCLUSION: Chitosan nanoparticles effectively inhibit the proliferation of human gastric carcinoma cell line MGC803 *in vitro* through multiple mechanisms, and may be a beneficial agent against human carcinoma.

INTRODUCTION

Chitosan, the deacetylated derivative of chitin, is one of the abundant, renewable, nontoxic and biodegradable carbohydrate polymers, and available largely in the exoskeletons of shellfish and insects. Chitosan has been widely applied as a functional biopolymer in food and pharmaceutics. Chitosan is known to have various biological activities including immuno-enhancing effects, antitumoral, antifungal, and antimicrobial activities[1-3]. Chitosan nanoparticles have been previously synthesized as drug carriers[4-6]. In our previous reports, chitosan nanoparticles are prepared and characterized to investigate their heavy metal sorption, antibacterial, and antitumor activities[7-9]. The unique characteristics of chitosan nanoparticles could provide a higher affinity for negatively charged biological membranes and site-specific targeting *in vivo*[7]. Chitosan nanoparticles could elicit dose-dependent inhibitory effects on the proliferation of various tumor cell lines, while low toxicity against normal human liver cells[9].

In this paper, *in vitro* effects of chitosan nanoparticles on the proliferation of human gastric carcinoma (MGC803) cells were studied to illustrate the possible mechanisms involved. Cell viability was determined by MTT assay, necrotic cell morphology and DNA fragmentation were observed by electron microscopy and DNA agarose electrophoresis. Changes of mitochondrial membrane potential (MMP), cell cycle, and apoptotic peaks were analyzed by flow cytometry.

MATERIALS AND METHODS

Characterization of chitosan nanoparticles

Chitosan nanoparticles were prepared as described previously[7,8]. Particle size distribution and zeta potential of chitosan nanoparticles were determined using Zetasizer Nano-ZS90 (Malvern Instruments). The analysis was performed at a scattering angle of 90° at 25 ℃ using samples diluted to different intensity concentrations with de-ionized distilled water. Transmission electron microscopy (TEM, JEM-1200EX) was used to determine the morphology of chitosan nanoparticles.

Cell line and cell culture

Human gastric carcinoma MGC803 cell line was obtained from the Cell Bank of the Chinese Academy of Sciences, Shanghai, China. The cell line was cultured in RPMI-1640 supplemented with 10% heat-inactivated fetal bovine serum (GIBCO). The cell cultures were maintained at 37 ℃ in a humidified incubator in an atmosphere of 95% air and 50 mL/L CO_2.

Cell viability assay

In the case of floating MGC803 cells, 100 μL aliquot of

cell suspension containing 10^6 cells was added to each well of a 96-well plate (Corning, USA). After being cultured for 24 h, the cells were immediately treated with various doses (25, 50, 75, 100 μg/mL) of chitosan nanoparticles for another 24 or 48 h. The effect of different treatments on cell viability was assessed by the tetrazolium dye assay[10].

Scanning electron microscopy (SEM)

MGC803 cells grown on glass coverslips were incubated with 100 μg/mL chitosan nanoparticles at intervals from 30 min to 4 h. The appropriate solvent was added to the control. Chitosan nanoparticles-treated and untreated cells were fixed in glutaraldehyde/paraformaldehyde solution and prepared for SEM by the triple-fixation GTGO methods. Briefly, the glutaraldehyde/paraformaldehyde-fixed cell monolayer was post-fixed by 2% osmium tetraoxide (OsO_4) and the final fixation step was performed by 2% tannic acid/guanidine hydrochloride. Thereafter, the cells were dehydrated in graded ethanol solutions, ethanol was exchanged by graded solutions of Freon 113, and the cells were air-dried and gold-coated using a Polaron sputter coater. The surface morphology of cells was examined by a XL30-ESEM scanning electron microscope.

Transmission electron microscopy (TEM)

MGC803 cells grown on glass coverslips were incubated with 100 μg/mL chitosan nanoparticles for 24 h. The appropriate solvent was added to the controls. Chitosan nanoparticles-treated and untreated cells were fixed in glutaraldehyde/paraformaldehyde solution and prepared for TEM as previously described[11]. Observations and micrographs were made under a JEM-1200EX TEM.

DNA fragmentation

After treatment with 100 μg/mL chitosan nanoparticles for 6 or 24 h, cells were collected, washed with PBS, and lysed with a solution containing 10 mmol/L Tris-HCl pH 7.4, 10 mmol/L EDTA and 0.5% Triton X-100. The lysates were incubated with 200 mg/mL RNase A (Sigma) for 1 h followed by 200 mg/mL proteinase K (GIBCO) for 1 h at 37 ℃. These samples were then extracted with phenol/chloroform/isoamyl alcohol (25:24:1, v/v/v) followed by chloroform. DNA was precipitated in two volumes of ethanol in the presence of 0.3 mol/L sodium acetate. The DNA samples thus obtained were run on 1.5% agarose gel at 50 V and visualized by ethidium bromide staining under UV light.

Determination of mitochondrial membrane potential

To study the MMP, MGC803 cells were treated with various concentrations of chitosan nanoparticles (25, 50, 75, 100 μg/mL) for 4 h, and then stained with 10 μg/mL rhodamine 123 (Sigma) for 30 min, which is easily sequestered by the mitochondrial membrane[12]. Once the MMP was lost, rhodamine 123 was subsequently washed out of the cells. The MMP was determined using a FACSCalibur flow cytometer (Becton Dickinson, San Jose, CA) and analyzed by a CellQuest software program (BD PharMingen, Franklin Lakes, USA).

Cell cycle analysis

Flow cytometry was employed to determine the DNA content and the apoptotic peaks of the cells. MGC803 cells were seeded on 100-mm dishes and grown in RPMI-1640 supplemented with 10% fetal bovine serum. After being treated with various concentrations of chitosan nanoparticles (25, 50, 75, 100 μg/mL) for 24 h, the cells were harvested, trypsinized, washed with PBS, fixed by adding slowly 2 mL of cold 70% ethanol into the tube and then stored at 4 ℃. After fixation, the cells were washed, centrifuged, and resuspended in 0.05 mg/mL propidium iodide (Sigma, USA), 100 U/mL RNase (Sigma, USA) in PBS. The sample was incubated for 30 min at room temperature in the dark, and analyzed on a FACSCalibur flow cytometer. Cell cycle data originally obtained with CellQuest software were re-analyzed using ModFit software (Verity Software House, Topsham, USA). At the same time negative controls were constructed.

RESULTS

Size, zeta potential, and morphology of chitosan nanoparticles

The average particle size of chitosan nanoparticles was 65 nm and the size distribution ranged from 46 to 83 nm (Figure 1). Zeta potential, i.e., surface charge greatly influenced the particle stability in suspension through the electrostatic repulsion between the particles. It could also determine the interaction of nanoparticles *in vivo* with the tumor cell membrane, which was usually negatively charged. Chitosan nanoparticles had a positive charge about 52 mV (Figure 2A), much higher than that of chitosan in 0.25% acetic acid solution (Figure 2B). A solid dense structure and a round shape of chitosan nanoparticles were shown under TEM (Figure 3).

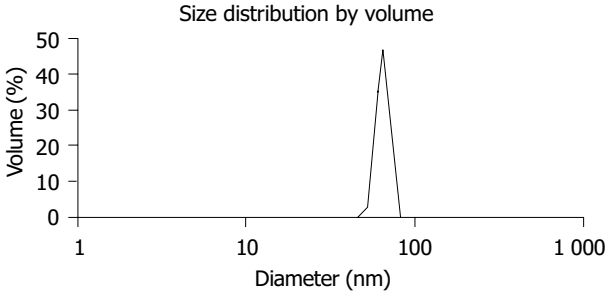

Figure 1 Size distribution of chitosan nanoparticles.

Cell viability assay

In this study, the exponentially grown gastric carcinoma MGC803 cells were treated with various concentrations of chitosan nanoparticles ranging from 25 to 100 μg/mL, and the cell viability was measured by the MTT assay. The inhibition of cell viability by chitosan nanoparticles was clearly observed in a dose- and time-dependent manner (Figure 4). The median lethal concentration of chitosan nanoparticles was 16.2 and 5.3 μg/mL for MGC803 cells at 24 and 48 h, respectively.

Necrotic cell morphology

Necrosis is known to occur due to the disruption of cellular and nuclear membranes under extreme physiological stimuli.

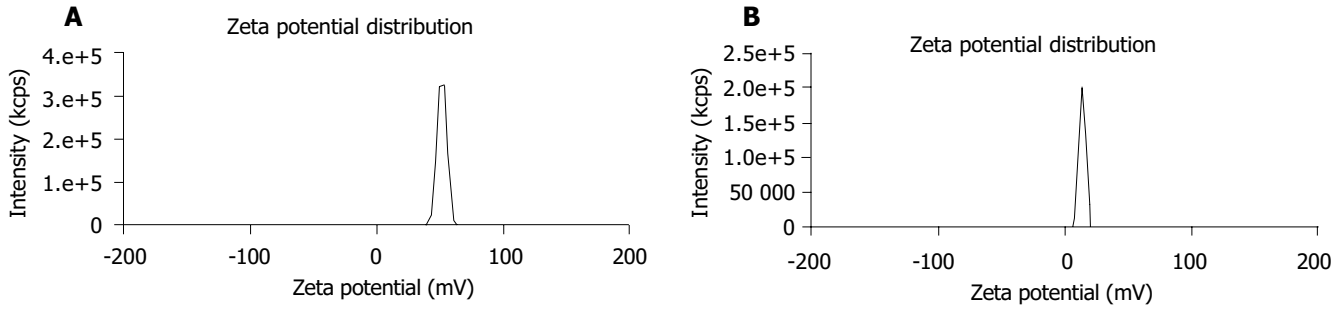

Figure 2 Zeta potential distribution of chitosan nanoparticles (**A**) and chitosan (**B**) in 0.25% acetic acid solution.

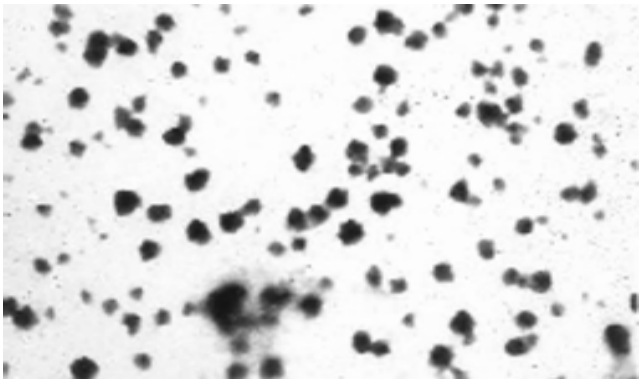

Figure 3 TEM photograph of chitosan nanoparticles. The bar stands for 100 nm.

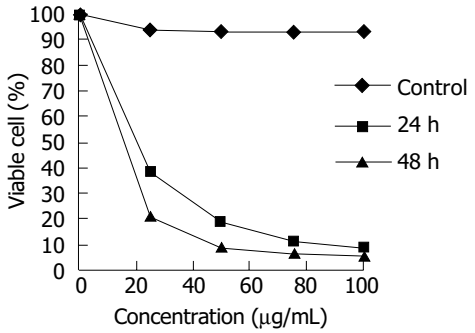

Figure 4 Inhibition of chitosan nanoparticles on MGC803 cell proliferation.

Rupture of the cellular membrane is one of the crucial criteria used to distinguish necrosis from apoptosis[12]. The ultrastructural alterations of MGC803 cells treated with chitosan nanoparticles were observed under scanning electron microscope and transmission electron microscope. MGC803 cells treated with chitosan nanoparticles displayed typical morphological features of necrosis. Control MGC803 cells showed their normal shape and surface morphology under SEM (Figure 5). The cell surface showed the presence of numerous, randomly distributed microvilli. Cell death induced by chitosan nanoparticles showed the features of necrosis as evidenced by an early membrane leakage and the microvilli reduction after 30-min treatment. Microvilli disappeared and irregular tiny holes appeared on the cells' surface when treated for 2 h, with fracturing membrane solubilization. MGC803 cells appeared extensively damaged. The cells that broke into pieces were observed as honeycomb shape after 4-h treatment. The loss of membrane integrity and pore forming surface morphology suggested a necrotic type of cell death and the unique mechanism of interaction between chitosan nanoparticles and plasma membrane.

Necrotic morphological features of MGC803 cells treated with chitosan nanoparticles such as disruption of the cytoplasm and appearance of remnants of swollen organelles were also revealed under TEM (Figure 6). Untreated cells showed integral membrane distributed with microvilli and normal organelle. While treated with chitosan nanoparticles for 24 h, cells became vacuolated, the plasma membrane was disrupted completely, and the content in the cells leaked out.

DNA fragmentation

DNA was extracted from cultured MGC803 cells treated with 100 μg/mL chitosan nanoparticles for 6 or 24 h, the occurrence of necrosis was detected by agarose gel electrophoresis. Specific DNA degradative smearing typical of necrotic degeneration[13] was prominent in cells incubated with chitosan nanoparticles for 6 h, and the fragmented DNA increased greatly in cells treated for 24 h (Figure 7).

Alterations of mitochondrial membrane potential (MMP)

One possible mechanism involved in the necrosis of MGC803 cells induced by chitosan nanoparticles is mitochondrial damage. In this study, chitosan nanoparticles caused a dose-dependent decrease of MMP in MGC803 cells treated for 4 h (Figure 8). The percentage of cells with the loss of MMP increased significantly with the increase of chitosan nanoparticles concentration, and reached 74% when treated with 100 μg/mL chitosan nanoparticles. The strong dissipation in MMP suggested a possible disruption of cell mitochondrial membrane after chitosan nanoparticle treatment.

Cell cycle effects

The effects of chitosan nanoparticles on cell cycle progression, population distribution and apoptotic incidence in MGC803 cells were determined by flow cytometry. Chitosan nanoparticles-induced effects were detected by comparing the cell cycle profiles between nanoparticles-treated and untreated cells. Results demonstrated a significant decrease of cells in the G_0/G_1 phase (Table 1). Apoptotic peaks were observed

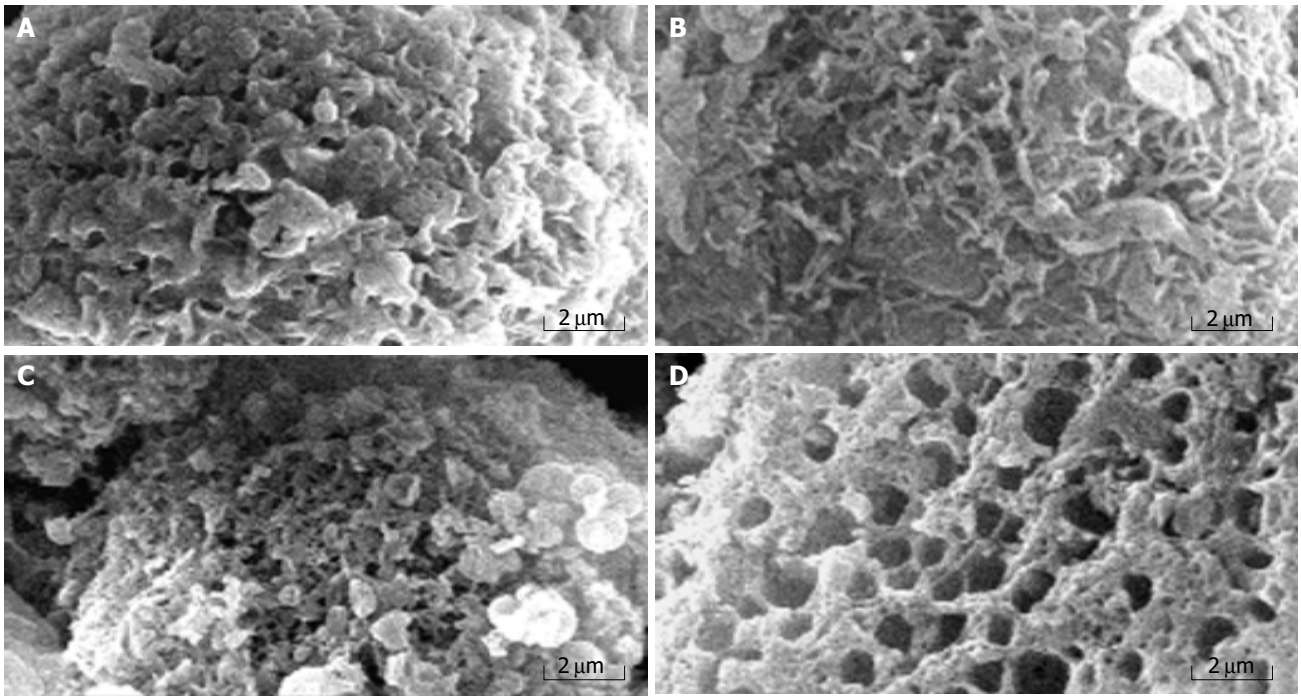

Figure 5 Surface morphology of control cells (**A**) and MGC803 cells treated with 100 μg/mL chitosan nanoparticles for 30 min (**B**), 2 h (**C**), and 4 h (**D**).

and cell apoptotic incidence increased in a dose-dependent manner after chitosan nanoparticle treatment. The apoptotic incidence increased to 9.9% after being treated with 100 μg/mL chitosan nanoparticles (Figure 9).

DISCUSSION

Due to its reported biocompatibility and biodegradability[14], chitosan has been applied in drug delivery systems to prepare microspheres or nanospheres for encapsulation of drugs, enzymes, proteins, and DNA[15-17]. Chitosans could be developed as sole drugs for its biological activities. Soluble chitosan and chitosan microspheres are reported to show some degree of toxicity towards a murine melanoma cell line, B16F10, chitosan hydrochloride is most toxic having an IC_{50} of 0.21±0.04 mg/mL[18]. Amino-derivatized cationic chitosan derivatives show dose-dependent inhibitory effects on the proliferation of several tumor cell lines, with a lowest IC_{50} of 22±4 μg/mL towards liver cancer[19].

Positively charged chitosan nanoparticles prepared by our laboratory exhibit a higher cytotoxicity than other chitosan derivatives against various tumor cell lines, and a low toxicity against normal human liver cells[9]. The present study demonstrated that chitosan nanoparticles could exert a high cytotoxicity against human gastric carcinoma MGC803 cell line. The gastric carcinoma cell line has been proved to be sensitive to chitosan nanoparticles with an IC_{50} value of 5.3 μg/mL after 48-h treatment, suggesting that chitosan nanoparticles may be a good candidate for antitumoral drugs. Particle size of nanoparticles plays a crucial role in their antitumor activity and *in vivo* distribution[20,21]. Smaller nanoparticles show a higher accumulation at tumor sites and prolong *in vivo* half-life due to their avoidable capture by the reticuloendothelial system[22,23]. Here, the particle size

AI: apoptotic incidence; [b]$P<0.01$ *vs* control.

of chitosan nanoparticles could be controlled only to 65 nm, which is in favor of the antitumor activity and prolongs efficacy of chitosan nanoparticles. Polymers with high cationic charge densities have higher cytotoxic effects than those with low charge densities[24]. As a kind of cationic polymers, the surface charge of chitosan derivatives is the major factor affecting its cytotoxic activity due to the electrostatic ionic interaction between the negatively charged groups of tumor cells and the positively charged amino groups of chitosans[19]. Therefore, the high surface charge about 52 mV of chitosan nanoparticles is responsible for its higher cytotoxic activity.

Morphologically, necrosis is quite different from apoptosis. During necrosis, cells first swell, then the plasma membrane collapses and cells are rapidly lysed, while apoptotic cells disintegrate into well-enclosed apoptotic bodies without loss of membrane integrity[25]. The ultrastructural alterations of MGC803 cells observed by electron microscopy displayed typical morphological features of necrosis due to the treatment of chitosan nanoparticles, suggesting that chitosan nanoparticles induce necrotic tumor cell death and can be used as a membrane-active drug. Chitosan nanoparticles are positively charged due to the cationic characteristics of chitosan[26]. Chitosan nanoparticles could be first adsorbed onto the negatively charged tumor cell membrane by electron interaction, then exhibit antitumoral effects by damaging membrane and disrupting organelle, and finally lead to cell death with the structure breakdown.

Fragmented DNA during apoptosis appears as a series of bands, which are described as "DNA ladders" on agarose gels, representing formation of oligonucleosomes with the characteristics of apoptosis[27,28]. In contrast, fragmented DNA during necrosis appears as a continuous spectrum of sizes[29]. In this study, chitosan nanoparticles-treated tumor

cells also yielded a continuous spectrum of DNA fragments of low molecular mass, indicating that necrosis is induced by chitosan nanoparticles.

It was reported that mitochondria play a crucial role in regulation of cell death[30]. Under extreme conditions (e.g., high Ca^{2+}, oxidative stress) mitochondria undergo drastic changes, accompanied with decrease of the mitochondrial potential, de-energization, swelling, and permeabilization of the inner membrane[31]. Furthermore, the occurrence of mitochondrial dysfunction is rapidly followed by or nearly coincident with the loss of plasma membrane integrity[32], thus leading to necrotic cell death at last. In this study, a drastic decrease of MMP was observed in chitosan nanoparticles-treated human gastric carcinoma cells, indicating that the mitochondrial membrane is damaged.

Cell cycle analysis showed a significant decrease of cells in the G_0/G_1 phase and the dose-dependent apoptosis in chitosan nanoparticles-treated cells, suggesting that apoptosis is also involved in the cell death induced by chitosan nanoparticles.

In summary, chitosan nanoparticles with a small particle size of about 65 nm and a positive surface charge of about 50 mV exhibit a high cytotoxicity towards human gastric carcinoma cell line MGC803 and induce cell death with predominant necrotic features. The antitumor mechanism of chitosan nanoparticles is related to their membrane-disrupting and apoptosis-inducing activities.

Abstract

AIM: To examine whether *trans*-10,*cis*-12 CLA (*t*10*c*12) or *cis*-9,*trans*-11 CLA (*c*9*t*11) inhibits heregulin (HRG)-β-stimulated cell growth and HRG-β-ErbB3 signaling in HT-29 cells.

METHODS: We cultured HT-29 cells in the absence or presence of the CLA isomers and/or the ErbB3 ligand HRG-β. MTT assay, [^{3}H]thymidine incorporation, Annexin V staining, RT-PCR, Western blotting, immunoprecipitation, and *in vitro* kinase assay were performed.

RESULTS: HRG-β increased cell growth, but did not prevent *t*10*c*12-induced growth inhibition. *T*10*c*12 inhibited DNA synthesis and induced apoptosis of HT-29 cells, whereas *c*9*t*11 had no effect. *T*10*c*12 decreased the levels of ErbB1, ErbB2, and ErbB3 proteins and transcripts in a dose-dependent manner, whereas *c*9*t*11 had no effect. Immunoprecipitation/Western blot studies revealed that *t*10*c*12 inhibited HRG-β-stimulated phosphorylation of ErbB3, recruitment of the p85 subunit of phosphoinositide 3-kinase (PI3K) to ErbB3, ErbB3-associated PI3K activities, and phosphorylation of Akt. However, *c*9*t*11 had no effect on phospho Akt levels. Neither *t*10*c*12 nor *c*9*t*11 had any effect on HRG-β-induced phosphorylation of ERK-1/2.

CONCLUSION: These results indicate that the inhibition of HT-29 cell growth by *t*10*c*12 may be induced via its modulation of ErbB3 signaling leading to inhibition of Akt activation.

INTRODUCTION

Conjugated linoleic acid (CLA) is a mixture of positional and geometric isomers of octadecadienoic acid found naturally in beef, cheese, and butter fat. During the past few years, CLA has attracted considerable attention as one of the most promising cancer chemopreventive agents[1]. Previously, we have shown that dietary CLA inhibited colon tumor incidence in rats treated with 1,2-dimethylhydrazine[2,3]. In addition to animal studies, *in vitro* studies have shown that CLA inhibits the growth of human colon cancer cells, SW 480[4] and HT-29 cells[5-7]. In contrast to these observations, other studies reported results that dietary treatment with CLA had no effect on tumor number or size in the $APC^{min/+}$ mouse, a genetic model of intestinal tumorigenesis[8]. Most of the experimental and *in vitro* studies on CLA have utilized synthetic CLA mixtures containing the two principal isomers, *cis*-9,*trans*-11 CLA (c9*t*11) and *trans*-10,*cis*-12 CLA (*t*10*c*12)[9]. Recently, Rajakangas *et al*.[10], reported that *t*10*c*12 increased the size of adenoma in the distal part of the small intestine in the multiple intestinal neoplasia (Min) mouse model. The reason for these conflicting results can be resolved, if we understand the mechanisms by which CLA regulates colon cancer cell growth.

The ErbB family of receptor tyrosine kinases currently includes four members: epidermal growth factor receptor (EGFR)/ErbB1, ErbB2, ErbB3, and ErbB4. Polypeptides in the EGF family individually bind to and activate one or more ErbB family members[11,12]. Ligand-induced receptor homo- and hetero-dimerization stimulates ErbB receptor activation and subsequent transphosphorylation between the dimerization partners.[13] Although ErbB3 is devoid of intrinsic kinase activity[14], heregulin (HRG) binds to ErbB3 and facilitates the formation of heterodimers with ErbB2, the most mitogenic family member[15,16].

The activated ErbB family receptors interact with diverse signaling pathways that ultimately may lead to cell division, differentiation, and chemotaxis. Two representative intracellular effectors of ErbB2/ErbB3 HRG coreceptor complex are mitogen-activated protein (MAP) kinase and phosphoinositide 3-kinase (PI3K). ErbB3, which incorporates multiple PI3K

binding sites, has been shown to be a major recruiter of PI3K. PI3Ks phosphorylate inositol phospholipids at position 3 of the inositol ring and PI3K lipid products interact with certain proteins and modulate their localization and/or activity[17]. Protein kinase B (PKB) or Akt is known as an important downstream target for PI3K, which can be activated by a variety of growth factors and cytokines via phosphorylation on serine and threonine residues[18-20] and may participate in growth factor stimulated cell cycle[21,22] and inhibition of apoptosis[23]. Disturbance of normal PKB/Akt signaling has been reported in several human cancers[24,25] and Akt is a focal point for deregulation in cancer[26].

Overexpression of the ErbB family of receptor tyrosine kinases has been implicated in a variety of tumors including breast, lung, prostate, colon and brain. Most solid tumors express one or more of these receptors, which can often be related to tumor aggressiveness and poor patient prognosis. Several agents that target one or more members of the ErbB family of receptor tyrosine kinases are currently undergoing clinical investigation[27]. Ciardiello and coworkers reported that ErbB3 mRNA transcripts were expressed in a majority of human colon cancer cell lines and in primary and metastatic human colorectal tumors[28]. In colorectal cancer, an increase in ErbB3 expression is frequently associated with an increase in ErbB2 expression. However, no difference in ErbB1 protein levels was apparent between normal colon and cancer[29]. In addition, HRG is co-expressed with ErbB2 proteins in human colon cancer specimens and autocrine activation of ErbB2 occurs through heterodimerization with ErbB3 in GEO colon cancer cells[30]. These results suggest that the HRG/ErbB2/ErbB3 pathway may be an important modulator of aberrant growth in colon cancer[31,32], and therefore, agents that inhibit the ErbB3 receptor activation may be useful for the prevention and/or treatment of human colon cancer.

We have previously observed that the *t*10*c*12 isomer inhibited HT-29 cell growth, whereas the *c*9*t*11 isomer had no effect[7]. Therefore, in this study, we assessed whether the growth inhibitory effect of *t*10*c*12 is related to changes in HRG-ErbB3 signaling and the Akt pathway.

MATERIALS AND METHODS

Materials

We purchased the following reagents from the indicated suppliers: HT-29 cells (the American Type Culture Collection, Rockville, MD, USA); Dulbecco's Modified Eagle's Medium/Ham's F-12 nutrient mixture (DMEM/F12), essentially fatty acid-free, bovine serum albumin (BSA), ascorbic acid, α-tocopherol phosphate, and 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) [Sigma Chemical Co., St. Louis, MO, USA]; fetal bovine serum (FBS) and transferrin (Gibco BRL, Gaithersburg, MD); rainbow molecular weight markers, [methyl-^{3}H]thymidine (5 Ci/mmol), horseradish peroxidase (HRP)-conjugated anti-rabbit and anti-mouse Ig, protein A-Sepharose beads (Amersham, Arlington Heights, IL, USA); *c*9*t*11 and *t*10*c*12 (Cayman Chemical Company, Ann Arbor, MI, USA); anti-PI3K p85 antibody (Upstate Biotechnology, Inc., Charlottesville, VA, USA); [γ-^{32}P]ATP (PerkinElmer Life and Analytical Sciences, Inc., Boston, MA, USA); anti-phosphotyrosine-RC20 antibody linked to HRP (PY20-HRP; Transduction Laboratories, San Diego, CA, USA); recombinant human HRG-β EGF domain (R & D Systems, Minneapolis, MN, USA); antibodies against Akt (29752), phospho-Akt (p-Akt, 473), extracellular signal-regulated kinase (ERK-1/2), and phospho-ERK-1/2 (p-ERK-1/2, Thr202/Tyr203) [New England Biolabs, Beverly, MA, USA]; antibodies against ErbB1 (1005), ErbB2 (C-18), ErbB3 (C-17), and HRG (C-20) [Santa Cruz Biotechnology, Inc., Santa Cruz, CA, USA].

Cell culture

We used HT-29 cells between the 135th and 145th passage for these experiments. The complete medium for cell maintenance consisted of DMEM/F12 supplemented with 10% FBS, 100 U/mL penicillin, and 100 μg/mL streptomycin. To examine the effects of the CLA isomers and HRG-β, cells in the monolayer culture were serum starved in DMEM/F12 supplemented with 5 μg/mL transferrin, 5 ng/mL selenium, 0.1 mg/mL BSA, 50 ng/mL ascorbic acid, and 20 ng/mL α-tocopherol phosphate (serum-free medium). After serum starvation, cells were incubated in serum-free medium in the presence or absence of 4 μmol/L *t*10*c*12 or *c*9*t*11 and/or 20 ng/mL HRG-β. Fatty acids were complexed to essentially fatty acid-free BSA, with the molar ratio of fatty acid to BSA being 4:1, as described previously[33]. Media were changed every 2 d. Viable cell numbers were estimated by the MTT assay[34]. To examine DNA synthesis, [^{3}H]thymidine incorporation assay was performed as previously described[35].

Fluorescence-activated cell sorting (FACS) analysis

The cells were plated in 24-well plates, serum starved, and incubated for 3 d in the absence or presence of 4 μmol/L *t*10*c*12 or *c*9*t*11 with or without 20 ng/mL HRG-β as described above. To estimate apoptotic cell number, the cells were trypsinized and incubated with phycoerythrin (PE)-conjugated Annexin V (Annexin V-PE) and 7-amino-actinomycin D (7-AAD) (BD Pharmingen, Franklin Lakes, NJ, USA) for 15 min at room temperature in the dark. Apoptotic cells were analyzed by flow cytometry within 1 h utilizing FACScan™ (Becton Dickinson, Franklin Lake, NJ, USA). The data were analyzed using ModFit V.1.2. software.

Immunoprecipitation and immunoblotting analyses

We treated HT-29 cells with various concentrations of *t*10*c*12 or *c*9*t*11 and/or 20 ng/mL HRG-β. Cell lysates (0.75 mg protein) were prepared and immunoprecipitated by using anti-ErbB3 antibody and protein A-Sepharose beads as previously described[35]. The immunoprecipitates or total cell lysates (50 μg protein) were resolved on a sodium dodecyl sulfate (SDS) - 4-20% polyacrylamide gel and transferred onto polyvinylidene fluoride membrane (Millipore, Bedford, MA, USA). The blots were blocked for 1 h in 1% BSA in TBS-T (20 mmol/L Tris-Cl, pH 7.5, 150 mmol/L NaCl, 0.1% Tween 20) or 5% milk TBS-T and incubated for 1 h with either anti-phospho-Tyr (1:5000), ErbB1 (1:250), ErbB2 (1:500), ErbB3 (1:1000), p85 (1:1000), Akt (1:1000), p-Akt (1:1000), ERK-1/2 (1:1000), p-ERK-1/2 (1:1000), or HRG (1:500) antibody. The blots were then

incubated with anti-mouse or anti-rabbit horseradish peroxidase-conjugated antibody. Signals were detected by using the enhanced chemiluminescence method using SuperSignal® West Dura Extended Duration Substrate (Pierce, Rockford, IL, USA). Immunoblots were probed with an antibody for β-actin (1:2000) as a control for protein loading. Protein expression levels are normalized to β-actin, and the levels in the untreated samples are always set at 100%.

Reverse transcriptase-polymerase chain reaction (RT-PCR)

HT-29 cells were seeded at the density of 1×10^6 cells/dish in 100-mm dishes and treated with various concentrations of *t*10*c*12 or *c*9*t*11 as described above. Total RNA was isolated using the guanidium isothiocyanate-phenol-chloroform method and RT-PCR was performed as previously described[35]. Sequences for PCR primer sets, annealing temperatures, and numbers of cycles used for PCR amplification were previously described[35]. The levels of mRNA were corrected as a ratio to the corresponding β-actin level and the levels in the untreated samples were always set at 100%.

PI3K assay

We estimated PI3K activity as previously described[36]. Seven hundred and fifty micrograms of cell lysate was immunoprecipitated with ErbB3 antibody followed by incubation with protein A-Sepharose beads. The immunoprecipitates were washed twice with 1% NP-40-PBS, twice with 100 mmol/L Tris-HCl (pH 7.5) containing 500 mmol/L LiCl and 1 mmol/L Na_3VO_3, and twice with 50 mmol/L Tris-HCl (pH 7.2) containing 150 mmol/L NaCl. After the last wash, the beads were resuspended in 20 μL kinase buffer (20 mmol/L Hepes, pH 7.2, 50 mmol/L NaCl, 1 mmol/L EGTA) containing 4 μg of phosphatidylinositol (Sigma), 10 μmol/L ATP, 5 mmol/L $MnCl_2$, and 10 μCi of [γ^{32}]ATP and incubated for 20 min at 30 ℃. The resulting ^{32}P-labeled phosphatidylinositol 3-phosphate (PIP) lipids were separated from other reaction products by thin layer chromatography and visualized by autoradiography. The PIP signals were quantitated by densitometry using the Bio-profile Bio-1D application (Vilber-Lourmat, France).

Statistical analysis

For all studies, 3-6 independent experiments were performed with separate batches of cells. We expressed the results as the mean±SE and analyzed by one-way, two-way, or two-factor repeated measurements analysis of variance (ANOVA). Differences between treatment groups were analyzed by Duncan's multiple range test or *t* test. Means were considered significantly different at $P<0.05$. All statistical analyses were done using the SAS System for Windows V8.1 (SAS Institute, Cary, NC, USA).

RESULTS

T10c12 abrogates the growth stimulatory effects of HRG-β in HT-29 cells

Previously, we have observed that *t*10*c*12 (0-4 μmol/L) inhibited HT-29 cell growth in a dose-dependent manner, whereas *c*9*t*11 had no effect. We observed a 66±2% decrease in cell number within 96 h after the addition of 4 μmol/L *t*10*c*12[7]. In the present study, we first assessed whether HRG-β stimulates HT-29 cell growth and inhibits the growth inhibitory effect of *t*10*c*12. We cultured HT-29 cells in the absence or presence of 20 ng/mL HRG-β with or without 4 μmol/L *t*10*c*12 or *c*9*t*11. HRG-β significantly increased viable HT-29 cell numbers. *T*10*c*12 CLA decreased viable cell numbers, which was not prevented by the addition of HRG-β. In fact, viable cell numbers were even lower in the presence of both HRG and *t*10*c*12 compared to those in the presence of *t*10*c*12 alone (Figure 1A). By contrast *c*9*t*11 had no effect on viable cell numbers in either the presence or absence of HRG-β (Figure 1B).

To examine whether *t*10*c*12 inhibits DNA synthesis of HT-29 cells, we treated the cells with 4 μmol/L *t*10*c*12 in the absence or presence of HRG-β for 2 d and estimated [^{3}H]thymidine incorporation. As illustrated in Figure 2A, *t*10*c*12 decreased the incorporation of [^{3}H]thymidine into DNA of HT-29 cells. HRG-β increased [^{3}H]thymidine incorporation but did not abrogate the effect of the *t*10*c*12 isomer. The incorporation of [^{3}H]thymidine further decreased in the presence of both HRG-β and *t*10*c*12 compared to that in the presence of *t*10*c*12 alone. *C*9*t*11 CLA had no effect on [^{3}H]thymidine incorporation (data not shown).

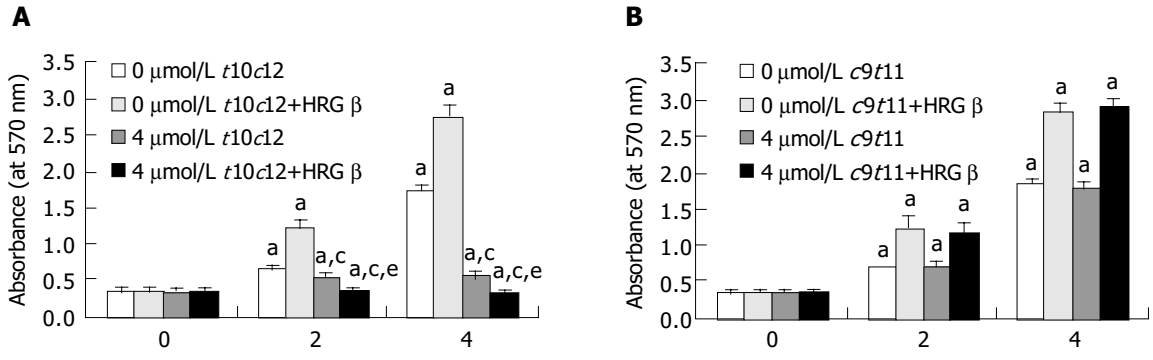

Figure 1 *Trans*-10,*cis*-12 (*t*10*c*12) CLA abrogates the growth stimulatory effect of heregulin (HRG)-β. HT-29 cells were plated in 24-well plates at 50000 cells/well in DMEM/F12 supplemented with 10% fetal bovine serum. A day later, the monolayers were serum-starved with serum-free DMEM/F12 supplemented with 5 μg/mL transferrin, 0.1 mg/mL BSA, and 5 ng/mL selenium for 24 h. After serum-starvation, cells were incubated in serum-free medium in the absence or presence of 4 μmol/L *t*10*c*12 (**A**) or *c*9*t*11 (**B**) with or without 20 ng/mL HRG-β. Cell numbers were estimated by the MTT assay. Each bar represents the mean±SE ($n = 6$). Comparisons between groups that yielded significant differences are indicated by different letters above each bar. For example, [a]$P<0.05$ *vs* 0 μmol/L *t*10*c*12, [c]$P<0.05$ *vs* 0 μmol/L *t*10*c*12 + HRGβ, [e]$P<0.05$ *vs* 4 μmol/L *t*10*c*12.

To examine whether HRG-β inhibits *t*10*c*12-induced apoptosis, we estimated the fractions of HT-29 cells undergoing apoptosis after treatment with *t*10*c*12 and/or HRG-β using Annexin-V staining followed by flow cytometry. As shown in Figure 2B, we observed an increase in apoptotic cell numbers after treatment with 4 μmol/L *t*10*c*12. HRG-β inhibited apoptosis in the absence and presence of *t*10*c*12 but did not completely abrogate *t*10*c*12-induced apoptosis. C9*t*11 did not induce apoptosis (data not shown).

T10c12 CL in italics A isomer inhibits HRG-b-ErbB3 signaling

We previously reported that HT-29 cells express ErbB1, ErbB2, and ErbB3 and ErbB3 was expressed at relatively higher levels than ErbB1 and ErbB2[35]. Because HRG-β increased DNA synthesis but did not abrogate the inhibitory effect of *t*10*c*12, we next wished to examine whether *t*10*c*12 inhibited ErbB3 signaling. We immunoblotted total cell lysates with antibodies specific for ErbB1, ErbB2, and ErbB3 to investigate whether *t*10*c*12 influences ErbB receptor expression in HT-29 cells. Treatment of HT-29 cells with increasing concentrations of *t*10*c*12 led to decreased ErbB1, ErbB2, and ErbB3 levels (Figure 3), whereas *c*9*t*11 had no effect (Figure 4). Neither *t*10*c*12 nor *c*9*t*11 affected levels of HRG or the p85 regulatory subunit of PI3K (Figures 3 and 4).

To determine whether *t*10*c*12 regulates the expression of ErbB1, ErbB2, and ErbB3 at an mRNA level, we similarly treated cells with the CLA isomer, isolated total RNA and determined mRNA levels using RT-PCR analysis. As shown in Figure 5, *t*10*c*12 decreased ErbB1, ErbB2, and ErbB3 transcripts in a concentration-dependent manner, whereas the same concentrations of *c*9*t*11 did not alter ErbB transcripts (Figure 6).

The tyrosine kinase subunits of the ErbB3 intracellular domain become tyrosine phosphorylated following activation by HRG-β. To determine whether *t*10*c*12 inhibits ErbB3 tyrosine phosphorylation, we treated cells with or without 4 μmol/L *t*10*c*12 for 3 d and prepared lysates after 0, 1, 5, or 60 min of stimulation with HRG-β. Using immunoprecipitation followed by immunoblotting, we measured levels of ErbB3 receptor expression and phosphorylation. Following the addition of HRG-β alone, ErbB3 levels remained invariable and increased ErbB3 phosphorylation was detected at 1 and 5 min, indicating that the receptor was being stimulated by the ligand (Figure 7A). Tyrosine phosphorylation of ErbB3 was drastically decreased and ErbB3 protein levels were decreased by approximately 35% in cells treated with

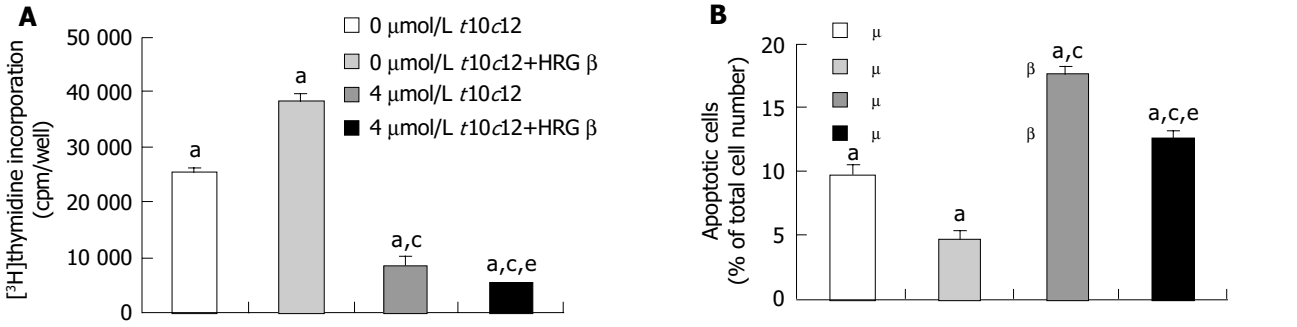

Figure 2 Effect of HRG-β and/or *t*10*c*12 on DNA synthesis and apoptosis of HT-29 cells. HT-29 cells were cultured and treated with 4 μmol/L *t*10*c*12 in the absence or presence of 20 ng/mL HRG-β. **A:** To estimate DNA synthesis, [^{3}H] thymidine incorporation into DNA was measured. **B:** To measure apoptosis, the cells were stained with 7-amino-actinomycin D (7-AAD) and Annexin V, and then analyzed by flow cytometry. The number of early apoptotic cells is expressed as a percentage of total cell number. Each bar represents the mean±SE from six independent experiments. Comparisons between groups that yielded significant differences are indicated by different letters above each bar. For example, $^aP<0.05$ *vs* 0 μmol/L *t*10*c*12, $^cP<0.05$ *vs* 0 μmol/L *t*10*c*12 + HRGβ, $^eP<0.05$ *vs* 4 μmol/L *t*10*c*12.

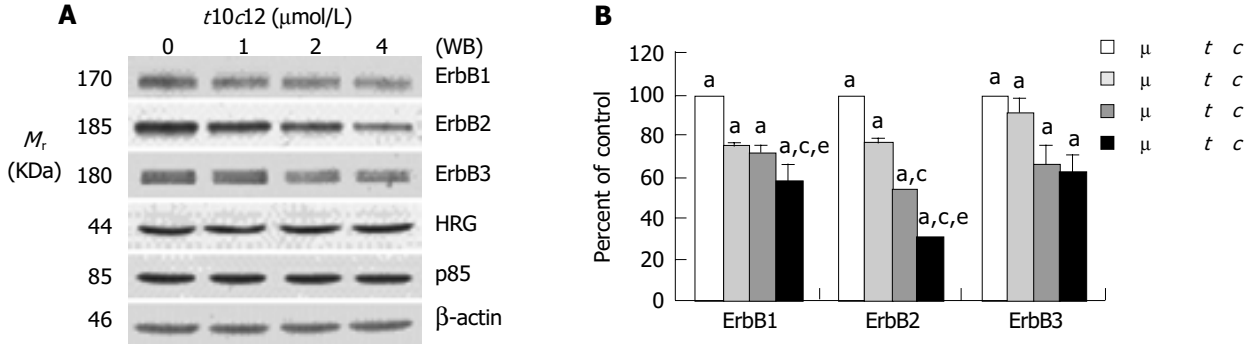

Figure 3 Effect of *t*10*c*12 on the protein expression of ErbB1, ErbB2, ErbB3, HRG, and the p85 subunit of PI3K. HT-29 cells were treated with various concentrations of *t*10*c*12 for 3 d. Cell lysates were subjected to immunoblotting with an antibody against ErbB1, ErbB2, ErbB3, p85 subunit of PI3K, HRG, or β-actin. **A:** Photographs of chemiluminescent detection of the blots, which were representative of three independent experiments, are shown; **B:** Quantitative analysis of immunoblots. The relative abundance of each band was estimated by densitometric scanning of the exposed films. Each bar represents the mean±SE (n = 3). Comparisons between groups that yielded significant differences are indicated by different letters above each bar. For example, $^aP<0.05$ *vs* 0 μmol/L *t*10*c*12, $^cP<0.05$ *vs* 1 μmol/L *t*10*c*12, $^eP<0.05$ *vs* 2 μmol/L *t*10*c*12.

4 μmol/L *t*10*c*12. The phosphotyrosine levels of ErbB3 were normalized to corresponding ErbB3 protein levels to distinguish whether the reduced tyrosine phosphorylation is a result of decreased ErbB3 protein levels or inhibition of phosphorylation of the signaling protein. After normalization, the reduced phosphorylation after *t*10*c*12 is still obvious (Figure 7B) indicating that the reduction is a result of both decreased ErbB3 levels and the inhibition of phosphorylation. These results are consistent with the finding that *t*10*c*12 prevented the effect of exogenous HRG-β on HT-29 cell growth.

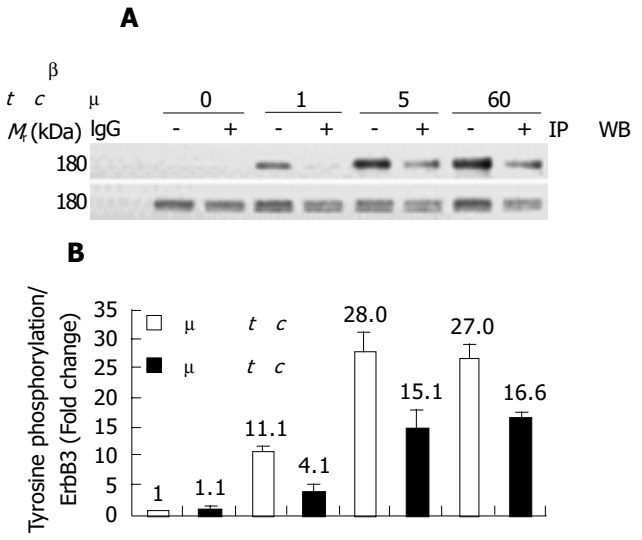

Figure 7 Effect of *t*10*c*12 on HRG-β-induced tyrosine phosphorylation of ErbB3 in HT-29 cells. Cells were treated in the absence or presence of 4 μmol/L *t10c12* for 3 d and lysed without stimulation (0) or after 1, 5, or 60 min of stimulation with HRG-β. Cell lysates were incubated with an anti-ErbB3 antibody and the immune complexes were precipitated with protein A-Sepharose. The immunoprecipitated proteins were analyzed by Western blotting with antibodies against phosphotyrosine or ErbB3. **A:** Photographs of chemiluminescent detection of the blots, which were representative of three independent experiments, are shown; **B:** The relative abundance of each band was estimated by densitometric scanning of the exposed films. Each bar represents the mean±SE (*n* = 3).

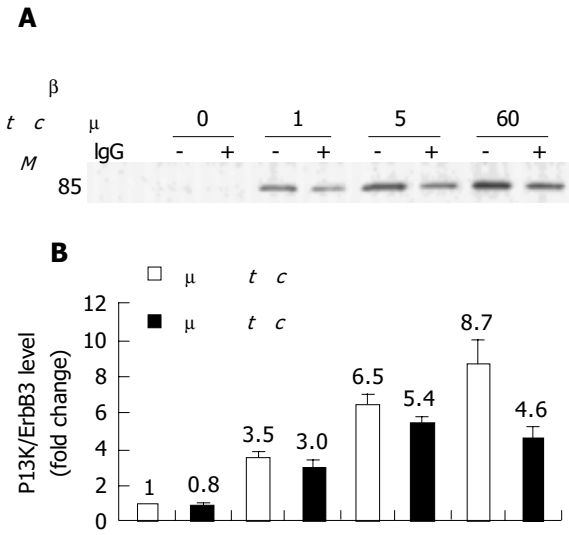

Figure 8 Effect of *t*10*c*12 on HRG-β-induced recruitment of the p85 subunit of PI3K to ErbB3 in HT-29 cells. Immunoprecipitation was performed with an anti-ErbB3 antibody and protein A-Sepharose as described above. The immunoprecipitated proteins were analyzed by Western blotting with an antibody against the p85 PI3K subunit. **A:** A photograph of chemiluminescent detection of the blot, which was representative of three independent experiments, is shown. **B:** The relative fold change in p85 to its own ErbB3 band on Western blots. Each bar represents the mean±SE (*n* = 3).

of PI3K. We examined the expression of the p85 regulatory subunit of PI3K in HT-29 cells treated with increasing amounts of *t*10*c*12 using Western blot analysis. We detected decreased levels of ErbB receptors without any change in p85 expression after the addition of *t*10*c*12 (Figure 3). We investigated whether *t*10*c*12 influences HRG-β-induced association of ErbB3 and p85. We performed immunoprecipitation with an anti-ErbB3 antibody followed by Western blotting with the p85 antibody. HRG-β stimulated association of p85 with ErbB3, and the association was reduced in *t*10*c*12-treated cells (Figure 8A). The levels of p85 associated with ErbB3 was normalized to ErbB3 expression levels to differentiate whether the reduced association after *t*10*c*12 treatment is a result of decreased ErbB3 levels or that of an inhibition of p85 recruitment. After normalization, the differences in p85 association between control and *t*10*c*12 are significant at 5 and 60 min after HRG-β addition (Figure 8B) indicating that both decreased ErbB3 levels and an inhibition of p85 recruitment are responsible for the decreased p85 association to ErbB3.

We analyzed PI3K activity in the anti-ErbB3 immunoprecipitates by *in vitro* kinase assays, wherein the PIP product was separated by thin layer chromatography. The spots of ^{32}P-labeled PIP on thin-layer chromatography plates are shown in Figure 9A with their activities plotted in Figure 9B. Similar to p85 Western blot analysis (Figure 8A), HT-29 cells incubated with HRG-β showed time-dependent changes in PI3K activity of their anti-ErbB3 immunoprecipitates. The PI3K activities increased 6-fold at 1 min after the HRG-β treatment and further increased at 5 min, and 4 μmol/L *t*10*c*12 decreased these changes.

It is well known that ErbB3 receptor activation of PI3K

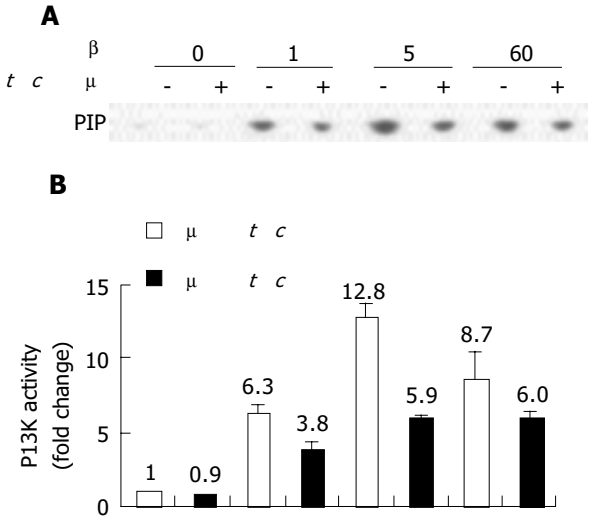

Figure 9 Effect of *t*10*c*12 and/or HRG-β on ErbB3-associated PI3K activity. Cells were treated, and lysates were prepared and immunoprecipitated with an anti-ErbB3 antibody as described in Figure 8. The immune complexes were incubated with phosphatidylinositol and [g-^{32}P]ATP. Phosphatidylinositol 3-phosphate (PIP) generated by immunoprecipitated PI3K was separated by thin-layer chromatography (TLC). **A:** An autoradiograph of the TLC plate, which was representative of three independent experiments, is shown; **B:** Relative fold changes in PIP. The radioactive PIP signals were quantitated by densitometry. Each bar represents the mean±SE (*n* = 3).

leads to movement of Akt to the membrane and its subsequent activation[20,37]. We immunoblotted total cell lysates using anti-p-Akt and whole Akt protein antibodies and quantitated the relative fold change in p-Akt to its own total Akt signal by densitometry. The time-dependent increase in Akt phosphorylation (p-Akt) by HRG-β is depicted in Figure 10. HRG-β induced phosphorylation of

AKT within 5 min, and the increase in p-Akt after HRG-β treatment was coherent with the increase in PI3K activity and ErbB3-associated p85 protein levels seen at 5 min after HRG-β treatment. We observed no changes in Akt protein levels during the 60-min HRG-β stimulation. However, p-Akt levels were substantially decreased in cells treated with *t*10*c*12, whereas the total Akt protein levels were only slightly decreased by *t*10*c*12 treatment. *C*9*t*11 did not cause any changes in HRG-β-induced Akt activation in HT-29 cells (data not shown).

T10c12 does not inhibit HRG-β-induced activation of ERK-1/2

Activation of ERK-1/2 has also been implicated in mitogenic signaling by the HRG-induced activation of ErbB3[38]. To examine the effect of *t*10*c*12 on HRG-β-induced activation of ERK-1/2, we performed Western blotting using antibodies raised against ERK-1/2 and p-ERK-1/2. HRG-β activation of ErbB3 receptor signaling resulted in an increase in phosphorylation of ERK-1/2 in HT-29 cells. Phosphorylated ERK-1/2 levels were increased at 5 min after HRG-β stimulation but HRG-induced ERK-1/2 phosphorylation was not changed by 4 μmol/L *t*10*c*12. Total ERK-1/2 levels did not change after *t*10*c*12 treatment (Figure 11). Neither phosphorylated nor total ERK-1/2 levels were altered by treatment with the same concentration of *c*9*t*10 (data not shown).

DISCUSSION

We previously reported that the *t*10*c*12, not the *c*9*t*11, isomer of CLA inhibited HT-29 colon cancer cell growth[7]. In the present study, the *t*10*c*12 isomer, which decreased viable HT-29 cell numbers, decreased the protein levels of ErbB1, ErbB2, and ErbB3. However, the *c*9*t*11 isomer, which did not alter viable HT-29 cell number, had no effect on ErbB protein levels. In addition, exogenous HRG-β stimulated cell growth in the absence of *t*10*c*12 but did not mitigate the growth inhibitory effect of *t*10*c*12. These results indicate that the decreased ErbB levels by the *t*10*c*12 isomer may be, at least in part, responsible for the decreased cell growth in HT-29 cells.

It has been observed in numerous types of cancers that cell proliferation and survival increased when control of the ErbB pathways is lost, leading to the malignant phenotype[39]. HRG is a potent mitogen for colon cancer cells and autocrine HRG generates growth factor independence and prevents apoptosis[30,40]. In order to study the mechanisms by which *t*10*c*12 decreases colon cancer cell growth, the present study examined the influence of *t*10*c*12 on ErbB3 signaling. In the present study, we provide the first evidence that *t*10*c*12 reduces ErbB2 and ErbB3 protein expression and ErbB3-mediated signaling. When HT-29 cells were incubated with HRG-β in serum-free medium, the cells reacted to HRG-β by increasing cell number. However, HRG-β was unable to increase the viable cell number in the presence of *t*10*c*12 suggesting that *t*10*c*12 downregulates the HRG-receptor signaling pathway. In fact, we observed decreased levels of the HRG receptor ErbB3 at 72 h after treatment with *t*10*c*12. However, the expression of HRG in HT-29 cells was not affected by *t*10*c*12. Previous studies have reported that HRG is expressed in gastrointestinal tissues[32,41] and human colon cancer samples, and is an autocrine growth regulator of GEO human colon cancer cells[30]. Because HT-29 cells express HRG and its receptor ErbB3, HRG may also be an autocrine growth regulator of HT-29 cells. Our present results indicate that *t*10*c*12 decreases cell's ability to respond to HRG without altering the production of this growth factor in HT-29 cells.

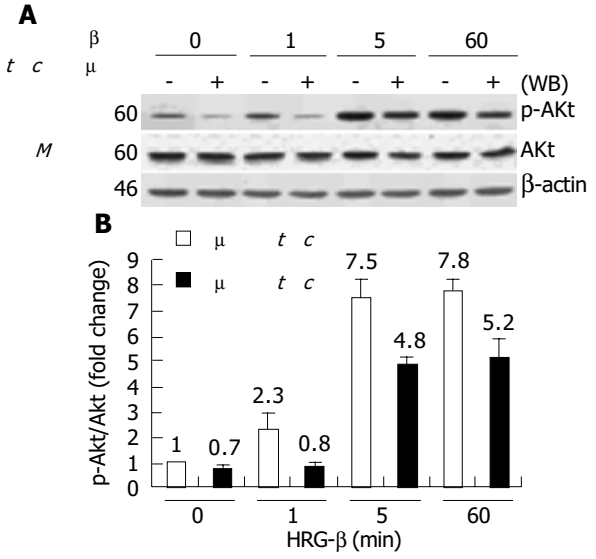

Figure 10 Effect of *t*10*c*12 on HRG-β-induced Akt activation. Similar protein samples as those in Figure 8 were analyzed by immunoblotting with anti-phospho-Ser473 Akt (p-Akt) or whole Akt protein antibodies. **A:** Photographs of chemiluminescent detection of the blots, which were representative of three independent experiments, are shown; **B:** Quantitative analysis of immunoblots. The relative fold change in p-Akt to its own Akt control band on Western blots was quantitated by densitometric analysis. Each bar represents the mean±SE (*n* = 3).

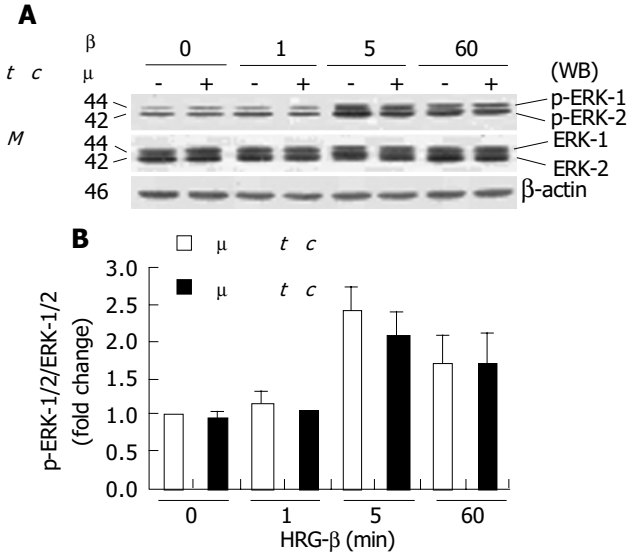

Figure 11 Effect of *t*10*c*12 on HRG-β-induced ERK-1/2 activation in HT-29 cells. Similar protein samples as those in Figure 8 were analyzed by immunoblotting with p-ERK-1/2 or whole ERK-1/2 antibodies. **A:** Photographs of chemiluminescent detection of the blots, which were representative of three independent experiments, are shown; **B:** Quantitative analysis of immunoblots. The relative fold change in p-ERK-1/2 to its own ERK-1/2 control band on Western blots was quantitated by densitometric analysis. Each bar represents the mean±SE (*n* = 3).

The present results indicate that the decrease in ErbB levels by *t*10*c*12 treatment was due to at least in part, to the decrease in mRNA expression. In this study, we did not examine the mechanisms by which the *t*10*c*12 isomer regulates ErbB genes. CLA has been reported to be an activator of the peroxisomal proliferators-activated receptor (PPAR) γ[42]. Ligands for PPARγ induce apoptosis and exert antiproliferative effects on several carcinoma cell lines[43,44]. Houseknecht *et al*.[45], have shown that mRNA levels of aP2, a PPAR responsive gene in the adipose tissue of fatty Zucker diabetic rats, were increased as a result of PPARγ activation by CLA. Other studies utilizing MCF-7 breast cancer cells have shown that the activation of PPARγ through the 15-deoxy-△-12,14-prostaglandin J2 ligand causes a dramatic inhibition of ErbB2 and ErbB3 tyrosine phosphorylation induced by HRG-α and HRG-β[46]. We speculate that *t*10*c*12 or its metabolites may activate the PPAR transcription factor family. It remains to be determined whether *t*10*c*12 inhibits ErbB gene expression by activating PPARγ and/or by other mechanisms.

Activation of tyrosine kinase receptors requires tyrosine phosphorylation of their intracellular subunits. *T*10*c*12 decreases HRG-β-induced tyrosine phosphorylation of ErbB3 when the data was normalized with ErbB3 protein levels indicating that *t*10*c*12 inhibits activation of this receptor in addition to decreasing the receptor protein levels. ErbB3 has been described as a key mediator of HRG-dependent activation of the PI3K pathway[47,48]. ErbB3 is especially well suited to mediate PI3K signaling because it contains six YXXM consensus-binding sites for p85[49]. We observed that HRG-β stimulated the recruitment of p85 to ErbB3 in HT-29 cells, and *t*10*c*12 decreased ErbB3-associated p85 protein levels and PI3K activities. These decreases do not appear to be due to changes in the p85 protein expression, but to the decrease in ErbB3 protein levels.

PKB/Akt is a downstream target of PI3K and plays a central role in PI3K-mediated protection against apoptosis[50]. The present results show that *t*10*c*12 inhibited HRG-β-induced activation of Akt, which could be attributed to both decreased ErbB3 levels and decreased ErbB3 activation. We speculate that *t*10*c*12 inhibits DNA synthesis and induces apoptosis of HT-29 cells by inhibiting the Akt signaling pathway. Increased expression and/or activity of ErbB receptors and downstream signaling proteins such as Akt are frequent events in cancer. Future studies are needed to study the effect of Akt on HT-29 cell growth.

The ERK/MAP kinase family of serine/threonine kinases comprises a cascade of three kinases; ERK-1/2, c-jun N-terminus kinase (JNK), and p38 MAP kinase. It is generally accepted that the balance between growth-factor-activated ERK-1/2 and stress-activated JNK and p38 pathways determines whether the cell lives or dies[51]. In the present experiment, *t*10*c*12 had no effect on either basal or HRG-β-induced phosphorylation of ERK-/2. It remains to be determined whether *t*10*c*12 alters stress activated JNK and p38 pathways in cancer cells.

In summary, *t*10*c*12 decreases viable HT-29 cell numbers, which was due to decreased DNA synthesis and induction of apoptosis. However, *c*9*t*11 had no effect on apoptosis or DNA synthesis. HRG-β stimulates DNA synthesis and inhibits apoptosis but did not abrogate the effects of the *t*10*c*12 isomer. In addition, the *t*10*c*12 isomer negatively regulates levels of ErbB receptors and subsequent activation of Akt but not activation of ERK-1/2 in HT-29 cells. These results suggest that the growth inhibitory effects of the *t*10*c*12 isomer may, at least in part, be mediated by decreasing HRG/ErbB3 signaling and the PI3K/Akt pathway. The ability of the *t*10*c*12 isomer to inhibit the PI3K/Akt pathway is especially important because aberrant activation of ErbB receptors and Akt signaling play a role in the development of many types of cancer. To date much attention has been focused on developing inhibitors of Akt for cancer therapy. However, in view of the recent study reporting that the *t*10*c*12 isomer increased the size of the adenoma in the small intestine of Min mouse[10], further animal studies are necessary to determine the effects of the *t*10*c*12 isomer on colon carcinogenesis.

Abstract

AIM: A few studies have applied genomic-wide gene expression analysis in inflamed colon tissue sample in ulcerative colitis (UC). We reported the first study of non-inflamed mucosal gene expression in UC and explored its clinical implication.

METHODS: Non-inflamed mucosa was obtained from 6 UC patients who received total colectomy. The gene expression of UC in noninflamed mucosa was monitored with a microarray. For a selected gene, RT-PCR was performed to verify array results and to further examine expression pattern in inflamed mucosa of UC, colorectal cancer tissue and normal mucosa using additional matched pairs.

RESULTS: Two genes showing 2.5-fold decreased expression with significance set at in UC samples were homeo box a4 (HOXa4) and mads box transcription enhancer factor 2, polypeptide B (MEF2b). RT-PCR showed that MEF2b expression in non-inflamed mucosa was significantly downregulated, whereas the expression of MEF2b increased in accordance with the severity of mucosal inflammation. HOXa4 expression both in inflamed and non-inflamed mucosa in UC was consistently downregulated, and the downregulation of HOXa4 was also found in colorectal carcinoma.

CONCLUSION: It is suggested that the MEF2b expression in UC which increase in accordance with inflammation may be induced by the inflammatory mediator. In contrast the downregulation of HOXa4 may be partly involved in the pathogenesis of disease including UC and UC-related carcinogenesis.

INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease (CD), two common inflammatory bowel diseases (IBDs) with shared clinical and demographic characteristics, harbor key differences in tissue damage and prognosis that suggest distinctive etiopathogeneic processes. In UC, inflammation with crypt abscess formation is limited to mucosa, while in CD, transmural granulomatous inflammation leads to fibrostenotic lesions and fistula formation[1]. Furthermore, these diseases have complicated clinical manifestations in which genetic, environmental, and microbial factors interact to determine the susceptibility response of immune and nonimmune cellular systems mediating inflammation[2].

In many murine models of colitis recently generated by gene targeting, bacterial flora in the gut appears to be a prerequisite for the development of acute and chronic inflammation[3]. Of great interest, although normal intestinal epithelial cell are hypo-responsive to normal flora *in vivo*, pathogenic bacteria and bacterial components can initiate an inflammatory response in colitis[4]. These reports suggest that UC mucosa is already a different gene expression compared to normal mucosa without inflammatory change.

Genome-wide gene expression analysis of tissue samples from affected and normal individuals can illuminate important events involved in disease pathogenesis. Recently, several research articles on IBD using cDNA or oligonucleotide array-based technology have been published[5-8]. But previous studies of genomic alteration of IBD-related genes using microarray were directed to inflamed and non-inflamed UC mucosa.

In this study, we first applied this approach of comparing gene expression in non-inflamed UC mucosa to normal human colonic mucosa and searched for these specific

changes in gene expression pattern of inflamed UC mucosa and colorectal carcinoma.

MATERIALS AND METHODS

Tissue specimens for oligoneucleotide array

This study included 6 UC patients who received total proctocolectomy with ileal J pouch anal anastomosis because of severe distal colitis. The ages of the patients ranged from 20 to 58 years (average 36.1 years). Classic clinical, radiologic, endoscopic, and histopathological criteria were used to confirm all diagnoses[9]. For UC sample, specimens of macroscopically noninflamed proximal colonic mucosa such as cecum or ascending colon was obtained.

Histologically normal samples (six colonic mucosa) were obtained from 6 patients ranging from 40 to 68 years of age (average 53 years) undergoing bowel resection for adenocarcinoma (n = 4), diverticulitis (n = 1), mucosal prolapse syndrome (n = 1). Tissues used for control RNA extraction were obtained from at least 10 cm of the area of pathology and all were histologically normal. Use of patient material was in accordance with Institutional Review Board guidelines and protocol.

Total RNA isolation

All mucosa were dissected from underlying tissue and homogenized in Physcotron (NITI-ON, Japan) for the isolation of total RNA. Total RNA was extracted with Sepasol-RNA (Nacalai Tesque, Tokyo, Japan) and RNA quality was confirmed by agarose gel electrophoresis.

Preparation of fluorescent-labeled cDNA targets for microarray

cDNA targets for hybridizations were synthesized by RT from 20 μg/slide of UC- and normal colonic mucosa - total RNA samples with Superscript II RT (Invitrogen) according to the manufacturer's instructions. AA-dUTP labeled cDNA purified using QIAquick PCR purification Kit (28014: Qiagen). Each AA-dUTP labeled cDNA was coupled with either monoreactiveCy3 (PA23001 Amersham Bioscience) or Cy5 (PA25001 Amersham Bioscience) and incubated for 1 h at 40 ℃. Free dye was removed using P30 column (732-6223 BioRad). The separately synthesized Cy3- and Cy5-labeled targets was mixed with 15 μL of Human Cot-1 DNA (15279: Invitrogen), 1 μL of poly A (POLYA GF Invitrogen) and 0.5 μL of t RNA, Yeast (15401-011: Invitrogen) and the mixture was applied to Microcon-YM30 (43409 Millipore) and concentrated to 5-10 μL.

Hybridization

Diluted dye-labeled, 12.5 μL of 20×SSC, 2.5 μL of 10% SDS, 4 μL of 50× Denhardt's solution, 10 μL of hybridization solution (supplied with AceGene®: Hitachi Software Engineering Co., Ltd) and adequate sterile distilled water were added and concentrated to 44.5 μL. This solution was incubated for 2 min at 95 ℃, and cooled on ice, and 0.5 μL of salmon sperm DNA and 5 μL of formamide was added to the solution, and incubated for 5 min at 42 ℃. The target cDNA solution was applied directly to the AceGene® Human Oligo Chip (Hitachi Software Engineering Co., Ltd), and coverglass (24 mm×60 mm) was set. Hybridization was performed for 16 h at 42 ℃. After hybridization, the slides were washed and rinsed. Finally they were dried with air-spray.

Data analysis

Fluorescent signals were detected on a confocal laser scanner (HB GeneArray Scanner, Affymetrix) and analyzed with the DenasisArray (Hitachi Software Engineering) and Excel (Microsoft Redmond, CA). To eliminate data with low reliability, genes with each hybridization intensity = 0 and each average intensity {(Cy3-Cy3 background)+(Cy5-Cy5 background)<2000} were excluded from all data sets. In addition, genes with average intensity ratio that showed a >2- or 0.5-fold change were selected. In the remaining genes, 2-fold average intensity ratio genes with each intensity ratio <1 on array tests and 0.5-fold average intensity ratio genes with each intensity ratio >1 were excluded. Finally, selected genes were further analyzed for statistical comparison. Mann-Whitney U-test was used, with significance set at P<0.05.

RT-PCR

Total RNA was extracted from an additional 6 UC patients' paired non-inflamed mucosa and inflamed mucosa as well as 9 patients' paired colon cancer and histological normal colonic mucosa with Sepasol-RNAI. For cDNA synthesis, 2 μg of total RNA was reverse transcribed with Superscript II. RT-PCR was done using specific primers for the array-selected gene. Primers are described in Table 1. Optimum cycling parameters, in the linear range of amplification, consisted of 30 s of denaturation at 94 ℃, 30 s of annealing at 58 ℃, and 2 min of elongation at 72 ℃, and 28 cycles were performed for the selected gene. A control PCR was also done for G3PDH which served as a standard for sample normalization for 25 cycles. Amplified products were separated electrophoretically, visualized, and photographed under UV light after ethidium bromide staining. Gel density was calculated with Sicon image (downloaded sicon's web site: www.siconcorp.com) and gene expressions were quantified. For statistical comparison Mann-Whitney U-test was used, with significance set at P<0.05 to compare differences in the level of gene expression.

RESULTS

To investigate gene expression profiles of the colon in UC

patients, we used AceGene® Human Oligo Chip arrays containing probes for approximately 20 000 human genes. Low reliability data was eliminated by performing data trimming as described in Materials and methods section. After data trimming, the remaining genes were analyzed for statistical comparison between the average intensity of non-inflamed UC group and normal control.

Table 2 lists the gene transcripts displaying a two fold or higher increase or decrease in expression level that was significant at the $P<0.05$ level. Five gene transcripts displayed a 2.1-4.4-fold lower expression in the non-inflamed UC samples compared with the normal colon samples, whereas only one transcript displayed a 2.3-fold higher expression in the non-inflamed UC samples (Figure 1). Among the six genes, the difference in the expression of the two genes *homeo box a4* (NM_002141) and *mads box transcription enhancer factor 2* (NM_005919) were statistically significant ($P<0.01$).

To verify array results, expression of two genes at the $P<0.01$ as differentially expressed by oligonucleotide array analysis was examined by RT-PCR using six additional pairs (noninflamed UC mucosa and normal control).

As a result, the expression of HOXa4 and MEF2b in non-inflamed UC mucosa was significantly reduced compared to that in the normal mucosa ($P = 0.0490$ and $P = 0.0253$, respectively), which gave results consistent with those by oligonucleotide array analysis (Figures 2 and 3).

Gene expression patterns of both these genes obtained from inflamed UC mucosa were examined comparing them with the non-inflamed UC mucosa and normal mucosa using RT-PCR. MEF2b expression in inflamed UC mucosa was significantly upregulated compared to that in non-inflamed UC mucosa ($P = 0.0209$; Figure 3). But there is no difference in MEF2b expression between normal control and inflamed UC mucosa (Figure 3). In contrast, no difference in the expression pattern of HOXa4 was found between those with and without colonic inflammation ($P = 0.2603$; Figure 2). Furthermore, the expression of HOXa4 in inflamed mucosa was significantly downregulated compared to that in normal mucosa ($P = 0.0172$; Figure 2). RT-PCR on eight samples of matched colon cancer and normal mucosa showed that the expression of HOXa4 in colon cancer tissue was significantly downregulated in 8 of 8 (100%). But the expression of MEF2b had no difference between colorectal carcinoma and normal mucosa (Figure 4).

DISCUSSION

Our present study is the first trial which draws a comparison between genomic alternation in non-inflamed UC mucosa and normal human colonic mucosa. This approach has allowed us to examine whether non-inflamed UC mucosa shows a different gene expression compared to normal control mucosa. We showed the intensities of the two genes HOXa4 and MEF2b to be reduced in the non-inflamed mucosa in patients with UC using the cDNA microarray. In addition, we compared the levels of the expression of

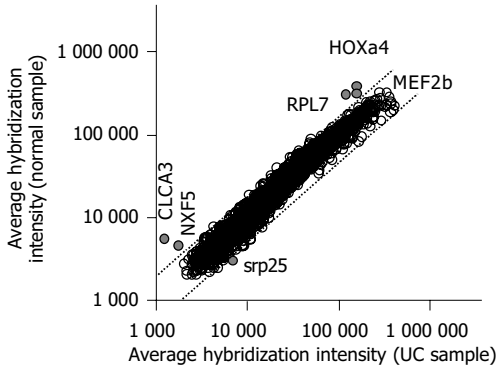

Figure 1 Comparison of expression of genes in non-inflamed mucosa of ulcerative colitis (UC) and normal control mucosa. The upper and lower boundaries represent a 2- and 0.5-fold difference in the mean of the expression of each gene between noninflamed UC mucosa and control, respectively. Axis scales are logarithmic.

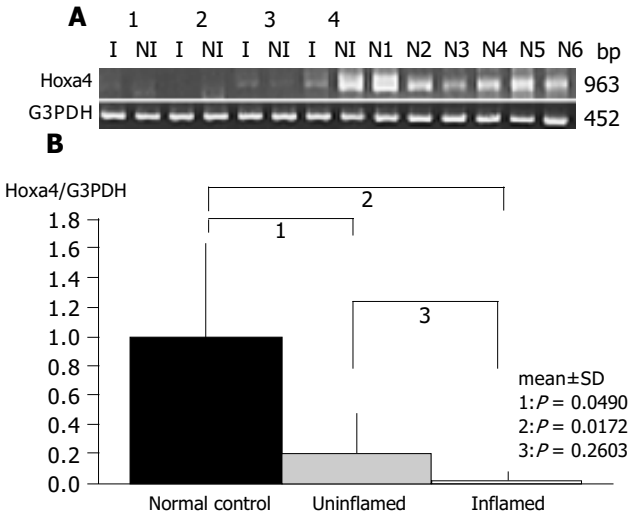

Figure 2 RT-PCR analysis of HOXa4 gene expression in normal colonic mucosa and UC mucosa (inflamed, non-inflamed). **A**: Showed RT-PCR was performed on four paired inflamed mucosa (I) and non-inflamed mucosa (NI) samples in UC as well as six normal control mucosa (N1-N6) G3PDH was used as a control for cDNA synthesis; **B**: Semiquantification of HOXa4 gene expression (HOXa4/G3PDH) was performed in six paired UC mucosa and six normal control mucosa using NIH image software.

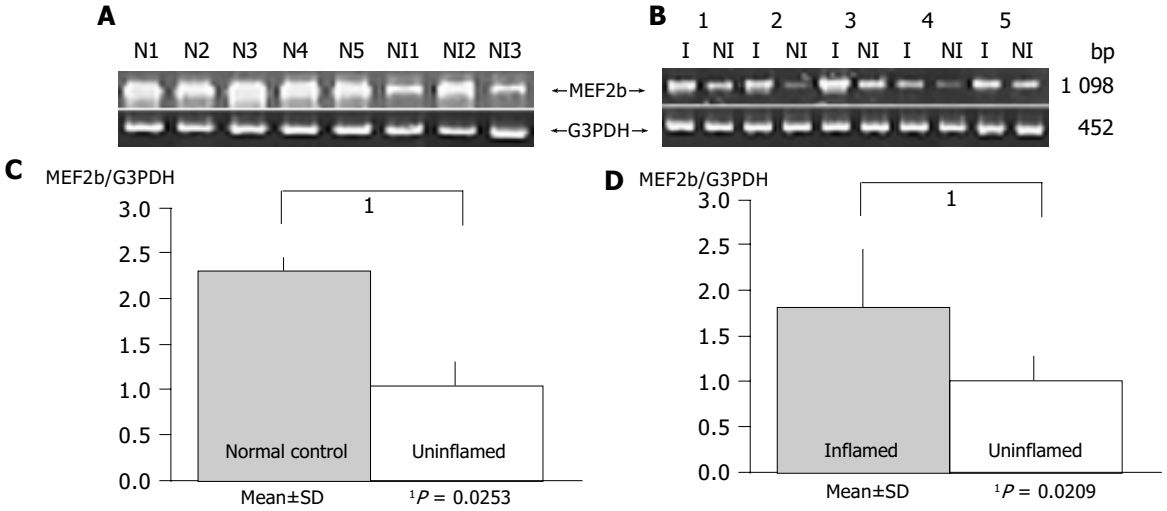

Figure 3 RT-PCR analysis of MEF2b gene expression in normal colonic mucosa and UC mucosa (inflamed, non-inflamed). **A**: Analysis was performed on five normal control mucosa (N1-N5) and three non-inflamed UC mucosa (NI) was performed on four paired inflamed mucosa (I) and non-inflamed mucosa (NI); **B**: Analysis was performed on four paired inflamed mucosa (I) and non-inflamed mucosa (NI). G3PDH was used as a control for cDNA synthesis; **C** and **D**: Semiquantification of MEF2b gene expression (MEF2b/G3PDH) was performed in six paired UC mucosa and six normal control mucosa using NIH image software.

mRNA of these two genes among control, non-inflamed and inflamed mucosa in UC, and colonic cancer tissues by RT-PCR.

HOXa4 includes the homeo box (HOX) family genes that are functionally homologous to the drosophila HOM-C gene. There are 39 HOX genes in the human genome that are arranged in four clusters on four different chromosomes. They are expressed at the beginning of gastrulation and define the body's axis formation. In adults, HOX B8 is involved in leukomorphogenesis[10]. Other HOX genes play a role in malignant transformation, through the regulation of cell-cycle checkpoints (e.g. P53) or protooncogenes (e.g. ras[11]). In cancer cells, HOX is either over-expressed (e.g. HOX C4 and HOX C6, in non-Hodgkin's lymphoma[10]) or downregulated (e.g. HOX B6, C8, C9 in adenocarcinoma and colon cells[12]). In our experiments, HOXa4 gene expression was downregulated in UC mucosa compared to normal mucosa whether colonic inflammation exists or not and this gene expression in colon cancer tissue was also significantly lower than normal mucosa with additional RT-PCR.

Earlier studies showed that HOX A4 is regulated both by retinoic acid and the ras oncogene[13]. Retinoic acid increased HOX A4 expression and guided the cells toward differentiation, while the ras oncogene decreased HOX A4 expression and guided the cells toward proliferation. Burmer previously reported that UC-associated neoplasia has a low incidence of *K-ras* mutations[14], but Ierardi *et al*., showed that the persistently increased epithelial proliferation associated with ras p21 expression in UC may be due to the action of an abnormal, mutated ras gene that could play a role in UC-related tumorigenesis[15]. Steingart *et al*.[16], previously reported that SNH (a lipophilic analog of vasoactive intestinal peptide (VIP)) increased the expression of HOX A4 and reduced Oct-3 mRNA level and demonstrated inhibition of HT 29 colon cancer cell line

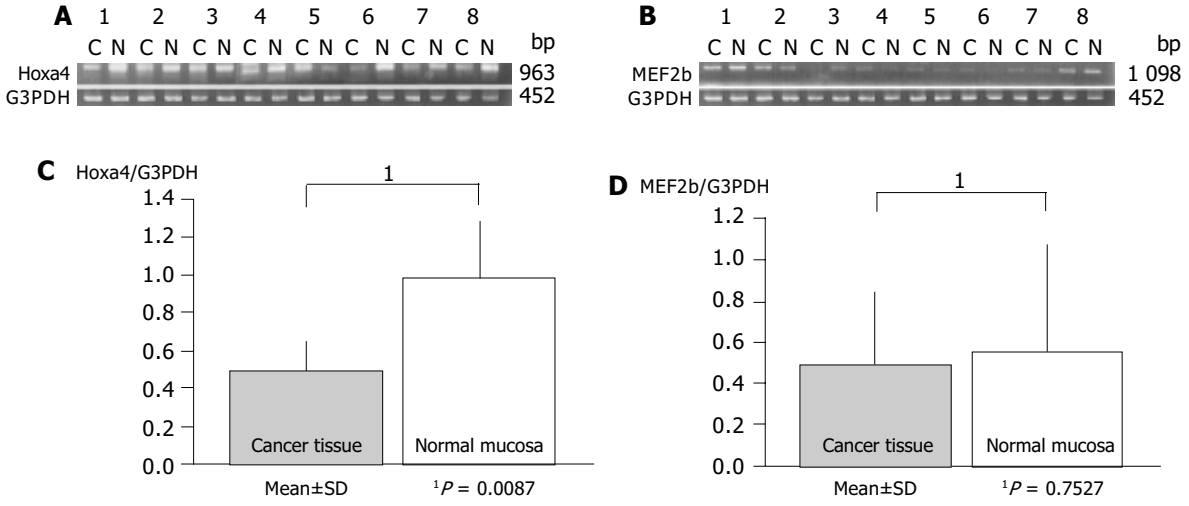

Figure 4 (**A** and **B**) RT-PCR analysis of *HOXa4* and *MEF2b* gene expression in eight paired colon cancer (**C**) and normal colonic mucosa (N). G3PDH was used as a control for cDNA synthesis. (**C** and **D**) Semiquantification of *HOXa4* and *MEF2b* gene expression (HOXa4, MEF2b/G3PDH) was performed in eight paired colon cancer and normal colonic mucosa using NIH image software.

proliferation by SNH.

This may suggest that decreased HOXa4 gene expression partly explains the pathogenesis of UC and UC-related carcinogenesis without ras protein participation and SNH might serve as a lead compound to prevent colitic cancer for UC patients who have received long-term medical therapy.

MEF2 (myocyte enhancer factor-2) was first described as a muscle-enriched transcription factor that bound to an A/T-rich DNA sequence in the control regions of numerous muscle-specific genes[17]. There are four human MEF2 genes, MEF2A, MEF2B, MEF2C and MEF2D, which are expressed in distinct, but overlapping patterns during embryogenesis and in adult tissues[18]. Recent studies have revealed a central role for MEF2 family of transcription factors in linking calcium-dependent signaling pathways to the genes responsible for cell division, differentiation and apoptosis[19]. In regulation of cell proliferation, it was made with the discovery that MEF2 regulates serum-inducible expression of c-jun, which positively regulates cell-cycle progression[20]. MEF2 has since been shown to play a role in the induction of the c-jun promoter in response to signals emanating from multiple cell surface receptors, including G-protein-coupled receptors[21], the epidermal growth factor receptor[22], the lipopolysaccharide receptor[23], and the CD28 co-stimulatory receptor in T lymphocytes[24]. It is therefore, conceivable that constant decreased expression of MEF2 might regulate epithelial cell proliferation and cell-cycle progression and result in difficulty of epithelial cell regeneration in noninflamed UC mucosa.

Interestingly, the present study demonstrated that MEF2 was overexpressed in inflamed UC mucosa compared to non-inflamed UC mucosa using RT-PCR. MEF2 stimulates the expression of the gene encoding the orphan nuclear hormone receptor Nur77[25], which is a potent activator of cytochrome *c*-mediated apoptosis. The present results suggest that ulceration of mucosa might be related to epithelial cell apoptosis induced by MEF2 overexpression in inflamed UC mucosa.

In conclusion, the present study indicates that UC mucosa already has a different gene expression compared to normal mucosa without inflammatory change. Downregulated HOXa4 expression pattern in UC mucosa consistently as well as in colorectal carcinoma may play an important role for carcinogenesis in UC mucosa. Since MEF2 expression pattern correlated to inflammation, it is a key molecule for colonic epithelial cell apoptosis in inflamed mucosa and cell remodeling difficulty in non-inflamed UC mucosa. In a subsequent research, we hope to study further to identify the function of selected UC-related gene.

Abstract

AIM: The genes were divided into seven categories according to biological function; apoptosis-related, immune response-related, signal transduction-related, cell cycle-related, cell growth-related, stress response-related and transcription-related genes.

METHODS: We compared the gene expression profiles of SNU-C4 cells between amygdalin-treated (5 mg/mL, 24 h) and non-treated groups using cDNA microarray analysis. We selected genes downregulated in cDNA microarray and investigated mRNA levels of the genes by RT-PCR.

RESULTS: Microarray showed that amygdalin downregulated especially genes belonging to cell cycle category: exonuclease 1 (*EXO1*), ATP-binding cassette, sub-family F, member 2 (*ABCF2*), MRE11 meiotic recombination 11 homolog A (*MRE11A*), topoisomerase (DNA) I (*TOP1*), and FK506 binding protein 12-rapamycin-associated protein 1 (*FRAP1*). RT-PCR analysis revealed that mRNA levels of these genes were also decreased by amygdalin treatment in SNU-C4 human colon cancer cells.

CONCLUSION: These results suggest that amygdalin have an anticancer effect via downregulation of cell cycle-related genes in SNU-C4 human colon cancer cells, and might be used for therapeutic anticancer drug.

INTRODUCTION

The incidence of colorectal cancer has been increasing rapidly since 1975[1] with about 300 000 new cases and 200 000 deaths in Europe and USA every year[2,3]. Death from colorectal cancer is the second commonest cause of any cancer in men in the European Union[4]. The stage of the disease is an important effect to long-term survival of colorectal cancer. If detected early, it may be curable by surgery. But once metastases develop the prognosis becomes poor. At least 40% of patients with colorectal cancer develop metastases during their illness[5]. Although various therapies as surgery, radiotherapy, and chemotherapy are used on advanced cancer, the most effective approach is yet to be discovered.

Amygdalin is ingredient of *Prunus persica* Batsch (Persicae semen, Rosaceae), *Prunus armeniaca* L. var. *ansu* Max (Armenicae semen, Rosaceae) and *Prunus amygdalus* Batsch var. *amara* (Amygdali semen amara, Rosaceae), and these are abundant in the seeds of bitter almond and apricots[6]. The evidence for effect of amygdalin has been reviewed as prevention and control of cancers. Due to cyanide toxicity, there has been controversy for amygdalin as cancer drug[7-9]. However, Moertel *et al*., demonstrated that, in human, intravenous infusion of amygdalin produced neither cyanidemia nor signs of toxicity but that oral administration resulted in significant blood cyanide levels and that, in one case, oral amygdalin plus almond extract produced transient symptoms of cyanide intoxication and further increase of blood cyanide[9]. Additionally, Fukuda *et al*.[10], reported anti-tumor effect of amygdalin and other components of *Prunus persica* seeds. Kwon *et al*.[13], reported that controversy on anticancer effect of amygdalin was due to its conversion to inactivate isoform, and Persicae semen extract induced apoptosis. Although taking a growing interest and reports for amygdalin as cancer drug, anti-cancer mechanism of amygdalin has not been reported.

In this study, we determined whether amygdalin-treated SNU-C4 cells were susceptible to cell death, and compared the expression profiles of SNU-C4 cells between amygdalin-treated group and non-treated group using cDNA

microarray analysis. We also performed RT-PCR for genes selected by cDNA microarray analysis.

MATERIALS AND METHODS

Preparation of amygdalin

Both 500 g of Armeniacae semen hatched from the shell and 10 L of 4% citric acid solution were refluxed for 2 h. Filtered when it was still hot, the filtrate was passed through the column packed with HP-20. The substance absorbed within the column was concentrated after it had been eluted by ethanol. 4.2 g of amygdalin (with the yield rate of 0.84%) was obtained by recrystallizing the extract with ethanol. The amygdalin was used after it had been determined to be over 95.0% of purity, by means of high-pressure liquid chromatography (HPLC) to measure its purity (Figure 1).

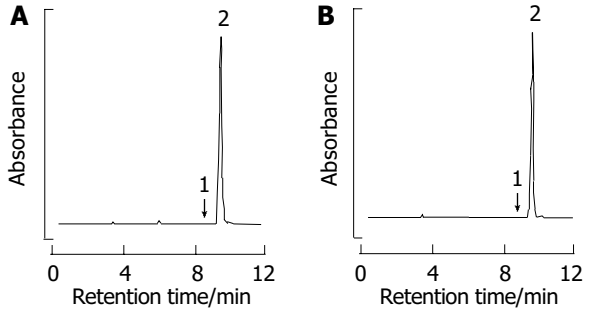

Figure 1 Reverse-phase HPLC separation of amygdalin by phosphate buffer. (**A**) D-amygdalin standard. (**B**) D-amygdalin obtained by our method; peaks: 1, neoamygdalin; 2, D-amygdalin.

Cell culture

The SNU-C4 cell line was obtained from the Korean Cell Line Bank (KCLB, Seoul, South Korea). Cells were cultured in RPMI-1640 medium (Gibco, NY, USA) supplemented with 10% heat-inactivated FBS (Gibco). Cultures were maintained in a humidified incubator at 37 ℃ in an atmosphere of 50 mL/L CO_2, 95% air, and the medium was changed every 2 d.

MTT assay

Cell viability was determined by 3-(4,5-dimethylthiazol-2-yl) -2,5-diphenyltetrazolium bromide (MTT) assay. Cells were seeded in triplicate at a concentration of 1×10^5 cells/well on a 96-well plate. SNU-C4 cells were treated with amygdalin at concentrations of 0.25, 0.5, 2.5, and 5 mg/mL for 24 h. After MTT (Sigma, MO, USA) was added to each group, the cells were incubated for 4 h. Then, they were further incubated for 1 h, including the solution in which MTT was dissolved. The viability was measured with a microtiter plate reader (Bio-Tek, VT, USA) at a test wavelength of 595 nm with a reference wavelength of 690 nm. The optical density (A) was calculated as the difference between the reference wavelength and the test wavelength. Percent viability was calculated as (A of drug-treated sample/A of untreated sample)×100.

cDNA synthesis

Total RNA was extracted using RNAzol™ B (TEL-TEST, TX, USA) as per the manufacturer's protocol. cDNA synthesis was performed with 3DNA™ Array 50™ detection method (Genisphere, PA, USA) as per the manufacturer's protocols. In the control and amygdalin treatment (5 mg/mL, 24 h), cDNA was synthesized from total RNA as follows: 3 μL of RT primer, total RNA and additional nuclease-free water were mixed to form a 29 μL RNA-RT primer mix, which was microfuged briefly, heated to 80 ℃ for 10 min, and immediately transferred to ice. One microliter of the RNase inhibitor Superase-In™ was added to the RNA-RT primer mix. Eight microliters of 5× SuperScript II First Strand Buffer (Gibco), 2 μL of dNTP mix (10 mmol/L each of dATP, dCTP, dGTP, dTTP), 4 μL of 0.1 mol/L dithiothreitol, 2 μL of Superscript II enzyme (400 units), and 3 μL of RNase-free water were mixed in each microtube, and the RNA-RT primer mix was then added. The tubes were then incubated at 42 ℃ for 2 h, and the reaction was heated by adding 7 μL of 0.5 mol/L NaOH/50 mmol/L EDTA. The microtubes were then incubated for denaturation at 65 ℃ for 10 min, and neutralization was carried out by adding 10 μL of 1 mol/L Tris-HCl at pH 7.5. The contents of two tubes were combined to yield a 130 μL cDNA solution in one single tube. The original tubes were rinsed with 16 μL of 10 mmol/L Tris at pH 8.0/1 mmol/L EDTA.

Upon completion of the synthesis procedure, the cDNA solution was concentrated by ethanol precipitation. Three microliters of thoroughly vortexed 5 mg/mL linear acrylamide solution was added to the cDNA solution. Six microliters of NaCl and 540 μL of 95-100% ethanol was then added and moderately vortexed. The mixture was then incubated at -20 ℃ for 30 min, centrifuged at >10 000 *g* for 15 min, and the supernatant was aspirated. The cDNA pellet was washed with 300 μL of 70% ethanol. After centrifuging again at >10 000 *g* for 5 min, the supernatant was aspirated, and the cDNA pellet was completely dried at 65 ℃ over a period of 10-30 min.

Microarray hybridization

A cDNA chip of TwinChip™ Human 8K (Digital Genomics, Seoul, South Korea) was used. The concentrated cDNA and 3DNA™ were hybridized on two identical arrays in a slide for a duplicate experiment. Two times formamide-based hybridization buffer was thawed and responded by heating at 55 ℃ for 10 min with intermittent inversions, and then microfuged for 1 min. Ten microliters of nuclease-free water was added to the cDNA pellet, and the cDNA was completely resuspended by heating at 55 ℃ for 10 min with intermittent inversions, and then microfuged for 1 min. Ten microliters of nuclease-free water was added to the cDNA pellet, and the cDNA was completely resuspended by heating at 65 ℃ for 10-15 min and vortexing for 5 min. Thirty microliters of hybridization mixture was prepared from 10 μL of cDNA, 15 μL of 2× hybridization buffer, 2 μL of Array50 dT Blocker, and 3 μL of nuclease-free water. The hybridization mixture was incubated at 80 ℃ for 10 min and then at 50 ℃ for 30-60 min. The hybridization mix was then added to the pre-warmed chip. After a disposable coverslip was applied, the chip was incubated

overnight in a dark humidified chamber at 50 ℃. After serial washing, the array was incubated for 2 min at room temperature with 95% ethanol. The slide was immediately transferred to a dry 50-mL centrifuge tube and dried by centrifugation for 2 min at 800-1 000 r/min. Array50 capture reagent was then thawed in the dark at room temperature over a period of 20 min and vortexed for 3 s. Thirty microliters of hybridization mixture was prepared from 15 μL of 2× hybridization buffer, 2.5 μL of 3DNA TM capture reagent #1 (Cy3), 2.5 μL of 3DNA TM capture reagent #2 (Cy5), and 10 μL of nuclease-free water. Following gentle vortexing and brief microfuging, the hybridization mixture was incubated at 80 ℃ for 10 min and then at 50 ℃ for 20 min. The hybridization mixture was applied to the pre-warmed chip after it was removed from the incubator. After a disposable coverslip was applied, the microarray was incubated in a dark humidified chamber at 50 ℃ for 2-3 h. After serial washing, the slide was immediately transferred to a dry 50-mL centrifuge tube and dried by centrifugation for 2 min at 800-1 000 r/min, and then transferred to a dark slide box.

Scanning and data analysis

The hybridized microarray was scanned with a confocal laser scanning microscope (ScanArray 5000; Packard Inc., CT, USA) at 532 nm for Cy3 and 635 nm for Cy5. Image analysis using GenePix (Axon Inc., CA, USA) produced quantitative values for each microarray spot. Pixel intensity of the background was subtracted from those of microarray spots. Spot intensities were normalized using the intensities generated by intensity/location dependent method[11]. Normalized spot intensities were calculated into gene expression ratios between the control and treatment groups. Mean data acquired from two identical arrays in a single slide of TwinChip™ were analyzed.

RT-PCR

Two micrograms of sample of RNA isolated from SNU-C4 cells using RNAzol™ B (TEL-TEST) and 2 μL of random hexamers (Promega, WI, USA) were added together, and the mixture was heated at 65 ℃ for 10 min. AMV reverse transcriptase (Promega) of 1 μL, 5 μL of 10 mmol/L dNTP (Promega), 1 μL of RNasin (Promega) and 5 μL of 10× AMV RT buffer (Promega) were then added to the mixture, and the final volume was brought up to 50 μL with diethyl pyrocarbonate-treated water. Subsequent PCR amplification was performed in a reaction volume of 40 μL containing 1 μL of the appropriate cDNA, 1 μL of each set of primers at a concentration of 10 pmol/L, 4 μL of 10× reaction buffer, 1 μL of 2.5 mmol/L dNTP and 2 U of *Taq* DNA polymerase (TaKaRa Bio Inc., Shiga, Japan). We selected five genes, exonuclease 1 (*EXO1*), ATP-binding cassette (ABC), sub-family F, member 2 (*ABCF2*), MRE11 meiotic recombination 11 homolog A (*MRE11A*), topoisomerase (DNA) I (*TOP1*), and FK506 binding protein 12-rapamycin associated protein 1 (*FRAP1*) downregulated in microarray analysis by treatment of amygdalin and performed PCR. Primer sequences, annealing temperatures and products size of genes are summarized in Table 1. The RT-PCR products were electrophoresed on a 1.5% agarose gel and visualized by staining with ethidium bromide.

Statistical analysis

Results were expressed as mean±SE. The data were analyzed by one-way ANOVA following the Dunnett's post hoc analysis, using SPSS. Differences were considered significant at $P<0.05$.

RESULTS

Cytotoxicity of amygdalin in SNU-C4 cells

When treated with amygdalin of 0.25, 0.5, 2.5, and 5 mg/mL concentrations for 24 h, viabilities of SNU-C4 cells were 96.1±7.4%, 87.8±2.4%, 82.9±5.5%, and 63.7±8.3%, respectively, compared with those of non-treated cells (Figure 2), and MTT assay showed dose-dependent cytotoxicity of amygdalin on SNU-C4 cells. Therefore, to compare the precise effect of amygdalin, further experiments were carried out, using 5 mg/mL amygdalin.

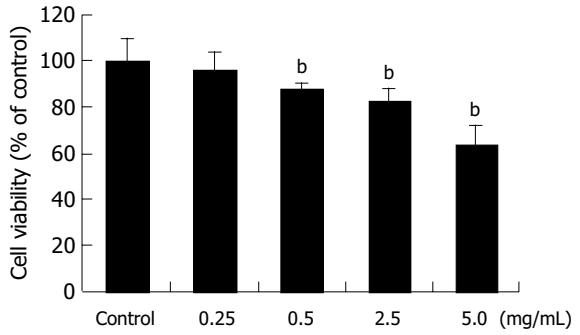

Figure 2 Cytotoxicity of amygdalin. SNU-C4 human colon cancer cells were treated with various concentrations (0.25, 0.5, 2.5, and 5 mg/mL) of amygdalin for 24 h prior to the determination of cellular viability through 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Independent experiment was repeated thrice. Results are presented as mean±SE (^bP<0.01 *vs* control group).

Analysis of microarray expression data

In order to assess the expression profiles in SNU-C4 cells treated with amygdalin (5 mg/mL, 24 h), cDNA microarray that contained duplicate cDNA probes from 8k human clones was performed to be screened at a time. Figure 3 showed the image of 8k human cDNA microarray. The green spots represented genes of control group that was labeled by Cy3-captured reagent and overexpressed than amygdalin group. In contrast, the red spots represented genes of amygdalin group that was labeled by Cy5-captured reagent and were overexpressed than control. The yellow spots represented genes that showed no difference in expression level between control and amygdalin group.

Figure 3 Expression pattern in a 8k human cDNA microarray.

To normalize intensity ratio of each gene expression pattern, global M method was used in this study. First, the primary data were normalized by the total spots of intensity between two groups, and then normalized by the intensity ratio of reference genes, such as housekeeping genes in both groups. Finally, the expression ratio of control and amygdalin group was converted to $\log_2$ ratio of each gene, and was represented by a scattered plot in Figure 4.

After normalizing the data, a difference in the normalized intensity ratio was selected. The genes of expression ratio were observed to be lower than -1 for which the observed expression was downregulated by amygdalin (Table 2). The genes downregulated by amygdalin were divided into seven categories by biological function; apoptosis-related gene, response to immune-related gene, signal transduction-related gene, cell cycle-related gene, cell growth-related gene, response to stress-related gene and transcription-related gene. We paid attention to genes belonging to cell cycle category. *EXO1*, *ABCF2*, *MRE11A*, *TOP1* and *FRAP1* cannot belong to category of cell cycle but category of cell growth, stress response, and transcription.

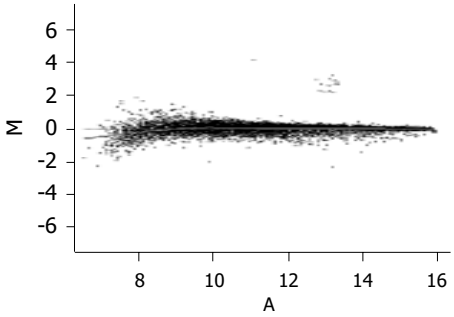

Figure 4 Scattered plot of the normalization results by global M method.

Confirmation of cDNA microarray findings by RT-PCR

We selected *EXO1*, *ABCF2*, *MRE11A*, *TOP1*, and *FRAP1* among the downregulated genes by amygdalin treatment, and observed mRNA expressions of *EXO1*, *ABCF2*, *MRE11A*, *TOP1*, and *FRAP1* using RT-PCR that reproduced the results of cDNA microarray. The efficiency of the reaction was adjusted by *CYCLOPHILIN* amplification. As shown in Figure 5, the expressions of *EXO1*, *ABCF2*, *MRE11A*, *TOP1*, and *FRAP1* were decreased by amygdalin treatment (5 mg/mL, 24 h).

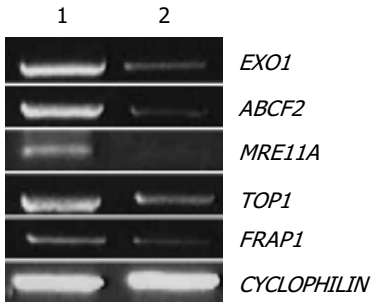

Figure 5 Confirmation of cDNA microarray results of downregulated genes by RT-PCR. Five genes, exonuclease 1 (*EXO1*), ABC, sub-family F (GCN20), member 2 (*ABCF2*), MRE11 meiotic recombination 11 homolog A (*MRE11A*), topoisomerase (DNA) I (*TOP1*), and FK506 binding protein 12-rapamycin associated protein 1 (*FRAP1*), were analyzed by RT-PCR with total RNA from control and amygdalin (5 mg/mL, 24 h)-treated human colon cancer cells. As an internal control, *CYCLOPHILN* was amplified.

DISCUSSION

Amygdalin belongs to a family of compounds called cyanogenic glycosides. Cyanide is believed to be the active cancer-killing ingredient in amygdalin. Amygdalin would be broken down by an enzyme in cancerous tissue, and toxic

Table 2 List of genes downregulated by amygdalin treatment

Gene	Chromosome	Title	Global M
Cell cycle			
FRAP1	1p36.2	FK506 binding protein 12-rapamycin associated protein 1	–1.029

cyanide to release from broken amygdalin would kill the cancer. It is further hypothesized that another enzyme, rhodanese, which has the ability to detoxify cyanide, is present in normal tissues but deficient in cancer cells. These two factors supposedly combine to effect a selective poisoning of cancer cells by the cyanide, while normal cells remain undamaged[6,12]. However, amygdalin is not approved by the Food and Drug Administration (FDA) for use in USA, and the anticancer effect of amygdalin has admitted controversy. Kwon *et al*., demonstrated that the controversy on amygdalin was due to its conversion to inactivate isoform, and Persicae Semen extract induced apoptosis in human promyelocytic leukemia (HL-60) cells with IC50 of 6.4 mg/mL in the presence of 250 nmol/L of β-galactosidase[13].

One of the advantages of cDNA microarray is the possibility to observe the expression pattern of the whole

genes and compare with different conditions. This study is the first work of comparison of the gene expression profiles of SNU-C4 human colon cancer cells after amygdalin treatment. cDNA microarray analysis showed that amygdalin treatment downregulated genes belong to categories of cell cycle-related gene, and related to cell growth, response to stress and transcription.

Anticancer agents targeting DNA and DNA-associated processes are widely used in the treatment of human cancers and produce significant increases in the survival of patients[14]. In general, four complex systems have evolved to respond to DNA damage: DNA repair, cell cycle checkpoint control, apoptosis, and damage tolerance[15]. *EXO1* is involved in mismatch repair and recombination, and has been considered as a candidate gene for colorectal susceptibility[16,17]. *ABCF2* is a member of the superfamily of ABC transporters. ABC proteins transport various molecules across extra- and intracellular membranes[18]. *MRE11A* encodes a nuclear protein involved in homologous recombination, telomere length maintenance, and DNA double-strand break repair[19,20]. *TOP1* acts as a swivel during replication, transcription, and recombination to relieve overwinding if duplex DNA[15,21]. DNA topoisomerase inhibitors represent a major class of anticancer agents (e.g. camptothecin; CPT) with documented activities against a broad spectrum of human malignancies[22]. *FRAP1* has been identified as the downstream target of the FKBP12-rapamycin complex, which inhibits progression through G_1 of the cell cycle[23], and mediates cellular responses to stresses such as DNA damage and nutrient deprivation[24,25]. *EXO1*, *ABCF2*, *MRE11A*, *TOP1*, and *FRAP1* particularly belong to categories of cell cycle-related gene and associated to DNA replication, repair or recombination. Thus, downregulation of these genes by amygdalin would induce DNA damage in SNU-C4 cells. In confirmation through RT-PCR, mRNA expressions of these five genes were also decreased by amygdalin treatment. Our results indicate that amygdalin induced DNA damage, involved in cell cycle on SNU-C4 human colon cancer cells and amygdalin might be used for therapeutic anticancer drug.

Abstract

AIM: We optimized a rapid and efficient tissue lysis method using the MagNA Lyser (Roche, Germany). Using this novel method combined with immunoblot analysis, we investigated the correlation between abnormal Bcl-X_L expression and clinicopathological characteristics in colorectal cancer.

METHODS: Tissue samples from Sprague-Dawley rats were tested to determine optimal lysis conditions for use with MagNA Lyser. We next used the new method to extract tissue proteins from the tumor tissue of a colorectal cancer patient. The availability of extractable tissue proteins for proteomic study was demonstrated by two-dimensional (2D) gel electrophoresis and subsequent matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry. In addition, we prepared tissue lysates from paired tumor tissues and adjacent nontumor tissues of 50 colorectal carcinoma patients. Ensuing immunoblot analyses were performed to detect the level of Bcl-X_L expression.

RESULTS: The optimal sample sizes processed were found to be around 200 mg, with oscillation frequency of 6 500 r/min for 80 s. Test of the first human tissue lysate confirmed that the MagNA Lyser method was adequate for protein extraction and subsequent identification by current proteomic protocols. The method was also applicable to immunoblot analysis. Thirty of 50 (60%) colorectal patients exhibited higher level of Bcl-X_L expression in their tumor tissues. Raised level of Bcl-X_L expression correlated with patients' gender and tumor cell proliferation index ($P = 0.037$ and $P<0.001$, respectively), but was independent of clinicopathological characteristics and overall survival.

CONCLUSION: We report a novel tissue lysis method applicable to proteomic and immunoblot analyses, which can facilitate the discovery and detection of cancer protein alterations.

INTRODUCTION

Cancer is a complicated and heterogeneous disease involving multiple molecular alterations. To globally explore protein alterations in cancer tissues, the first and most essential step is to rapidly and efficiently extract tissue proteins from the study specimens. Conventional methods for tissue lysis usually require grinding, homogenization and sonication to disrupt tissues and cells[1,2]. It is not only tedious, but also carries biohazard concerns for laboratory personnel. Recently, the Roche Company (Penzberg, Germany) developed a machine called the MagNA Lyser, and it could be combined with certain commercially available reagent kits to rapidly isolate DNA or RNA from tissue specimens[3,4]. The basic principle of tissue lysis centers on the ability of the machine to make fast and reciprocal oscillations, which produce collisions between tissue samples and ceramic beads provided in special centrifuge tubes. The whole procedure is simple and quick, and is therefore highly suitable for protein extraction from tissues, even though protein extraction had not been previously published, as a function of the MagNA Lyser. In this study, we have optimized a rapid tissue lysis protocol for use with the MagNA Lyser. The tissue proteins prepared by this new method can be resolved by two-dimensional (2D) gel electrophoresis and further identified by matrix-assisted laser

desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry. In addition, this novel method is also applicable to immunoblot analysis. We prepared tissue lysates from the tumor tissues and adjacent non-tumor tissues of 50 colorectal carcinoma patients. The ensuing immunoblot analyses were performed to detect the level of Bcl-X_L expression. Bcl-X_L is an important member of the Bcl-2 family proteins, contributing to the anti-apoptotic characteristic during the progression of tumors[5-7]. Previously, 43-60% of colorectal cancer patients have been reported to exhibit elevated level of Bcl-X_L expression in their tumor tissues by immunohistochemical staining[8,9]. In this study, elevated Bcl-X_L expression in tumor tissues was observed in 60% of colorectal cancer patients using the new tissue lysis method and immunoblot analysis. Raised levels of Bcl-X_L expression correlated with patients' gender and tumor cell proliferation index ($P = 0.037$ and $P<0.001$, respectively), but were independent of patients' age, tumor site, tumor size, grade of tumor cell differentiation, depth of tumor invasion, nodal or distant metastasis, and 5-year overall survival rate.

MATERIALS AND METHODS

Rat tissues

Sprague-Dawley rats weighing approximately 250 g (obtained from National Animal Center, Taiwan) were used in our pilot studies and fed with standard laboratory chow and water *ad libitum*. All procedures were performed in accordance with the Taipei Veterans General Hospital Animal Committee's guidelines for animal care. The rats were killed under anesthesia, and their organs were surgically taken and rinsed with phosphate-buffered saline (PBS). All specimens were cut into pieces, snap-frozen immediately and stored at -80 ℃ until use.

Patients and tumor specimens

Tumor specimens were obtained from 50 patients who received surgical resection for colorectal cancer at Taipei Veterans General Hospital during the time period of 1994-2004. Informed consent was obtained from each patient. Tissue specimens, both tumor and non-tumor parts, were frozen in liquid nitrogen immediately after resection and PBS rinse. All were kept in a -80 ℃ freezer until retrieval for the study. The non-tumor parts, taken from a site at least 10 cm away from the tumor part, were pathologically certified to be free from tumor cells.

Conventional grinder method for tissue lysis

Tissue specimens were ground in mortars with liquid nitrogen. The tissue powder obtained was then incubated overnight at -20 ℃ with 10% trichloroacetic acid plus 0.3% dithiothreitol (DTT) in acetone, then spun down, washed with acetone, and air-dried, followed by the addition of TLysis buffer, which is made up of 30 mmol/L Tris-HCl, pH 9.0, 9 mol/L of urea, 4% of CHAPS, 1% of DTT, 1 mmol/L of phenylmethylsulfonyl fluoride, 10 μg/mL of aprotinin, 10 μg/mL of pepstatin A, and 10 μg/mL of leupeptin. The mixture underwent three 20-s duration of homogenization on ice before further sonication at 10% output for 20 pulses. The lysate was then centrifuged at 100 000 *g* for 1 h at 4 ℃, and the supernatant was saved and assayed for protein concentration by the Lowry method[10].

MagNA Lyser method for tissue lysis

Tissue pieces were put into ceramic beads-containing special centritubes (Roche, Penzberg, Germany), 1 mL of pre-chilled TLysis buffer was immediately added, and subjected to oscillation made by the MagNA Lyser machine at 6 500 r/min for time periods as indicated. The lysate was then centrifuged at 100 000 *g* for 1 h at 4 ℃, and the supernatant was saved and assayed for protein concentration (Lowry method).

Two-dimensional (2D) gel electrophoresis

Prior to 2D gel electrophoresis, 2% of Ampholines/pharmalytes pH 3-10 (Amersham Biosciences, Piscataway, NJ, USA) was added to the tissue lysates. Immobilized linear pH gradient (IPG) strips were rehydrated with tissue lysate samples in the dark at room temperature overnight[11]. Isoelectric focusing was performed using IPG phor apparatus (Amersham Biosciences) for a total of 17 500 Vh at 20 ℃. The strips were then equilibrated for 15 min in 50 mmol/L Tris-HCl, pH 8.8, 6 mol/L urea, 2% (w/v) sodium dodecyl sulfate (SDS), 64 mmol/L DTT, 300 mL/L glycerol, and a trace of Bromophenol blue. Equilibrated IPG strips were transferred onto 12% uniform polyacrylamide gels. Standard SDS-polyacrylamide gel electrophoresis was performed, and the 2D gels were then stained with Coomassie blue and scanned directly using AlphaImager 2000 (Alpha Innotech Co., Avery Dennison, CA, USA). The images were further analyzed using ImageMaster 2-D Elite v3.01 software (Amersham Biosciences).

Protein spot identification

Spots of interest were manually excised from the 2D gels. After washing twice in 25 mmol/L ammonium bicarbonate/50% acetonitrile and once in 100% acetonitrile, gel pieces were vacuum-dried and rehydrated with 10 μg/mL of trypsin (Promega, Madison, WI, USA) in 25 mmol/L ammonium bicarbonate, pH 8.0. Proteins were proteolysed for 16-24 h at 37 ℃. Supernatants were collected, and the peptides in gel pieces were further extracted with 5% trifluoroacetic acid (TFA)/50% acetonitrile. The peptide extracts were vacuum-dried and re-solubilized in 5 μL of 0.1% TFA. The peptide extracts (1 μL for each) were then spotted onto the target plate, and α-cyano-4-hydroxycinnamic acid was added as a matrix (1 μL for each). Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry was performed using M@LDI *R*™ reflector time-of-flight mass spectrometer (Micromass, Manchester, UK). All mass spectra were internally calibrated with ACTH peptide and trypsinized alcohol dehydrogenase peaks. Peptide mass mapping was carried out using the MS-Fit program (Protein Prospector, University of California, San Francisco, CA).

Immunoblot analysis

The expression levels of Bcl-X_L and Ki-67 in human tissue lysates were detected by conventional immunoblot analysis[12]. In brief, 40 μg of protein samples were resolved in 10% SDS-polyacrylamide gels and then electrotransferred onto

polyvinylidene membranes (Amersham Biosciences). After blocking with PBST (PBS plus 0.1% Tween-20) plus 5% non-fat milk, the blots were incubated with anti-Bcl-X_L (Santa Cruz Biotechnology, Santa Cruz, CA, USA) or anti-Ki-67 (NeoMarkers, Fremont, CA, USA) antibody at 4 ℃ for 12 h. The blots were then washed thrice with PBST buffer, and incubated with horseradish peroxidase-conjugated secondary antibody for 1 h at room temperature. Blots were again washed thrice with PBST buffer, and the protein band signals were obtained by enhanced chemiluminescence (ECL, Amersham Biosciences). The levels of β-tubulin in the tissue lysates were also analyzed as internal control. The antibody against β-tubulin was obtained from Santa Cruz Biotechnology.

Statistical analyses

Statistical analyses were performed using the SPSS 11.0 software (SPSS, Chicago, IL, USA). χ^2 or Fisher's exact test was used to analyze the relationship between Bcl-X_L expression and patients' clinicopathological characteristics. Independent sample *t* test was used to compare the ages and tumor sizes between the patients with or without Bcl-X_L overexpression. Overall survival rates were calculated by the Kaplan-Meier method and the statistical comparison was made using the log rank test. The difference was considered significant if the *P* value was less than 0.05 (two-tailed test).

RESULTS

Determination of conditions for tissue lysis using the MagNA Lyser

Different organs derived from the Sprague-Dawley rats were utilized as test tissue materials for a series of pilot studies. First, we intended to determine the optimal tissue size for lysis by MagNA Lyser. For each organ, we used four pieces of tissue specimens ranging from 100 to 600 mg. Tissue lysis was performed by setting the oscillation rate to 6 500 r/min durations of 20, 40, 80, 120, or 180 s. Evaluation of the lysing efficiency was preliminarily based on protein recovery rates. From the data shown in Figure 1, we realized that there was a ceiling limit to the size of tissue specimen tested, because the larger tissue pieces usually resulted in a low protein recovery rate. The big tissue samples were probably

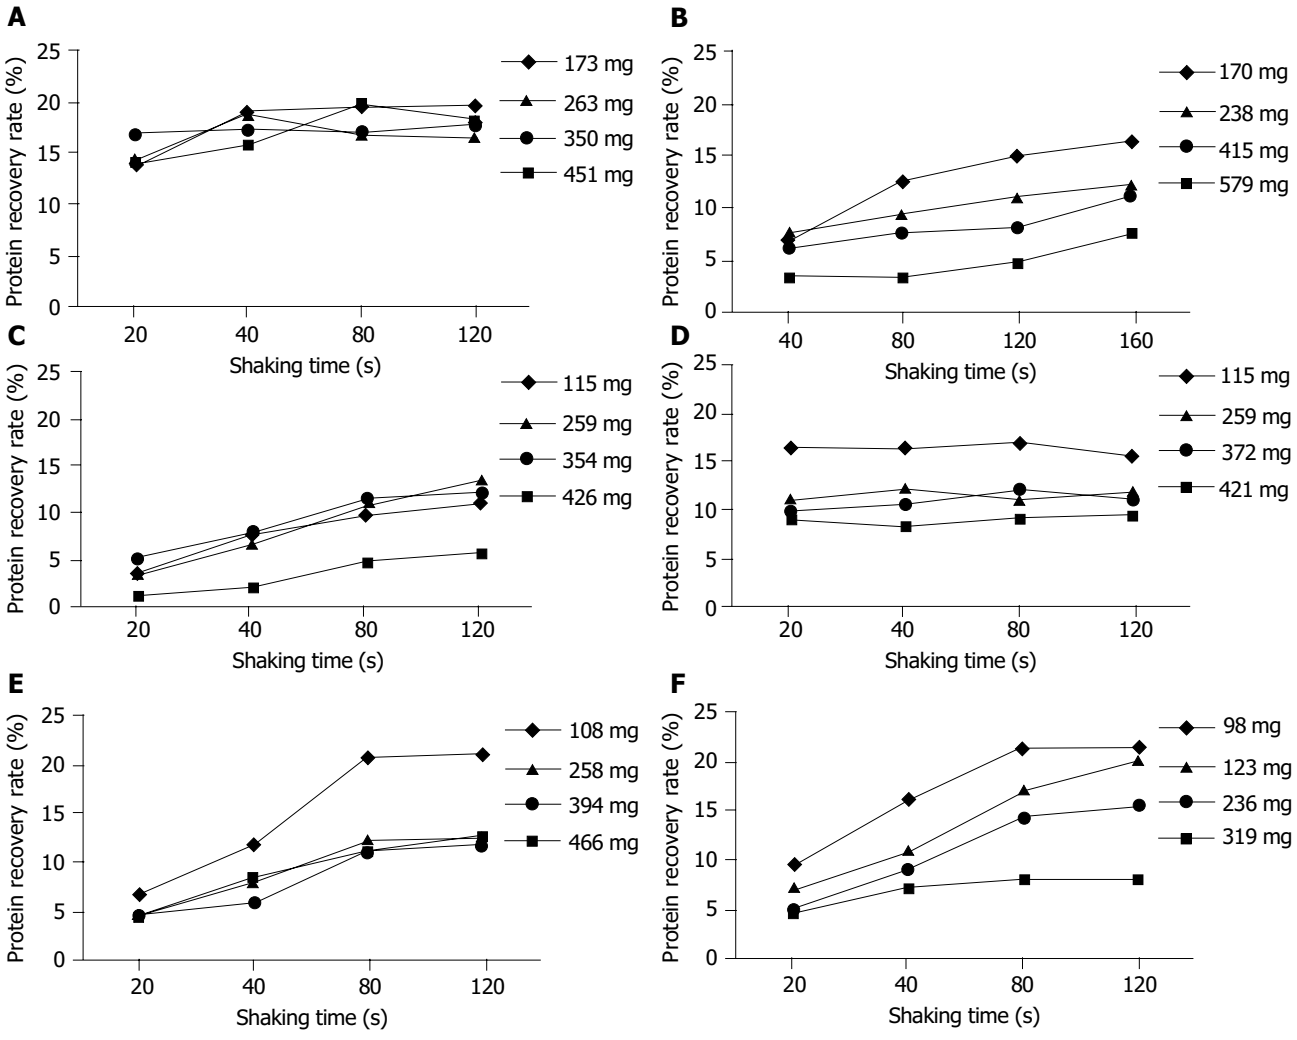

Figure 1 Determination of the optimal specimen size from different organs for tissue lysis by the MagNA Lyser. Four specimen sizes, ranging from 100 to 600 mg, of rat organs were tested for the protein recovery rates from the new tissue lysis method using the MagNA Lyser. The oscillation frequency and duration was set at 6 500 r/min for 20, 40, 80, 120, or 180 s as indicated. Protein concentrations of tissue lysates were assayed by the Lowry method. The protein recovery rate from tissue lysis was calculated as the amount of total protein obtained divided by the original weight of the specimen. **A**: Liver; **B**: Stomach; **C**: Colon; **D**: Kidney; **E**: Spleen; **F**: Heart.

subjected to incomplete lysis and thus were being wasted. Up to 350 mg of liver and colon tissues could be processed efficiently, but in general, the optimal tissue size of each organ for this study should not be more than 200 mg.

Next, the optimal shaking duration was determined. Tissue pieces in sizes ranging from 150 mg to 200 mg were oscillated in MagNA Lyser for different time periods. The protein recovery rate after each time period is shown in Figure 2A. Based on these data, optimal shaking time set at 80 s resulted in almost maximal protein recovery rates from the various organ tissues. When shaking time extends beyond 20 s, the lysates unavoidably became heated. To ascertain the impact of heat on tissue proteins, the tissue lysates prepared after different shaking periods in the MagNA Lyser were further analyzed by 2D gel electrophoresis. As shown in Figure 2B, the 2D profiles of tissue lysates prepared by 80-s oscillation seemed not worse than those prepared from shorter duration oscillations.

MagNA Lyser method vs conventional grinder method

According to the above test results, for optimal protein extraction from tissue samples using the MagNA Lyser, tissue size should be no more than 200 mg, and oscillation frequency should be set at 6 500 r/min for 80 s. Furthermore, in comparing tissue extraction efficiency using the MagNA Lyser or the conventional grinding method, protein recovery rates obtained through the MagNA Lyser were significantly superior at tissue specimens weighing between 150 and 200 mg (Figure 3A). The profiles from 2D gel electrophoresis were similar between tissue lysates prepared through either method (Figure 3B). Some protein spots appear to differ on two profiles, this could not be entirely attributed to the two different methods used for protein extraction, and quality variation during the 2D gel electrophoresis could also contribute to the differences. From our series of quality control pilot studies, we conclude that the MagNA Lyser method is indeed a convenient and efficient method for protein extraction from tissue samples.

MagNA Lyser method compatible with ensuing proteomic and immunoblot analyses

After the previous pilot studies using rat tissues as test material, we attempted protein extraction from human tumor specimen obtained from a colon cancer patient using the MagNA Lyser. The tissue lysate was resolved by 2D gel electrophoreses and several protein spots on the 2D profile were identified after standard procedure, including trypsin digestion, peptide extraction and MALDI-TOF mass spectrometric analyses (Figure 4). Our results confirmed that tissue lysate prepared using the MagNA Lyser method was entirely adequate for subsequent protein identification by the current proteomic protocols.

In order to ascertain whether the novel tissue lysis method is also applicable to immunoblot analysis, we used the MagNA Lyser to prepare tissue lysates from paired tumor and non-tumor tissues obtained from 50 colorectal cancer patients, followed by performing immunoblot analyses to compare the levels of Bcl-X_L expression in these patients. The results from six patients are shown in Figure 5 as representative examples. Only one of 50 colorectal cancer patients exhibited down regulation of Bcl-X_L expression in their tumor tissues, whereas 30 patients (60%) had raised levels of Bcl-X_L expression in the tumor tissues rather than their adjacent non-tumor tissues. Statistical analyses revealed that elevated Bcl-X_L expression correlated with patients' gender and elevated Ki-67 expression (P = 0.037 and P<0.001,

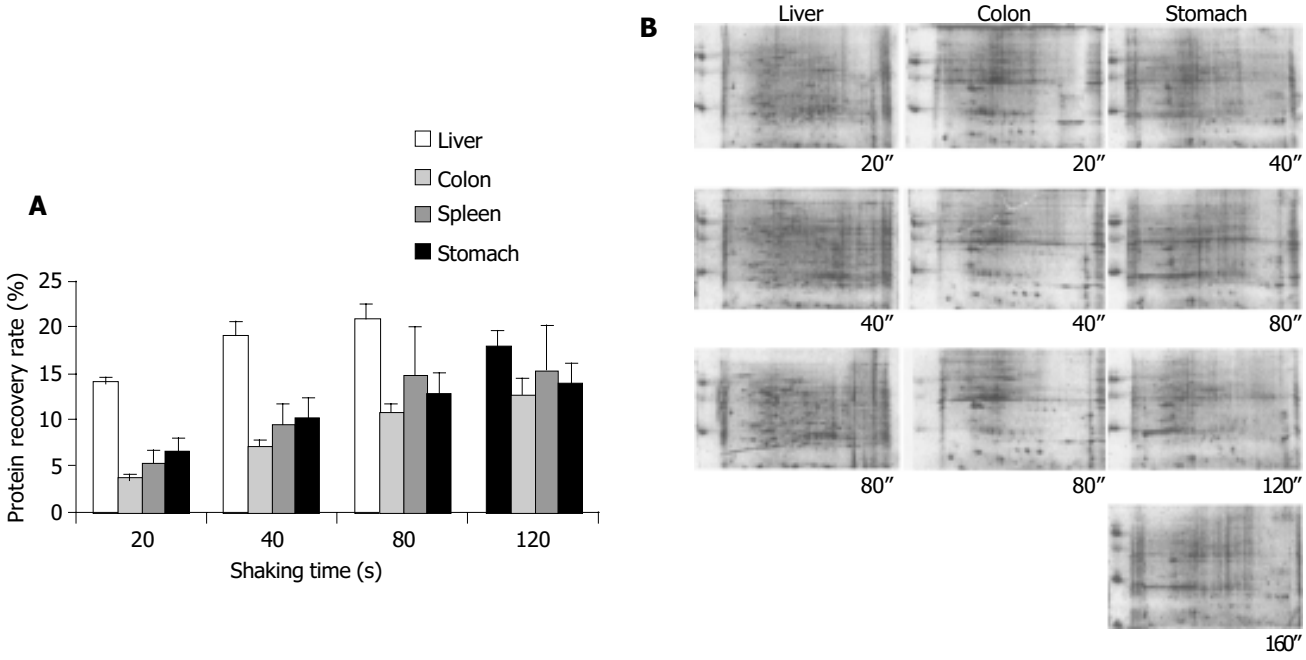

Figure 2 Determination of the optimal shaking time for tissue lysis by the MagNA Lyser. Tissue pieces in sizes ranging from 150 to 200 mg were subjected to reciprocal oscillation by the MagNA Lyser at 6 500 r/min for different time periods. Protein concentrations of tissue lysates were assayed, and protein recovery rates were calculated as above. Additionally, an aliquot (200 μg) of each tissue lysate was resolved on a 7-cm IPG strip, pH 3-10, then run in an 8×9-cm 12% SDS-polyacrylamide gel, and visualized by AlphaImager 2000 after staining with Coomassie blue dye. The optimal shaking time for tissue lysis by MagNA Lyser was determined according to both the protein recovery rates (**A**) and the protein profiling from 2D gel electrophoresis (**B**).

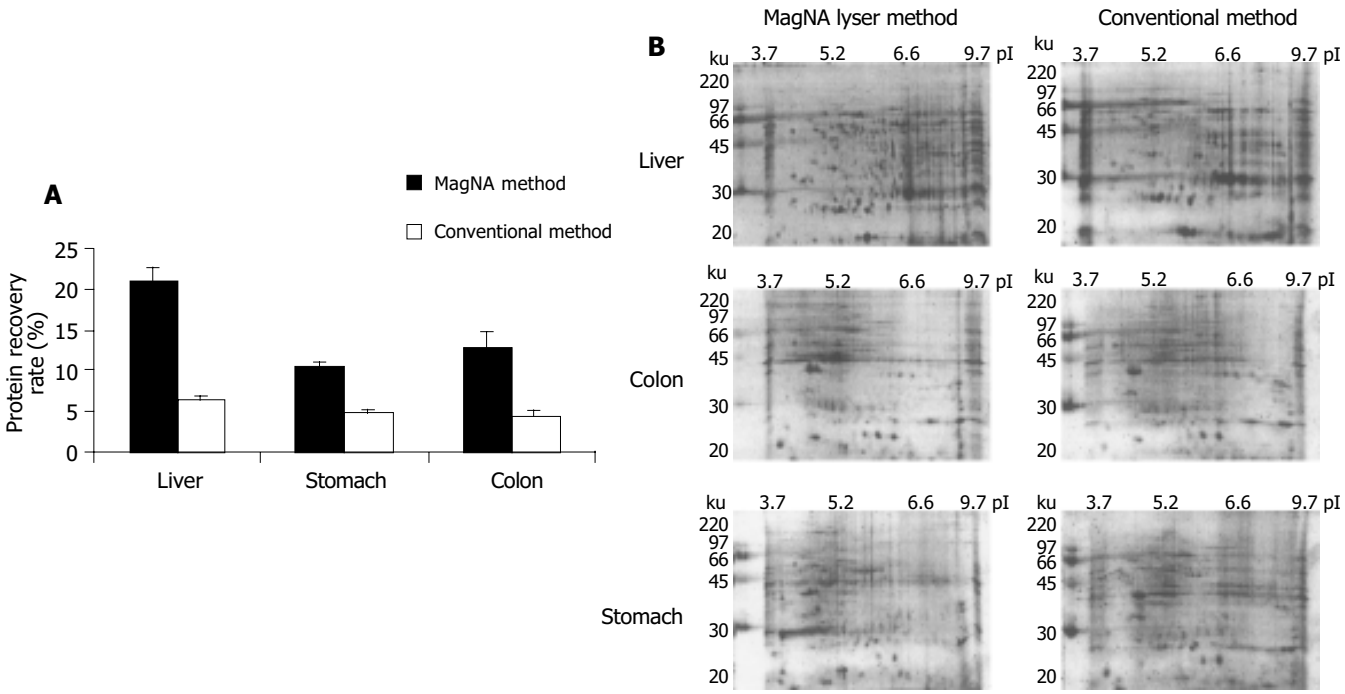

Figure 3 Comparison between conventional tissue lysis with the new method using MagNA Lyser. Tissue specimens ranging from 150 to 200 mg in size were processed using the conventional tissue lysis protocol and the new MagNA Lyser method. The protein recovery rates (**A**) and 2D gel profiling (**B**) were compared for the two methods.

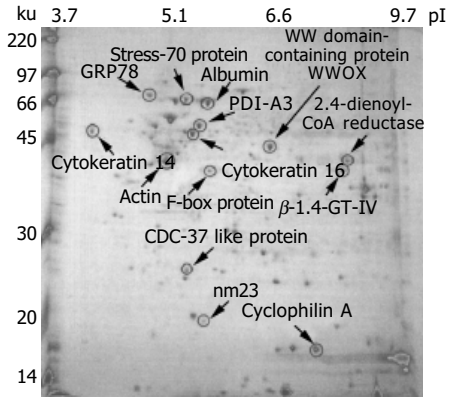

Figure 4 Proteomic analysis of the human colorectal cancer tissue lysate prepared by the MagNA Lyser. Approximately 150 mg of tumor specimen from a colon cancer patient was subjected to tissue lysis by the new MagNA Lyser method. One aliquot (600 μg) of tissue lysate was resolved on a 13-cm IPG strip, pH 3-10, and subsequently run in a 14 cm×15 cm 12% SDS-polyacrylamide gel, then visualized by staining with Coomassie blue dye. Protein spots were cut from the gel, after trypsin digestion and peptide extraction, the spots were identified through MALDI-TOF mass spectrometry, and have been labeled on the gel image.

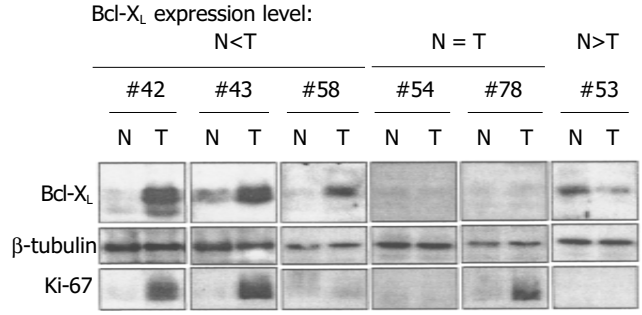

Figure 5 Differential expression levels of Bcl-X_L in colorectal cancer tissue specimens. Immunoblot analyses were performed to analyze the protein levels of Bcl-X_L in the lysates from nontumor tissues (N) and tumor tissues (T) of colorectal cancer patient #42, #43, #53, #54, #58, and #78. The levels of β-tubulin in the same-paired tissue lysates were analyzed as internal control.

respectively), but was not associated with patients' age, tumor site, tumor size, grade of tumor cell differentiation, depth of tumor invasion, lymph node or distant metastasis, and 5-year overall survival rate (Table 1).

DISCUSSION

Conventional methods for protein extraction usually require tedious grinding, homogenization and sonication steps to disrupt tissues and cells. A novel device, the MagNA Lyser (Roche, Germany) was recently designed and optimized to combine with different commercially available kits to facilitate the isolation of DNA and RNA from a variety of tissue samples, although without publication for protein extraction. In this study, we have firmly established the feasibility of using the MagNA Lyser to extract tissue proteins for subsequent proteomic and immunoblot analyses. Firstly, we exploited different organs of Sprague-Dawley rats as test samples in a series of pilot studies to determine the optimal tissue sizes for study as well as the time periods necessary for oscillation. The results suggest that the optimal tissue size should be no more than 200 mg, with oscillation frequency set at 6 500 r/min for 80 s. In addition, our data showed that protein recovery rates of the MagNA Lyser method were superior, when compared with those obtained through the conventional method, and visualization of the protein profiles provided by 2D electrophoreses showed both

	Elevated Bcl-X_L expression		
	Yes (n = 30, %)	No (n = 20, %)	P

superior quality as well as quantity in protein extracted.

Completion of pilot studies in rats established preliminary conditions of study for human specimen. Study of the first colon cancer patient identified several proteins by 2D gel electrophoresis and MALDI-TOF mass spectrometry, suggesting that the MagNA Lyser method can foster clinical proteomic studies to assist us in the understanding of diverse processes of carcinogenesis, develop new biomarkers for diagnosis and early detection of cancer, and ultimately determine new therapeutic targets for future therapeutic manipulation. In addition, the MagNA Lyser method is adequate for large-scale tissue lysate preparation, which can be linked with ensuing immunoblot analyses to facilitate the rapid detection of cancer protein alterations in large-scale cancer tissues. As an example, we detected elevated Bcl-X_L expression in colorectal cancer patients. Further statistical analyses revealed that raised level of Bcl-X_L expression correlated with elevated Ki-67 expression (P<0.001), providing clinical evidence that abnormal Bcl-X_L expression contributed to tumor cell proliferation during colorectal cancer progression. The potency of tumor cell proliferation does not only depend on tumor cell growth, but also associates with tumor cell survival (e.g. anti-apoptosis) and cell cycle control[5-7]. However, the close correlation between elevated Bcl-X_L expression and tumor cell proliferation did not extend to enlargement of tumor size (P = 0.631), probably because the formation of tumor mass requires the involvement of other events like angiogenesis.

Bcl-2 family proteins comprise both pro-apoptotic members, e.g. Bax, Bak, BH3-only proteins, as well as anti-apoptotic molecules such as Bcl-2 and Bcl-X_L[5-7]. BH3-only proteins function as mediators of apoptotic response to elicit activation and translocation of Bax or Bak to the mitochondria, thereby facilitating Bax and Bak interaction with mitochondrial channels to release cytochrome *c*[13]. Bcl-2 and Bcl-X_L sequester Bax or BH3-only proteins and thus block this apoptotic process[14]. Much evidence indicates that induction of apoptosis is accompanied by an increase in Bax or Bak expression and/or a decrease in the expression of Bcl-2 or Bcl-X_L[15-18]. Overexpression of Bcl-2 or Bcl-X_L can prevent apoptotic cell death induced by diverse events including abnormal expression of p53 or c-Myc and exposure to chemotherapeutic agents[19-22]. In contrast, down-regulation of Bcl-2 or Bcl-X_L by antisense, siRNA or ribozymes sufficiently sensitize various types of cells destined for apoptosis[23-26]. Clinically, a characteristic feature of follicular lymphoma is the t(14;18) translocation, which brings *bcl-2* under the control of the immunoglobulin heavy chain gene locus leading to elevated Bcl-2 expression[27]. However, a survey of 30 colorectal carcinoma and 24 adenomatous polyps patients suggested that a transition from Bcl-2 to Bcl-X_L expression might occur during progression of colorectal tumors[8]. Only 10% of colon carcinoma patients had increased levels of Bcl-2 in tumor tissues rather than adjacent normal colonic mucosa, and in fact 83% of patients exhibited down regulation of Bcl-2 expression in their tumors[8]. But instead, the level of Bcl-X_L expression was increased in 18 (60%) of 30 colon carcinoma patients. Besides, there

was another study showing elevation of Bcl-X_L expression in 43% of 58 colorectal carcinoma patients[9]. These results were all obtained by immunohistochemical staining. In this study, we exploited the new tissue lysis method and immunoblot analysis to detect 30 (60%) of 50 colorectal carcinoma patients with elevated Bcl-X_L expression. This data compares well with previous immunohistochemical staining data.

Our study also suggests that elevated Bcl-X_L expression preferentially occurred in female colorectal cancer patients ($P = 0.037$). The underlying pathophysiological basis is unclear, but it could be partly attributed to the findings that Bcl-X_L expression can be regulated by female hormones estrogen and progesterone[28,29]. Further investigation is needed to elucidate the relationship between gender and elevated Bcl-X_L expression.

In conclusion, we report a rapid and efficient tissue lysis method compatible with subsequent proteomic and immunoblot analyses, which can facilitate the discovery or detection of cancer gene alterations at the protein level.

Abstract

AIM: p53-Inducible ribonucleotide reductase small subunit 2 (p53R2) encodes a 351-amino-acid peptide, which catalyzes conversion of ribonucleoside diphosphates to the corresponding deoxyribonucleotides required for DNA replication and repair. A recent study reported that a point mutation (G/T) in the p53 binding sequence in a colon cancer cell line completely impaired p53R2 protein activity.

METHODS: We screened the p53R2 gene coding regions and a regulatory region which contains a p53 binding sequence in 100 patients with colorectal adenoma and 100 control subjects using PCR, cold SSCP, and direct DNA sequencing.

RESULTS: Although we did not identify genetic variation in all nine exons, four regulatory-region variants were found, of which three were single nucleotide polymorphisms (SNPs) (nt 1 789 C/G, nt 1 928 A/G, 1 933 T/C), and one was 20 bp insertion which replaced a ATTTT between nt 1 831 and 1 835. Additionally, we determined the frequency of these p53R2 variants in a recently concluded case-control study of incident sporadic colorectal adenomas (163 cases and 210 controls).

CONCLUSION: Although more detailed functional characterizations of these polymorphisms remain to be undertaken, these polymorphic sites may be useful for identifying alleles associated with mis-splicing, additional transcript factors and, more generally, in cancer-susceptibility association studies.

INTRODUCTION

The p53 gene is a major target for genetic alterations or biochemical activations in human cancer. However, the mechanism by which p53 exerts its effects or alters other signaling systems is largely unknown. In recent years, a number of specific p53 target genes have been discovered that are likely to be involved in downstream target effects of altered p53 protein, including cell-cycle arrest, apoptosis, and tumor suppression. Recently, an important p53 downstream target gene, p53-inducible ribonucleotide reductase small subunit 2 (p53R2) consisting of nine exons and a p53-banding sequence in intron 1, was identified in cancer cell lines[1]. Human ribonucleotide reductase catalyzes the rate-limiting step in the production of deoxyribonucleotide triphosphate (dNTP), which is required for DNA replication and repair[2]. This enzyme is also regulated by the cell cycle[3]. The R2 subunit is made late in the G1 phase before DNA replication, and disappears in late S or early G2. p53R2 is a gene that is essential for DNA repair, and loss of function of this gene results in dysfunctional repair mechanisms[1]. Polymorphisms in either the regulatory or coding regions of the p53R2 gene may affect its expression and protein function, altering an individual's response to DNA damage, and thus affecting the risk of colorectal cancer. We screened the p53R2 gene coding regions and a regulatory region, which contains a p53 binding sequence, in 100 patients with colorectal adenoma and 100 control subjects for single-nucleotide polymorphisms and other mutations using PCR, cold SSCP, and direct DNA sequencing. Herein, we report several novel genetic variations designated as *Dde*I, *Nde*I, *Hha*I (according to restriction enzymes cut sites), and 20 bp insertion. Subsequently, we determined the allele frequencies

of the observed polymorphisms in 163 cases of incident sporadic colorectal adenoma and 216 colonoscopy negative controls.

MATERIALS AND METHODS

Study population

From 1994 to 1997, the Markers for Adenomatous Polyps (MAP) case-control study was conducted to assess the validity of colonic epithelial cell proliferation as a biomarker of risk for incident sporadic colorectal adenomatous polyps. Prior to the beginning of the study, MAP was approved by the Institutional Review Board of Wake Forest University School of Medicine in accordance with an assurance filed with and approved by the Department of Health and Human Services. Informed consent was obtained from each participant.

Eligibility criteria for study subjects consisted of English speaking adults from 30 to 74 years of age, of either sex, and of all races who were scheduled for elective outpatient colonoscopy by four large gastroenterology practices in Winston-Salem and Charlotte, North Carolina. Patients increased in number over a 24-mo period. Cases were identified as eligible colonoscopy patients who were determined to have a study index of pathologist-confirmed incident adenomatous polyps according to the criteria adapted from the National Polyp Study[4]. Controls consisted of all eligible colonoscopy patients with no previous history of adenomatous polyps and who were found to be free of adenomatous polyps. Persons with familial polyposis, Gardner's syndrome, ulcerative colitis, Crohn's disease, bowel resection, newly diagnosed recurrent adenomatous polyps, and incident colon cancer were excluded, as they had a history of cancer other than non-melanoma skin cancer. Blood was drawn and stored at -70 ℃ for possible later measurement of various genotypes.

Subjects

Among all three clinical sites, 2 246 colonoscopy patients were identified. Of these, 669 were eligible on initial screening (eligibility rate 29.8%), and of these 633 were willing to discuss the study, 617 of these were contacted, and 417 of these signed consent and had study colonoscopies (consent rate 63.1%). Of the 417 participants, 259 had some types of polyp, and of these, 179 had adenomatous polyps. Nine of the 417 total patients were subsequently determined ineligible for the study and 8 additional patients had incident colon cancer and were not eligible for the primary case-control analyses; thus, 400 patients were available for genotypic analysis. Of these 400 patients, viable DNA was isolated from 373 (163 cases and 210 controls) for genotyping.

Genomic DNA isolation

Genomic DNA was obtained from stored white blood cells (WBCs) digested in 500 μL of lysis buffer (50 mmol/L Tris-HCl, pH 8.5, 1 mmol/L EDTA, 0.2% SDS, 200 g/mL proteinase K) overnight at 55 ℃ with shaking. The digestion was precipitated directly with isopropanol and the pellets were washed with 70% ethanol. The genomic DNA pellets (50-100 μg) were dissolved in 300-800 μL of TE buffer, of which about 1 μL was used for each PCR reaction.

PCR amplification

The primers (Table 1) and PCR product sizes were designed following published genomic DNA sequences (GenBank accession no.: NC_000008). We designed primers that were 18-25 bases long with a 40-60% GC content and an annealing temperature (T_m) around 52-68 ℃. To obtain the optimal conditions for PCR amplification, we ran a set of PCRs with various concentrations of Mg^{++}, template DNA, dNTPs, and primers for each fragment.

Cold single-strand conformation polymorphism analysis

Five microliters of the PCR product was mixed with 15 μL denatured buffer [0.4 μL 1 mol/L MMH (methylmercury hydroxide), 12.6 μL 1.25×TBE, 2.0 μL 15% Ficoll containing 0.1% bromophenol blue, and 0.1% cyanol xylene blue], and then incubated for 10 min at room temperature, heated for 5 min at 95 ℃, and put on ice before being loaded on 20% TBE polyacrylamide gel and electrophoresed in a Novex Thermoflow system for 4-5 h at 10-15 ℃ at 300 V. The gel was stained in 1×TBE with 5 μg/mL ethidium bromide for 10 min and visualized on a UV lamp (Figure 1B). The shift bands were cut and re-amplified for direct sequencing.

DNA sequencing

For direct sequencing, the PCR products amplified from genomic DNA were purified and directly used for sequencing. DNA was sequenced with the Thermal Sequenase Cycle Sequencing Kit from Amersham Life Science (Cleveland, OH, USA) according to manufacturer's instructions. In cycle sequencing, the thermal cycle consisted of 2 min at 94 ℃, 45 cycles of 1 min at 94 ℃, 1 min at 60 ℃, and 1 min at 72 ℃. The reaction mixture was loaded on a 6% polyacrylamide sequencing gel made from Sequagel DNA Sequencing Solutions (National Diagnostics, GA, USA).

Restriction fragment length polymorphism

Since polymorphisms at the nt 1 789 G and nt 1 923 C alleles created *Dde*I and *Hha*I restriction enzyme cut sites, respectively, each PCR product was subjected to *Dde*I and *Hha*I restriction enzymes digestion prior to electrophoresis for determining genotype frequencies. The DNA fragments were then separated using 3% 2:1 Nusiev/SeaKern agarose gel. The allele types were determined for *Dde*I analysis as follows: three fragments of 6, 171, and 373 bp for the C allele, four fragments of 6, 97, 171, and 276 bp for the G allele; and five fragments of 6, 171, 276, and 373 bp for the C/G allele. The allele types were determined for *Hha*I analysis as follows: three fragments of 550 bp for the T allele, two fragments of 299 and 251 bp for the C allele; and three fragments of 550, 299, and 251 bp for the T/C allele nt 1 928 A/G, the polymorphism does not have a suitable restriction enzyme site. Therefore, we changed an A nucleotide to a T in the near 3' end of the forward primer. This change combines with the wild type allele (A) to create an *Nde*I cutting site, but does not do so with the variant allele (G). The PCR products (10 μL) were subjected to *Nde*I restriction enzyme. Bands for the wild-type (A/A) allele

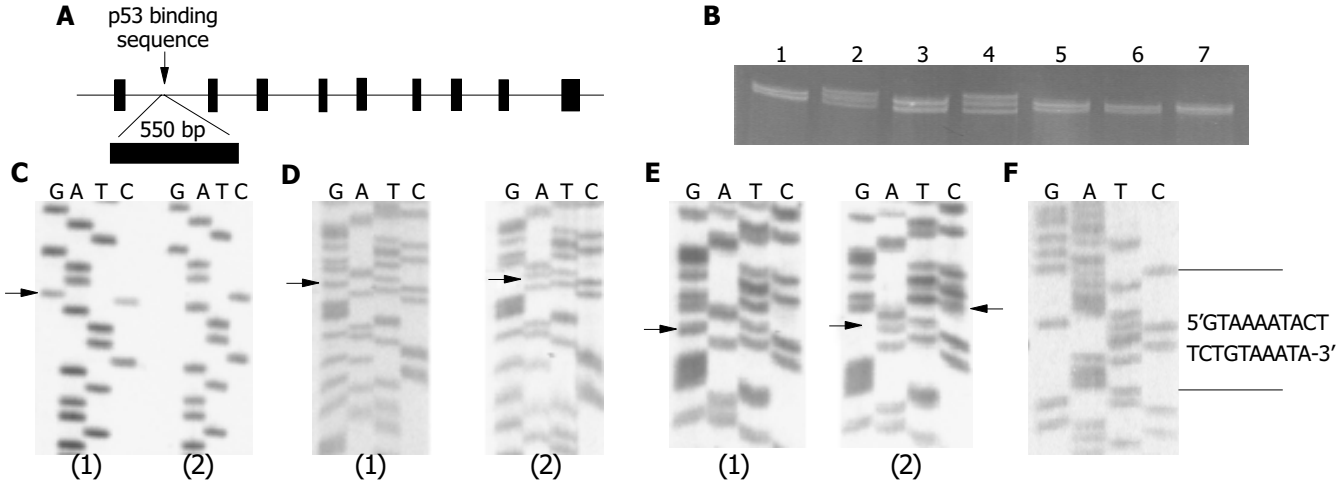

Figure 1 Structural feature and genetic variation analysis of p53R2. **A:** A representative p53R2 gene structure including a regulatory region with p53 binding sequence within intron 1; **B:** representative cold SSCP result. p53R2 Regulatory region was amplified, and PCR products were run on a 20% SSCP gel at 15 ℃. Lanes 2 and 4 are the heterozygous polymorphism pattern; **C:** alterations in regulatory region of p53R2 gene: (1) DdeI G/C, and (2) DdeI C/C genotypes; **D:** Alterations in regulatory region of p53R2 gene: (1) NdeI G/G and (2) A/A genotypes; **E:** Alterations in regulatory region of p53R2 gene: (1) NdeI G/G and HhaI T/T, and (2) NdeI A/A and HhaI T/C genotypes; **F:** Alterations in regulatory region of p53R2 gene: 20 bp insertion which replaced an ATTTT between nt 1 831 and nt 1 835.

were cut into 246 and 26 bp; the G/G variant allele showed at 272 bp; and the heterozygote (A/G) allele was cut into 272, 246, and 26 bp fragments (Figure 2).

Statistical analyses

All statistical inquiries were conducted using R language version 1.9.0 from http://www.R-project.org. Homogeneity test was used to check the non-dependency between genotypes and the frequencies of the p53R2 gene variants between the patients with colorectal adenoma and the control groups. Consistency of the genotype frequencies with the Hardy-Weinberg equilibrium was also tested by χ^2-analysis.

RESULTS

We screened nine exons and a regulatory region in first intron of p53R2 gene in 200 subjects including 100 patients with colorectal adenoma and 100 control subjects for mutation identification. No mutation was found in any of the nine exons; however, three SNP variations (nt 1 789 C/G, nt 1 928 A/G, and nt 1 933 T/C) were identified in the first intron of the p53R2 gene by cold SSCP (Figure 1B), and confirmed by direct DNA sequencing (Figures 1C-E and Table 2). A 20 bp variant, which is a short insertion variation that replaced 5 bp between nt 1 831 and nt 1 835 (Figure 1F and Table 2), was also found (Table 2). These polymorphisms are summarized in Figure 2.

Restriction enzyme mapping showed two restriction enzymes that could be used for population screening for nt 1 789 C/G (*Dde*I) and nt 1 933 T/C (*Hba*I) variations. We also designed a modified RFLP (*Nde*I) method for population screening for the nt 1 928 A/G alteration (Figure 2).

Figure 2 Representation of p53R2 intron 1. The human p53R2 partial intron 1, as enumerated in the original description of the p53R2 gene (GenBank accession no.: NC000008), is shown. The three variable loci are underlined, boxed 5 bp is replaced by 20 bp nucleotides (5'-GTAAAATACTTCTGTAAATA-3'), the p53 binding sequence is italicized, and forward and reverse primers set in bold.

Therefore, C/G, T/C, and A/G polymorphisms were designated *Dde*I, *Hba*I, and *Nde*I, respectively. Then, frequencies of these variations were determined in all of the 373 subjects (cases = 163, control = 210) from case-control study (Table 2). Since each of these four variations is close to the p53 binding sequence, they may play important roles in maintaining a three-dimensional structure with the p53 binding sequence. Of the four variations, the *Hba*I polymorphism occurred at a very low frequency (2.78%). The 20 bp variant was found in only 4 patients, all adenoma cases. The distribution of *Dde*I genotypes C/C, C/G, G/G, and G/G combined with C/G were 87.7%, 11.7%, 0.6% and 12.3% in cases, compared to 85.7%, 13.4%, 0.9% and 14.3% in controls, respectively. The distribution of *Nde*I genotypes G/G, G/A, A/A, and A/A combined with G/A were 80.0%, 18.4%, 1.23% and 19.6% in cases, compared with 82.8%, 14.4%, 2.79%, 17.2% in controls, respectively. All polymorphisms were in Hardy-Weinberg equilibrium in all populations, with the exception of the 20 bp variant, which was found in 4 patients only, all with colorectal adenoma. There is no statistical difference between the cases and control subjects (Table 2).

DISCUSSION

p53-Inducible ribonucleotide reductase small subunit 2 (p53R2) is an important p53 downstream target gene that is essential for DNA repair[1]. It has been demonstrated that p53R2 has an important role in delivering dNTP and maintaining the dNTP pool in response to DNA damage. Loss of function of this gene results in dysfunctional repair mechanisms.

Single-strand conformation polymorphism (SSCP) is a technique for detecting known and unknown genetic variation using PCR products[5]. Using this method about 70-90% of unknown mutations can be detected. Single strands assume a specific folded conformation, when double-stranded PCR product is denatured to single strand. These conformers

are separated by non-denaturing polyacrylamide gel electrophoresis. A single base mutation can cause a change in the folded conformation compared to the wild type and can change the separation pattern. This means that a change in separation pattern compared to that of the wild type indicates a mutation.

Using these methods, we here report mutation screening of the p53R2 gene, identification of four novel genetic variations in a regulatory region, their allele frequencies in both normal and colorectal adenoma populations, and the predicted functional impact of resulting transcriptional changes. Since each of these four mutations is close to the p53 binding sequence, these variations may play an important role in maintaining a three-dimensional structure with the p53 binding sequence. As of May 2004, only two polymorphisms of the p53R2 gene (-88 C/A and 8 bp insertion) have been reported[6,7]. We searched the available literature and the NCBI SNP database, and found no published information on these novel variants. To our knowledge, this is the first report of allele frequencies of novel p53R2 polymorphisms in a population consisting of patients with colorectal adenoma and controls.

Somatic mutation screening of p53R2 has been previously investigated in cancer. On the whole, two studies investigated the genetic variation of p53R2 in gastric and urothelial carcinoma[8,9]. Byun *et al*., did not detect any somatic variations in the p53R2 gene in 105 gastric carcinomas, including 15 cell lines[8]. One non-synonymous coding variant (Glu136/Asp) was identified in urothelial carcinoma; however, the frequency was rare (1/108)[9]. It was concluded that p53R2 is not a critical target of genetic inactivation in tumorigenesis.

Genetic polymorphisms have been identified in many genes related to DNA synthesis and repair, such as thymidylate synthase (TS)[10,11], MTHFR[11,12], and XRCC1[13,14]. Genetic polymorphisms could affect gene expression, enzyme function, or the protein's interaction with environmental and nutritional factors to modify the risk of neoplasia as we have demonstrated for other polymorphisms[15]. An 8 bp tandem repeat and a -88 C/A polymorphism were discovered in the 5'-untranslated region of the p53R2 gene[8,9]. Three polymorphisms in 3'-untranslated region of p53R2 gene were also identified[16]. Since we focused only on exons and the first intron regulatory regions, we did not investigate these polymorphisms.

As physical locations of these polymorphisms are so close to the p53 binding sequence as described above, it will be quite interesting to investigate their associations with cancer risk. Because polymorphic alleles at loci as close together as these are likely to be transmitted together, it will also be of interest to define haplotypes for the p53R2 gene.

In summary, we have reported newly identified polymorphisms in the p53R2 gene, and shown allele frequencies of the new variants in a case-control study population consisting of 163 patients with colorectal adenoma and 210 control subjects. Since p53R2 is important in response to DNA damage, and thus may also be in colon cancer prevention, genetic polymorphisms that may alter the expression of this gene are of interest. Further studies of the functional impact of these polymorphisms are needed. It would also be of great interest to investigate their possible association with colorectal cancer risk.

Abstract

AIM: To study *Helicobacter pylori* (*H pylori*) infection in relation to *E-cadherin* (*E-cad*) promoter polymorphism and hypermethylation in GCs.

METHODS: Specimens were taken from representative cancerous lesions and adjacent non-cancerous epithelia of 67 resected GCs. *H pylori* was detected by real-time PCR of the *cagA* gene from non-neoplastic epithelium. *E-cad* promoter polymorphism and hypermethylation were determined by restriction fragment length polymorphism analysis and methylation-specific PCR, respectively. Expression of *E-cad* protein was determined by immunohistochemistry.

RESULTS: *H pylori* was found in 57% of patients with GC. *H pylori* infection was more frequently found in tumors with the -160C/C genotype than those with the -160C/A and -160A/A genotypes (74% *vs* 47%, $P = 0.02$). *H pylori* infection was associated with *E-cad* methylation in non-neoplastic epithelium; however, no significant difference in *H pylori* was observed between methylated and unmethylated cancerous lesions.

CONCLUSION: Patients with the -160C/C genotype might require *H pylori* infection to promote the inactivation of *CDH1*, suggesting that *H pylori* infection might affect GC in an initial stage because polymorphism is germ line. Mechanism of hypermethylation of *CDH1* promoter in GC is complex, and *H pylori* infection might affect it in an initial stage.

INTRODUCTION

E-cadherin (E-cad, also known as CDH1) is a member of a family of transmembrane glycoproteins expressed on epithelial cells and is responsible for calcium-dependent cell-to-cell adhesion[1]. E-cad forms complexes and connects actin filaments with α-, β-, and γ-catenins[2,3], which is crucially involved in neoplastic transformation and metastasis[4,5]. Loss of cell adhesion may contribute to loss of contact inhibition of growth, which is an early step in the neoplastic process. Furthermore, loss of cadherin activity may result in cancer cell detachment and metastasis[6,7].

Gastric carcinogenesis is a multistep process with morphological progression involving multiple genetic and epigenetic events, whereas *CDH1* is an important putative tumor suppressor gene. In gastric carcinoma (GC), the percentage reduction in E-cad expression varies from 17% to 92%, and is more frequent in diffuse type carcinomas than in intestinal types[8-13]. Germ-line mutation of the *CDH1* gene is found in familial GCs[14,15]. Somatic mutations of *E-cad* are found in more than 50% of gastric carcinomas of the diffuse type[16-18]. In addition to the classic two-hit inactivation mechanism, *CDH1* can be silenced by cytosine-guanosine (CpG) sequence methylation in GC[17,18]. Moreover, Li *et al*., reported that -160C/A polymorphism has a direct effect on the transcriptional regulation of CDH1[19].

Helicobacter pylori (*H pylori*) is the single most important

etiological factor for gastric cancer development. The strongest evidence comes from three independent, nested case-control studies in which pre-existing infection markedly increased the risk of GC[20-22]. It is estimated that approximately 60% of all GC cases can be attributed to *H pylori* infection[20]. However, there are few data in the molecular profiles of E-cad of *H pylori*-positive and *H pylori*-negative GCs[23].

El-Omar *et al*.[24], reported that interleukin-1 polymorphisms that cause the up-regulation of interleukin-1β with *H pylori* infection are associated with an increased risk of GC. Moreover, Hmadcha *et al*.[25], found that interleukin-1β might induce gene methylation through the production of nitric oxide and the subsequent activation of DNA methyltransferase. It is possible that *H pylori* infection induces methylation through the production of interleukin-1β. In this study, we investigated the relationship between *H pylori* infection and *CDH1* methylation. Since -160C/A polymorphism is germ line, we also investigated the relationship between *H pylori* infection and polymorphism, to find if *H pylori* infection affects tumorigenesis in the initial stage.

MATERIALS AND METHODS

Patients and samples

The specimens were surgically obtained from 67 patients with GC between 2000 and 2002, at the Division of General Surgery, Department of Surgery, Tri-Service General Hospital, Taipei, Taiwan. None of the subjects received preoperative anti-cancer therapy. Clinical information was obtained from medical records. Samples were taken from representative cancerous lesions and the corresponding non-cancerous epithelia. All tumor DNA samples were obtained by microdissection from 5-μm-thick hematoxylin and eosin-stained paraffin-embedded tissue sections[26]. Non-cancerous DNA was extracted from tissues which were flash-frozen in liquid nitrogen and stored in -80 ℃. All 67 samples were classified according to the Lauren criteria[27]: 26 as intestinal, 41 as diffuse types. The tumors were staged at the time of surgery using the standard criteria for TNM staging, with the unified international gastric cancer staging classification[28].

H pylori detection with real-time PCR

Real time PCR amplification of the *cagA* gene was conducted by adding 62.5 ng of DNA from stomach normal tissues isolates to 20 μL reactions containing 10 μL of 2X QuantiTect SYBR Green PCR Master Mix (QIAGEN, Hilden, Germany), 0.5 μmol/L S1227 Sense Primer (nt 154-175: 5'-GATAACAGGCAAGCTTTTGAGG-3'), 0.5 μmol/L AS1576 Antisense Primer (nt 503-583:5'-CTGCAAA-AGATTGTTTGGCAG-3') and 0.4 U of Uracil-N-glycosylase (New England Biolabs, Boston, USA).

Real-time PCR amplification was carried out in a LightCycler™ (Roche, Basel, Switzerland). After a preincubation step at 50 ℃ for 2 min, 95 ℃ for 15 min in order to activate the Uracil-N-glycosylase and HotStar Taq DNA polymerase, amplification was performed during 65 cycles including denaturation (94 ℃, 15 s with a temperature transition rate of 20 ℃/s), annealing (60 ℃, 25 s, with a temperature transition rate of 20 ℃/s) and extension (72 ℃, 18 s with a temperature transition rate of 20 ℃/s). A single fluorescent signal was obtained once per cycle at the end of the extension step with detection channel F1. After amplification, melting curve analysis was performed on the products by heating to 95 ℃ for 0 s, cooling to 65 ℃ for 15 s, followed by a temperature increase to 95 ℃ with a temperature transition rate of 0.2 ℃/s while continuously collecting the fluorescent signal.

To analyze the data of the real-time PCR assay, the derivative melting curves were obtained with the LightCycler data analysis software, version 3.5 (Roche). The melting temperature (*T*m) of the melting curve in each sample was used to detect the *H pyloric cagA* gene.

Restriction-fragment length polymorphism analysis to identify nucleotide changes at -160 of the CDH1 promoter

The -160 polymorphic site contained either a C or a A residue. The tumor type was determined by *Bst*EII digestion of the PCR products amplified using the primer set 5'-TGATCCCAGGTCTTAGTGAG-3' (upstream) and 5'-AGTCTGAACTGACTT CCGCA-3' (downstream). The 318-bp PCR product was cut into two fragments (208 and 110 bp) it contained the A residue. To ensure that the observed polymorphism was specific and not an experimental artifact, the results were confirmed by direct DNA sequencing.

Methylation-specific PCR and bisulfite-modified genomic sequencing to detect promoter hypermethylation of CDH1

The bisulfite modification procedure was carried out by the Zymo's EZ DNA Methylation Kit (Zymo Research, USA). One microliter of bisulfite-modified DNA was amplified in a total volume of 25 μL containing 1×PCR Buffer II, 2 mmol/L $MgCl_2$, 0.25 mmol/L deoxynucleotide triphosphate (dNTPs), 0.2 μmol/L each primer, and 0.04 U of Ampli Taq Gold™ DNA polymerase (Applied Biosystems, USA) at 95 ℃ for 30 s, the specific annealing temperature for 30 s, and 72 ℃ for 45 s. Water was used as a negative control. Seven millimole per liter/L of PCR product was directly loaded onto 3% agarose gel stained with ethidium bromide and directly visualized under UV illumination. Samples were scored as methylation, when there was a clearly visible band on the gel with the methylation primers[29].

Immunohistochemical staining and evaluation of E-cad expression

In immunohistochemical studies, sections (5 μm thick) from fixed, paraffin-embedded tumors were reacted with monoclonal anti-E-cad antibody (Cappel, Aurora, OH, USA), then with secondary antibody, and the signal was detected using an avidin-biotin complex and diaminobenzidine (DAB) kit (Vector Laboratories, Burlingame, CA, USA). DAB produced a yellowish brown stain, if the sample was positive. If more than 90% of the tumor cells exhibited intense membranous staining similar to that of normal cells, the result was considered positive (++). If the staining intensity was demonstrably reduced in comparison with that of normal cells and/or the staining pattern was heterogeneous (10-90% positive), the result was deemed to be weakly

positive (+). If E-cad expression was completely lost or positive in less than 10% of cells, the result was defined as negative (-).

Statistical analysis

Analyses were performed using S-Plus®2000 for Windows Statistical Software (CANdiensten, Amsterdam, The Netherlands). The level of significance was set at $P<0.05$ for all tests. Continuous variables are expressed as mean±SD, and were tested using Student's *t* test; categorical variables were tested using Fisher's exact test.

RESULTS

Of these 67 patients, 45 were men, and 22 were women. Their median age was 68.56 years (range, 31-88 years). All patients underwent surgical resection of the primary tumor. Twenty-six and 41 tumors were of the intestinal and diffuse histotypes, respectively. Reduced E-cad expression was observed in 88% (36/41) of diffuse type tumors and in 50% (13/26) of intestinal type tumors ($P = 0.0015$). Representative examples of immunohistochemical staining for E-cad expression in non-cancerous epithelium (++) and diffuse type tumor (-) are shown in Figures 1A and B.

H pylori infection was detected by real-time PCR (iCycler iQ Real-Time Quantitative System) for *H pylori cagA* gene in non-cancerous gastric epithelial samples adjacent to tumors. *H pylori* was found in 57% of GC patients. No significant difference in *H pylori* infection was observed between intestinal and diffuse type tumors (23/41, 56% *vs* 15/26 58%). There was no significant difference in reduced E-cad expression between *H pylori*-positive tumors and *H pylori*-negative tumors (27/38, 71.1% *vs* 22/29, 76%).

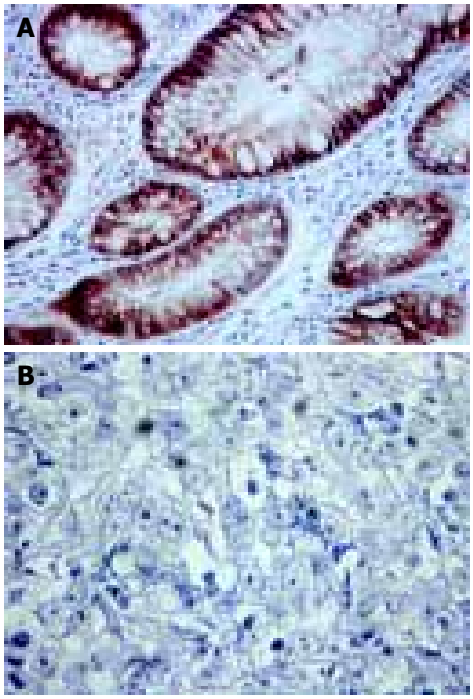

Figure 1 Immunohistochemical staining. **A**: Positive (++) immunohistochemical staining for E-cad expression in non-cancerous epithelium; **B**: Negative (-) immunohistochemical staining for E-cad expression in cancerous lesion in diffuse type tumor.

H pylori and -160C/A polymorphism

Among the 67 patients, 27 were genotype C/C (40%), 26 were genotype A/C (39%), and 14 were genotype A/A (21%) (Figure 2). There was no significant difference in the frequency of the C/A+A/A genotypes between tissues with normal and reduced E-cad expression (13/18, 72% *vs* 27/49, 55%). Interestingly, analyzing 67 available cases of *H pylori* infection and polymorphism status, *H pylori* infection was more frequently observed in tumors with C/C genotype of *CDH1* promoter than in C/A+A/A genotype tumors (20/27, 74% *vs* 18/40, 45%; $P = 0.02$, Table 1).

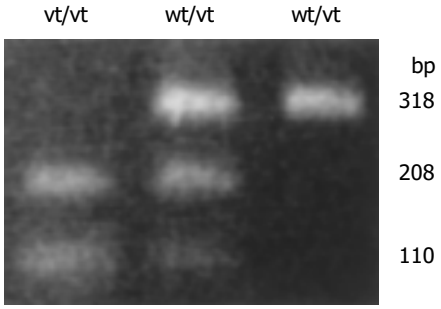

Figure 2 RFLP analysis of genetic polymorphism of the 160 site of the *E-cad* promoter. The C/A polymorphism was differentiated by *Bst*EII digestion of PCR products homozygous for the wild-type (high-activity) allele (wt/wt, CC genotype), heterozygous for the variant (low-activity) allele (wt/vt, CA genotype), and homozygous for the low-activity allele (vt/vt, AA genotype).

H pylori infection and hypermethylation in non-cancerous gastric epithelia

Promoter hypermethylation was found in 87% non-cancerous gastric epithelia of 67 GC patients (Figure 3A). Hypermethylation was frequently associated with *H pylori* positive than *H pylori* negative (36/38, 95% *vs* 22/29, 76%, $P = 0.025$, Table 1).

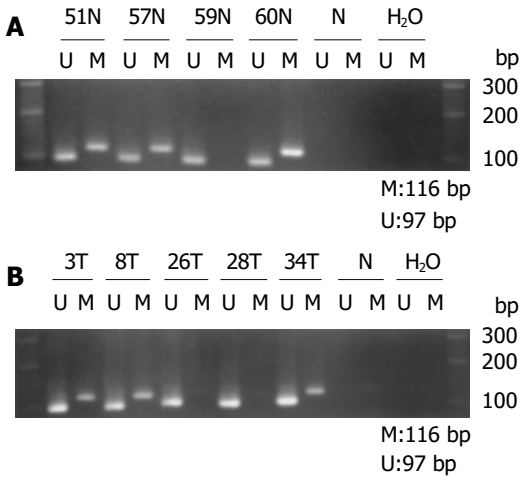

Figure 3 Gel electrophoresis picture demonstrating aberrant methylation in E-cad. Primer sets used for simple amplification are designed as unmethylated (U), methylated (M), unmodified DNA (N). Water is used as a negative control (H_2O). Molecular weight marker is 100-bp DNA ladder. **A**: Methylation in non-cancerous epithelium. Samples 51, 57, and 60 N are methylated. Sample 59 N is unmethylated; **B**: Methylation in cancerous lesion. Samples 3, 8, and 34 T are methylated. Samples 26 and 28 T are unmethylated.

H pylori infection and hypermethylation in cancerous lesions

Results from MSP indicated that the *CDH1* promoter was hypermethylated in 45 (67%) of 67 GCs (Figure 3B). Hypermethylation was more frequent in diffuse type tumors (76%, 31/41) than in intestinal type tumors (50%, 13/26; $P = 0.03$). Furthermore, hypermethylation was more frequent in GCs with reduced E-cad expression than normal expression (37/45, 82% *vs* 12/22, 55%, $P = 0.02$). No significant difference in *H pylori* infection was observed between methylated and unmethylated tumors (26/45, 58% *vs* 12/22, 55%, Table 1).

NS: not significant.

DISCUSSION

H pylori is responsible for the pathogenesis of atrophic gastritis and intestinal metaplasia[30,31]. Epidemiological studies have indicated that infection with *H pylori* is a risk factor for GC[20-22]. Moreover, Mongolian gerbils develop chronic gastritis, intestinal metaplasia, and adenocarcinoma after inoculation with *H pylori* into the stomach. However, the link between *H pylori* infection and the molecular mechanism of human gastric carcinoma remains to be investigated. Lim *et al*., reported that the increased expression of cell adhesion molecules (galectin 1, aldolase A, integrin α5, LMO7) and the decrease in E-cad expression induced by *H pylori* might contribute to cell adhesion, invasion, and possibly cell proliferation in gastric epithelial cells[32]. Kitadai *et al*., reported that coculture with *H pylori* increased the expression of interleukin-8, vascular endothelial growth factor (VEGF), angiogenin, uPA, and MMP-9 and increased angiogenic and collagenase activities in gastric carcinoma cells[33]. Sharma *et al*., reported that the activation of interleukin-8 gene expression by *H pylori* is regulated by the transcription factor, nuclear factor-kappa B, in gastric epithelial cells[34]. Akhtar *et al*., reported that promoter methylation regulates *H pylori*-stimulated cyclooxygenase-2 expression in gastric epithelial cells[35]. However, *in vivo* data on the differences in the molecular profile (ras, *MDM2*, c-erbB-2, cyclin D1, p53, *CDH1*) of *H pylori*-positive and *H pylori*-negative gastric carcinomas are almost non-existent[23].

In this study, *H pylori* was found in 57% of patients with GC. No significant difference in *H pylori* infection was observed between intestinal and diffuse type tumors (56% *vs* 58%). This is consistent with the current view that 60% of all GC cases are related to *H pylori* infection, irrespective of the histological tumor type[20,23].

H pylori and promoter polymorphism

Li *et al*., reported that the A allele of the -160C/A promoter polymorphism altered transcriptional binding, resulting in a reduction in transcriptional efficiency of 68% relative to that of the C allele[19]. In this study, *H pylori* was significantly more frequent in the C/C genotype of *CDH1* promoter than in the C/A+A/A genotypes. The C allele shows better transcriptional activity than the A allele, so patients with the C/C type may require *H pylori* infection to promote the inactivation of *CDH1*. Since -160C/A polymorphism is germ line, *H pylori* infection might affect *CDH1* inactivation in an early, possibly preneoplastic stage.

H pylori and promoter hypermethylation

In this study, hypermethylation of the *CDH1* promoter was present in 67% GCs, and was more frequent in diffuse type tumors (76%) than in intestinal type tumors (50%, $P = 0.03$). *CDH1* promoter hypermethylation was associated with decreased immunohistochemical expression of E-cad (82% *vs* 55%, $P = 0.02$). These data are similar to the results reported by Tamura *et al*., and Graziano *et al*.[37], which indicated that *CDH1* promoter methylation may play a major role, together with mutations or deletions, in causing inactivation of the *CDH1* gene in GC, especially in diffuse type tumors.

Chan *et al*.[18], investigated *CDH1* hypermethylation in the gastric mucosa of 35 patients with dyspepsia and found that hypermethylation was age-related and associated with *H pylori* infection. In our study, hypermethylation was found in 87% non-cancerous gastric epithelia of 67 GC patients and frequently associated with *H pylori* positive than *H pylori* negative epithelia. Therefore, our results of promoter hypermethylation of *E-cad* in non-cancerous gastric epithelia are compatible with hypothesis proposed by El-Omar *et al*.[24], and Hmadcha *et al*.[25]. However, we observed no association between *H pylori* infection and *CDH1* methylation in the gastric cancerous epithelia. It seems that *H pylori* is unrelated to *CDH1* methylation in GC. However, on the basis of current knowledge, *H pylori* should be considered as a factor facilitating the multifactorially determined process of gastric carcinogenesis, but by itself does not initiate or trigger the carcinogenic process (the "hypothesis of no return")[23,38]. Moreover, few *H pylori* are detected in cancerous epithelia in the human stomach. Under *in vivo* conditions, *H pylori* infects the non-cancerous epithelia surrounding the tumor and up-regulates methylation, and may indirectly stimulate hypermethylation in GCs at the tumor-normal tissue interface[33]. In addition, DNA methylation is catalyzed by DNA methyltransferase, and DNA CpG islands can be demethylated by MBD2[39]. *H pylori* infection might induce activation of DNA methyltransferase. However, Oue *et al*., reported that the mechanism of

CpG island hypermethylation is complex in the GC microenvironment and may not result from a simple transcriptional up-regulation of methyltransferase or down-regulation of *MBD2*[40]. Thus from the results of this study and the above statement, we conclude that the mechanism of hypermethylation of *CDH1* in GC is complex, and *H pylori* might affect hypermethylation in an initial stage.

In conclusion, patients with the -160C/C genotype might require *H pylori* infection to promote the inactivation of *CDH1*. *H pylori* infection might affect *E-cad* promoter hypermethylation of GC in an initial stage. Therefore, *H pylori* infection should be considered as a factor that facilitates a multifactorially determined process of gastric carcinogenesis in an initial stage.

Abstract

AIM: To evaluate the gastro-protective effect of capsaicin against the ethanol- and indomethacin (IND)-induced gastric mucosal damage in healthy human subjects.

METHODS: The effects of small doses (1-8 μg/mL, 100 mL) of capsaicin on the gastric acid secretion basal acid output (BAO) and its electrolyte concentration, gastric transmucosal potential difference (GTPD), ethanol- (5 mL 300 mL/L i.g.) and IND- (3×25 mg/d) induced gastric mucosal damage were tested in a randomized, prospective study of 84 healthy human subjects. The possible role of desensitization of capsaicin-sensitive afferents was tested by repeated exposures and during a prolonged treatment.

RESULTS: Intragastric application of capsaicin decreased the BAO and enhanced "non-parietal" component (GTPD) in a dose-dependent manner. The decrease of GTPD evoked by ethanol was inhibited by the capsaicin application, which was reproducible. Gastric microbleeding induced by IND was inhibited by co-administration with capsaicin, but was not influenced by two weeks pretreatment with a daily capsaicin dose of 3×400 μg i.g.

CONCLUSION: Capsaicin in low concentration range protects against gastric injuries induced by ethanol or IND, which is attributed to stimulation of the sensory nerve endings.

INTRODUCTION

Spicy or hot foods are traditionally considered as dietary factors implicated in the causation of peptic ulcer[1,2]. Early and more recent studies[3-6] in human beings with pungent chilli powders and extracts have come to controversial conclusions about their injurious influence on gastric mucosa. Capsaicin is a hot topic in studies on gastro-protection[7-16]. In contrast, the effect of this pure ingredient of red peppers in defined concentrations on the human gastric mucosa seems not to be interesting for research. Capsaicin activates the TRPV1/VR1 capsaicin (vanilloid) receptor expressed by a subgroup of primary afferent nociceptive neurons. The TRPV1/VR1 receptor has been cloned[21] and turns out to be a cation channel. It is gated besides capsaicin and some vanilloids by low pH, noxious heat and various pain-producing endogenous and exogenous chemicals. Thus, these sensory nerve endings equipped with these ion channels are prone to be stimulated in gastric mucosa. The aim of the present study was to analyze the effect of capsaicin on mucosal injury induced by ethanol or the non-selective cyclooxygenase inhibitor, indomethacin (IND). Particular attention was paid to define whether the action of capsaicin was related to its acute stimulatory effect or to the sensory desensitization, a well known long lasting consequence of sensory stimulation in animal experiments[22,23].

MATERIALS AND METHODS

The observations were carried out in 84 healthy human subjects aged 25-65 years (40±10 years). The physical, laboratory, and iconographic examinations were normal and indicated normal.

The healthy persons were randomized into different groups to study the effect of intragastric application of capsaicin on their gastric mucosa and gastric acid secretion under different conditions.

The observations were carried out according to the good clinical practice. The studies were carried out from 1997 to 2002, which were permitted by the Regional Ethical Committee of Pécs, University of Pécs, Hungary. Written informed consent was obtained from all participants.

Identification of gastric basal acid output (BAO) without and with capsaicin

After an overnight fasting, a nasogastric tube was introduced at 8:00 a.m., and the total gastric content was completely suctioned.

Then the secreted gastric juice was suctioned every 15 min for 1 h (basal acid output, BAO). The healthy human subjects received intragastric capsaicin at the doses of 100, 200, 400, and 800 μg in 100 mL volume of saline solution. In

the control group, 100 mL of saline solution was given through the nasogastric tube and the same doses of capsaicin. Gastric acid secretion was measured by titration of gastric juice with 0.1 N NaOH to pH 7 (pH titrimeter, Radelkis, Budapest, Hungary). Gastric acid outputs were calculated and expressed in mEq/h after capsaicin administration. The values effective inhibitory dose of capsaicin (ED_{50}) was identified on the gastric BAO.

Chemical composition of gastric juice without and with capsaicin

The concentrations of Na^+, K^+, and Ca^{2+} in gastric juice were measured flamephotometrically. The concentration of Mg^{2+} was measured by atom absorption spectrometry, the chloride concentration by colorimetric method, the protein concentration by the method of biuret reaction.

The chloride linked to H^+ and sodium was calculated for the determination of "parietal" (chloride linked to H^+) and of "non-parietal" (liked to sodium) components of the gastric BAO[30].

Measurement of gastric transmucosal potential difference (GTPD)

GTPD was measured during endoscopy. The exploring mucosal electrode was passed through the biopsy force channel of gastroscope and the reference electrode was placed on the volar surface of the left forearm. The electrodes were connected to a digital voltmeter (Radelkis, Budapest, Hungary, OP 211/1). GTPD measurements were done at the greater curvature of the gastric body and the results were expressed in -mV (without and with intragastric application of different doses of capsaicin)[24-27]. Capsaicin in 5 mL saline solution was intragastrically applied and only saline solution was given to identify the baseline in GTPD.

The GTPD values were expressed in -mV, while -△PD max was calculated after intragastric application of capsaicin (n = 10).

Effect of capsaicin on ethanol-induced GTPD changes

The GTPD baseline was identified, and ethanol (5 mL 300 mL/L i.g.) was given intragastrically. The GTPD change was determined after the ethanol passed through the biopsy force channel of gastroscope without and with capsaicin (given in different doses in the same pathway after 1 min of ethanol administration) (n = 10).

Gastric microbleeding measurement during 1-d treatment with indomethacin (IND) and indomethacin plus capsaicin (n = 14)

Fourteen healthy human subjects were studied. They were randomly divided into different treatment groups.

Examinations were carried out before and after treatment after an overnight fasting. A plastic tube was inserted through his or her mouth until the intragastric end was 55 cm from the incisors. There were six openings in the intragastric part of the tube.

A test solution containing 100 mL of saline solution and 10 mL solution of concentrated phenol red (40 mg/100 mL), as a non-absorbable marker, was installed into the stomach without and with capsaicin (at doses of 200, 400, and 800 μg). The gastric content was recovered 10 min later[28-30]. The whole procedure was repeated thrice before and after the administration of IND (without and with application of capsaicin).

Gastric juice was aspirated. The strength of suction was adjusted to -50 mmHg.

The volume of each recovery sample was measured after homogenization for 10 min. Hemoglobin was determined as previously described[36,37]. The quantity of blood in the aspirated gastric samples was measured. Blue color developed (640 nm, pH 3.78, room temperature) and could be determined. Phenol red was measured spectrophotometrically[29,30]. The values of gastric microbleeding were expressed as milliliter per day.

Chronic capsaicin (3×400 μg i.g./d) treatment for 2 wk

Ten healthy human subjects were treated with capsaicin (3×400 μg orally) for 2 wk. Capsaicin substance (400 μg) was put into a gelatin capsule containing 0.23 g lactose.

The extent of IND-induced gastric mucosal bleeding and gastric mucosal preventive effect of capsaicin (200, 400 μg) were tested before and after capsaicin treatment. Prospective randomized studies were done for three consecutive days before and after capsaicin treatment.

Chemicals

Capsaicin was from Sigma, Budapest, Hungary. IND was from Sanofi-Synthelabo, Budapest, Hungary. Capsaicin solution was made by dilution with distilled water.

Statistical analysis

The results were calculated as mean±SE. The unpaired or paired Student's t-tests were used for the calculation of the results between the identical observations. $P<0.05$ was considered statistically significant.

RESULTS

The BAO decreased significantly and dose-dependently (Figure 1). The ED_{50} value of capsaicin was 400 μg.

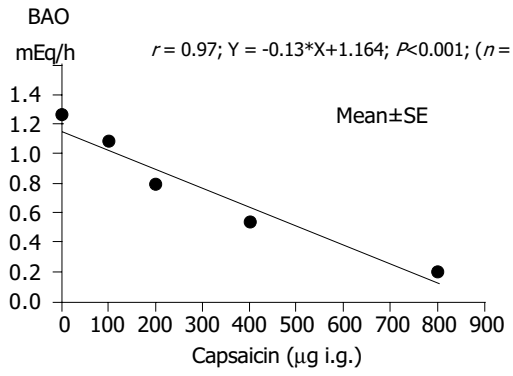

Figure 1 Inhibition of gastric acid output (BAO) by capsaicin in 16 healthy human subjects.

Electrolyte and albumin concentrations in gastric juice were measured in the healthy human subjects without and with capsaicin treatment. H^+, K^+, Ca^{2+}, and Mg^{2+} significantly

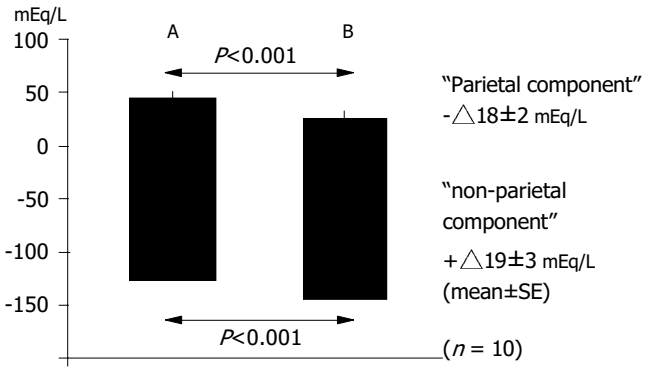

Figure 2 "Parietal" and "non-parietal" components before (A) and after (B) intragastric application of capsaicin in 10 healthy human subjects.

decreased (P<0.001), while Na^+ and its protein content increased (P<0.001) after capsaicin treatment (Table 1).

The "parietal" and "non-parietal" components of BAO were calculated by taking the H^+ output equivalent to Na^+ and Cl^- as gastric H^+, Na^+, and chloride in gastric juice without and with capsaicin treatment. The parietal component decreased (-△18 mmol/L) while the non-parietal component increased (+△19 mmol/L) in the BAO after capsaicin application (Figure 2).

Capsaicin increased the GTPD in a dose-dependent manner. The peak values reached within 3-5 min after capsaicin application (Figure 3A).

After intragastric application of ethanol (300 mL/L), the GTPD dropped from -33.4±2.7 to -10.5±2.4 mV (P<0.001) within 3 min (Figure 3C).

Capsaicin application (at doses of 400 and 800 μg) significantly prevented the ethanol-induced decrease in GTPD (Figure 3C).

The protective effect of capsaicin was reproducible before (Figure 3B) and after (Figure 3D) ethanol administration.

The gastric microbleeding was measured before and after IND (3×25 mg orally) application alone and in combination with 200, 400, and 800 μg capsaicin in 14 healthy human volunteers. The gastric microbleeding induced by IND increased (8; 25±0.5 mL/d from the basic level of 2.1±0.1; P<0.001) which was dose-dependently prevented by capsaicin at the dose of 200-800 μg (Y = 0.0071X+7.78; r = -0.98; P<0.001, Figure 4A).

In order to decide the potential role of desensitizing in the gastric protective effect of capsaicin, a daily dose of 3×400 μg capsaicin was applied for 2 wk in 14 healthy human subjects. Capsaicin protected gastric mucosal against IND-induced gastric microbleeding. There was no difference between the pretreated group and the central group (Figure 4B).

DISCUSSION

The present study provides evidence for the powerful gastroprotective potency of capsaicin. The threshold concentration of capsaicin in producing definite hot sensation is around 1-2 μg/mL and the capsaicinoid level in chilli sauce varies from 25 μg/mL to 0.5 mg/mL[22,24]. Therefore, the observed defensive responses using capsaicin have a clear dietary relevance.

Chronic peptic ulcer patients are warned to avoid spicy foods, although in the era of H_2-inhibitors this praxis is far less restrictive[2]. Nevertheless contradictory observations cannot decide whether spicy foods are harmful to or beneficial for gastric injury. In healthy subjects mucosal microbleeding with exfoliation and aggravation of aspirin-induced gastric bleeding are observed in response to chilli powder or red pepper "preparations"[3,4]. On the other hand, ingestion of "highly spiced" meals or chilli by normal individuals does not cause endoscopically gastric or duodenal mucosal damage[25] although gastric acid and pepsin secretion increases[31-33]. In other studies, red pepper sauce induces prolongation of gastric emptying[7] and chilli powder evokes protective effect against aspirin-induced gastric mucosal injury[6]. Improvement in dyspeptic symptoms of patients with and without gastro-esophageal reflux disease and irritable bowel syndrome after intake of red pepper powder in gelatin capsules has been reported[8,9]. In the latter case, the improvement of functional dyspepsia is attributed to desensitization of gastric nociceptive C-fibers induced by capsaicin although this conclusion is not supported by experimental evidence. In our earlier and present studies, pure capsaicin solution was injected into the stomach (1-8 μg/mL in 100 mL) of healthy subjects which inhibits the H^+ output and total secreted volume of gastric juice for about 1 h in a dose-dependent manner and increases its "non-parietal" component, gastric emptying[23].

The important role of capsaicin-sensitive peptidergic sensory fibers in maintaining of gastric mucosal integrity against injurious interventions has been well established in rats[10-13,15]. Capsaicin-sensitive primary afferent neurons and their nerve endings express the TRPV1/VR1 vanilloid receptor[14,21,23]. Stimulation of these chemoreceptive nerve terminals by H^+ or bradykinin, etc. is accompanied with release of CGRP, tachykinins, somatostatin, and NO from them. The arterial wall in stomach receives dense supply of these peptidergic fibers and capsaicin elicits neurogenic vasodilatation with enhanced mucosal blood flow. Clear evidence indicates that hyperemia is induced by sensory neuropeptides of CGRP neurokinin A with NO as well as somatostatin are involved in the sensory neuron-mediated gastroprotection[17-20].

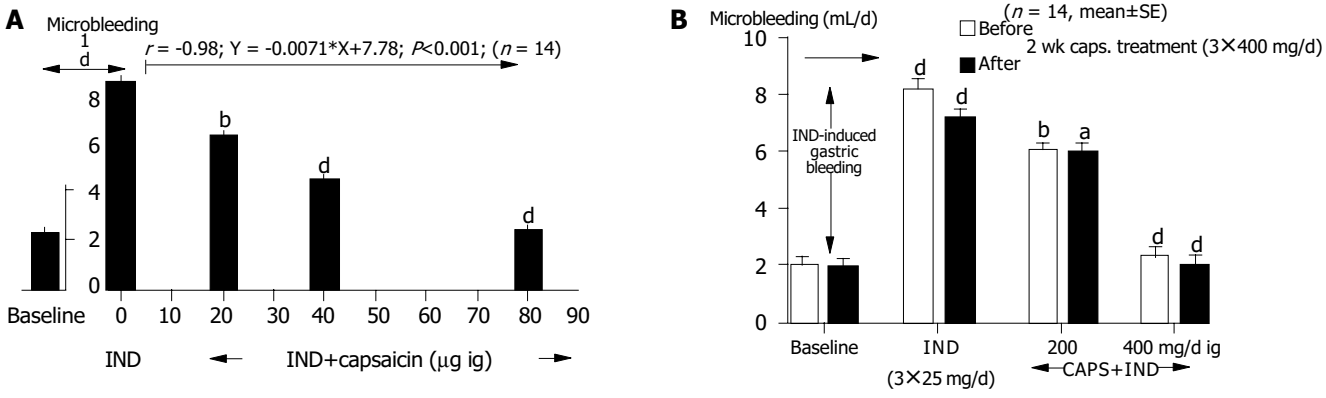

Figure 4 Gastric mucosal protection produced by capsaicin on IND-induced gastric mucosal damage before (**A**) and after (**B**) capsaicin treatment. [a]*P*<0.05, [b]*P*<0.01, [d]*P*<0.01 *vs* others.

Opposite effect has been observed in rats desensitized by capsaicin. Functional blockade of gastric sensory nerve endings elicited by systemic or intragastric capsaicin application results in impaired mucosal protection against various ulcer-provoking agents[10-14]. Repeated topical or systemic capsaicin application elicits reproducible effects at low concentrations and induces decreasing responses (desensitization) at high concentrations. In the rat's eye, 10 μg/mL concentration of capsaicin does not induce any desensitization[22]. On the human oral mucosa, this concentration of capsaicin induces some diminished sensation of irritation but only for a short time[28].

In the present study, the following evidence suggests that capsaicin-induced gastric mucosal protection against the injurious effects of ethanol or IND is due to the acute stimulatory effect of the compound. Microbleeding detected after IND administration does not differ from that in the controls. Enhanced GTPD evoked by the first and second capsaicin exposure in 1 h shows no sign of decrement. Counteraction of the ethanol-induced drop of gastric transmucosal potential is identical after the first and second capsaicin application.

The enhancement of gastric transmucosal potential is probably related to the mucosal hyperemia[32,34]. This response plays a significant role in capsaicin-induced gastroprotection. Furthermore, the present and earlier[27] findings reveal that intragastric administration of capsaicin in low concentration inhibits but does not increase[4,5,26] the acid output of stomach

and enhances the gastric emptying rate in healthy human subjects[29]. All these responses can be attributed to CGRP and NO released from the activated capsaicin-sensitive, TRPV1/VR1 expressing sensory nerve terminals. The present findings suggest that patients taking anti-inflammatory-analgesic agents regularly can decrease the incidence and severity of gastric ulceration, if they have moderate spicy foods[35-37].

Abstract

AIM: To investigate the intestinal anti-inflammatory effect and mechanism of a probiotic *Lactobacillus salivarius ssp. salivarius* CECT5713 in the TNBS model of rat colitis.

METHODS: Female Wistar rats (180-200 g) were used in this study. A group of rats were administered orally the probiotic *L. salivarius ssp. salivarius* (5×10^8 CFU suspended in 0.5 mL of skimmed milk) daily for 3 wk. Two additional groups were used for reference, a non-colitic and a control colitic without probiotic treatment, which received orally the vehicle used to administer the probiotic. Two weeks after starting the experiment, the rats were rendered colitic by intracolonic administration of 10 mg of TNBS dissolved in 0.25 mL of 500 mL/L ethanol. One week after colitis induction, all animals were killed and colonic damage was evaluated both histologically and biochemically. The biochemical studies performed in colonic homogenates include determination of myeloperoxidase (MPO) activity, glutathione (GSH) content, leukotriene B_4 (LTB_4) and tumor necrosis factor α (TNF-α) levels, as well as inducible nitric oxide synthase (iNOS) expression. In addition, the luminal contents obtained from colonic samples were used for microbiological studies, in order to determine Lactobacilli and Bifidobacteria counts.

RESULTS: Treatment of colitic rats with *L. salivarius ssp. salivarius* resulted in amelioration of the inflammatory response in colitic rats, when compared with the corresponding control group without probiotic treatment. This anti-inflammatory effect was evidenced macroscopically by a significant reduction in the extent of colonic necrosis and/or inflammation induced by the administration of TNBS/ethanol (2.3±0.4 cm *vs* 3.4±0.3 cm in control group, $P<0.01$) and histologically by improvement of the colonic architecture associated with a reduction in the neutrophil infiltrate in comparison with non-treated colitic rats. The latter was confirmed biochemically by a significant reduction of colonic MPO activity (105.3±26.0 U/g *vs* 180.6±21.9 U/g, $P<0.05$), a marker of neutrophil infiltration. The beneficial effect was associated with an increase of the colonic GSH content (1 252±42 nmol/g *vs* 1 087±51 nmol/g, $P<0.05$), which is depleted in colitic rats, as a consequence of the oxidative stress induced by the inflammatory process. In addition, the treatment of colitic rats with *L. salivarius* resulted in a significant reduction of colonic TNF-α levels (509.4±68.2 pg/g *vs* 782.9±60.1 pg/g, $P<0.01$) and in a lower colonic iNOS expression, when compared to TNBS control animals without probiotic administration. Finally, treated colitic rats showed higher counts of Lactobacilli species in colonic contents than control colitic rats, whereas no differences were observed in Bifidobacteria counts.

CONCLUSION: Administration of the probiotic *L. salivarius ssp. salivarius* CECT5713 facilitates the recovery of the inflamed tissue in the TNBS model of rat colitis, an effect associated with amelioration of the production of some of the mediators involved in the inflammatory response in the intestine, such as cytokines, including TNF-α and NO. This beneficial effect could be ascribed to its effect on the altered immune response that occurs in this inflammatory condition.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic disease of

the digestive tract, and usually refers to two related conditions, namely ulcerative colitis and Crohn's disease, characterized by chronic and spontaneously relapsing inflammation. Although the etiology of IBD remains unknown, there is increasing experimental evidence to support a role for luminal bacteria in the initiation and progression of these intestinal conditions; probably related to an imbalance in the intestinal microflora, relative predominance of aggressive bacteria and insufficient amount of protective species[1,2]. This could justify the remission achieved in intestinal inflammation, after treatment with antibiotics such as metronidazole or ciprofloxacin[3], or the fact that germ-free animals may fail to develop experimental intestinal inflammation[4]. In consequence, a possible therapeutic approach in IBD therapy is the administration to these patients of probiotic microorganisms, defined as viable nutritional agents conferring benefits to the health of the human host. In fact, it has been reported that administration of a mixture of *Bifidobacterium* and *Lactobacillus*[5] or of non-pathogenic viable *Escherichia coli*[6] prolongs remission in ulcerative colitis. Moreover, there are reports on successful induction and maintenance of remission of chronic pouchitis after oral bacteriotherapy[7,8]. However, treatments of Crohn's disease with probiotic preparations reported conflicting results[9-12].

Different mechanisms have been proposed to participate in the therapeutic effects exerted by probiotic microorganisms. First, probiotic microorganisms may exert their action through a modulation of the intestinal bowel flora, which may result from competitive metabolic interactions with potential pathogens, production of anti-microbial peptides, or inhibition of epithelial adherence and translocation by pathogens[5,13]; second, probiotics have been proposed to modulate the host defenses by influencing the intestinal immune system[14,15]; and third, these microorganisms have been reported to positively affect the intestinal barrier function[16,17]. However, the detailed mechanisms by which these bacteria mediate their effects are not fully understood.

Although the results obtained after probiotic treatment in both human IBD and experimental colitis are promising, new studies are required in order to further understand this new concept for the therapy of IBD, even if we consider the fact that many studies have shown that not all bacterial species have equal activities in reducing intestinal inflammation[18,19]. Hence, the selection of new probiotic strains for the treatment of IBD can be based on their ability to regulate the immune response of the intestinal mucosa. This can be the case of *Lactobacilli* strains, which were able to downregulate the production of tumor necrosis factor α (TNF-α). In fact, previous *ex vivo* experiments have reported the ability of *L. casei* and of *L. bulgaricus* to downregulate TNF-α production in colonic explants from patients with Crohn's disease[20], thus supporting their future development for IBD therapy. This may be of special relevance, since several studies have attributed a key role in the pathogenesis of IBD to this pro-inflammatory cytokine, as evidenced by the increased production of TNF-α in the intestinal mucosa from IBD patients[21,22] as well as by a number of clinical studies using anti-TNF-α mAb therapy that have clearly shown a beneficial effect in these patients[23].

The aim of the present study was to test the preventative effects of a *L. salivarius ssp. salivarius* strain in the trinitrobenzenesulfonic acid (TNBS) model of rat colitis, a well-established model of intestinal inflammation with some resemblance to human IBD[24]. The selection of this lactobacilli strain was based on previous *in vitro* studies that showed its ability to adhere to human intestinal cells, to inhibit pathogenic bacterial growth (unpublished results) and to reduce the production of inflammatory cytokines by immune cells. Special attention was paid to its effects on the production of some of the mediators involved in the inflammatory response, such as TNFα, leukotriene B_4 (LTB_4) and nitric oxide (NO). In addition, the correlation among the intestinal anti-inflammatory effect of *L. salivarius ssp. salivarius* and modifications on colonic flora induced by this probiotic was also studied.

MATERIALS AND METHODS

This study was carried out in accordance with the 'Guide for the Care and Use of Laboratory Animals' as promulgated by the National Institute of Health.

Reagents

All chemicals were obtained from Sigma Chemical (Madrid, Spain), unless otherwise stated. Glutathione (GSH) reductase was provided by Boehringer Mannheim (Barcelona, Spain).

In vitro modulation of cytokine production by bacteria

Puleva Biotech's lactic acid bacteria collection was screened for *Lactobacilli* bacteria with the ability to reduce the production of inflammatory cytokines by activated macrophages. For this purpose, rodent bone marrow-derived macrophages, obtained as previously described[25], were stimulated with 100 ng/mL LPS, in the presence or absence of 10^6 CFU/mL of each bacteria for 2 h. Then, cells were washed with culture media to eliminate non-attached bacteria, and cultured with new media for 12 h. TNF-α, IL-12, and IL-10 production was evaluated by ELISA in cell supernatants (CytoSets™, Biosource International, Nivelles, Belgium) following manufacturer's instructions.

Preparation and administration of the probiotic

L. salivarius ssp. salivarius CECT5713 was provided by Puleva Biotech (Granada, Spain) and it was normally grown in MRS media at 37 ℃ in anaerobic conditions using the AnaeroGen system (Oxoid, Basingstoke, UK). For probiotic treatment, bacteria was suspended in skimmed milk (10^9 CFU/mL) and stored at -80 ℃ until usage.

Experimental design

Female Wistar rats (180-200 g) were obtained from the Laboratory Animal Service of the University of Granada (Granada, Spain) and maintained in standard conditions. The rats were randomly assigned to three groups (n = 10); two of them (non-colitic and control groups) received no probiotic treatment and the other (treated group) received orally the probiotic (5×10^8 CFU suspended in 0.5 mL of skimmed milk) daily for 3 wk. Both non-colitic and control groups received orally the vehicle used to administer the probiotic (0.5 mL daily). Two weeks after starting the

experiment, the rats were fasted overnight and those from the control and treated groups were rendered colitic by the method originally described by Morris *et al*.[26]. Briefly, they were anesthetized with halothane and given 10 mg of TNBS dissolved in 0.25 mL of 500 mL/L ethanol by means of a Teflon cannula inserted 8 cm through the anus. Rats from the non-colitic group were administered intracolonically 0.25 mL of PBS instead of TNBS. All rats were killed with an overdose of halothane, 1 wk after induction of colitis.

Assessment of colonic damage

The body weight, water and food intake were recorded daily throughout the experiment. Once the rats were killed, the colon was removed aseptically and placed on an ice-cold plate, longitudinally opened and luminal contents were collected for the microbiological studies (see below). Afterwards, the colonic segment was cleaned of fat and mesentery, blotted on filter paper; each specimen was weighed and its length measured under a constant load (2 g). The colon was scored for macroscopically visible damage on a 0-10 scale by two observers unaware of the treatment, according to the criteria described by Bell *et al*.[27] (Table 1), which takes into account the extent as well as the severity of colonic damage. Representative whole gut specimens were taken from a region of the inflamed colon corresponding to the adjacent segment to the gross macroscopic damage and were fixed in 4% buffered formaldehyde. Cross-sections were selected and embedded in paraffin. Equivalent colonic segments were also obtained from the non-colitic group. Full-thickness sections of 5 μm were obtained at different levels and stained with hematoxylin and eosin. The histological damage was evaluated by two pathologist observers (AN and AC), who were blinded to the experimental groups, according to the criteria described previously by Stucchi *et al*.[28] (Table 2). The colon was subsequently divided into four segments for biochemical determinations. Two fragments were frozen at -80 ℃ for myeloperoxidase (MPO) activity and inducible nitric oxide synthase (iNOS) expression, and another sample was weighed and frozen in 1 mL of 50 g/L trichloroacetic acid for total GSH content determinations. The remaining sample was immediately processed for the measurement of TNF-α and LTB_4 levels. All biochemical measurements were completed within 1 wk from the time of sample collection and were performed in duplicate.

MPO activity was measured according to the technique described by Krawisz *et al*.[29]; the results were expressed as MPO units per gram of wet tissue; one unit of MPO activity was defined as that degrading 1 μmol hydrogen peroxide/min at 25 ℃. Total GSH content was quantified with the recycling assay described by Anderson[30], and the results were expressed as nanomole per gram of wet tissue. Colonic samples for TNF-α and LTB_4 determinations were immediately weighed, minced on an ice-cold plate and suspended in a tube with 10 mmol/L sodium phosphate buffer (pH 7.4) (1∶5 w/v). The tubes were placed in a shaking water bath (37 ℃) for 20 min and centrifuged at 9 000 r/min for 30 s at 4 ℃; the supernatants were frozen at -80 ℃ until assay. TNF-α was quantified by ELISA (Amersham Pharmacia Biotech, Buckinghamshire, UK) and the results were expressed as picogram per gram of wet tissue. LTB_4 was determined by enzyme immunoassay (Amersham Pharmacia Biotech, Buckinghamshire, UK) and the results expressed as nanogram per gram of wet tissue.

iNOS expression was analyzed by Western blotting as previously described[31]. Control of protein loading and transfer was conducted by detection of the β-actin levels.

Table 1 Criteria for assessment of macroscopic colonic damage

Score	Criteria
0	No damage
1	Hyperemia, no ulcers
2	Linear ulcer with no significant inflammation
3	Linear ulcer with inflammation at one site
4	Two or more sites of ulceration / inflammation
5	Two or more major sites of ulceration and inflammation or one site of ulceration / inflammation, extending >1 cm along the length of the colon
6-10	If damage covers >2 cm along the length of the colon, the score is increased by one, for each additional centimeter of involvement

Table 2 Criteria for assessment of microscopic colonic damage

Mucosal epithelium	
	Ulceration: none (0); mild - surface (1); moderate (2); extensive-full thickness (3)
Crypts	
	Mitotic activity: lower third (0); mild mid-third (1); moderate mid-third (2); upper third (3)
	Mucus depletion: none (0); mild (1); moderate (2); severe (3)
Lamina propria	
	Mononuclear infiltrate: none (0); mild (1); moderate (2); severe (3)
	Granulocyte infiltrate: none (0); mild (1); moderate (2); severe (3)
	Vascularity: none (0); mild (1); moderate (2); severe (3)
Submucosal	
	Mononuclear infiltrate: none (0); mild (1); moderate (2); severe (3)
	Granulocyte infiltrate: none (0); mild (1); moderate (2); severe (3)
	Edema: none (0); mild (1); moderate (2); severe (3)

Maximum score: 27. Modified from Stucchi *et al*.[28].

Microbiological studies

Luminal content samples were weighed, homogenized, and serially diluted in sterile peptone water. Serial 10-fold dilutions of homogenates were plated on specific media for *Lactobacillus* (MRS media, Oxoid) or *Bifidobacterium* (MRS media supplemented with 0.5 mg/L dicloxacillin, 1 g/L LiCl and 0.5 g/L L-cysteine hydrochloride) and incubated under anaerobic conditions in an anaerobic chamber for 24-48 h at 37 ℃. Coliforms and enterobacteria were also determined by using specific Count Plates Petrifilm (3M, St. Paul, MN). After incubation, the final count of colonies was reported as $\log_{10}$ colony forming units per gram of material.

Statistical analysis

All results are expressed as mean±SE. Differences between means were tested for statistical significance using a one-way analysis of variance (ANOVA) and post hoc least significance tests. Non-parametric data (score) are expressed as the median (range) and were analyzed using the Mann-Whitney *U*-test. Differences between proportions were analyzed with the χ^2 test. All statistical analyses were carried

out with the Statgraphics 5.0 software package (STSC, MD), with statistical significance set at $P<0.05$.

RESULTS

More than 30 lactic acid bacterial strains with the ability to adhere to human intestinal cell lines and to inhibit pathogenic bacterial growth *in vitro* belonging to the own Puleva Biotech collection were screened for their ability to modulate the production of inflammatory cytokines in LPS-stimulated macrophages. The results obtained were highly diverse, including bacteria with the ability to enhance or to reduce inflammatory cytokine production (TNF-α and IL-12) modifying or not the expression of the anti-inflammatory cytokine IL-10 (data not shown).

Among all the screened bacteria, *L. salivarius ssp. salivarius* (CECT5713) showed the best TNF-α/IL-10 and IL-12/IL-10 ratio (Figure 1), since it was able not only to reduce the LPS-induced TNF-α and IL-12 production, but also to increase the levels of IL-10. For these reasons, we decided to use this strain to test its ability to prevent the inflammatory response in the *in vivo* assay of experimental colitis.

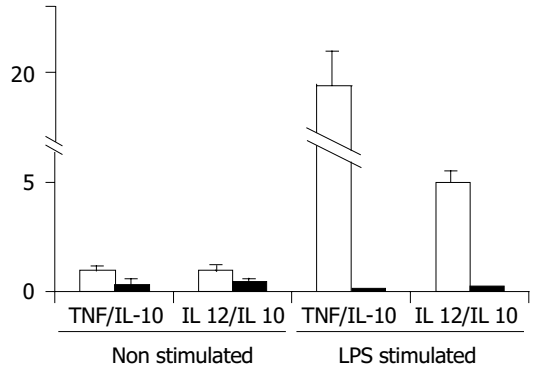

Figure 1 Production of inflammatory cytokines by bone marrow-derived macrophages (BMDM). TNF-α, IL-12, and IL-10 production was analyzed by ELISA in the supernatants of BMDM stimulated or not with LPS (100 ng/mL) and incubated with 10^6 CFU/mL of *L. salivarius ssp. salivarius* (CECT5713) (black bars) or in absence of bacteria (gray bars). The results are the mean of three assays±SE of the ratio between the pro-inflammatory cytokines (TNF-α and IL-12) and IL-10.

L. salivarius ssp. salivarius administration for 2 wk did not induce any symptoms of diarrhea or affected weight evolution. However, once the colitis was induced, the probiotic-treated rats showed an overall lower impact of TNBS-induced colonic damage compared to the TNBS control group. The anti-inflammatory effect was evidenced macroscopically by a significantly lower colonic damage score than that of control rats ($P<0.05$), with a significant reduction in the extent of colonic necrosis and/or inflammation induced by the administration of TNBS/ethanol (Table 3). This anti-inflammatory effect was also associated with a significant reduction in the colonic weight/length ratio between both colitic groups, an index of colonic edema, which increased significantly as a consequence of the inflammatory process (Table 3). The histological studies confirmed the intestinal anti-inflammatory effect exerted by *L. salivarius* (Figure 2). Histological assessment of colonic samples from the TNBS control group revealed severe transmural disruption of the normal architecture of the colon, extensive ulceration and inflammation involving all the intestinal layers of the colon, giving a score value of 18.9±1.1 (mean±SE). Colonic samples were characterized by severe edema, interstitial micro-hemorrhages and diffuse leukocyte infiltration, mainly composed of neutrophils in the mucosa layer and, to a lesser extent, lymphocytes in the submucosa. Most of the rats showed epithelial ulceration of the mucosa affecting over 75% of the surface. The inflammatory process was associated with crypt hyperplasia and dilation, and moderate goblet cell depletion. However, histological analysis of the colonic specimens from rats treated with the probiotic revealed a more pronounced recovery in the intestinal architecture than controls, with a score of 11.2±2.4 (mean±SE) ($P<0.01$ *vs* TNBS control group). Thus, most of the samples (7 of 10) showed almost complete restoration of the epithelial cell layer, in contrast to the extensive ulceration observed in non-treated animals; in fact, the zones with ulceration were surrounded by tissue in process of re-epithelization. Moreover, the transmural involvement of the lesions was reduced. The goblet cell depletion was less severe and thus they appeared replenished with their mucin content, and no dilated crypts were observed. The improvement in colonic histology was accompanied by a reduction in the inflammatory infiltrate, which was

Figure 2 Histological sections of colonic mucosa from colitic rats 1 wk after TNBS instillation stained with hematoxylin and eosin. **A**: Non-colitic group showing the normal histology of the rat colon (original magnification ×20); **B**: TNBS control group showing complete destruction of the mucosa, which has been substituted by inflammatory granulation tissue. There is evident edema and intense diffuse transmural inflammatory infiltrate (original magnification ×100); **C**: *L. salivarius ssp. salivarius* treated group showing amelioration of the inflammatory process and 'restoration' of the mucosal tissue with presence of mucin replenished goblet cells (original magnification ×100).

Table 3 Effects of *L. salivarius ssp. salivarius* (5×10^8 CFU/rat·d) treatment on macroscopic damage score, extent of the inflammatory lesion along the colon and changes in colon weight in TNBS experimental colitis in rats

Group (n = 10)	Damage score (0-10)	Extent of damage (cm)	Colon weight (mg/cm)
Non-colitic	0	0	63.3±2.5
TNBS control	6.5 (5-8)	3.4±0.3	209.7±17.0
TNBS probiotic	5 (3-7)[a]	2.3±0.4[b]	143.3±11.8[b]

Damage score for each rat was assigned according to the criteria described in Table 1 and data are expressed as median (range). Extent of damage and colon weight data are expressed as mean±SE. [a]P<0.05, [b]P<0.01 *vs* TNBS control. All colitic groups differ significantly from non-colitic group.

slight to moderate with a patchy distribution, although neutrophils were the predominant cell type.

The lower leukocyte infiltration was also assessed biochemically by the reduction in colonic MPO activity, a marker of neutrophil infiltration that was enhanced in the TNBS control group (Table 4). In addition, probiotic-treated colitic rats showed a significant increase in colonic GSH content, which is depleted in colitic rats as a consequence of the colonic oxidative stress induced by the inflammatory process, as previously reported in this model of experimental colitis[32] (Table 4). Finally, the colonic inflammation induced by TNBS was characterized by increased levels of colonic TNF-α and LTB_4 (Table 4) as well as by higher colonic iNOS expression (Figure 3) in comparison with non-colitic animals. Treatment of colitic rats with *L. salivarius* resulted in a significant reduction of colonic TNF-α levels (Table 4), that did not show any statistical differences with normal rats. No significant modification was observed on colonic LTB_4 levels. Finally, lower colonic iNOS expression was also seen in colitic animals that received the bacterial suspension, when compared to TNBS control animals (Figure 3).

Effects of L. salivarius administration on colonic bacterial profile

TNBS colitis resulted in a significant reduction in fecal lactobacilli count in comparison with normal rats (P<0.05). Probiotic-treated colitic rats showed higher counts of Lactobacilli species in colonic contents than control colitic rats, without showing statistical differences with both non-colitic and colitic control groups (Figure 4). No statistical differences were observed in Bifidobacteria counts among three groups (P>0.1, Figure 4) nor in the amount of other fecal potential pathogenic bacteria such as enterobacteria or coliform bacteria (data not shown).

DISCUSSION

The results obtained in the present study reveal the efficacy of probiotic therapy with a *L. salivarius ssp. salivarius* strain in intestinal inflammation, incorporating a new microorganism to the probiotics that have been reported to attenuate the development of colonic injury in experimental and human IBD[33]. Thus, oral administration of the probiotic facilitated recovery from TNBS-induced colonic damage, as it was evidenced histologically, with a significant reduction in the extent and severity of inflamed tissue. This beneficial effect was also stated biochemically by a decrease in colonic MPO activity, a marker of neutrophil infiltration that has been previously described to be upregulated in experimental colitis[29], and is widely used to detect and follow intestinal inflammatory processes. In consequence, a reduction in the activity of this enzyme can be interpreted as a manifestation of the anti-inflammatory activity of a given compound[34]. The ability of the probiotic to reduce granulocyte infiltration, showed by MPO activity reduction, was confirmed histologically, since the level of leukocyte infiltrate in the colonic mucosa was lower in treated colitic animals than in

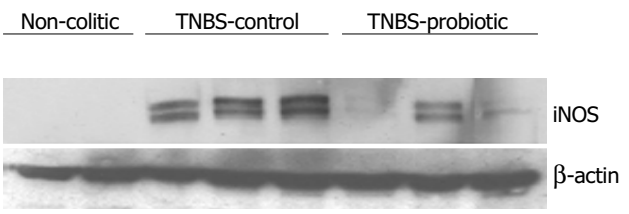

Figure 3 Effects of *L. salivarius ssp. salivarius* treatment (5×10^8 CFU/rat·d) on colonic nitric oxide synthase (NOS) expression in TNBS experimental colitis in rats.

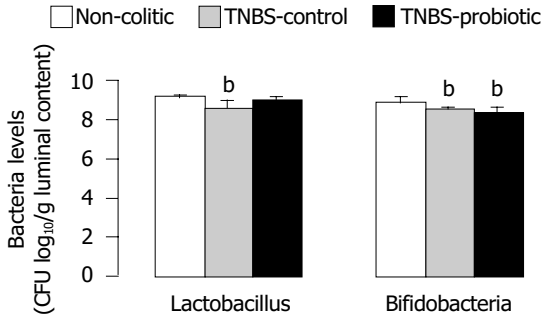

Figure 4 Effects of *L. salivarius ssp. salivarius* (5×10^8 CFU/rat·day) treatment on bacteria levels (Lactobacillus and Bifidobacteria) in TNBS experimental colitis in rats. [b]P<0.01 *vs* non-colitic group.

Table 4 Myeloperoxidase (MPO) activity, total GSH content, TNF-α and LTB_4 levels in colon specimens from non-colitic rats, TNBS control colitic rats and TNBS colitic rats treated with *L. salivarius ssp. salivarius* (5×10^8 CFU/rat·d)

Group (n = 10)	MPO activity (units MPO/g)	GSH (nmol/g)	LTB_4(ng/g)	TNF-α (pg/g)
Non-colitic	23.4±7.2	1 540±41	2.9±0.4	441.5±39.1
TNBS control	180.6±21.9[d]	1 087±51[d]	6.5±0.9[d]	782.9±60.1[d]
TNBS probiotic	105.3±26.0[a,d]	1 252±42[a,d]	6.9±0.8[d]	509.4±68.2[b]

the corresponding TNBS control groups. The inhibitory effect on the infiltration of inflammatory cells into the colonic mucosa might account for the beneficial effect of this probiotic against tissue injury, because margination and extravasation of circulating granulocytes contribute markedly to the colonic injury in this model of IBD[35]. These results are in agreement with other studies, that describe the attenuation exerted by several probiotics in leukocyte-endothelial cell adhesion in this experimental model of rat colitis[36]. This effect can justify the inhibition of the synthesis and/or release of different mediators that participate in the inflammatory process, such as NO, since probiotic treatment of colitic rats was associated with a reduction in colonic iNOS expression. Moreover, this can also explain the improvement in the colonic oxidative stress in colitic rats after probiotic treatment, as evidenced by a partial restoration of the GSH depletion that took place as a consequence of the TNBS colonic damage.

During the last decade, it has become increasingly evident that chronic colonic inflammation, both in human IBD and in experimental colitis, is associated with enhanced NO production, mainly via iNOS activity[37-39], as well as with increased release of reactive oxygen metabolites, including superoxide[40-42]. The simultaneous overproduction of NO and superoxide can yield the highly toxic radical, peroxynitrite in the inflamed intestine[43], which have been demonstrated to produce widespread colonic injury[44]. It is important to note that neutrophils are thought to be important source of both NO[45,46] and reactive oxygen metabolites[47]. Considering the above, the effect exerted by *L. salivarius ssp. salivarius* in decreasing the neutrophil infiltration that occurs in response to TNBS, may preserve the colonic mucosa from oxidative insult. In fact, beneficial effects have previously been reported either after NOS inhibition[37,38] or by antioxidant therapy[31,42] in different experimental models of intestinal inflammation.

Probiotic treatment could attenuate neutrophil infiltration via inhibition of different mediators with chemotactic activity. The results obtained in the present study revealed that probiotic treatment did not significantly modify colonic LTB_4 levels, an eicosanoid with chemotactic activity involved in the pathogenesis of IBD[1]. In consequence, the inhibitory effect of leukocyte infiltration exerted by the probiotic should be related to the downregulation of other pro-inflammatory mediators, given the ability of this lactobacilli strain to modulate the immune response as demonstrated by the *in vitro* studies. In fact, the intestinal anti-inflammatory activity exerted by *L. salivarius ssp. salivarius* was also characterized by downregulation of colonic TNF-α. This may be relevant since TNF-α acts as a potent chemoattractant, thus contributing to the recruitment of neutrophil in the inflamed colonic mucosa and initiating the inflammatory pathogenic cascade that definitively perpetuates colonic inflammation[48]. The important role attributed to TNF-α in intestinal inflammation is strongly supported by the fact that different drugs capable of interfering with the activity of this mediator are being developed for IBD therapy[23]. The ability of probiotic bacteria to downregulate TNF-α production has been reported previously for other lactobacilli strains such as *L. casei* and of *L. bulgaricus*, when they were cultured with inflamed mucosa from patients with Crohn's disease[20]. This effect was attributed to the existence of a cross talk between bacteria and mucosal cells, being able to downregulate the degree of activation of intestinal immune cells[20]. This has also been demonstrated in the present study for *L. salivarius ssp. salivarius* since it was able to modify the cytokine profile in macrophages, reducing the amount of inflammatory cytokines (TNF-α and IL-12), while increasing the amount of the anti-inflammatory cytokine IL-10. The high diversity of immuno-modulatory action of probiotics observed in the screening of the bacteria are in concordance with previous works showing both the ability of some lactic bacteria to promote TNF-α production[49] while others such as *L. rhamnosus* GG (LGG) reduced it[50]. LGG, a probiotic that also reduces the ratio TNF-α/IL-10, has been reported to exert intestinal anti-inflammatory effects both in human[12] and in experimental intestinal inflammation[51]. This effect of some probiotics on the immune response may be of special relevance because it would promote a possible shift from a T_H1-mediated immune response toward a T_H2/T_H3 profile, similarly to that proposed to occur with Lactobacillus GG[15]. It is important to note that replacing the bacteria responsible for the constant antigenic drive leading to T_H1 cellular activation with probiotic species that preferentially induce protective immune responses may alter the normal course of these relapsing intestinal conditions. In addition, probiotics like *Bifidobacterium longum* or *L. bulgaricus* have been shown to inhibit the IL-8 secretion in intestinal epithelia, when stimulated by the pro-inflammatory cytokine TNF-α, thus reducing the activity of other pro-inflammatory cytokines with chemotactic activity[52].

However, the participation of the modification in the immune response in the intestinal anti-inflammatory effect exerted by this probiotic does not exclude mechanisms proposed for other probiotics, mainly due to a role in preventing the imbalance in the intestinal microflora, given the relative predominance of aggressive bacteria and insufficient amount of protective species that has been reported in these intestinal conditions[1,2]. Previous studies have suggested that in TNBS-induced colitis, specific strains from colonic microflora invades the colonic wall after disruption of the epithelium and the presence of bacteria within the wall participates in the transmural inflammation[53]. In fact, the present study reveals that the colonic damage induced by TNBS was associated with a significant reduction of lactobacilli count in the colonic lumen, which was counteracted after the probiotic treatment, since probiotic-treated rats showed no statistical differences from non-colitic rats in the lactobacilli content.

In conclusion, administration of the probiotic *L. salivarius ssp. salivarius* CECT5713 facilitates the recovery of the inflamed tissue in the TNBS model of rat colitis, an effect associated with amelioration of the production of some of the mediators involved in the inflammatory response of the intestine, such as cytokines, including TNF-α, and NO. This beneficial effect could be ascribed to its effect on the altered immune response characteristic of this inflammatory condition, which would attenuate the exacerbated immune response evoked by the colonic instillation of the hapten TNBS in the rats.

Abstract

AIM: To identify the trend, possible risk factors and any pattern change of hepatocellular carcinoma (HCC) in Egypt over a decade.

METHODS: All HCC patients attending Cairo Liver Center between January 1993 and December 2002, were enrolled in the study. Diagnosis of HCC was based on histopathological examination and/or detection of hepatic focal lesions by two imaging techniques plus α-fetoprotein level above 200 ng/mL. The duration of the study was divided into two periods of 5 years each; period I (1993-1997) and period II (1998-2002). Trend, demographic features of patients (age, gender, and residence), risk factors (HBsAg, HCV-Ab, schistosomiasis and others) and pattern of the focal lesions were compared between the two periods. Logistic regression model was fitted to calculate the adjusted odds ratios for the potential risk factors. The population attributable risk percentage was calculated to estimate the proportion of HCC attributed to hepatitis B and C viral infections.

RESULTS: Over a decade, 1 328 HCC patients out of 22 450 chronic liver disease (CLD) patients were diagnosed with an overall proportion of 5.9%. The annual proportion of HCC showed a significant rising trend from 4.0% in 1993 to 7.2% in 2002 (P = 0.000). A significant increase in male proportion from 82.5% to 87.6% (P = 0.009); M/F from 5:1 to 7:1 and a slight increase of the predominant age group (40-59 years) from 62.6% to 66.8% (P = 0.387) in periods I and II respectively, reflecting a shift to younger age group. In the bivariate analysis, HCC was significantly higher in rural residents, patients with history of schistosomiasis and/or blood transfusion. Yet, after adjustment, these variables did not have a significant risk for development of HCC. There was a significant decline of HBsAg from 38.6% to 20.5% (P = 0.000), and a slight increase of HCV-Ab from 85.6% to 87.9% in periods I and II respectively. HBV conferred a higher risk to develop HCC more than HCV in period I (OR 1.9 *vs* 1.6) and period II (OR 2.7 *vs* 2.0), but the relative contribution of HBV for development of HCC declined in period II compared to period I (PAR% 4.2%, 21.32%). At presentation, diagnostic α-fetoprotein level (⩾200 ng/mL) was demonstrated in 15.6% *vs* 28.9% and small HCC (⩽3 cm) represented 14.9% *vs* 22.7% (P = 0.0002) in periods I and II respectively.

CONCLUSION: Over a decade, there was nearly a twofold increase of the proportion of HCC among CLD patients in Egypt with a significant decline of HBV and slight increase of HCV as risk factors. α-Fetoprotein played a limited role in diagnosis of HCC, compared to imaging techniques. Increased detection of small lesions at presentation reflects increased awareness of the condition.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common malignancy in the world[1] complicating liver cirrhosis in most cases. Its incidence is increasing worldwide ranging between 3% and 9% annually[2]. In Egypt, HCC was reported to account for about 4.7% of chronic liver disease (CLD) patients[3]. The epidemiology of HCC is characterized by marked demographic and geographic variations.

HBV is considered as a major risk factor for the progression to liver cirrhosis and HCC[4]. The relative risk of developing HCC for HBV carriers may be 100-200-fold higher than

that for non-carriers[5]. Integration of the viral DNA into host genome was suggested to be the initiating event for HBV-induced carcinogenesis[6]. A recent study suggests that the HBx protein may inactivate p53 (tumor suppressor gene) leading to development of HCC[7]. However, the prevalence of HBV infection in Egypt has been declining over the last two decades[3].

The rising trend of HCC has been associated with increased prevalence of hepatitis C virus (HCV) infection[1]. In Egypt, the prevalence of HCV infection among general population has been estimated to be around 14%[8]. The fundamental mechanism by which HCV is related to HCC is not definitely known. Several lines of evidence indicate a strong causal association between HCV and HCC, as shown by the raised prevalence of anti-HCV[2,3] and/or HCV-RNA[9] in patients with HCC.

HCV mostly plays an indirect role in tumor development and appears to increase the risk of HCC by promoting fibrosis and cirrhosis. On the other hand, HCV may play a direct role in hepatic carcinogenesis through involvement of viral gene products in inducing liver cell proliferation[10]. However, it seems that cirrhosis is the common pathway by which several risk factors exert their carcinogenic effect[11].

Exposure to aflatoxin is an additional risk factor for the development of HCC, through damage of DNA in liver cells and mutation in p53 tumor suppressor gene[7]. A previous study showed that aflatoxin B1 has a considerable role in the development of HCC among Egyptians[3].

The aim of this study was to detect the trend of HCC in Egypt over the past decade, identify the possible risk factors and the proportion attributed to hepatitis B and C viral infections and changes in HCC pattern.

MATERIALS AND METHODS

The study was conducted at Cairo Liver Center (CLC), a private institute established to provide specialized care for patients with liver disease. The center receives patients from almost all regions of Egypt, besides patients from the neighboring Arab countries.

A specially designed database application was employed for collecting and managing data of the Egyptian patients attending the center during the period from January 1993 to December 2002. Patients were assigned unique records, which were presented through a designed form interface. The form consisted of three sections on socio-demographic characteristics (age, gender, occupation, and residence), history of exposure to known risk factors of viral hepatitis - blood transfusion and parenteral anti-schistosomal therapy, and laboratory findings (HBsAg status, HCV-Ab status, α-fetoprotein level). Another patient record-linked application was employed to record the imaging characteristics of HCC cases such as location, number, and size of hepatic focal lesions, as well as, portal vein status.

HCV-Ab was detected using second generation ELISA (Boehringer Mannheim Immunodiagnostics for ES-300). HBsAg was confirmed by ELISA test (ELISA-Abbot Laboratories), α-fetoprotein level was tested using Abbot Laboratories' method. No study in Egypt has stated the cut-off level of α-fetoprotein in Egypt yet; however, we considered a cut-off level of 200 ng/mL as reported internationally[12]. Ultrasonography was performed using Toshiba Sonolayer 600, with a convex linear probe using B mode.

Diagnosis of HCC was based on histopathological examination and/or detection of hepatic focal lesions by two imaging techniques (ultrasonography and dynamic CT) plus α-fetoprotein level above 200 ng/mL.

Statistical analysis

Data analysis was done using SPSS computer package. Trend of HCC among CLD patients was studied annually and χ^2 test for trend was used to detect significant annual differences. Also, the 10-year period was divided into period I from 1993 to 1997, and period 2 from 1998 to 2002. The differences in the characteristics of HCC patients between the two periods were compared. χ^2 test for association was used to detect significant associations between proportions.

Logistic regression model was fitted to identify the impact of the various risk factors on HCC. The dependent outcome was HCC (0 = absent, 1 = present) and the independent factors were age, sex, previous history of blood transfusion, schistosomiasis, HCV-Ab positivity and HBsAg positivity.

The population attributable risk percent (PAR%)[13] was calculated to express the proportion of HCC in the study population that was attributed to HCV-Ab or HBsAg positivity and thus can be eliminated, if exposure is prevented. PAR% was calculated as follows:

PAR% = Pe(OR-1)/Pe(OR-1)+1

Where Pe is the proportion of exposed individuals in the population and OR represents the adjusted odds ratio.

RESULTS

A total of 22 450 Egyptian patients with CLDs were registered at CLC between the year 1993 and 2002 (Table 1). Their ages ranged from 33 to 74 years (mean±SD = 53.3±11.67 years). 77.7% were males and 22.3% females and most of them (75.2%) resided in rural areas. Around 50% had history of parenteral anti-schistosomal therapy and 12.9% had history of blood transfusion. HCV-Ab accounted for 72.3% and HBsAg for 20.4%.

There were 1 328 HCC cases diagnosed over the 10-year period giving an overall proportion of 5.9%. HCC was diagnosed mainly among males between 40 and 59 years of age living in rural areas. Schistosomiasis, blood transfusion, HCV-Ab, and HBsAg were more prevalent among HCC-positive cases than HCC-negative cases (Table 1).

As shown in Table 2 and Figure 1, there was a significant annual increase (χ^2 = 29.9, df = 9, P = 0.000) in the proportion of patients with HCC attending CLC, during the study period ranging from 4.0% in 1993 to 7.2% in 2002.

Comparing the two periods (Table 3), there was a slight shift in age distribution to younger age group from age group ⩾60 years, to the most predominant age group 40-59 years, but the difference did not reach a statistical significance (P = 0.387). There were no significant changes as regards residence and history of schistosomiasis between the two periods. However, there was a significant increase in the proportion of males (χ^2 = 6.7, df = 1, P = 0.009) in period II (Table 3).

χ^2 = 33.5, df = 9, P = 0.0000.

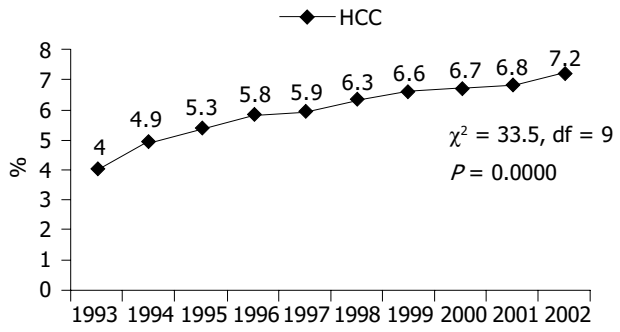

Figure 1 Annual number and proportion of HCC among chronic liver diseased patients attending CLC during the period 1993-2002.

Analysis of the major risk factors of HCC in period I compared to period II revealed appreciable changes (Table 3). There was a significant drop of HBsAg positivity from 38.6% to 20.5% (χ^2 = 52.3, df = 1, P = 0.000), in hepatitis C and B co-infection from 27.0% to 10.8% (χ^2 = 58.4, df = 1, P = 0.000) among HCC cases and decline in the proportion of patients with previous history of blood transfusion from 19.6% to 12.4% (χ^2 = 12.7, df = 1 , P = 0.000). There was a slight increase of HCV-Ab positivity from 85.6% to 87.9% (χ^2 = 1.42, df = 1, P = 0.23). Diagnostic α-fetoprotein level (⩾200 ng/mL) was reported in 15.6% of patients in period I and 28.9% in period II (χ^2 = 32.8, df = 1, P = 0.000, Table 3).

All HCC cases presented with focal hepatic lesions on imaging. The right lobe was affected in 65%, the left lobe in 13.4% and both lobes in 21.6%, most of which (54.9%) were diffusive or multinodular hepatic focal lesions. At presentation, the lesions tended to be multifocal (χ^2 = 7.65, df = 1, P = 0.006), more on the right side (χ^2 = 30.4, df = 1, P = 0.000) and large (>3 cm) in size (χ^2 = 86.1, df = 2, P = 0.000). However, there was a significant increase in the detection of small lesions in the second period more than in the first period (χ^2 = 12.7, df = 1, P = 0.000). Portal vein thrombosis was demonstrated in 18.0% of cases in period I and 17.9% in period II with no significant difference between the two periods (Table 3).

The adjusted odds ratios (Table 4) have shown that men were at higher risk to develop HCC than women (OR = 2.9) as well as patients of older age (age group 40-59 years, OR = 3.7 times and ⩾60 years, OR = 11.2, P = 0.000). HCV-Ab-positive cases were at double risk, while HBsAg were at nearly triple risk of developing HCC. Residents of rural areas, patients with previous history of schistosomiasis and/or blood transfusion were significantly related to HCC in the bivariate analysis. However, after adjustment for other risk factors in the logistic regression model, their impact on acquiring HCC did not reach statistical significance. Although HBsAg occurrence conferred a higher risk of HCC than HCV in both periods, HBsAg appears to have a less share in HCC development as the PAR% revealed that 42.0% of

HCC cases were attributed to HCV positivity, while only 23.4% of them were attributed to HBV positivity. HBsAg has a lower contribution for development of HCC in period II (PAR% = 4.2%) than in period I (PAR% = 21.3%).

DISCUSSION

Worldwide, HCC is one of the most common malignancies associated with poor prognosis[14]. According to recent reports, the incidence of HCC has increased sharply in the last 5-10 years[1,2,15]. In USA, the rate of HCC has increased by 70% over the last two decades[16]. Registry data in Canada and Western Europe show similar trends[16]. So far, no enough attention has been paid to explore the magnitude of the problem of HCC in Egypt. In the current study, there has been a remarkable increase of the proportion

of HCC among CLD patients from 4.0% to 7.2% over a decade. This rising proportion may be explained by the increasing risk factors such as the emergence of HCV over the same period of time, the contribution of HBV infection, improvement of the screening programs and diagnostic tools of HCC[17], as well as the increased survival rate among patients with cirrhosis to allow time for some of them to develop HCC.

HCC is more prevalent in men than in women[18], which may be at least in part explained by differences in exposure to risk factors. However, sex hormones and other x-linked genetic factors may also be important[19]. It has been speculated that estrogens and androgens could modulate hepatocarcinogenesis and explain the higher incidence of HCC in men[20]. A significant increase in the proportion of HCC among males from 82.5% in periods I to 87.6% in period II ($P = 0.009$) was observed. The calculated risk of development of HCC was nearly three times higher in men than in women. This is consistent with the findings of Kasahara *et al*.[21], where men were at 4.35 times risk to develop HCC than women.

Analysis of age distribution among HCC patients revealed that the most predominant age group (40-59 years) showed a slight increase in period II compared to period I at the expense of older age group (⩾60 years) but the difference did not reach a statistical significance ($P = 0.387$). This shift to younger age group over the last two decades may be attributed to emergence of HCV infection[22,23], as well as to acquisition of both hepatitis B and C virus infection at younger age[2,24].

Velazquez *et al*.[2], found that cirrhotic patients older than 54 years are at four times greater risk to develop HCC. This is consistent with our findings, where patients of the age group 40-59 years were at 3.7 times and of age group ⩾60 years were at 11 times more risk to develop HCC.

Analysis of the risk factors of HCC in patients with CLD has been performed in several studies[25,26]. HBV and HCV infection are considered as the major risk factors that contribute to the development of HCC. During the entire study period, the proportions of HCV-Ab and HBsAg among HCC cases were 86.9% and 28.4% respectively. Surprisingly, there was a significant decline of HBsAg from 38.6% to 20.5% ($P = 0.000$) and slight increase in HCV-Ab from 85.6% to 87.9% ($P = 0.233$) in periods I and II respectively. Consequently, the proportion of co-infection of hepatitis C and B declined from 27% to 10.8%. The decline of HBsAg may be partially attributed to successful control measures of blood transfusion introduced in the mid-seventies and partially to the development of mutant or occult HBV infection, which requires costly assays for diagnosis. However, this decline could not be attributed to vaccination programs in children[27], which has been launched in Egypt about 10 years ago. It has been reported that the reduction of the incidence of HBV will be seen 30-40 years after the launch of the universal hepatitis B vaccination program[27]. Although HBV and HCV are both important causes of HCC, data do not suggest, neither do they conclusively refute, a super-additive interaction between the two infections in the development of HCC[28,29].

HBV conferred a higher risk to develop HCC more than HCV (OR 2.5 *vs* 2.0 respectively). Yet, the low prevalence of HBV render the relative contribution of HBV to HCC (PAR% = 23.4%) lower than HCV contribution (PAR% = 42%). Velazquez and his colleagues[2] in Spain, considered HBV as an insignificant risk factor for development of HCC due to the considerable small number of infected patients as well as low chronicity rate in acute HBV infection (10%) compared to high chronicity rate (50-80%) in acute HCV patients. Studies from earlier years indicated that the rise in the incidence of HCC was directly related to the increase in the prevalence of HCV infection[30]. The prevalence of HCV in Egypt is much more increased[31], which needs to intervene with the acquisition of acute HCV infection as a primary prevention measure. Hepatitis C vaccine is not available; therefore, the rising trend of HCC is most likely attributed to HCV infection[32].

The role of HBV infection in pathogenesis of HCC differs from that of HCV infection; HBV-DNA genome integrates in hepatocellular chromosomes[10], while HCV exerts its effect, most probably, through production of cirrhosis with severe liver damage[30]. The major part of the data shows that HCV plays an indirect role in hepatocarcinogenesis, and this may appear as a consequence of long-standing associated cirrhosis through the direct promotion of the chronic liver inflammation[33]. Recently, many reports point to a direct role of HCV in hepatocarcinogenesis, it is now believed that the core component of HCV may directly participate in the hepatocarcinogenesis[7].

In the current study, viral hepatitis markers were negative in 2.8% of HCC patients in period I and 2.4% of them in period II with no significant difference. A higher percent was reported by El-Serag[1], who found that 14.5% of patients with HCC remain without specific risk factors and diagnosed as non-specific cirrhosis. This could be explained by the development of mutant or occult viral infection or exposure to other risk factors such as aflatoxins, alcohol abuse, or heavy smoking.

A unique invisible risk factor for development of HCC in Egypt could be schistosomal infection and its parenteral therapy. Schistosomiasis induces immune suppression, which could result in increased persistence viremia, following acute infection of both hepatitis B and C[34]. Whereas, parenteral anti-schistosomal therapy had played a role in transmission of HBV and HCV through improperly sterilized glass syringes[35]. In spite that patients with history of schistosomiasis were at higher risk to develop HCC but the results did not reach a statistical significance, which could be attributed to the absence of direct causal effect of schistosomiasis in development of HCC[34].

According to the recommendations of a previous study[3], the awareness about HCC has been greatly improved, which subsequently led to better screening and earlier diagnosis of HCC. This is evidenced by increased rate of diagnosis of small lesions from 14.9% to 22.7% and decreased rate of diagnosis of large HCC lesions from 85.1% to 77.3% in periods I and II respectively.

α-Fetoprotein is the most widely used tumor marker, but has poor diagnostic accuracy and ethnic variability[12]. Diagnostic α-fetoprotein level (⩾200 ng/mL) was demonstrated only in 15.6% of cases in period I and 28.9%

in period II. The increased proportion of patients with diagnostic α-fetoprotein level may be attributed to the increasing adoption of HCC screening program as well as the use of more sensitive assay methods introduced over the recent years.

These results suggest a rising trend of HCC with increasing risk among HCV-infected men of older age groups; such patients should be carefully followed-up and screened for early detection of HCC.

Abstract

AIM: As tumor markers for pancreatic carcinoma, carcinoembryonic antigen (CEA) and carbohydrate antigen (CA) 19-9 have been used, but the sensitivity and specificity are not enough for the diagnosis of pancreatic carcinoma.

METHODS: A novel serum tumor marker, RCAS1, was compared with two conventional serum tumor markers, CEA (highly specific for pancreatic cancer) and CA 19-9 (highly sensitive for pancreatic cancer), in 48 patients with pancreatic exocrine tumors.

RESULTS: When the diagnosis of benign or malignant conditions was examined by one tumor marker, the sensitivity of RCAS1 alone (55%) was higher than that of CEA alone (27%) and the specificity of RCAS1 alone (92%) was greater than that of CA19-9 alone (78%). When examined by a combination of two markers, the sensitivity of a combination of RCAS1 and CA19-9 (95%) was superior to those of CA19-9 alone (78%), RCAS1 alone (55%, $P = 0.002$), CEA alone (27%) ($P<0.001$), RCAS1 and CEA (59%) and CA19-9 and CEA (82%).

CONCLUSION: These results suggest that the combination of RCAS1 and CA19-9 is highly sensitive for pancreatic carcinoma.

INTRODUCTION

RCAS1 (receptor-binding cancer antigen expressed on SiSo cells) is a novel tumor-associated antigen expressed in malignant conditions of various organs. A human cancer cell line, SiSo, was established from a patient affected with uterine cervical adenocarcinoma[1]. The mAb 22-1-1 was manufactured from mice immunized with SiSo cells. Then a cDNA encoding the antigen 22-1-1 was isolated and named RCAS1[2]. The predicted amino acid sequences of RCAS1 (213 aa) possess an N-terminal transmembrane region and a coiled-coil structure in the C-terminal portion, indicating that RCAS1 is a type II membrane protein and is able to form oligomers through the coiled-coil structure.

RCAS1 was found to be identical to EBA G9 (estrogen receptor-binding fragment-associated gene), which was initially identified by cloning of CpG binding sites in the human genome as estrogen responsive gene and mapped to chromosome 8q23. RCAS1 expresses a pattern different from other known tumor-associated antigens, such as YH206, GA733, CA125, CEA, and sialyl Le molecules. Immunohistochemical studies have reported the presence of RCAS1 in malignant diseases of several organs including the uterus[3], endometrium[4], ovary, skin[5], breast[6,7], liver[8], gallbladder[9], stomach[10], lymphocytes[11], and lung[12] as well as pancreas[13]. Previous studies have also indicated that RCAS1 acts as a ligand for a putative receptor present on various human cells including T, B, and NK cells and RCAS1 inhibits *in vitro* growth of receptor-expressing cells and induces apoptosis[14]. It is suggested that tumor cells might evade host immune surveillance by expression of RCAS1. Recently, soluble RCAS1 was also detected by ELISA from the culture supernatant of a human cell line derived from bile duct carcinoma[15], suggesting a possible role of RCAS1 as a diagnostic or prognostic tumor marker. There are few reports on serum levels of RCAS1 in patients with pancreatic diseases. In this series, clinical implication of serum RCAS1 was examined by comparing with conventional tumor markers, carcinoembryonic antigen (CEA) and carbohydrate antigen (CA) 19-9, in 48 patients with pancreatic tumors.

MATERIALS AND METHODS

This series consisted of 48 patients with pancreatic exocrine neoplasms and 23 with benign inflammatory pancreato-biliary diseases (control group). Out of the 71 patients, 35 were men and 36 women, and their age ranged from 18 to 89 years with a mean of 61.9±12.5 years. The 23 patients in the control group consisted of 18 with benign inflammatory biliary diseases (four cholecystolithiasis, four cholangitis, four benign gallbladder polyp, three hepatolithiasis, two adenomyomatosis of the gallbladder and one choledocholithiasis) and five with

benign pancreatic diseases (four chronic pancreatitis, one pancreatolithiasis). The 48 patients with pancreatic neoplasms included 30 patients in the preoperative state of benign or malignant diseases (10 intraductal papillary-mucinous adenoma, 20 pancreatic carcinoma) and 18 patients in the postoperative state (3 intraductal papillary-mucinous adenoma, 4 intraductal papillary-mucinous adenocarcinoma and 11 pancreatic adenocarcinoma). Of the 15 postoperative patients with pancreatic carcinoma, 2 had unequivocal recurrence as judged by clinical findings including imagings, and the other 13 had no evidence of recurrence. In total, 22 patients were therefore considered to have pancreatic carcinoma. Serum levels of RCAS1, CEA, and CA19-9 were examined in all these 71 patients.

Peripheral blood was obtained in the early morning for the examination of RCAS1, CEA, and CA19-9. Serum RCAS1 level was measured using ELISA kit, which was kindly donated from Medical and Biological Laboratories Co., Ltd, Nagoya, Japan. The RCAS1 ELISA kit measures RCAS1 by sandwich ELISA. The assay used mAbs against RCAS1. The serum obtained was pre-treated with neuraminidase. Pretreated samples to be measured or standards were incubated in the cells coated with anti-human RCAS1 mAb; 22-1-1. After washing, a biotin-conjugated anti-human RCAS1 mAb was added into the microwell and incubated. After another washing, the streptavidin-peroxidase was added into the microwell and incubated. After another washing, the peroxidase substrate premixed with chromogen was added and allowed to incubate for an additional period of time. An acid solution was then added to each microwell to terminate the enzyme reaction and to stabilize the developed color. The optical density (*A*) of each microwell was then measured at 450 nm using a microplate reader. The concentration of RCAS1 was calibrated from a dose-response curve based on reference standards. Cut-off level was set at 20 U/mL by constructing a receiver operating characteristic curve (Figure 1). Serum CEA and CA19-9 levels were measured in Clinical Laboratory of Kyushu University Hospital. Their cut-off levels were 2.5 ng/mL and 37.4 IU/mL, respectively.

Clinical stages of malignant pancreatic diseases were determined by the Classification of Pancreatic Carcinoma from Japan Pancreas Society (First English Edition)[16]. Out of the 22 patients with primary or metastatic pancreatic adenocarcinoma, 1 was in stage I, 1 in stage III, 3 in stage IVa and the other 17 in stage IVb. Four of the twenty-two patients underwent pancreatic resection; three pylorus preserving pancreato-duodenectomy and another distal pancreatectomy.

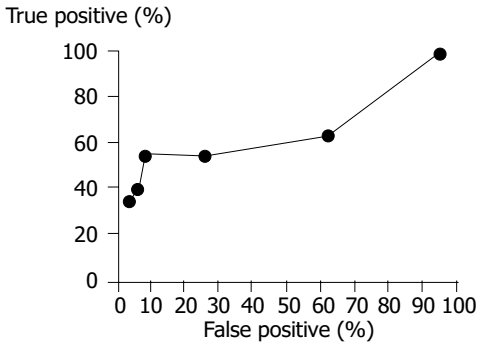

Figure 1 Receiver operating characteristic curve indicating test performance indicating pancreatic carcinoma for the following threshold values, 5, 10, 15, 20, 25, and 30 U/mL. ●–●, performance in distinguishing benign from malignant pancreatic disease.

Informed consent was obtained from each patient. The protocol was submitted to and was preapproved by the Senior Staff Committee of the Department.

Statistical analysis

Values were expressed as mean±SD. Mean values were measured by the Student's *t* test and the distribution of patients was measured by the χ^2 test. Sensitivity, specificity, positive predictive value, negative predictive value, and efficiency were measured. $P<0.05$ was considered as statistically significant.

RESULTS

RCAS1, CEA, and CA19-9 levels

Serum levels of RCAS1, CEA, CA19-9 in 26 patients with benign inflammatory bilio-pancreatic diseases were 12.1±1.1 U/mL, 1.1±0.1 ng/mL and 30.5±6.6 U/mL; 10 with adenoma of the pancreas (intraductal papillary-mucinous adenoma) 14.1±2.9, 1.2±0.2, and 13.5±4.4; and 22 with adenocarcinoma of the pancreas 113.0±70.8, 4.8±2.3, and 9 947.9±6 814.1, respectively. There were no statistically significant differences among the RCAS1, CEA, and CA19-9 values of the three conditions.

Diagnosis of benign and malignant conditions

Data concerning the diagnosis of benign and malignant conditions are shown in Table 1. When comparing by one

Table 1 Diagnosis of malignant and benign diseases by serum RCAS1, CEA and CA19-9

Specificity	92		94		78		86		69		75	
Positive predictive value	80		75		67		72		66		67	
Negative predictive value	78		68		82		78		96		87	
Efficiency	78		69		76		76		79		78	

[b]$P<0.001$ *vs* RCAS1+CA19-9; [d]$P<0.001$ *vs* CA19-9+CEA; [1]$P = 0.003$ *vs* CA19-9; [2]$P = 0.033$ *vs* RCAS1+CEA; [3]$P = 0.002$ *vs* RCAS1+CA19-9.

tumor marker, the sensitivity was highest in CA19-9 (73%), while the specificity was highest in CEA (94%). The total efficacy was highest in RCAS1 (78%). When two tumor markers were joined, the sensitivity was highest by a combination of RCAS1 and CA19-9, the value being 95%, whereas the specificity was highest by a combination of RCAS1 and CEA (86%). The total efficiency was highest by a combination of RCAS1 and CA19-9 (79%).

Tumor stage of pancreatic carcinoma and three markers

The positivity of the three markers increased by the progression of tumors (Table 2).

Prediction of unresectability of pancreatic carcinoma by three markers

The sensitivity of prediction of unresectability was highest by CA19-9 alone (71%), while the specificity was highest by CEA alone (100%, Table 3). When combination assay was done, the sensitivity was highest by RCAS1 and CA19-9 (94%), while the specificity was highest by RCAS1 and CEA (80%).

Recurrence of pancreatic carcinoma after surgical resection

Data are present in Table 4. When examined by one tumor marker, RCAS1 alone and CA19-9 alone showed a high sensitivity and specificity. When two tumor markers were combined, a combination of RCAS1 and CA19-9 showed a high sensitivity (100%) and high specificity (92%).

DISCUSSION

CA19-9 (a highly sensitive marker for pancreatic carcinoma) and CEA (a highly specific marker for pancreatic carcinoma) have been used as serum tumor markers for pancreatic diseases. Usefulness of RCAS1, as a tumor marker, was studied in 48 patients with pancreatic tumors. The sensitivity of RCAS1 alone for pancreatic carcinoma was 55%, which was higher than 27% of CEA alone and lower than 73% of CA19-9 alone. When combination assay was done, the sensitivity of a combination of RCAS1 and CA19-9 was highest, the value being 95%. The specificity of RCAS1 alone for pancreatic carcinoma was 92%, which was lower than 94% of CEA alone and higher than 78% of CA19-9 alone. The specificity by a combination of RCAS1 and CA19-9 was 69%. Combination assay of RCAS1 and CA19-9 was the most powerful marker for the detection of pancreatic carcinoma.

Clinical differentiation of benign inflammatory disease and malignant disease is important as well as that of benign

neoplasm and malignant conditions. Mean serum levels of RCAS1, CEA, and CA19-9 in pancreatic carcinoma were higher than those of benign inflammatory diseases and pancreatic adenoma. The values in benign inflammatory diseases and adenoma were not different from each other. Therefore, although the differentiation of benign inflammatory diseases and adenoma was difficult by serum tumor markers alone, that of benign diseases and malignant conditions may be possible. Clinical diagnosis of pancreatic diseases should be made by clinical findings and imaging with the aid of serum tumor markers.

Originally, RCAS1 was suspected to be elevated only at advanced stage of pancreatic carcinoma, because RCAS1 is related with immune escape from the host immune and with carcinoma invasion. The specificity of RCAS1 for the presence of pancreatic carcinoma was expected to be high and the sensitivity was suspected to be low. The sensitivity of RCAS1 alone for malignant condition was 55%, which was higher than 27% by CEA alone, and the specificity of RCAS1 alone was 92%, higher than 78% of CA19-9 alone. Combination assay of RCAS1 and CA19-9 showed the highest sensitivity of 95%, although the specificity was 69%. The sensitivity of tumor marker is important to decrease the missing of pancreatic carcinoma and the specificity is also important to decrease the over diagnosis. Thus, combination assay of CA19-9 and RCAS1 is recommended for the detection of pancreatic carcinoma.

It is true that the surgical decision making is made on imaging or macroscopic findings, but the prediction of resectability by serum tumor marker is of great value for surgeons. The sensitivity of prediction of unresectability was 94% by a combination of RCAS1 and CA19-9 and the specificity was 80%. These findings indicate that elevation of serum RCAS1 and CA19-9 may be suggestive of unresectable pancreatic carcinoma, although the number of patients examined was so small, that the data obtained was not conclusive.

One of the purposes of serum tumor marker is to predict clinical outcome of patients with pancreatic carcinoma. Recent immunohistochemical reports suggest that RCAS1 expression is related to early stage of carcinogenesis[7], poor differentiation[4], progression of the disease[5,10], and poor prognosis of cancer[9,13,17]. In this series, clinical follow-up was so short that we could not yield data concerning the clinical outcome. Further examination using long-term follow-up is necessary to evaluate predictability of RCAS1.

Although this series is a preliminary report on serum RCAS1 in pancreatic diseases, combination assay of RCAS1 and CA19-9 showed 95% sensitivity for pancreatic carcinoma, suggesting usefulness of this combination as a checking-up marker for pancreatic carcinoma.

Abstract

AIM: We designed two synthetic-core-specific peptides core 1 (C1) and core 2 (C2), and an E1-specific peptide (E1). We produced specific polyclonal antibodies against these peptides and used the antibodies for detection of HCV antigens on surface and within infected peripheral blood leukocytes.

METHODS: Peripheral blood from a healthy individual who tested negative for HCV RNA was incubated with HCV type 4 infected serum for 1 h and 24 h at 37 ℃. Cells were stained by direct and indirect immunofluorescence and measured by flow cytometry.

RESULTS: After 1 h of incubation, antibodies against C1, C2, and E1 detected HCV antigens on the surface of 27%, 26% and 73% of monocytes respectively, while 10%, 5% and 9% of lymphocytes were positive with anti-C1, anti-C2 and anti-E1 respectively. Only 1-3% of granulocytes showed positive staining with anti-C1, anti-C2 and anti E1 antibodies. After 24 h of incubation, we found no surface staining with anti-C1, anti-C2 or anti-E1. Direct immunostaining using anti-C2 could not detect intracellular HCV antigens, after 1 h of incubation with the virus, while after 24 h of incubation, 28% of infected cells showed positive staining. Only plus strand RNA was detectable intracellularly as early as 1 h after incubation, and remained detectable throughout 48 h post-infection. Interestingly, minus RNA strand could not be detected after 1 h, but became strongly detectable intracellularly after 24 h post-infection.

CONCLUSION: Monocytes and lymphocytes are the preferred target cells for HCV infection in peripheral blood leukocytes. Our specific anti-core and anti-E1 antibodies are valuable reagents for demonstration of HCV cell cycle. Also, HCV is capable of infecting and replicating in peripheral blood mononuclear cells as confirmed by detection of minus strand HCV RNA as well as intracellular staining of core HCV antigen.

INTRODUCTION

Hepatitis C virus (HCV) is the major etiology of non-A, non-B hepatitis that infects 170 million people worldwide. Approximately 70-80% of HCV patients develop chronic hepatitis, 20-30% of which progress to liver cirrhosis[1]. At present, there is no vaccine available to prevent HCV infection, and current therapies are not optimal. The initial steps of HCV infection (binding and entry) that are critical for tissue tropism, and hence pathogenesis, are poorly understood. Studies to elucidate this process have been hampered by the lack of robust cell culture systems or convenient small animal models that can support HCV infection. HCV is an enveloped, positive-strand RNA virus that belongs to the *Flaviviridae* family. Based on the sequence heterogeneity of the genome, HCV is classified into six major genotypes and 100 subtypes[1]. The viral genome (~9.6 kb) is translated into a single polyprotein of ~3 000 amino acids (aa). A combination of host and viral proteases are involved in polyprotein processing to give at least nine different proteins[2]. The structural proteins of HCV are believed to comprise the core protein (~21 kDa) and two envelope glycoproteins: E1 (~31 kDa) and E2 (~70 kDa). Like other enveloped viruses, E1 and E2 proteins are most likely play a pivotal role in HCV life cycle: in the assembly of infectious particles and in the initiation of viral infection by binding to its cellular receptor(s). Since hepatocytes represent the

primary site of HCV replication *in vivo*, the HCV genome has also been found in lymphoid cells. Infection of the lymphoid cells has been implicated in extrahepatic manifestations of HCV infection such as mixed cryoglobulinemia and B-lymphocyte proliferative disorders[3-5]. Virus-cell interaction is a multistep process and frequently involves more than a single receptor. There are, at least, three ways employed by virus to bind its target cells. First, virus can harbor two receptor-binding sites that allow binding to alternative receptors expressed on different cell types (e.g., adenovirus type 37)[6]. Second, virus can bind to a "common" surface molecule that captures and concentrates virus at the cell surface, and this event is followed by binding to a high-affinity primary receptor (e.g., herpes simplex virus)[7]. Third, virus binds to a high-affinity receptor, and this event induces conformational changes leading to the exposure of binding sites for a co-receptor (e.g., HIV type 1)[8,9]. So far, little is known about which mechanism is adopted by HCV to bind and enter target cells. The association of CD81 and the LDL-R with E2 protein or HCV virion, respectively, have led to the assumption that either one may represent the cellular receptor for HCV[10-12]. Despite several reports demonstrating the E2 binding to CD81[13,14], the interaction between HCV virion with this molecule is less clear. CD81 molecule only inhibited the binding of truncated E2 protein, but not HCV virion, to Molt-4 cells[15], suggesting that the HCV virion may use other receptor(s) for entry into cells. Also, Triyanti *et al*.[16], demonstrated that HCV-LPs can be used as a valuable tool to study the mechanism of binding and entry of HCV infection. Further characterization of HCV-LP and its interaction with cells will help us understand the early steps of HCV infection and will facilitate studies to identify other candidate receptor(s) for HCV. In the present study, we aimed to use in-house polyclonal antibodies against HCV peptides from core and envelope regions for the detection of surface and intracellular HCV antigens in PBMCs infected with HCV type 4 positive serum, based on direct and indirect immunofluorescence labeling followed by flow cytometric analysis.

MATERIALS AND METHODS

Infected serum samples

For infection experiments, we utilized serum samples positive for HCV RNA as determined by nested RT-PCR and genotyped as genotype 4 using the method described by Ohno *et al*.[17].

Infection of peripheral blood with HCV type 4

Whole blood cells were obtained from a healthy volunteer (only a single subject was used for the sake of fixing the host factor throughout the experiment). Serum from this blood sample was tested negative for HCV RNA by using a standard nested RT-PCR. Whole blood was incubated at 37 ℃ for 1, 24 and 48 h with a serum sample that tested positive for HCV RNA (viral loads: 9 million copies/mL, G4 HCV RNA) at a ratio of 20 μL serum to 110 μL whole blood). After incubation, blood cells were thoroughly washed four times with PBS. Detection of HCV RNA strands in peripheral blood cells will be described later.

Design of HCV synthetic peptides

Sequence analysis of HCV quasispecies in local patients (results not shown) revealed several conserved regions within the core and the E1 proteins. We designed four synthetic-core-specific peptides and a E1-specific peptide, and results showed that all peptides detect HCV antibodies in infected sera to varying degrees. The relative sensitivities and specificities of these synthetic peptides in detecting circulating HCV antibodies in infected human sera were described[18]. In the present study, we raised HCV-specific polyclonal antibodies against two core peptides anti-C1 (DVKFPGGGQIVGGVYLLPRR), anti-C2 (IPKA-RRPEGRTWAQPGY) as well as a E1 peptide (anti-E1, GHRMAWDMM).

Production of polyclonal antibodies against core and envelope regions of HCV

New Zealand rabbits (2 rabbits per each peptide and 2 per control, injected only with KLH) were immunized independently with purified synthetic peptides coupled with KLH protein. Equal volume of diluted core 1 (C1), core 2 (C2) and E1 synthetic peptides and Freund's complete adjuvant were emulsified and injected subcutaneously into the rabbits in three different sites. On d 15 and 28, the rabbits were immunized again with the same protein emulsified with incomplete Freund's adjuvant. On d 32, the rabbits were killed and sera were separated and stored at -20 ℃. For direct immunofluorescence, immunized polyclonal antibodies were digested with pepsin A (porcine 1∶60 000 grade (sigma P-7012), St. Louis, MO, USA) at acidic pH and the $F(ab)_2$ portion was labeled with fluorescence isothiocyanate (FITC) according to Hudson and Hay[19].

Surface and intracellular staining of infected peripheral blood cells and flow cytometric analysis

After incubation of normal blood cells with HCV-infected serum positive for blood cells, they were washed four times with phosphate-buffered saline (PBS). Surface labeling was performed by direct and indirect immunofluorescence. Primary polyclonal antibodies (C1, C2 and E1) were incubated with cells for 30 min at 4 ℃. RBCs were ruptured by lysis buffer (83% ammonium chloride). Cells were centrifuged and supernatants were removed. Cell pellets were washed twice with PBS containing 1% normal goat serum, then incubated with anti-rabbit IgG labeled with FITC (1∶100 dilution, Sigma, St. Louis, MO, USA) for 30 min. Cells were washed once more, resuspended in PBS and kept at 4 ℃ until flow cytometric analysis. For intracellular staining, cells were incubated with 4% paraformaldehyde for 10 min and 0.1% Triton X-100 in Tris buffer (pH 7.4) for 6 min. After washing with PBS, cells were incubated with FITC-labeled $F(ab)_2$ portion of HCV core antibody (at 1∶2 000 dilution) for 30 min at 4 ℃. Cells were washed thrice with PBS containing 1% normal goat serum and cells were suspended in 500 μL and analyzed.

Isolation of PBMC and extraction of RNA

Infected peripheral blood cells were isolated, as reported by Lohr *et al*.[20]. Briefly, peripheral blood samples were

diluted with 5 volumes of a freshly prepared RBC lysis buffer (38.8 mmol/L NH_4Cl, 2.5 mmol/L K_2HCO_3, 1 mmol/L EDTA, pH 8.0), incubated at room temperature for 10 min and the nucleated cells were precipitated and washed in the same buffer to remove adherent viral particles before lysis in 4 mol/L guanidinium isothiocyanate containing 25 mmol/L sodium citrate, 0.5% sarcosyl and 0.1 mol/L β-mercaptoethanol. Cellular RNA was extracted using the single-step method described originally by Chomczynski and Sacchi[21].

PCR of genomic and anti-genomic RNA strands of HCV

Reverse transcription-nested PCR was carried out according to Lohr *et al*.[20], with few modifications. Retrotranscription was performed in 25 μL reaction mixture containing 20 U of AMV reverse transcriptase (Clontech, USA) with either 400 ng of total PBMCs RNA or 3 μL of purified RNA from serum samples as template, 40 U of RNAsin (Clontech, USA), a final concentration of 0.2 mmol/L from each dNTP (Promega, Madison, WI, USA) and 50 pmoL of the reverse primer 1CH (for plus strand) or 50 pmol of the forward primer 2CH (for minus strand). The reaction was incubated at 42 ℃ for 60 min and denatured at 98 ℃ for 10 min. Amplification of the highly conserved 5'-UTR sequences was done using two rounds of PCR with two pairs of nested primers. First round amplification was done in 50 μL reaction mixture, containing 50 pmol from each of 2CH forward primer and P2 reverse primer and P2 reverse primer, 0.2 mmol/L from each dNTP, 10 μL from RT reaction mixture as template and 2 U of Taq DNA polymerase (Promega, USA) in a 1× buffer supplied with the enzyme. The thermal cycling protocol was as follows: 1 min at 94 ℃, 1 min at 55 ℃ and 1 min at 72 ℃ for 30 cycles. The second round amplification was done similar to the first round, except for use of the nested reverse primer D2 and forward primer F2 at 50 pmol each. A fragment of 179 bp was identified in positive samples. Primer sequences were as follows:

1CH: 5'-ggtgcacggtctacgagacctc-3'
2CH: 5'-aactactgtcttcacgcagaa-3'
P2: 5'-tgctcatggtgcacggtcta-3'
D2: 5'-actcggctagcagtctcgcg-3'
F2: 5'-gtgcagcctccaggaccc-3'

To control false detection of negative-strand HCV RNA and known variations in PCR efficiency[22,23], specific control assays and rigorous standardization of the reaction were employed. Specific control assays were included: (1) cDNA synthesis without RNA templates to exclude product contamination; (2) cDNA synthesis without RTase to exclude Taq polymerase RTase activity; (3) cDNA synthesis and PCR step done with only the reverse or forward primer to confirm no contamination from mixed primers. These controls were consistently negative. In addition, cDNA synthesis was carried out using only one primer present followed by heat inactivation of RTase activity at 95 ℃ for 1 h, in an attempt to diminish false detection of negative-strand prior to the addition of the second primer.

RESULTS

Surface detection of HCV antigens by flow cytometry on infected blood leukocytes

The borders of the respective cell regions of lymphocytes, monocytes and granulocytes were clearly defined on the cytograms of flow cytometry based on the size and the granularity of cells (Figure 1). Using control healthy blood, no immunostained positive cells were found using any of the polyclonal antibodies (C1 or C 2 and anti-E1) compared with normal rabbit serum. After 1 h of incubation at 37 ℃ with HCV positive serum, indirect immunofluorescence-labeled anti-E1, antibody demonstrated positive staining in 9%, 73% and 1-2% of lymphocytes, monocytes and granulocyte respectively. Anti-C1 demonstrated positive staining in 10%, 27%, and 1% of lymphocytes, monocytes and granulocyte respectively. Staining with anti-C2 showed positive cells in 5%, 26% and 1% of lymphocytes, monocytes, and granulocyte respectively (Table 1 and Figure 1). Interestingly, after 24 h of incubation with HCV positive serum, no detectable viral antigens were demonstrated on the surface of any cell type.

Intracellular staining with direct immunofluorescence

Direct immunostaining of total peripheral mononuclear cells using FITC-F(ab)$_2$ portion of anti C2 antibody could not

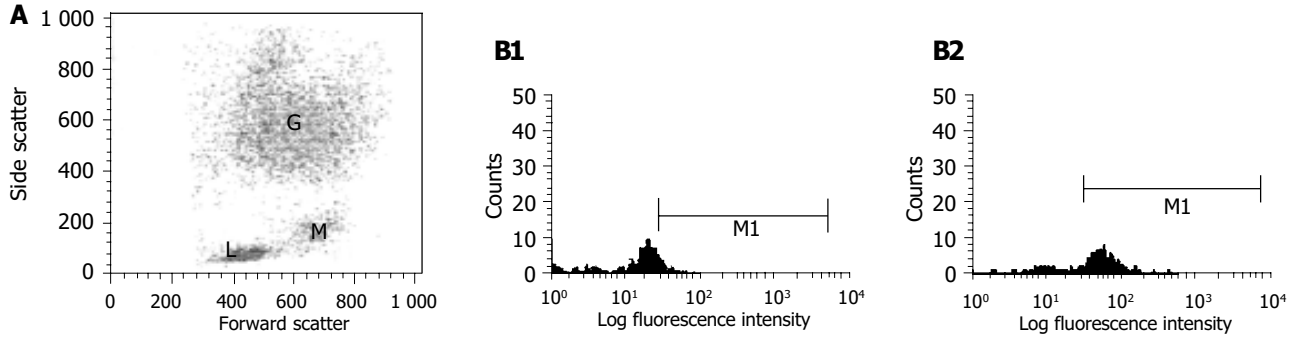

Figure 1 The borders of the respective cell regions of lymphocytes (L), monocytes (M) and granulocytes (G) were clearly defined on the cytograms of flow cytometry based on the size and the granularity (*x*-axis, forward scattered cells and *y*-axis, side scattered cells of cells after surface immunostaining) (**A**); Histograms from gated monocytes obtained from fluorescent activated cell sorter analysis of HCV-infected peripheral blood mononuclear leukocytes. Cells were stained with anti-E1 antibody against HCV E1 region. Histograms represent gated monocytes from (**B_1**) infected cells stained with normal rabbit serum as control or (**B_2**) infected cells stained with antibody against E1 after incubation of blood with serum sample after 1 h at 37 ℃ in which *x*-axis represents fluorescence intensity. M1 is marker for positive cell population.

detect intracellular viral antigens after 1 h of incubation with HCV-positive serum. However, after 24 h of incubation, 28% of infected cells stained positive for viral core antigen (Figure 2).

Cells were stained intracellularly with anti-C2 antibody conjugated with FITC. Histogram represents gated leukocytes from (**A**) healthy uninfected cells or (**B**) infected cells stained with anti-C2 antibody conjugated with FITC after incubation of blood with serum sample after 24 h at 37 ℃ in which *x*-axis represents fluorescence intensity. M1 is marker for positive cell population.

RT-PCR for minus and plus RNA strand of HCV RNA in PBMCs

The genomic plus (+) strand was weakly detectable in PBMCs after 1 h of incubation, whereas antigenomic (-) strand was undetectable. After 24 and 48 h of incubation, both strands were detectable with stronger signal of the anti-genomic (-) strand (Figure 3).

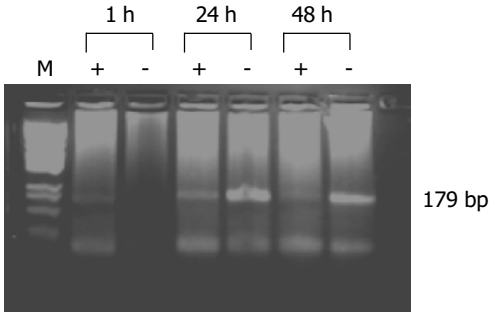

Figure 3 Analysis of HCV RNA plus strand and minus strand from infected PBMC. PCR amplification products of the genomic strand (+) and the replicative strand (-) of HCV from total cellular RNA of PBMC infected with HCV for 1, 24 and 48 h. Lane M represents the M.W. marker PGem.

DISCUSSION

Extrahepatic HCV replication has long been a controversial topic, since the finding of the high rate of re-infection of grafts after orthotopic liver transplantation in patients with the end-stage HCV-induced liver diseases. However, whether PBMCs are supportive for HCV replication is still uncertain. The detection of the minus strand HCV RNA is thought to be a reasonable marker for HCV replication, because the minus RNA strand is the replicative intermediate of HCV. In past decade, several reports on the detection of HCV RNA in PBMCs have been published[24-26]. Gribier *et al*.[27], incubated PBMCs from healthy donors with HCV positive sera, and detected HCV RNA plus and minus strands using RT-PCR and *in situ* hybridization. Results of Gong *et al*.[28], showed that HCV is capable of infecting and replicating in PBMCs, and HCV NS5 protein was clearly expressed in these cells. On a previous study by El-Awady *et al*.[29], we utilized PBMCs as a cellular component to assess viral replication in chronic HCV patients. This study demonstrated higher sensitivity of concomitant PCR amplification of plus and minus strands in PBMCs together with plus strand in serum samples over the traditional amplification of viral RNA in serum. Later, we employed this apparent intracellular amplification in PBMCs as a predictor for treatment relapse after interferon therapy[30]. After 1 h of incubation, in the present study, only plus RNA strand of the virus was weakly detectable. When incubation with positive serum was extended for 24 and 48 h, both plus and minus RNA strands have become strongly detectable (Figure 3). Flow cytometry is advantageous over RT-PCR in its ability to count directly the rate of infection into the cells. Furthermore, it is more specific than traditional immunocytochemical analyses via its ability to quantify the intensity of fluorescence per cell, thus facilitating clear distinction between specific and non-specific immunofluorescence. A greater number of cells are allowed to be counted, which is very important while considering that *in vitro* viral infections are variable biological phenomena. This gives us the possibility of testing several replicates simultaneously and elevating the accuracy in statistical analysis. In case of cells that are relatively less susceptible, such as PBML, it is desired to count large number of cells to obtain a significant number of positives, turning manual counting very laborious. Therefore, in our case, to gain a better understanding of the cell-specific tropism of HCV, we designed the experiments to detect HCV antigen on blood leukocyte subsets, lymphocytes, monocytes and granulocytes. Simultaneously, we planned to evaluate the usefulness of specific polyclonal anti-sera raised against synthetic core and envelope HCV peptides made from conserved sequences among several HCV isolates[18]. In a parallel investigation, the antibodies currently used

Table 1 Percentage of positive cells after 1-h incubation of peripheral blood with serum positive for HCV RNA

Antibody	Lymphocytes percentage of positive cells	Monocytes percentage of positive cells	Granulocytes percentage of positive cells
E1	5	73	1
C1	10	27	2
C2	9	26	3

Positive cells were determined by indirect immunofluorescence and flow cytometric analysis.

demonstrated 100% sensitivity and 100% specificity in detecting circulating viral antigens in HCV RNA-positive and HCV RNA-negative subjects, respectively (data not shown). Results presented here revealed that about 73% of infected monocytes were immunostained positive for envelope antigen. A well-defined HCV positive population in infected peripheral blood leukocytes showed that the monocytes are the preferred target for HCV. However, the results of previous studies have been conflicting; several investigators have reported inconsistent presence of HCV in B and T lymphocytes[26,31]. However, flow cytometry using specific monoclonal antibody could detect the presence of HCV core antigen that was demonstrated in monocytes but not in lymphocytes[32]. These reports demonstrated the presence of HCV RNA which was detected in peripheral blood mononuclear cells (PBMC) by PCR in 17 of 24 HCV-infected patients with chronic hepatitis with or without cirrhosis. In 29% of patients whose PBMC contained HCV RNA, flow cytometry with a murine monoclonal antibody to HCV core epitopes revealed cytoplasmic staining of peripheral blood monocytes, whereas cell surface of monocytes and lymphocytes did not stain for HCV core epitopes. The discrepancy between the current results and those of Bouffard *et al*.[32], may be related to either the difference between *in vivo* and *in vitro* infection of PBMCs or to the degree of the antibody specificity. In the present study, HCV tropism in peripheral leukocytes is not only limited to polymorphonuclear leukocytes, since granulocytes were also shown to stain positive with HCV antibodies after short incubation with positive sera. Since minus RNA strand of the HCV can hardly be detected in infected serum, its detection in PBMCs can be taken as a molecular indicator of intracellular genomic replication of HCV and ruling out false positive, due to contamination of cellular preparations with infected sera. In acute HCV infection, HCV RNA minus strand is rare in PBMCs, but in the chronic group, the minus strand HCV RNA is common in the PBMCs (14 of 35, 40%), which is similar to what Chang *et al*.[33], reported. The ratio of HCV RNA minus strand detected in chronic hepatitis C is much higher than that in acute hepatitis C, suggesting that the replication of HCV in PBMCs may play an important role in the processes of chronicity, and the mechanism could be that HCV in PBMCs escapes from host immunity, and makes the infection of HCV persistent. On one hand, the dysfunction of the HCV-infected PBMCs leads to immune function decline and this becomes more difficult for the host to clear intrahepatic HCV[34]. On the other hand, some authors are still arguing that the minus strand HCV RNA in the blood cells including PBMC may be artifacts from contamination or passive absorption by circulating virus[11] or self-priming/mis-priming during PCR reaction[35,36]. For this reason, the expression of HCV-related proteins in extrahepatic cells has become the key point for demonstrating intracellular HCV replication. HCV was repeatedly reported to replicate and express structural and non-structural proteins, primarily in PBMC[28,37,38]. In the present study, we utilized the combined results of nested RT-PCR of plus and minus RNA strands coupled with core and E1 protein expression to follow steps of viral binding, entry, replication and protein expression in human PBMCs. The detection of E1 and core antigens on cell surface as early as 1 h of incubation with virus, followed by disappearance of viral antigens after 24 h, suggests that viral entrance into cells occurs within 24 h. The concomitant intracellular appearance of E1 and core antigens suggests that binding, entry and expression of structural proteins occurs within 24 h. At the level of genomic replication, failure of minus strand detection after 1 h, followed by strong detection after 24 h supports the hypothesis that processing of HCV polyprotein and release of viral antigens with subsequent acceleration of genomic replication of viral RNA occurs within the first 24 h of infection. In conclusion, we suggest that the present method for detection of E1 and core antigens is useful in monitoring of HCV life cycle and can contribute to analysis of HCV infection more precisely. Therefore, the study of virus-host cell interaction may lead to interesting and probably non-expected concepts of HCV pathology.

Abstract

AIM: To evaluate our experience in endoscopic retrograde cholangio-pancreatography (ERCP) in terms of fulfilling the ASGE guidelines in indications, positive findings, and complications in the post-magnetic resonance cholangiopancreatography (MRCP) era.

METHODS: Between November 2001 and February 2003, consecutive ERCP cases were prospectively evaluated with regard to the indications, findings, cannulation techniques, devices used during the procedure, sedation given, duration of procedure, and complications. These data were entered in a database for subsequent processing and analysis.

RESULTS: Of 336 cases, 21.4% were diagnostic and 78.6% therapeutic ERCP. The indications for ERCP fulfilled the ASGE guidelines in 323 cases (96.1%). Suspected bile duct stone was the most frequent indication (26.8%), and this was followed by cholangitis (24.4%), dilated common bile duct (14.9%), and cholestatic jaundice (13.4%). Cannulation success rate was 94%. Biliary sphincterotomy was performed in 175 (52.1%) patients. Repeated ERCP was performed on 31.5% of the patients. Overall, the complication rate was 9.8% with 0.3% being procedure-related mortality. The complications were pancreatitis (5.4%), bleeding (0.8%), cholangitis (2.4%) and others (1.5%). No significant difference was observed between the complication rate and the type of ERCP performed.

CONCLUSION: Our study showed that post-ERCP complication rate was comparable with the other large prospective studies and there was no difference in the complication between the diagnostic and therapeutic ERCP.

INTRODUCTION

Endoscopic retrograde cholangio-pancreatography (ERCP) is the most complex endoscopic procedure. It is the preferred treatment for the majority of pancreatico-biliary diseases. Since its introduction in 1968[1], ERCP has evolved from a purely diagnostic to a therapeutic procedure because noninvasive imaging techniques such as magnetic resonance cholangio-pancreatography (MRCP) is increasingly being used for the diagnosis of conditions, otherwise previously diagnosed only by ERCP. Endobiliary sphincterotomy (ES) has become a common procedure in the era of endoscopic management of biliary and pancreatic diseases. However, these procedures carry certain mortality and morbidity[2-5] with acute pancreatitis, being the most common complication. The purpose of this study was to evaluate our experience in ERCP in terms of fulfilling acceptable ASGE guidelines[6] in indications, positive findings, and complications in the post-MRCP era.

MATERIALS AND METHODS

Study population

A prospective study was conducted at the National University Hospital, Singapore from November 2001 to February 2003. A total of 336 consecutive ERCPs were performed during the study period. All patients signed an informed consent for the procedures, after receiving an explanation on the risks, benefits and alternatives of ERCP and associated therapeutic procedures. Patients were given topical pharyngeal spray with 10% lignocaine spray, and sedated with midazolam and pethidine or fentanyl. All procedures were performed by Olympus duodenoscope JF200 or JF 240. Prophylactic antibiotics were routinely given to all patients.

Data on patients' characteristics, ERCP indications and findings, cannulation techniques, devices used during the procedure, sedation given, duration of procedure and complications were collected prospectively during the procedure, recovery period and hospitalization. These data were entered in a database for subsequent processing and analysis.

ERCP complications

Post-ERCP complications were defined as any adverse effect

related to the ERCP that prolonged hospitalization or required readmission for previously discharged patients. The complications were defined according to the previously published criteria[6]. Acute pancreatitis was defined as a new onset of abdominal pain with a rise in the level of amylase at least three times the upper limit of normal at more than 24 h after the procedure, requiring more than one night of hospitalization. Bleeding was defined as a clinical evidence of hemorrhage with decrease in hemoglobin greater than 2 g/dL or the need for a blood transfusion. Cholangitis was defined as a fever greater than 38 ℃ for more than 24 h that was thought to have biliary causes. Additional procedure-interrupting events such as hypoxia (decrease in oxygen saturation to below 90% for 2 min), duodenal tear and bradycardia (decrease in heart rate to less than 50 beats per minute for 2 min) were considered as post-ERCP complications. Any intensive care unit admission after procedure was graded as a severe complication.

ERCP was defined as therapeutic, where endoscopic sphincterotomy, precut, drainage, stricture dilatation, stent exchange, sphincter of Oddi manometry or biliary stone removal had been performed singularly or in combination.

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Science (SPSS) version 10.0[9]. Comparison of diagnostic and therapeutic ERCP complications were evaluated using the χ^2- or Fisher's exact test. All tests of significance were two-tailed and a *P* value <0.05 was considered significant.

RESULTS

A total of 336 ERCPs were performed during the study period. Median age of the patients was 65 years (range 17-93 years). There were an equal number of males and females (167 men and 169 women). The ethnic distribution was Chinese in 78.3%, Malay in 11.3%, Indian in 5.7% and others in 4.8%. Indications of ERCP were suspected choledocholithiasis (26.8%), cholangitis (24.4%), dilated common bile duct (14.9%), cholestatic jaundice (13.4%), gallstone pancreatitis (7.7%), stent-related problems (6.3%) and others (6.5%, Figure 1). These indications fulfilled ASGE guidelines in 323 (96.1%) patients.

One hundred and seventy-three (51.5%) patients had co-morbidity such as diabetes mellitus with renal impairment, ischemic heart disease, heart failure, old stroke, atrial fibrillation, chronic renal failure and others. Twenty-seven (8%) patients were on anticoagulation or antiplatelet drugs for their underlying diseases. Anesthetist assistance (general anesthesia) was required in 8 patients (2.4%), whereas the endoscopic team assisted in sedation for all the remaining patients. Midazolam (dose 0.5-10 mg) was used in 97.6%, pethidine (dose 7-125 mg) in 97% and fentanyl (dose 20-75 μg) in 0.6% of all patients. Prophylactic antibiotics were routinely given to all patients.

ERCP failed in 20 patients (6%) because of unsuccessful cannulation and/or suboptimal ductal opacification whereas in 21 patients (6.3%), only shallow cannulation was achieved preventing further therapeutic procedure. Successful cannulation of the desired duct was obtained in 295 patients (87.7%).

Biliary sphincterotomy was performed in 175 patients (52.1%). Indications for sphincterotomy were common bile duct stones in 119 cases (68%), suspected passed biliary stone in 27 (15.4%), and biliary drainage in 11 (6.3%). Overall, therapeutic procedures were performed in 264 patients (78.6%). Sphincterotomy was the most common therapeutic procedure (66.5%) and this was followed by stenting (33.3%) and stone extraction (27.7%). Sphincter of Oddi manometry was performed in two (0.6%) patients (Table 1).

Of 336 patients undergoing ERCP, 33 complications (9.8%) were reported (Table 2). Eighteen cases were immediate and 16 cases were delayed complications. Post-ERCP pancreatitis was the most frequent complication and occurred in 18 patients (5.4%). Pancreatitis was mild in 15 patients (4.5%), moderate in 2 patients (0.6%) and severe in 1 patient (0.3%). Bleeding occurred in three patients (0.8%); two bled immediately after sphincterotomy (mild hemorrhage) and one had delayed hemorrhage (moderate hemorrhage), after dilatation and biopsy of malignant biliary stricture. All three of them were successfully treated with endoscopic therapy and only one required blood transfusion. Cholangitis occurred in eight patients (2.4%); mild cholangitis in four patients, moderate in three patients and severe in one patient. The cholangitis occurred after plastic stenting for biliary stricture or stones in three patients, after biliary stone extraction in another three, after biopsy of biliary stricture in one, and after diagnostic ERCP in the other. One patient had a duodenal tear (0.3%) sustained during intubation of a Bilroth 2 anatomy, one (0.3%) developed choledocho-duodenal fistula due to forceful cannulation, one (0.3%) had subcapsular liver perforation due to vigorous biliary stenting, one (0.3%) desaturated during the procedure, and one (0.3%) developed bradycardia. These patients were treated conservatively and recovered well with no ill sequelae. Six (1.8%) patients died within 1 mo of the procedure, but only one was deemed procedure-related (0.3%). This post-ERCP death was due to severe cholangitis 2 d after sphincterotomy and stone extraction for biliary stones. Four died of underlying severe cholangitis on presentation and one died of cardiac arrest 8 d after the procedure. No significant difference was observed between the complication rate and the type of ERCP performed (Table 2).

Table 1 Therapeutic procedure in 264 patients

Type of procedure	*n*	%
Sphincterotomy alone	40	11.9
Sphincterotomy+stone extraction	86	25.6
Sphincterotomy+biliary stenting	42	12.5
Stricture dilatation±sphincterotomy	3	0.9
Nasobiliary drainage±sphincterotomy	2	0.6
Biliary stenting/stent removal alone	73	21.7
Stone extraction alone	7	2.1
Dilatation and stenting	5	1.5
SOD manometry	2	0.6
Biopsy/cytology	4	1.2

Table 2 Major complications in 336 patients: comparison between diagnostic and therapeutic ERCP

Complication	Diagnostic ERCP *n* = 72 (%)	Therapeutic ERCP *n* = 264 (%)	*P*
Pancreatitis	5 (6.9)	13 (4.9)	0.50
Cholangitis	1 (1.4)	8 (3)	0.53
Hemorrhage	0	3 (1.1)	0.36
Other complications	2 (2.8)	3 (1.1)	0.31
Total	8 (11.1)	26 (9.8)	0.68

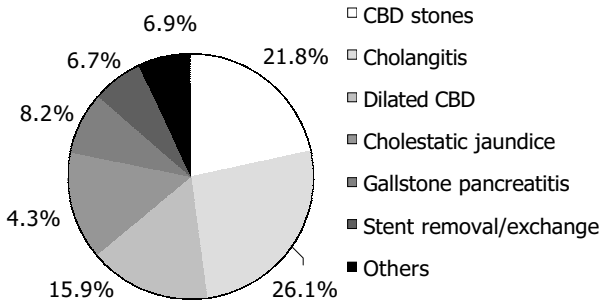

Figure 1 Indication of ERCP.

DISCUSSION

In recent years, ERCP had evolved from a purely diagnostic to a therapeutic procedure with the introduction of non-invasive investigative tools such as MRCP. Most of the ERCP procedures in the present series, were therapeutic (78.6%) compared to earlier studies[7-9] in which therapeutic ERCP only comprised 40-55% of the total number of procedures. The post-ERCP complication rate in the present series was no different compared to other studies[9-13]. The overall complication rate was 9.8%. There was no significant difference in the complication rate between diagnostic and therapeutic ERCP. This finding is consistent with that of a retrospective US survey by Male *et al*.[14], but was in contrast with those from a British survey[15] and an Italian study[16] in which therapeutic ERCP was associated with three- to four-fold higher complication rates.

The reported incidences of post-ERCP pancreatitis ranged 0-40%[17] but were commonly quoted as 2-7%[10,18,19]. The variation is likely due to the difference in definition of pancreatitis, method of data collection and indications for ERCP. In the present study, acute pancreatitis was the most common complication (5.4% of patients) and most cases were mild. This finding is comparable with those of two recently published large prospective studies by Freeman *et al*.[10], and Loperfido *et al*.[16]. In the former study, which only considered therapeutic procedure, the overall complication rate was 9.8%. Procedure-related pancreatitis occurred in 5.4% of patients; mild in 2.3%, moderate in 2.8% and severe in 0.4%. In the latter survey which also included diagnostic procedure (one-third of procedures), reported major complication rate was 4%, and pancreatitis (moderate and severe only) occurred in 1.3%. The risk of pancreatitis was similar for diagnostic and therapeutic ERCP in our study. This is similar to the finding from a prospective study from Boston[9] even though some studies[20,21] reported higher pancreatitis complication rates in therapeutic ERCP. Risk factors of procedure-related pancreatitis identified were factors related to patients' characteristics such as younger age[10,16,22], suspected dysfunction of sphincter of Oddi[10], history of ERCP-related pancreatitis[9], recurrent pancreatitis[9] and factors related to endoscopic technique such as pancreatic duct opacification[16,19], small bile duct[16,23], multiple cannulation attempt[9] or difficult cannulation[10], development of abdominal pain during the procedure[9], precut sphincterotomy[10,22] and pancreatic duct brushing for cytology[9]. ERCP-induced pancreatitis remains an important clinical problem even in diagnostic ERCP.

Incidence of post-ERCP hemorrhage varies between 0.65% and 4% in earlier retrospective studies[24,25]. In our study, procedure-related hemorrhage was only 0.8%. This low figure is similar to those from a few large prospective studies[9,10,16,22]. Cholangitis is an uncommon complication in ERCP, ranged 0.5-1.1%[9,10,16,22]. However, cholangitis seems to be slightly higher (2.3%) in our study, even though routine antibiotics were given before starting the procedure. Three patients with cholangitis had stent migration after plastic stenting for biliary stricture or stones (one required repeat ERCP), three had cholangitis after biliary stone extraction (one had incomplete stone removal and required the ERCP repeat for stones clearance and one who had severe cholangitis subsequently died), one developed cholangitis after biopsy of biliary stricture and one after diagnostic ERCP. Most of the patients with cholangitis resolved after one course of antibiotics.

Our study showed that post-ERCP complication rate was comparable with those of other large prospective studies and there was no difference in the complication rates between the diagnostic and therapeutic ERCP. In line with the current post-MRCP, most of our ERCPs were therapeutic (78.6%). Future research should focus on developing clinical pathways to guide clinicians in selecting patients who should undergo ERCP or MRCP as the initial investigation and those who would benefit from MRCP followed by ERCP.

Abstract

AIM: To determine whether -238G/A and -857C/T polymorphisms of tumor necrosis factor-alpha (TNF-α), gene promoter and hepatitis B (HB) viral genotypes were associated with outcomes of HBV infection.

METHODS: A total of 244 HBV self-limited infected subjects, 208 asymptomatic carriers, and 443 chronic HB patients were recruited to conduct a case-control study. TNF-α -238G/A and -857C/T gene promoter polymorphisms were examined by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP), and HBV genotypes were examined by nested PCR.

RESULTS: The positive rate of HBV DNA in asymptomatic carrier group and chronic HB group was 46.6% and 49.9%, respectively. HBV genotype proportion among the asymptomatic carriers was 2.1% for genotype A, 25.8% for genotype B, 68.0% for genotype C, and 4.1% for genotype B+C mixed infection, and 0.9% for genotype A, 21.7% for genotype B, 71.5% for genotype C, 5.9% for genotype B+C mixed infection in chronic HB group. There was no significant difference in genotype distribution between the asymptomatic carrier group and chronic HB group ($\chi^2 = 1.66$, $P = 0.647$). The frequency of -238GG genotype in self-limited group was 95.1%, significantly higher than 90.7% in chronic HB group and 89.0% in asymptomatic carrier group ($P = 0.041$ and $P = 0.016$, respectively).The frequency of TNF-α-857 CC in chronic HB group was 79.7%, significantly higher than 64.4% in asymptomatic carrier group and 70.9% in self-limited group ($P<0.001$ and $P = 0.023$, respectively). A multiple logistic regression analysis revealed that TNF-α-238GA and -857CC were independently associated with chronic HB after gender and age were adjusted.

CONCLUSION: TNF-α promoter variants are likely to play a substantial role in the outcome of HBV infection.

INTRODUCTION

It is estimated that HBV has infected more than 350 million people worldwide. HBV infection causes various clinical outcomes in patients. Ninety to ninety-five percent of adults infected with HBV can eliminate the virus and only 5-10% of them become chronic HBV carriers; 20-30% of chronic HBV carriers develop chronic hepatitis B (HB) and 5% of them develop liver cirrhosis and hepatocellular carcinoma in a long term of disease course. HB has become one of the severe public health problems.

The outcome of HBV infection may be associated with host genetic factors. Cytokines play an important role in defense against viral infection, indirectly through determination of the predominant pattern of the host response, and directly through inhibition of viral replication[1]. TNF-α is one of the important cytokines involved in noncytotoxic antiviral mechanism, and participates in the viral clearance and the host immune response to HBV[2]. It was found that individuals with acute HB have higher TNF-α plasma levels than controls[3]. The capacity for the cytokine production in individuals largely depends on promoter genetic polymorphisms[4]. At present, few studies corresponding to these results are reported in China.

The outcome of HBV infection is also associated with the genetic variability of virus, which influences the expression of viral antigens. In recent years, HBV genotypes A, B, C, and D have been reported in China, and genotypes B and C are the predominant genotypes[5].

In this case-control study, we analyzed TNF-α -238G/A and -857C/T promoter genetic polymorphisms among self-limited group, asymptomatic carrier group and chronic HB group, and HBV genotypes in asymptomatic carrier group and chronic HB group to elucidate whether host genetic and viral factors were associated with the outcome of HBV infection.

MATERIALS AND METHODS

Subjects

From November 2002 to March 2004, 244 self-limited HBV-infected subjects, 208 asymptomatic carriers, and 443 chronic HB patients were recruited at Beijing You'an Hospital. The diagnostic criteria used for three groups of subjects were determined, according to the protection and treatment protocol for viral hepatitis amended by Infectious Disease Branch and Liver Disease Branch of Chinese Medical Association in September 2000, and the diagnostic criteria and treatment principle of viral HB published by National Technical Supervision Bureau and Ministry of Public Health in January 1996 (GB15990-1995). All subjects enrolled in this study provided the informed consent. All subjects were Chinese Han people and not infected with other viral hepatitis.

Serological test

ELISA was used for detection of serum HBsAg, anti-HBs, and anti-HBc (IMX, Abbott Diagnostics, North Chicago, IL, USA).

Measurement of TNF-α gene promoter polymorphism

Genomic DNA was extracted from peripheral blood leukocytes collected in EDTA by standard phenol-chloroform extraction. Allelic polymorphisms in the TNF-α gene promoter at positions -238G/A[6] and -857C/T[7,8] were amplified into 152- and 131-bp fragments by PCR with the primers (for 152-bp fragment, sense 5'AGAAGACCCCCCTCGGAACC3' and antis-ense 5'ATCTGGAGGAAGCGGTAGTG3'; for 131-bp fragment, sense 5'AAGTCGAGTATGGGGACCCCCCGTTAA3' and anti-sense 5'CCCCAGTGTGTGGCCATATCTTCTT3'). Amplifications of the -238 and -857 fragments were performed in a volume of 25 μL containing 50 ng of genomic DNA, 20 pmol/L of each primer, 200 μmol/L dNTP, 1.5 mmol/L $MgCl_2$, buffer and 1 U *Taq* polymerase (Shanghai Biocolor). PCR conditions of -238 were as follows: pre-denaturation at 94 ℃ for 2 min, 30 cycles of denaturation at 94 ℃ for 30 s, annealing at 60 ℃ for 30 s, extension at 72 ℃ for 30 s, and a single final extension at 72 ℃ for 10 min in Perkin Elmer thermocycler (2700, Applied Biosystems, Foster City, CA, USA). For amplification of -857 polymorphism, annealing temperature was at 64 ℃ and other thermal cycling parameters were as the same as those for amplification of -238.

The PCR products of -238 and -857 were digested with *Msp*I and *Hinc*II restriction enzymes respectively. TNF-α -238 allele 1 was identified by 20- and 132-bp fragments and allele 2 by a single 152-bp fragment. TNF-α -857 allele 1 was identified by 25- and 106-bp fragments and allele 2 by a single 131-bp fragment.

HBV genotyping

Sequence data for the amplified region of HBV DNA were aligned from GenBank. Alignment of the sequences was performed with Vector NTI suite and Tree View software.

According to the comparisons of HBV DNA sequences and other papers[9,10], outer primers and inner primers specific for HBV genotypes are summarized in Table 1.

HBV genotypes were determined by PCR. Nested PCR primers amplified HBV DNA with two stages (Table 1). The first-stage amplification was performed in a volume of 30 μL containing 5 μL of genomic DNA, 0.1 mol/L of primers Ps1 and Ps2, 200 μmol/L dNTP, 1.5 mmol/L $MgCl_2$, buffer and 1 U *Taq* polymerase (Shanghai Biocolor). The procedure of amplification was as follows: pre-denaturation at 94 ℃ for 3 min, 35 cycles of denaturation at 94 ℃ for 40 s, annealing at 55 ℃ for 40 s, extension at 72 ℃ for 45 s. Two microliters of PCR products were required in the second-stage amplification, which involved two groups. The primers contained 0.1 μmol/L B2, 0.08 μmol/L BA1R, BB1R, and BC1R in group A. In group B, the primers contained 0.1 μmol/L B2R, 0.08 μmol/L BD1, BE1, and BF1. Thermal cycling parameters involved 94 ℃ for 3 min, 20 cycles of 94 ℃ for 40 s, 58 ℃ for 40 s, and 72 ℃ for 40 s, and 20 cycles of 94 ℃ for 40 s, 60 ℃ for 40 s, and 72 ℃ for 40 s. PCR products of the amplification were illuminated using ultraviolet rays, after electrophoresis on 6% acrylamide gel stained by EB.

Statistical analysis

Comparisons were performed using one-way ANOVA and χ^2 test. SAS version 6.12 software package was used to analyze data. All P values were two-tailed, and $P<0.05$ was considered statistically significant. Haplotypic analysis was performed using EH2.0 program.

RESULTS

Characteristics of subjects

The average age of chronic HB patients, asymptomatic carriers, and self-limited subjects was 33.37±12.67, 31.2±10.78, and 34.68±11.34 years, respectively. A significant difference was found in age of the three groups ($F = 4.985$, df = 2, $P = 0.008$).

The ratio of male to female patients (354/89) in the chronic HB group was significantly higher than those (136/108 and 113/95) of the self-limited group and the asymptomatic carrier group ($P<0.01$).

Association of HBV genotypes with outcomes of HBV infection

The positive rate of HBV DNA in the asymptomatic carrier group and the chronic HB group was 46.6% and 49.9%, respectively (Table 2).

The proportions of subjects with HBV genotypesA, B, C and mixed genotype B+C among the asymptomatic carriers were 2.1%, 25.8%, 68.0% and 4.1%. Among the chronic HB patients, the proportion of HBV genotypes was 0.9% for genotype A, 21.7% for genotype B, 71.5% for genotype C, 5.9% for mixed genotypes B+C. The difference in genotype distribution between the asymptomatic carrier group and chronic HB group was statistically significant ($\chi^2 = 1.66$, $P = 0.647$) (Table3).

Table 2 Positive rate of HBV DNA in asymptomatic carrier group and chronic HB group

Group	*n*	HBV DNA positive (%)
Carrier	208	97 (46.6)
Chronic HB	443	221 (49.9)

Table 3 Proportions of HBV genotype in asymptomatic carrier group and chronic HB group

Group	*n*	A	B	C	B+C
Carrier group	97	2 (2.1)	25 (25.8)	66 (68.0)	4 (4.1)
Chronic HB group	221	2 (0.9)	48 (21.7)	158 (71.5)	13 (5.9)

$\chi^2 = 1.66$, df = 3, $P = 0.647$.

Association of TNF-α -238G/A and -857C/T genotypes with outcomes of HBV infection

The frequency of -238GG genotype in the self-limited group was 95.1%, significantly higher than 90.7% in the chronic HB group and 89.0% in the asymptomatic carrier group ($P = 0.041$ and $P = 0.016$), respectively. No significant difference was found between chronic HB and carrier groups ($P = 0.496$). The frequency of -238G allele in the self-limited group was 97.5%, significantly lower than that in the other two groups ($\chi^2 = 3.99$, $P = 0.046$). There was no significant difference in Hardy-Weinberg among the three groups ($\chi^2 = 0.155$, $P = 0.69$, Table 4).

The frequency of TNF-α -857CC in chronic HB group was 79.7%, significantly higher than 64.4% of carrier group and 70.9% of self-limited group ($P<0.001$ and $P = 0.023$), respectively. The frequency of -857C allele in chronic HB group was 87.6%, significantly higher than those of the two groups ($\chi^2 = 17.953$, $P<0.001$). There is no significant difference in Hardy-Weinberg among the three groups ($\chi^2 = 3.54$, $P = 0.059$, Table 5).

The results of haplotype analysis are summarized in Table 6. The frequency of haplotype -238G/-857 C in asymptomatic carrier group was lower than that in the self-limited group ($P = 0.035$) and that of carrier group ($P = 0.04$). Frequency of haplotype -238G/-857T in carrier group was higher than that of chronic HB group ($P = 0.030$, Table 6).

used to analyze the association of the outcome of HBV infection with sex, age, TNF-α promoter polymorphisms. The results showed that, after confounding effects of gender and age were adjusted, TNF-α -238GA and -857CC were independently associated with chronic HB compared to self-limited group and asymptomatic carrier group. TNF-α -238GA was associated with asymptomatic carrier compared to self-limited group (Table 7).

DISCUSSION

HBV has eight different genotypes (A-H) according to the homogeneity of the viral sequence[11]. HBV genotypes have distinct geographical distribution. The results of several studies[12,13] indicated that HBV genotypes B, C, and mixed genotype are prevalent in China, and genotypes B and C are the major genotypes. The results of our study are in agreement with the studies conducted in other areas of China[12,13].

Some studies[13] indicated that there is a significant difference in HBV genotype distribution in different places of China. It was reported that the proportion of genotype C in northern cities is higher than that of southern cities of China[13]. In addition, infection with mixed genotypes has also been found in China.

We also found that there was no statistically significant difference in genotype distribution between the asymptomatic carrier group and chronic HB group, But another study[14] reported that the proportion of genotype C in the chronic HB group was higher than in the asymptomatic carrier group. The results are similar to another study[14].

Our findings suggest that both genotypes TNF-α -238GA and -857CC are positively associated with chronic HB. The frequency of -238GA genotype in self-limited group was significantly lower than that in the chronic HB group and asymptomatic carrier group, which is consistent with that in Caucasian[6] and Korean[15] population. The frequency of TNF-α -857CC in the chronic HB group was significantly higher than that in the self-limited group, which is consistent with another study[2]. TNF-α can suppress expression and replication of HBV. *In vitro* recombinant TNF-α inhibits HBV replication through a post-translational mechanism that accelerates the degradation of HBV messenger RNA[16]. Furthermore, HBV core promoter element is sensitive to TNF-α[17].

The results of multiple logistic regression analysis indicate that TNF-α -238GA and -857CC are independently associated with chronic HB, after adjustment for sex and age. Males seem more likely to develop chronic HB. The mechanism underlying the association remains unclear, but viral replication is sensitive to sex hormones[18].

In conclusion, HBV genotypes may play an important role in the outcome of HBV infection, and TNF-α promoter genetic polymorphisms may play an important role in the development of HBV infection.

Abstract

AIM: To investigate the antitumor and synergistic effect of Chinese medicine "Bushen huayu jiedu recipe" (recipe for invigorating the kidney, removing blood stasis and toxic substances) and chemotherapy on mice hepatocarcinoma.

METHODS: Bushen huayu jiedu recipe (BSHYJDR) consisting of Chinese Cassia Bark, Psoralea, Zedoary, Rhubarb, *etc.* is equal to 1.5 g/mL liquid of originated herbs after being decocted, filtered, and concentrated. Kunming mice, weighing 18-22 g, were injected with 0.2 mL ascitic hepatocarcinoma H_{22} containing 1×10^7 cells/mL into armpit of the right forelimb of mice. After 24 h, the mice were weighed and randomly divided into tumor-bearing model control group, cisplatin (DDP) group, BSHYJDR high dosage group, low dosage BSHYJDR group, DDP combined with high and low dosage BSHYJDR group, 10 mice in each group. DDP group received injection intraperitoneally (ip) at the dosage of 1 mg/kg (equal to 1/10 LD_{50}), once a day for 4 d. High and low dosage BSHYJDR groups received intragastric BSHYJDR at the dosages of 26.6 and 13.3 g/kg (20 and 10 times each of clinical adult dosage) respectively, while tumor-bearing model group received the equal volume of distilled water once a day for 10 d. On the 11th d, the mice were weighed and killed, then the tumor was dissected and weighed, the repression rate (RR) was calculated according to the mean weight of tumor (MWT).

RESULTS: Compared to the model group (MWT: 1.30±0.73), DDP group (MWT: 0.41±0.09, RR: 68.46%) had a significant difference in the inhibition of hepatocarcinoma H_{22} ($P<0.01$). High dosage BSHYJDR group (MWT: 0.69±0.29, RR: 46.92%) also had a significant difference in inhibition ($P<0.05$), while no difference was found in low dosage BSHYJDR group (MWT: 0.85±0.34, RR: 34.62%) ($P>0.05$). When DDP was combined with high dosage BSHYJDR (MWT: 0.29±0.17, RR: 77.69%) and low dosage BSHYJDR (MWT: 0.38±0.21, RR: 70.77%) respectively, we could see improvement of the inhibition effect of DDP on transplanted hepatocarcinoma H_{22}. DDP combined with high dosage BSHYJDR had a significant difference ($P<0.001$) compared to DDP, while DDP combined with low dosage BSHYJDR only had a little improvement that is not remarkable.

CONCLUSION: Chinese medicine BSHYJDR in combination with chemotherapy can inhibit transplanted hepatocarcinoma in mice.

INTRODUCTION

Bushen huayu jiedu recipe (BSHYJDR) is used in treatment of many kinds of cancer, especially digestive tract and respiratory system cancer. We have discovered that BSHYJDR could obviously improve clinical symptoms, quality of life and prolong the life span of cancer patients. BSHYJDR could restrain transplanted lung cancer cells, and has a synergistic effect, when combined with chemotherapy. After animals received intragastric BSHYJDR, it could inhibit the expression of drug-resistance gene, increase the level of DDP in drug-resistant cells, and regulate the activity of calcium channel of resistant cells. Meanwhile, BSHYJDR could also restrain transplanted Lewis lung cancer[1,2]. In order to investigate whether BSHYJDR in combination with chemotherapy could synergistically inhibit hepatocarcinoma, we selected transplanted mice hepatocarcinoma H_{22}, and investigated the inhibitory effect of BSHYJDR on transplanted hepatocarcinoma.

MATERIALS AND METHODS

Drugs

To prepare BSHYJDR decoction, Chinese Cassia Bark, Psoralea Fruit, Zedoary, Rhubarb, etc., were put into a container, cold water of about 5-7 times as the herbs was added. After being soaked for 1-2 h and boiled for 30 min, the decoction was filtered. Once again, water of about 3-5

times as the herbs was added, decocted and boiled for 20 min before the second filtration. The two decoctions were mixed. Then the mixture was concentrated into medical fluid (equals 1.5 g/mL originate herbs in water bath). The fluid was poured into a sterilized vial after cooling and stored at 4 ℃ for use. DDP was produced by Qilu Pharmacy Factory in Jinan, Shandong Province, China.

Animals

Kunming mice were supplied by Experimental Animal Center of Shandong University of traditional Chinese medicine.

Tumor strains

Hepatocarcinoma H_{22} was provided by Tumor Pharmacology Laboratory of Tumor Prevention and Treatment Center in Shandong University of traditional Chinese medicine.

Main instruments

Ultra-clean worktable was from Suzhou Yuhua Equipment Co. Electronic balance (Type FA2004) was purchased from Shanghai Balance Instrument Factory.

Inhibition of BSHYJDR on mice hepatocarcinoma H_{22}

Experimental animal model and grouping Ascites was drawn from hepatocarcinoma mice H_{22} under aseptic condition, and diluted in normal saline at 1:4. Concentration of tumor cells was 1×10^7 cells/mL. Then 40 healthy Kunming mice weighing 18-22 g were selected, 0.2 mL tumor cells was injected into the armpit of right forelimb of each mouse. After 24 h, they were weighed and randomly divided into model control group, high dosage BSHYJDR group, and low dosage BSHYJDR group and DDP group, 10 mice in each group.

Drug dosages and methods DDP group received intraperitoneal injection of DDP at the dosage of 1 mg/kg (equals to 1/10 LD50), once a day for 4 d. High and low dosage BSHYJDR groups received intragastric BSHYJDR decoction at the dosages of 26.6 and 13.3 g/kg (20 and 10 times each of clinical adult dosage) respectively, while tumor-bearing model group received the same dosage of distilled water, once a day for 10 d. On the 11th d, all the mice were weighed and killed, and then the tumor was dissected and weighed. The repression rate (RR) was calculated, according to the mean weight of tumor (MWT).

Synergistic effect of BSHYJDR and DDP on mice hepatocarcinoma H_{22}

Experimental animals model and grouping The mice were divided into tumor-bearing model control group, DDP group, DDP combined with high dosage BSHYJDR group, DDP combined with low dosage BSHYJDR group, 10 mice in each group.

Drug dosages and methods After grouping, DDP group received intraperitoneal injection DDP (1 mg/kg). DDP combined with high dosage BSHYJDR group received intraperitoneal injection of DDP (1 mg/kg) and intragastric BSHYJDR (26.6 g/kg). DDP combined with low dosage BSHYJDR group received intraperitoneal injection of DDP (1 mg/kg) and intragastric BSHYJDR (13.3 g/kg). Model control group received an equal volume of distilled water. DDP was injected once a day for 4 d, while Chinese medicine and distilled water were lavaged once a day for 10 d. Then on the 11th d, all the mice were weighed and killed, and then the tumor was dissected and weighed. The RR was calculated according to the MWT and the formula of calculating the RR. RR of the tumor (%) = tumor weight of the control group-tumor weight of the experimental group/tumor weight of the control group×100%.

Statistical analysis

The data were expressed as mean±SD. Student's *t*-test was used to assess the significant differences among groups. All statistical analyses were performed with the PEMS statistical software package.

RESULTS

Inhibition of BSHYJDR on mice hepatocarcinoma H_{22} (Table 1)

Table 1 shows that compared to the control group, significant inhibitory effect of BSHYJDR was found in DDP group ($P<0.01$) and high dosage BSHYJDR group ($P<0.05$). But no significant difference of inhibitory effect was found in low dosage BSHYJDR group ($P>0.05$). The inhibitory effect in high and low dosage BSHYJDR groups was lower than that in DDP group ($P<0.01$).

Table 1 Inhibition of BSHYJDR on hepatocarcinoma H_{22}

Group	Dose (mg/kg)	Mice (*n*) (before/after)	Tumor weight (g) (mean±SD)	RR (%)
Model	–	10/10	1.30±0.73	–
DDP	1×4	10/10	0.41±0.09[b]	68.46
BSHYJDR	26 600×10	10/10	0.69±0.29[a,d]	46.92
BSHYJDR	13 300×10	10/10	0.85±0.34[d]	34.62

Synergistic effect of BSHYJDR and DDP on mice hepatocarcinoma H_{22} (Table 2)

Table 2 shows that compared to control group, DDP exhibited significant inhibition on H_{22} ($P<0.01$). Both high and low dosage BSHYJDR could significantly improve the inhibition of DDP when used in combination with DDP ($P<0.001$). But low dosage BSHYJDR had no such effects compared to DDP ($P<0.05$).

Table 2 Synergistic effect of BSHYJDR and DDP on hepatocarcinoma H_{22}

Group	Doses (mg/kg)	Mice (*n*) (before/after)	Tumor weight (g) (mean±SD)	RR (%)
Model	–	10/10	1.30±0.73	–
DDP	1×4	10/10	0.41±0.09[b]	68.46
DDP+BSHYJDR	1×4+26 600×10	10/10	0.29±0.17[d]	77.69
DDP+BSHYJDR	1×4+13 300×10	10/10	0.38±0.21[b]	70.77

[b]$P<0.01$, [d]$P<0.001$ *vs* control group.

DISCUSSION

Hepatocarcinoma is one of the malignant tumors, and has high death rate in the world. Most patients in the middle or

late period are diagnosed of having the tumor. Therefore, it is very important to find a new therapy with Chinese medicine for middle and late hepatocarcinoma.

The present study has indicated that extractions from some herbs can restrain hepatocarcinoma. Alkaloids have cellulotoxic effect on hepatocarcinoma cells[3]. The herbal extractions of flavonoid and arsenic trioxide can not only restrain proliferation of hepatocarcinoma cells, but also induce apoptosis of hepatocarcinoma cells[4,5]. It was reported that Chinese medicine can induce cytodifferentiation of hepatocarcinoma[6].

Toxic side effect of chemotherapy is an important influencing factor in treatment of hepatocarcinoma. Chinese medicine combined with chemotherapy can reduce the toxic side effects and improve inhibition of chemotherapy on hepatocarcinoma cells, reduce the metastasis, enhance the quality of life and prolong the life span[7]. The use of Xuefu Zhuyu Tang (recipe for removing blood stasis in the vessels) combined with chemotherapy can enhance the effect of chemotherapy and prolong the life span of mice bearing hepatocarcinoma[8].

According to the theory of traditional Chinese medicine, the occurrence of tumor is closely related with stagnation of qi and blood and combination of blood stasis and poison, which are caused by deficiency of the kidney and invasion of poisonous pathogenic factors. BSHYJDR can reinforce the kidney and support yang, remove blood stasis and toxic substances.

It has been proved that cinnamic acid in Cassia Bark and its derivatives could induce apoptosis of cancer cells, promote the breakage of DNA, inhibit the proliferation of A549 cells in adenocarcinoma and promote its differentiation[9,10]. The psoralen in psoralea fruit has cellulotoxic effects on hepatocarcinoma cells, promotes the adherence and excursion of melanoma cells *in vitro*[11,12] by preventing cancer cells from metastasis. The extractions of Zedoary could improve immunogenicity of tumor cells and enhance the killer effect of the cells. Moreover, Zedoary could strengthen the antitumor effect of tumor necrosis factor. Zedoary preparation is mainly used to treat hepatocarcinoma. The main components of Rhubarb are Rhubarb substance and Rhubarb acid. Rhubarb substance could restrain proliferation of hepatocarcinoma cells, induce apoptosis, and promote gene expression of P53 and P21[13-16]. Rhubarb acid could restrain cell proliferation of various tumors, such as mastocarcinoma, lung cancer, hepatocarcinoma and colonocarcinoma, and has synergistic effects when used in combination with mutamycin. It could inhibit synthesis of DNA, promote apoptosis of cancer cells. It also has been found that the inhibitory effect of repression of Rhubarb on cancer cells is closely related with cell signal transduction[17].

Our research showed that BSHYJDR decoction could significantly restrain transplanted hepatocarcinoma H_{22} in mice, enhance the effect of DDP on transplanted hepatocarcinoma H_{22}, indicating that BSHYJDR restrains tumor and has synergistic effects when used in combination with chemotherapy. But the mechanisms still remain unknown and need further studies.

ACKNOWLEDGMENTS

The authors thank Professors Li-Ying Xia, and Guang-Juan Zheng, Dr. Dan Zhang and lecturer Jing Zhang, Tumor Pharmacology Laboratory in Shandong University of Traditional Chinese Medicine for their support and direction in the study.

Abstract

AIM: To establish a kind of standardization of the clinical chemotherapeutic prototypes for unresectable hepatocellular carcinomas (HCC).

METHODS: 10-Hydroxycamptothecin (HCPT) was applied through transcatheter arterial embolization (TAE) to HCC patients who were categorized into three groups: (1) test group: treatment with HCPT twice (HCPT d1 and 14) through TAE and portal venous embolization. (2) Control I: treatment with anticancer drugs without HCPT. (3) Control II: treatment with HCPT as a major component in anticancer drugs once (HCPT d1). A set of comparisons between test groups and control I and II groups were performed before and after the treatment to study the effectiveness of each treatment, in terms of tumor volumes, dynamic variations in serum alpha-fetoprotein (AFP), gamma-glutamyl transferase hepatoma-specific band (GGT-II), patient survival and adverse events.

RESULTS: The general effectiveness rate of the test group reached 62.1% (72/116), remarkably higher than that of control I (32.1%, 40/124) and control II (54.7%, 47/56), (P<0.01 and P<0.05, respectively). Especially, the reduction rate or disappearance of the portal vein tumor emboli was as high as 88.4% (61/69) in the test group, in contrast with 13.9% (10/72) in control I and 35.9% (18/51) in control II (P<0.01 and P<0.01, respectively). After treatment, AFP decreased or turned to negative levels at 52.3% (34/65) in control I, 67.3% (35/52) in control II, and 96.8% (60/62) in the test group. Also GGT-II declined or became negative at 37.8% (28/74) in control I, 69.5% (57/82) in control II, and 94.7% (89/94) in test group (P<0.01 and P<0.05, respectively).

CONCLUSION: We have designed a good protocol (test group) to treat HCC with excellent advantages of high efficiency, low cost, low toxicity and low adverse events and easy application. It could be recommended as one of the standardizations for HCC treatment in clinical practice.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common and rapidly spreading fatal malignancies worldwide, and has been ranked as the 2nd cancer killer in China since the 1990s, particularly in the southeastern provinces, including the inshore area of the Yangtze river[1-3]. Major risk factors for HCC in these areas are exposure to aflatoxin B1 and infection by hepatitis viruses[4,5]. HCC prognosis is poor and early detection is of utmost importance[6]. Treatment options are severely limited by the frequent presence of metastases. Recent studies of DNA isomerase inhibitors for clinical use have made some progress[7,8]. The direct injection of 10-hydroxycamptothecin (HCPT) into tumor vessels in primary hepatic carcinoma has proved promising due to its high efficiency and low toxicity[9-11]. However, treatment protocols differ greatly in drug-application routes, methods, doses and final results[12-14].

Since October 2000, we have used HCPT as a major component in chemotherapy in combination with 5-fluorouracil (5-FU) and cisplatin (CDDP). Drugs were administered through transcatheter arterial embolization (TAE) and subsequent portal venous embolization (PVE) to treat hepatic cancer on d 1 and 14, respectively. We compared this method (called test group) with chemotherapy protocols with and without HCPT through TAE d1 and reported here the excellent results.

MATERIALS AND METHODS

Study populations

We evaluated 326 HCC patients treated at Affiliated Hospital

of Nantong University, China. Patients were divided into three groups: test group, control I, and control II. All patients were confirmed by alpha-fetoprotein (AFP), gamma-glutamyl transferase hepatoma-specific band (GGT-II) serological examination[7], and by ultrasonography (US), computed tomography (CT) or magnetic resonance imaging, partly by pathological checking. The diagnosis of HCC was based on the criteria stipulated in 2001 Chinese National Conference on HCC[15]. The test group consisted of 116 HCC patients (91 males and 25 females) aged 30-68 years with an average age of 46.2 years. Among them, 12 were in stage I, 86 in stage II, and 18 in stage III, respectively; and the liver function was categorized according to the Child-Pugh scale with 46 cases of level A, 61 cases of level B, and 9 cases of level C, respectively.

Control I had 124 HCC patients, who received chemotherapeutic agents such as 5-FU, doxorubicin (ADM), CDDP without HCPT through TAE and were hospitalized at the same time as test group or earlier. Control II had 86 patients, who received chemotherapeutic agents HCPT, 5-FU, CDDP through TAE only on d 1.

HCC patients in the three groups had similar general conditions. Actually, mostly patients were at mid-late stage, often some of them already had metastasized cancerous emboli in portal vein or hepatic vein, and some even had remote lymph nodes affected according to the UICC criteria, most HCC belonged to $T_{3-4}N_{0-1}M_{0-1}$.

Treatment drugs

HCPT was purchased from Hubei Lishizheng Pharmaceutical Co., Ltd. HCPT 40-50 mg, 5-FU 750-1 000 mg, CDDP 60-80 mg, ADM 40-50 mg, lipiodol (LP) 10-30 mL, and gelatin sponge 1-2 pieces were used for treatment (one dose).

Therapeutical methods

Arterial embolization was performed according to Seldinger's procedure via the femoral artery. After the catheter was sent into the hepatic artery and right or left hepatic artery, arteriography was carried out for further confirmation of the characteristics, location and size of the tumor. The types and doses of drugs varied with the Child-Pugh grades of hepatic functional reserve, clinical stages and the number, size and extent of tumors. Usually a combination of full dose of 5-FU, 4/5 of HCTP, and 2/3 of CDDP was infused to attack the tumor. Then 1/5 dose of HCPT, and 1/3 of CDDP were mixed with LP or gelfoam to embolize the blood-providing arteries.

We selected a puncture site using the portal vein branch which supplied blood for tumor foci, or proximal to cancerous emboli. The drugs used were the same but half of the dose 3-6 mL of LP was used. The operation was performed on d 14 after TAE.

Blood and urine analysis were routinely checked twice a week, and the liver function and serum tumor markers (AFP, GGT-II) were determined once in every 2 wk. US and CT were also checked on d 21-28, to observe LP precipitates and variations in volume of tumor foci.

Statistical analysis

Differences between groups were assessed by the χ^2 test. The survival time was calculated according to the Lifespan method. $P<0.05$ was considered to be significant.

RESULTS

The therapeutic effects were evaluated with regard to tumor-emboli volume alteration, changes of serum tumor markers (AFP, GGT-II) changes and survival time, based on the Criteria of Diagnosis and Treatment of HCC proposed at Chinese National Collaborative Cancer Research Group[15].

Tumor-emboli volume alteration

The overall effective rate of the test group was 62.1% (72/116), much higher than that of control I (TAE without HCPT, 32.1%, $P<0.01$) and control II (TAE with HCPT d1, 54.7%, $P<0.05$) as shown in Table 1. Six patients had survived for over 3-6 years, repeated follow-up with US and CT showed no occupied lesions. More importantly, color Doppler reported high frequency of arteries or veins around tumors with a resistance index >0.50, mostly more than 0.60-0.80 in 59 of 66 partial response patients. After treatment with TAE and PVE, 42 cases reported disappearance of the high blood flow frequency, and the rest showed remarkable reduction of blood supply. Fifteen patients acquired complete removal of tumor by surgery, among them six were reported as having pathologically complete necrosis in the tumors with large amount of lymphocytes encircling and infiltrating around the tumors.

In test group, the reduction rate of cancerous emboli in portal vein reached 88.4%, which was much higher than that in control I (13.9%, 10/72) or control II (35.3%, 18/51) with statistically significant difference ($P<0.01$). In the eight cases in which the main portal vein was affected, the tumor emboli showed no change or even progress, so the portal vein branch I or II in the other site had to be chosen for infusion of chemotherapeutic agents.

Dynamic changes of tumor markers

In test group, 62 cases showed AFP>400 ng/mL, with 53.4% positive. After treatment, the concentration of serum AFP decreased in 60 cases, accounting for 96.8%, which was much higher than that in control I (52.3%, 34/65) and control II

Table 1 Tumor-emboli volume after treatment

	Tumor volume Cases	CR	PR	NC	PD	Cases	Dis	Red	Un-ch	Prog
		Portal vein emboli								
Test	116	6	66	43	1	69	8	53	6	2
Control I	124	1	39	76	8	72	1	9	38	24
Control II	86	1	47	36	2	51	2	16	21	12

CR: complete response; PR: partial response; NC: no change; Dis: disappear; Red: reduction; PD: progressive disease; Un-ch: unchanged; Prog: progression.

(67.3%, 35/52) with significant difference ($P<0.05$). AFP was termed negative in 25.8% (16/62) of test group, in 1.5% (1/65) of control I, and in 9.6% (5/52) of control II, respectively. Significant difference ($P<0.01$) was found between test group and control groups.

The number of GGT-II positive cases in test group was 94, accounting for 81.0%. After treatment, 89 cases turned negative or its concentration decreased, accounting for 94.7%, much higher than that in control I (37.8%, 28/74) and control II (69.5%, 57/82) with striking differences ($P<0.01$ and $P<0.05$), respectively (Table 2).

Survival time

The survival time was calculated according to the Lifespan method. The survival rates of 1, 2 and 3 years in test group were 94.6%, 65.9% and 39.1% respectively, which were significantly different from those in control I (65.1%, 36.3%, and 20.5%, respectively) and control II (80.6%, 52.4%, and 31.5%), respectively ($P<0.05$).

Adverse events

Almost all patients had nausea, vomiting, fever and hepatic pain to some extent after TAE treatment, i.e., "post embolization syndrome". Fever was relatively higher and lasted longer in groups with HCPT as a chemotherapeutic agent. In all three groups, digestive responses such as nausea and vomiting were slight and transient. Hepatic pain varied with the embolization state and the amount of LP and gelfoam used in the operation. Generally, in control I (without HCPT), the patient's temperature would rise to 39 ℃ 1 or 2 d after TAE, began to decrease on d 3, and returned to normal on d 5-7. In the group with HCPT, the temperature would rise to 39 ℃, decrease on d 4. Sometimes, it took 2 wk for the patients to recover.

The adverse events after PVE on d 14 were slight. Only a few cases reported a little bloating pain in the operated area. Nausea and vomiting were seldom reported. Fever was moderate and lasted shorter than 1 wk. No serious complications such as pneumothorax, and bleeding in the abdominal cavity were found.

Regular check of blood and urine routine showed that only nine cases in the test group had slight decrease in the WBC or platelet counting, and no bleeding was found. In control I and control II, 7 and 11 cases respectively showed slight decrease of WBC and platelet count. Statistical analysis showed no difference among the three groups ($P>0.05$).

DISCUSSION

HCPT has been in use for more than 20 years. Recently, the American FDA has approved two drugs, irinotecan and topotecan, which are HCPT analogs with similar molecular structure. Cellular and molecular biology has proven that this class of drugs belongs to DNA topoisomerase I inhibitors, which have strong anti-cancer activities, and wide-spread antagonizing spectrum, low resistance, low toxicity and the ability to induce differentiation of tumor cells and apoptosis[16,17]. The combined use of this drug with other kinds of drugs may enhance efficacy[18-20]. It is the common interest of many basic and clinical scientists to know how to reasonably standardize the application and maximize the efficacy of the drugs[21-23]. Therefore, international standardization remains a common focus. Based on the treatment of 326 cases of HCC patients with or without HCPT in our hospital, we systematically studied the application of this drug, and proposed our own standardized protocol.

In vitro drug sensitivity tests of tumor cell line showed that at low dose, HCPT played double roles in human liver carcinoma cell lines (HepG2, Bel-7402, and Bel-7404): inducing differentiation and inhibiting cell growth slightly. The greater the dose, the stronger the inhibitory action was, and the effects became stronger with time[9].

For the unresectable hepatic carcinoma patients who had wide ranges of foci together with high rates of portal vein emboli[24-26], we adopted double-passaged intervening chemotherapy with HCPT in combination with other drugs for treatment[27-29]. We emphasized three aspects in the treatment: drug dose, treatment time and continuous treatment. For drug applying routes, we utilized both artery and portal vein for tumors. Under the guidance of digital subtraction angiography of tumor and US, the needle was directed into supplying artery and veins, exerting high dose for close attack on cancerous area, followed by chemical embolization to keep the drug-LP mixture in the suffered area for a longer time.

The drug action period is no longer than several hours or several days, but lasting for weeks or months[30]. This method keeps the local drug concentration high, hundred times more than that by systemic intravenous drip[12]. It has been reported that after tumor arteries were blocked through TAE, portal vein branches increased remarkably[31]. Therefore, to perform PVE, 2 wk after TAE not only accorded with blood dynamics but also increased drug administration frequency. And at the same time, it struck an attack with high drug dose on portal vein cancerous emboli. Drugs accumulated at low concentration in normal tissue areas or organs. It has been reported that HCPT is not affected by multi-drug resistance protein and multi-drug resistance related proteins, therefore, it seldom has drug resistance. With the development of diagnostic techniques

Table 2 Hepatic cancerous marker alterations before and after treatment

	Hepatic cancerous marker							
	AFP				GGT-II			
	P	N	D	I	P	N	D	I
Test	62	16	44	2	94	29	60	5
Control I	65	1	33	31	74	6	22	46
Control II	52	5	30	17	82	8	49	25

P: positive; N: negative; D: decrease; I: increase.

and agents, super-selection ability of drugs greatly enhanced. It is a common practice in clinic that the catheter head is directed to the closest area of tumor artery to achieve segment embolization, thus greatly enhancing effectiveness. Some patients were able to achieve partial regression or even complete regression, known as "chemical resection". In our test group, PR+complete response (CR) reached 62.1%, among them six were CR, with portal vein cancerous emboli disappearance or reduction rate of 88.4%. In eight cases, cancerous emboli disappeared completely. Such a high efficacy was probably related to the above-mentioned pharmacology (our HCPT protocol in d 1 and 14) and methodology (by TAE and PVE)[32]. The earliest and most frequent passages for hepatic carcinoma metastasis are portal veins. Therefore, treatment through/on portal venous emboli is the key step to control its metastasis across the liver.

Pharmacological study indicated that the effectiveness of application of topoisomerase I and II inhibitors rely on the sequence of drug application. Subsequent administration of topoisomerase I and II inhibitors exerted co-operative effect; while co-administration of them antagonized each other[9]. The method of TAE or PVE is a way to apply drugs to tumor feeding vessels (veins or arteries); therefore, here we considered to use combined application of HCPT (topoisomerase I inhibitor) as a major component in the chemotherapeutic agents with 5-FU and CDDP, which are highly liver-specific drugs and act during S phase and S, G_1 or G_2/M phase respectively. HCPT exerted its action on DNA topoisomerase inhibitor I to directly suppress the DNA and RNA synthesis, and induced sister chromatid exchanges, distortions and breaks, so that it selectively killed S phase cells and induced G_2 arrest. In addition, both HCPT and CDDP can induce apoptosis. Drug dose and concentration, infusing speed, and emboli-forming rate for HCC patients were most important in all detailed manipulations based on the above-mentioned pharmacological features[33]. During 5-FU full dose attack, two major points should be emphasized: injection time and injection route. When 5-FU concentration is more than effective concentration in the blood, higher dose would only increase its toxicity, while elongation of injection time can remarkably enhance the effectiveness. Therefore, it is better to slow down the injection time, usually to longer than 30-40 min.

The route was dependent upon the tumor location or cancer emboli location[28]. For example, if tumor was located in the right liver lobe, then the passage route would be: (1) superior mesentery artery→superior mesentery vein→right portal vein→tumor location; (2) common hepatic artery→right hepatic artery→tumor location. If tumor was located in the left lobe of the liver, then pass through: (1) celiac trunk→splenic artery→splenic vein→left portal vein→tumor location; (2) common hepatic artery→left hepatic artery→tumor location. Since the hepatic artery provides blood to tumor center, while the portal vein provides blood to tumor surroundings, our protocol not only the whole tumor (center and surrounding) made double attacks on through arteries and veins, but also elongated the drug action time. On d 14, through PVE, the tumor and the cancerous emboli would receive the 3rd attack, which greatly enhanced local drug concentration and drug-acting time.

HCPT was marketed and used widely in 1970s; the number of patients receiving HCPT had accumulated to more than a thousand[11,14]. However, due to various reasons no formal phase I and II pharmacodynamic studies have been carried out.

We report here the so-called HCPTd_1, d_{14}-TAE, PVE double passaged tumor intervening chemotherapy for hepatic carcinoma. The local concentration of HCPT reached as high as 40-50 mg in hepatic artery +20-25 mg in portal vein, without observing dose-limiting toxicities like drastic bone marrow inhibition and diarrhea. There was a slight decrease in WBC and platelet counting in nine cases. No dramatic hematuria, skin rashes, but only self-limiting tumor necrotic fever and transient digestive response were observed. For those who acquired chances to be operated on, there were widespread necroses around tumor and large amount of lymphocyte infiltration[34]. Our protocol exhibited high efficiency and low toxicity. HCPT does not induce drug resistance. It has anti-infection activity and the ability to increase body immunity. It is inexpensive and convenient to use. Thereby, we recommend the protocol as one of the standardizations in treating liver cancer with HCPT.

ACKNOWLEDGMENTS

We would like to express our sincere appreciation to Professor Sheng-Long Ye of the Liver Cancer Institute of Zhongshan Hospital, Fudan University for his guidance and help. We also thank Dr. Li Xu of Nantong University.

Abstract

Intra-abdominal fibromatosis (IAF) is a benign mesenchymal lesion that can occur throughout the gastrointestinal tract. Although rare, it is the most common primary tumor of the mesentery and can develop at any age. We describe a rare case of primary IAF involving the mesentery and small bowel which clinically, macroscopically and histologically mimicked malignant gastrointestinal stromal tumor (GIST). This report highlights the fact that benign IAF can be misdiagnosed as a malignant GIST localized in the mesentery or arising from the intestinal wall. Their diagnostic discrimination is essential because of their very different biological behaviors and the fact that the introduction of effective therapies involving tyrosine kinase inhibitor STI571 (imatinib mesylate) has greatly changed the clinical approach to intra-abdominal stromal spindle cell tumors.

INTRODUCTION

Although rare in humans, intra-abdominal fibromatosis (IAF) is the most common primary mesenteric tumor with spindle cell morphology. It may occur at any age, can be solitary or multiple, and may involve the small bowel, omentum, mesocolon and/or retroperitoneum[1,2]. It can sometime mimic the clinical characteristics, radiological imaging and histopathological appearance of a gastrointestinal stromal tumor (GIST), thus leading to an incorrect diagnosis.

It has been clearly established that GISTs originate from gastrointestinal pacemaker Cajal cells, which are the primary effectors controlling gut motility[7,8]. Although they have been considered as a distinct tumoral entity for about 10 years, they can now be more precisely identified as a result of the widespread use of immunohistochemistry with *c-kit* (CD117, a protein synthesized in interstitial Cajal cells) for the diagnostic analysis of spindle cell lesions of the mesentery and gastrointestinal tract. This marker has emerged as their most important defining feature, and is probably the gold standard for GIST diagnosis[2]. *c-kit* gene mutations and *kit* protein overexpression also seem to be essential for the pathogenesis of GISTs[9].

We describe here a rare, localized variant of primary IAF involving the mesentery and small bowel, which mimicked a GIST by strongly expressing the *c-kit* protein. Because of the remarkably overlapping immunophenotype of the two lesions, the aim of this report is to highlight the need to discriminate them because of the introduction of specific therapeutic strategies and the fact that they have different biological behaviors: IAF is benign and exclusively locally aggressive, whereas GISTs are malignant and may lead to distant metastases.

CASE REPORT

A 50-year-old white man with recent weight loss was admitted to Istituto Clinico Humanitas (Rozzano, Milan, Italy) because of abdominal discomfort in the left iliac fossa and suprapubic region, and sub-occlusive symptoms. He had undergone a partial sigmoid resection to treat perforated diverticular disease, one year before.

During the instrumental evaluation of suspected recurrent diverticulitis, abdominal ultrasound analysis revealed a mass involving the small bowel loops, and computed tomography (CT) demonstrated the presence of a round, lobulated, suprapubic neoplasm in the mesenteric region near the small bowel, that was presumably its site of origin (Figure 1). On the basis of the available clinical data and radiological imaging, an initial hypothesis of malignant GIST was made.

After surgical exploration of the abdominal cavity, the ileal tract with the tumoral mass and the adjacent mesenteric adipose tissue were excised. No other signs of disease were found in the other abdominal organs.

Figure 1 Abdominal CT scan showing a round, lobulated mass in the mesenteric region, tightly related to the bowel wall.

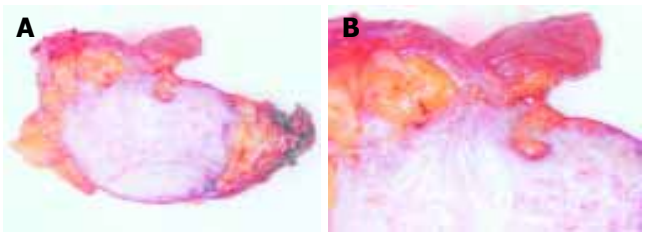

Figure 2 The resected small bowel with a well circumscribed firm mass in the mesenteric adipose tissue which exhibits an expanding growth pattern (**A**). The tumor has a tan-gray appearance on cut surface, and focally infiltrates the bowel wall (**B**).

Macroscopic examination of the specimen revealed a 7 cm×5 cm×5 cm encapsulated, well-circumscribed, firm, tan-gray mass infiltrating the adipose tissue and bowel wall (Figure 2).

Light microscopy showed a neoplasm with a prevalently hypocellular appearance consisting of spindle cells growing in long sweeping fascicles. At higher magnification, the neoplastic population was found to consist of uniformly shaped cells with abundant eosinophilic cytoplasm and delicate, sometimes plump, nuclei with clearly evident nucleoli (Figure 3A). The mitotic activity index ranged from 1 to 10 mitoses/50 high power fields in the hypercellular areas.

The presence of these hypercellular areas with partially circumscribed borders, and the infiltration spreading to the *muscularis propria* of the small bowel, consistently favored a microscopic diagnosis of GIST, thus supporting the clinical, radiological and macroscopic findings.

However, this hypothetical diagnosis was not supported by the generally hypocellular growth pattern, the digitiform infiltration margins inside the adjacent fat tissue, and the absence of foci of necrosis, hemorrhages or cysts. Immunohistochemistry showed that the cells making up the lesion were immunopositive for *c-kit* protein (Figure 3B), and some were positive for smooth muscle actin (Figure 3C) and desmin (Figure 3D); however, no CD34 or S100 expression was ever found.

The final diagnosis was localized IAF of the mesentery and small bowel. A control CT scan, 6 mo after surgery, showed no signs of recurrent disease.

DISCUSSION

Primary IAF of the mesentery is a rare variant of benign stromal neoplasms of fibroblast-myofibroblast origin that may arise *ex novo*, but is usually secondary to trauma or hormonal stimulation, or associated with familial polyposis coli or Gardner's syndrome[1-6]. This neoplastic disease most

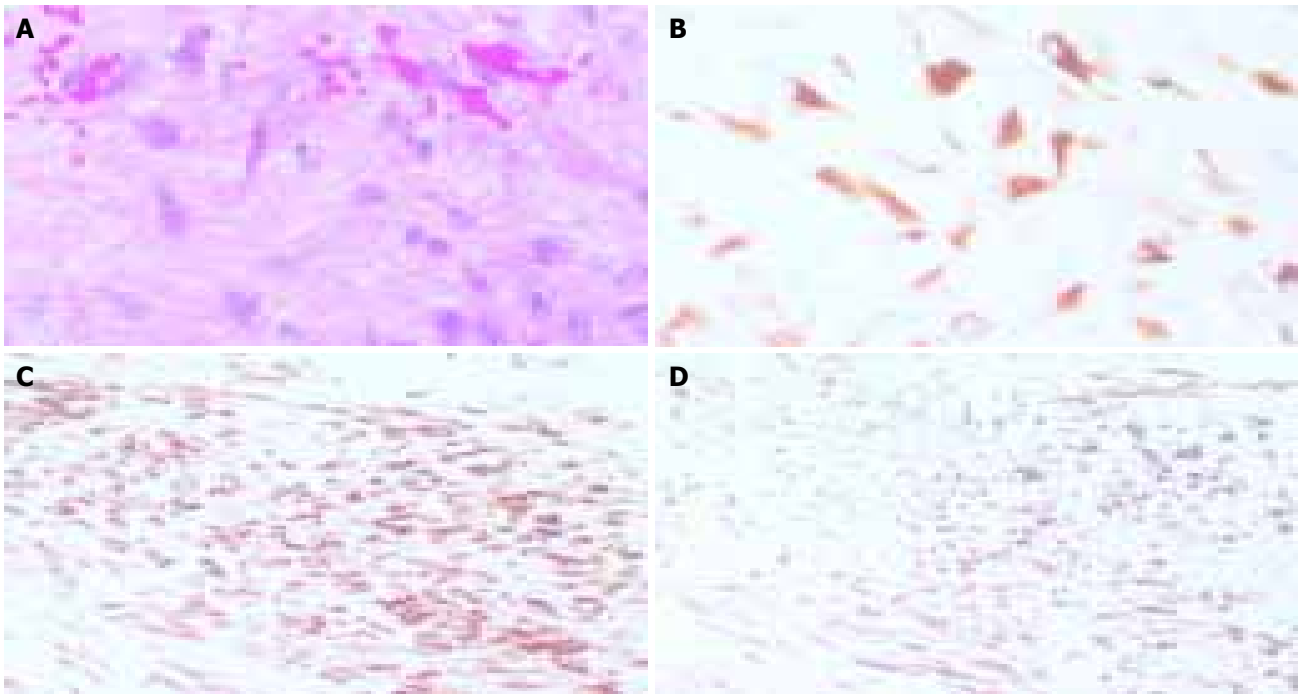

Figure 3 The tumoral lesion consisted of spindle cells growing in sweeping fascicles, with eosinophilic cytoplasm and sometimes plump nuclei (**A**, H&E 400×). Most of the tumor cells show immunoreactivity for *c-kit* (CD117) in their cytoplasm (**B**, IHC 400×). Immunohistochemical stain for smooth muscle actin (**C**, IHC 200×) and for desmin (**D**, IHC 200×) is also present in some hypercellular areas of the lesion.

frequently occurs in the anterior abdominal wall, and is usually treated exclusively by means of surgical excision with a wide margin of uninvolved tissue; however, local recurrences due to incomplete resection have been described in an estimated 16% of cases, leading to intestinal obstruction and death in 6%[2].

Although it is generally easy to diagnose primary IAF, the localized tumor growth and its apparent source in the bowel wall may lead to misinterpretations and clinical, radiological, macroscopic and microscopic hypotheses of a GIST (a mesenchymal tumor of the gastrointestinal tract).

The case presented here had a number of additional characteristics usually found in GISTs, such as *c-kit* cytoplasmic immunoreactivity, the fascicular arrangement of neoplastic cells with well-circumscribed borders, with many mitotic figures and cytological atypia with plump nuclei and prominent nucleoli.

However, light microscopy evaluation of the available tissue sections revealed the morphological features of fibromatosis, which can be summarized as: (a) spindle cells oriented along their long axis; (b) broad sweeping fascicles of varying cellularity with abundant collagenous stroma; (c) the absence of necrosis, hemorrhages, cysts and skenoid fibers deposits; and (d) the protrusion of the tumor into the lumen and ulceration of the overlying mucosa. Moreover, according to Monihan *et al*., the absence of CD34 and S100 expression supports the fibromatous nature of the lesion and highlight the fact that these proteins may be helpful in discriminating IAF from GIST[10].

Yantiss *et al*., have recently underlined the importance of making a more complete evaluation in order to distinguish these two very different neoplastic lesions, putting greater emphasis in their clinical, radiological, macroscopic, histological, immunophenotypical and ultrastructural features[11].

GISTs are potentially misdiagnosed as localized IAF arising within or involving the bowel wall, and their immunophenotypes may vary and overlap[1,2]. The overexpression of *c-kit* protein has been found in a large number of mesenchymal, epithelial and hematopoietic neoplasms, including fibromatosis, dermatofibrosarcoma protuberans, synovial sarcoma, anaplastic large cell lymphoma, glioma and germinoma[12]. These findings all confirm that *c-kit*, smooth muscle actin and desmin cannot help in differential diagnosis and their immunoreactivity must be interpreted in conjunction with the morphological analysis and clinical evaluation. In cases such as the one reported here, the clinical and histological differential diagnosis with GIST are mandatory, above all in the light of the current criteria predicting GIST outcomes (the number of mitoses and the size of the lesion), which classified our case as being at intermediate/high risk of sarcoma, which would require the consideration of a further therapeutic approach[13].

It is now well known that fibromatosis expresses *c-kit*, against which STI571 (imatinib mesylate) is a target-based molecule that has remarkable clinical effects and is well tolerated by patients with non-resectable GISTs or non-resectable extra-abdominal desmoid tumors[9]; however, the potential therapeutic role of this small molecule in IAF is still unclear.

In conclusion, although intra-abdominal lesions with spindle cell morphology are relatively rare, and similarities in their clinical data and radiological and histological appearances may lead to misdiagnoses, it is also true that tumor diagnoses based on immunohistochemical staining or traditional histological criteria alone are not specific enough[4].

Our report highlight the need for reliable new criteria for discriminating IAF and GIST because of the introduction of sophisticated therapeutic strategies (in order to select patients to be admitted to clinical trials) and their different biological behaviors: IAF is benign and exclusively locally aggressive, whereas GISTs are malignant and potentially capable of leading to distant metastases.

Abstract

We report a case of a 74-year-old woman with a 16-year history of a double bilo-enteric anastomosis due to resected hilar cholangiocarcinoma [Type IIIb Klatskin tumor]. The patient presented with cholangitis secondary to benign anastomotic stenosis which resulted in a large intrahepatic biloma. In order to restore the patency of the anastomosis and overcome cholangitis, several attempts took place, including endobiliary stenting, balloon-assisted biloplasty and transhepatic billiary drainage. Anastomotic patency was achieved, complicated, however, by persistent upper gastro-intestinal bleeding, presented as hemobilia. A biloma-induced pseudoaneurysm of the left hepatic artery was diagnosed. This had ruptured into the biliary tract, and presented the actual cause of the hemobilia. Selective embolism of the pseudoaneurysm resulted in control of the hemorrhage, and was successfully combined with transhepatic dilatation of the anastomosis and percutaneous drainage of the biloma. The patient was ultimately cured and seems to be in excellent condition, 5 mo after treatment.

INTRODUCTION

Bleeding into the biliary tree, either traumatic or iatrogenic, represents a rare cause of gastro-intestinal hemorrhage, which occurs in less than 3% of liver injuries[1]. Besides bleeding, typical signs of hemobilia include jaundice and pain[1,2]. Ten percent of hemobilia cases are reported to be secondary to ruptured hepatic artery aneurysms[3]. Apart from trauma and atherosclerosis, hepatic artery pseudoaneurysms may be created as a result of arterial wall erosion by local inflammation such as infected bilomas related to bile stasis and cholangitis[3].

In this case, we report an unusual pathological entity of an infected intrahepatic biloma secondary to a stenotic bilo-enteric anastomosis, complicated with a pseudoaneurysm of the left hepatic artery. This resulted in persistent hemobilia, which was ultimately treated by an aggressive combination of interventional radiological procedures.

CASE REPORT

Sixteen years ago, a 58 year-old woman, was operated on, due to malignant obstruction of the bile duct (Klatskin tumor, stage IIIb). At exploratory laparotomy, the tumor was resected (RO resection) and a double choledocho-jejunal anastomosis was performed (Roux-en-Y). She recovered well and was discharged 15 d later in good health. Histology of the resected specimen verified an adenocarcinoma of the bile ducts. Ever since, she has been in good condition, without evidence of tumor recurrence.

In October 2002, the patient was admitted to hospital, suffering from cholangitis. Transhepatic cholangiography demonstrated a longitudinal stenosis of the main left hepatic duct, at the area of the left bilio-enteric anastomosis, causing dilatation of the left bile ducts (Figure 1A). Considering the results of MRI as well as the long period after resection, the stenosis was finally attributed to benign postoperative fibrosis. Percutaneous balloon-assisted biliary decompression followed by transhepatic insertion of two expandable metallic stents through the bilo-enteric anastomosis resulted in clinical and radiological palliation of the cholangitis.

Two years later, a new severe episode of cholangitis led the patient to hospital again. Transhepatic cholangiography showed severe stenosis of the stent lumen that seemed to be secondary to endothelial hyperplasia. A nearby biloma was also depicted, due to bile leakage, probably related to bile stasis (Figure 1B). External drainage of the biloma and percutaneous transhepatic stent re-dilatation (Figures 2A and B) were performed. After receiving antibiotics for five days, the external drainage catheter was removed and the patient was discharged in acceptable clinical condition.

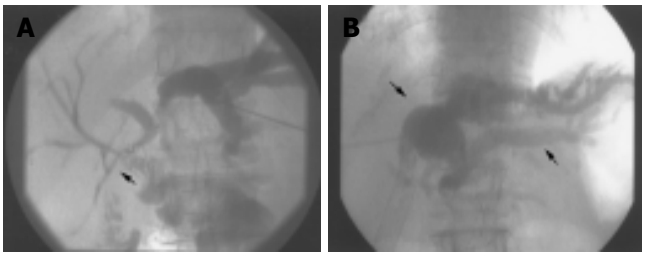

Figure 1 Percutaneous transhepatic cholangiography. **A:** A longitudinal stenosis affecting the area of the left bilio-enteric anastomosis is shown. The left bile ducts are markedly dilated; **B:** Percutaneous transhepatic cholangiography exhibits the extraductal bile collection in the form of a biloma (small arrow) and the dilatation of the left lobe bile ducts (big arrow).

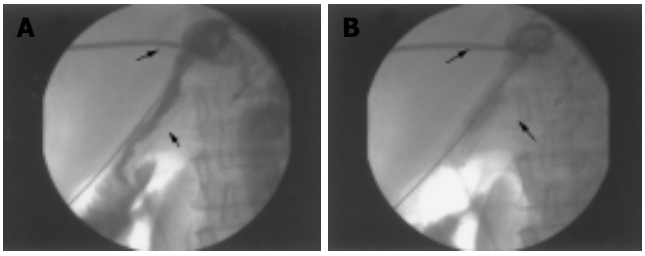

Figure 2 Bile stasis, secondary to stent lumen stenosis (small arrow, **A**), was managed with external drainage of the biloma (thin arrow, **A, B**) combined, in the same session, with transhepatic balloon-assisted stent re-dilatation (**B**).

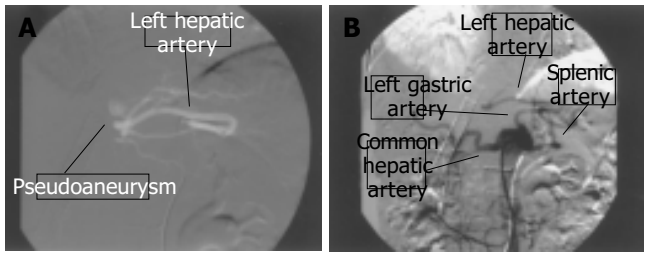

Figure 3 Catheter-directed, selective angiography demonstrates the presence of a pseudoaneurysm arising from the left hepatic artery. Note that the left hepatic artery originates from the left gastric artery (**A** and **B**).

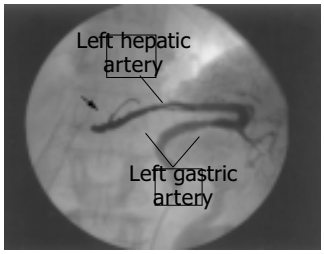

Figure 4 Trans catheter embolization. Detachment of adequate metallic coils (arrow) resulted in full occlusion of the aneurysmal sac.

Four weeks later, the patient returned to hospital due to weakness and anemia. She reported a 10-d history of melena. Urgent endoscopy disclosed no evidence of active gastro-duodenal bleeding. Computed tomography-assisted angiography displayed an aneurysmal sac located at the left hepatic arterial tract. A subsequent catheter-directed selective angiography detected precisely a pseudoaneurysm originating from a branch of the left hepatic artery. Technically, this was a particularly demanding procedure, due to an abnormal origin of the left hepatic artery from the left gastric artery (Type II variation, according to Hiatt's classification[4]) (Figures 3A and B). By means of super-selective catheterization, the neck of the pseudoaneurysm was approached and detachment of adequate metallic coils was performed resulting in full occlusion of the vascular lesion (Figure 4) and immediate control of the bleeding. The patient recovered well and was discharged a week later in good condition.

Five months later, the patient remained in good condition, without clinical or laboratory evidence of hemobilia or cholangitis.

DISCUSSION

Trauma (iatrogenic or accidental) and atherosclerosis consist of the most common causes of hepatic artery aneurysms[3,5], however, their formation may be less frequently encountered as a result of biliary inflammation. This is usually related to parasitic infection or stone impaction into the biliary tree[6]. The reported case suggests that other additional inflammatory factors such as infected, long lasting, intrahepatic bilomas may erode the arterial wall and lead to pseudoaneurysms.

Nonetheless, arterial injury is an unusual (2%), but possible complication of percutaneous transhepatic billiary drainaging (PTBD), which may also result in severe hemobilia[7]. The reported patient however, had been hospitalized for 5 d after PTBD and was discharged without any evidence of significant blood loss. This makes the scenario of a biloma-induced hepatic pseudoaneurysm that finally ruptures into a bile duct, more reasonable.

Hemobilia usually presents either with melena (90%) or hematemesis (72%)[1]. Other clinical manifestations include upper abdominal pain (71%) and obstructive jaundice (60%)[1]. The complete triad of bleeding, pain and jaundice is reported only in 22% of cases[1]. Hemobilia represents a potential life-threatening complication depending not only on the size of vessel wall deficit[7] but also on the fibrinolytic action of the bile that inhibits proper clot formation[1,8].

Liver angiography is the standard diagnostic method in cases of hemobilia especially, when endoscopic procedures fail to establish diagnosis[1,9]. This minimally invasive method detects precisely the bleeding site, also allowing simultaneous therapeutic intervention, by selective catheterization and embolization with the use of adequate embolic agents. Successful hemostasis rates exceed 95%[1] while procedure-associated morbidity and mortality are considerably lower than surgery[10]. The aforementioned advantages play a significant role especially in the management of patients with anatomic variations of the hepatic artery as well as for elderly patients with poor surgical prognosis, as in this case.

Apart from iatrogenic and accidental injury of the biliary tree, hemobilia may also occur under more complicated circumstances. The possibility of a biloma-induced hepatic pseudoaneurysm that finally erodes a bile duct should be taken into account, especially in patients with chronic obstructive jaundice, extra-ductal and encapsulated bile collections, repetitive episodes of cholangitis and hemobilia.

Transhepatic arterial embolization provides a safe and effective alternative in controlling patients with persistent hemobilia.

Abstract

A 76-year-old man with known situs inversus totalis presented with left-sided discomfort. Abdominal ultrasonography and CT scan confirmed the diagnosis of a gallstone, as well as, situs inversus; the liver and gallbladder on the left side and the spleen on the right. The biliary system was thought to be left-right reversal, mirror image in the view of drip infusion cholangiogram and MRI. Laparoscopic cholecy stectomy was safely performed, despite of unexpected aberrant cystic artery running inferior to cystic duct of situs inversus. Laparoscopic surgeon should be careful for view of reversed relationships and also existence of other anomalies.

INTRODUCTION

Recently, laparoscopic cholecystectomy has become the standard technique for surgical removal of the gallbladder for symptomatic gallstones[1-3]. Situs inversus totalis is uncommon anatomic anomaly, with gallbladder on the left side. Some investigators reported that laparoscopic cholecystectomy was successfully applied in situs inversus totalis, but the patients of all these cases were without other additional anomaly. We recently encountered a patient in situs inversus, who had anomaly of the cystic artery with symptomatic gallstones and was managed by laparoscopic cholecystectomy.

CASE REPORT

A 76-year-old man, who was known to have situs inversus, was seen complaining of recurrent left-sided upper quadrant abdominal pain for 2 mo. Abdominal ultrasound and CT scan confirmed the solitary radiolucent gallstone and presence of chronic gallbladder wall inflammation as well as situs inversus with the liver and gallbladder on the left side and the spleen on the right. The cardiac shadow and stomach bubble were displayed on the right side of the chest roentgenogram. The endoscopic retrograde cholangiopancreatography (ERCP) was performed, but it was too difficult to perform cholangiography (Figure 1A). The ERCP revealed the right sided pancreatic duct. Three dimensional (3D) drip infusion cholangiogram (DIC)-CT and magnetic resonance cholangio-pancreatography (MRCP) revealed the right-left reversal biliary system (Figures 1B and C). We did not perform the abdominal angiography before operation. All the preoperative examinations we performed revealed the mirror image anatomy without additional anomaly. Unexpected aberrant cystic artery was encountered as predicted by preoperative ultrasonography, CT, and MRCP.

OPERATION

At first, small laparotomy was placed in the sub-umbilical portion, and a 10-mm trocar with a balloon was inserted into the abdominal cavity. A 10-mm trocar was placed in the sub-xiphoid locations, and two 5-mm trocars were placed in the left sub-costal and left lateral regions under the view of laparoscope (Figure 2). The surgeon mainly used the forceps inserted through the trocar of sub-xiphoid. By laparoscopic view of left upper abdomen, gallbladder was placed on the left side and hepatic round ligament on the right (Figure 3A). We grasped and tracted the fundus of gallbladder and the cord was revealed lying inferior to the cystic duct by dissection of Calot's triangle (Figures 3B and C). The whole of the cystic duct was revealed by the dissection of the surroundings of the cystic duct after the traction of the cord (Figure 3D). We performed clip ligature and cut the cystic duct (Figure 3E). After cystic duct had been ligated, more dissection of the neck of the gallbladder was done and it revealed that the cord lead only to the gallbladder (Figure 3F). We thought that the cord was the cystic artery that was not placed on the mirror image of normal position. We performed the clip ligature and cut the cord. Finally the gallbladder was dissected and removed as usual.

DISCUSSION

Situs inversus viscerum is a rare condition, occurring in 1:5 000-1:10 000 hospital admissions[4]. As reported by Sato *et al*., laparoscopic observations were performed in 1 802

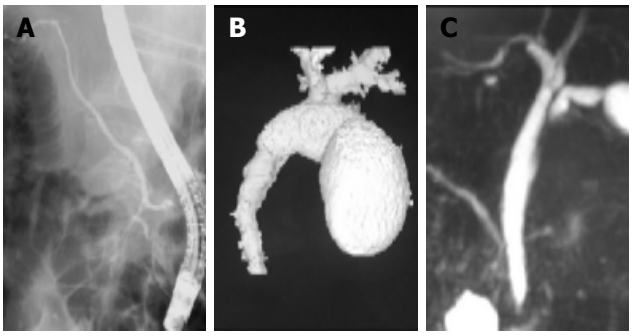

Figure 1 Reversed cholangiopancreatograms. **A:** ERCP; **B:** 3D-DIC CT; **C:** MRCP.

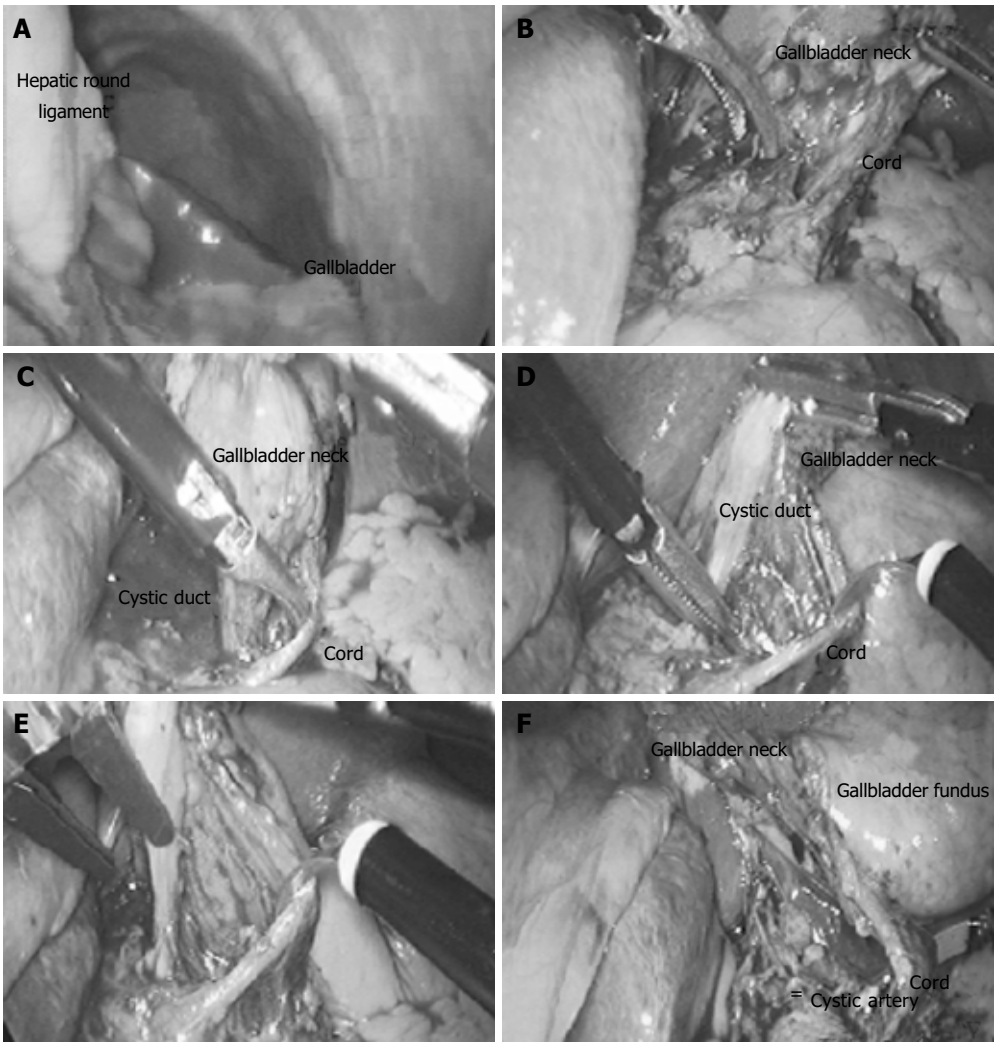

Figure 3 Laparoscopic view during cholecystectomy. **A:** Gallbladder was placed on the left side and hepatic round ligament on the right; **B:** the fundus of gallbladder was grasped and tracted; **C:** the cord was revealed lying inferior to the cystic duct; **D:** the surroundings of the cystic duct were dissected after the cord was tracted; **E:** the cystic duct was cut after the clip ligature; **F:** the cord lead only to the gallbladder.

consecutive patients and situs inversus was investigated in 0.2%[5]. Because the number of laparoscopic cholecystectomy recently becomes large, the reports of that of in situ inversus totalis have been increasing[6-15]. Ten cases of laparoscopic cholecystectomy in situs inversus totalis were reported.

In all reports, in which we can investigate about anatomy of cystic artery[6-10,12-15], it is reported that the cystic artery runs with the mirror image against normal patient. According to the report described by Hugh *et al*.[16], the cystic artery arises as a branch of the right hepatic artery within the hepato-biliary triangle and runs immediately cephalic to the cystic duct toward the gallbladder in 70-80% of patients without situs inversus totalis. It is also reported that "Inferior" cystic artery arises outside the hepatobiliary triangle, runs ventral to the bile duct and lies inferior to the cystic duct in 6% of the patients. We thought that the cystic

artery in our case is the mirror image of this anomaly. Because we did not perform the angiography, the anomalies of hepatic artery and cystic artery cannot be revealed indeed. However, we successfully and safely performed laparoscopic cholecystectomy in our case. According to consideration of our case, the angiography may be done in situs inversus totalis.

Since we carefully operated under the laparoscopic view and cut the cord recognized as the cystic artery, we have successfully carried out laparoscopic cholecystectomy in the patient with situs inversus totalis, despite the reversed anatomic relationships and other arterial anomaly. In the future, the frequency of anomalies of cystic artery detected in situs inversus totalis will increase under the laparoscopic cholecystectomy. In conclusion, we suggest that the experienced laparoscopic surgeons can successfully perform laparoscopic cholecystectomy in situs inversus totalis with care for the reversed relationships and possible existence of other anomalies.

Abstract

We present the gray-scale ultrasonography (GSUS), power Doppler ultrasonography (PDUS), abdominal computed tomography (CT), and magnetic resonance imaging (MRI) findings for a case of splenic hamartoma in a 27-year-old man, showing a φ 50 mm homogeneous, iso- and hypo-echoic splenic mass with evidence of a small plural cystic lesion. This splenic hamartoma showed increased vascularity on power Doppler sonograms. PDUS showed multiple circular blood flow signals inside the mass (i.e. a basket pattern), which was consistent with the small plural cystic lesion shown by GSUS. Spectral analysis also confirmed arterial and venous flow. CT scans showed that the mass had low-density relative to the normal spleen and MRI showed that the mass was isodense, relative to the normal spleen. Therefore, CT and MRI are not useful for the diagnosis of splenic hamartoma. Ultrasonography can be used to diagnose splenic hamartoma without administration of a contrast material and therefore is an indispensable method for the diagnosis of splenic hamartoma.

INTRODUCTION

Splenic hamartoma is a rare benign tumor with a mortality rate of 0.13%[1]. Since the first description by Rokitansky in 1 861[2], more than 100 cases have been reported. However, hamartoma images have rarely been reported. On sonograms, most splenic hamartomas are a homogeneous and solid mass, with varying echogenicity relative to the normal splenic parenchyma[3-6]. Also, the power Doppler ultrasonography (PDUS) findings of splenic hamartomas show increased vascularity[7]. To our knowledge, PDUS findings, computed tomography (CT), magnetic resonance imaging (MRI) features, and pathologic findings of a splenic hamartoma have not been reported.

CASE REPORT

The patient was an asymptomatic 27-year-old man. Routine physical examination and blood test had no remarkable finding.

Sonographic examination of the patient's spleen was performed using the Aplio80 (Toshiba SSA-770A) equipped with a 4.5-MHz convex-array transducer. Gray-scale ultrasonography (GSUS) showed a φ 4.3 cm×4.7 cm hypo-echoic and iso-echoic (i.e. mixed pattern) solid mass (Figure 1A) at the middle pole of the spleen. The mass was homogeneous with evidence of cystic changes in the center, but without calcification. Sonography also showed a clear and smooth margin, and PDUS showed multiple circular blood flow signals inside the mass (i.e. basket pattern) (Figure 1B). Arterial and venous flow was confirmed by spectral analysis (Figure 1C) and the peak systolic velocity of the arterial flow noted in the mass was 16.4 cm/s with a resistance index of 0.38 and a pulsatility index of 0.52.

Abdominal CT scan before administration of a contrast material revealed a low-density mass (Figure 2). During the arterial phase of contrast-enhanced dynamic CT, the mass was enhanced earlier than the normal splenic parenchyma. During the delayed phase, the intensity of the mass was the same as that of the normal splenic parenchyma.

MRI showed that the mass in the spleen was iso-intense relative to the normal spleen on T1-weighed images and mild hyper-intense on T2-weighed images (Figure 3). During the arterial phase of contrast-enhanced dynamic MRI, the mass was enhanced earlier than the normal splenic parenchyma. During the delayed phase, the mass was mild hyperintense relative to the normal splenic parenchyma. These findings were suggestive of hemangioma, metastatic tumor, malignant lymphoma, angiosarcoma or hamartoma.

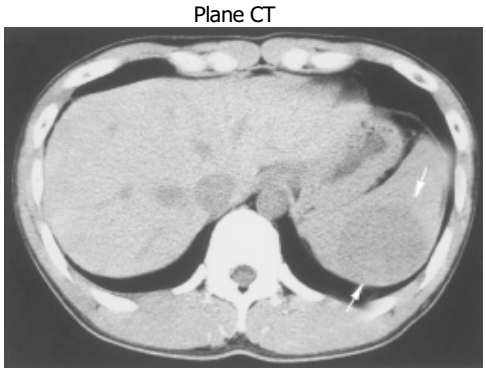

Figure 2 A low-density mass in the spleen shown by plane CT scan (arrows).

A splenectomy was performed because a malignant splenic neoplasm or metastasis could not be ruled out, as it could prevent the mass from spontaneous rupture. Histologic examination of the lesions revealed dilated vessels and congestion. The border of the mass and normal splenic parenchyma was smooth and clear (Figure 4A). The mass was composed of red pulp and lacked fibrous trabeculae and white pulp. The normal splenic parenchyma was compressed, and no capsule was found (Figure 4B).

The final pathologic diagnosis was a splenic hamartoma of the red pulp.

DISCUSSION

Splenic hamartoma is prevalent in either sex and has been reported in all age groups. However, it was reported that 50% of pediatric patients with a splenic hamartoma have clinical manifestations such as pancytopenia, anemia or thrombocytopenia[3]. Spontaneous rupture of the hamartoma with acute abdominal pain in adults has also been reported[2,8]. Here we present a case who was asymptomatic, and the splenic

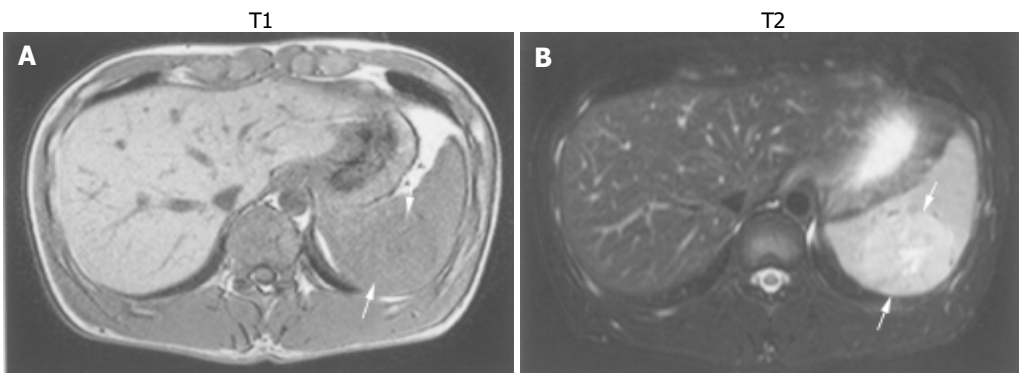

Figure 3 Isointense mass on standard T1-weighed MRI mass on (**A**) and mild hyperintense T2-weighed MRI (arrows **B**).

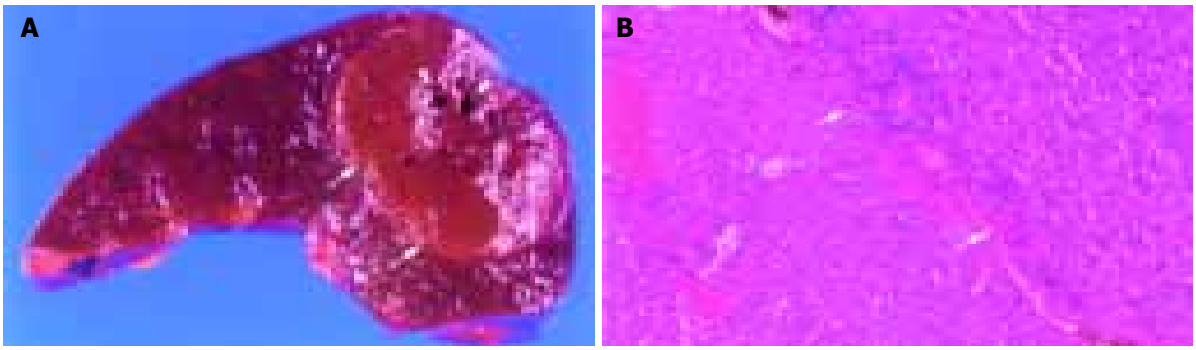

Figure 4 Dilated vessels (arrowheads) and border of the mass and normal splenic parenchyma (arrows) (**A**) and a mass consisting of red pulp **(B)** (HE×100).

tumor was coincidentally discovered, during a complete medical checkup.

Splenic hamartoma is a rare benign tumor. Wan *et al*.[9], have reported the sonographic findings in 53 cases of verified focal splenic lesions, such as cysts, infarcts, abscess, and hemangioma, spontaneous rupture, tuberculosis, lymphangioma, and hamartoma.

On gray-scale sonograms, most splenic hamartomas are solid and homogeneous masses with various echogenicities relative to the normal splenic parenchyma[3-6]. However, sonographic echogenicity indicates that splenic hamartoma is usually hypo-echoic[7,10], and occasionally heterogeneous and may exhibit cystic changes or calcification[4,11]. In our case, splenic hamartoma showed some solid and homogeneous characteristics via the gray-scale sonographic findings. However, internal echogenicity of the mass showed mixed pattern echoes containing a cystic area, but the posterior echo was only slightly enhanced. Gray-scale sonographic findings on tissue harmonic imaging (THI) have not been reported regarding the boundary echo of a splenic hamartoma. The gray scale of the boundary echoes shows a clear, smooth, and hyper-echoic rim. THI improves the resolution, because the high-condition wave beam is sharper than a standard wave beam. Also, THI is useful for improving the resolving power of the tumor. Splenic hamartomas are usually detected as hypo-echoic tumors, but in our case the echogenicity of the splenic hamartoma was iso-echoic and hypo-echoic (i.e. mixed pattern) on THI for gray-scale sonography. Splenic hamartomas are usually detected as hypervascular tumors by arteriography. Angiograms of the mass on power Doppler imaging (PDI) show tumor vessels with aneurysmal dilatation, arterio-venous shunts, vascular lakes, and tumor blush, presenting a typically malignant vascular pattern[12]. This is different from those on color Doppler image (CDI), because there is almost no dependence on the angle. Therefore, PDI exhibits excellent sensitivity compared to CDI. Tang *et al*.[7], have reported color Doppler sonographic findings in splenic hamartoma, and found that blood flow is concentrated around the mass as multiple radial blood flow signals. However, we found that blood flow was concentrated around the mass as surrounding blood flow signals coincident to the boundary echo and as multiple circular blood flow signals. Histologic analysis following splenectomy showed multiple vessels consistent with the PDUS findings.

Contrast-enhanced abdominal CT scans revealed that splenic hamartoma is iso-dense relative to the normal splenic parenchyma, before and after administration of intravenous contrast material[7,11]. The mass in our patient was iso-dense during the delay phase of contrast-enhanced dynamic CT, but had a low density relative to the normal splenic parenchyma, before administration of the intravenous contrast material. Also during the artery phase of contrast-enhanced dynamic CT, the mass had a high density relative to the normal splenic parenchyma.

Hamartomas of the spleen usually are iso-intense on T1-weighed MR images and hyper-intense on T2-weighed images[6,7] and the same was true for our case. However, Fernandez-Canton *et al*.[13], described that a histologically proven case presents a small (2.5 cm) focal mass, which is iso-intense to the splenic parenchyma on T1-weighed images and hypo-intense on turbo-spin-echo T2 and short T1 inversion recovery images. In addition, Chevallier *et al*.[10], reported that a fibrous-type splenic hamartoma measuring 7 cm in diameter that MRI showed is hyper-intense on T1-weighed MRI and hypo-intense on T2-weighed MRI.

Splenic hamartoma shows expansive growth and compresses the surrounding splenic tissue without a true capsule. Two histologic types of splenic hamartoma have been described[1]: the white-pulp (lymphoid) type and the red-pulp (pulposal) type. The white-pulp type is entirely composed of lymphoid tissue, whereas the red-pulp type defined by the Armed Forces Institute of Pathology as a hamartoma in 1995[14] is composed of sinuses and is histologically similar to that of normal splenic red pulp. Hamartomas are of the red-pulp type are the most reported cases, as was the case for our patient's splenic hamartoma.

Sonography permits differential diagnosis of tumor of the spleen. A splenic hemangioma is hyper-echoic on gray-scale sonograms[5,15] and color Doppler sonograms show few color echoes similar to the findings in hepatic hemangiomas. Color Doppler sonograms show an avascular pattern of metastatic tumors and malignant lymphoma of the spleen[5]. Sonograms of angiosarcomas show multiple hyper-echoic masses[16] and color Doppler sonograms show a fluctuating low-velocity flow pattern[17].

Since splenic hamartomas do not always exhibit hypervascularity[4], it should be included in the differential diagnosis of splenic tumors in which color Doppler sonograms show abundant blood flow. However, splenic

hamartomas are usually hypervascular tumors. The circular signals on power Doppler sonograms (basket pattern) in our case are consistent with the histologic findings.

In conclusion, abdominal CT and MRI require the administration of a contrast material to make an exact diagnosis. However, PDUS does not require the administration of a contrast material. Furthermore, PDUS does not affect the body. Therefore, the results of PDUS are equivalent to abdominal CT and MRI.

Abstract

Cholangiocarcinoma is the second most common primary hepato-biliary malignancy. The majority of patients with primary hepatic tumors are not suitable candidates for resection, due to advanced stage of the disease at presentation, anatomic limitations and medical co-morbidities. At present, radiofrequency ablation (RFA) may offer an alternative, feasible and safe therapy for selected patients with hepatic tumors, who are not otherwise candidates for hepatic resection. Herein, we present the case of successful RFA in a patient with a solitary, primary intrahepatic cholangiocarcinoma. The patient remained free of disease 24 mo after the procedure, and is still followed up. This is the first report of RFA application in the treatment of primary intrahepatic cholangiocarcinoma.

INTRODUCTION

Cholangiocarcinoma is a rare, malignant neoplasm arising from the biliary epithelium. The worldwide incidence of this malignancy is increasing and the annual incidence in USA is approximately 3 000-4 000 cases (0.85 per 100 000 rate)[1]. These cases are equally distributed between intrahepatic and extrahepatic lesions. The highest incidence rates of intrahepatic cholangiocarcinoma are noted in Northeast Thailand (96 per 100 000 for men and 38 per 100 000 for women). This variation in incidence is related to variations in the prevalence of risk factors. For example, in Thailand it is closely associated with liver fluke infestations[2]. The only potentially curative treatment for cholangiocarcinoma is surgical resection, but resectability of these tumors is determined by several factors including stage of the disease, anatomic conditions and patient's medical co-morbidities.

At present, RFA in selected cases of intrahepatic cholangiocarcinoma may be one alternative treatment approach, particularly for patients who are not candidates for major surgery. Herein, we present a case of successful RFA application in the patient with primary intrahepatic cholangiocarcinoma.

CASE REPORT

Subsequent to right upper abdominal discomfort, a 78-year-old man was found to have a solitary tumor in the right posterior hepatic lobe, by abdominal ultrasound examination. On physical examination, no significant findings were noted. Magnetic resonance scan confirmed the presence of an enhancing lesion located in segment VII, measuring approximately 4 cm×4 cm with enhancement on post-contrast images (Figure 1). No additional liver lesions or lymphadenopathy were identified. The patient's history was remarkable for radical right nephrectomy and partial left (upper-pole) nephrectomy for bilateral renal cell carcinoma, one year prior to the presentation. Given the history and radiographic findings, the most likely diagnosis was considered to be that of metastatic renal cell carcinoma. While the lesion was amenable to resection by proper posterior sectorectomy (segments VI, VII), the patient suffered from morbid obesity with BMI = 36, insulin-dependent diabetes, hypertension, renal insufficiency (baseline creatinine 1.8 mg/dL); placing him at significant risk for morbidity from major surgery. Treatment options inclusive of laparoscopic-guided RFA were presented to the patient and subsequently the patient underwent diagnostic laparoscopy with intent to perform RFA. At operation, no evidence of extrahepatic disease was identified. The lesion was observed to encompass the inferior-most aspect of the segment VI/VII interface with significant post right nephrectomy adhesions. To prevent inadvertent thermal injury to the colon at the hepatic flexure, the procedure was converted to open using a lateral sub-costal mini-laparotomy incision. A core needle biopsy of the lesion was performed and sent for permanent pathology review. Using the RITA 7-0 XLi device, and saline infusion, the lesion was targeted by intraoperative ultrasound, and the RFA system was deployed and placed at a 1.0 cm forward-throw distance from the deepest tumor margin. The system was initiated as per the manufacturer's instructions at 2 cm and subsequently advanced sequentially to 4-7 cm. The device needle was retracted in tract-ablation mode and the patient was awakened without complication. The post-operative period

was uneventful and the patient was discharged at d 4 with post-operative follow-up imaging at 1 mo (Figure 2).

Unexpectedly, the tumor biopsy pathology revealed primary bile duct adenocarcinoma with strong immunoreactivity for Cytokeratin 7, Cytokeratin CAM 5.2 and CEA. The tumor cells were negative for Cytokeratin 20 and Vimentin. The patient remained free of detectable disease after 24 mo (Figure 3) with stable normal liver function tests.

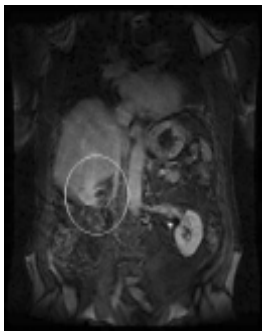

Figure 1 Magnetic resonance scan confirmed the presence of an enhancing lesion located in segment VII, measuring approximately 4 cm×4 cm with enhancement on post-contrast images.

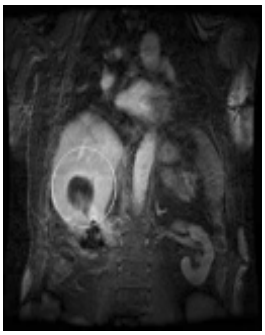

Figure 2 The post-operative period was uneventful and the patient was discharged at d 4 with post-operative follow-up imaging at 1 mo.

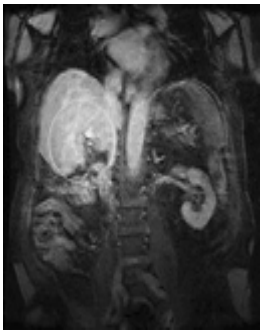

Figure 3 The patient remained free of detectable disease after 24 mo with stable normal liver function tests.

DISCUSSION

We have presented a case of successful ablation of incidentally found primary intrahepatic cholangiocarcinoma using the RFA technique. RFA has become a common treatment for patients otherwise not candidates for resection either as potentially curative or within the context of consolidation therapy in the multi-disciplinary management of patients with primary hepatic malignancy in the liver (including hepatocellular carcinoma) and hepatic metastasis from colon and rectum, lungs, breast, and numerous other sites[3-5]. RFA can be performed during an open intraoperative procedure, laparoscopically or percutaneously under ultrasound guidance. The tumor is destroyed by generating heat within the lesion which results in coagulative necrosis of the neoplastic tissue. Once tissue is heated above 48-50 ℃ for 4 min, mitochondrial death ensues, cell membranes melt and fuse, and with continued heating, protein denaturation and irreversible cell death occurs. A typical treatment results in local tissue temperatures that exceed 100 ℃. RFA has been reported to be relatively safe with acceptable rate of complications, when used by experienced surgeons. The combined overall early and late complication for this technique has been reported as 9.5% with higher risk in cirrhotic patients.

RFA has been previously reported as a salvage therapy for intrahepatic recurrent cholangiocarcinoma with a reported 10 mo survival after the procedure and ongoing follow-up. The present case report illustrates the potential expanding application of RFA technology in patients with primary cholangiocarcinoma, who are not otherwise surgical candidates. We emphasize that the selection criteria for RFA ablation should agree with the criteria used in selecting patients for potentially curative resection; i.e. tumor diagnosis that has demonstrated benefit from resection, no evidence of extrahepatic disease, capacity to encompass the entire lesion with a "margin", and recognition that ablation results in hepatic parenchymal destruction which is equivalent to resection volume loss, thus the underlying Child's status of the liver needs to be considered to prevent post-procedure hepatic failure. In the case presented, the diagnosis of cholangiocarcinoma was unknown and confirmed post procedure. The observed relatively long survival of this patient (24 mo) supports that, for selected patients, RFA may be a reasonable approach for effective therapy. However, until equivalence and/or survival data from appropriately designed clinical studies becomes available, the authors caution the judicious application of this technology.

Abstract

Various hepato-biliary complications are an increased incidence in patients with inflammatory bowel disease, and portal bacteremia is well documented in patients with ulcerative colitis (UC). However, few reports mention UC in association with liver abscesses. Recently, there are several reports describing cytomegalovirus (CMV) infection in association with disease exacerbation and steroid refractoriness in patients with UC. Here we present a case of refractory UC accompanied with multiple liver abscesses and CMV colitis. The patient, a 72-year-old male, with a five-year history of repeated admissions to our hospital for UC, presented with an exacerbation of his UC. Sigmoidoscopy performed on admission suggested that his UC was exacerbated, then he was given prednisolone and mesalazine orally, and betamethasone enemas. However, he had exacerbated symptoms. Repeat sigmoidoscopy revealed multiple longitudinal ulcers and pseudopolyps in the rectosigmoid colon. Although immunohistochemical staining of biopsy specimens and the serum testing for antigenemia were negative on admission and after the repeat sigmoidoscopy, they became histologically positive for CMV. Nonetheless, the patient developed spiking fevers, soon after ganciclovir was administered. Laboratory studies revealed an increased white cell count with left shift, and *Enterococcus fecalis* grew in blood cultures. An abdominal computed tomography (CT) scan was obtained and the diagnosis of liver abscesses associated with UC was made, based on CT results. The hepatic abscesses were successfully treated with intravenous meropenem for 6 wk, without further percutaneous drainage. To our knowledge, this is the first reported case of multiple liver abscesses that develop during UC exacerbation complicated by CMV colitis.

INTRODUCTION

Bacteremia involving the portal venous system is well documented in patients with inflammatory bowel disease (IBD)[1,2]. While studies of patients with ulcerative colitis (UC) suggest an increased incidence of portal bacteremia[1,2], the development of liver abscesses in these patients is relatively rare[3,4]. Only six such cases have been reported so far[5].

Cytomegalovirus (CMV) infection has been implicated in cases of refractory IBD[6,7], and can complicate severe steroid-resistant UC[8,9]. CMV infection characteristically forms discrete ulcers in the colon that can be seen during colonoscopy and may provide a clue to the diagnosis of this infection in UC patients[10]. The ulceration and loss of mucosal integrity that occur in CMV colitis are likely a predisposing factor for microbial invasion of the portal venous system. The subsequent development of any portal bacteremia might be related to the occurrence of liver abscesses in UC.

In this paper, we report a case of refractory UC accompanied with CMV colitis and multiple liver abscesses. To our knowledge, this is the first reported case of multiple liver abscesses that develop in the course of UC exacerbated by CMV colitis.

CASE REPORT

A 72-year-old male, with a 5-year history of repeated hospital admission for UC, was again admitted to our hospital with a month-long history of bloody diarrhea.

On admission, the patient with unremarkable vital signs complained of bloody diarrhea occurring six to ten times per day. On physical examination, his abdomen was slightly distended with normoactive bowel sounds but no tenderness, while his right upper quadrant was unremarkable. Initial

laboratory studies were remarkable for a slightly elevated white blood cell count of 8 640 per microliter (normal range 3 300-8 190/μL) with 66.5% neutrophils and an elevated C-reactive protein of 0.59 mg/dL (normal<0.25 mg/dL). All other laboratory values including liver function tests, were unremarkable. Additionally, the patient had no evidence in his serum of CMV antigen pp65, and stool cultures revealed no pathogenic organisms.

An abdominal X-ray revealed a normal bowel gas pattern, but no evidence of colonic dilatation. Abdominal computed tomography (CT) scan showed the presence of multiple liver cysts, bilateral renal cysts, and colonic inflammation extending from the distal sigmoid colon to the rectum. Sigmoidoscopy revealed diffuse mucosal edema, loss of normal vascular patterns, and friability without ulcerations in the rectum and distal sigmoid colon (Figure 1A).

Initially, the patient received 30 mg prednisolone orally in addition to 2 250 mg mesalazine orally and 3 mg betamethasone enema daily. Although, this treatment resulted in temporary resolution of the diarrhea, he subsequently developed bloody diarrhea, occurring as often as 14 times per day, accompanied with tenesmus, crampy lower abdominal pain, and elevated temperatures (Lichtiger's clinical activity index[11] was 17). Sigmoidoscopy on hospital d 18 revealed multiple longitudinal ulcers and pseudopolyps in the recto-sigmoid colon (Figure 1B). Although, colonoscopic findings suggested CMV infection in addition to UC, immunohistochemical CMV studies and serum testing for CMV antigenemia remained negative. Leukocytapheresis was initiated in addition to the other treatment; however, the patient's bloody and watery diarrhea persisted.

Repeat sigmoidoscopy performed in the hospital on d 29, revealed worsened progression of the previous findings. Biopsy specimens, obtained from the margin and base of the ulcers, showed CMV nuclear inclusion bodies in histiocytes (Figure 2A). Immunohistochemical staining revealed that these cells were indeed positive for CMV (Figure 2B). Moreover, the patient's serum also became positive for CMV antigenemia. These findings suggested that CMV infection was associated with the patient's UC exacerbation. His prednisolone was therefore gradually tapered, and ganciclovir (600 mg twice daily) was administered intravenously for 3 wk. Following the initiation of treatment with ganciclovir, his abdominal symptoms gradually resolved. After 3 wk of antiviral treatment, the Lichtiger's clinical activity index fell from 16 (on the day before ganciclovir was started) to 5.

Eight days after ganciclovir was started on, the patient had a spiking temperature of 38.5 ℃ associated with chills. Laboratory tests revealed an increase in his white blood cell count to 1 240 per microliter with 22.5% band forms, 73.0% polymorphonuclear leukocytes, and 4.5% lymphocytes. His C-reactive protein rose to 4.95 mg/dL. A CT scan demonstrated multiple, small hypo-dense lesions in the right lobe of the liver, suggesting multiple hepatic abscesses (Figure 3A). Blood cultures were positive for *Enterococcus fecalis*.

The patient was treated with intravenous human immunoglobulin (5 g daily) for 3 d, and 1.0 g meropenem intravenously every 12 h for 6 wk. Fever and diarrhea slowly resolved. Twenty-two days later, follow-up CT scan showed a decrease in the number of hypo-dense lesions in the liver. Another CT scan in the hospital on d 119, revealed no evidence of residual liver abscesses (Figure 3B). A colonoscopy performed in the hospital on d 120, demonstrated marked improvement in the appearance of the longitudinal ulcers. He was discharged from the hospital on the following day.

DISCUSSION

Various hepato-biliary complications are known to have an increased incidence in patients with IBD[3]. These complications include fatty changes in the liver, cholelithiasis, pericholangitis, primary sclerosing cholangitis, cirrhosis, chronic active hepatitis, amyloidosis, and bile duct cancer[3]. Even though portal bacteremia is well documented in patients with IBD[1,2], liver abscess is a rare complication[3,4]. In an epidemiological study of 1 274 UC patients in Sweden over a 25-year period, Broome *et al*.[12], found only three cases of liver abscesses. To our knowledge, there are only six such case reports in the literature[5,12-17].

Recently, there are several reports that associate CMV infection with UC exacerbation and steroid refractoriness[6,18,19]. Several retrospective studies of UC patients undergoing proctocolectomy, document CMV anywhere from 4.6% to 13% of surgical specimens[20-22]. In a retrospective, case-control study of 80 patients, Kambham *et al*.[8], reported that immunohistochemistry detects CMV in 10 of 40 (25%) patients with refractory UC and one of 40 (2.5%) patients with non-refractory UC. Cottone *et al*.[9], looked at the prevalence and outcome of CMV infection in a prospective study and reported that CMV is detected in 5 out of 16 (31%) patients with refractory UC. Together, the data from these studies imply that untreated CMV infection is significantly associated with steroid-refractory UC.

Patients with IBD are at a higher risk of CMV infections, due to the following reasons: (1) the common use of immunosuppressive therapies including steroids, thiopurines, methotrexate, cyclosporine A, mycophenolate, tacrolimus, or other newer immunosuppressive agents; (2) suggested tropism for CMV at sites of inflammation and altered immunity in malnourished IBD patients[7]. Given the association of CMV infection with refractory UC, CMV infection should be ruled out with rectal biopsy and CMV serology, prior to initiating immunosuppressive therapy in UC patients presenting with exacerbation[7,8].

In the present case, we had difficulty in making a diagnosis of complicating CMV infection. Both admission immunologic testing for CMV antigen pp65 and finding from the first sigmoidoscopy did not present any evidence of a complicating CMV infection. After the patient failed to improve with initial therapy, although colonoscopic findings suggested CMV infection in addition to UC, immunohistochemical CMV studies and serum testing for CMV remained negative.

Papadakis *et al*.[7], suggested that CMV infection should be suspected in those with systemic symptoms and signs such as high fever, dyspnea, lymphadenopathy, or splenomegaly; and in those whose bowel disease is unresponsive to steroids; as well as in those who develop worsening clinical symptoms after an initial improvement while on immunosuppression. Though the patient had multiple negative results, we were highly suspicious of CMV colitis, and repeated rectal biopsies and serum antigen testing. Treatment with steroids might be a major predisposing factor for activation of CMV. Our experience suggests that discrete and longitudinal ulcers found during colonoscopy might be indicative of CMV infection in UC patients[10].

Although portal bacteremia does occur in UC patients, the incidence of portal vein bacteremia is unknown. Manousos *et al*.[23], and Brooke *et al*.[24], performed portal vein blood cultures at laparotomy and noted that portal bacteremia occurs in about 25% of patients with active UC. Nonetheless very few reports on liver abscess associated with IBD are available. Song *et al*.[5], reviewed six cases of UC reported until 2003. Approximately 30 cases of CD with liver abscess were reported until 1994[25]. Pylephlebitis, steroid administration, intra-abdominal abscesses related to the bowel, the presence of enteric fistula and perforation of the bowel are associated with the development of liver abscess[5,16,25,26]. However, the significance of these factors in UC patients remains undetermined.

Liver abscess is rare in UC patients. Treusch *et al*.[14], and Taylor[27], suggested that the rarity may be due to the fact that the infection is a chronic one in which the body has the opportunity to throw up local barriers and produce a certain amount of systemic immunity. Song *et al*.[5], described that considering portal bacteremia and pylephlebitis in UC patients, ulceration and loss of integrity of the normal mucosal barrier may predispose to microbial invasion of the portal venous system. The most common microorganisms that go on to cause liver abscesses are Gram-negative aerobes, such as *Escherichia coli*, *Streptococci*, *Proteus* species, *Klebsiella species*, and *Enterobacter* species[28]. In our patient, *Enterococcus* species grew in blood and stool cultures, suggesting that there might be an association between liver abscess and rectal ulcer. The time of the development of liver abscess, after steroid treatment and exacerbation of rectal ulcer, seems to indicate that CMV infection plays an important role in their development. Multiple abscesses have a higher mortality rate than single ones, probably in part related to the inability to effectively drain all sources of infection. However, in some cases, pharmacotherapy alone has produced good results[28,29]. Because of steroid treatment, we considered that he had an immunocompromised status, and then intravenous human immunoglobulin was administered. We believe that early diagnosis of CMV colitis complicating UC ultimately helps the resolution of liver abscesses. It should be considered that administration of ganciclovir and the gradual termination of steroid treatment result in remission of colitis and liver abscesses.

In conclusion, in cases of refractory UC, one should highly suspect underlying CMV infection, and early diagnosis of complicating CMV infection in UC patients may contribute to the resolution of liver abscesses and excellent clinical outcome.

Abstract

A 69-year-old male with chronic lymphocytic leukemia presented with iron deficiency anemia and post-prandial abdominal fullness. Endoscopy showed a large polyp on a stalk, protruding through the pylorus into the duodenum causing intermittent gastric outlet obstruction. While prolapsing gastric antral polyps are usually benign and hyperplastic, inflammatory or regenerative in type, excisional snare polypectomy here led to complete resolution of his symptoms, but showed a malignant polyp.

INTRODUCTION

Gastric epithelial polyps are uncommon, estimated to be present in less than 2% of all endoscopic examinations[1]. Up to 90% of all gastric polyps are benign, can usually be classified as inflammatory, regenerative or hyperplastic, and are often less than 1 cm in size[2,3]. Only 5-10% of all gastric polyps are adenomas. Malignant change occurs in less than 1%, usually only in those that are over 1 cm[4].

Since the vast majority of gastric polyps are not neoplastic, and have a very low risk of containing a carcinoma, some authorities have argued that polyp biopsy alone may be sufficient; indeed, most adenomas are reported to display a maximal degree of dysplastic change in the most superficial portion of the polyp permitting biopsy detection [5]. Polyps may also cause symptoms related to bleeding or intermittent outlet obstruction, and may be removed endoscopically or at surgical resection. However, in some centers, even larger asymptomatic polyps may be biopsied, rather than excised, especially in elderly patients[5]. It has been argued that polypectomy is not without significant risk, particularly from hemorrhage after gastric polypectomy where risk has been historically estimated to be as high as 4%[5,6].

Gastric adenomas are usually solitary and asymptomatic. They occur primarily in the antrum and their frequency increases with aging[4]. Logically, gastric adenomas are best completely excised, so that the malignant potential, although very low, is removed. If endoscopic removal is not possible, then surgical resection might be considered, but then the individual risk and benefits must be weighed compared to long-term endoscopic monitoring, since it has been estimated that about 11% of gastric adenomas develop carcinoma within 4 years[4]. Unless the polyps cause symptoms, however, some have advocated that it may be reasonable to do nothing[5].

The present case was unusual in that a prolapsing adenomatous gastric polyp, complicated by an adenocarcinoma, was responsible for gastric outlet obstructive symptoms and these were completely resolved with endoscopic excision of the gastric polyp.

CASE REPORT

A 69-years old Indo-Canadian male with chronic lymphocytic leukemia was referred by his hematologist for investigation of a progressively developing iron deficiency anemia over the prior year. He felt occasional fullness and nausea after meals. There were no other symptoms. He denied hematemesis, rectal bleeding, melena and occult blood testing was negative. Except for a single pea-sized cervical lymph node, there was no other lymphadenopathy. There was no hepatomegaly or splenomegaly. Laboratory studies revealed a hemoglobin of 109 g/L (normal, 135-175) and a white blood cell count of 13.4×A9/L (normal, 4.0-11.0), the majority being lymphocytes. Serum ferritin was 3.1 ug/L (normal, 20-300). INR and PTT were normal. Prior studies, including flow cytometry, had confirmed the typical immunophenotype of chronic lymphocytic leukemia. Upper endoscopic evaluation showed a large polyp with a stalk originating in the gastric antrum and prolapsing through the pylorus (Figure 1). After the polyp was maneuvered into the stomach, it was noted to be irregular with evidence of surface friability and ulceration (Figure 2). After the polyp was excised by snare polypectomy, pathological evaluation was reported to show an adenomatous polyp with high grade dysplasia along with foci of intramucosal carcinoma. Additional sections through the base of the polyp stalk, however, confirmed that polyp excision was

complete without evidence of invasion into the submucosa. No malignant cells were detected in the polyp stalk or cut margin. Other gastric biopsies were normal and stains for *Helicobacter pylori* were negative.

Figure 1 Polypoid lesion with long stalk protruding through the pylorus into the duodenum.

Figure 2 Slightly irregular gastric antral polyp with eroded surface. Polypectomy specimen showed adenoma with high-grade dysplasia and invasive intramucosal carcinoma. No invasion into stalk or submucosa.

DISCUSSION

This patient presented with a large gastric antral polyp that had prolapsed through the pylorus, causing symptoms due to a gastric outlet obstruction. The polyp was endoscopically excised and proved to be a large gastric adenoma complicated by adenocarcinoma. This is distinctly unusual. Endoscopic removal or excision of symptomatic and prolapsing gastric polyps have been occasionally reported in the literature, however, these have been, as might be anticipated, primarily large, sometimes pedunculated polyps with inflammatory, regenerative or hyperplastic histopathologic features, rather than adenomas or adenomas with superimposed carcinomas[7-12].

In the earlier endoscopic literature, endoscopic biopsy alone for most lesions was thought to be sufficient, and if the histopathologic changes in these biopsies were consistent with an adenoma, then endoscopic polypectomy, or surgical resection, could be considered[13-16]. Later, endoscopic excision, rather than biopsy alone, was recommended since the procedure could be done safely and since foci of *in situ* malignant change could be detected in some adenomas. Others have also demonstrated the detection of carcinoma or dysplastic change in hyperplastic gastric polyps[17-19]. Given the evolution of endoscopic accessories for control of post-polypectomy bleeding vessels (e.g., loops, clips), the excision of large, especially solitary, gastric polyps has clearly been facilitated.

An additional management issue for the future was also considered here. Gastric polyps that have been completely excised and contain invasive cancer may require additional evaluation. Data is currently very limited for gastric polyps on the role of a further local surgical resection to examine adjacent lymph nodes for metastases. It appears that the risk of lymph node metastases is exceedingly low, but it is not zero[20]. Previous studies of so-called early gastric cancer confined to the mucosa or submucosa may provide some guidance. For early gastric cancers of the polypoid subtype (type 1) treated with surgical resection, 1.8% of patients with intramucosal carcinoma had nodal metastases compared to 18.5% with submucosal involvement[5]. Thus, until more data is available, it would appear reasonable to treat all polyps with pathologically-defined intramucosal carcinoma alone with endoscopic resection alone, while an additional surgical resection should be considered, if submucosal infiltration is present.

Abstract

We report on a case of Churg–Strauss syndrome (CSS) with colon erosion, cholecystitis and liver abscesses. A 21-year-old woman with a history of bronchial asthma for 3 years was admitted with a complaint of abdominal pain. Laboratory findings included remarkable leukocytosis and eosinophilia, and a colonoscopy revealed erosion from the rectum to the ileocecal region. In addition, a colonic biopsy specimen showed necrotizing vasculitis and marked eosinophilic infiltration. On the basis of the clinical features and histopathological findings, she was diagnosed with CSS and subsequently treated with oral prednisolone, after which the eosinophilia and abdominal pain disappeared. However, on the 15th d in hospital she developed cholecystitis and liver abscesses. She was therefore treated with antibiotics and as a result went into clinical remission.

INTRODUCTION

Churg and Straus[1] histopathologically investigated a group of 13 patients who first developed asthma, followed by fever, hypereosinophilia and systemic small vessel vasculitis noted that it was characterized by necrotizing vasculitis and extravascular granuloma with hypereosinophilia, which distinguished it from classic PAN. The following year, Zeek[2,3] referred to this vasculitis as allergic granulomatous angitis and distinguished it from hypersensitivity vasculitis as a type of necrotizing vasculitis. We have therefore referred to this as Churg-Strauss syndrome, a disease which is manifested as asthma, eosinophilia and vasculitis. When its biopsy specimen histopathologically shows hypereosinophilia or extravascular granuloma, we refer to it as allergic granulomatous angitis. Mononeuritis[4,5] multiplex and gastrointestinal involvement are common in CSS, but cholecystitis is less common. In the literature, six cases[6-11] of cholecystitis complicated with CSS have been reported, while for liver abscesses, only one[14] has been reported. We describe herein a case of CSS presented with colon erosion, cholecystitis and liver abscesses.

CASE REPORT

A 21-year-old woman was admitted on July 2, 2002, with a complaint of abdominal pain. The patient had a history of bronchial asthma and sinusitis 3 years prior to admission, and mentioned that her mother was an asthmatic. A year prior to admission, the patient had been diagnosed with eosinophilic infiltrating pneumonia and was treated with an oral corticosteroid, which had been tapered and continued until admission. On June 22, 2002 she felt severe pain in her left upper quadrant subsequently and on June 27, she consulted a doctor at our hospital and had her stomach examined. However, gastrofiberscopy showed no abnormalities. The patient was suspected to be constipated and thus administered a laxative. However, her abdominal pain had persisted, and so she went to the emergency department and was admitted for further evaluation and treatment. On physical examination, no rash or lymphadenopathy was found, no crackle was present over both lung fields, and no cardiac murmurs were heard, her abdomen was soft and flat, and there was no tenderness. In addition, her lower legs were not edematous. On neurologic examination, the patient was alert and oriented. Her cranial nerve functions, muscle strength, and deep-tendon reflexes were normal. Her hematologic findings showed a leukocyte count of 2.93×10^4 per microliter with 56.0% eosinophils, and a platelet count of 39.9×10^4 per microliter. Her C-reactive protein level was 2.5 mg/dL, but her lactate dehydrogenase was elevated to 398 IU/L. Her total protein was 7.7 g/dL with γ-globulin at 25.2%, serum alanine aminotransferase (ALT) level was 118 IU/L (normal range of 10-35 IU/L), aspartate aminotransferase (AST) level was 63 IU/L (normal range of 10-35 IU/L), and alkaline phosphatase level was 254 IU/L (normal range of 120-340 IU/L). In addition, the patient's and Leucine aminopeptidase level was 51 IU/L (normal range of 23-50 IU/L), and her γ-glutamyl-

transpeptidase level was 43 IU/L (normal range of 8-60 IU/L). Her total bilirubin and albumin levels were within normal limits and her immunoglobulin IgG and IgE levels were 1 980 mg/dL and 27 U/mL, respectively. A test for antinuclear antibody was borderline positive, rheumatoid factor was positive, but C-anti-neutrophil cytoplasmic antibodies (C-ANCA) and myeloperoxidase anti-neutrophil cytoplasmic antibodies (MPO-ANCA) were negative. The circulating levels immune complex CH50, C3 and C4 levels in the serum were all normal, renal function was almost normal, and there was no hematuria or sedimentation in the urine. Sputum bacteriology showed only normal flora and no tubercle bacilli and a worm egg test was negative, but the results of an occult blood test were positive. Radiographs of the chest showed a faintly nodular density in the left lower lung field, but radiographs of the abdomen were almost normal. A CT showed that her gallbladder had shrunk, but her liver and pancreas, GI tract and colon were normal. Ultrasonography (US) showed similar findings. Spontaneous pain emanating from her epigastrium to her left upper quadrant was so strong that the repeated use of analgesics had no effect. A colonoscopy showed multiple aphthous ulcers and erosion from the rectum to the ileocecal region (Figure 1). Furthermore, a colonic biopsy specimen showed marked eosinophilic infiltration from the muscular layer of the mucosa to the submucosa, and for the small vessels, lumen stenosis with thickening of the intima indicative of vasculitis was noted (Figure 2). On the basis of her clinical features such as bronchial asthma preceding vasculitis, the laboratory findings including remarkable leukocytosis and eosinophilia, and histopathological findings of eosinophilic vasculitis, a diagnosis of CSS was established. She was administered with oral prednisolone daily since her 10th d in hospital, so her eosinophil count gradually decreased and abdominal pain slowly disappeared. However, she was examined by abdominal CT because she developed a low grade fever, and laboratory findings showed increased liver function on the 15th d. CT showed that the gallbladder was distended and had a thickened wall (Figure 3). We could not detect stones in her gallbladder, but found low density areas, that were faintly enhanced at S6 and S8 of right lobe of the liver ,which we suspected to be abscesses (Figure 3). US showed similar findings. From these examinations, our diagnosis was cholecystitis and liver abscesses, and so intravenous antibiotic (IPM/CS) were administered. CT on the 38th d in hospital revealed low density areas at S6 and S8 that were fading, and that her gallbladder was becoming atrophic with simultaneous wall thickening. After 41 d in hospital, her prednisolone was gradually tapered. She continued to be asymptomatic without recurrence, and was discharged, on the 58th d. After discharge, US revealed a projection in her gallbladder 20 mm in diameter. We proposed its surgical removal because we could not distinguish it from a polyp. Therefore, a laparoscopic cholecystectomy was performed on October 15. No polyp was found, but debris was noted in the resected specimen. Histopathological findings of the resected gallbladder revealed necrotized vessels with occlusive intimal proliferation below the tunica serosa vesicae felleae, which had passed the peak of fibrinoid necrosis. We could not detect eosinophilic infiltration in the specimen (Figure 4), and a liver biopsy performed at the same time showed no remarkable abnormalities.

Figure 1 Colonoscopy showing multiple aphthous ulcers and erosion from the rectum to the ileocecal region.

Figure 2 A colonic biopsy specimen showing marked cellular infiltration from the muscular layer of the mucosa to the submucosa and small vessels, lumen stenosis with thickening of the intima, indicative of vasculitis. A H&E,×100.

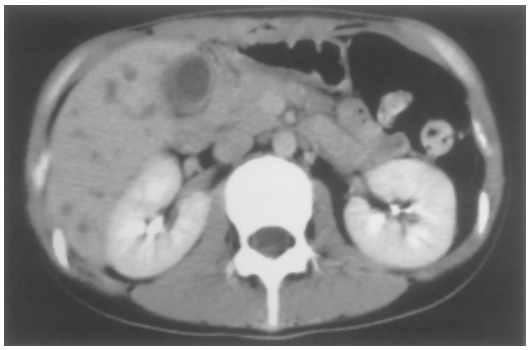

Figure 3 CT showing the gallbladder distended with a thickened wall. In addition, low density areas faintly enhanced at S6 and S8 in the right lobe of the liver suspected to be abscesses are seen.

DISCUSSION

Six criteria used for the classification of CSS were selected: (1) Bronchial asthma;(2) Eosinophilia >10% by differential WBC count; (3) Mononeuropathy or polyneuropathy, (4) Non-fixed pulmonary infiltrates on roentgenography, (5) Paranasal sinus abnormality, and (6) Biopsy containing a

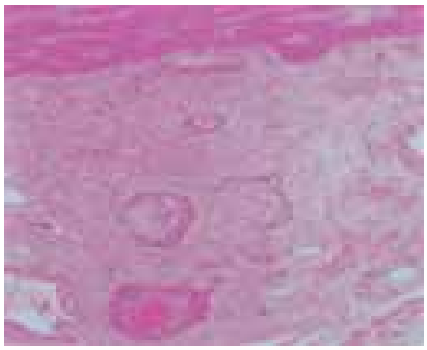

Figure 4 Histopathological findings of the resected gallbladder revealed necrotized vessels with occlusive intimal proliferation below the tunica serosa vesicae felleae, which had passed acute phase in the resected specimen. We could not detect eosinophilic infiltration in this specimen.

blood vessel with extravascular eosinophils[6,12]. Masi *et al*., reported that the existence of four or more of these six criteria yields a sensitivity of 85% and a specificity of 99.7%[12]. The present patient did not suffer from mononeuropathy or polyneuropathy, but fulfilled the other five criteria. Furthermore, she suffered from leukocytosis, an elevated RF level, thrombocytosis except an increased IgE level, and her histopathological findings showed necrosis with marked eosinophilic infiltration. Therefore, we diagnosed her condition as CSS. We can cite as differential diagnosis, eosinophilic leukocytosis, Wegener's granulomatosis, microscopic polyangitis, and PAN (polyarteritis nodosa). CSS is similar to eosinophilic leukocytosis in clinical manifestation, but we could distinguish it from the condition of this case as eosinophilic leukocytosis in thrombocytopenia was not observed and so many impaired internal organs were noted. We could distinguish this case from Wegener's granulomatosis in respect that she did not suffer from kidney trouble or exhibit positive reaction by the C-ANCA[13] test, supported by her histopathological findings. In addition, her past history of sinusitis was typical of one of the major features of CSS in America. She was not afflicted with microscopic polyangitis, because she did not exhibit any positive reaction for MPO-ANCA or the rapid progression of glomerulonephritis, and she did not have PAN because she did not have the various symptoms and showed remarkable eosinophilic infiltration as seen from her histopathological findings. We could only diagnose her with typical CSS judging from her initial course of asthma followed by systemic small vessel vasculitis after 4 years, and because she also had been suffering from eosinophilic infiltrating pneumonia before admission. Lanham *et al*., reported that for about 40% of case of CSS, such pneumonia with eosinophilic infiltration proceeds systemic small vessel vasculitis[5]. The present case developed cholecystitis and liver abscesses, and we could not detect stones in the resected GB. Therefore, we diagnosed her as having acalculous cholecystitis. There was no eosinophilic infiltration found in the resected specimen of the gallbladder because steroid treatment had been carried out. However, we detected necrotized vessels that had passed acute phase in that specimen. Therefore, we believed that her cholecystitis had been caused by CSS. Regarding her liver abscesses, since we could detect no remarkable abnormalities such as those found in the gallbladder among the pathological findings of her liver, we thought that the abscesses had been caused by infection via the blood circulation from cholecystitis or colitis. We report this case because the clinical manifestations of CSS usually include gastroenteritis and ischemic ulcerations of the stomach as well as the small and large bowel, but less often include cholecystitis and liver abscesses.

Abstract

A 60-year-old female patient suffered unhealed wounds over left flank for around 30 years after surgical removal of left renal stones. Fecal material spilled from the two small openings of the scar, bothered her all day long. During the course of the 30 years, she suffered from intermittent fever, diarrhea and wound pain and presented with malnourished condition. After serial examinations, tumor associated with iatrogenic colo-cutaneous fistula was impressed and she received en bloc resection. Pathology revealed squamous cell carcinoma arising from the fistula with colon and spleen invasion. To the best of our knowledge, no such case has been reported, as yet.

INTRODUCTION

Malignant tumors arising from previously existing fistulas are rare. Squamous cell carcinoma arising from colocutaneous fistula has never been reported. Herein, we report a case of squamous cell carcinoma arising from previously existing longstanding colocutaneous fistula. The diagnosis made has been based on high suspicion, history, imaging and pathology.

CASE REPORT

A 60-year-old female patient was admitted due to general weakness, anorexia accompanied with fever and chills for 2 wk. She denied any other systemic disease. The patient originally was diagnosed with left renal stones and had left nephrectomy, at some other hospital three decades ago. She got stool spillage from surgical wound on left flank after that surgery. Despite wound treatment, two fistulous openings were left with intermittent fecal discharge. During this period, she received supportive treatment while infective symptoms such as fever, chills, diarrhea and local cellulites were present.

We noted that she was a cachectic, frail female with pale conjunctivae. The abdomen was palpated without tenderness and the bowels were normally peristaltic on auscultation. Two chronic unhealing wounds involving the left flank with fecal discharge were noted (Figure 1A). Local erythematous, swollen and tender to palpated were noted. No enlarged lymph nodes were palpated. Anemia (Hb 4.4 g/dL) and chronic renal insufficiency (Cr 2.3 mg/dL) were noted. Abdominal computed tomography discovered splenomegaly with soft tissue density adjacent to it and the splenic flexure of T-colon with air bubbles (Figure 1B). After infection had subsided, fistulograms revealed communication between skin and bowel tract (Figures 1C and D). Under a period of nutritional support, surgical intervention was performed. At laparotomy, the low pole of the spleen adhered to the splenic flexure of T-colon densely with irregular soft tissue beside the region (Figure 1E). Partial wall of the jejunum, 10 cm distal to Treitz's ligament, adhered to the distal T-colon was noted (Figure 1F). En bloc resection with splenectomy, segmental resection of colon with primary anastomosis and wedge resection of jejunum were performed (Figure 1G). Postoperative course was grossly smooth. She is being followed up at the outpatient department.

The pathologist reported moderately differentiated squamous cell carcinoma in virtually all specimens (Figure 2A). However, the microscopic photographs revealed the tumor cells arising from the fistulas (Figure 2B) with spleen (Figure 2C) and colon invasion (Figure 2D).

DISCUSSION

It is well-known that surgery is still the most common cause of entero-cutaneous fistula. The causes of persistent entero-cutaneous fistula include foreign body, radiation, infection, inflammation, epithelization, neoplasm and distal obstruction[1]. Squamous cell carcinoma can develop from chronic ulcers, scars, wounds, sinuses, and fistulas[2]. The latent periods are long and take around 37 years for patients

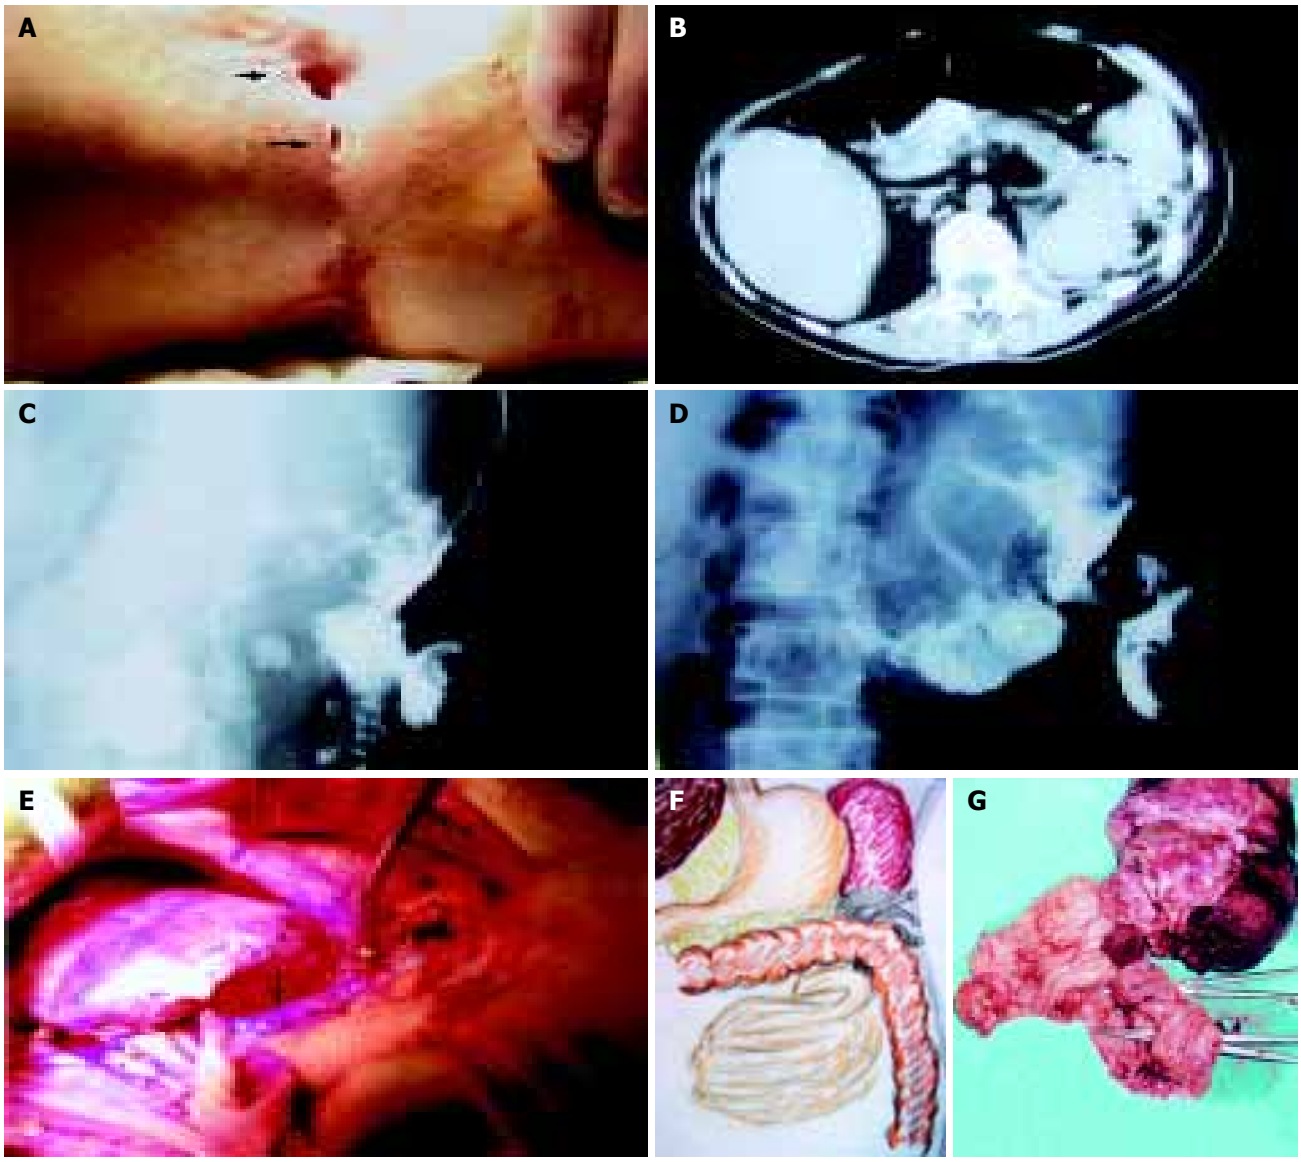

Figure 1 **A:** Surgical scar over left flank with two fistulous openings; **B:** Abdominal CT scan revealed irregular mass between the pancreatic tail, spleen and left lateral abdominal wall with air bubbles; **C:** The fistulogram revealed communication between the skin and sinus tract; **D:** The fistulogram revealed communication between the skin and intestinal tract; **E:** At laparotomy, splenomegaly and dense adhesion to the splenic flexure of colon (arrow) and the left abdominal wall were noted; **F:** The drawing revealed the relation between the fragile soft mass, the fistulas, the spleen and the bowels; **G:** The specimen was shown and these two openings in the colon communicating with skin were indexed with the instruments.

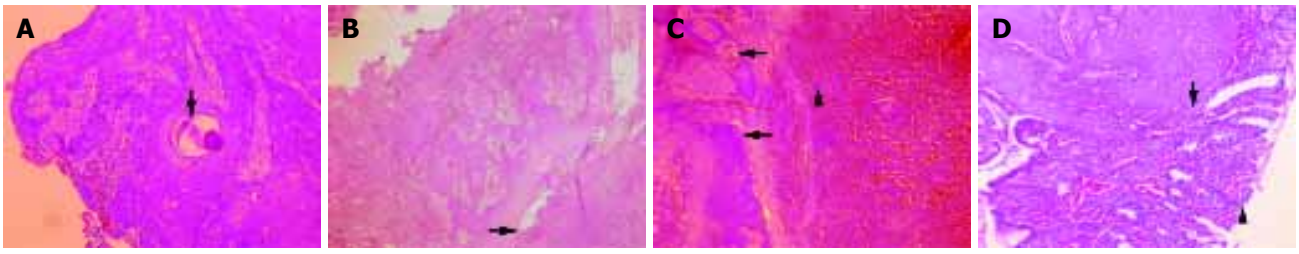

Figure 2 Microscopic photograph. **A:** The squamous cancer cells and keratin pearls (arrow) were shown on the microscopic photograph; **B:** The pathological photograph revealed fistulous tract (arrow) and the tumor cells arose from its epithelium; **C:** The microscopic photograph revealed the tumor cells (arrow) invading the spleen (triangular arrow); **D:** The microscopic photograph revealed the tumor cells (arrow) invading the colon (triangular arrow).

with burn scars except 1-7 years for immunocompromised patients[2,3]. The most significant factor reported in predicting the outcome for the squamous cell carcinoma from the pre-existing scar or sinus was the grade of the tumor[4]. Squamous cell carcinoma associated with prior renal stones have always been reported[5] and the median survival time was 3.6 mo[6]. It was dismal and was not compatible with the long-term history of the patients. We might consider

the development of squamous cell carcinoma as the result of chronic irritation and infection due to unhealed wounds[7]. The strong evidence was that the microscopic photographs revealed the origination of tumor cells from the epithelium of the fistulous tract. However, there are no prior reported articles available as this case. Because of its insidious course, the long-standing colo-cutaneous fistula should be examined carefully for tumor development. The early nutritional intervention is important for patients with entero-cutaneous fistula[8] and surgery is inevitable for long-term unhealed fistula.

Acknowledgments to Reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those were published and those were rejected in this issue) during the last editing period of time.

ELSEVIER

World J Gastroenterol 2005;11(33):5256-5257
World Journal of Gastroenterology ISSN 1007-9327
© 2005 The WJG Press and Elsevier Inc. All rights reserved.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG*, ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published jointly by

The WJG Press and Elsevier Inc.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the Editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Elsevier Inc., and may not be reproduced by any means, in whole or in part without the written permission of both the Authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com for assistance. If you submit manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

World Journal of Gastroenterology
Apartment 1066 Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors originating from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be involved. Titles should be concise and informative (removing all unnecessary words), emphasize what is NEW, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initials and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 3-10 key words that could reflect content of the study.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or Figures and Tables, not both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should add into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) and not RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by Freehand and Illustrator, or TIFF from Photoshop. EPS files must be accompanied by a version in native file format for editing purposes. Scans of existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size at which they will appear when printed, not smaller. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...;C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be involved under the tables. This part should add into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data which is not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used; Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^1F, ^2F, ^3F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

References

Cited references should mainly be drawn from journals covered in the Science Citation Index (http://www.isinet.com) and/or Index Medicus (http://www.ncbi.nlm.nih.gov/PubMed) databases. Mention all references in the text, tables and figure legends, and set off by consecutive, superscripted Arabic numerals. References should be numbered consecutively in the order in which they appear in the text. Abbreviate journal title names according to the Index Medicus style (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=journals). Unpublished observations and personal communications are not listed as references. The style and punctuation of the references conform to ISO standard and the Vancouver style (5th edition); see examples below. Reference lists not conforming to this style could lead to delayed or even rejected publication status. Examples:

Standard jounal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]
2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]
3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287 [CMFAID:1082371101835979]

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http / / www.cdc.gov / ncidod / EID / eid.htm

PMID requirement

From the full reference list, please submit a separate list of those references embodied in PubMed, keeping the same order as in the full reference list, with the following information only: (1) abbreviated journal name and citation (e.g. *World J Gastroenterol* 2003;9(11): 2400-2403; (2) article title (e.g. Epidemiology of gastroenterologic cancer in Henan Province, China; (3) full author list (e.g. Lu JB, Sun XB, Dai DX, Zhu SK, Chang QL, Liu SZ, Duan WJ; (4) PMID (e.g. 14606064). Provide the full abstracts of these references, as quoted from PubMed on a 3.5 inch disk or CD-ROM in Microsoft Word format and send by post to The *WJG* Press. For those references taken from journals not indexed by *Index Medicus*, a printed copy of the first page of the full reference should be submitted. Attach these references to the end of the manuscript in their order of appearance in the text.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean±SD and mean±SE.

Statistical expression

Express *t* test as *t*(in italics), *F* test as *F*(in italics), chi square test as χ^2 (in Greek), related coefficient as *r*(in italics), degree of freedom as γ(in Greek), sample number as *n*(in italics), and probability as *P*(in italics).

Units

Use SI units. For example: body mass, m(B) = 78 kg; blood pressure, p (B)=16.2/12.3 kPa; incubation time, t(incubation)=96 h, blood glucose concentration, c(glucose) 6.4±2.1 mmol/L; blood CEA mass concentration, p(CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23,243,641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italicization

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *Helicobacter pylori*, *H pylori*, *E coli*, *etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the WJG Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of WJG to acquire copyright in all contributions. Papers accepted for publication become the copyright of WJG and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

Abstract

Potassium (K^+) ions are critical for the activation and catalytic cycle of the gastric H^+,K^+-ATPase, resulting in the secretion of hydrochloric acid into the parietal cell canaliculus. As both symptom, severity and esophageal mucosal damage in gastro-esophageal reflux disease (GERD) are related to the degree of acid exposure, K^+ is a logical target for approaches to inhibit acid production. The probable K^+ binding site on the gastric H^+,K^+-ATPase has recently been described and studies are elucidating how K^+ activates the enzyme. K^+ channels in the apical membrane of the parietal cell are implicated in the recycling of K^+ and, to date, three potential K^+ channels (KCNQ1, Kir2.1 and Kir4.1) have been identified. The channels represent theoretical sites for agents to control acid secretion but it will be difficult to develop selective blockers. An alternative strategy is to prevent K^+ from activating gastric H^+,K^+-ATPase; the potassium-competitive acid blocker (P-CAB) class inhibits acid secretion by binding at or near the K^+ binding site. Ongoing research is further defining the role of K^+ in the functioning of the gastric H^+,K^+-ATPase, as well as determining the clinical utility of agents directed toward this important cation.

INTRODUCTION

Gastric acid is essential for the sterilization of food and water and for digestion. The very low pH of gastric juice (pH~1) is the result of H^+ and Cl^- ion secretion (hydrochloric acid [HCl] production) by parietal cells in the oxyntic mucosa of the stomach. Each day, these cells secrete 1-2 L of HCl to achieve a concentration of 150-160 mmol/L in the stomach lumen. This acid concentration, which represents a very high accumulation of H^+ in the lumen compared with parietal cell plasma, is facilitated by the activity of gastric H^+,K^+-ATPase in the apical membrane of the cell. K^+ has a critical role in the activation of gastric H^+,K^+-ATPase and is essential for the functioning of the enzyme[1-3]. This review examines the central role of K^+ in acid secretion and assesses how targeting this cation may provide novel ways of inhibiting gastric acid production.

GASTRIC H^+,K^+-ATPASE AND ACID SECRETION

Gastric H^+,K^+-ATPase is located in the apical membrane of the parietal cell and transports H^+ into the parietal cell canaliculus in exchange for K^+. The cations are exchanged in a 1:1 ratio, which maintains electroneutrality[4,5]. The enzyme is a member of the P-ATPase family that also includes Na^+,K^+-ATPase, Ca^{2+}-ATPase and colonic H^+,K^+-ATPase[6-8]. Gastric H^+, K^+-ATPase shares many features, including structure and enzymatic mechanism, with other members of the family. A central feature of the P-ATPase family is that the energy for the translocation of ions is provided by ATP.

The amount of energy released on hydrolysis of an ATP molecule effectively limits the concentration gradient that can be created by a P-ATPase enzyme. The transport of ions is also constrained if their exchange generates a charge. As the translocation of H^+ and K^+ is electroneutral, gastric H^+,K^+-ATPase achieves a 3-4 million-fold ion concentration gradient (the difference in H^+ concentration between plasma and parietal cell canaliculus), which is among the highest observed in the mammalian body.

The process of acid secretion also involves the movement of other ions into and out of the parietal cell[1,9,10]. In the classical model of gastric acid secretion, we find that for each H^+ ion that is transported into the canaliculus by the H^+,K^+-ATPase, the basolateral Cl^-/HCO_3^- exchanger delivers a HCO_3^- molecule into the plasma and a Cl^- ion into the cytosol (Figure 1)[11,12]. Cl^- is secreted into the canaliculus via Cl^- channels in the apical membrane of the parietal cell, and it is possible that more than one type of channel is involved, as is likely to be the case with K^+. However, so far there is only evidence for the ClC-2 channel[13]. These Cl^- channels allow Cl^- to act as a counter ion for the K^+ flux across the membrane, thereby balancing the charge and ensuring electroneutral HCl secretion.

In common with most other cells, the level of K^+ in the parietal cell is higher than that in the plasma. The higher intracellular K^+ level is dependent on the activity of the Na^+,

K^+-ATPase. This enzyme is located on the basolateral membrane of the cell where it exchanges intracellular Na^+ for extracellular K^+[14]. The level of K^+ within the cell is also regulated by K^+ channels that allow ion movement across the basolateral membrane. These channels have a particularly an important role in generating negative cell membrane potential.

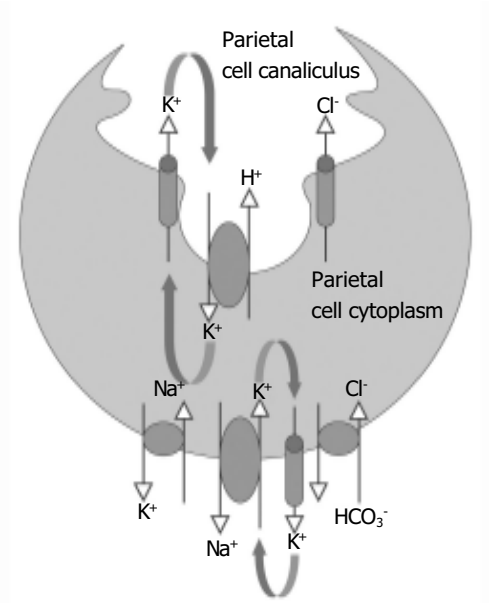

Figure 1 A simplified model for the secretion of gastric acid by the parietal cell. The H^+,K^+-ATPase located on the apical membrane of the parietal cell exchanges H^+ for K^+. K^+ is recycled from the canaliculus into the cytoplasm by K^+ channels in the apical membrane. The combined actions of K^+ channels and enzymes on the basolateral membrane regulate cytoplasmic K^+ levels. Cl^- enters the cell cytoplasm via a Cl^-/HCO_3^- exchanger and moves from the cytoplasm into the canaliculus via a Cl^- channel (most likely ClC-2).

ACTIVATION OF GASTRIC H^+,K^+-ATPASE BY K^+

When a parietal cell is in a resting state, H^+,K^+-ATPase is localized to tubulovesicular elements within the cell[15]. The concentration of K^+ in the tubulovesicular elements is low and their membranes are impermeable to K^+. Consequently, the enzyme cannot be activated and transport H^+ ions[1]. Stimulation of the parietal cell (e.g. by histamine) causes the tubulovesicular elements to fuse with the apical membrane of the cell[16,17]. The H^+,K^+-ATPase does not appear to undergo any chemical modification during activation of acid secretion but, as a result of the membrane fusion events, the enzyme is exposed to K^+-containing luminal fluid and can start to exchange H^+ for K^+.

This process of ion exchange involves several steps and conformational changes in the 3D structure of the H^+,K^+-ATPase (Figure 2)[5]. The enzyme exists in two important conformational states. In one of these states (referred to as E_1), the ionbinding site faces the parietal cell cytoplasm with high affinity for H^+ and low affinity for K^+; in the other state (E_2), the ion-binding site faces the extracellular canaliculus with low affinity for H^+ and high affinity for K^+. It is likely that the shape of the K^+ binding site or the path through which the ion accesses the binding site is different for the E_1 and E_2 forms[18], which may explain the relative affinity of the two forms for K^+.

In the E_1 form, the enzyme takes up H^+ and then converts into the E_2 form with the hydrolysis of ATP. As well as providing the energy for the shift between these conformational states, the hydrolysis of ATP also results in the phosphorylation of the enzyme (a state referred to as E_2P). The transformation to the E_2 form causes the translocation of H^+ from the parietal cell membrane into the canaliculus. Subsequently, the phosphorylated E_2 form binds K^+, which is required for the dephosphorylation of the H^+,K^+-ATPase.

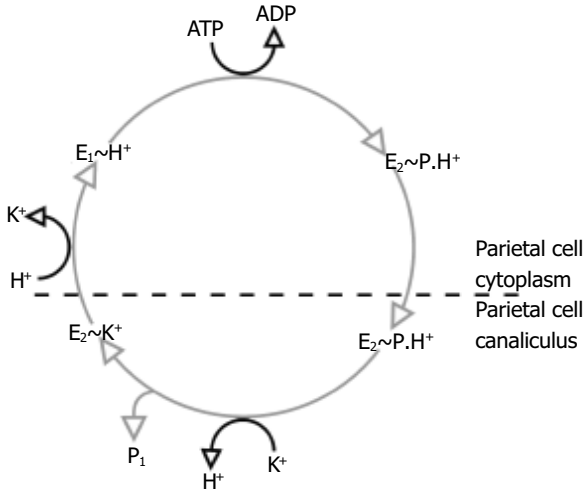

Figure 2 Post-Albers catalytic cycle of gastric H^+,K^+-ATPase.

During the cycling of the enzyme, K^+ becomes temporarily occluded within the transmembrane segments and the cations no longer have free access to the cytoplasm or canaliculus. It is in this state that the cation causes dephosphorylation of the H^+,K^+-ATPase[19]. The mechanism for this process is not fully elucidated. It is likely that K^+ does not stimulate dephosphorylation of the phosphorylated intermediate directly, but acts by neutralizing the inhibitory effect of a negative charge in the membrane[20]. After dephosphorylation, the enzyme returns to its E_1 form and releases K^+ into the parietal cell cytoplasm.

Some investigators have reported that one H^+ and one K^+ are exchanged for each ATP hydrolyzed[21], while others have found that there is reciprocal exchange of two pairs of ions per ATP hydrolysis[22,23]. The hypothesis that one H^+ is swapped for one K^+ ion is supported by recent modeling work, which demonstrated that gastric H^+,K^+-ATPase has a single K^+ binding site[24]. There are single ion binding sites in other P-type ATPases, such as yeast and plant H^+-ATPase[25], which provides support for the existence of a single cation binding site in gastric H^+,K^+-ATPase. Moreover, it has been proposed that one single binding site could more easily explain the ability of the H^+,K^+-ATPase to transport H^+ against a high concentration gradient[24].

K^+ BINDING SITE IN GASTRIC H^+,K^+-ATPASE

Much work has been directed at elucidating the identity of

the K^+ binding site (or sites) and potential sites have been located within the transmembrane segments M4, M5, M6 and possibly M8 of the α-subunit of the enzyme[26-29]. In accordance with the physiological role and location of K^+ (i.e. in the parietal cell canaliculus), the evidence suggests that the site is located towards the luminal face of the membrane domains[30]. When K^+ occupies this binding site, it appears to affect the conformation of a large intracellular loop in which phosphorylation occurs[20]. Moreover, K^+ is required for stabilization of a tight loop or 'hairpin' between M5 and M6[31]. This hairpin has a direct link with the phosphorylation domain on the intracellular loop that contains the ATP binding site, suggesting that it is involved in coupling ATP hydrolysis with cation transport[31].

As noted, recent work indicates that there is one high-affinity cation binding site in gastric H^+,K^+-ATPase[24]. The K^+ binding site is formed by amino acids from M4, M5 and M6, with the ion being held in place by six oxygen atoms provided by these domains[24]. The presence of a negative charge within the pocket (at residue 820) is thought to be important to the functioning of the enzyme[24].

This understanding of the likely structure of the K^+ site and its interaction with the phosphorylation domain has led to a theory on how K^+ activates the enzyme. The negative charge in the ion-binding pocket may exert an indirect inhibitory effect on the phosphorylated intermediate form of the enzyme, thereby preventing its hydrolysis[20]. When the cation-binding pocket is occupied by K^+, the negative charge is neutralized. A signal is then transferred to the nearby phosphorylation domain of the enzyme, possibly via a lysine amino acid residue, which results in enzyme dephosphorylation[32] and the subsequent translocation of K^+ from the parietal cell canaliculus to the cytoplasm.

K^+ SELECTIVITY OF THE H^+,K^+-ATPASE

The H^+,K^+-ATPase is highly selective for K^+, although it can also be activated *in vitro* by NH_4^+[33,34]. The cation selectivity of the enzyme appears to be generated through interactions with the residues of the transmembrane segments of the α-subunit and the flanking loops that connect these transmembrane domains[35]. The degree of K^+ affinity, along with the ATPase activity of the gastric H^+,K^+-ATPase, is also influenced by a salt bridge from M5 to M6 that exists only when the enzyme is in the E_2 form[24]. Importantly, this salt bridge only allows space for a single K^+ binding site and so prevents the formation of another K^+ binding site within the enzyme[24].

The β-subunit is also implicated in determining the K^+ affinity of gastric H^+,K^+-ATPase[36,37], as shown in a study comparing the pig and rat gastric H^+,K^+-ATPase. The different K^+ affinity of the enzymes from the two species was influenced by both the lipid matrix in which the enzymes were embedded and the identity of the β-subunit[37].

ROLE OF K^+ CHANNELS IN K^+ RECYCLING

At basal (i.e. unstimulated) levels of parietal cell activity, gastric juice consists mainly of NaCl, with only small amounts of K^+ and H^+. Stimulation of the parietal cell results in a sharp drop in pH. At a pH of approximately 1, the canaliculus of the parietal cell contains 150-160 mmol/L HCl[14]. Given the low concentration of K^+ ions in the unstimulated state, achieving such a low pH would appear to be difficult through 1:1 exchange of H^+ for K^+. However, stimulation actually elevates K^+ concentration (measured as KCl) in the gastric milieu (to 10-20 mmol/L KCl)[14]. Nevertheless, even at these levels there would be rapid K^+ depletion without a mechanism for replenishing of K^+ levels in the parietal cell canaliculus.

The K^+ ions that are exchanged with H^+ by the H^+,K^+-ATPase are provided by the parietal cell, while the Na^+,K^+-ATPase enzyme on the basolateral membrane accumulates K^+ within the parietal cell. Theoretically, a K–Cl co-transporterd could supply the H^+,K^+-ATPase enzyme with K^+, while also delivering Cl^- into the parietal cell canaliculus. This does not however appear to be the case, as Cl^- channels are present in the parietal cell apical membrane, and there is evidence that K^+ is recycled and enters the parietal cell canaliculus via specific K^+ channels[1].

To date, three different types of K^+ channels that may contribute to K^+ recycling have been identified in the apical membrane of the parietal cell. These K^+ channels belong to one of the largest and most diverse group of ion channels in the body[38]. There are over 60 K^+ channels, categorized according to whether they have 2, 4 or 6 transmembrane domains, and sharing a common feature of a pore-forming loop as part of the K^+ selective filter. Associated with these pore-forming subunits are additional regulatory units. Although the subunits are not essential for the formation of the ionic pore, they are responsible for membrane targeting and functional properties of the channel. The identity of the subunits in a cell, along with the type of K^+ channel they co-assemble with, determines the electrophysiological properties of that cell. In any given cell, there may be several types of channel and various subunits; some of the subunits may associate with more than one channel and so may result in channels with different functional attributes.

The K^+ channel KCNQ1 (formerly known as KvLQT1) was found to co-localize with gastric H^+,K^+-ATPase and to be abundantly expressed in human and mouse gastric mucosa[39,40]. Electrophysiological assessment of the KCNQ1 channel confirmed it had sustained activity at low pH[39,40]. This is an essential property of ion channels involved in acid secretion, as they must be capable of functioning at a low pH. The subunit KCNE2 (and possibly KCNE3) appears to co-assemble with KCNQ1 to form a functional K^+ channel in the apical membrane of parietal cells[40]. It is this subunit that is thought to determine the voltage dependence of KCNQ1 and its activation in response to extracellular acidification[40].

KCNQ1 has been proposed as an important K^+ channel in the apical membrane, as gastric acid secretion was inhibited by the 'specific' KCNQ1 channel inhibitor, chromanol 293B[40]. However, it has since been suggested that chromanol 293B has an alternative, unidentified target in the parietal cell[41]. Nevertheless, the contribution of this channel to acid secretion is further supported by the fact that KCNQ1 gene disruption leads to a loss of acid secretion in knockout mice[42].

Several members of another type of K^+ channel family,

the inward rectifying K^+ (Kir) family, have been shown to be expressed in rat gastric mucosa[43]. The Kir channels that were detected included Kir4.1, 4.2 and 7.1, although only Kir4.1 was found in parietal cells, where it was located at the apical region and appeared to co-localize with the β-subunit of H^+,K^+-ATPase.

Another member of the Kir family may also be involved in gastric acid secretion[41]. In rabbit gastric mucosa, high levels of Kir2.1 were detected along with lower levels of Kir4.1 and 7.1. Kir2.1 was found to be expressed in parietal cells from rabbit gastric mucosa and appeared to co-localize with H^+,K^+-ATPase and ClC-2 Cl^- channels. The K^+ channels were more likely to be open (i.e. allow K^+ transit) when they were obtained from stimulated stomach than from resting stomach. A reduction in pH also tended to increase the likelihood that the channels would be open, which suggests that these channels are regulated in a similar fashion to ClC-2 Cl^- channels. These findings, in a model that has been widely used to study the physiology of gastric acid secretion, suggest a role for Kir2.1 in K^+ recycling. However, as the electrophysiological properties of the channel were studied in gastric vesicles, caution must be applied when extrapolating the results to the native environment of the cell[41]. As with the Kir4.1 channel, the Kir2.1 channel associates with four subunits to form a functional K^+ channel.

Studies thus far have revealed a variety of potassium channels (i.e. KCNQ1, Kir2.1 and Kir4.1), albeit in different species, in the apical membrane of the parietal cell. All three channels have properties that are consistent with a role in K^+ recycling. However, it is uncertain which of these channels, if any, plays the major role in K^+ efflux and, as with the Cl^- channel(s), a complete understanding of the K^+ channel(s) involvement has yet to be achieved. Further study in both native tissues and transgenic animals may allow a more definite answer. A variety of K^+ channels have also been identified on the basolateral membrane of parietal cells, each with distinctive properties[44]. Thus, it is not unreasonable to assume that more than one type of K^+ channel in the apical membrane of the parietal cell may be involved in recycling the cation. Moreover, as noted previously, alongside this potential diversity of K^+ channels, different subunits may exist in the same cell, which may affect the properties of the channels[45,46]. This raises the possibility of a variety of functional channels with subtly different electrophysiological properties, making elucidation of the relative contribution of different K^+ channels extremely difficult. The present evidence indicates that more than one channel protein localizes to the apical region of the gland; as a result, the elimination of one channel may only lead to the upregulation of an alternative channel.

Caution must be applied in translating the findings in animal studies to man. For example, a single amino acid change can have a major influence on function. Thus, detailed studies need to determine the identity and composition of K^+ channels in humans before it can be confirmed which channel or channels are important in apical membrane K^+ flux. It also remains to be ascertained whether these channels are constitutively active or are regulated upon cell activation.

K^+ AS A TARGET FOR BLOCKING GASTRIC ACID PRODUCTION

The importance of K^+ in the production of gastric acid makes it a potential target for therapeutic intervention. One strategy is to block the K^+ channels that are responsible for the flow of the ion across the parietal cell apical membrane, while an alternative pharmacological approach is to compete with K^+ at the level of the gastric H^+,K^+-ATPase.

K^+ channel blockers

The K^+ channels in the apical membrane of the parietal cell represent a site for pharmacological modulation. The inhibition of gastric acid secretion by isolated gastric glands exposed to the 'specific' KCNQ1 K^+ channel blocker, chromanol 293B, indicates the potential of such an approach[40]. Even if a K^+ channel blocker did prevent H^+, K^+-ATPase activity, other challenges hinder the development of a therapeutic K^+ channel blocker. The identity of the channel(s) involved in K^+ recycling in the parietal cell will require further investigation, as will the possibility that more than one channel is involved in cation flux (which would require either several blockers or a drug that could inhibit a variety of channels). In addition to this potential problem, many of the identified ion channels can also be found in a variety of tissues (e.g. Kir4.1 is found on brain astrocytes[47] as well as in the apical membrane of parietal cells). This multi-organ distribution of channel proteins make organ-specific inhibitors a requirement, but a difficult target given the degree of cross-tissue homology exhibited by channel proteins.

Potassium-competitive acid blockers (P-CABs)

This group of mechanistically similar, developmental compounds has been identified as a potential therapeutic option for gastro-esophageal reflux disease (GERD) and other acid-related disorders[48]. They inhibit gastric H^+, K^+-ATPase by binding ionically to the enzyme and thus prevent activation by the K^+ cation. It is likely that P-CABs bind at or near the K^+ binding site and so prevent access of the cation to the site.

The early developmental compound, SCH28080, exemplifies the mechanism of action of P-CABs. This agent inhibited gastric acid production in healthy volunteers[49] and, although clinical development was not continued, it has been used extensively to explore the mechanisms of inhibition of gastric H^+,K^+-ATPase.

The large size of SCH28080 compared with K^+ ions suggests that the ion-binding site and inhibitor-binding site are not identical. Furthermore, mutational analysis of the gastric H^+,K^+-ATPase suggests that there are separate binding sites for SCH28080 and K^+. For example, mutations of several amino acid residues in the membrane domains reduce affinity for SCH28080 but have no effect on K^+ affinity[50,51]. Mutational analysis also indicates that the binding site of SCH28080 is closer to the luminal surface of the parietal cell than the ion-binding site[18].

SCH28080 gains access to its binding site and competes with K^+ when the gastric H^+,K^+-ATPase is in the phosphorylated E_2 form[52,53]. When the P-CAB binds to the H^+,K^+-ATPase, it stabilizes the enzyme in the E_2 conformation and, thereby,

prevents the movement of H^+ ions into the parietal cell canaliculus. Mutational data suggest that SCH28080 binds near the loop between M5 and M6, and at the luminal end of M6, about two helical turns away from the ion-binding site[18]. Homology modeling has suggested that SCH28080 interacts with residues in the M1–M6 domains[54], and, more specifically, it docks in a cavity formed by the M1, M4, M5, M6 and M8 transmembrane segments and by loops formed by M5/M6, M7/M8 and M9/M10[55]. This specificity was also demonstrated by another P-CAB, SPI447 in the same study[55]. A P-CAB molecule cannot occupy its binding pocket when the enzyme is in the E_1 form, due to rearrangement of the loop between M3 and M4, which alters the shape of the P-CAB binding cavity[55].

Inhibition of gastric acid production by P-CABs

The principle that P-CABs inhibit gastric H^+,K^+-ATPase was shown by studies with the experimental agents BY841[56], SCH28080[49], SK&F 96067[57], and SPI-447[58]. All P-CABs inhibit the gastric H^+,K^+-ATPase by competing with K^+[57-60], and their physico-chemical properties allow them to concentrate preferentially in highly acidic environments. Clinical develop-ment of the class is continuing with AZD0865, CS-526 (R-105266), revaprazan (YH1885) and soraprazan (BY359). Animal and early clinical studies have demonstrated that P-CABs are highly selective for gastric H^+,K^+-ATPase and inhibit gastric acid secretion with a fast onset of action[57,58,61-68]. Treatments that provide faster onset of effect and increased duration of action would offer improvement for patients with GERD and other acid-related disorders. An interesting observation is that the gastric isoform of the H^+,K^+-ATPase has been identified in only in two organs: the stomach and the kidney. Drugs targeted directly at this protein have shown no adverse effects on renal function, in either animal models or in humans following prolonged use. This is likely due to the relatively high pH in the kidney, which serves to preclude accumulation of these agents. Publication of ongoing studies investigating the efficacy of P-CABs in the treatment of GERD and other acid-related disorders are awaited.

CONCLUSION

In summary, we continue to gain insights into the role of K^+ in gastric H^+,K^+-ATPase function. This cation is not only the counterpart for H^+ that allows the generation of a highly acidic environment in the parietal cell canaliculus, but it is also an essential ion for the functioning of the enzyme itself. Investigations into the structure of the gastric H^+,K^+-ATPase indicate that the K^+ binding site is formed by amino acids from the M4, M5 and M6 domains of the enzyme. With the development of transgenic animals and new molecular markers, we are now only beginning to examine some of the subtle mechanisms by which K^+ induces the conformational changes that result in ion translocation.

The dependence of gastric H^+,K^+-ATPase on K^+ requires that relatively high levels of the cation are available in the parietal cell canaliculus. There is evidence that K^+ is recycled and enters the parietal cell canaliculus via specific K^+ channels. Three potential K^+ channels (KCNQ1, Kir2.1, and Kir4.1) that may contribute to K^+ recycling have been identified in the apical membrane of the parietal cell. The essential contribution of K^+ to gastric acid secretion makes K^+ channels attractive candidates for approaches to block acid production.

The specific KCNQ1 K^+ channel blocker, chromanol 293B, suggests the potential of such an approach. However, when the apical K^+ channels are inhibited by barium, the gastric H^+,K^+-ATPase continues to function. Despite the theoretical attractiveness of this approach, it is uncertain which of these channels, if any, plays the major part in cation recycling across the cell membrane and it is possible that more than one channel is involved. Moreover, homologous (or identical) K^+ channels can occur in different tissues, thereby making the development of an organ-specific channel blocker a challenging task. As research continues into the molecular identification of the apical K^+ channel(s) and their occurrence in other tissues, we will be able to assess whether these proteins are viable targets for inhibition of gastric acid secretion.

A group of mechanistically similar developmental compounds, the P-CAB class has been identified as a potential option for acid suppression therapy. P-CABs compete with K^+ at the level of the enzyme to inhibit acid production; the binding site of these agents appears distinct from the likely pocket that K^+ occupies. When the P-CAB occupies its binding site, it prevents K^+ from binding to and activating the enzyme. Animal and early clinical studies demonstrate that P-CABs are highly selective for gastric H^+,K^+-ATPase and inhibit gastric acid secretion with a fast onset of effect. Such treatments that offer the potential of a fast onset of effect and a long duration of action may provide significant benefits to patients with GERD and other acid-related disorders.

Clearly, by continuing to define the role of K^+ in gastric acid secretion, we will advance the development of novel approaches to regulate the production of gastric acid.

Abstract

AIM: To describe the significant over-expression of fibroblast growth factor receptor 3 (FGFR3), which is a signal transduction and cell proliferation related gene in hepatocellular carcinoma (HCC).

METHODS: Following DNA microarray, Northern blot and quantitative real-time PCR were employed to confirm FGFR3 expression difference in HCC tissues and surrounding non-neoplastic liver tissue. FGFR3 expression levels were further determined by immunohistochemical study in 43 cases of HCC.

RESULTS: Northern blot results showed the significant over-expression of FGFR3 in HCC tissues, which was consistent with that from DNA microarray. Quantitative real-time PCR demonstrated that the mean ratio of FGFR3 mRNA to glyceraldehyde-3-phosphate dehydrogenase (GADPH) mRNA in HCC tissue was 0.250, whereas the ratio in non-neoplastic liver tissue was 0.014. Statistical analyses of 43 cases of HCC revealed that HCC scored higher than the matched non-neoplastic liver tissues. Examination of clinicopathological features revealed a strong correlation of over-expression of FGFR3 with poor tumor differentiation and high nuclear grade.

CONCLUSION: Over-expression of FGFR3 may play an important role in liver carcinogenesis. FGFR3 may be an ideal candidate as a molecular marker in the diagnosis of HCC and a potential therapeutic target.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers in many parts of the world such as the Far East, Southern Sahara and Southern Europe, accounting for nearly half a million deaths worldwide[1]. Recent epidemiological data suggest that the incidence of HCC is increasing in USA, and the annual rate of new cases is 17 300[2]. Many risk factors, such as viral hepatitis, alcohol abuse, biliary disease, metabolic disorders, drugs, and toxins are related to carcinogenesis in HCC. These risk factors result in hepatocellular injury and replacement of normal acini by nodules. Regenerative hyperplasia of fibrous tissue and acini nodules profoundly disturbs the hepatic parenchymal structure and vascular network, which can directly or indirectly contribute to carcinogenesis, as a final stage of liver disease. Therefore, neoplastic transformation of HCC constitutes a long and complex course related to hepatocyte damage and the repair process, which involves multiple oncogenes and tumor suppressor genes.

With the development of the new molecular technology, DNA microarrays make it possible to study gene expression profiles in a global setting and screen thousands of genes rapidly and efficiently. Based on the panel of genes provided in the DNA microarray, further studies can be performed to determine the function of genes which have been identified to be significantly enriched or decreased, and these results can be used to discover new therapeutic target genes for the improvement of HCC prognosis[3]. This technology has been applied successfully in the identification of key genes in neoplastic transformation and as a diagnosis tool in molecular pathology[4,5].

In a previous study, a DNA microarray is used to compare the gene expression profile of HCC tissues with that of matched non-neoplastic tissue[6]. In this study, we focused on the expression change of transcription and translation-related genes in microarray gene profile. Among the 17 genes whose expression levels changed most significantly in this profile, 10 over-expressed genes and 7

under-expressed genes were identified in HCC. FGFR3 is a member of the FGFR family, which is involved in cell growth control, cell differentiation and migration. Based on the unclear role of amplification of these receptors in carcinogenesis in digestive tract carcinoma, we studied the role of FGFR3 in carcinogenesis in HCC. The expression of FGFR3 significantly increased in HCC tissue, which was confirmed by Northern blot. Quantitative real-time PCR study further demonstrated that the mean ratio of FGFR3 mRNA to GAPDH mRNA in HCC tissue was 0.250, whereas the ratio in non-neoplastic liver tissue was 0.014 (P<0.01). Immunohistochemical (IHC) studies of 43 cases of HCC proved the over-expression of FGFR3 in HCC and the extent of over-expression was associated with tumor differentiation and nuclear grade of HCC. Thus, over-expression of FGFR3 may play an important role in carcinogenesis in HCC.

MATERIALS AND METHODS

Patients and specimens

Four specimens of fresh HCC tissue, coupled with non-neoplastic liver tissue from each individual, were obtained from City of Hope National Medical Center and St. Vincent Hospital. All tissue specimens were submitted for routine pathological evaluation and diagnosis confirmation. Forty-three HCC tissue paraffin blocks were collected from surgical pathology files at the City of Hope National Medical Center with a highly controlled manner to ensure patient confidentiality. A section was stained with hematoxylin and eosin (H&E) and examined to confirm the diagnosis and tumor type.

DNA microarray and Northern blot analysis

All fresh tissue samples were cut into small pieces and snap-frozen in liquid nitrogen immediately. The tissues were confirmed by histopathologic examination to validate the adequate HCC cells in the tumor samples. No HCC cells were contaminated in non-neoplastic liver tissues which were reassured before further approach. RNA isolation, cRNA preparation and microarray hybridization were performed as described previously[6]. The microarray format, scanning and data analysis were performed at the Microarray Core Facility, Children's Hospital, Los Angeles,USA. For each sample, at least two hybridizations were carried out. The average of median ratios from replicates was calculated for each spot. We then used 2.0 SD as our cut-off for the determination of expression outlines.

Normal human embryonic liver cell line CL-48, and human HCC cell lines, HepG2 and Hep3B, were purchased from American Type Culture Collection (ATCC; Manassas, VA, USA) and cultured in high glucose Dulbecco's modified Eagle's medium (DMEM), 10% fetal bovine serum (FBS) and 1% P/S (100 U/mL penicillin and 100 μg/mL streptomycin) at 37 ℃ in 50 mL/L CO_2. Total RNA was isolated from the HCC and non-neoplastic liver tissues used for microarray analysis and from logarithmically growing CL-48, HepG2 and Hep3B cells using RNeasy Mini kit (Qiagen, Valencia, CA, USA). The RNA was electrophoresed in 1.2% formaldehyde-agarose gel, blotted to a Hybond-N membrane (Amersham, Arlington, IL) and UV-cross-linked. ^{32}P-labeled FGFR3 probe was prepared according to the protocol of the random priming probe kit from Roche (Indianapolis, IN, USA). The blots were hybridized for 1 h at 68 ℃, washed twice with 2×SSC/0.1% SDS at room temperature, and washed twice with 0.1×SSC/0.1% SDS at 60 ℃. After hybridization, membranes were exposed for 18-48 h to Kodak XAR-5 film (Eastman Kodak, Rochester, NY, USA) with intensifying screens and exposed to a phosphorimager screen for 18 h, then read by phosphorimager scanner. All experiments were repeated thrice for confirmation. The DNA probe for FGFR3 was generated by RT-PCR from CL-48 total RNA with the following primers: 5'-ATG GGC GCC CCT GCC TGC-3' (sense primer starting with FGFR3 cDNA nucleotide 40) and 5'-GTG GTG TGT TGG AGC TCA TG-3' (anti-sense primer starting with FGFR3 nucleotide 1 337). The PCR product included FGFR3 axons 2 and 3 sequence (according to the FGFR3 sequence NM_000142 in GenBank). The PCR conditions were as follows: 1 cycle at 95 ℃ for 15 min; 35 cycles at 94 ℃ for 40 s, at 60 ℃ for 40 s, at 72 ℃ for 2 min; and 1 cycle at 72 ℃ for 10 min. The products were purified and cleaned up using a gel extract and purification kit (Qiagen).

Quantitative real-time PCR

To further confirm and validate the microarray data, quantitative real-time PCR was employed to measure the FGFR3 messenger RNA expression in HCC tissue and matched non-neoplastic liver tissue. RNAs isolated from the fresh-frozen tissues for microarray were treated using RNA-free DNase I (Promega, Madison, WI, USA) according to the protocol to remove contaminated DNA. cDNA was reverse transcribed from total RNA using AMVRT and Oligo (dT) 12-18 primer. The forward primer 5'-TGC TGA ATG CCT CCC ACG -3', reverse primer 5'-CGT CTT CGT CAT CTC CCG AG-3', and probe 5'-FAM- TGT GCG GGT GAC AGA CGC TCC AT -TAMRA-3' were employed for the amplification of FGFR3. To avoid the genomic DNAs background, primers and TaqMan probes were designed to span axons 2 and 3. Pre-developed TaqMan assay reagent control kit (Perkin-Elmer Applied Biosystems, Foster City, CA, USA), including forward, reverse primer and VIK-probe of GAPDH, was used as internal control. FGFR-3-pCDNA3.1 plasmid and GAPDH-pT7T3D-PAC plasmid, containing the full-length FGFR3 and GAPDH structure genes respectively, were used to generate the standard curve. The PCR conditions were as follows: 1 cycle at 50 ℃ for 2 min, at 95 ℃ for 10 min; 40 cycles at 95 ℃ for 15 s, at 60 ℃ for 60 s. Each point of data was performed in duplicate.

Quantification of gene expression was performed using the ABI PRISM 7700 sequence detection system (Perkin-Elmer Applied Biosystems, Foster City, CA, USA) according to the Pre-developed TaqMan assay reagent gene expression quantification protocol. The normalized reporter signal was defined as the intensity of fluorescent reporter dye (FAM or VIK) relative to the passive reference dye TAMRA. The threshold line was determined as high as 10 times of the standard deviation of the baseline fluorescence signal. After reaching the threshold, the sample was designated positive and the threshold cycle (Ct) was

defined as the cycle number at this point. Standard curves for FGFR3 and GAPDH were generated by serial dilution of control plasmids and the amount of mRNA of FGFR3 and GAPDH in each test sample was calculated based on the standard curve. Values were expressed as the ratio of FGFR3 to GAPDH in each sample.

Immunohistochemical study

Paraffin sections were deparaffinized in xylene and rehydrated in a graded alcohol series. After retrieval in pH 8.0 EDTA for 20 min, the slides were blocked with DAKO protein block serum for 5 min (DAKO, Carpinteria, CA, USA). The primary rabbit anti-human polyclonal FGFR3 antibody (200 μg/mL, Santa Cruz Biotechnology, Santa Cruz, CA, USA) was used at an 1:100 dilution for 25 min and washed thrice (5 min each) with DAKO wash buffer. After 7 min of hydrogen peroxide treatment, the slides were incubated with labeled polymer HRP anti-rabbit antibody (DAKO, Carpinteria, CA, USA) for 30 min. Then, DAB (0.05 g DAB and 100 μL 30% H_2O_2 in 100 mL PBS) was applied for 5 and 10 min respectively. Each slide was counterstained with DAKO's hematoxylin. For all IHC studies, PBS was used as a negative control. Granular cytoplasmic staining was assessed as positive. The evaluation of staining intensity was performed by three independent observers.

Scoring and data analysis

The diagnosis of HCC, tumor cell differentiation, nuclear grade and growth pattern were assessed based on the examination of H&E-stained sections, according to the Edmondson's grade and nuclear grade criteria[7,8]. Briefly, well-differentiated HCC was composed of cells with minimal atypia and an increased nuclear/cytoplasmic ratio. In moderately-differentiated HCC, tumor cells were arranged in trabeculae of three or more cells in thickness and had abundant eosinophilic cytoplasm and round nuclei with distinct nucleoli. In poorly-differentiated HCC, tumor cells had an increased nuclear/cytoplasmic ratio, frequent pleomorphism and bizarre giant cells. Nuclear grade was classified in a four-tiered system. Nuclear grade I HCC comprised of adenoma-like cells that had abundant cytoplasm showing little variation in size and shape and was closely similar to benign hepatocyte nuclei, with an even distribution of chromatin. Nuclear grade II HCC contained cells with large and prominent nucleoli, some degree of nuclear membrane irregularity, and chromatin clumping, and were characterized by greater nuclear pleomorphism, angulated nuclei and occasionally multinucleated cells. Nuclear grade IV HCC was noted by its distinct pleomorphism, hyperchromatism, and anaplastic giant cells. Tumor growth pattern was also classified according to its trabecular, compact, pseudoglandular, cirrhotic and solid architecture. In cases that had several architectural patterns, the predominant one was captured for the statistics. The staining pattern of FGFR3 was classified in a subjective spectrum of 0 to ++: 0 as negative expression in tissue, + as weak staining, and ++ as strong staining. For each level of staining, the percentage of cells with the corresponding score was estimated visually. A combined weighed score, consisting of the sum of the percentage of cells at each staining intensity level, was calculated for each sample. In each case, staining of FGFR3 in matched surrounding non-neoplastic hepatocytes was evaluated at the same time. Statistical analysis of FGFR3 expression differences in HCC and surrounding non-neoplastic liver tissue was conducted using the Wilcoxon signed rank test. The association between the expression of FGFR3 and clinicopathologic parameters was examined by the non-parametric χ^2 tests. The relationship of the patients' demographic features, such as age, gender and hepatitis B status, to FGFR3 expression was examined with the *F*-statistic test for linear effects and non-parametric Kruskal-Wallis test for singly ordered tables. SPSS 10.0 statistical analysis software was used to calculate the statistics. $P<0.05$ was considered statistically significant.

RESULTS

Microarray and Northern blot analysis

The partial result of microarray has been published in our previous study[6]. Among the 59 genes whose expression levels were most significantly changed, 30 over-expressed genes and 29 under-expressed genes were identified in HCC. In this study, we focused on the expression change of transcription and translation-related genes in microarray gene profile. In this profile, a total of 10 genes including translational initiation factor EIF-2, GTP binding protein, CDC2-related protein kinase, FGFR3, elongation factor-1β, were over-expressed in HCC. Whereas, insulin-like growth factor, MAP2K5, cyclin D1 and other 4 genes were under-expressed (Table 1). Our results revealed that transcription and translation-related genes also played a very important role in hepatocarcinogenesis besides oncogenes and tumor suppressor genes. Based on the increasing importance of FGFR3 in carcinogenesis in digestive tract carcinoma, we studied the role of FGFR3 in carcinogenesis in HCC. Northern blot showed that the FGFR3 gene was strongly expressed in HCC tissue, HepG2 and Hep3B HCC cell

Table 1 Different expressions of transcription and translation-related gene in HCC

Gene name	Coding number
Most over-expressed genes in HCC	
Translational initiation factor EIF-2, alpha subunit	1 154
Homo sapiens GTP binding protein mRNA complete code	38 708
Human mRNA for elongation factor-1-β	35 748
Human CDC2-related protein kinase mRNA	1 793
Fibroblast growth factor receptor 3	36 165
Elongation factor-1-γ	1 676
mRNA for erythropoietin receptor	396
Human G protein-coupled receptor	1 097
Glutathione S-transferase	31 919
Homo sapiens NADH-ubiquinone oxidoreductase subunit CI-SGDH	32 232
Least expressed genes in HCC	
Human insulin-like growth factor binding protein gene	1 232
Homo sapiens mRNA for TGF-β IIR α	1 815
Heterogeneous nuclear ribonucleoprotein H	41 292
Polyubiquitin Ubc	32 334
Nucleic acid binding protein gene	32 841
MAP2K5	33 071
Cyclin D1	40 436

lines were opposed to match non-neoplastic liver tissue and CL-48 human normal embryonic liver cell lines (Figure 1). Under the image quantity measurement relative to the internal control by GAPDH, the expression of FGFR3 in HCC and HCC cell lines was as high as 4- or 2.5-folds in non-neoplastic liver tissue and CL-48, respectively. Therefore, our Northern blot analysis was consistent with the expression patterns generated by microarray data.

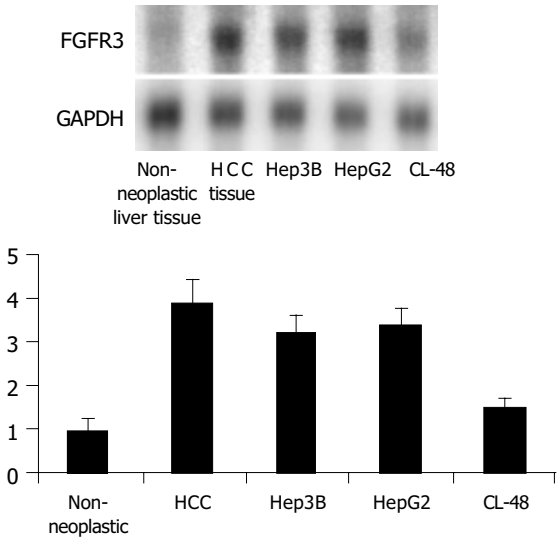

Figure 1 Northern blot validation of FGFR3 expression in matched HCC/non-neoplastic liver tissue and cell lines.

Quantitative analysis of mRNA expression in FGFR3 by real-time PCR

The standard curve formulas $Y = 45.01\text{-}3.86X$ ($r^2 = 0.994$) for FGFR3 and $Y = 38.38\text{-}3.31X$ ($r^2 = 0.991$) for GAPDH were derived from the lines of the calibration curves. The results from four liver cancer tissue and matched non-neoplastic liver tissue specimens were plotted on the standard curve. The mRNA expression in FGFR3 was calculated as mentioned above. The mean ratio of FGFR3 mRNA to GAPDH mRNA in HCC tissue was 0.250, and the ratio in non-neoplastic liver tissue was 0.014. The average mRNA expression in HCC tissue was significantly less than that in non-neoplastic liver tissue ($P<0.01$), compared to GAPDH. The typical analysis result is shown in Figure 2.

IHC study

To validate the specificity of DNA microarray and real-time PCR, IHC analysis was performed in paraffin sections of HCC tissue with surrounding non-neoplastic liver tissues (Figure 3). Immunostaining was performed under 10 high power fields (×400) in the most densely cellular areas. Areas having necrosis or fibrosis were excluded. Among the 43 HCC cases, 2 were cirrhotic, 24 trabecular, 6 psuedoglandular, 3 solid, 7 compact, and 1 sarcomatoid. H&E staining was examined first and used as a control. The positive staining of FGFR3 was diffuse brownish cytoplasmic staining. FGFR3 was predominantly localized in the tumor cells, with lower levels in the non-neoplastic hepatic cells. Among the 43 cases of HCC, only 2 cases of non-neoplastic tissues demonstrated very weak staining, and the difference in the distribution of FGFR3 staining in the HCC area and non-neoplastic liver tissue was noticeable ($P<0.01$) (Figure 3). Stromal cells, bile ductal epithelial cells, vascular epithelial cells and fibrotic tissue were negative for FGFR3. Less intense staining was observed in infiltrated lymphocytes, Kupffer's cells and smooth muscle cells.

Clinicopathological features correlated with FGFR3 expression

We further examined the expression of FGFR3 in 43 cases of HCC tissue samples to confirm our above findings. As shown in Table 2, the age of the patients ranging from 26 to 82 years with a mean age of 59.79 years, 79% were men (34/43) and 21% were women (9/43). HBV positive patients accounted for 65.12% (28/43). Compared to the surrounding non-neoplastic liver tissue, 23.26% (10/43) of patients showed moderate staining for FGFR3 and 48.84% (21/43) of patients showed strong staining for FGFR3 in HCC tissue, indicating significant over-expression of FGFR3 in malignant tissues *vs* non-malignant tissues ($P<0.01$). Table 3 demonstrates the correlation between FGFR3 expression and clinicopathological features. Higher expression of FGFR3 was observed in most moderately- and poorly-differentiated HCC tissue samples. Nine of 20 cases with strong FGFR3 expression were poorly-differentiated. In 4 cases of well-differentiated HCC tissue samples, only 1 case showed very weak staining, whereas no FGFR3 staining was detectable in the other 3 cases. In the same manner, 11 of 20 cases with strong FGFR3 expression were nuclear grade 3, and 9 were nuclear grade 2. Only 1 of 3 HCC tissue samples with nuclear grade 1 showed very weak staining, whereas no FGFR3 staining was detectable in the other 2 cases. A significant correlation was observed between cancer differentiation ($P<0.05$) and nuclear grade ($P<0.05$) based on χ^2 test. These findings suggested that HCC could be distinguished by a significant increase of FGFR3, being compatible with the current clinical parameters. The association between FGFR3 staining and HCC differentiation and nuclear grade is illustrated in Figure 4. HCC with poor differentiation and nuclear grade 3 demonstrated very strong staining of FGFR3.

Table 2 Patients demographic features and FGFR3 expression ($n = 43$)

Demographic features	$n = 43$
Age (yr)	59.79
Gender	
Male	34
Female	9
Hepatitis B	
Positive	28
Negative	15
FGFR3 expression (%)	
0	3 (6.98)
+	20 (46.51)
++	20 (46.51)

DISCUSSION

To understand the characteristics of gene expression in HCC and the molecular processes involved in the cellular transformation from normal cells to neoplastic cells, global gene expression profiling with microarray was used to analyze the expression level change of 12 588 genes and oligos in HCC tissue and matched non-neoplastic liver tissue. Among the 17 transcription and translation-related genes whose expression levels changed most significantly, 10 over-

Table 3 Relationship between FGFR3 expression, HCC differentiation and nuclear grade ($n = 43$)

	Differentiation			Nuclear grade			
FGFR3 expression	Well	Moderate	Poor	1	2	3	4
0	3	0	0	3	0	0	0
1	1	17	2	0	16	4	0
2	0	11	9	0	9	11	0

expressed genes and 7 under-expressed genes were identified in HCC tissue. Due to the high false positive and false negative rates in microarray study, significant over-expression of FGFR3 in HCC tissue was validated by Northern blot and quantitative real-time PCR.

FGFR family has been reported to encode a set of transmembrane tyrosine kinase receptors, which are composed of an extracellular ligand-binding domain, a transmembrane domain, and a split intracellular kinase domain[9]. FGFR family can bind to a number of related mitogenic fibroblast growth factors, resulting in receptor dimerization, autophosphorylation, and downstream signal transduction[10]. Up to now, four members of the family have been identified with domains of similar constitution, namely extracellular immunoglobulin-like domain, transmembrane domain, and intracellular kinase domain[11]. Since the alternative mRNA splicing of FGFR1, FGFR2 and FGFR3, seven prototype receptors have been reported[12]. Each prototype receptor has a different ligand binding capacity and tissue distribution[13]. Given the multiple forms of the receptors, the enormous potential for diversity of FGFR family is involved in cell growth control, cell differentiation and migration. Recently a number of studies have provided increasing evidence that FGFR family may be involved in carcinogenesis[14,15]. However, the detailed mechanism still needs to be further elucidated.

Activation and dimerization of FGFR3 result in cell proliferation or differentiation via signal transduction pathways[10]. Point mutations in the transmembrane domain of FGFR3 have been identified as a causative factor for skeletal development disorders such as achondroplasia and hypochondroplasia[16,17]. Moreover, activating mutations of FGFR3 have been reported to be related with superficial low-grade non-invasive bladder tumors and primary urothelial cell carcinomas[18-21]. Recurrence of tumors with mutated FGFR3 often presents as solitary tumors in the same region of bladder and the presence of wild-type FGFR3 often precipitates multiple lesions in different regions of the bladder[22]. Several novel mutant transcripts caused by aberrant splicing and activation of cryptic splice sequences have been reported recently in digestive tract tumors, and high frequency of dysregulation of mRNA splicing is proposed to confer a selectable advantage on clones of cells in colorectal tumorigenesis[23]. More recently, two novel mutations of FGFR3 in colorectal carcinomas have also been identified[24]. All identified mutations occur at highly conserved sequences, not only in the FGFR family of molecules but also throughout evolution and are clustered in the immunoglobulin-like loop-III domain, highlighting the functional importance of this domain[24]. All the observations support that FGFR3 represents an important example of a single gene, causing different human developmental and tumoral diseases[25].

As malignant cells are characterized by uncontrolled growth genes that are over-expressed in malignant cells and not detectable in normal tissues, studies are conducted to elucidate the complicated process of carcinogenesis. In our study, IHC study of 43 clinical cases of HCC revealed that expression of FGFR3 increased significantly in HCC. More importantly, over-expression of FGFR3 was correlated with pathological factors including HCC differentiation and nuclear grade, suggesting that clinicopathologic index, morphologic grade, and molecular grade are consistent. Therefore, activation of FGFR3 may play an important role in hepatocarcinogenesis. The identification of FGFR3 somatic mutation in HCC is currently under investigation. However, the detailed mechanism needs to be further studied.

Abstract

AIM: To investigate the molecular mechanisms by which tea pigments exert preventive effects on liver carcinogenesis.

METHODS: HepG2 cells were seeded at a density of 5×10^5/well in six-well culture dishes and incubated overnight. The cells then were treated with various concentrations of tea pigments over 3 d, harvested by trypsinization, and counted using a hemocytometer. Flow cytometric analysis was performed by a flow cytometer after propidium iodide labeling. Bcl-2 and $p21^{WAF1}$ proteins were determined by Western blotting. In addition, DNA laddering assay was performed on treated and untreated cultured HepG2 cells.

RESULTS: Tea pigments inhibited the growth of HepG2 cells in a dose-dependent manner. Flow-cytometric analysis showed that tea pigments arrested cell cycle progression at G_1 phase. DNA laddering was used to investigate apoptotic cell death, and the result showed that 100 mg/L of tea pigments caused typical DNA laddering. Our study also showed that tea pigments induced upregulation of $p21^{WAF1}$ protein and downregulation of Bcl-2 protein.

CONCLUSION: Tea pigments induce cell-cycle arrest and apoptosis. Tea pigments may be used as an ideal chemopreventive agent.

INTRODUCTION

Liver cancer is the sixth most common cancer and the third most common cause of death from cancer in the world. In general, the disease is relatively uncommon in developed countries. In the developing world, however, liver cancer is very common, accounting for more than 80% of the global cases, with China alone accounting for 55% of the worldwide incidence. Liver cancer is almost always fatal and has no effective treatment. The survival rate is low, with only a 6% 5-year survival rate in the USA. In developing countries, the survival rate is even lower. Therefore, high prevalence, high death rate, and ineffective therapy have spurred the search of novel strategies in the prevention rather than treatment of liver cancer.

Nowadays, chemoprevention is gaining more attention. This approach aims to decrease overall cancer morbidity and mortality by using substances that are capable of preventing cancer progression. Several classes of compounds have been evaluated for this purpose. Tea is one of the most popular beverages consumed in the world. The two major types of tea consumed worldwide are black tea and green tea. Green tea polyphenols and extracts have been shown in a number of animal models to prevent against chemically-induced carcinogenesis in lung, forestomach, esophagus, duodenum, pancreas, breast, and colon[1-3]. Tea pigments, a major flavonol component in black tea, have strong antioxidant potency[4]. In our previous studies, we found tea pigments to be effective in preventing the occurrence and progression of precancerous liver lesions in rats[5]. However, studies on tea pigments are still limited, especially in terms of mechanism.

The purpose of this study was to investigate the molecular mechanisms by which tea pigments exert preventive effects on liver cancer cells and to provide the scientific rationale for using tea pigments as a chemopreventive agent against liver cancer.

MATERIALS AND METHODS

Tea pigments

Tea pigments were provided by the Institute of Tea Science and Research, Chinese Academy of Agricultural Sciences (Hangzhu, China).

Cell culture and growth inhibition studies

Human hepatoma cell line HepG2 was obtained from Beijing University Hospital (Beijing, China) and cultured in DMEM medium (Sigma, USA) supplemented with 10% fetal bovine serum and 1% penicillin-streptomycin in a 50 mL/L CO_2 atmosphere at 37 ℃. The cells were seeded at a density of 5×10^5/well in six-well culture dishes and incubated overnight. The cells then were treated with various concentrations of tea pigments over 3 d, harvested by trypsinization, and counted using a hemocytometer.

Flow-cytometric analysis

HepG2 cells were seeded at a density of 5×10^5/well in six-well culture dishes. To synchronize the cells at the G_0 phase, HepG2 cells were incubated in serum-free medium for 24 h before treatment with tea pigments. The cells were then treated with or without 100 mg/L tea pigments and harvested at one, or after 2 and 3 d by trypsinization. The cells were centrifuged at 2 000 r/min for 5 min, washed with phosphate-buffered saline (PBS), fixed with 70% ethanol, then subjected to flow cytometric analysis on a flow cytometer after propidium iodide labeling.

Protein extraction and Western blot analysis

Control cells, as well as cells treated with tea pigments, were harvested by scraping the cells from cultured dishes using a cell scraper and collected by centrifugation. Whole cell extracts were then prepared by lysing the cells using 4% sodium dodecyl sulfate (SDS) gel sample buffer. Cell extracts were boiled for 10 min and chilled on ice, subjected to 12% SDS-polyacrylamide gel electrophoresis, and transferred to a nitrocellulose membrane. Each membrane was cut into two pieces, one piece was incubated at 4 ℃ overnight with $p21^{WAF1}$ or Bcl-2 antibodies, and the other one with β-actin (used as a control for protein loading). All antibodies were obtained from Zymed Laboratories (USA). Then membranes were incubated at 37 ℃ for 1 h with secondary antibody conjugated with peroxidase, and the signal was detected using chemiluminescence detection reagent. The relative protein level was calculated as the ratio of the optical density of $p21^{WAF1}$ or Bcl-2 and that of β-actin.

DNA laddering assay

Treated and untreated cultured HepG2 cells were harvested and centrifuged at 2 000 r/min for 5 min. The cells were resuspended in lysis buffer and centrifuged for 15 min at 15 000 *g*. DNA was extracted with phenol, precipitated with 100% cold ethanol, resuspended in TE buffer, electrophoresed on 1.5% agarose gel, stained with ethidium bromide, detected by ultraviolet transillumination, and photographed.

RESULTS

Effect of tea pigments on cell growth

Treatment of HepG2 cells with tea pigments for 24-72 h resulted in a dose-dependent inhibition of cell proliferation. The effects of tea pigments on the proliferation of HepG2 cells are depicted in Figure 1. Tea pigments inhibited HepG2 cell growth at >25 mg/L over 3 d. The IC_{50}, as measured by the number of viable cells 72 h after the addition of tea pigments, was 50 mg/L.

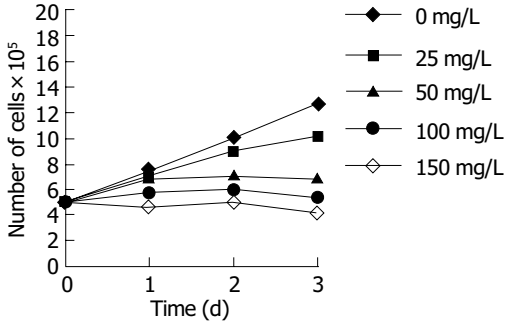

Figure 1 Effect of tea pigments on HepG2 cell growth.

Tea pigments induced G1 cell cycle arrest in HepG2 cells

Flow cytometric analysis of HepG2 cells treated with 100 mg/L tea pigments showed a G1 arrest. The percentage of cells in the G1 phase rose from a baseline of 38.0-55.2% after 24 h of treatment and increased from 37.5% to 76.7% after 72 h (Table 1).

Effect of tea pigments on $p21^{WAF1}$ expression

Western blot analysis of cell extracts from tea pigments-treated HepG2 cells showed upregulation of $p21^{WAF1}$, an inhibitory protein that could modulate cell growth and cell cycle. The result of a typical experiment is shown in Figure 2. To obtain a quantitative value for the protein expression of $p21^{WAF1}$, the optical density of $p21^{WAF1}$ was measured. The ratio of $p21^{WAF1}$ to β-actin was calculated, and the relative protein level of $p21^{WAF1}$ was measured as presented in Figure 2, which clearly shows the upregulation of $p21^{WAF1}$.

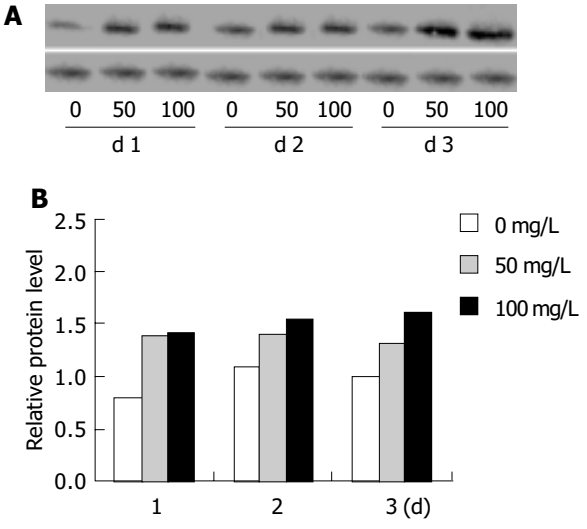

Figure 2 Upregulation of $p21^{WAF1}$ protein expression in HepG2 cell lines treated with tea pigments visualized by ECL detection system (**A**) and plotted as relative protein level (**B**).

Table 1 Flow cytometric analysis of HepG2 cells treated with 100 mg/L tea pigments

Tea pigments (mg/L)	D 1			D 2			D 3		
	G_1 (%)	S (%)	G_2/M (%)	G_1 (%)	S (%)	G_2/M (%)	G_1 (%)	S (%)	G_2/M (%)
0	38.0	48.0	14.0	47.1	39.5	13.4	37.5	50.3	12.2
100	55.2	27.8	17.0	68.7	22.0	9.3	76.7	10.3	13.0

Induction of apoptosis

Firstly, agarose gel electrophoresis was used to demonstrate low-molecular-weight DNA ladder formation. Nuclear DNA fragmentation, a classical feature of apoptotic cell death, was clearly shown in HepG2 cells with 100 mg/L tea pigments over 3 d (Figure 3). Then, we observed the expression of Bcl-2 protein, a known inhibitor of apoptosis. Western blot analysis showed downregulation of Bcl-2 protein. The result of a typical experiment is shown in Figure 4. The ratio of Bcl-2 to β-actin was calculated. The relative protein level of Bcl-2 was measured as presented in Figure 4.

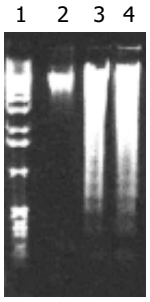

Figure 3 Induction of apoptosis by tea pigments in HepG2 cells. Lane 1: DNA molecular weight marker; lane 2 (control): DNA collected from untreated HepG2 cells after 3 d; lanes 3 and 4: DNA collected from HepG2 cells treated with 100 mg/L after 2 and 3 d.

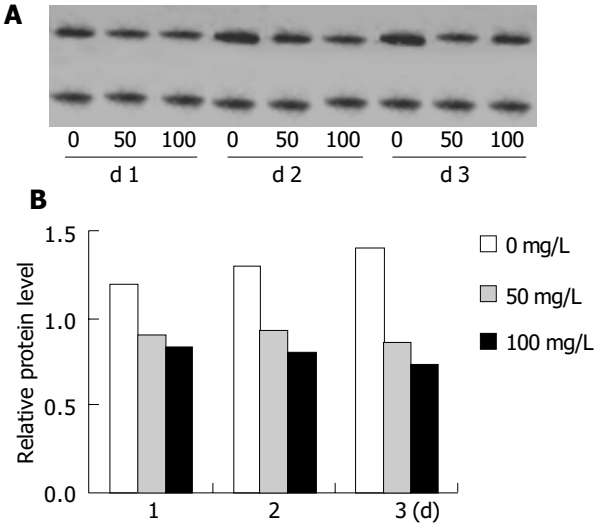

Figure 4 Downregulation of Bcl-2 protein expression in HepG2 cell lines treated with tea pigments visualized by ECL detection system (**A**) and plotted as relative protein level (**B**).

DISCUSSION

Green tea and its polyphenols have been demonstrated as chemopreventive agents in a number of experimental models[6]. However, the mechanism of chemoprevention by black tea compared with that of green tea is not quite clear. Tea pigments used in this study are the main constituents of black tea, mainly theaflavins and thearubigins. Morse *et al*.[7], demonstrated that theaflavins inhibit NMBA-induced esophageal tumorigenesis in rats. Another study showed that black tea constituents inhibit NNK-induced lung tumorigenesis in A/J mice[8]. Previously, we also found that tea pigments had an inhibitory effect on liver precancerous lesions in rats[5]. However, the exact mechanism is unclear.

Eukaryotic cell cycle is regulated by signal transduction pathways mediated by a series of cell-cycle regulators. Cyclins are positive regulators of cell-cycle progression and function by forming a complex with and activating cyclin-dependent kinases (CDKs). CDK inhibitors are negative regulators of cell cycle and bind to and inhibit the activity of cyclin-CDK complexes[9]. $p21^{WAF1}$ has gained much attention as a universal inhibitor of cyclin-dependent kinases, and overexpression of $p21^{WAF1}$ has been shown to induce tumor cell growth arrest and apoptosis[10]. In this study, we have demonstrated that the inhibition of HepG2 cell growth by tea pigments is accompanied with a G1 cell cycle arrest and upregulation of $p21^{WAF1}$ protein. The modulation of cell-cycle regulatory protein is thus a novel effect of tea pigments, suggesting the possible molecular mechanism by which tea pigments inhibit cell growth in HepG2 cells. Lee *et al*.[11], showed that doxorubicin, a commonly used anticancer drug, induces G_1 arrest and upregulation of $p21^{WAF1}$ in HepG2 cells. Qin *et al*.[12], also demonstrated that cisplatin induces a transient G_1 arrest and upregulation of $p21^{WAF1}$ expression in HepG2 cells. These results are similar to the effects of tea pigments in this study. Although we have recognized that tea pigments can modulate the expression of $p21^{WAF1}$, we do not fully understand how $p21^{WAF1}$ and cyclin-CDK complexes are working to elicit cell growth. Experiments are being conducted in our laboratory to elucidate the exact molecular mechanism by which tea pigments inhibit cell growth.

After treatment with tea pigments, the number of HepG2 cells decreased over time, suggesting the possibility of an increase in the rate of cell death. Agarose gel electrophoresis verified this suggestion. Nuclear DNA fragmentation, a classical feature of apoptotic cell death, was clearly shown in HepG2 cells with 100 mg/L tea pigments over 3 d. Additionally, we observed the expression of Bcl-2 protein. Modern molecular biological investigations indicate that apoptosis is regulated by many oncogenes, such as bcl-2, bax and p53[13]. Bcl-2 protein is an apoptosis-related protein and plays an important role in regulating apoptosis[14]. In our study, Western blot analysis showed that Bcl-2 protein expression was significantly downregulated in HepG2 cells after treatment with tea pigments. Bax is a homologous protein of Bcl-2, in the form of homopolymer (Bax/Bax) or isodipolymer (Bcl-2/Bax). Studies have demonstrated that the ratio of Bax and Bcl-2 protein influences the apoptotic rate of cells[15].

In conclusion, tea pigments inhibit cell growth and induce apoptosis in HepG2 cells, suggesting that tea pigments may be used as an ideal chemopreventive agent.

ACKNOWLEDGMENTS

The authors thank Professor Qi-Kun Chen (Institute of Tea Science, Chinese Academy of Agricultural Sciences) for providing tea pigments.

Abstract

AIM: To study the effects of *Pinus massoniana* bark extract (PMBE) on cell proliferation and apoptosis of human hepatoma BEL-7402 cells and to elucidate its molecular mechanism.

METHODS: BEL-7402 cells were incubated with various concentrations (20-200 μg/mL) of PMBE for different periods of time. After 48 h, cell proliferation was determined by 3-(4,5-dimethyl-thiazolyl-2)-2,5-diphenyl tetrazolium bromide (MTT) assay. Apoptosis was evaluated by morphological observation, agarose gel electrophoresis, and flow cytometry analysis. Possible molecular mechanisms were primarily explored through immunohistochemical staining.

RESULTS: PMBE (20-200 μg/mL) significantly suppressed BEL-7402 cell proliferation in a time- and dose-dependent manner. After treatment of BEL-7402 cells with 160 μg/mL PMBE for 24, 48, or 72 h, a typical apoptotic "DNA ladder" was observed using agarose gel electrophoresis. Nuclear condensation and boundary aggregation or split, apoptotic bodies were seen by fluorescence and electron microscopy. Sub-G_1 curves were displayed by flow cytometry analysis. PMBE decreased the expression levels of Bcl-2 protein in a time-dependent manner after treatment of cells with 160 μg/mL PMBE.

CONCLUSION: PMBE suppresses proliferation of BEL-7402 cells in a time- and dose-dependent manner and induces cell apoptosis by possibly downregulating the expression of the *bcl-2* gene.

INTRODUCTION

Pinus massoniana needles and bark have been commonly used in diet therapies in eastern Asia (mainly China and Japan) for thousands of years, but until the last decade of the 20th century, bioactive substances from *P massoniana* bark have not been successfully extracted through crude sieving, centrifugation, or micro- and ultra-filtration with hollow fiber and coiled-spiral nanofiltration membranes[1]. Standard PMBE contains 26.0-28.3% flavonoids (mainly procyanidins) as important bioactive substances. The most important of these are included in the procyanidin B series, which only differ in the number and position of hydroxyl groups, as can be seen for procyanidin B_3 in Figure 1[2].

PMBE is well known for its antioxidant properties, which may result from its ability to scavenge free radicals[1]. It is this antioxidant activity that may be helpful in the prevention and therapy of diseases and degenerative processes associated with oxidative stress. The bark of *P massoniana* has been mentioned in the traditional Chinese pharmacopoeia, and has been mainly used to promote hemostasis and detoxification, and for the treatment of rheumatic arthralgia, hypertension, and chilblain in China and other countries of the Orient[3]. Our previous research results showed that PMBE can broadly inhibit the growth of eight different cancer cell lines *in vitro*[4]. Additionally, we found that PMBE can selectively inhibit the proliferation of human hepatoma BEL-7402 cells without impacting the growth of normal human liver L-02 cells at an effective concentration range similar to that of the chemotherapeutic agent, cisplatin[4]. It may play a role in cancer clinic as both antidote and potentiator of surgical therapy.

Considering that hepatoma is the most common malignant tumor occurring in both men and women in China, we wished to assess the processes by which PMBE inhibits growth and affects apoptosis of BEL-7402 cells and elucidate a possible molecular mechanism for these actions. It is reported that extracts from *P maritima* bark (*pycnogenol*)[5] and from *P radiata* bark (*enzogenol*)[6] have been used therapeutically in southwestern Europe (mainly France, Germany, and Spain), Australia, and New Zealand for nearly

10 years. Huynh and Teel[7] once reported that *pycnogenol* selectively induces apoptosis of human mammary cancer cells (MCF-7), but does not induce apoptosis of normal human mammary MCF-10 cells. It is reasonable to hypothesize that PMBE may also be helpful in therapies of human hepatoma, possibly through the regulation of cell proliferation and/or cell death. Therefore, this study aimed to assess the processes by which PMBE inhibits cancer cell growth, affects apoptosis of BEL-7402 cells, and the possible molecular mechanism for these actions.

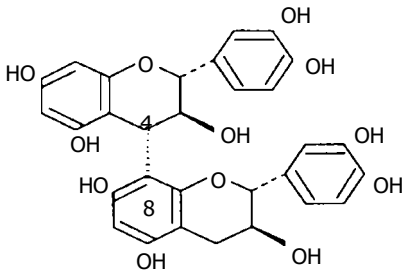

Figure 1 Chemical structure of procyanidin B_3.

MATERIALS AND METHODS

Preparation of PMBE

PMBE was provided by the Institute of Songzhen (Guangdong Province, China). A stock solution of 10 mg/mL PMBE was made in 100% dimethylsulfoxide (DMSO) and filtered via a 0.22 μm minipore membrane. The stock solution was aliquoted and stored at -20 ℃, thawed just before testing, and diluted with the culture medium. The final concentration of DMSO for all treatments was less than 0.25%.

Cell culture and treatment

Human hepatoma BEL-7402 cells were purchased from the Animal Cell Center, Medical College, Sun Yat-Sen University, China. BEL-7402 cells were incubated in RPMI 1640 medium (Sijiqing Co., Zhejiang, China) supplemented with 10% heat-inactivated fetal bovine serum (FBS), 100 U/mL penicillin, 100 μg/mL streptomycin, and 10 mmol/L HEPES, pH 7.4, and kept at 37 ℃ in a humidified 50 mL/L CO_2 incubator. For this study, cells were either incubated in the absence or presence of different concentrations of PMBE for 48 h or exposed to 160 μg/mL PMBE for different time periods.

Measurement of cell growth inhibition

Growth inhibition of BEL-7402 cells by PMBE was measured by 3-(4,5-dimethyl-thiazolyl-2)-2,5-diphenyl tetrazolium bromide (MTT) assay[8,9] with minor modifications. Briefly, cancer cells were seeded into 96-well microtiter plates at appropriate densities to maintain the cells in an exponential phase of growth during the experiment. BEL-7402 cells were exposed to PMBE either at 20, 40, 80, 160, or 200 μg/mL for 48 h or to 160 μg/mL PMBE for either 24, 48, or 72 h. Each concentration was tested in quadruplicate. At the end of the treatment, 20 μL of 5 mg/mL MTT (Sigma, St. Louis, MO, USA) was added to each well and the plates were incubated for 4 h at 37 ℃. DMSO (150 μL) was then added to each well and the plates were rotated for 10-20 min at 200 r/min by a shaker (THZ-C, Shenhua BioTech Co., Shenzhen, China). The optical absorbance was read on a plate reader (BIO-RAD Co., USA) at a wavelength of 570 nm. Media and DMSO controls were included for all experiments. The inhibitory rate of cell proliferation was calculated using the following formula: Growth inhibition (%) = $(A_{control}-A_{treated})/A_{control}\times100$. Results were measured in triplicate.

Cell morphology

Fluorescence microscopy BEL-7402 cells were seeded in sterile culture dishes on coverslips at a density of 10^5 cells/mL and cultured in 10% FBS-RPMI 1640 medium at 37 ℃ in a humidified atmosphere of 50 mL/L CO_2. Cells were grown to 80-90% confluence and synchronized by incubation in 0.5% FBS-RPMI 1640 for 56 h. The experiments were divided into test and control groups. Cells in the test group were incubated in 10% FBS-RPMI 1640 medium containing 160 μg/mL PMBE for 24 or 48 h. Cells in the control group were incubated in 10% FBS-RPMI 1640 alone for 24 h. The coverslips were washed with PBS (containing Ca^{2+}, Mg^{2+}) for 3-5 min, then a 1 000:1 mixture of methanol: DAPI was added and placed at 4 ℃ for 15-30 min, and then washed thrice with PBS for 3-5 min to reduce the background signal. Finally, the cells fixed on the coverslips were analyzed, and photographed under fluorescence microscope (BH-2, Olympus, Japan).

Electron microscopy BEL-7402 cells were incubated in 10% FBS-RPMI 1640 medium with or without 160 μg/mL PMBE at 37 ℃ in a humidified atmosphere of 50 mL/L CO_2 for 72 h. After treatment with 0.25% trypsin, 5×10^6 cells were collected, centrifuged at 10 000 *g* for 5 min and then washed twice with PBS for 5 min. Cell pellets were fixed in 2.5% glutaraldehyde in PBS at 4 ℃ overnight. After washing thrice (10 min each) in PBS, the pellets were incubated in 1% osmium tetroxide (Electron Microscopy Sciences) in PBS for 1 h at room temperature. After three more 10-min washes in PBS, the pellets were dehydrated using a successive ethanol series of 300, 500, 700, 800, and 950 mL/L in double distilled water (10 min each) at room temperature. The pellets were further dehydrated at room temperature in 100% acetone (3×10 min), incubated in 50% acetone/50% epoxy resin (Durcupan ACM, EMS) at room temperature for 1 h, and infiltrated with 100% epoxy resin (3×1 h) at room temperature. After the final incubation, the resin-infiltrated pellets plus excess resin were poured into capsules and polymerized at 70 ℃ overnight. Ultrathin (500 Å) sections were made using a heat-swelling ultramicrotome (LKB-NoVa-V, Switzerland). After being stained with uranium acetate and plumbum citrate, the sections were observed under a transmission electron microscope (JEM 100CX-II, Houghton, MI, USA) and electron micrographs were taken.

DNA fragmentation assay[10]

BEL-7402 cells were seeded in two 25-mL flasks at a density

of 10^5 cells/mL and incubated in 10% FBS-RPMI 1640 medium as previously described in the presence or absence of 160 μg/mL PMBE for 24 h. After harvesting the cells, samples were washed with PBS and centrifuged at 1 000 r/min. The cell pellets were resuspended in a 40-μL solution of 0.2 mol/L NaH_2PO_4/0.1 mol/L citric acid (192:8) and incubated at room temperature for 60 min. After centrifugation for 30 min at 480 r/min, the supernatant was transferred to a 1.5 mL microcentrifuge tube. Three microliters of NP-40 (2.5 mg/mL) and 3 μL RNase A (10 mg/mL) were added to the tube and incubated at 37 ℃ for 60 min. After the addition of 3 μL proteinase K (10 mg/mL), the tube was once again incubated at 50 ℃ for 50 min. At the end of the reaction, 5 μL loading buffer was added and samples were electrophoresed on a 10 g/L agarose gel containing 0.5 μg/mL ethidium bromide, at 7.5 V/cm in 1×TAE buffer for 1.5 h. Analyses and photography were performed with the gel imaging and analysis system (BIO-RAD Co., USA).

Flow cytometry

Cellular DNA content and cell distribution were quantified by flow cytometry using propidium iodide (PI)[11]. After treatment with PMBE, the cells were collected, washed in PBS, and fixed in 700 mL/L ethanol at 4 ℃ overnight. After fixation, the cells were washed in PBS and pellets obtained by centrifugation were stained with PI staining solution containing 50 μg/mL PI, 10 μg/mL RNase A, 5 mL/L Triton X-100, and 0.1% (w/v) trisodium citrate for 30 min at room temperature in the dark. DNA content was determined by flow cytometry (ELITE, BECKMAN Co., USA). Cell populations in the sub-G_1 area (the position where apoptotic cells located) were quantified from a standard count of 10^4 cells using MULTYCYCLE software (PHEONIX Co., USA).

Immunohistochemistry

BEL-7402 cells were seeded in sterile culture dishes on coverslips at a density of 10^5 cells/mL, and incubated as described previously. The experiments were divided into test and control groups. Cells in the test group were incubated with 10% FBS-RPMI 1640 medium containing 160 μg/mL PMBE for 24, 48, or 72 h. Cells in the control group were incubated with 10% FBS-RPMI 1640 alone for 24 h. Cells were first washed thrice (1 min each) with PBS, fixed in acetone for 10 min, immersed in 0.75% H_2O_2-PBS at 37 ℃ for 30 min to inactivate the peroxidase, and washed twice with PBS for 3 min. Normal goat serum was used to eliminate the unspecific staining. Fixed cells were incubated for 30 min at room temperature with mouse anti-human Bcl-2 mAb (primary antibody, Oncogene Research Products) and washed five times with PBS. Slides were then incubated at 37 ℃ for 30 min with biotinylated goat anti-mouse IgG (secondary antibody), washed twice with PBS, and visualized using the immunoperoxidase-based SABC kit (Boster Co.) under a phase contrast microscope. According to the kit protocol, BEL-7402 cells treated with 160 μg/mL of PMBE for 24 h without the addition of primary antibody were used as the negative control. Cells were regarded as positive, when the cell membrane was stained in a brown coffee color similar to the positive control provided by the kit manufacturer.

Statistical analysis

Data were expressed as mean±SD. All experiments were performed in triplicate, unless otherwise indicated. Statistical significance was evaluated either by Student's *t*-test or by one-way ANOVA using *SPSS10.0* software ($P<0.05$ was considered statistically significant, $P<0.01$ very statistically significant).

RESULTS

Dose- and time-dependent effects of PMBE on proliferation of BEL-7402 cells

Human hepatoma BEL-7402 cells were incubated with PMBE for different periods of time at concentrations ranging 20-200 μg/mL and analyzed by MTT assay. PMBE was shown to inhibit the proliferation of BEL-7402 cells in a dose- and time-dependent manner. After exposure of BEL-7402 cells to 20, 40, 80, 160, or 200 μg/mL of PMBE for 48 h, cell proliferation was inhibited by 16.97%, 25.20%, 30.64%, 36.64%, and 43.17%, respectively (Figure 2A). Treatment of BEL-7402 cells with 160 μg/mL PMBE for 24, 48, or 72 h, inhibited cell proliferation by 21.96%, 30.47%, and 34.36%, respectively (Figure 2B).

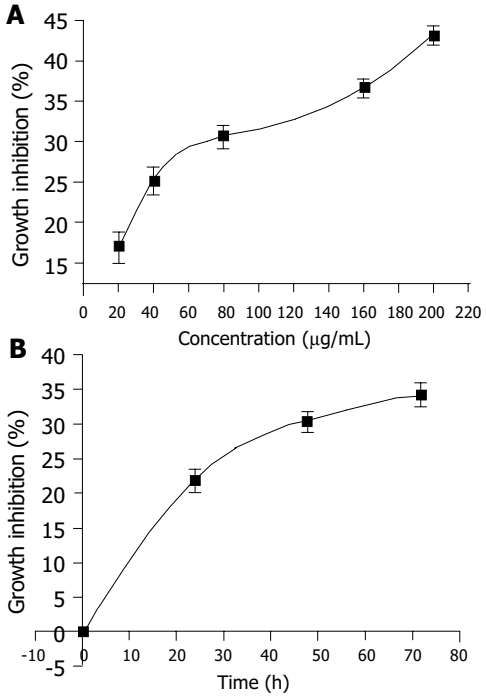

Figure 2 Dose-dependent effects (**A**) and time-dependent effects (**B**) of PMBE on inhibition of BEL-7402 cell growth.

Morphological changes

Under fluorescence microscope, untreated BEL-7402 cells displayed extended, flat cell bodies with uniform chromatin in the nuclei (Figure 3A). The nuclei of BEL-7402 cells, treated with 160 μg/mL PMBE for 24 h, showed the characteristic morphological changes of apoptosis, including nuclear condensation, boundary aggregation and split,

even DNA fragmentation (Figure 3B), which dramatically increased over time (Figure 3C). Under transmission electron microscope, apoptotic bodies were observed in cells treated with 160 μg/mL PMBE for 72 h (Figure 3D).

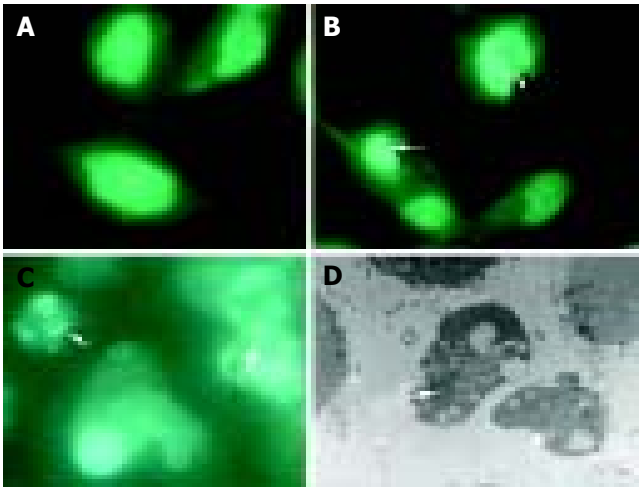

Figure 3 Morphological changes in BEL-7402 cells incubated without PMBE for 24 h (**A**), with 160 μg/mL PMBE for 24 (**B**), 48 (**C**) and 72 h (**D**). Arrows denote condensed, fragmented nuclei, apoptotic bodies.

Inter-nucleosomal DNA degradation induced by PMBE

In order to demonstrate that PMBE was able to induce an apoptotic response, we analyzed DNA degradation in PMBE-treated BEL-7402 cells by agarose gel electrophoresis. PMBE, at a concentration of 160 μg/mL, induced the typical inter-nucleosomal DNA fragmentation in multiples of 180-200 bp after 24 h, a hallmark of apoptosis (Figure 4). No chromosomal DNA cleavage was observed in the untreated control cells (Figure 4).

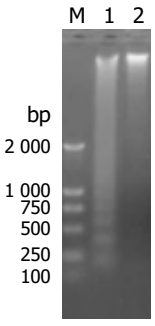

Figure 4 Apoptosis induced by PMBE. M: DNA marker DL2000; 1: Treatment with PMBE; 2: Untreated negative control.

Quantitative detection of apoptosis induced by PMBE

Apoptotic cells could be recognized by PI staining due to DNA degradation and subsequent leakage of stain from the cells. The hypodiploid population, formed by cells with a reduced DNA content in frequency histograms (sub-G_1 peak), could be quantified by flow cytometry and effects of PMBE on BEL-7402 cell distribution could be observed. Results showed that incubation with 160 μg/mL of PMBE for different time periods or with 140, 160, or 180 μg/mL of PMBE for 24 h resulted in accumulation of cells at G_1 or S phase (Figures 5A and B) and a blockade of cell proliferation. Arrest of the cell cycle at G_1 or S phase eventually led to cell death, as the prolonged incubation with 160 μg/mL PMBE induced an increasing apoptotic response, resulting in the rapid appearance of cells with a DNA content less than that at G_1 phase, characteristic of apoptotic cells (Figures 5C). In addition, PMBE induced apoptosis of BEL-7402 cells in a dose-dependent manner. In untreated BEL-7402 cells, the mean apoptotic population was 2.23%, which increased to 7.03%, 28.3%, and 8.43% after a 24-h treatment with 140, 160, and 180 μg/mL PMBE, respectively (Figure 5D). For the time-dependent relationship, the number of apoptotic cells increased with prolonged incubation in PMBE. The number of apoptotic cells increased from 2.23% to 25.1%, 70.6%, and 81.7% after 24, 48, and 72 h of exposure to 160 μg/mL PMBE, respectively (Figure 5E). Therefore, PMBE induced apoptosis of BEL-7402 cells in a dose- and time-dependent manner.

Role of Bcl-2 in PMBE-induced apoptosis

The involvement of the *bcl-2* gene in apoptosis was reported in several studies of anticancer drugs[12-14]. The role of Bcl-2 in PMBE-induced apoptosis of human hepatoma BEL-7402 cells was evaluated by immunohistochemical analysis. Three hundred cells were observed under a microscope and the positive cell ratio was calculated from three independent experiments. The results showed that cells in the control group had higher expression levels of Bcl-2, with a (21.3±1.5)% positive staining ratio, while Bcl-2 expression in test group cells decreased to (16.3±1.2)%, (9.3±0.9)%, and (9.7±1.4)% after treatment with 160 μg/mL PMBE for 24, 48, or 72 h, respectively (Figure 6). Compared with control, all test groups displayed significant differences ($P<0.05$). The positive staining ratio of Bcl-2 protein expression decreased with PMBE treatment time, suggesting that PMBE might play a role in inducing apoptosis of human hepatoma BEL-7402 cells by possibly down-regulating the expression of the *bcl-2* gene.

DISCUSSION

Hepatoma is one of the most common malignant tumors in China and Asia. Therefore, we chose the human hepatoma cell line BEL-7402, as an *in vitro* model to explore the effects of PMBE on cancer cell growth and apoptosis to evaluate the value of PMBE in cancer prevention and therapy.

Our results showed that PMBE at doses ranging 20-200 μg/mL, significantly suppressed cell proliferation in a time- and dose-dependent manner and induced characteristic morphological and biochemical changes associated with apoptosis of human hepatoma BEL-7402 cells. The inhibitory effect of PMBE on cancer cell growth may be attributed to its antioxidant function[1]. Additionally, PMBE appears to induce apoptosis via downregulation of the Bcl-2 protein. Moreover, we have observed that PMBE exhibits more potent effects on apoptosis than on growth inhibition at similar concentrations as described in the results. When exposed to 160 μg/mL of PMBE for 24, 48, and 72 h, the growth inhibition ratio and apoptosis ratio of

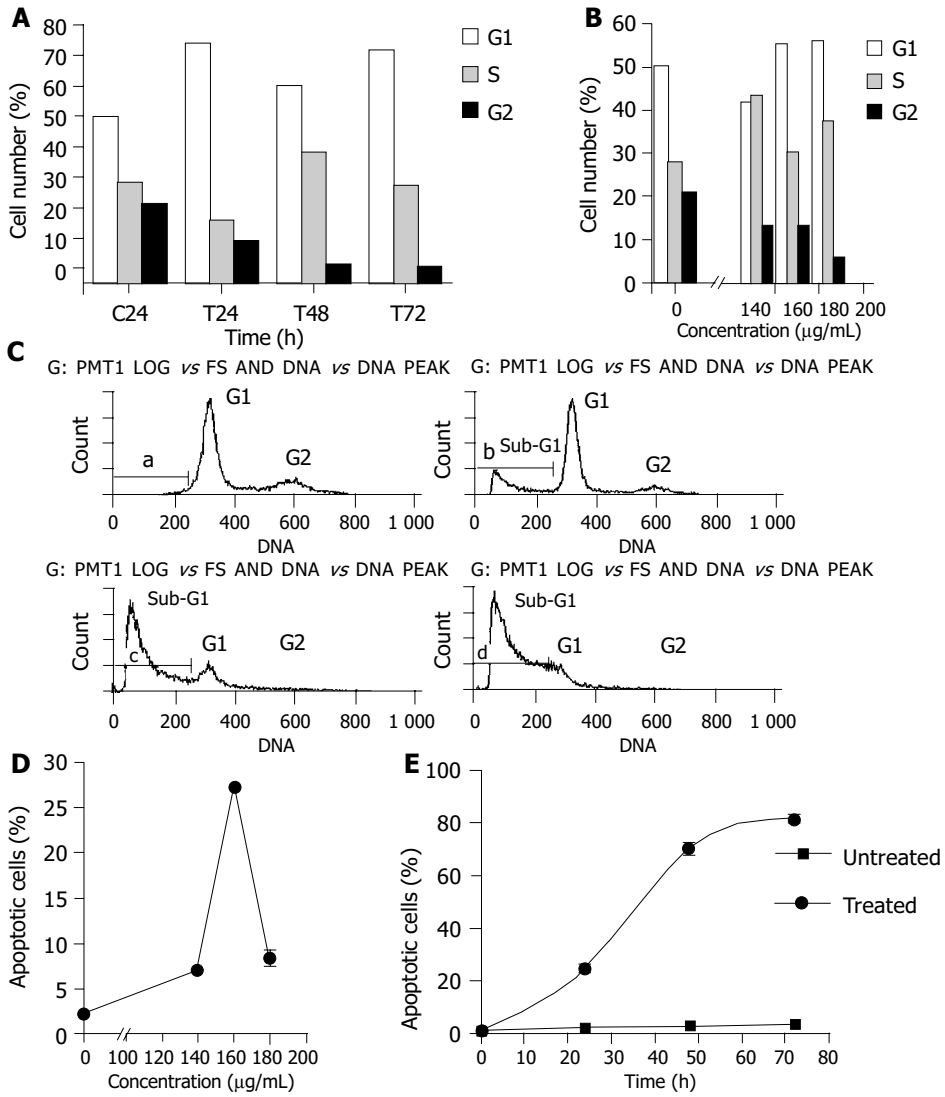

Figure 5 Time-course effects and dose–response effects of PMBE on cell cycle distribution (**A** and **B**) and apoptosis of BEL-7402 cells (**C**-**E**). a: control 24 h; b: 24 h; c: 48 h; d: 72 h.

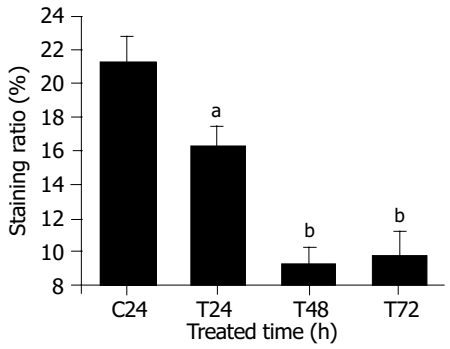

Figure 6 Expression of Bcl-2 protein in BEL-7402 cells treated with 160 μg/mL PMBE for different time periods. C: control; T: treatment with PMBE; $^{a}P<0.05$ as significant, $^{b}P<0.01$ very significant *vs* the control.

BEL-7402 cells were 21.96%, 30.47%, 34.36% and 25.1%, 70.6%, 81.7%, respectively. These distinct actions on cell cycle progression and apoptosis suggest that PMBE is able to trigger different signal transduction pathways, and to exert effects on two key processes during cancer treatment. Taken together, our data demonstrate PMBE has a high capacity of suppressing cell proliferation and triggering apoptosis of human hepatoma cells. Therefore, PMBE may have a therapeutic potential in human liver cancer and may find its use as an anticancer candidate.

The activities of PMBE may account for previously reported cytotoxic effects of this extract[4]. In this study, we showed compelling evidence for pro-apoptotic activity of PMBE using a combination of different techniques. Furthermore, these actions are time- and dose-dependent. We have also found that PMBE could induce accumulation of cells arrested at G_1 and S phases of the cell cycle. Therefore, the antitumor effects of PMBE may result from multiple mechanisms of action, such as interfering with cell cycle progression and inducing apoptosis, possibly by decreasing Bcl-2 protein expression. Oncogenes such as *bcl-2*, are often involved in the development of tumors, and may be related to tumor cell drug resistance[15]. Our results showed that PMBE not only induced BEL-7402 cell apoptosis, but also drastically decreased Bcl-2 protein expression concurrently. The identification of the genes involved and their related signal transduction pathways critical to tumorigenesis await further study.

In conclusion, PMBE is capable of inhibiting growth and inducing apoptosis of human hepatoma BEL-7402 cells in a dose- and time-dependent manner, indicating that PMBE may hold promise as an anticancer agent.

Abstract

AIM: To investigate the long-term consequences of chemotherapy-related HBV reactivation in patients with lymphoma.

METHODS: This study was based on the database of published prospective study evaluating HBV reactivation in HBV lymphoma patients during chemotherapy. Deteriorated liver reserve (DLR) was defined as development of either one of the following conditions during follow-up: (1) newly onset parenchyma liver disease, splenomegaly or ascites without evidence of lymphoma involvement; (2) decrease of the ratio (albumin/globulin ratio) to less than 0.8 or increase of the ratio of INR of prothrombin time to larger than 1.2 without evidence of malnutrition or infection. Liver cirrhosis was diagnosed by imaging studies.

RESULTS: A total of 49 patients were included. The median follow-up was 6.2 years (range, 3.9-8.1 years). There were 31 patients with and 18 patients without HBV reactivation. Although there was no difference of overall survival (OS) and chemotherapy response rate between the two groups, DLR developed more frequently in patients with HBV reactivation (48.4% *vs* 16.7%; $P = 0.0342$). Among the HBV reactivators, HBV genotype C was associated with a higher risk of developing DLR ($P = 0.0768$) and liver cirrhosis ($P = 0.003$). Four of five patients with sustained high titer of HBV DNA and two of three patients with multiple HBV reactivation developed DLR. Further, patients with a sustained high titer of HBV DNA had the shortest OS among the HBV reactivators ($P = 0.0000$). No patients in the non-HBV reactivation group developed hepatic failure or liver cirrhosis.

CONCLUSION: Chemotherapy-related HBV reactivation is associated with the long-term effect of deterioration of hepatic function.

INTRODUCTION

Reactivation of HBV is a well-recognized complication in patients with chronic HBV infection, who receive cytotoxic chemotherapy or immunotherapy management for cancers[1-16]. This complication is especially important in Taiwan, Hong Kong, Singapore and Mainland China, which have high HBV carrier rates of approximately 15-20% in the general population. Although the reported frequency of HBV reactivation in hepatitis B surface antigen (HBsAg)-positive non-Hodgkin's lymphoma (NHL) patients undergoing cancer chemotherapy has ranged widely from 14% to 72%[8-10], our recent prospective study indicated a HBV reactivation rate of around 70% in patients receiving

conventional glucocorticoids-containing systemic chemotherapy[17]. In the near-term, hepatitis flare-up in patients undergoing chemotherapy may jeopardize scheduled chemotherapy or cause severe hepatic damage and even lethal hepatic failure of the patients. However, for survivors of lymphoma who have HBV reactivation during chemotherapy, the long-term hepatic consequences have not been elucidated.

In this study, we analyzed the long-term hepatic consequence in HBV lymphoma patients with HBV reactivation during chemotherapy by using the database of the TCOG (Taiwan Cooperative Oncology Group)-1495, initiated in 1995 and a prospective multi-center randomized clinical study, to evaluate HBV reactivation in HBsAg (+)-lymphoma patients[17]. Most of the patients in this study were followed up for more than 6 years. Our results indicated that though there is no difference in overall survival (OS) in the patients with or without HBV reactivation, HBV reactivation during systemic chemotherapy may have long-term adverse effect on the livers of the lymphoma survivors.

MATERIALS AND METHODS

Patients

This retrospective study used data collected during the long-term follow-up of patients enrolled in a multi-center randomized clinical study conducted from November 1995 to February 2000, which compared steroid-containing and steroid-free chemotherapy in HBsAg (+)-lymphoma patients (T-1495)[17]. All 49 patients who participated in that prospective trial were included in this study. HBV DNA, hepatitis B e antigen (HBeAg) status, HBV genotype and biochemical data (albumin, globulin, bilirubin in total and direct forms, serum aspartate aminotransaminase, serum alanine aminotransaminase (ALT), and prothrombin time (PT)) were regularly examined before treatment and every 2 wk during chemotherapy. All these exams except HBV studies were regularly checked every 2 mo during follow-up. Imaging studies (i.e., abdominal ultrasonography and computed tomography) were performed every 3 mo during chemotherapy and annually during the long-term follow-up.

Hepatitis B virus serology and definition of HBV reactivation

Briefly, HBV DNA was tested in duplicate using the Chiron bDNA assay (VERSANT HBV DNA assay, Chiron Diagnostics, Emeryville, CA, USA). This assay has a sensitivity of 2.5 pg/mL. HBV genotypes were determined using PCR-restriction fragment length polymorphism (RFLP) of the surface gene of HBV[18]. Six genotypes (A-F) of HBV could be identified by the restriction patterns of DNA fragments.

Clinical hepatitis flare-up was defined as a threefold or greater increase in serum ALT level that exceeded 100 IU/L. The hepatitis or hepatitis flare-up was attributed to reactivation of chronic hepatitis B, when there was a five-fold or higher elevation of serum HBV DNA compared with the pre-chemotherapy baseline level or re-appearance of HBV DNA or HBeAg in the serum. Liver biopsy was electively performed to determine the etiology of hepatitis in this study. Only six patients received liver biopsy before or after chemotherapy. Three patients who developed HBV reactivation after early 1999 were treated with lamivudine.

Definition of subtype HBV reactivation during chemotherapy

The HBV reactivation pattern was categorized into three groups as transient, protracted and multiple reactivations[17]. Transient pattern was characterized by a rapid and transient surge of HBV DNA, which usually resolved in a few weeks. Protracted HBV reactivation was defined as a prolonged period of persistently high HBV DNA titer. Some patients with protracted HBV reactivation finally achieved resolution after several bouts of clinical hepatitis (protracted/resolved), while others maintained a high-titer of HBV DNA status throughout the entire period of chemotherapy (protracted/unresolved). Multiple HBV reactivations were characterized by repeated HBV increment after apparent resolution of previous episodes.

Definition of deteriorated liver reserve

In this retrospective study, hepatic images, albumin/globulin ratio (A/G ratio)[19-22] and international normalized ratio (INR) of PT[23-25] were used for the evaluation of liver status. Deteriorated liver reserve (DLR) was defined as the development of either one of the following conditions during the following period: (1) New onset of parenchyma liver disease, liver cirrhosis, splenomegaly or ascites[26] without evidence of lymphoma involvement of the liver; (2) Decrease of the ratio (A/G ratio) to less than 0.8 [(post-chemotherapy A/G ratio)/(pre-chemotherapy A/G ratio)] or increase of the ratio of INR of PT [(post-chemotherapy INR)/(pre-chemotherapy INR)] to larger than 1.2 without evidence of malnutrition or infection status.

Statistical analysis

All analyses were carried out according to the intent-to-treat principle. Survival curves were estimated by the Kaplan-Meier method. Chi-square test was used to compare variables between patients with and without HBV reactivation. A two-tailed P value less than 0.05 was considered statistically significant. SPSS statistical software (version 10.0) was used for the analysis in this study.

RESULTS

Baseline characteristics

The baseline characteristics of the NHL patients according to the occurrence HBV reactivation are shown in Table 1. The median follow-up of the patients was 6.2 years (range, 3.9-8.1 years). There were 31 patients (63.3%) in the HBV reactivation group and 18 patients (36.7%) in the non-HBV reactivation group. Among 31 patients with clinical HBV reactivation, only one patient had his liver biopsied to confirm the diagnosis. Patients who were more than 45 years old or those who had a lower pre-chemotherapy HBV DNA load (<100 copy numbers) had a significant tendency to develop HBV reactivation ($P = 0.019$ and $P = 0.010$, respectively). The likelihood of developing HBV reactivation was slightly higher in HBeAg (-) patients ($P = 0.0841$). Gender and HBV genotype did not contribute to HBV reactivation.

Long-term effect of HBV reactivation

None of the patients developed varices bleeding or hepatocellular carcinoma during the follow-up period. The median survival was 1 886 d in the HBV reactivation group (1 537±188 d, 95%CI as 1 168-1 907 d) and 828 d in the non-HBV reactivation group (1 255±217 d, 95%CI as 829-1 680 d) group. Although there was no difference in treatment response to chemotherapy (P = 0.3897) and OS between patients with and without HBV reactivation (P = 0.601, Figure 1A), DLR was developed more frequently in patients with HBV reactivation (48.4% *vs* 16.7%, P = 0.0342, Figure 1B).

Risk factors for developing deteriorated liver reserve

Among the HBV reactivators, those with HBV genotype C had a higher risk of developing DLR (P = 0.0768). No other factor including HBeAg status, age, gender, reactivation pattern and peak value of bilirubin, ALT and HBV DNA level was found to be associated with poor liver outcome (Table 2). Three of thirty-one patients who had viral genotype C had new onset of liver cirrhosis by imaging criteria with Child-Pugh classification A. Genotype C was associated with the development of liver cirrhosis after chemotherapy among lymphoma patients who had HBV reactivation during chemotherapy (P = 0.003, Figure 2).

The characteristics and outcome of patients who developed DLR with patterns of protracted/unresolved (A) and multiple reactivations (B) are listed in Table 3. Four of five patients with pattern A and two of three patients with pattern B developed DLR. All 3 of the 31 patients who died of hepatic failure had protracted/unresolved (A) or multiple reactivation (B) patterns. No cases of hepatic failure or new onset of liver cirrhosis developed in the non-HBV reactivation group.

H: HBV reactivation related hepatic failure; N: newly developed coarse liver echotexture; NA: not available.

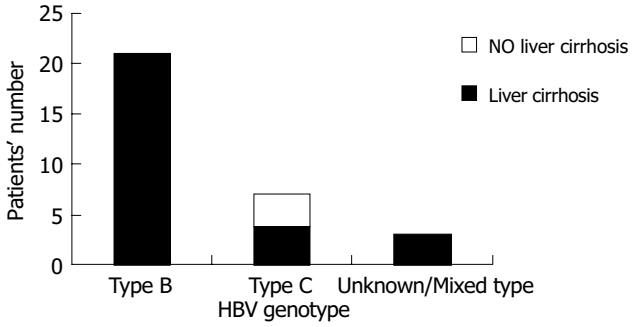

Figure 2 Relationship between genotype and liver cirrhosis in HBV reactivators (P = 0.003).

Treatment efficacy among HBV reactivators with different reactivation patterns

Response to chemotherapy (partial response or complete remission) occurred in 10 of 16 patients with transient reactivation, 4 of 5 patients with protracted/resolved reactivation, 2 of 5 patients with protracted/unresolved flare-up, 2 of 3 patients with multiple reactivation and none of 2 patients with unsure pattern. No correlation was found between reactivation pattern and treatment response (P = 0.325). However, patients with a protracted/unresolved reactivation pattern had shorter OS (189±41 d, 95%CI as 108-269 d, Figure 3, P = 0.000).

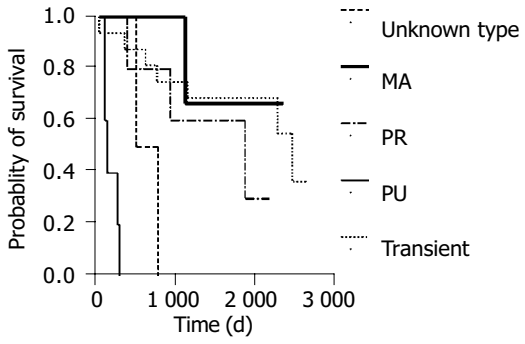

Figure 3 OS in HBV reactivation patients with different reactivation patterns (P = 0.000). (MA: multiple reactivations; PR: protracted/resolved; PU: protracted/unresolved.).

DISCUSSION

In this study, we demonstrated that though there is no survival difference between NHL patients with and without HBV reactivation during chemotherapy, the patients with HBV reactivation do have a long term effect on liver function or liver cirrhosis of the lymphoma survivors by biochemical tests or by imaging modality. HBV genotype C patients may have a higher risk of developing DLR and liver cirrhosis after chemotherapy. Moreover, patients with protracted/unresolved or multiple reactivations are associated with a higher risk of developing DLR and a high incidence of lethal hepatic failure. Furthermore, patients with sustained high titer of HBV DNA leads to poor OS duration compared to other HBV reactivators.

This study had several limitations. DLR after chemotherapy was defined by common biochemical tests with A/G and PT[19-25] and imaging modality because the condition of the patients (i.e. neutropenia and thrombocytopenia during chemotherapy) made routine performance of liver biopsy during lymphoma treatment problematic. The relatively short follow-up duration also limited this study. The longest follow-up duration was only 8.1 years and this might not have been long enough to observe the full clinical course of HBV infection, such as decompensated liver cirrhosis and hepatocellular carcinoma[27]. The small size was another limitation of this study; and in this study, only 31 patients were HBV reactivation patients. So genotype C of HBV only had a borderline of contribution to develop DLR (P = 0.0768). Therefore, further research is needed to establish the relationships among HBV, chemotherapy and host, and to determine the long-term effects of chemotherapy in lymphoma patients who are hepatitis B carriers.

Icteric hepatitis in HBV reactivation during chemotherapy may jeopardize the treatment schedule and thereby increase the risk of lymphoma progression and change the OS of patients with HBV reactivation. No difference was found in the treatment response rate and OS (Figure 1A) of between patients with and without HBV reactivation; however, as shown in Table 3 and Figure 3, patients with a protracted/unresolved reactivation pattern had a shorter OS. Protracted/unresolved reactivation was associated with a higher probability of subsequent hepatic failure or postponed chemotherapy schedule, both of which might contribute to shorter OS. However, in this study, only small proportion patients (4 of 31, 13%) was identified with protracted-unresolved pattern of HBV reactivation; so maybe we should enroll more patients to identify whether the reactivation patterns have influence on the survival.

The worldwide distribution of HBV genotype can be summarized as follows: genotype A is predominant in northern Europe; genotypes B and C are confined to

populations with origins in eastern Asia and the Far East; genotype D is found worldwide, but prevails in the Mediterranean area, the Near and Middle East and south Asia; genotype E is indigenous to western sub-Saharan areas; genotype F is likely to be present in populations with origins in the American continent and the newly identified genotype G is found in France and the USA[28]. In Taiwan, the major serotype of HBV is genotype B (about 81%)[29]. Generally speaking, genotype C is associated with more severe liver disease and hepatocellular carcinoma, which may be due to increased risk of HBeAg positivity, higher serum HBV DNA level, less frequent precore stop codon mutation, and a longer immune clearance phase[28].

In this study, patients with HBV genotype C contributed had a higher rate of impaired liver outcome including post-chemotherapy-related liver cirrhosis. However, among HBV re-activators, the proportion with genotype C who became HBeAg seropositive (1 of 7, 14.3%) was not significantly higher compared to those with genotype B (1 of 21, 4.8%) ($P = 0.4444$, Fisher's exact test). Besides, the pre-chemotherapy baseline HBV DNA copy numbers of all genotype C patients were not elevated, and all of them were within 100 copies. This suggests that the mechanism of DLR resulting from genotype C in HBV patients might not be fully explained by HBV DNA amount and HBeAg seropositivity. Host immune reaction response to hepatitis virus[19,30] and viral genomic factors[31,32] may be more predominant factors. Further studies are needed to test this hypothesis.

Antiviral drugs (i.e. lamivudine) are now commonly used for treatment and prevention of HBV reactivation in HBsAg seropositive patients undergoing cytotoxic chemotherapy[33,34]. They have shown a complete preventative effect of lamivudine, when used before chemotherapy in HBV carriers with lymphoma. However, there is a lack of data on the response to these antiviral drugs in treating or preventing chemotherapy-related HBV reactivation in cancer patients with different HBV genotypes. Further monitoring of the long-term consequences of HBV infection patients either treated or receiving prophylaxis with antiviral agents during chemotherapy and follow-up of the efficacy of these drugs in different HBV genotypes is needed.

Abstract

AIM: To examine the differences of clinical behaviors between hepatocellular carcinomas (HCC) and hepatoblastomas (HB) in children.

METHODS: From 1979 to 1997, we collected 73 HCC and 54 HB from two major medical centers in Taiwan. Demographic, laboratory and radiological data, and survival curves were statistically compared.

RESULTS: HCC clinically differed from HB in mean age (10.6 *vs* 2.5 years; $P<0.001$), status of hepatitis B infection (56/56 *vs* 4/35, $P<0.001$) and accompanying liver cirrhosis (26/40 *vs* 0/30, $P<0.001$), portal vein thrombi (22/56 *vs* 5/38, $P = 0.006$) and para-aortic lymphadenopathy (10/56 *vs* 1/38, $P = 0.026$). Due to a higher recurrence rate (7/12 *vs* 2/13, $P = 0.041$), stage I HCC compared poorly in survivals with stage I HB ($P = 0.0183$). Chemotherapy could only benefit HB as evidenced by 66.7% of resectability conversion and improve survivals for advanced HB, even with unsuccessful conversion. The survival difference between stage I HB and advanced HB with delayed complete resection was of borderline insignificance ($P = 0.0507$).

CONCLUSION: HCC and HB were preliminarily distinguishable by some clinical clues. Delayed resection after chemotherapy was only possible for HB. However, further studies are needed to strengthen our observation that appropriate reliance upon chemotherapy to subsequently resect advanced HB could achieve the comparable survival to that of stage I HB.

INTRODUCTION

Hepatocellular carcinomas (HCC) and hepatoblastomas (HB) are the most common primary hepatic malignancies in children. The two malignancies usually receive identical management. In the literature dealing with the two tumors, the main emphasis has often been on facilitating surgical management by more effective chemotherapy[1,2]. However, the two malignancies have lots of basic differences. Physicians should take these differences into consideration during the diagnostic work-up, before therapy is instituted. Because the tumors are rare, comparisons of their clinical behaviors have rarely been made in any detail. This study enrolled children with HCC or HB at Chang Gung Children's Hospital (CGCH) and National Taiwan University Hospital (NTUH), two major medical centers in northern Taiwan. Its purpose was to examine the differences of the clinical behaviors of these two malignancies.

MATERIALS AND METHODS

We collected the cases of children with HCC or HB at CGCH and NTUH from 1979 to 1997. A total of 127 children were eligible for inclusion in this study. Their diagnosis was confirmed by tissue obtained from laparotomy or needle biopsy. There were 73 cases of HCC and 54 cases of HB. Demographic data included gender and age at diagnosis. Laboratory investigations included alpha-fetoprotein (AFP), hepatitis B surface antigen (HBsAg), and Child's grading. Anti-hepatitis C antibody was checked after 1990 only in 13 cases (9 HCC and 4 HB) and all had negative results. The Child's classification employed was a modified classification (Table 1) based upon encephalopathy, the sonographic finding of ascites, and the levels of albumin, bilirubin and prothrombin time prolongation[3]. By evaluating the five parameters, 1, 2, or 3 points were scored for increasing severity of each parameter measured. Those whose score totaled 5 or 6 were categorized in good-risk grade A, 7-9 in moderate-risk grade B and 10-15 in poor-risk grade C. Radiological examinations included plain chest films, sonography, computed tomography (CT), magnetic resonance imaging (MRI), or angiography. They were evaluated to define tumor extent with special emphasis on distant metastasis,

Table 1 Points scored for clinical and laboratory parameters in Pugh modification of Child's classification of liver disease severity

Clinical and laboratory parameters	Points scored		
	1	2	3
Hepatic encephalopathy[1]	None	Grade 1 or 2	Grade 3 or 4
Ascites	Absent	Slight	Moderate
Bilirubin (mg / dL)	<2	2-3	>3
Albumin (g / dL)	>3.5	2.8-3.5	<2.8
Prothrombin time prolongation (s)	1-4	4-10	>10

[1]Grade 0: normal consciousness, personality, neurological examination; Grade 1: restless, sleep disturbed, irritable / agitated, tremor, impaired hand writing; Grade 2: lethargic, time-disoriented, inappropriate, asterixis, ataxia; Grade 3: somnolent, stuporous, place-disoriented, hyperactive reflexes, rigidity; Grade 4: unrousable coma, no personality / behavior, decerebrate.

portal vein (PV) or inferior vena cava (IVC) thrombi, para-aortic lymphadenopathy, and hilar involvement. Those made tumors inadvisable to attempt from primary tumor extirpation. Chemotherapy would be administered only in the case of consent from the family. Its regimens were the combination of vincristine, cyclophosphamide, doxorubicin and 5-fluouracil before 1991[4]. Cisplatin (or carboplatin) and doxorubicin (or epirubicin) were substituted for the former regimens after 1991[1,2]. The resected specimens indicating the surgical surface and the location of sections were taken for microscopic examination to identify the presence or absence of tumor at the section margins. Cirrhosis was examined in all cases if possible. The histologic subtype of HB was also investigated. The two liver malignancies were staged according to intergroup staging system raised by Children's Cancer Group (CCG) and the Pediatric Oncology Group (POG)[5], mainly based upon the initial operative findings and procedure, and the final pathologic examination. Stage I: Completely resected at initial surgery. Stage II: Resection with microscopic residual disease at margin. Stage III: Unresectable, tumor spillage or resection with gross residual disease but not metastatic. Stage IV: Metastatic disease, regardless of the status of primary tumor.

Chi-square test was used to compare the proportions. When the sample size in a 2×2 table was 20 or less, Fisher's exact test was calculated. Student's *t* test was used to compare the means. As for survival analysis, the survival time was defined by estimating the length of time from the date of initial diagnosis to the event of interest or the date of last follow-up. A patient who died was considered to have experienced an event. Otherwise, the patient was considered censored at last follow-up. Plots of survival time were constructed by Kaplan-Meier method. The log rank test was employed to compare survival curves. Differences were regarded as significant if $P<0.05$.

RESULTS

The demographic characteristics and clinical features in this group of patients are summarized in Figure 1 and Table 2. The mean age (10.6 years) of HCC patients was significantly older than that (2.5 years) of HB patients ($P<0.001$). Both tumors were male predominant with a male to female ratio of 3.3:1 in HCC and 2.4:1 in HB, but the difference between them was not statistically significant ($P = 0.420$).

The AFP level was elevated in 54 of 55 HCC patients

and 34 of 37 HB patients ($P = 0.299$). Among them, 66.7% of those with HCC and 61.8% of those with HB had the AFP level of more than 35 000 ng/mL. HBsAg was tested in 56 HCC patients and 35 HB patients. There was a significantly higher rate of positivity for HBsAg in HCC patients (100% *vs* 11.4%; $P<0.001$). Among 55 HCC patients and 37 HB patients whose tumors could be completely graded by modified Child's classification, 41 HCC patients and 29 HB patients were in Child's group A, 14 HCC patients and 8 HB patients in Child's group B, and no patients in Child's group C. Both tumors appeared to have a Child's A predominance in an A to B ratio of 2.9:1 for HCC and 3.6:1 for HB without a statistically significant difference ($P = 0.673$).

There were 19 HCC patients and 11 HB patients with lung metastasis at diagnosis. Additional brain metastasis was found in 1 HCC patient and additional skin metastasis in 1 HB patient. Radiological images of 94 patients (56 with HCC and 38 with HB) were available for review of tumor extent and invasiveness. A summary of these findings that were compared between HCC and HB is listed in Table 3. The variables to reach statistical significance were PV invasion (39.3% *vs* 13.2%; $P = 0.006$) and para-aortic lymphadenopathy (17.9% *vs* 2.6%; $P = 0.026$).

Cumulative survival curves for patients with liver malignancies in each intergroup stage are shown in Figure 2. Resection with a histologically clear margin (stage I) could be achieved in 12 HCC patients and 13 HB patients, contributing to primary resectability rates of 16.4% and 24.1%, respectively (Table 2, $P = 0.285$). Adjuvant chemotherapy was administered postoperatively to 2 HCC patients and 11 HB patients. However, intrahepatic recurrence ensued in 7 HCC patients (1 with chemotherapy) and 2 HB patients (both with chemotherapy). Therefore, HCC posed a higher recurrence rate than HB after curative resection (Table 2, 58.3% *vs* 15.4%; $P = 0.041$). Repeated hepatectomy could only be performed in 2 HCC patients, one of whom remained alive at last follow-up exam (184 mo). Conclusively, stage I HB compared favorably in survival with stage I HCC with the 5-year survival rate of 32.4% for HCC and 82.5% for HB by the Kaplan-Meier survival curves ($P = 0.0183$). As for stage II tumor, there was none for HCC but 4 for HB. All the 4 HB patients died of recurrence, despite postoperative chemotherapy in one. Stage III disease was found in 42 HCC and 26 HB, which included 5 ruptured HCC and 1 ruptured HB on account of potential tumor spillage into the peritoneal cavity. Stage IV disease consisted of 19 HCC and 11 HB as evidenced by distant metastasis at diagnosis. Due to the heterogenous management for those advanced tumors (III and IV) ranging from no treatment, chemotherapy

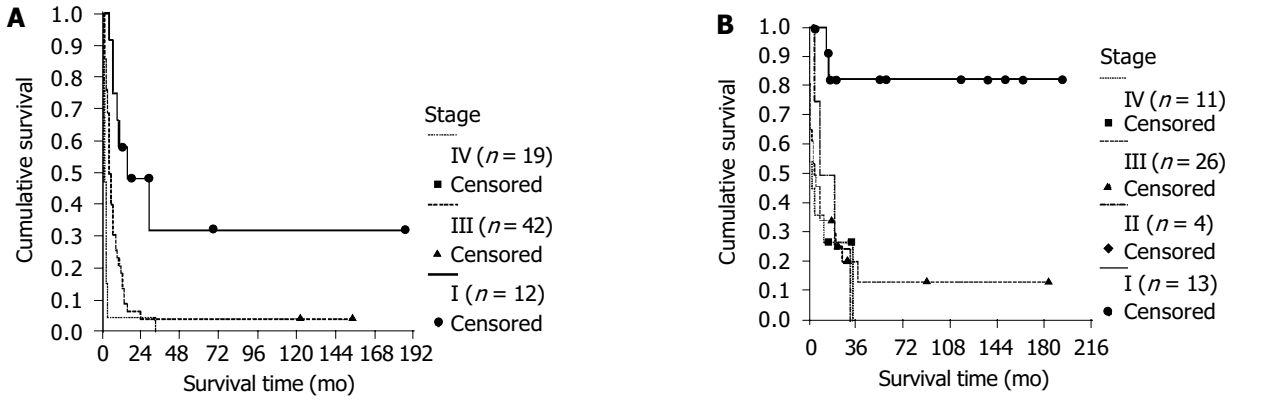

Figure 2 Cumulative survival curves for patients with liver malignancies in each intergroup stage. **A**: HCC (I *vs* III, $P = 0.0011$; III *vs* VI, $P = 0.0002$; log rank test); **B**: HB (I *vs* II, $P = 0.0019$; II *vs* III, $P = 0.8783$; III *vs* VI, $P = 0.5365$; log rank test).

Table 3 Summary of tumor extent and invasiveness on imaging studies of children with hepatic malignancies

	Hepatocellular carcinoma (%)	Hepatoblastoma (%)	*P*
Bilobar involvement	38/56 (67.9)	20/38 (52.6)	0.136
Portal vein invasion	22/56 (39.3)	5/38 (13.2)	0.006
Inferior vena cava invasion	8/56 (14.3)	3/38 (7.9)	0.516[1]
Para-aortic lymphadenopathy	10/56 (17.9)	1/38 (2.6)	0.026[1]
Hepatic hilum involvement	3/56 (5.4)	2/38 (5.3)	1.000[1]
Distant metastasis at diagnosis	19/73 (26.0)	11/54 (20.4)	0.458

[1]Fisher's exact test.

alone, resection after chemotherapeutic conversion to resection with adjuvant chemotherapy, the comparison of survivals between HCC and HB within the same stage could not be free from bias. However, in view of the survivals of HCC or HB patients in different stages shown in Figure 2, differences among the curves of stages I, III and IV HCC could reach statistical significance (I *vs* III, $P = 0.0011$; III *vs* VI, $P = 0.0002$). As regards HB, this difference of survival curves was only seen between stages I and II ($P = 0.0019$) but not among stages II, III and VI (II *vs* III, $P = 0.8783$; III *vs* VI, $P = 0.5365$).

In consideration of advanced tumors (III & IV), 38 HCC and 15 HB were left untreated. There were 14 HCC and 18 HB receiving intensive chemotherapy with the successful conversion into delayed complete resection in 12 of 18 HB but none of 14 HCC (Table 2, $P<0.001$). It contributed to the overall HB resectability of 46.3%, which compared favorably with that of HCC ($P<0.001$). Statistically, the survival difference between 13 stage I HB and 12 advanced HB with delayed complete resection after chemotherapy was of borderline insignificance ($P = 0.0507$). The remaining patients whose tumors failed to be chemotherapeutically converted (14 HCC and 6 HB) eventually succumbed to disease progression. It was found that advanced HB with unsuccessful conversion by chemotherapy had the significantly better survival than HB untreated (Figure 3, $P = 0.0015$) However, this beneficial effect of chemotherapy could not favor advanced HCC (Figure 3, $P = 0.0690$). HCC either with chemotherapy only or untreated had the better survival experience than HB untreated (Figure 3, $P = 0.0015$ and 0.0040, respectively). However, the differences of survivals could not reach statistical significance when compared with HB with chemotherapy only (Figure 3, $P = 0.8139$ and 0.0718, respectively).

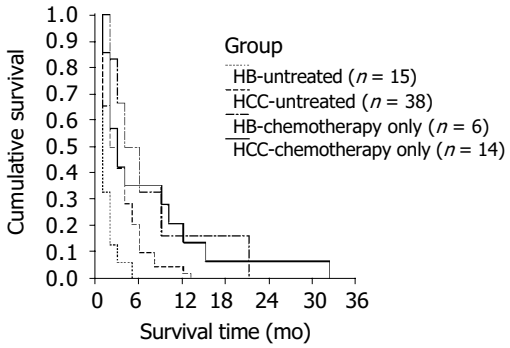

Figure 3 Cumulative survival curves for eventually unresected HCC and HB (stages III and IV). HB-untreated compared poorly in survival with HB-chemotherapy only, HCC-untreated and HCC-chemotherapy only ($P = 0.0015$, 0.0040 and 0.0015; log rank test).

Among 40 HCC specimens and 30 HB specimens available for pathologic evaluation, liver cirrhosis was demonstrated in 65.0% of HCC but none of HB (Table 2, $P<0.001$). It made no difference of sex ratio between cirrhotic and non-cirrhotic HCC ($P = 0.281$). There were 15 children whose HCC resection stayed margin-free (including 5 ruptured HCC). Of them, 6 had cirrhotic HCC and all succumbed to intrahepatic recurrence. HCC recurrence after complete resection was statistically associated with the presence of cirrhosis ($P = 0.007$). The survival of non-cirrhotic resected HCC was significantly better than cirrhotic resected HCC (Figure not shown, $P = 0.0209$). Among 22 resectable HB whose histologic subtypes could be traced, there were 13 with mixed epithelial-mesenchymal component and 9 with epithelial component, including mixed fetal and embryonal types in 3, pure fetal type in 2, embryonal type in 2 and macrotrabecular type in 2. Given the small number of HB patients in whom the histologic subtypes were known, comparisons of survivals between different histologic subtypes could not be done.

DISCUSSION

As shown in this study, childhood HCC and HB could be generally differentiated by some clinical data such as age, the status of hepatitis B virus (HBV) and the findings of imaging studies. HCC was mostly found in school age children, whereas HB was mainly diagnosed in infancy and rarely occurred after 3 years of age. The age distribution of HCC was somewhat skewing to the left with the peak age at around 12 years (Figure 1). It was in sharp contrast to the figure reported from Exelby *et al*., in which there are two age peaks, one below 4 years and a second peak between 12 and 15 years[6]. However, the age distribution of HB showed great resemblance to that of Exelby's series[6], looking rather asymmetric and skewing to the right (Figure 1). Imaging studies disclosed that HCC was more inclined to invade the PV and para-aortic lymph nodes than HB. As for AFP, its level was often extremely high, but not a reliable test to differentiate HCC from HB. However, it was a good marker for monitoring recurrence if its preoperative level was high.

In this series, HBV infection was found in 100% of the HCC patients who had been examined for HBsAg. A positive HBsAg status has long since been a critical marker for children with HCC in Taiwan[7]. As a hyper-endemic area of HBV infection, Taiwan launched a nationwide hepatitis B vaccination in 1984. After a 10-year universal immunization, evidence showed that this program has effectively reduced both the HBV carrier rate[8] and the incidence of HCC in children[9]. As for hepatitis C virus (HCV), it has also been etiologically linked with HCC development[10]. Since specific serologic tests for HCV became available in 1989[11], only 13 cases in this cohort study have been checked for HCV and all showed negative results. Based upon the limited data, it was hard to conclude a causal relationship between HCV and childhood hepatic malignancies. Despite a low seroprevalence of HCV infection in children, HCV can be transmitted to infants and children either perinatally or through blood transfusion[12]. However, the progression from chronic hepatitis to cirrhosis and sometimes to HCC is most commonly a slow and silent process. It may take about 30 and occasionally even more years to reach its end point[10,13]. Therefore, those infected by HCV in childhood may be at risk of developing HCC at their young adult age. This may explain why HCV-related HCC has never been reported in children in spite of overwhelming evidence indicating a strong correlation

between HCV and HCC in adults.

In the Western countries, childhood HCC does not differ from the adult counterpart in terms of gross and microscopic features, except in the lack of an association with cirrhosis in most childhood HCC[14]. We had found that liver cirrhosis occurred in 65% of HCC children, comparable to adult cases (70%) in Taiwan[15], while cirrhotic HB was never seen in this series. Undoubtedly, this strong association between childhood HCC and cirrhosis could be attributed to the preceding HBV infection. Cirrhosis represented as a pessimistic histologic feature with a worse outcome for resected HCC in adults[16] and children, as evidenced by inevitable intrahepatic recurrence. Although HCC in both adults and children are frequently associated with liver cirrhosis, it is well recognized that adult patients more frequently decompensate or develop liver failure, if an overaggressive resection for cirrhotic HCC is attempted[17]. Hence, it has been suggested that hepatectomy be performed in cirrhotic adult patients who have good-risk Child's A grading[18]. In considering the resection of childhood liver malignancies, liver function is rarely an unfavorable factor. Child's A group accounted for over 70% in both types of tumors but Child's C group was never observed in this series. Why liver function was better preserved in childhood liver malignancies was not well explained. However, it might have been due to a short duration of cirrhotic HCC[17] and low incidence of cirrhotic HB in children.

Complete resection of liver malignancies is the only therapeutic modality that could offer patients long-term survival or even a cure[6,19,20]. Primary resection could be achieved only in 16.4% of HCC and 24.1% of HB mainly because most liver malignancies presented with distant metastasis, PV thrombi, IVC thrombi, para-aortic lymphadenopathy, or hepatic hilar invasion at the time of diagnosis. Bilobar involvement was not always a hindrance to complete resection unless resection required compromise of critical vessels. Although HCC was more inclined to invade the PV and para-aortic lymph nodes in comparison with HB, this made no difference between the two tumors' primary resectabilities. Tumor recurrence is the major cause of unsatisfactory results in adults with resectable HCC, occurring in around 50% of cases[21]. A rather pessimistic background was observed in childhood HCC. Even with a successful resection, tumor recurrence in this series happened in over half of the HCC patients but only in 15% of the HB patients. Due to the higher intrahepatic recurrence of HCC, stage I HCC compared poorly in survival with stage I HB. Although repeated hepatectomy has been considered to remain the best treatment for tumor recurrence[21], it could only benefit two of 11 recurrent HCC in this series.

Our data were not sufficient to conclude the necessity of postoperative chemotherapy for stage I disease. However, HCC compared poorly with HB in response to chemotherapy. A better response of HB to chemotherapy might be attributed to the higher proliferation rate of HB[22]. This could, on the other hand, reflect a more ominous natural course of disease as evidenced by the fact that if untreated, advanced HB apparently had a worse survival experience than advanced HCC. It was reported that delayed resection for childhood HCC after combined chemotherapy was the rare exceptions[1,4,20]. We even never experienced any successful conversion of unresectable HCC by chemotherapy for these years despite the higher incidence of HCC in Taiwan. In contrast, we had 66.7% of successful rate to use chemotherapy as a detour leading to complete resection for initially unresectable HB. Even if chemotherapy failed to facilitate resection, it could substantially bring advanced HB to better survivals when compared with untreated HB.

The stage of tumors was reported as the most important criterion for determining the prognosis of HCC and HB in children[23]. In this study, stage I HCC or HB still represented the best prognosis. However, the differences among the survival curves of stages II-IV HB became indistinguishable from one another due to delayed complete resection of advanced HB, which had become an attainable goal since the advent of chemotherapy. Another important issue in dealing with an advanced HB was whether the survival of those tumors with delayed complete resection could catch up with that of stage I HB. As we knew, diagnostic imaging studies are important in assessing the resectability of hepatic malignancies. Although better imaging techniques have improved the accuracy, they do not provide an absolutely reliable evaluation of resectability. The error rate may reach 20% with a combination of sonography and either CT or MRI[24]. Whenever there is the indeterminable resectability of HB on imaging studies, pediatric surgeons will be in a dilemma as to whether they should show boundless enthusiasm for an aggressive surgical approach or rely upon preoperative chemotherapy to subsequently perform a delayed resection. We found that the survival difference between stage I HB and advanced HB resected after chemotherapy could only reach borderline insignificance with a P value of 0.0507. Although it was not solid enough in consideration of survival to support appropriate reliance upon chemotherapy in advance to deal with a potentially risky surgical problem for strategically located HB, this approach could render a delayed but safe hepatectomy with less blood loss, minimal operative complications and more substantial preservation of normal hepatic tissue[25]. There was also evidence showing that if an attempted primary resection for HB ended up as incompleteness and was then boosted by postoperative chemotherapy, such a therapeutic modality did not necessarily achieve a more favorable outcome than initial chemotherapy with delayed resection[26]. Thus, the therapeutic philosophy of "stage creep" from the enrollment of more stage III HB and then preoperative reliance upon chemotherapeutic cytoreduction can be justified in some aspects, but requires further investigations for its impact on survival. As for strategically located HCC, pediatric surgeons should show the enthusiasm for aggressive surgical intervention in view of their unresponsiveness to chemotherapy because primary resection of HCC is undoubtedly the only chance for a cure or long-term survival. Although liver transplantation can be an alternative for advanced HCC[27], it was rarely pursued in Taiwan due to unfavorable factors including large tumor size, nearly absolute HBV carrier status, nonfibrolamellar histology, and a high frequency of local and metastatic spread[17].

Abstract

AIM: To generate and characterize the synthetic transcriptional control units for transcriptional targeting of the liver, thereby compensating for the lack of specificity of currently available gene therapeutic vector systems.

METHODS: Synthetic transcriptional control unit constructs were generated and analyzed for transcriptional activities in different cell types by FACS quantification, semi-quantitative RT-PCR, and Western blotting.

RESULTS: A new bifunctionally-enhanced green fluorescent protein (EGFP)/neo^r fusion gene cassette was generated, and could flexibly be used both for transcript quantification and for selection of stable cell clones. Then, numerous synthetic transcriptional control units consisting of a minimal promoter linked to "naturally" derived composite enhancer elements from liver-specific expressed genes or binding sites of liver-specific transcription factors were inserted upstream of this reporter cassette. Following liposome-mediated transfection, EGFP reporter protein quantification by FACS analysis identified constructs encoding multimerized composite elements of the apolipoprotein B100 (ApoB) promoter or the ornithin transcarbamoylase (OTC) enhancer to exhibit maximum transcriptional activities in liver originating cell lines, but only background levels in non-liver originating cell lines. In contrast, constructs encoding only singular binding sites of liver-specific transcription factors, namely hepatocyte nuclear factor (HNF)1, HNF3, HNF4, HNF5, or CAAT/enhancer binding protein (C/EBP) only achieved background levels of EGFP expression. Finally, both semi-quantitative RT-PCR and Western blotting analysis of Hep3B cells demonstrated maximum transcriptional activities for a multimeric 4xApoB cassette construct, which fully complied with the data obtained by initial FACS analysis.

CONCLUSION: Synthetic transcriptional control unit constructs not only exhibit a superb degree of structural compactness, but also provide new means for liver-directed expression of therapeutic genes.

INTRODUCTION

One of the major challenges in liver gene therapy is the achievement of hepato-specific therapeutic gene expression[1,2]. In general, transcriptional targeting is highly desirable for all *in vivo* gene therapy applications as it can prevent expression of the transgene in non-target cells, thus mimicking physiological regulation[3-5].

For the liver, numerous approaches to incorporate house-keeping cellular promoters or organ-specific regulatory sequences into retroviral, lentiviral or adenoviral vectors have been reported so far[6-8], with variable and repeatedly disappointing results. On one hand, the level of expression does not approach that of strong viral promoters such as human cytomegalovirus immediate early gene (hCMV IE) promoter. On the other hand, a functional tissue specificity only rarely has been demonstrated. As a consequence, the search for effective liver-restricted promoters has been extended to intensive screening of liver-expressed sequence tag (EST)-libraries still awaiting breakthrough[9,10].

For these reasons, promoter units providing sufficient transcriptional activity and concomitantly also tissue specificity still are required. Such promoter units can be built up synthetically on so-called minimal promoters, providing a basic/minimal transcriptional activity, which are combined with enhancer elements of either natural or synthetic origin being composed of suitable transcription factor binding sites (TFBS). This alternative approach should enable both a high degree of structural compactness and a

high degree of liver specificity[11-13].

We here report the results of a comparative study addressing this issue. We employed a minimal core promoter derived from the Herpes simplex virus thymidine kinase promoter (HSV TK-37) which was combined in various arrangements with either "naturally" derived composite enhancer elements from liver-specific expressed house-keeping ally genes or binding sites for transcription factors guiding expression of liver-specific genes.

The enhancer elements of natural origin employed in this work were from the liver-specific human apolipoprotein B100 (ApoB) gene promoter which is located upstream at the region -109-55 of the transcription start site and exhibits binding sites for liver-specific transcription factors HNF1, HNF3, HNF5, CAAT/enhancer binding protein (C/EBP)[14-16] and from the liver-specific enhancer of the rat ornithine transcarbamoylase (OTC) gene promoter which is located 11 kbp upstream of the transcription start site and exhibits binding sites for liver-specific transcription factors HNF4 and C/EBP[17].

Sequences for single binding sites for liver-specific transcription factors were taken from the human albumin gene promoter (TFBS sequences for HNF1 and C/EBP[18]) and from the ApoB gene promoter (TFBS sequences for HNF3/4/5[14-16]).

All newly generated constructs were analyzed for transcriptional activity in different cell types in cell culture.

MATERIALS AND METHODS

Basic minimal HSV TK-37 core promoter construct

All synthetic transcriptional control unit constructs were based on a Herpes simplex virus thymidine kinase derived minimal core promoter (HSV TK-37), which only comprises the RNA initiation site and 37 upstream base pairs[19]. As a basic construct for the generation of new reporter plasmids, we used plasmid pTK-37CAT, in which the HSV TK-37 minimal core promoter drives expression of the chloramphenicol acetyltransferase (CAT) reporter gene[20].

Generation of a new fusion reporter gene EGFP/neo^r

Plasmid pEGFP-C1 (BD Biosciences Clontech, Heidelberg, Germany) facilitating the creation of protein fusions to the C-terminus of enhanced green fluorescent protein (EGFP), which constitutes a human codon-optimized cDNA of GFP[21, 22] was used to generate a new EGFP/neo^r fusion reporter gene. For this purpose, the neomycin aminoglycoside phosphotransferase coding sequence of transposon 5 (i.e., neomycin resistance - neo^r) was cut out of plasmid pNEO (Pharmacia, Freiburg, Germany) and inserted in frame downstream of the EGFP coding sequence. This EGFP/neo^r fusion gene was cut out and used for exchange with the CAT coding sequence in pTK-37CAT, thus a new reporter construct pGreeN (i.e., encoding the "GreeN(eo) fusion") was yielded. Since expression of EGFP in pEGFP-C1 is driven by the strong, constitutive hCMV IE promoter, this vector was used also as a simple transfection marker for all cell lines of interest.

Generation of synthetic transcriptional control unit constructs

Since pGreeN was designed to exhibit a multiple cloning site (MCS) upstream of the HSV TK-37 minimal core promoter, insertion of composite enhancer elements from liver-specifically expressed genes or TFBS sequences via *Bam*HI and *Bgl*II endonuclease restriction sites was facilitated. Insertion of complementary oligonucleotides encoding the binding sites of liver-specific transcription factors, namely hepatocyte nuclear factor 1 (HNF1; TFBS sequence originating from the human albumin gene promoter), hepatocyte nuclear factors 3/4/5 (HNF3/4/5; TFBS sequences all originating from the human apolipoprotein B100 gene promoter), C/EBP (TFBS sequence originating from the human albumin gene promoter) led to the generation of synthetic transcriptional control unit constructs p1×HNF1-GreeN, p3×HNF1-GreeN (exhibiting three consecutive HNF1 TFBS), p1×HNF3-GreeN, p1xHNF4-GreeN, p1×HNF5-GreeN, p1×C/EBP-GreeN, respectively. Insertion of "natural" composite enhancer elements being important for liver-specific expression of the ApoB gene (60 bp; encoding TFBS for HNF3, HNF4, HNF5, and C/EBP) or the OTC gene (52 bp; encoding TFBS for HNF4 and C/EBP) also was inserted upstream of the HSV TK-37 minimal core promoter giving rise to synthetic transcriptional control unit constructs p1×ApoB-GreeN and p1×OTC-GreeN (Figure 1; first lines of upper and middle panel). Finally, plasmids encoding up to 16 monotype ApoB cassettes (Figure 1; upper panel), up to 16 monotype OTC cassettes (Figure 1; middle panel), and mixed ApoB/OTC cassettes (Figure 1; lower panel; exhibiting up to 4 mixed ApoB and OTC units) were constructed. All PCR-derived segments/constructs were sequenced thereby confirming their predicted composition (More detailed information about the construction process is available from the authors upon request).

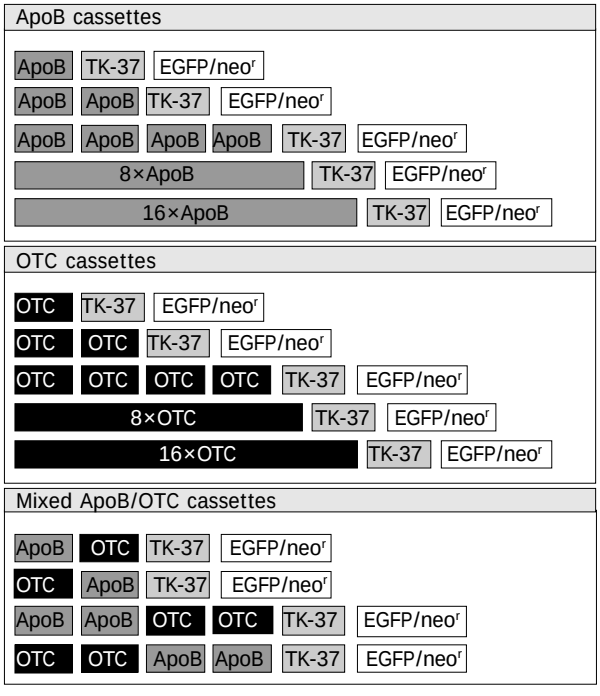

Figure 1 Schematic representation of synthetic transcriptional control unit constructs.

Cell culture

Cell lines HepG2 (human hepatocellular carcinoma), Hep3B (human hepatocellular carcinoma), HeLa (human cervix carcinoma), HEK293 (human embryonic kidney) all were purchased from the European Collection of Cell Cultures (ECACC). Cell line HuH7 (human hepatocellular carcinoma) was generated originally and provided by Nakabayashi[23]. All cell lines were grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum (FCS) at 37 ¡æin 50 mL/L CO_2. No antibiotics were added.

Transfection experiments

Cells were plated at 3×10^5 cells/well into 6-well trays (Falcon-Becton Dickinson Labware, Franklin Lakes, NJ, USA) and transfected 24 h later with 2 µg DNA complexed with either the multi-component lipid-based FuGENE 6™ transfection reagent (Roche Diagnostics, Mannheim, Germany), the cationic lipid reagent Lipofectamine™ 2000 (Invitrogen, Karlsruhe, Germany), the 1:1 (w/w) DOTMA/DOPE liposome Lipofection™ reagent (Invitrogen), the polycationic DOSPER™ reagent (Boehringer, Mannheim, Germany), or the monocationic cholesterol DAC-30™ reagent (Eurogentec, Seraing, Belgium), according to the protocols of the manufacturers. To determine the transfection efficiencies, two separate transfections with samples were performed in triplicates, respectively.

Flow cytometry

Forty-eight hours after transfection, cells were washed with PBS, trypsinized and spun by centrifugation at 1200 r/min for 2 min. Cell pellets were resuspended in 500 µL PBS. The percentage of EGFP expressing cells was calculated by FACS analysis using the FL1-H profile employing a flow cytometer (FACS Calibur™, BD Biosystems, Heidelberg, Germany) with the CellQuest software according to the manufacturer's instructions. To standardize the transfection efficiencies, all cell lines obtained underwent triple transfections with hCMV IE-driven control plasmid pEGFP-C1. The resulting pEGFP-C1-mediated mean EGFP positive cells were set to 100%; EGFP positive cells obtained by transfection with synthetic transcriptional control unit constructs were set in relation to this EGFP standard level, thereby defining the ratio of relative EGFP expression. Data plotted represented the mean ± SD of two separate transfections performed in triplicates, respectively.

Reverse transcription and semi-quantitative PCR

Total RNA was extracted 48 h after transfection with the NucleoSpin RNA II kit (Macherey Nagel, Düren, Germany). Reverse transcription was performed using the SuperScript™ II RT kit (Invitrogen, Karlsruhe, Germany). Semi-quantitative PCR analysis was done using the Taq DNA polymerase kit (QIAGEN, Hilden, Germany). All protocols were performed according to the manufacturer's instructions. The sequences of primers for semi-quantitative PCR are as follows. The 5' primer for amplification of the EGFP gene is 5'-ATG GTG AGC AAG GGC GAG GAG CTG TTC-3' and the 3' primer is 5'-CTT GTA CAG CTC GTC CAT GCC GAG AGT-3', giving rise to a specific band of 717 bp; the 5' primer for amplification of the α-tubulin house-keeping gene (used as an internal standard) is 5'-ATG CCA AGC GTG CCT TTG TTC ACT GGT AC-3' and the 3' primer is 5'-GAA ATT CTG GGA GCA TGA CAT GCT GCA G -3', giving rise to a specific band of 208 bp.

Western blot

Forty-eight hours after transfection, cells were washed in PBS and trypsinized, proteins were extracted with 120 µL lysis buffer (50 mmol/L Tris-HCl, 150 mmol/L NaCl, 1% Nonidet P-40, 200 mmol/L PMSF). Then 50 µL of cell lysates was loaded onto a 10% SDS polyacrylamide gel and separated by electrophoresis and transferred to a polyvinylidene difluoride membrane (Amersham Pharmacia Biotech, Freiburg, Germany). After the non-specific binding sites were blocked with 5% non-fat milk in TBS-T (10 mmol/L Tris-HCl, 150 mmol/L NaCl with 0.05% Tween20) overnight at 4 ¡æ; the membrane was incubated for 3 h with monoclonal mouse anti-α-tubulin antibody (Sigma, Saint Louis, USA) and monoclonal mouse anti-GFP antibody (Roche Applied Science, Indianapolis, USA). Proteins were visualized using horseradish peroxidase-conjugated anti-mouse antibody (BioRad, Hercules, USA) diluted in TBS for 45 min at room temperature followed by enhanced chemoluminescence (ECL; Amersham Pharmacia Biotech, Freiburg, Germany).

RESULTS

Generation of a new EGFP/neo^r fusion reporter gene

To facilitate both the quantification of transcriptional activities of newly designed synthetic transcriptional control cassettes and the selection of stable cell clones transfected with such constructs, a new bifunctional EGFP/neo^r fusion gene cassette was generated. Employing plasmid pEGFP-C1, a neomycin aminoglycoside phosphotransferase coding sequence, was linked in frame downstream of the EGFP coding sequence. Subsequently, this EGFP/neo^r fusion gene was cut out and used for exchange with the CAT coding sequence encoded in reporter plasmid pTK-37CAT[20], yielding the new reporter construct pGreeN, which also exhibits a multiple cloning site (MCS) upstream of the HSV TK-37 minimal core promoter.

Generation of synthetic transcriptional control unit constructs

New reporter construct pGreeN was used to generate synthetic transcriptional control unit constructs. For this purpose, either composite enhancer elements from liver-specifically expressed genes or binding site sequences of transcription factors guiding expression of liver-specific genes were inserted into the MCS-located upstream of the HSV TK-37 minimal core promoter.

Insertion of "natural" composite enhancer elements which are important for liver-specific expression of the human apolipoprotein B100 (ApoB) or the rat ornithin transcarbamoylase (OTC), generated synthetic transcriptional control unit constructs pApoB-GreeN and pOTC-GreeN. In addition, plasmids encoding up to 16 monotype ApoB

cassettes, up to 16 monotype OTC cassettes, as well as mixed ApoB/OTC cassettes were constructed (Figure 1).

Insertion of complementary oligonucleotides encoding the binding sites of liver-specific transcription factors HNF1/3/4/5 or C/EBP led to the generation of synthetic transcriptional control unit constructs p1×HNF1-GreeN, p3×HNF1-GreeN (exhibiting three consecutive HNF1 TFBS), p1×HNF3-GreeN, p1×HNF4-GreeN, p1×HNF5-GreeN, p1×C/EBP-GreeN, respectively (constructs not depicted).

Comparison of transfection efficiencies of cell lines of liver and non-liver origin in correlation to different lipid-based transfection reagents

To evaluate the tissue-related transcriptional activities of pGreeN-based synthetic transcriptional control unit constructs, three human hepatoma cell lines (HepG2, Hep3B, HuH7) were chosen and compared with two carcinoma cell lines of cervix (HeLa) and human embryonic kidney (HEK293) origin, respectively. By mixing reporter plasmid pEGFP-C1 with five different commercially available lipid-based transfection reagents (FuGENE 6™, Lipofectamine 2000™, Lipofection™, DOSPER™, DAC-30™) followed by subsequent FACS quantitation of EGFP expressing cells, we identified the multi-component lipid-based FuGENE 6 transfection reagent and yielded the best overall transfection efficiencies considering all five cell lines tested (data not shown). In particular, the transfection efficiencies obtained by FuGENE 6 were in the range of 60-75% for four of five cell lines tested (Figure 2; cell lines Hep3B, HuH7, HeLa, HEK293). Only HepG2 cells yielded a significant lower transfection efficiency of nearly 20% (Figure 2; first bar). However, none of the other transfection reagents tested was found to be able to achieve a roughly equivalent transfection efficiency in HepG2 cells (data not shown). Therefore, all successive transfection experiments were performed using FuGENE 6. Cell line-dependent differences in transfection efficiencies were normalized by setting EGFP expression levels obtained with hCMV IE-driven control plasmid pEGFP-C1 to 100% for each cell line tested. EGFP expression levels obtained by transfection with synthetic transcriptional control unit constructs were related to this cell line-dependent EGFP standard level.

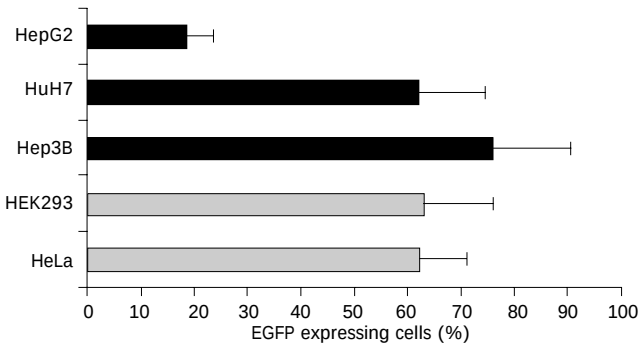

Figure 2 Transfection efficiencies of cell lines of human hepatoma and non-liver origin.

Transfection experiments for comparison of transcriptional activities of synthetic transcriptional control unit constructs

Following FuGENE 6-mediated transfection of cell lines HepG2, Hep3B, HuH7, HeLa, HEK293, with synthetic transcriptional control unit constructs, percentages of EGFP expressing cells were determined in a simplified first round of testing by FACS analysis, constituting a first rough correlation for the individual transcriptional activities of each construct.

As a result, constructs comprising monotype ApoB cassettes (Figure 3; upper panel) exhibited high EGFP levels of over 60% (Figure 3; Hep3B and HepG2 cells transfected with 4×ApoB cassette construct) only in human hepatoma derived cell lines. In contrast, EGFP expression of non-liver origin cell lines HeLa and HEK293 transfected with monotype ApoB cassette constructs only reached background levels below or around 10% of cell line-dependent EGFP standard levels (Figure 3; black and grey bars in upper panel).

Therefore, monotype ApoB cassette constructs (encoding TFBS for HNF3, HNF4, HNF5, and C/EBP) could provide a strong liver-directed gene expression. Interestingly, maximum hepatoma cell-based reporter gene expression was obtained with the 4×ApoB cassette construct (Figure 3). In contrast, constructs exhibiting 8 or 16 multimeric ApoB cassettes only demonstrated EGFP expression levels between 30% and 40% or just below 30%, respectively, a phenomenon which could be referred to excess presentation of TFBS encoded by these highly multimeric ApoB cassette constructs.

Constructs comprising monotype OTC cassettes (Figure 3; middle panel) exhibited high EGFP-levels of over 50% (Figure 3; Hep3B cells transfected with 4× or 8× OTC cassette constructs) only in human hepatoma derived cell lines. EGFP expression of non-liver origin cell lines HeLa and HEK293 transfected with monotype OTC cassette constructs only reached background levels below or around 10% of cell line-dependent EGFP standard levels (Figure 3; black and grey bars in middle panel).

Therefore, monotype OTC cassette constructs (encoding TFBS for HNF4 and C/EBP) could also provide a strong liver-directed gene expression in Hep3B and HepG2 hepatoma cells. On the contrary, HuH7 cells transfected with monotype OTC cassette constructs exhibited only EGFP expression levels of up to 16% (Figure 3; middle panel transfected with 8×OTC cassette construct). Again, all hepatoma cell lines (HepG2, Hep3B, HuH7) transfected with construct p16×OTC-GreeN exhibiting 16 multimeric OTC cassettes demonstrated lower EGFP expression levels in comparison to transfections with constructs p4×OTC-GreeN and p8×OTC-GreeN (Figure 3; middle panel), a phenomenon which again could be referred to excess presentation of TFBS encoded by this highly multimeric (16×) OTC cassette construct.

Transfection experiments with non-liver origin cell lines HeLa and HEK293 employing mixed ApoB/OTC cassette constructs (Figure 3; lower panel; exhibiting up to 4 ApoB/OTC units) exhibited EGFP expression levels being unexceptionally below the 5% margin of cell line-dependent EGFP standard levels. In contrast, maximum EGFP expression levels between 30% and nearly 50% were obtained in hepatoma cell lines HepG2, Hep3B, and HuH7

(Figure 3; yellow, orange and brown bars in lower panel).

Therefore, mixed ApoB/OTC cassette constructs (encoding TFBS for HNF3, HNF4, HNF5, C/EBP plus HNF4, C/EBP) could not only provide a strong liver-directed gene expression, but also exhibit a high ratio of liver cell to non-liver cell origin reporter gene expression. Furthermore, mixed ApoB/OTC cassette constructs did not exhibit any significant orientation effect related to the order of ApoB/OTC subcassettes (Figure 3; EGFP expression levels obtained with p1×ApoB/OTC-GreeN *vs* p1×OTC/ApoB-GreeN and p2×ApoB/OTC-GreeN *vs* p2×OTC/ApoB-GreeN).

In sharp contrast to all constructs made up of "natural" composite enhancer elements of the ApoB or the OTC gene, constructs encoding single TFBS of liver-specific transcription factors (p1×HNF1-GreeN, p3×HNF1-GreeN, p1×HNF3-GreeN, p1×HNF4-GreeN, p1×HNF5-GreeN, p1×C/EBP-GreeN) did not achieve EGFP expression levels much higher than background levels (data not shown). Therefore, neither liver-directed nor strong reporter gene expression could be obtained with such single TFBS encoding constructs, demonstrating the superiority of "natural" composite enhancer element constructs.

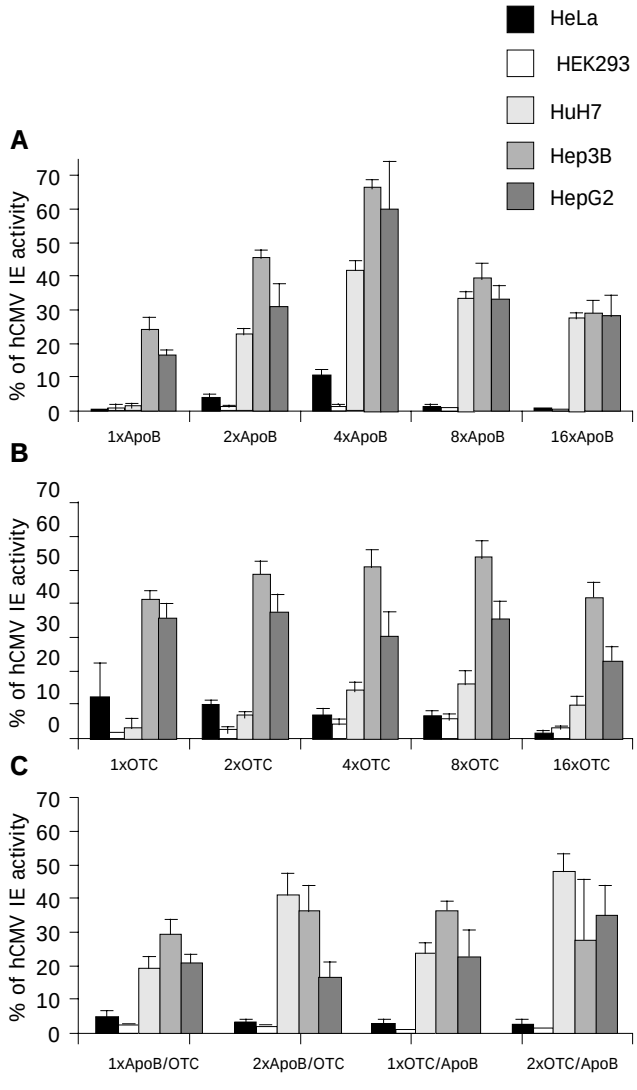

Figure 3 Transcriptional activities of synthetic transcriptional control unit constructs (A-C).

Semi-quantitative RT-PCR and Western blotting analysis of transcriptional activities of synthetic ApoB transcriptional control units

Since transcriptional control unit constructs encoding ApoB cassettes could exhibit high relative EGFP levels (in our first round of testing by FACS analysis: 4×ApoB construct reaching nearly up to 70% of expression obtained with the strong hCMV IE driven control plasmid pEGFP-C1; FACS analysis data is depicted in upper panel of Figure 3), we additionally performed a more precise second round testing and also analyzed synthetic ApoB transcriptional control unit transcriptional activities by semi-quantitative RT-PCR and Western blotting (Figures 4 and 5).

For this purpose, Hep3B cells were transiently transfected with enhancer module plasmids exhibiting single or multimeric ApoB cassettes. Following total RNA extraction and reverse transcription, EGFP expression was analyzed by semi-quantitative PCR analysis which showed a specific band of 717 bp (Figure 4; EGFP). As an internal standard, the α-tubulin house-keeping gene was amplified in parallel giving rise to a specific band of 208 bp (Figure 4; α-tubulin). As a result, a maximum EGFP signal was obtained with the p4×ApoB-GreeN construct (Figure 4; lanes 5, 6), which corresponded with the FACS analysis data and also exhibited the strongest EGFP expression level for Hep3B cells transfected with the p4×ApoB-GreeN construct (Figure 3; upper panel, 4×ApoB, orange bar).

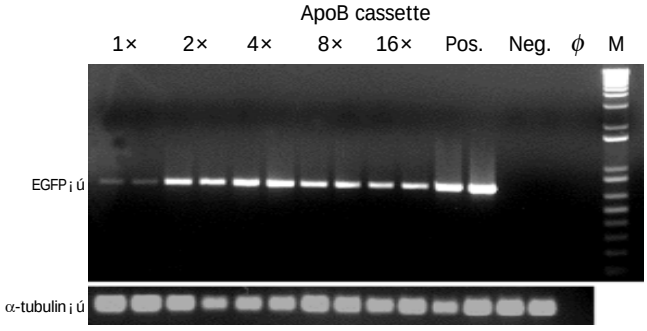

Figure 4 Transcriptional activities of synthetic ApoB transcriptional control units.

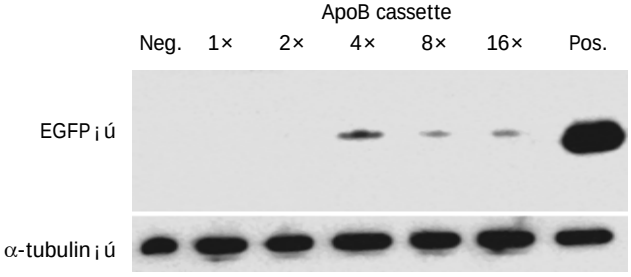

Figure 5 Western blot of EGFP expression driven by synthetic ApoB transcriptional control units. Lane 1: untransfected Hep3B cells used as a negative control (Neg.); lanes 2-6: detection of a 27 kDa band specific for EGFP expressing Hep3B cells transiently transfected with enhancer module plasmids exhibiting single (lane 2: 1×) or multimeric ApoB cassettes (lane 3: 2×; lane 4: 4×; lane5: 8×; lane 6: 16×); lane 7: Hep3B cells transfected with EGFP-encoding hCMV IE promoter plasmid pEGFP-C1 used as a positive control (Pos.), and Western blot detection of á-tubulin used as an internal standard.

Furthermore, EGFP protein contents obtained in cell lysates from Hep3B cells transiently transfected with enhancer module plasmids exhibiting single or multimeric ApoB cassettes were analyzed by Western blotting (Figure 5), using α-tubulin protein expression as an internal standard. As a result, a maximum EGFP signal was again obtained with the p4 × ApoB-GreeN construct (Figure 5; lane 4), which again corresponded with the FACS analysis data and also exhibited the strongest EGFP expression level for Hep3B cells transfected with the p4 × ApoB-GreeN construct (Figure 3; upper panel, 4 × ApoB, orange bar). Similar results were obtained under neomycin(G418)-selection of Hep3B cells transfected with the p4 × ApoB-GreeN construct, again demonstrating potent expression of the neo^r/neomycin aminoglycoside phosphotransferase coding sequence driven by the 4 × ApoB-TK-37 promoter cassette (data not shown).

Taken together, semi-quantitative RT-PCR, Western blotting analysis, and G418-selection of Hep3B cells demonstrated maximum transcriptional activities for the multimeric 4 × ApoB cassette construct (p4 × ApoB-GreeN), which fully complied with the data obtained by simple FACS analysis. Importantly, this finding could underline the possibility to first perform simple and quick FACS screening analysis based on our new EGFP/neo^r fusion reporter gene before doing any detailed analysis on a direct reporter mRNA or protein level.

DISCUSSION

Proper transcriptional regulation of therapeutic transgene expression constitutes a major requirement in liver-directed gene therapy. Gene regulatory elements used in liver gene therapy should meet several requirements. First, they should drive expression of the therapeutic gene at a sufficient high level. Second, they should restrict expression to the liver. Third, they should be well characterized and have suitable size to allow a most versatile usage in the context of a variety of different gene vector systems. Fourth, the well-known phenomenon of interaction of viral vector sequences with internal liver-specific promoters[24] should be kept at a minimum to avoid any interrelation with the expression of therapeutic transgenes.

Promoters of cellular genes expressed preferentially in the liver have been studied extensively and are used for hepatocyte/hepatoma-specific gene delivery[25-29]. However, the major shortcomings considering their widespread usage in liver gene therapy are the big size (contradictory to the restricted cloning space offered by many vector systems), the low transcriptional activity compared to hCMV or long terminal repeat (LTR) promoter sequences widely used in current gene therapy protocols[30-32], and/or interaction with viral vector sequences influencing expression of therapeutic transgenes[33].

Synthetic promoter/enhancer elements based on minimal promoters offer a promising alternative approach[34]. Combining DNA fragments encoding liver gene transcription factor binding sites potentially enables both a high degree of structural compactness and a high degree of liver specificity[12,13,35]. Also control elements derived from genes exhibiting a strict liver-restricted regulation like albumin, apolipoproteins, and alpha-1-antitrypsin can be used for this purpose[36,37]. In addition, this synthetic approach helps to exclude any repressor coding sequences preventing unwanted interactions of endogenous repressor factors with TFBS encoded in naturally originating promoter/enhancer elements.

In an attempt to construct promoters of high liver specificity and activity, we selected hepatospecific transcriptional sequences using the following criteria: short size, wellknown TFBS, expression independent of tight metabolic or hormonal control, and non-species-specificity. We first set out to evaluate both therapeutic efficiency and tissue specificity of this approach in our tissue culture model systems in order to subsequently pre-select liver-specific expression cassettes which could finally be tested within the context of different viral vectors (e.g., adenoviral or lentiviral vectors) both *in vitro* and *in vivo* as effective new liver gene transfer systems.

For this purpose, it worked out to be quite helpful to use a newly generated bifunctional EGFP/neo^r fusion gene cassette, which proved its flexible usage both for transcript quantification by simple FACS analysis (Figure 3) and for selection of stable cell clones (data not shown). Thereby, a proof of principle could be provided demonstrating the possiblity to first perform widespread simple and quick FACS screening analysis based on our new EGFP/neo^r fusion reporter gene before doing any detailed analysis on a direct reporter mRNA or protein level (Figures 4 and 5). This new approach is of great help in screening any of the numerous modifications of yet available or newly designed promoter cassette constructs.

As a leading result, our comparative analysis of transcriptional activities of synthetically generated promoter cassettes showed that it was not possible to achieve liver-directed gene expression fully approaching that of strong viral promoters such as the hCMV IE promoter. We chose the strong hCMV IE promoter as a reference promoter since it is believed to be similarly active in most tissues at least when used for short term expression. Of the different synthetic promoter cassette configurations tested, the most efficient construction was a multimeric 4 × ApoB cassette construct (p4 × ApoB-GreeN construct) as evidenced by FACS quantification (Figure 3), semi-quantitative RT-PCR (Figure 4), and Western blotting (Figure 5). These results clearly demonstrate that our multimeric 4 × ApoB cassette is a novel regulatory module that allows for an efficient and specific expression of therapeutic transgenes in liver cells. Of particular importance is the small size of this module, which makes it possible to accommodate this transcriptional control unit in any type of viral or non-viral vector, even in conjunction with large effector genes. Therefore, the 4 × ApoB cassette potentially represents a helpful new tool to explore the feasability of liver-directed gene therapy in further detail.

A further advantage of our synthetic minimal promoter based expression cassettes is the possibility to enable finely adjustable levels of therapeutic proteins (low to high) to be delivered/expressed by choosing a 1 × ApoB cassette or a 4 × ApoB cassette. Thereby, increasing or decreasing the number of multimeric monotypic or mixed TFBS-encoding cassettes can adjust the level of therapeutic transgene

expression.

In contrast to the good results obtained with "naturally" derived composite enhancer elements from liver-specifically expressed genes, our results with single binding sites of liver-specific transcription factors inserted upstream of the EGFP/neo^r fusion gene cassette are disappointing (data not shown). This might reflect the strict necessity for optimal spacing of TFBS, a feature that is neglected when single binding sites of liver-specific transcription factors are coupled together in a simple head-to-tail manner.

In comparison to promoters of viral origin, synthetic minimal promoter-based expression cassettes should not undergo *in vivo* shutdown as a result of DNA methylation processes or because of the presence of transcription factor binding sites at which cognate proteins are not expressed in the quiescent liver[38,39], thereby enabling long-term gene expression. Furthermore, usage of liver-specific promoters in the context of adenoviral vectors has been demonstrated to prevent the generation of antibodies against therapeutic transgenes[40], an eventuality that may occur when a ubiquitous promoter (e.g., hCMV IE) is used. Thus, our synthetic minimal promoter-based expression cassettes might also be helpful in focusing the therapeutic gene expression to the liver concurrently avoiding induction of any significant host immune response to the transgenic protein of choice, thereby prolonging transgene expression *in vivo* as demonstrated recently for liver-specific gutless adenoviral vectors[41].

In conclusion, we have identified a number of liver-specific promoter sequences that may be valuable tools for targeting heterologous genes to the liver when acceptable levels of therapeutic proteins need to be produced. For reasons of expression efficiency, vector security (especially in the context of suicide gene or other cytotoxic gene expression), and prevention of immune system-induced destruction of transduced cells, our synthetic liver-directed transcriptional control units seem to be a good choice for expression of potential therapeutic genes in the liver. Also clinical usage of non-viral constructs encoding these synthetically generated transcriptional cassettes might be facilitated. This view is based on the recent progress in techniques for delivery of naked DNA to the human liver as well as on their easier high-scale production and better acceptance by regulatory boards than the currently used viral vectors.

Abstract

AIM: To focus on the role of CD40 and CD40L in their pathogenesis.

METHODS: We analyzed by immunohistochemistry the CD40 and CD40L expression in the pouch mucosa of 28 patients who had undergone RPC for UC, in the terminal ileum of 6 patients with UC and 11 healthy subjects. We also examined by flow cytometry the expression of CD40 by B lymphocytes and monocytes in the peripheral blood of 20 pouch patients, 15 UC patients and 11 healthy controls.

RESULTS: Ileal pouch mucosa leukocytes presented a significantly higher expression of CD40 and CD40L as compared to controls. This alteration correlated with pouchitis, but was also present in the healthy pouch and in the terminal ileum of UC patients. CD40 expression of peripheral B lymphocytes was significantly higher in patients with UC and pouch, respect to controls. Increased CD40 levels in blood B cells of pouch patients correlated with the presence of spondyloarthropathy, but not with pouchitis, or inflammatory indices.

CONCLUSION: High CD40 expression in the ileal pouch mucosa could be implied in the pathogenesis of pouchitis following proctocolectomy for UC, whereas its increased levels on peripheral blood B lymphocytes are associated with the presence of extraintestinal manifestations.

Key words: Ulcerative colitis; Pouchitis; Spondyloarthropathy; CD40; CD40L; Arthritis

INTRODUCTION

The etiology of ulcerative colitis (UC) is not clear, but abnormal immunological activity against normally tolerated antigens has been demonstrated[1,2]. This disease is usually treated by immunosuppressive or anti-inflammatory drugs, but, in the case of unresponsive or steroid-dependent patients, or dysplasia, surgical treatment is indicated.

The standard of care for elective surgical treatment of patients with UC is restorative proctocolectomy (RPC), with ileal pouch-anal anastomosis (IPAA). After RPC, over 90% patients have shown good long-term function and high satisfaction, with full continence at 5 years in 72% of subjects and a mean stool frequency of six bowel movements per day[3,4]. The health-related quality of life reported by these patients is similar to that in subjects with UC in remission and better than in patients with moderate-severe colitis[5]. However, these patients sometimes suffer from pouchitis and extraintestinal manifestations such as arthritis, uveitis, erythema nodosum or pyoderma gangrenosum.

Pouchitis, an inflammation of the ileal reservoir, can develop in up to 50% of the patients that undergo RPC for UC, but in less than 1% of those operated on RPC for familial adenomatous polyposis (FAP)[6-8]. Clinically it is characterized by bloody diarrhea, fever, abdominal cramps and urgent defecation, and, at times, the symptoms resemble those of UC. Fortunately excision of the pouch is required in only 1-2% of these patients in whom the disease becomes chronic[9,10]. Several different hypotheses have been made to explain the etiology of pouchitis, which might be caused by ischemia of the ileal reservoir, transformation of the microbial flora, or fecal stasis possibly causing bacterial overgrowth or by a recurrence of UC. The last postulation has been sustained by many studies demonstrating immunological aspects that are similar to those in UC. A comparable expression to what is seen in UC of interleukin (IL)-1β, IL6, IL8 and tumor necrosis factor (TNF)α in the gut[11], an increased concentration of IgG and the activation of CD4 T cells[12,13] are all patterns demonstrating immunologic over-activity.

CD40 and CD154 (CD40 ligand or CD40L), two surface molecules, both members of TNF receptor family, are co-stimulators, expressed respectively by the antigen presenting cell and the T cells. While their presence is necessary to activate the immune response toward the antigen during its presentation, their absence leads to tolerance[14]. It has been reported that the expression of CD40 and CD40L by gut leukocytes is elevated in patients with UC and Crohn's disease even during remission, as compared to healthy controls or to other inflammatory events[15-17]. Sawada-Hase *et al*., also found an increased expression of CD40 by the blood B cells of patients with active UC and by the blood monocytes of patients with active Crohn's disease[18]. Recent studies on inflammatory bowel diseases (IBD) have demonstrated that CD40/CD40L interaction plays a key role not only in setting off an immune reaction, but also in the late inflammatory stage. In fact, there is evidence that CD40L positive T cells can induce cell adhesion molecules and expression of soluble mediators by CD40-positive human intestinal fibroblasts and microvascular endothelial cells. This event recruits more T cells from the blood to the tissue, thus amplifying intestinal inflammation[19].

The aim of this study was to evaluate if CD40 and CD40L may have a role in the pathogenesis of pouchitis. It was with this interest that we analyzed CD40 and CD40L expression by leukocytes from the ileal pouch mucosa and from the blood of patients who underwent RPC for UC, comparing it to that in non-operated UC patients and normal controls. The correlation between elevated levels of these molecules and the presence of pouchitis or extra-intestinal manifestations was also evaluated.

MATERIALS AND METHODS

Immunohistochemistry

Patients In the first part of the study, histologic samples were obtained from the ileal pouch biopsies of 28 patients (16 males, 12 females) who had undergone RPC for UC. Patients' mean age was 36 years (range 22-52 years) and time interval after RPC was in mean 5±4 years. According to the pouchitis disease activity index (PDAI) classification[20], 14 of these patients presented pouchitis (score ⩾7), while the other 14 presented a healthy pouch (score <7). A total of 76 pouch biopsies (35 from pouchitis and 41 from healthy pouches) were analyzed. Histochemical analyses were also carried out on ileal biopsies taken during standard surveillance colonoscopy of 6 consecutive un-operated patients with UC without ileitis and of 11 healthy subjects (who underwent endoscopy for screening, and whose test result was normal).

Methods All the samples were kept in formalin and subsequently paraffin embedded. The expression of CD40 (clone MAB 89, mouse, Immunotech) and CD154 (clone H-125, rabbit, Santa Cruz Biotechnologies) were analyzed in the same sample by immunohistochemical staining. Staining was performed using avidin-biotin complex (ABC), as described elsewhere[15].

In order to quantify the number of CD40+ and CD154+ cells present, we counted the percentage of leukocytes stained by the ABC immediately below the epithelium. We examined 10 fields at ×60 magnification from each sample. The percentage of the molecular expression was determined in a "blind" way by a single pathologist, who did not know the sample's origin.

Blood flow cytometric analysis

Patients In the second part of the study, we collected blood for flow cytometric analysis from 20 patients (12 males and 8 females, mean age 47 years, range 31-70 years) who had undergone RPC for UC (10 of them also participated in the first part of the study performed with immunohistochemistry), 15 patients with UC (7 males, 8 females, mean age 47 years, range 23-59 years) and 11 healthy subjects (controls). Patients receiving immunosuppressive or steroid treatment were excluded. Of the 20 patients who had undergone IPAA, 7 presented diagnosis of pouchitis, according to the PDAI (score ⩾7) and 13 did not (score <7). Extraintestinal diseases were found in 7 (6 with spondyloarthropathy, 1 pyoderma gangrenosum), while 13 were asymptomatic. Presence of both pouchitis and extraintestinal manifestations was found in 3. The diagnosis of spondyloarthropathy was made according to the European Spondyloarthropathy Study Group criteria[21]. Of the 15 patients with UC, 10 were in remission, 5 were in activity according to clinical and endoscopic patterns[22,23]. Extraintestinal symptoms were reported in five patients (three with spondyloarthropathy, one uveitis, one arthritis and pyoderma gangrenosum).

ESR and CRP were also measured respectively by Westergren method and immunonephelometry. We considered 6 mg/L and 15 mm/h the cut-off points for CRP and ESR, respectively.

All sampling procedures for histology and flow cytometry were performed after informed consent was obtained from each patient.

Methods Blood samples were collected in heparinized tubes. A four flow cytometric analysis was performed, with the sequent associations:

- CD45, CD40, CD20, CD14
- CD45, CD3, CD154

Anti-CD20 and anti-CD45 mAb were obtained from Coulter Beckman (Coulter Inc., Fullerton, CA, USA), anti-CD14 mAb, anti-CD40 mAb and anti-CD154 (CD40L) from Becton Dickinson & Co., (San Jose, CA) (Table 1). Anti CD-3 mAb was obtained from Caltag Laboratories (Bayshore Burlingame, CA, USA) (Table 1). For flow cytometry, all mAbs were used at optimal saturating concentrations as recommended by the manufacturers.

Quadruple staining was performed for CD20 (FITC), CD45 (ECD), CD14 (PE), CD40 (PC5) on one hand and triple staining for CD45 (ECD), CD154 (PC5), CD3 (FITC) on the other hand. As for the quadruple staining the cells were washed in FACS buffer containing PBS, 5% FCS, 0.05% sodium azide and incubated with 10 mg of human IgG (Sigma Chemical Co., St. Louis, MO) for 30 min at 4-8 ℃ to block Fc receptors. Cells were washed to remove excess IgG and were quadruple-stained with either PC5-conjugated mAb against human CD40 or PC5-control IgG_1 mAb, PE-conjugated mAb against CD14, or PE-control IgG

Table 1 Antibodies and sources for flow cytometry

Cluster differentiation	Clone	Isotype	Fluorochromes	Excitation	Emission	Source
CD45	J.33	IgG1	ECD	486–575	610–635	Coulter
CD20	H299 (B1)	IgG2a	FITC	468–505	504–541	Coulter
CD14	M5E2	IgG2a	PE	486–575	568–590	Becton–Dickinson
CD40	5C3	IgG1	PC5	486–580	660–680	Becton–Dickinson
CD154	TRAP1	IgG1	PC5	486–580	660–680	Becton–Dickinson
CD3	UCHT1	IgG1	FITC	468–505	504–541	Caltag

mAb, FITC-conjugated mAb against CD20 or FITC-control IgG mAb and ECD-conjugated mAb against CD45 for 30 min at 4-8 ℃. Cells were washed twice, re-suspended in FACS buffer, fixed with 1% paraformaldehyde, and analyzed by flow cytometry using Coulter EPICS XL-MCL (Beckman Coulter Inc., Fullerton, CA, USA). PBMCs were gated according to their CD45 expression characteristics. Different subsets of cells (CD20, CD14) were gated further based on FL1 and FL2 staining. A similar procedure was utilized for the co-staining of CD154, CD45, and CD3. An immunologic gate on CD20+ and CD14+ cells to evidence CD40 and on CD3+ to reveal CD154+ were respectively performed. As CD40 is expressed by most of the peripheral blood-except terminally differentiated-B cells, but the number of molecules on the lymphocytes surface rises during UC activity[18], we arbitrarily regulated the FL3 photomultiplicator voltage, positioning the CD40 expression below the threshold, previously set by the negative isotypic control of the relative antibody. In this way, all the B cells with homogeneous CD40 expression were below, while those with high CD40 expression were above the cut-off. In the present manuscript, we have called these cells as "high fluorescence intensity (hfi) CD40+". This instrumental setting was performed utilizing blood samples from four healthy controls (not included in the study). After that, isotypic controls were used for all the samples, maintaining the voltage setting of the photomultiplicator at the new level. We considered the CD40 expression by B lymphocytes above the cut-off level a pattern of activated B cells[18]. The same methods were utilized to detect monocytes CD14+ with high CD40 expression.

Statistical analysis

The aim was to detect a 50% difference, since a 300% difference was found in previous studies on CD40 tissue and blood expression in UC patients with respect to controls[15,18]. So the minimum sample sizes were calculated at one-sided alpha of 5%, a power of 80% and an estimated standardized effect size of 100%.

Results are expressed as mean±SE. Statistical analysis was performed by multi-way ANOVA followed by least significant difference (LSD) test. When only two samples were compared, Mann-Whitney *U* test was utilized. Frequency analysis was performed with Fisher exact test. Correlations were assessed using Spearman's rank correlation test. Statistical significance was set at $P<0.05$.

RESULTS

Immunohistochemistry

Results of immunohistochemical analysis are presented in Table 2. In healthy controls, the percentage of leukocytes exposing CD40 on the cell surface in the ileal mucosa was 4.0±1.62%. They were located just below the epithelium, probably in response to stimuli of luminal origin, as previously found in the normal colon[15]. Higher CD40 expression was found in the ileal pouch mucosa (14.0±1.72%, $P<0.05$) and in the ileal mucosa of non-operated UC patients (9.60±2.73%, in this case, although Mann-Whitney *U* test gave a statistical significant difference ($P<0.05$), the comparison with healthy controls did not reach the full statistical significance with LSD test). In the mucosa of the ileal pouch, there were more CD40+ cells in patients with active pouchitis compared to subjects with a healthy pouch (19.7±2.75% *vs* 8.6±1.76%, $P<0.01$) and their percentage correlated with the PDAI score ($P<0.01$). Similarly, we found more CD40L+ cells in the ileal mucosa of the pouch (17.5±2%), rather than in healthy controls, in whom the expression of this molecule was hardly detectable (0.4±0.21%, $P<0.01$, Figure 1). CD40L+ cells percentage (26.0±6.12%, $P<0.01$) in the ileal mucosa of non-operated patients with UC was also high. During an episode of pouchitis, CD40L -just as CD40 - expression was increased (20.4±2.54% *vs* 12.3±2.64%, $P = 0.01$, Figure 2) and correlated with the PDAI score ($P<0.01$). The ileal tissue of healthy pouches had significantly more CD40L than negative controls ($P<0.01$). CD40 and CD40L expression was not influenced by the pouch age.

Table 2 CD40 and CD154 expression by lymphocytes in the intestinal mucosa

	Controls	Ileum UC	Pouch	Pouchitis	Healthy pouch
CD40 (%)	4.0±1.62	9.60±2.73	14.0±1.72[a]	19.7±2.75[a,c]	8.6±1.76[a]
CD40L (%)	0.4±0.21	26.0±6.12[a,c]	17.5±2[a]	20.4±2.54[a,c]	12.3±2.64[a]

[a]$P<0.05$ *vs* controls; [c]$P<0.05$ *vs* healthy pouch.

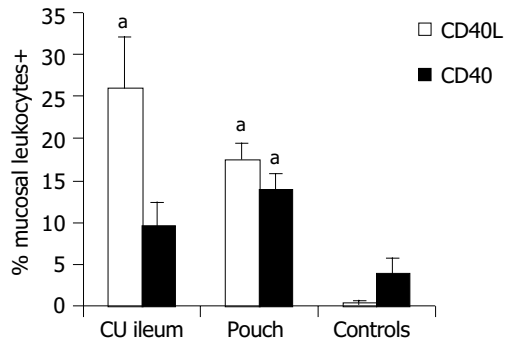

Figure 1 Mean percentages with standard error of CD40L+ and CD40+ leukocytes in the mucosa of UC ileum, ileal pouch, and controls. [a]*P*<0.05 *vs* controls.

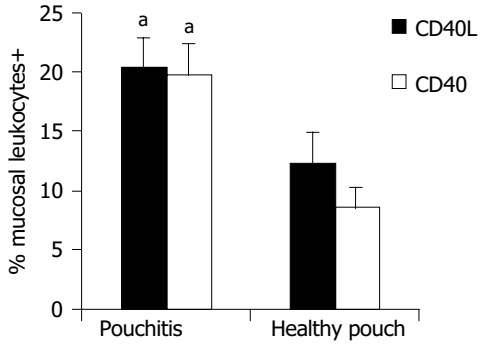

Figure 2 Comparison of CD40L and CD40 leukocytes' expression between pouchitis and healthy pouch mucosa. [a]*P*<0.05 *vs* healthy pouch.

Flow cytometric analysis

Results of flow cytometric analysis are presented in Table 3 There was a less homogeneous distribution of blood CD40+B cells in the flow cytometry diagram in samples presenting elevated CD40 expression, with respect to that in normal controls (Figure 3). Blood B cells of pouch and UC patients presented higher CD40 expression compared to controls (hfiCD40+/CD20+ cells percentage respectively 9.0±2.37% in patients with pouches, 9.7±1.34% in those with UC and 3.6±0.99% in controls, $P<0.05$, Figure 4). All except 1 control presented a percentage of hfiCD40+/CD20+ blood cells <7% (10/11, 91%), while 11/15 (73%) UC patients and 10/20 (50%) pouch patients presented a percentage ⩾7%. No significant increase in CD40 expression by CD14+ blood population (monocytes) was found in UC (0.38±0.13%) or pouch (0.16±0.06%) with respect to controls (0.09±0.06%). It was found that CD40L was not expressed in the CD3 population of the subjects analyzed.

No significant difference in CD40 expression by B cells was found between normal (hfiCD40+/CD20+ 11.00±3.6%) and inflamed pouches (6.40±2%). Moreover, no correlation was found with PDAI score or with pouch age. Enhanced CD40 expression in B lymphocytes of pouch population, instead, was correlated with extra-intestinal manifestations. Patients with extraintestinal manifestations (spondyloarthropathy, or pyoderma gangrenosum) showed a significant increase of CD40 expression (hfiCD40+CD20+ 16.86±5.25% *vs* 5.30±1.58% in patients without extraintestinal manifestations, $P<0.05$). The difference was statistically significant also considering only patients with spondyloarthropathy (Figure 5). The CD40 expression in blood monocytes was not correlated to extraintestinal manifestations. Patients with pouchitis did not present a higher incidence of extraintestinal manifestations.

CD40 expression in B lymphocytes or in monocytes did not correlate with the levels of ESR or CRP.

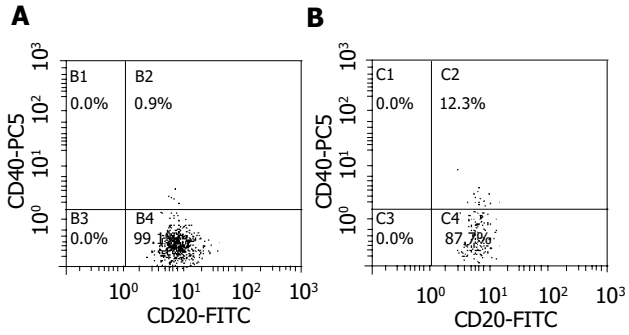

Figure 3 CD40 expression in B cells (CD20+) in controls (**A**) is homogeneously distributed under the cut-off. This expression is instead above the cut-off value, in several B cells in pouch patients with spondyloarthropathy (**B**), as in those with UC.

DISCUSSION

The pathogenesis of pouchitis after proctocolectomy remains to be elucidated. From our results, pouchitis does not seem to represent the manifestation of systemic disease. In fact we found activated peripheral B cells in the presence of arthritis, but not in the presence of pouchitis. Moreover, pouchitis was not related to extraintestinal manifestations. Our results are in disagreement with those reported by

Table 3 Flow cytometry results: CD40 expression on B cells and monocytes

	HfiCD40+CD20+ (%)	*P*	HfiCD40+CD14+ (%)	*P*
UC *vs* controls	9.7±1.34 *vs* 3.6±0.99	<0.05	0.38±0.13 *vs* 0.09±0.06	NS
Pouch *vs* controls	9.0±2.37 *vs* 3.6±0.99	<0.05	0.16±0.06 *vs* 0.09±0.06	NS
Extraint+ *vs* extraint-	16.86±5.25 *vs* 5.30±1.58	<0.05	0.1±0.03 *vs* 0.2±0.13	NS

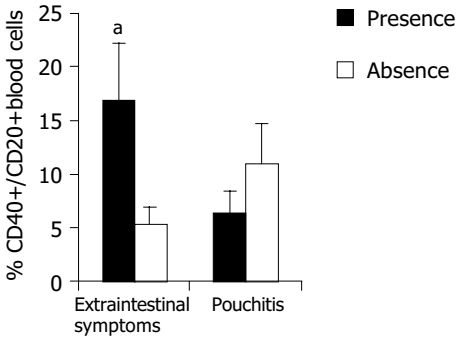

Figure 5 Blood B cells in pouch patients with extraintestinal manifestations, such as spondyloarthropathy or pyoderma gangrenosum, present a higher expression of CD40 with respect to the other pouch patients. Instead no difference is present during pouchitis. Hfi, high fluorescence intensity. [a]*P*<0.05 *vs* absence.

Lohmuller *et al*.[24], and Hata *et al*.[25], which found higher rates of pouchitis in patients with extraintestinal manifestations than in those without. Our findings were supported instead by Thomas *et al*.[26], who observed that histological scores of pouch inflammation were not different in patients with and without joints diseases.

Increased CD40 and CD40L expression was found in the terminal ileum of some patients with UC who had not undergone surgery. This finding is in agreement with the hypothesis that the ileal segment used for pouch construction, even if apparently regular, could nevertheless be abnormal with regard to its immunology and function[27]. Known underlying diseases in the terminal ileum could be Crohn's disease, indeterminate colitis, or backwash ileitis[6]. In a study by Battaglia *et al*.[17], the ileal tissue of patients with Crohn's disease presented higher levels of CD40L and CD40 on T and B lymphocytes, with respect to controls. Backwash ileitis has already been considered as a risk factor for pouchitis. Schmidt *et al*.[28], analyzed 67 preoperative terminal ileal and colonic resections in patients with UC who underwent proctocolectomy. In their study ileal inflammation or pancolitis were significant predictors of subsequent pouch inflammation. On the other hand, Gustavsson *et al*.[29], found a similar incidence of pouchitis in patients presenting backwash ileitis at surgery than in those without. The alteration we found in CD40 and CD40L expression in the terminal ileum of patients with UC is not associated with clear inflammatory patterns. Nevertheless it could yield a reduced tolerance status that becomes clinically evident only in certain conditions, such as, probably, the presence of fecal stasis, different bacterial flora or colonic metaplasia. Colonic metaplasia alone cannot cause pouchitis, since this histologic pattern has been found in 50% of pouch constructed for patients with FAP, which rarely becomes inflamed[30].

The analysis of CD40 and CD40L in the ileum of patients with UC who are possible candidates for RPC could represent a predictive marker for the future development of pouchitis or fistulas. Prospective studies are needed to clarify this hypothesis.

The analysis of soluble CD40L in the serum using ELISA could be easier than the research by flow cytometry of CD40 and CD40L on B lymphocytes' and monocytes' surface, but it was excluded from this study because it was mainly expressed by platelets[31]. The presence of increased CD40 expression in blood B lymphocytes of IBD patients has already been reported by others. Sawada-Hase *et al*.[18], found a higher CD40 expression in the CD19+ blood cells in patients with active UC and in the CD14+ blood cells in subjects with active Crohn's disease. CD40 expression in peripheral B cells has however never been analyzed in pouch patients. An increased CD40 expression in the blood B lymphocytes of subjects who have undergone RPC demonstrates that some systemic alterations persist following the surgical treatment of UC, suggesting that it is a systemic rather than just a colonic disease. Nevertheless, only half of the pouch patients presented an altered expression of this molecule on peripheral B-cells' surface. Extraintestinal manifestations of UC-such as spondyloarthropathy-seem to be related to CD40 levels on blood B cells, while other analyzed factors, like pouchitis, pouch age, ESR or CRP, do not.

The importance of CD40 and CD40L in arthritis has been previously demonstrated. In patients with rheumatoid arthritis (RA), in fact, increased expression of CD40 on synovial monocytes, fibroblasts and dendritic cells has been reported[32-34] and blocking CD40-CD154 interaction improved collagen-induced arthritis in a murine model of RA[35]. Thomas *et al*.[26], studied 97 UC patients with pouch for rheumatological diseases. Articular symptoms in joints were reported in 31% of the patients, but clinical and radiological findings were nearly normal. On the basis of our findings, increased CD40 expression by blood B cells seems to be a measurable marker of this disease.

In conclusion, pouchitis is characterized by an increased expression of CD40 and CD40L on mucosal leukocytes. This result, also found in the terminal ileum of some UC patients who were analyzed here, could represent a predisposing factor for pouchitis, activated in the presence of bacteria and feces following pouch construction or colonic metaplasia.

High levels of CD40 on the surface of blood B cells did not correlate with pouchitis, but with spondyloarthropathy. These findings suggest a different pathogenesis of the two diseases, with local events the first, systemic immunological alterations the second. Prospective studies, before and after

pouch construction and before and after symptoms, are mandatory to evaluate these analyses as prognostic markers for the development of pouchitis, if conducted in the ileal mucosa, and of spondyloarthropathy following RPC, if performed on blood samples.

Abstract

AIM: To evaluate the cellular synthetic ability of cytokines involved in pro- and anti-inflammatory reactions in patients with AP.

METHODS: Sixty-seven patients with AP (16 severe, 51 mild) and 10 controls were included in the study. Cultures of whole blood were performed in samples obtained within the first 72 h from the onset of pain. Serum levels of interleukins (IL) 6, 8, 10, and TNF-α were measured at baseline and in the supernatant of cultures with (functional reserve) or without stimulation with phytohemaglutinin.

RESULTS: Basal levels of cytokines were significantly higher in patients with severe AP. A significant increase of all pro-inflammatory cytokines *vs* basal levels was observed in the supernatant after 24 h of whole blood cultures in patients, but not in controls. In contrast, IL-10 increased significantly in the supernatant of cultures only in patients with mild AP. Cells showed a statistically significant functional reserve for all IL in patients with mild, but only for pro-inflammatory cytokines in patients with severe AP.

CONCLUSION: A marked activation of immune system may be observed in patients with AP, being balanced between pro- and anti-inflammatory cytokines in patients with mild but not severe AP. A reduced functional reserve for the synthesis of IL-10 may be observed in patients with severe AP, which might lead to a worst prognosis.

INTRODUCTION

Patients with acute pancreatitis (AP) show an exacerbated local inflammatory reaction, likely as the consequence of the pancreatic cellular injury[1,2], which may be followed by a generalization of the process, leading to a potentially severe systemic form of the disease with multiple organ failure and eventually death[3]. This clinical situation is at least partially mediated by a marked host's immune response and a prolonged or exacerbated synthesis of pro-inflammatory cytokines, such as tumor necrosis factor-α (TNF-α) and interleukins (IL) 1, 6 and 8[4-8]. In fact, recent findings have shown the existence of a significant correlation between the serum levels of the mentioned cytokines and the severity of AP[8-12].

The liberation of pro-inflammatory cytokines is followed by the synthesis of anti-inflammatory cytokines, such as IL-10, whose function is to counterbalance the hypothetical deleterious effects of an exacerbated immune response[7,13]. There is scarce and conflicting information regarding the possible effect of IL-10 in the control of the inflammatory process in patients with AP[14,15].

A main drawback in the study of cytokines in any clinical setting is its intermittent pattern of secretion and short half-life[16]. To overcome these complications, several approaches have been considered, such as the measurement of the more durable soluble cytokine receptors[9], or the measurement of the cytokine secretion patterns *in vitro* either by the culture of mononuclear cells[16] or whole blood with or without the addition of cellular stimulants.

The *in vitro* model has been utilized in different clinical settings[17,19], and it has revealed as simple, reproducible, and accurate method for evaluation of the cytokine secretion patterns, allowing the estimation of functional immune cellular reserve[20,21]. To our knowledge, no study has evaluated the usefulness of this method to investigate the inflammatory response in patients with AP. Then, the aims of this study

have been to investigate the *in vitro* secretion pattern of pro- and anti-inflammatory cytokines by whole blood cultures in patients with AP, and the estimation of the functional cellular reserve.

MATERIALS AND METHODS

Patients

A prospective series of patients with clinical diagnosis of AP and less than 48 h from the onset of symptoms admitted to the Gastroenterology Departments of two academic hospitals were consecutively included in a prospective study. The diagnosis of AP was defined as the presence of clinically compatible abdominal pain with an increase of serum amylase three times above the upper normal limit, evidence of pancreatic swelling by imaging techniques and exclusion of other possible causes of abdominal pain.

Patients with severe or mild forms of AP according to Atlanta's criteria[22] of severity were analyzed separately. A group of healthy subjects were considered as controls. The Hospital General Universitario Ethics Committee approved the study protocol, and all patients gave their informed consent for the inclusion in the study.

Methods

Blood was obtained for routine hematological, biochemical, and coagulation studies within 72 h from the onset of symptoms. Ten milliliters of blood was inoculated into two rubber-sealed pyrogen-free tubes (Endo Tube ET, Chromogenix AB, Vienna, Austria). One of the aliquots was centrifuged 10 min at 3 500 r/min and stored at -70 ℃ until analysis. Tubes were not exposed to free air.

Whole blood cultures Blood was distributed in a 24-well plate with or without the addition of 40 μL of phytohemaglutinin (PHA) at a concentration of 1 μg/mL for 24 h at 37 ℃ in a humidified atmosphere with 50 mL/L CO_2. Supernatants were obtained by centrifugation at 2 500 r/min for 5 min and stored at -80 ℃ until assay. The maximum period of time between being frozen and thawing was 3 mo, and none of the specimens was thawed and refrozen prior to analysis in the current study.

Measurement of TNF-α, IL-6, IL-8, and IL-10 Immunoenzymometric assays for the quantitative measurement of human TNF-α, IL-6, 8 and 10 in serum samples and in the supernatant of whole blood cultures were performed by handling Biosource IFN-γ EASIA Kit (Biosource Europe SA, Nivelles, Belgium), human TNF-α HS Quantikine®, and IL-6, IL-8 and IL-10 Quantikine® (R&D Systems, Minneapolis, MN, USA) according to manufacturer's instructions. All samples were tested in duplicate and read at 450 and 490 nm in a ThermoMax microplate reader (Molecular Devices, Sunnyvale, CA, USA). The lower levels of sensitivity for measurement of cytokines were 1.7 pg/mL for TNF-α, 5 pg/mL for IL-6, 2 pg/mL for IL-8 and 10 pg/mL for IL-10.

We consider the presence of a status of cellular pre-activation, when the levels of the different cytokines measured in the supernatant of non-stimulated whole blood cultures were significantly higher to that measured in basal samples. We considered that cellular functional reserve exists for the synthesis and secretion of cytokines, when the levels of the different parameters measured in the supernatant of whole blood cultures plus the addition of PHA were higher to those measured in the non-stimulated cultures, and conversely, no functional reserve was considered, when the levels obtained with cellular stimulants were similar to those obtained without PHA.

Statistical analysis

All the observations are reported as median and 25th and 75th percentiles. Statistical differences were analyzed using the Mann-Whitney *U* test for the comparison among different groups and the Wilcoxon test for the comparisons within each group at different times. A P value <0.05 indicated statistical significance. Analyses were performed with the SPSS Statistical package (SPSS Inc., version 11.0, Chicago, IL).

RESULTS

Sixty-seven patients diagnosed of AP were included in the study. AP was considered severe in 16 patients (6 male, mean age 66±16 years) and mild in 51 cases (23 male, mean age 61±16 years). Ten healthy subjects were studied as controls (6 male, mean age 45±19 years). The etiology of AP was biliary in 37 patients (55.3%), alcoholic in 8 patients (11.9%) and others (hypertriglyceridemia, post-endoscopic cholangiopancreatography (ERCP), drugs or idiopathic) in 22 cases (32.8%). We did not find statistically significant differences in sex, age, and etiology of AP among groups. Five patients developed respiratory insufficiency (7.5%) and one progressed to acute renal failure (1.5%). Regarding local complications, five patients developed a pseudocyst (7.5%), pancreatic necrosis was observed in five cases (7.5%), and infected pancreatic necrosis in one patient (1.5%). Overall, seven patients died during admission (10.4%), all being considered as severe AP.

Table 1 shows the levels observed in all parameters studied in basal conditions and in the supernatant of whole blood cultures with all recorded statistical significances. Basal levels of IL-6 in patients with SAP were significantly higher than that observed in controls and patients with mild AP ($P<0.05$). Basal IL-8 and TNF-α measured in patients with severe AP were significantly higher than those in patients with mild AP, but not *vs* healthy controls ($P<0.01$ in both cases). Quite opposite, statistically significant differences were observed when comparing IL-10 levels between patients with severe *vs* mild AP ($P<0.05$), but not *vs* controls (Figure 1).

When comparing basal values with those measured in the supernatant of non-stimulated cultures, significant differences were observed in all pro-inflammatory cytokines in patients with mild or severe AP, but not in controls. IL-10 increased significantly in these experimental conditions only in patients with mild AP (Figure 2).

When analyzing the cellular functional reserve (i.e., values measured in the supernatant of non-stimulated *vs* stimulated cultures), significant increases in pro-inflammatory cytokines were observed in all groups of patients (Figure 3).

Table 1 IL-6, IL-8, TNF-α and IL-10 levels in groups I–III

		IL-6 (pg / mL)	IL-8 (pg / mL)	TNF-α (pg / mL)	IL-10 (pg / mL)
SAP	Basal	105.6 (52.0–210)[a]	46.8 (26.2–95)[b]	15.8 (7.1–21.7)[b]	17.7 (7.5–29.4)[c]
	24 h	208.0 (140–476)[e]	872.0 (316–3 280)[e]	58.7 (52–132)[e]	12.5 (8.4–34.6)
	24 h+PHA	925.0 (303–1 219)[g]	2 715.0 (760–8 599)[g]	473.0 (308–518)[g]	7.2 (2.2–47.3)
MAP	Basal	15.0 (5.4–33.2)	18.5 (1.2–33.6)	7.9 (4.1–17.7)	7.3 (4.1–-1.6)
	24 h	133.0 (53.6–856)[e]	1 611.0 (484–4 336)[e]	62.4 (45.5–100.5)[e]	20.8 (6.5–44.1)[e]
	24 h+PHA	2 057.0 (605–4 189)[g]	8 045.0 (3 377–28 209)[g]	540.5 (422–824.7)[g]	51.9 (32.1–131.3)[g]
Controls	Basal	3.2 (0.9–6.7)	35.6 (17.9–93.7)	4.3 (2.2–6.1)	9.4 (6–14.4)
	24 h	7.1 (4.9–9.6)	46.9 (32.2–94.5)	7.1 (4.1–10.1)	21.3 (18.3–34.5)
	24 h+PHA	610.0 (404.7–1 026)[g]	1 396.0 (962–3 065.2)[g]	792.0 (573.2–1 064.7)[g]	53.0 (43.4–80.1)[g]

Data are shown as median (25th–75th percentiles). SAP: severe acute pancreatitis; MAP: mild acute pancreatitis; controls: healthy controls; basal: samples obtained within 72 h from the onset of symptoms; 24 h: supernatant of culture after 24 h without stimulation; 24 h+PHA: supernatant of culture after 24 h with addition of PHA to the culture media; IL-6, IL-8, and IL-10: interleukins 6, 8 and 10 respectively; TNF-α: tumor necrosis factor-α. [a]$P<0.05$ *vs* the corresponding values in groups II and III; [b]$P<0.01$ *vs* the corresponding value in group II; [c]$P<0.05$ *vs* the corresponding value in group II; [e]$P<0.05$ *vs* basal levels within each group; [g]$P<0.05$ *vs* 24 h levels within each group.

However, a significant functional reserve for IL-10 was observed only in controls and in patients with mild, but not severe AP (Figure 3).

For better measurement of functional reserve, we estimated the increase observed in each studied parameter with values obtained in non-stimulated *vs* stimulated cultures in all three groups, and observed that this increment is higher in patients with mild than in severe AP, although this reached significance only when measuring IL-6 and IL-10 (Figure 4).

DISCUSSION

Cytokines are soluble components of the inflammatory cascade that play a seminal role in the pathogenesis of the systemic response syndrome that usually takes place in patients with AP[4-8]. Different works have shown a relationship between the levels of different pro-inflammatory cytokines reached in serum and the severity of AP, and patients with highest levels of these factors in the early phases of the disease are those developing systemic complications[8-12].

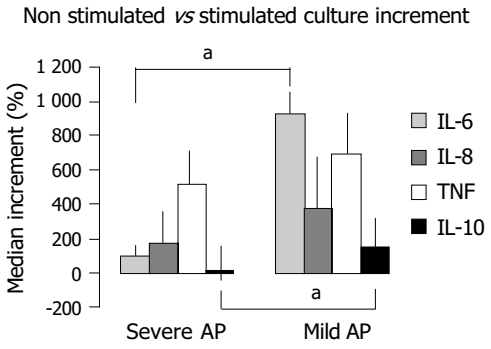

Figure 4 Cellular functional reserve represented as increments of all studied cytokines in patients. [a]*P*<0.05 *vs* others.

It has been recently described the anti-inflammatory role of certain cytokines, namely IL-10, and the most accepted hypothesis suggests that this is a mechanism devoted to compensate the systemic inflammatory response that precedes the development of multi-organ failure[7,13,23,24]. The existence of a misbalance between pro- and anti-inflammatory cytokines would participate in the genesis of the systemic complications that may develop in some patients with AP[25]. The information available regarding IL-10 levels in patients with AP is controversial, and the results obtained in the different studies show a great variability[13-15,23,24]. However, the experimental administration of IL-10 in animal models of induced AP has been shown to reduce cytokine release, the severity of AP and also mortality[26-28]. Similarly, the administration of this cytokine has been shown to reduce the incidence of AP in patients undergoing ERCP[29].

The discrepancies found when studying the cytokine profile in the clinical setting may be a reflection of several drawbacks inherent to the study of cytokines, such as the moment of obtaining the blood samples, its intermittent pattern of secretion, its autocrine or paracrine natural way of action[16], and short half-life. The culture of immunocompetent cells and measurement of cytokines and effector molecules in the supernatant has revealed that it is a useful method to investigate the inflammatory status and cellular functional reserve in different clinical settings[17-19]. Although early attempts with the culture of monocytes did not give satisfactory data, likely due to a different environmental situation to what is expected to find *in vivo*[16], the culture of whole blood and measurement of cytokines in the supernatant appears to be a simple, reproducible and accurate method in the evaluation of synthesis of components of the inflammatory cascade, since it closely approximates to what is expected to find *in vivo*. In addition, it allows the study not only of the basal status of cellular activation, but also of the cellular functional reserve, when comparing the spontaneous cellular ability to synthesize cytokines with that when the cells are further stimulated[20,21]. To our knowledge, this methodological approach has not been explored in patients with AP.

We have observed a spontaneous and significant increase in the synthesis of pro-inflammatory cytokines in patients, when compared to controls after 24 h of non-stimulated culture that represents the degree of cellular preactivation (Figure 2), which likely supports the contention of the existence of an inflammatory pre-activation status in patients with AP. The fact that IL-10 increases significantly in non-stimulated cultures with respect to basal values in patients with mild AP (Figure 2B) likely suggests that an anti-inflammatory response follows a parallel course to the inflammatory reaction, probably as a balancing mechanism in patients with mild AP. This situation is not found in patients with severe AP (Figure 2A), and it is similar to what is observed, when comparing the non-stimulated IL-10 synthetic ability with that after culture stimulation in this same subgroup of patients (Figure 3A), suggesting the absence of cellular functional reserve for this anti-inflammatory cytokine. The rest of the cytokines evaluated in both groups of patients show a significant increase when cultures are stimulated with PHA *vs* values obtained in the supernatant of cultures without stimulation (Figures 2 and 3). Then, cells obtained from patients with AP, either mild or severe, show a marked pre-activation status that is reflected in the amount of pro-inflammatory cytokines that spontaneously secrete in culture (Figure 2) and show a certain degree of cellular functional reserve when PHA is added to the culture medium (Figure 3). This is not, however, the case with respect to IL-10, as a key parameter of anti-inflammatory cytokines, since in both situations, i. e., in spontaneous culture, and after stimulation with PHA, the levels of this cytokine stabilize or even decrease (Figures 2 and 3). Figure 4 reinforces this concept when analyzing the increments of all parameters evaluated in different experimental situations.

We cannot exclude that a continuous status of inflammatory activation in patients with severe AP may lead to an early depletion of anti-inflammatory cytokines and incapacity to counterbalance the inflammatory cascade. Following this same line of thinking, it would be logical to hypothesize that an insufficient anti-inflammatory response might exert a causative effect in a subgroup of patients with AP, favoring a worse clinical evolution. The conserved cellular reserve in patients with mild AP (Figure 3B) likely supports our hypothesis.

In conclusion, the practice of whole blood cultures and measurement of cytokines either in non-stimulated *vs* stimulated conditions allows the estimation of the pre-activation status and the cellular functional reserve in patients with AP. In our series, the synthetic pattern of cytokines shows a different behavior in patients with mild or severe AP, and suggests that a reduced ability to synthesize anti-inflammatory cytokines in cases of severe AP may play a role in the clinical evolution of patients.

Abstract

AIM: To evaluate the association between the severity of liver steatosis and metabolic syndrome in apparently healthy Korean adults.

METHODS: We examined 1 022 men and women, aged 30-79 years, who participated in a health screening test. A standard interview, anthropometrics, biochemical studies, and abdominal ultrasonography were conducted for each participant. Metabolic syndrome was defined according to the National Cholesterol Education Program Adult Treatment Panel III, with a modification for the waist circumference cut-off level. The severity of liver steatosis was evaluated using liver ultrasonography, and serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), and γ-glutamyl transferase (γ-GT) levels were determined.

RESULTS: Ultrasonographic liver steatosis was strongly associated with metabolic syndrome and common metabolic abnormalities. Compared with people without steatosis, people with mild, moderate, and severe steatosis had adjusted odds ratios for metabolic syndrome of 1.72 (95%CI, 1.01-2.94), 2.89 (1.75-4.76) and 3.53 (1.25-9.98) in men, and 2.86 (1.64-5.01), 3.19 (1.80-5.65) and 3.70 (0.82-16.73) in women, respectively. The serum AST level was not associated with metabolic syndrome. The serum ALT and γ-GT levels were significantly associated with metabolic syndrome in men but not in women.

CONCLUSION: The occurrence of metabolic syndrome shows a stronger association with the severity of ultrasonographic steatosis than with the serum liver enzyme levels. The degree of fatty infiltration detected on ultrasonography can be used as an indicator of liver dysfunction attributable to metabolic abnormalities.

INTRODUCTION

Non-viral non-alcoholic fatty liver disease (NAFLD) is an increasingly recognized condition that accompanies an increase in obesity[1-3]. NAFLD is known to be associated with various metabolic abnormalities including central obesity, type 2 diabetes, dyslipidemia, and high blood pressure[2,4-9], which are also well-established cardiovascular risk factors. Recently, it was suggested that fatty liver disease can be considered to be the hepatic consequence of metabolic syndrome or of a cluster of metabolic disorders[10-14]. In a previous report, we showed that NAFLD is closely associated with various metabolic abnormalities even in non-obese non-diabetic Korean people[15].

NAFLD has a wide clinical spectrum, and its severity can be measured by several methods. Liver biopsy represents the best diagnostic test for staging liver steatosis, inflammation, and fibrosis, but medical and ethical considerations limit its use in subjects with non-progressive fatty liver conditions[14,16]. The severity of fatty liver disease can also be evaluated based on the serum levels of liver enzymes such as aspartate aminotransferase (AST), alanine aminotransferase (ALT), and γ-glutamyl transferase (γ-GT)[1,2]. These enzymes are sensitive markers of liver cell damage, but they cannot provide information on the underlying causes of that damage. It has been shown that liver ultrasonography, although not sufficiently sensitive to detect liver inflammation and fibrosis, demonstrates a good correlation with histological findings of fatty infiltration, and international guidelines have been proposed for the diagnosis of different degrees of steatosis[17-19]. However, there are few data available on the

association of metabolic syndrome with the severity of liver steatosis assessed by ultrasonography.

Therefore, in the present study, we expanded our investigation to examine the sex-specific association between the severity of ultrasonographic liver steatosis and the presence of metabolic syndrome. In addition, we also examined the sex-specific association between the serum liver enzyme levels and metabolic syndrome.

MATERIALS AND METHODS

Subjects

This study was performed as part of the Korean metabolic syndrome study, which was undertaken to evaluate the role of metabolic syndrome as a risk factor for cardiovascular disease in Korean adults. We measured the metabolic profile, evaluated the cardiovascular risk factors, and performed abdominal ultrasonography scans on 1 244 men and women. The measurements were made over a 3-mo period (April-June, 2001) at a health screening center in Seoul, South Korea. All participants were healthy, independently functioning individuals who visited the health center for health-screening tests. From among the 1 244 initial volunteers, we selected 1 142 people who were between 30 and 79 years and who had completed anthropometric measurements, serum biochemistry profiles, and liver ultrasonography. We excluded 120 people who had a previous history of coronary heart disease or stroke and 35 people who tested positive for hepatitis B virus surface antigen (HBsAg). Ultimately 1 022 subjects (557 men and 465 women) were included in the analyses.

Measurements

Trained nurses interviewed all participants and obtained their medical history, family history of chronic disease, and information on life style factors, using a standardized questionnaire. The weight and height of each participant were measured while the participant was clothed only in a light gown, and the body mass index was calculated as body weight divided by height squared (kg/m^2). The waist circumference was measured midway between the lowest rib margin and the iliac crest in a standing position, by the same examiner. The percent body fat was measured by bioelectrical impedance analysis (Inbody 2.0, Biospace Co., South Korea). The participants were required to rest for at least 5 min prior to two repeated measurements of their blood pressure at an interval of at least 1 min. The mean value of these two measurements was used for the analyses. Blood samples were obtained from each participant after a fasting period of at least 8 h. The blood glucose level was measured using the glucose oxidase method. The serum insulin level was measured using a radioimmunoassay that had an interassay coefficient of variation of 4%. As an index of insulin resistance, we used the fasting insulin-glucose product. When divided by 22.5, this product is numerically equivalent to the homeostasis model assessment of insulin resistance (HOMA-IR)[20], which has been shown to correlate well with the results of the euglycemic hyper-insulinemic clamp in population-based studies[21]. Serum total cholesterol, high-density lipoprotein (HDL) cholesterol, and triglyceride levels were measured on an autoanalyzer using enzymatic colorimetry. Serum levels of AST, ALT, and γ-GT were also measured using enzymatic methods.

The carotid arteries were evaluated by the same examiner using high-resolution B-mode ultrasonography with a 7.5-MHz probe. The carotid intima-media thickness (IMT) was obtained by measuring the distance between the first and second echogenic lines using a caliper. For each common carotid artery, three measurements were performed and the maximum IMT of each common carotid artery was selected. All measurements were made by the same examiner. Liver ultrasound scans were performed to assess the presence and degree of liver steatosis. All ultrasound scans were performed by the same operator, who was unaware of the participants' medical histories and laboratory findings, using a high resolution B-mode scanner (SSD-5500, Aloka, Tokyo, Japan). Liver steatosis was assessed semi-quantitatively on a scale of 0-3 (0, absent; 1, mild; 2, moderate; 3, severe), on the basis of abnormally intense, high-level echoes arising from the hepatic parenchyma, liver-kidney difference in echo amplitude, echo penetration into the deep portion of the liver, and clarity of the blood vessel structure in the liver (Figure 1)[17].

Metabolic syndrome was defined according to the criteria established by the National Cholesterol Education Program Adult Treatment Panel III (ATP III), except for the determination of abdominal obesity by waist circumference[22]. We used a waist circumference cut-off level of >90 cm in men and >80 cm in women, based on the report by the International Diabetes Institute/Western Pacific World Health Organization/International Obesity Task Force[23]. Hence, in this study, participants having three or more of the following five criteria were defined as having metabolic syndrome: high blood pressure (≥130/85 mmHg), elevated fasting blood glucose (≥110 mg/dL or 6.05 mmol/L), hypertriglyceridemia (≥150 mg/dL or 1.65 mmol/L), low HDL-cholesterol (men, <40 mg/dL or 1.05 mmol/L; women, <50 mg/dL or 1.30 mmol/L), and abdominal obesity by waist circumference (men, >90 cm; women, >80 cm). Participants taking anti-hypertensive or anti-diabetic medications were included in the high blood pressure group and the high fasting blood glucose group, respectively.

Statistical analysis

We reported the clinical and biochemical characteristics of the participants according to the severity of the liver steatosis on ultrasound examination, separating the data for the men and women. For each variable, the linear trend with the severity of ultrasound liver steatosis was tested. The prevalence of abnormal metabolic conditions and metabolic syndrome were calculated for each level of severity of liver steatosis, and the linear trends were also tested. In order to assess the independent association between liver steatosis and metabolic syndrome, age- and multivariate-adjusted logistic regression models were used. First, we estimated the age-adjusted odds ratios of having metabolic syndrome for each level of severity of liver steatosis. In the multivariate model, we estimated the corresponding odds ratios after adjustments for age, menopause (women only), body mass index, cigarette smoking, and alcohol intake. We also estimated the adjusted

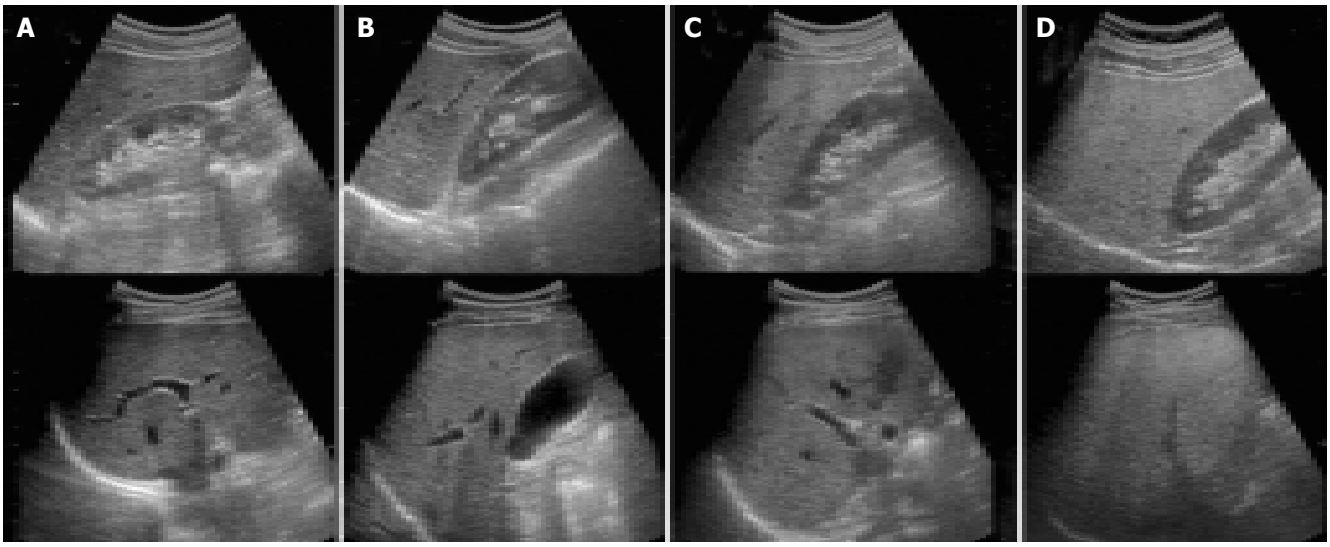

Figure 1 Ultrasonographic findings of liver according to the degree of steatosis. (**A**) Normal liver, (**B**) mild steatosis: a slight augmentation in liver echogenicity, a slight exaggeration of echogenic discrepancy between liver and kidney, and a relative preservation of echo line in the portal vein wall. (**C**) Moderate steatosis: a loss of echo line in the portal vein wall, particularly from the peripheral branches, resulting in a featureless appearance of the liver. (**D**) Severe steatosis: much greater reduction in echo penetration, a loss of echogenicity in most of the portal vein wall, including the main branches, and a large echo discrepancy between liver and kidney. Adapted from Saverymuttu *et al*.[17].

odds ratios of having metabolic syndrome for the different levels of the serum liver enzymes, AST, ALT, and γ-GT. For each enzyme, four categories were established using cut-off values determined by the level at which the number of individuals in each category was nearest to the number in the corresponding level of ultrasonographic severity. The SAS System version 8.01 (SAS Institute, Cary, NC, USA) was used to perform all statistical analyses. All statistical tests were two-sided, and *P*-values less than 0.05 were considered statistically significant.

RESULTS

Among the 557 men and 465 women examined, ultrasonographic scans revealed mild steatosis in 133 (23.9%) men and 87 (18.7%) women, moderate steatosis in 165 (29.6%) men and 93 (20.0%) women, and severe steatosis in 19 (3.4%) men and 10 (2.2%) women. The clinical characteristics and laboratory data of the participants with different degrees of steatosis as detected on ultrasonography are shown in Table 1. In men, the mean age was similar among the groups with different severities of steatosis, but in women there was a positive association between age and liver steatosis. With increasing severity of liver steatosis, there were statistically significant progressive increases in mean body mass index, waist circumference, body fat percent, blood pressure, total serum cholesterol, and serum triglycerides, and there was a statistically significant decrease in mean HDL-cholesterol. A statistically significant increase was also observed in the mean fasting glucose and insulin levels, and in insulin resistance, as assessed by mean HOMA values. The levels of liver enzymes (AST, ALT, and γ-GT) and carotid IMT were also positively associated with the degree of fatty infiltration. In contrast, cigarette smoking and alcohol intake were not associated with liver steatosis.

In both men and women, fatty liver detected by ultrasonography was strongly associated with metabolic syndrome and the five metabolic abnormalities, which are criteria for its clinical diagnosis. Among the 515 people without liver steatosis, only 19.6% (16.3% for men and 22.6% for women) had metabolic syndrome, whereas almost half (48.3%; 41.0% for men and 60.5% for women) of those with liver steatosis had metabolic syndrome. In addition, the prevalence of metabolic syndrome and of each of the five metabolic abnormalities progressively increased with the severity of liver steatosis (Table 2).

In the age-adjusted logistic regression model, the participant group with liver steatosis had a significantly higher odds ratio of having metabolic syndrome than did the group without steatosis. The odds ratio also increased with increasing severity of liver steatosis. When we adjusted for age, menopause, body mass index, cigarette smoking and alcohol intake, the association between liver steatosis and metabolic syndrome was attenuated but still was highly significant (Table 3). To assess the possible confounding effects of alcoholic hepatitis, we examined the association between liver steatosis and metabolic syndrome by frequency of alcohol intake and found similar results regardless of the frequency of alcohol consumption (data not shown).

The possible associations of serum levels of AST, ALT, and γ-GT with metabolic syndrome were also examined. The serum AST level was not significantly associated with metabolic syndrome in either sex. Serum ALT and γ-GT levels were significantly associated with metabolic syndrome in men but not in women (Table 4).

DISCUSSION

Metabolic syndrome is very common in Western countries and is also increasingly frequent in most developing countries. Fatty liver is a common condition increasingly detected by

HDL: high density lipoprotein. [1]Including subjects taking anti-hypertensive medication. [2]Including subjects taking anti-diabetic medication.

routine abdominal ultrasonographic examination; however, the spectrum of fatty liver varies from mild NAFLD to progressive non-alcoholic steatohepatitis (NASH). NAFLD is a benign fatty liver disease, which accounts for the majority of elevated aminotransferase levels in asymptomatic patients[24]. In contrast, NASH is a more progressive form of fatty liver disease that can progress to liver fibrosis and even cirrhosis[1,14,25]. It has been suggested that fatty liver develops as the result of various metabolic conditions that promote fat accumulation and inflammation in the liver[10-14].

Liver biopsy is the only diagnostic test that is able to differentiate benign NAFLD from progressive NASH, but

AST: aspartate aminotransferase; ALT: alanine aminotransferase; γ-GT: γ-glutamyl transferase. [1]Adjusted for age, menopause (in women), body mass index, cigarette smoking, and alcohol intake.

it should not be performed on the majority of patients with asymptomatic or mild fatty liver disease. Thus, the clinical evaluation of the severity of fatty liver disease in people with metabolic syndrome is usually based on a combination of ultrasonographic findings and laboratory tests. Liver ultrasonography is frequently used to assess fatty infiltration of the liver, but there is little information on the association between the metabolic diseases and the severity of fatty liver detected by ultrasonography. One previous study reported an association between common metabolic disorders and the severity of liver steatosis assessed by routine ultrasonography in 340 patients[14]. The present study showed that various metabolic abnormalities and metabolic syndrome were positively associated with the severity of ultrasonographic liver steatosis detected in 1 022 healthy people. Our findings suggest that liver ultrasonography can be used to monitor liver dysfunction that occurs in association with common metabolic abnormalities and metabolic syndrome.

Serum aminotransferase assays have also been widely used to detect and diagnose NAFLD[2,9], which is the most common cause of unexplained aminotransferase elevations in most Western populations and in some Asian populations. Thus, we assessed the associations between metabolic syndrome and the levels of several liver enzymes. In our data, metabolic syndrome showed a significant association with ALT and γ-GT levels only in men and showed no significant association with AST levels in either sex. For purposes of comparison, we categorized the enzyme levels so that the distribution of participants in the categories was similar to the distribution of subjects by ultrasonographic severity of steatosis; however, this type of categorization would not be relevant in clinical settings. Thus, we performed further analyses using different classification schemes and obtained similar findings.

The serum AST level is a sensitive marker of liver cell damage, but it has been less frequently used than ALT and γ-GT levels to monitor liver dysfunction because it is relatively non-specific for liver disease and correlates poorly with the clinical severity of liver disease[26]. Our findings support the use of serum ALT and γ-GT levels as indicators of the development of liver steatosis in men with metabolic syndrome. Recently, Jeong and colleagues reported that serum ALT levels were positively associated with metabolic disorders in a population, even when the levels were in the

normal range[27]. The results of that study differed from ours in that, the authors found a significant association in both sexes, although the association in women was weaker than that in men.

The sex-specific differences in the associations between liver enzyme levels and metabolic syndrome were not fully explained by the data. One contributing factor may be that, compared with men, women have relatively low ALT and γ-GT levels that fall within relatively narrow ranges[28,29]. Thus, serum enzyme levels in women might show a poor correlation with liver dysfunction. Another contributing factor to the sex-specific differences might be that the underlying causes of the enzyme elevation may differ by sex. For example, if central obesity is a major cause of enzyme elevation in men but not in women, the relationship between enzyme elevation and metabolic syndrome would likely differ by sex. Sakugawa *et al*., reported that serum γ-GT was correlated with the components of metabolic syndrome and its risk factors in the univariate analysis, but four variables were independently associated with γ-GT: age, hemoglobin, triglyceride, and diabetes[30]. The sex-specific differences shown by our analysis may also be attributable to chance observation. Thus, the association between the serum enzyme levels and metabolic syndrome in women requires further investigation.

The association between fatty liver disease and metabolic syndrome may be explained by several mechanisms. Type 2 diabetes (or insulin resistance) and central obesity have been frequently reported to be associated with both benign NAFLD and progressive NASH[2,4-9]. Insulin resistance is a key component of metabolic syndrome and is also a well-known risk factor for the development of NAFLD[31-33]. However, it is still controversial whether liver disease plays a primary role in the development of hyper-insulinemia and insulin resistance or is a consequence of insulin resistance. Recent studies have added evidence supporting the interpretation that insulin resistance is the primary phenomenon, by showing that hyper-insulinemia and insulin resistance do not stem from a reduction in hepatic insulin extraction, but from an enhancement in pancreatic insulin secretion that is compensatory to reduced insulin sensitivity[12,34-36].

Fatty liver disease has been reported to be closely related to indices of central obesity, such as waist circumference, waist-to-hip ratio, and visceral fat thickness[5,35,37]. Central obesity may contribute to insulin resistance, and increased visceral adiposity might be relevant in the pathogenesis of NAFLD[35,38]. Compared with adipose tissue in other sites, visceral adipose tissue is more resistant to insulin, exhibits greater lipolysis, and produces more free fatty acids[39]. The increased availability of substrates for lipogenesis and the relative hyperinsulinemia that accompany insulin resistance promote lipogenesis in the liver[40]. Visceral adipose tissue is also known to be a potent modulator of insulin action in hepatic glucose production and gene expression[41]. However, the significance of central obesity in the association between liver steatosis and metabolic syndrome may differ by ethnicity. It is well known that Asian people have lower body mass indices and waist circumferences than do Caucasians, but they have higher percent body fat and more cardiovascular risk factors for a given level of obesity[42,43]. In further analysis, we found that the association between liver steatosis and metabolic syndrome remained after additional adjustments were made for waist circumference; the odds ratios for mild, moderate, and severe steatosis were 1.37, 2.39, and 2.72 for men (P for trend <0.001), and 2.47, 2.57, and 3.27 for women (P for trend <0.001), respectively. Moreover, we have already reported that NAFLD was associated with various metabolic abnormalities in non-obese non-diabetic subjects[15]. Further studies will be required to investigate the ethnic and regional differences in the relationship between liver steatosis and metabolic syndrome.

Our study had several strengths. First, we showed an association between the degree of severity of liver steatosis detected by ultrasonography and the occurrence of metabolic syndrome in apparently healthy subjects. The progressive association between ultrasonographic liver steatosis and common metabolic diseases had previously been observed in data collected from patients, but had not yet been studied in the general population. Second, we were able to diminish the sources of inter-observer measurement error, for the liver ultrasonography in particular, because all of the measurements were performed by the same examiner in the same regulated setting, over a relatively short period (3 mo). Third, we were able to assess the association between metabolic syndrome and serum liver enzyme levels. Our data suggest that liver ultrasonography may be a better diagnostic tool than the determination of serum enzyme levels for monitoring liver function in people with metabolic syndrome.

We should point out some of the limitations of the present study. First, we could not assess the temporal relationship between fatty liver disease and metabolic syndrome because the study had a cross-sectional design. Although there is increasing evidence indicating that NAFLD is a hepatic consequence of metabolic syndrome[2,12,34,35], further prospective studies should be conducted to examine the temporal relationship between aminotransferase levels and metabolic syndrome in the general population. Second, we could not take into consideration any variation in the metabolic profile over time because we obtained only one measurement in each participant. Third, it is possible that we did not control entirely for confounding effects caused by viral and alcoholic liver diseases. We excluded subjects who were positive for HBsAg from the analyses because HBV infection is the most common liver disease in Korea, but we could not rule out the effects of other types of viral hepatitis. Alcoholic liver diseases are also common forms of chronic liver disease, but, in a further analysis, the association between liver steatosis and metabolic syndrome was not significantly affected by the level of alcohol intake. However, the possibility of residual confounding effects still exists because we measured alcohol intake with a simple questionnaire and did not use any objective index for alcohol intake. Finally, the study participants were apparently healthy members of the general population, but they were recruited from within a health screening center. Therefore, our study population was not necessarily representative of the general Korean population.

In conclusion, the present study showed a strong positive

association between the severity of ultrasonographic liver steatosis and the prevalence of metabolic syndrome in 1 022 apparently healthy Koreans. Our findings indicate that the degree of fatty infiltration detected on ultrasonography can be used as an indicator of liver dysfunction attributable to metabolic abnormalities. In addition, ultrasonography may be a better diagnostic tool than serum enzyme assays for monitoring liver function in people with metabolic syndrome.

Abstract

AIM: To examine the expression of E-cadherin, β-catenin, γ-catenin, VEGF, and p53 in 39 patients with hepatic metastasis from colorectal cancer immunohistochemically.

METHODS: The patients were divided into two groups: those (n = 16) who had no chemotherapy for at least 6 mo before the liver resections and those (n = 23) who were treated with chemotherapy before liver resections. A score from 0 to 3 was given for the number of positive cells and from 0 to 3 for the intensity of staining in these cells, in both healthy and metastatic liver parenchyma.

RESULTS: No significant differences in the expression of E-cadherin, β- and γ-catenin, VEGF and p53, could be observed between patients who received and did not receive chemotherapy, in both normal and metastatic liver parenchyma.

CONCLUSION: Despite the assumption that chemotherapy had an effect on liver metastasis, no influences were noticed immunohistochemically.

INTRODUCTION

Colorectal cancer is one of the most common solid tumors and is the second leading cause of cancer deaths in Western countries. Approximately half of all patients develop metastatic disease[1]. Lymph node or hematogenic metastasis (liver or lung metastasis) are thought to be most significant prognostic factors for patients with colorectal cancer.

Until recently, 5-fluorouracil (5-FU) and leucovorin (LV) were the standard of care, however without major impact on survival. Two new drugs, irinotecan and oxaliplatin have demonstrated survival improvement, when given either alone or in combination with 5-FU+LV, in first- or second-line therapy. Recently, Tournigand *et al*., described that FOLFIRI (irinotecan and 5-FU/LV) followed by FOLFOX6 (oxaliplatin and 5-FU/LV) or the reverse in advanced colorectal cancer achieved a prolonged survival with a median of 24 mo and similar efficacy[2].

The metastatic cascade of colorectal cancer starts with the infiltration of neoplastic cells through the basement membrane, which enables tumor cells to leave epithelial structures, to invade the surrounding stroma, to enter either blood or lymphatic vessels and create a metastasis in the appropriate target organs.

The cadherin-mediated cell-cell adhesion system plays a critical role in cancer invasion and metastasis[3,4]. Cadherins are calcium-dependent transmembrane adhesion molecules that connect cells homotypically. The cytoplasmic domain of E-cadherin interacts with intracellular proteins called α-, β- and γ-catenins, which are the major elements in the intracytoplasmic microfilament network[4,5]. Both β- and γ-catenin bind directly to E-cadherin; Alpha or-catenin links the bound β- or γ-catenin to the actin cytoskeleton, thereby forming complexes of either E-cadherin/β-catenin/α-catenin or E-cadherin/γ-catenin/α-catenin[5]. Loss of expression of E-cadherin and catenins is found to be associated with de-differentiation, invasion, and metastasis, and is, therefore, suggested as a potential prognostic factor in colorectal carcinoma[6,7]. β-catenin, apart from linking with E-cadherin, forms complexes with the tumor-suppressor protein - aden-omatous polyposis coli (APC) gene products, which are independent from the cadherin/catenin[8-10]. The APC gene is often mutated in colorectal cancer tissue. *In vitro* and *in vivo* data suggest a pivotal role of cadherins and catenins in various aspects of tumor progression.

Angiogenesis is required for tumor growth and metastasis of human solid tumors. This process is driven by a balance of stimulatory and inhibitory influences[11]. The potent angiogenic factor - vascular endothelial growth factor (VEGF)

is associated with metastasis in human colon cancer[12]. An association exists between VEGF expression, angiogenesis, and metastasis in colon cancer. Warren *et al*., demonstrated that antibodies to VEGF inhibit metastasis in a murine model of human colon cancer[13].

On the other hand, tumor progression is known to occur through the sequential deregulation of rearrangement of proto-oncogenes together with the inactivation of tumor suppressor genes[14]. *In vitro* studies demonstrated the important role of p53 tumor suppressor gene in controlling tumor angiogenesis[15,16].

Direct effect of treatment on the liver consisting of hepatocyte steatosis is a common response to liver injury and is characterized by macro- and microvesicular fatty infiltration of hepatocytes[17]. These fatty changes may be accompanied by hepatocyte ballooning, an inflammatory infiltrate, fibrosis and even cirrhosis[18,19].

Limited data are available about the effect of chemotherapy on healthy and malign liver parenchyma. One study described a small necrotic focus of hepatocytes on normal liver of Wistar rats who were treated with 5-FU[20]. Therefore, in the present study we analyzed by immunohistochemistry the expression of E-cadherin, β- and γ-catenin, VEGF and p53 in normal and metastatic liver parenchyma of colorectal cancer patients. The percentage of macro- and microvesicular steatosis was also analyzed. The patients were divided into two groups: those who received chemotherapy and those who did not.

MATERIALS AND METHODS

Patients

Paraffin-embedded tumor specimens from 39 patients with liver metastasis of colorectal carcinoma who had undergone surgery were retrieved from the archival material of the Department of Pathology of the Ghent University Hospital. The characteristics of primary tumors are listed in Table 1. The mean age of patients at the time of liver metastasis diagnosis was 60±12 years (range 28-81 years). The study population consisted of 27 males and 12 females. Sixteen patients received no chemotherapy for at least 6 mo before the liver resections. Twenty-three patients received chemotherapy for at least 6 mo before the liver resections (Table 2). The study was approved by the Ethical Committee of the Ghent University Hospital.

5-FU: 5-fluorouracil, LV: leucovorin.

Immunohistochemical staining

Monoclonal anti-E-cadherin, anti-β-catenin, and anti-γ-catenin antibodies (clones 36, 14, and 15, respectively) were obtained from BD Biosciences (San Diego, CA,USA). Monoclonal anti-VEGF antibody (C-1) was purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA,USA). Monoclonal anti-p53 antibody was obtained from Biogenex (San Ramon, CA, USA). Immunohistochemical staining was based on the labeled streptavidin-biotin method and carried out using a DAKO LSAB® +Kit (DAKO Corporation, Carpinteria, CA,USA). Tissue sections (5 μm) were deparaffinized with xylene and dehydrated in graded ethanol. For unmasking the antigens, the slides were heated in a microwave oven in citrate buffer (0.01 mol/L, pH 6) (except for anti-VEGF staining). Endogenous peroxidase activity was quenched by incubating in 0.3% hydrogen peroxidase for 20 min. Slides were then incubated with appropriately diluted antibodies for 30 min (anti-γ-antibody) and 1 h (for the other molecules). Immunostaining was visualized using diaminobenzidine tetrahydrochloride solution (for p53) or 3-amino-9-ethylcarbazole (for the other molecules); both products were obtained from DAKO. The sections were counterstained with hematoxylin. Isotype-specific irrelevant antibodies were used to control nonspecific binding of the primary antibodies.

Histology of liver parenchyma

Histology of the liver parenchyma was reviewed for the presence of macro- and microvesicular steatosis. The extent of steatosis was determined as the percentage of hepatocytes involved, in the range of 10%.

Evaluation and analysis

Sections were examined by light microscopy and the same scoring system was used for the hepatocytes and the metastatic cells. A score from 0 to 3 was given for the number of positive cells and from 0 to 3 for the intensity of staining in these cells. The sum of both scores, with a maximum of 6, was made[21]. The differences in the numerical data between the two groups (chemotherapy or no chemotherapy) were evaluated using the Mann-Whitney *U* test. Values are expressed as median and range. *P* values of less than 0.05 were considered statistically significant.

RESULTS

Expression of the adhesion molecules in normal and metastatic liver parenchyma

Table 3 summarizes the expression of E-cadherin, β- and

γ-catenin in normal and metastatic liver parenchyma. One patient was not evaluated in the metastatic liver parenchyma due to the low number of metastatic cells. E-cadherin was expressed in 100% in normal and in 97% of the cases in metastatic liver parenchyma (Figure 1). β-catenin was expressed in 90% of the cases in normal and in 95% of the cases in metastatic liver parenchyma. γ-catenin was expressed in 46% of the cases in normal and in 66% of the cases in metastatic liver parenchyma. VEGF was expressed in 100% in normal and in 84% of the cases in the metastatic liver parenchyma (Figure 2). No staining for p53 was found in normal liver parenchyma, and p53 staining was found in 66% of the tumors (Figure 3).

Table 3 Positive staining of the adhesion molecules in normal and metastatic liver parenchyma

	Normal (%)	Metastatic (%)
E-cadherin	39/39 (100)	37/38 (97.37)
β-catenin	35/39 (89.74)	36/38 (94.74)
γ-catenin	18/39 (46.15)	25/38 (65.79)
VEGF	39/39 (100)	32/38 (84.21)
p53	0/39 (0)	25/38 (65.79)

Effect of chemotherapy on the expression of adhesion molecules and macro- and microvesicular steatosis

The patients were divided into two groups: those who received no chemotherapy (n = 16) and those who received chemotherapy (n = 23) for at least 6 mo before the liver resection. Both in normal and in metastatic liver parenchyma, no significant differences in the expression of adhesion molecules could be observed between the patients who received and who did not receive chemotherapy (Table 4).

Also, no significant differences were observed in macro- and microvesicular steatosis between patients receiving chemotherapy and no chemotherapy (Table 5).

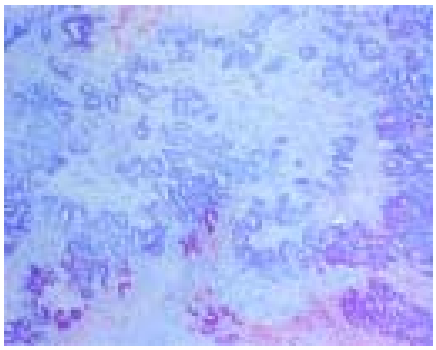

Figure 2 VEGF expression in a liver metastasis. Magnification x40.

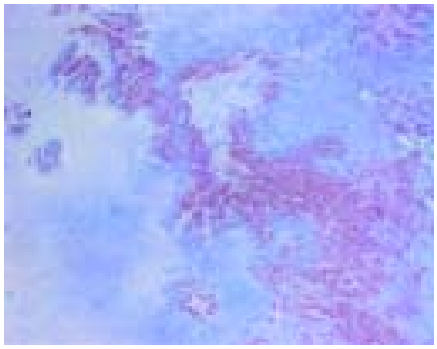

Figure 3 p53 expression in a liver metastasis. Magnification x40.

Table 5 Percentage of macro- and microvesicular steatosis (median and range)

	Chemotherapy (n = 23, %)	No chemotherapy (n = 16, %)
Macrovesicular	10 (0-40)	10 (0-30)
Microvesicular	0 (0-10)	0 (0-10)

DISCUSSION

Invasion and metastasis of tumor cells are the primary causes of fatal outcome of cancer. E-cadherin plays a major role in the cell-cell adhesion of normal epithelial cells. The reduced expression of E-cadherin has been correlated with de-differentiation, tumor invasion, and metastasis in various cancer tissues. Several immunohistochemical studies describe a reduced expression of the E-cadherin/α-catenin in primary

Table 4 Expression of the adhesion molecules in normal and metastatic liver parenchyma (median and range)

	Normal		Metastatic	
	Chemotherapy (n = 23)	No chemotherapy (n = 16)	Chemotherapy (n = 23)	No chemotherapy (n = 16)
E-cadherin	3 (2-4)	3 (2-6)	3 (0-6)	4 (2-6)
β-catenin	3 (0-5)	3 (0-5)	6 (0-6)	5 (0-6)
γ-catenin	0 (0-3)	1 (0-2)	2 (0-4)	2 (0-4)
VEGF	5 (3-5)	5 (3-5)	4 (0-5)	3 (0-4)
p53	0 (0-0)	0 (0-0)	3 (0-6)	2.5 (0-6)

colorectal carcinomas[6,7,22,23]. In contrast, the marked reduction in E-cadherin and α-catenin, β- and γ-catenin were seldom reduced[7]. Hugh *et al*., described that α-catenin expression was reduced or lost more frequently than either E-cadherin or β-catenin on 60 colorectal cancer specimens[24].

Little information is available about the expression of E-cadherin/catenin complex in colorectal cancer liver metastases. Ghadimi *et al*., found a reduced E-cadherin and α-catenin expression in 48% and 36% of the cases, respectively[7]. The expression of β- and γ-catenin was preserved in colorectal liver metastases in more than 85% and 96% of the cases, respectively. Gofuku *et al*., described a reduced expression of E-cadherin/α-catenin in metastatic liver tumors[6]. In contrast, Ikeguchi *et al*., described an increased expression of E-cadherin, α- and β-catenin in metastatic liver tumors[23].

In the present study, we analyzed by immunohistochemistry the expression of E-cadherin, β- and γ-catenin in normal and metastatic liver parenchyma of colorectal cancer patients. The expression of E-cadherin and β-catenin was preserved in 97% and 95% of the cases in metastatic liver parenchyma, respectively. γ-catenin expression was reduced in 34% of the cases. Re-expression of E-cadherin, α-catenin and β-catenin, but not of γ-catenin was found in metastatic tissue from breast cancer patients[25]. Mayer *et al*., reported that E-cadherin expression in the metastatic liver tumors was stronger than in the primary tumors in many cases of gastric cancer[26]. Another study in advanced gastric cancer showed a re-expression of the cadherin/catenin complex in lymph nodes with metastasis[27]. The mechanism behind this re-expression remains unclear. Mareel *et al*. showed that tumor cells re-express E-cadherin at the metastatic site[28]. Whether the same mechanism is true for catenins is not known. Re-expression of these adhesion molecules by tumor cells after release from the primary site may be important and perhaps necessary for tumor cells to adhere in remote organs.

Over the past decade, numerous studies have demonstrated that the neo-vascularity of tumors correlates with aggressiveness and metastatic potential[29-31]. VEGF is one of the critical factors in determining the angiogenic phenotype in a majority of human colon cancers. The overexpression of VEGF is correlated with liver metastasis and poor prognosis in colorectal cancer patients[32,33]. The most common genetic alteration in colorectal cancer is reported to be the loss of p53 tumor suppressor gene function[14]. Protein p53 has various important functions in cellular aggregation, including cell growth control, response to DNA damage, regulation of transcription and control of genetic stability.

In the present study we analyzed by immunohistochemistry the expression of VEGF and p53 in normal and metastatic liver parenchyma of colorectal cancer patients. The expression of VEGF and p53 was seen in 84% and 66% of the cases in metastatic liver parenchyma, respectively. VEGF and p53 expression status coincided in 19 of 39 tumors (48%). Kang *et al*., described that the incidence of liver metastasis was very high, 52% in patients whose primary colorectal tumors were both p53 and VEGF positive[34].

No data are available in the literature about the effect of chemotherapy on the expression of adhesion molecules. In the present study, 23 patients received chemotherapy for at least 6 mo before the liver resection. No significant differences in the expression of E-cadherin, β-, γ-catenin, VEGF and p53 could be observed between patients receiving and patients receiving no chemotherapy before the liver resection. We could not make a distinction in type of chemotherapy due to small groups of patients. Further investigation is necessary with greater number of patients in each type of chemotherapy.

Despite the assumption that chemotherapy had an effect on the liver metastasis, no significant differences were observed immunohistochemically on the expression of E-cadherin/catenin complex, VEGF and p53.

Abstract

AIM: To investigate whether American ginseng (AG, *Panax quinquefolium*) supplementation was able to improve endurance exercise performance.

METHODS: Thirteen physically active male college students were divided into two groups (AG or placebo) and received supplementation for 4 wk, before the exhaustive running exercise. Treadmill speed was increased to a pace equivalent to 80% VO_{2max} of the subject. A 4-wk washout period followed before the subjects crossed over and received the alternate supplement for the next 4 wk. They then completed a second exhaustive running exercise. The physiological variables that were examined included time to exhaustion and oxygen pulse. Moreover, the plasma creatine kinase (CK) and lactate were measured prior to the exercise, at 15 and 30 min during exercise, immediately after exercise, and 20, 40, 60, and 120 min after exercise.

RESULTS: The major finding of this investigation was that the production plasma CK during the exercise significantly decreased for group AG than for group P. Secondary physiological finding was that 80% VO_{2max} running was not improved over a 4-wk AG supplementation regimen.

CONCLUSION: Supplementation with AG for 4 wk prior to an exhaustive aerobic treadmill running reduced the leakage of CK during exercise, but did not enhance aerobic work capacity. The reduction of plasma CK may be due to the fact that AG is effective for the decrease of skeletal muscle cell membrane damage, induced by exercise during the high-intensity treadmill run.

INTRODUCTION

Traditional Chinese medicine plays a key role in the formation of integrative medicine[1]. Ginseng (*Genus Panax*) root has been a popular Chinese medicine with the belief of restoring *Qi* or life energy. It is also thought to be a tonic to stimulate appetite, counteract fatigue, boost the immune system, relieve pain and headaches, and improve mental function and physical stamina[2]. The mechanism of action of ginseng is not known, but it is thought to have effects on production of corticotropin and cortisol, immunomodulation, antioxidants and neuroendocrine activity, modulate carbohydrate and lipid metabolism, and stimulation of nitric oxidation production in cardiovascular system[3-6].

Adequate dietary supplements or nutritional ergogenic aids are an important means to optimize exercise performance and to ward off fatigue. Ergogenic aids are believed to increase performance by some of the following mechanisms: renewing or increasing energy stores in the body, facilitating the biochemical reactions that yield energy, reducing or neutralizing performance-inhibiting metabolic byproducts, and facilitating recovery[7,8]. Performance in aerobic-type events depends on the ability to maintain a high output per unit of time. There is a growing inclination among athletes to use herbs to improve endurance performance or increase recovery after exercise.

The most studied herb for human aerobic physical performance is ginseng. Although the mechanism underlying the alleged ergogenicity of ginseng on physical performance has not been defined, theories include stimulation of the hypothalamic-pituitary-adrenal cortex axis and increased resistance to the stress of exercise, enhanced myocardial metabolism, increased hemoglobin levels, vasodilatation, increased oxygen extraction by muscles, and improved mitochondrial metabolism in the muscle, all of which theoretically

could enhance aerobic exercise performance[9-13].

In the review studies of Bahrke and Morgan, administration of ginseng or its components enhanced exercise endurance by altering fuel homeostasis during exercise, increased free fatty acid utilization in preference over glucose for cellular energy demands in rats and mice[14,15]. However, the evidence for ginseng as an endurance aerobic exercise ergogenic supplementation in men is variable. As ginseng is touted as a dietary ergogenic aid, incomplete study on performance has yielded little proof to reinforce performance affirmations.

A number of chemically similar steroid glycosides or saponin chemicals, known as ginsenosides, have been identified as active ingredients in ginseng. The original medicinal species of ginseng is Chinese or Korean ginseng (Panax ginseng C.A. Meyer). American ginseng (*Panax quinquefolius*) contains many of the same compounds, although in slightly different proportions. It is the North American variety of ginseng, which grows in eastern and central USA and Canada.

There is relatively little research that shows a performance benefit of American ginseng (AG) in human beings. The purpose of the present study was to determine, whether 4 wk of oral supplementation with AG had any benefit on endurance exercise and/or recovery after exercise.

MATERIALS AND METHODS

Subjects and anthropometric measurements

Thirteen male volunteers completed this randomized, double blind, crossover experimental research study with a washout period of 4 wk. Both body height and body weight were measured by an auto-anthropometer, Nakamura KN-3000 (Nakamura, Tokyo, Japan). Body weight was measured to the nearest 0.1 kg with subjects not wearing shoes or outerwear. Body weight was recorded to the nearest 0.1 cm. Age, weight, and heights (mean±SD) were 23.0±1.6 years, 70.2±6.3 kg, and 172.5±5.2 cm, respectively. A medical examination was performed on each subject before entering the study. Written voluntary consent to participate was obtained from all subjects after informing them of the purpose of the experiment, the procedure, and the possible risks. This investigation received the approval of the National College of Physical Education and Sports (Taoyuan, Taiwan). All subjects were healthy, physically active, college students with normal dietary habits.

American ginseng supplementation

Each subject was instructed to ingest either 4 AG capsules (400 mg AG per capsule) daily or a hydroxymethylcellulose placebo in the same capsule form (both provided by Taiwan Biotech Co., Taiwan), and received his allotment of CS or placebo in 4 weekly portions.

The Panax-bearing ginsenosides content was determined from its degree of concentration in a hot water extract. The compositions of the AG that we used were, ginsenosides Rb1 (8.67%, w/w), Rc (0.99%, w/w), Rd (1.05%, w/w), and Re (5.08%, w/w). At an initial meeting, 4 wk prior to commencing any supplementation, subjects were asked to cease taking any dietary supplementations that contained ginsenosides and were instructed to maintain a consistent diet before and during the experimental period.

Procedures

VO_{2max} was determined in the pre-experimental period. Each subject came to the laboratory 7 d before the start of the actual study, and performed an incremental running test on a motor-driven treadmill (Quinton Instruments, Model 1 860, Washington, USA) according to the Bruce protocol until exhaustion. In order to determine the baseline endurance performance time, maximum oxygen consumption (VO_{2max}) was determined by the automated system (Model 29C, SensorMedics, Yorba Linda, CA,USA). The VO_{2max} was defined as the attainment of at least two of the three following criteria: (1) an increase of ≤140 mL VO_{2max} with an increasing workload; (2) heart rate within 10 beats of age-predicted maximum; and (3) rating of perceived exertion (RPE) greater than 17 using the Borg scale. Heart rate (HR) measured by the Sport Tester (PE 3 000, Polar Electro, Kempele, Finland) were monitored during the treadmill exercise. The RPE was recorded by using the modified Borg scale[16]. Endurance performance time was also recorded at the end of the test for each subject. On the day of the experiment, subjects reported to the laboratory at 7-9 a.m. following a 10-12 h overnight fast, and abstained from rigorous exercise for 48 h prior to the test. An antecubital vein connected to a three-way stopcock with a 10-cm extension tube for blood sampling was inserted in the subjects. The cannula was kept patent by periodic flushing with a sodium chloride solution (9 g/L) and remained in place throughout the experimental period. No heparin was used in the catheter.

Protocol

Baseline physiological data was collected, while subjects stood quietly on the treadmill (Quinton Instruments, Model 1 860, Washington, USA) for 3 min prior to commencing the running test. Subjects then commenced a 5 min warm-up at a running speed equivalent to 60% VO_{2max}, the treadmill speed was increased to a pace equivalent to 80% VO_{2max} of the subjects. The subjects ran until volitional fatigue. Volitional fatigue was defined as the point at which subjects could no longer maintain the required running speed. VO_{2max} and HR were monitored throughout the exercise and were recorded, and oxygen pulse was calculated from oxygen consumption and heart rate. In addition, oxygen pulse (mLO_2/beat) was calculated by dividing oxygen consumption (mLO_2/min) by heart rate (beat/min).

Blood sampling and analysis

Blood samples were taken prior to the exercise, at 15 and 30 min during exercise, immediately after exercise, and 20, 40, 60, and 120 min after exercise. At each sampling time, about 5 mL of venous blood was taken. Whole blood for determination of hematocrit and hemoglobin was collected in EDTA tubes cooled at -4 ℃ and examined within 4 h after venepuncture to correct relative changes in plasma volume by using hematocrit and hemoglobin values from each test, according to the methods described by Dill and Costill[17]. The other venous blood was to obtain EDTA-plasma and stored at -20 ℃ for later analysis. The plasma

creatine kinase (CK) and plasma lactate were measured by a spectrophotometer technique (Johnson & Johnson DT-60II, Orthoclinical Diagnostics, Rochester, NY,USA) by means of ultraviolet test kits (Orthoclinical Diagnostics, Rochester, NY,USA).

Statistical analyses

SPSS 11.0 for Windows statistical program was used to perform all analyses. The independent variables between the two supplements (AG *vs* placebo), including an endurance run time to exhaustion and VO_{2max} after supplements were compared using Student's *t*-test for paired data. Differences in oxygen pulse and plasma CK, and plasma lactate values between the two treatment levels were analyzed by factorial (two-way, time×treatment) ANOVA with repeated measures. A Tukey's *post hoc* test was used to locate any significant difference. Significance was accepted at the $P<0.05$ level. All data are presented as mean±SD.

RESULTS

Basic physical characteristics

There was no difference between groups in VO_{2max} and the run time to exhaustion (Table 1).

Table 1 Maximal oxygen consumption and run time to exhaustion[1,2]

Group	VO_{2max} (mL / min / kg)	Time to exhaustion (s)
AG	44.6±3.1	2 279.5±252.7
P	45.1±5.0	2 218.3±345.9

[1]AG: American ginseng supplement; P: placebo supplement. [2]Values are expressed as mean±SD (n = 13).

Oxygen pulse

Data of oxygen consumption were collected in the time period of 0-1, 14-15, and 29-30 min. The oxygen pulse had no significant difference between groups during these periods (Figure 1).

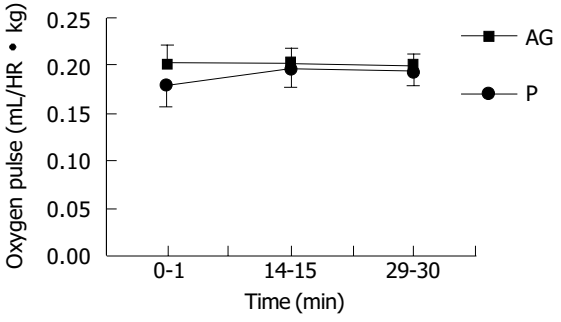

Figure 1 Oxygen pulse during exercise phase in group AG (—■—) and group P (—●—). Each point represents the mean±SD (n = 13).

Blood chemistry

In both placebo and AG groups, plasma CK and plasma lactate were significantly increased with the duration of exercise and reached a peak at exhaustive time (Figures 2 and 3). Blood lactate concentration at 15, 30 min of exercise, and 120 min after exercise in AG group (9.3±2.1, 11.4±2.7, and 2.2±0.4 mmol/L) were significantly lower than in the placebo group (10.6±2.4, 13.3±2.7, and 2.6±0.4 mmol/L), respectively (Figure 3). Moreover, plasma CK activity at 30 min of exercise, immediately, 20, 60, and 120 min after exercise in the AG group (181.2±78.0, 217.5±64.0, 167.5±56.2, 155.3±57.8, and 167.7±61.5 U/L) were significantly lower than in the placebo group (254.3±81.6, 280.2±90.0, 246.5±66.3, 227.8±58.4, and 231.9±67.8 U/L), respectively (Figure 2).

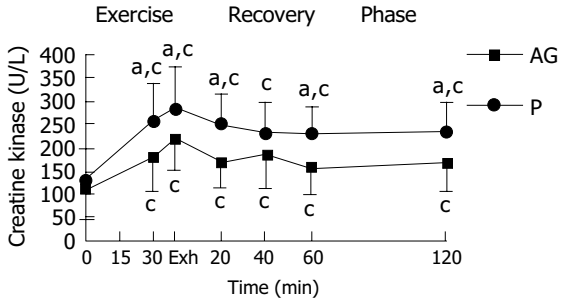

Figure 2 Plasma CK levels observed during exercise and recovery phases in group AG (—■—) and group P (—●—). Each point represents the mean±SD (n = 13). [a]$P<0.05$ *vs* P groups; [c]$P<0.05$ *vs* before exercise.

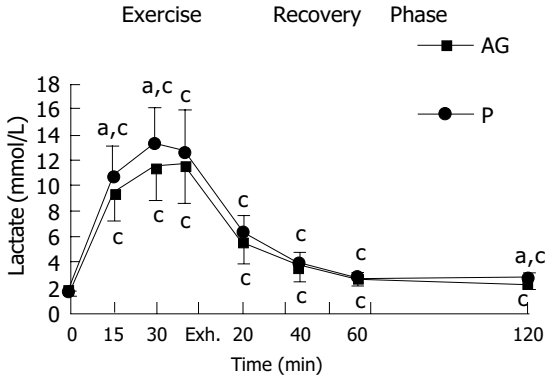

Figure 3 Plasma lactate levels observed during exercise and recovery phases in group AG (—■—) and group P (—●—). Each point represents the mean±SD (n = 13). [a]$P<0.05$ *vs* P groups; [c]$P<0.05$ *vs* before exercise.

DISCUSSION

The research was designed to determine whether or not supplementation with AG for 4 wk prior to 80% VO_{2max} run would increase the time to exhaustion and/or have any ergogenic benefit in healthy male college students. The variables that were examined included time to exhaustion, oxygen pulse, plasma CK, and plasma lactate. To our knowledge, this is the first study of AG in human clinical trials to determine endurance aerobic physical performance. The major finding of this investigation was that the production of plasma CK during exercise significantly decreased for

group AG over group P ($P<0.05$). Secondary physiological findings suggested that 80% VO_{2max} running was not improved over a 4-wk AG supplementation regimen.

The CK marker is used to determine muscle damage. The amount of plasma CK of healthy adults at rest is approximately 40-200 U/L for men[18]. In this study, the plasma CK concentrations before exercise are within the normal range in both groups and have no significant difference between groups (AG group, 108.1±62.4; P group, 138.6±94.6, respectively).

Although most studies indicate that muscle injury is assessed through prolonged endurance exercise, it is obvious that it can be caused during high intensity short-term exercise as well[19,20]. During running exercise, the extensor muscles of the lower limb performed eccentric actions as the foot touches the ground and the dorsiflexors of the ankle contract eccentrically. In eccentric exercise, the contracting muscle is forcibly lengthened as it develops tension, potentially causing damage. Therefore, endurance exercise, such as an exhaustive running exercise can induce damage and pathological alteration in skeletal muscle.

With high-intensity exercise, the high-force contractions cause muscle cell injury early in the exercise period[20]. Mechanical rupture of muscle fiber is one of the major mechanisms to explain how the muscle injury was induced by exercise. This stress on the cross bridges of the myofiber causes disruption of the muscle fibrils leading to Z-line in disintegration or Z-line streaming[21]. Moreover, strenuous exercise can also disrupt the sarcolemma and sarcoplasmic reticulum[22]. Mair *et al*., demonstrated a transient rise in the serum concentrations of muscle proteins such as CK, an indicator of muscle damage due to sarcolemma disruption, which cause a leakage of CK into the blood[23].

In this study, the total CK activity significantly increased in both groups during exhaustive running exercise. We assign this to plasma CK increasing in both groups of the subjects due to exercise-induced skeletal muscle damage. The increases in plasma CK in this study indicate that muscle damage had occurred during the exhaustive running in both groups.

Intense exercise may increase the production of free radicals or reactive oxygen species. A free radical prefers to steal electrons from the lipid membrane of a cell, initiating a free radical attack on the cell known as lipid peroxidation. Kanter *et al*., have demonstrated that post-exercise plasma CK elevations may be related to an exercise-induced lipid peroxidation[24]. The American ginseng *Panax quinquefolium* exhibits effective antioxidant, free radical scavenging activity, and inhibiting lipid peroxidation[25-29].

Lactate is an important indicator of muscle performance under stress. Lactate levels rise as intensity increases during exercise. The lower blood lactate concentration during running exercise presumably reflects a lower intramuscular lactate concentration and an increased relative contribution of anaerobic metabolism to ATP production. In this study, the AG group exhibited lower plasma levels of lactate at 15, 30 min of exercise than that in the placebo group. It seems unlikely to be due to amelioration of oxygen extraction from the blood by the working muscles as a consequence of AG supplementation, since VO_{2max} and oxygen pulse was unaffected by prior supplementation. Decreased blood lactate accumulation is not necessarily a result of muscle tissue anti-hypoxia. Factors other than an increased cellular PO_2, a decrease in intracellular calcium concentration, decreased activation of glycogen phosphorylase, or decreased intracellular pH can also cause a decrease in intramuscular lactate production[30]. Otherwise, the rate of efflux of lactate from the contractile muscle could be decreased due to the decreased muscle cell membrane permeability after exercise-induced damage[31].

In conclusion, a 4-wk AG supplementation reduced the leakage of CK from skeletal sarcoplasm into blood streaming during an exhaustive treadmill run, but did not enhance aerobic work capacity. The reduction of plasma CK level may be due to AG that is effective for the decrease of skeletal muscle cell membrane damage induced by exercise during the high intensity treadmill run. In the future, we will investigate if the reduction in CK efflux is simply an indication of increased sarcolemma stability or whether the muscles are in fact receiving less damage.

ACKNOWLEDGMENTS

We wish to extend our deep appreciation to all participating subjects for their dedication to this study.

Abstract

AIM: To report the comprehensive diagnosis and treatment of acute rejection in the first case of living-related small bowel transplantation with a long-term survival in China.

METHODS: A 18-year-old boy with short gut syndrome underwent living-related small bowel transplantation, with the graft taken from his father (44-year old). A segment of 150-cm distal small bowel was resected from the donor. The ileo-colic artery and vein from the donor were anastomosed to the infrarenal aorta and vena cava of the recipient respectively. The intestinal continuity was restored with an end-to-end anastomosis between the recipient jejunum and donor ileum, and the distal end was fistulized. FK506, MMF and prednisone were initially used for post-transplant immunosuppression. Endoscopic observation and mucosal biopsies of the graft were carried out through the terminal ileum enterostomy; serum was collected to detect the levels of IL-2R, IL-4, IL-6 and IL-8. The change of the graft secretion and absorption was observed.

RESULTS: Acute rejection was diagnosed promptly and cured. The patient was in good health, 5 years after living-related small bowel transplantation.

CONCLUSION: The correct diagnosis and treatment of acute rejection are the key to the long-term survival after living-related small bowel transplantation.

INTRODUCTION

The first patient after small bowel transplantation in China has survived for more than 5 years. The prompt diagnosis and treatment of acute rejection following transplantation are essential for a successful transplantation and long survival. However, there is no conventional standard for acute rejection diagnosis following small bowel transplantation. The present paper describes its comprehensive diagnosis post-transplantation and control.

MATERIALS AND METHODS

Clinical data

The patient, a 18-year-old man, suffered from volvulus necrosis and underwent a partial enterectomy in September 1998, the remaining jejunum was only 40 cm long. He was diagnosed as having short bowel syndrome. He was 185 cm high and weighed only 35 kg. He received intravenous feeding for a rather long period of time following transplantation. On May 20, 1999, he underwent living-related small bowel transplantation with a 150 cm long terminal ileum from his father as the donor intestine. The superior mesenteric artery from the donor was anastomosed to the infrarenal aorta and the mesenteric vein from the donor superior was anastomosed to the recipient portal vein or inferior vena cava. The arteries and veins from the donor intestine were anastomosed to the recipient's abdominal aorta and inferior vena cava in an end-to-side fashion respectively. The recipient's intestine was cut at 10 cm prior to the ileum. The proximal end of intestine from the donor was anastomosed to the proximal end of the recipient's jejunum in an end-to-end fashion. The distal end of intestine from the donor was anastomosed to the distal end of the recipient's jejunum in a side-to-end fashion. An intestinal fistula was made at 10 cm prior to graft as a viewing fenestra[1-4]. The recipient was given anticoagulant and anti-infectious treatment and total parenteral nutrition. He was treated with FK506, MMF and hydroprednisone and their combinations. On the next day following transplantation, intravenous administration of FK506 was replaced by intra-intestinal

administration. The patient recovered after transplantation. He could take fluid food 2 d after transplantation. On d 31 after transplantation, the absorption rate of xylitol was 30.6%. A month after transplantation he could feed himself, and gained weight steadily. MMF was stopped and the dosage of hydroprednisone was reduced. Discharge increased at the site of the intestinal fistula, and reached more than 1 500 mL/d, 60 d after transplantation, which suggested acute rejection. On the basis of the graft absorptive functional changes in the immunological indexes, endoscopic and pathologic examination, he was diagnosed as acute rejection and administered an impact treatment with a large dosage of immunosuppressive agents. Three days later, the symptoms were alleviated and all the indexes returned to normal gradually. Acute rejection did not occur again. One year after transplantation, the intestinal fistula was closed. At present, the patient is still alive, weighing 56-58 kg[5-8].

Endoscopic examination

Olympus GIF-XQ230 electron gastroscope was used to observe the mucous membrane with the remaining jejunum as a control. Mucous membrane from different sites was taken for pathological and microbiological examination. When we closed the intestinal fistula, we could examine the graft through the anus. However, no abnormal symptom has occurred since then.

Monitoring immunological indexes

Substrate coloration with ABTS was carried out, standard curve was drawn according to the standard, and then the serum levels of SIL-2R, IL-6, and IL-8 were determined with antagonistic sandwich ELISA kit. The serum level of IL-4 was determined with the biosource cytoscreen solid-phase sandwich ELISA kit (USA) for IL-4 detection. The above-mentioned four indexes were re-examined every 3 mo.

D-xylitol absorption test

D-xylitol absorption test was done to detect the absorptive function of the graft. The discharge at the site of the graft fistula and its changes were observed. The stool was also observed after the fistula was closed. The test was done every 3 mo.

RESULTS

Endoscopic and pathological findings

The graft membrane was present with the edema. The membrane appeared as an intensified light reflection. Yellowish white mucus was attached to the graft membrane and there were hemorrhage, erosions and round ulcers (0.3-0.6 cm in diameter) and linear ulcers (Figures 1 and 2). Under endoscope, the graft membrane was encrusted with yellowish white thin mucus. The graft wall was brittle and apt to bleed when touched, and it bled a lot when biopsy specimen was taken. The graft canal had hypanakinesia. On the other hand, these symptoms were absent in the remaining jejunum. Erosion occurred where there were lesions, some epithelial cells appeared in an atrophic short column shape, goblet cells became smaller or even disappeared. There was a general edema in lamina propria. Neutrophilic granulocytes were present at the lamina propria and tunica muscularis. Infiltration occurred in plasma cells and lymphocyte, neutrophilic granulocytes in blood vessels increased. Microbiological examination was negative and pathological examination showed that the patient's remaining jejunum was almost normal. When the intestinal fistula was closed one year later, the patient had no abnormal symptoms.

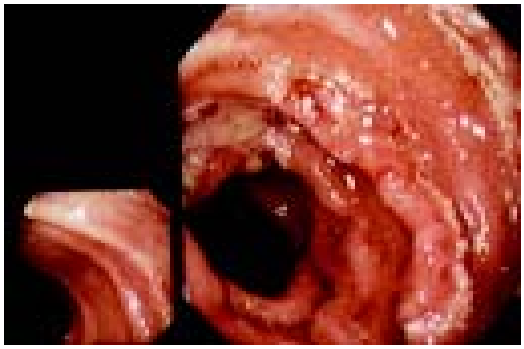

Figure 1 Mucous membrane at 70 cm of the graft fistula 67 d after transplantation.

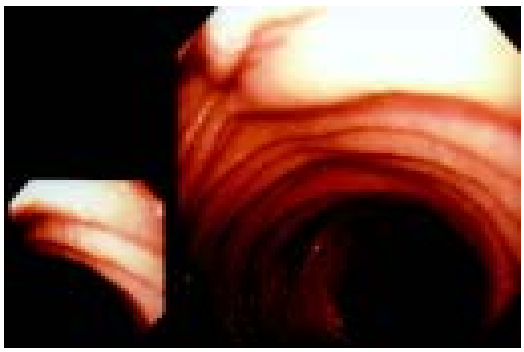

Figure 2 Normal mucous membrane of the recipient's remaining jejunum.

Absorptive function of the graft and discharge at the intestinal fistula

The absorptive function of the graft returned to normal 30 d after transplantation (the absorption rate of xylitol was 30.6%) and remained normal until the onset of rejection. Sixty-five days after transplantation, the absorption rate dropped to 24.6% and on 67th d, 19.6% increased gradually after treatment and returned to normal again 80 d after transplantation (Figure 3A). The discharge at the intestinal fistula remained normal just after transplantation. Sixty days after transplantation, the discharge began to increase and reached 1 520 mL, 61 d after transplantation. The discharge decreased after treatment and returned to normal, 80 d after transplantation (Figure 3B). Then, the absorptive function of the graft was examined every 3 mo and no change was found. After the intestinal fistula was closed, the patient's stool was solid and no loose and watery stool occurred.

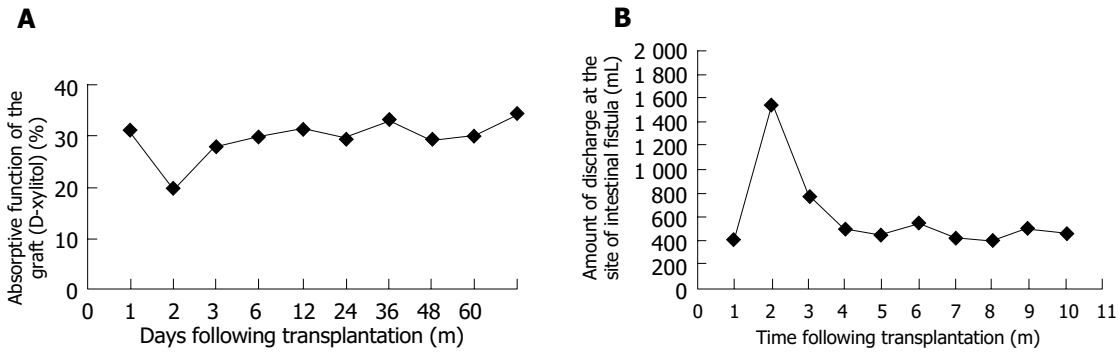

Figure 3 Changes in graft absorptive function (**A**) and discharge at the intestinal fistula (**B**).

Immunological indexes

The serum level of SIL-2R was 15.68 kU/L before transplantation, reached its first peak one day after transplantation, began to increase again 65 d after transplantation and reached its second peak 67 d after transplantation (243.98 kU/L). After treatment, its level decreased gradually and returned to normal, 80 d after transplantation (Figure 4A). The serum level of IL-8 was 0.26 μg/L before transplantation, reached its first peak one day after transplantation, began to increase again 65 d after transplantation, and reached its second peak 67 d after transplantation (1.47 μg/L). The level of IL-8 began to drop slowly when rejection was treated, and returned to the level before transplantation, 96 d after transplantation (Figure 4B). The serum level of IL-4 and IL-6 had no change before and after transplantation. Then, the four indexes were examined every 3 mo and no change was found.

DISCUSSION

Small bowel transplantation is the only therapy for end-stage intestinal diseases. However, since the small bowel is characterized by the existence of plenty of bacteria and a high immunogenicity, it is prone to rejection, which usually results in a transplantation failure. The incidence rate of acute rejection after small bowel transplantation is as high as 90% and acute rejection usually occurs 4-60 d after transplantation[9]. Prompt diagnosis and treatment of acute rejection after transplantation are crucial to a successful small bowel transplantation. However, the detecting indexes, which are instrumental in suggesting acute rejection of the graft, have not been identified yet. Based on the clinical symptoms, endoscopic and pathological findings and changes in absorptive function of the graft, acute rejection was diagnosed 67 d after transplantation. Following the control of immunological indexes and absorptive function of the graft, no significant changes were found and acute rejection did not recur.

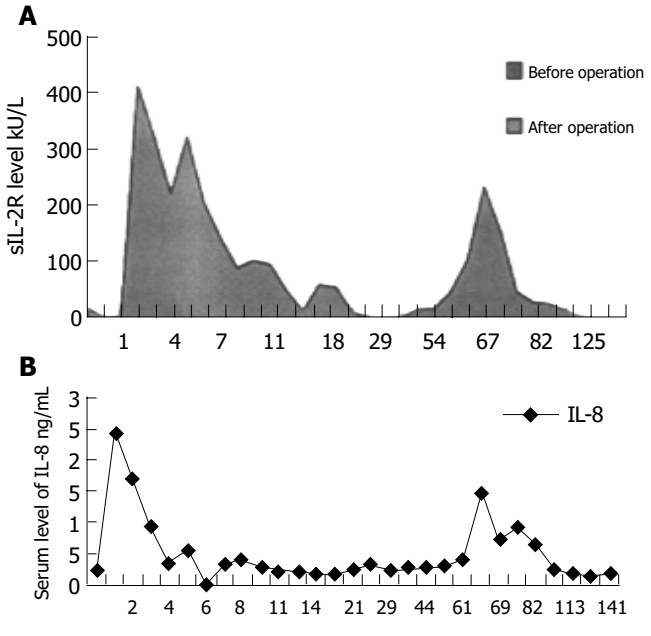

Figure 4 Serum level of sIL-2R (**A**) and IL-8 (**B**) before and after occurrence of acute rejection.

Endoscopic and pathological examinations

The first endoscopic examination was done 15 h following transplantation, once every day in the first 3 d, once every 2-3 d after 3 d, and once or twice every month after month. When there was evidence for acute rejection, endoscopic examination was performed more frequently. Since acute rejection of the graft is heterogeneous, biopsy specimens were taken at more than one site from the graft with the remaining jejunum as a control. Microbiological examination was done to exclude the risk for other intestinal pathological changes. The patient had an increased intestinal discharge and his immunological indexes were changed 2 mo after transplantation. Endoscopic examination and pathologic biopsy specimens suggested acute rejection, which accords with the findings of previous studies[9-12]. Treatment with intensive immunosuppressive drugs alleviated the symptoms. Endoscopic and pathological examinations are now essential for the control of acute rejection following transplantation[11]. When the intestinal fistula was closed one year later, no abnormal symptom was found.

Absorptive function of the graft and discharge at the intestinal fistula

The presence of congestion, edema, sporadic ulcer and necrosis on the graft at the early stage of acute rejection after transplantation, is theoretically followed by increased discharge and decreased absorptive function of the graft.

However, it has not been reported in any clinical case report. The present study showed that at the early stage of acute rejection after transplantation, increased discharge of the graft was the only clinical symptom. The absorptive rate of the graft decreased greatly and reached its lowest point when severe acute rejection occurred. After being treated with intensive immunosuppressive drugs, it returned to normal and then remained normal (30%) and no acute rejection occurred after the intestinal fistula was closed, suggesting that changes in the graft discharge and absorptive function are worth to consider in observing and identifying the presence of acute rejection of the graft.

Control of immunological indexes

The immunological indexes, which are instrumental in suggesting acute rejection of the graft, are still being studied. Rejection following homotransplantation is initiated by the T cell's recognition of the graft and antigen complex, which is compatible with the patient's own tissue with its specific T-cell antigen recognition receptor. Since the direct recognition pathway of $CD4^+$ T cells plays an essential role in the above process and in the presence of the first acute rejection[13], and $CD4^+$ T cells secrete such cell factors as IL-2, with which IL-2R can be combined and inhibit its mutual action with cells, the serum IL-2R level might be a sensitive immunological index of the presence of rejection following homotransplantations[13,14]. We detected many immunological indexes, which might be connected with rejection, and found that IL-2R increased one day after transplantation and then decreased gradually, but increased again and reached its second peak until acute rejection occurred, suggesting that there might be a close relationship between the serum level of IL-2R and the onset of acute rejection of the graft. Thus, the serum level of IL-2R can be used as an useful index for the onset of acute rejection following small bowel transplantation. When the graft rejection occurs, mononuclear leukocytes/macrophages, and T lymphocytes may be present with characteristic cellular infiltration, and these cells can secrete IL-8. It has been reported that the serum level of IL-8 increases in patients with acute rejection after transplantation of the liver or kidney and then decreases after being treated with intensive immunosuppressive drugs[15-17]. In the present study, the serum level of IL-8 reached its first peak one day after transplantation, which might be attributed to the long period of cold ischemia and lesions due to reperfusion. Since the serum level of IL-8 reached its second peak 67 d after transplantation, when acute rejection occurred no changes were observed after treatment with immunosuppressive drugs, there may be a close connection between the second peak of serum IL-8 and the onset of acute rejection. Therefore, it can be used as an important index for the diagnosis of acute rejection.

In addition, effective anti-infectious treatment and scientific nutrition arrangement may contribute to the survival rate of patients after the small bowel transplantation.

Abstract

AIM: To investigate the role of SPECT/CT in the diagnosis of hepatic hemangiomas whose anatomical positions are not ideal, situated adjacent to the heart, the inferior cava, hepatic vessels or abdominal aorta, etc.

METHODS: The hepatic perfusion, blood pool, and fusion imaging were carried out using SPECT/CT in 54 patients, who were suspected for hepatic hemangiomas. When the anatomical positions were not ideal, the diagnosis was difficult by SPECT only. So the information of computed tomography (CT) was applied to help in diagnosing. The results were recorded as hemangiomas or not.

RESULTS: Of the 54 patients, 31 patients were diagnosed as suffering from hepatic hemangiomas. The anatomical positions of eight patients' hepatic hemangiomas (25.81%) were not ideal. Among these lesions of the eight patients, three patients' hepatic lesions were located near to the abdominal aorta, one to the heart, and four to the inferior cava. In addition, six abnormal radioactivity accumulation regions, adjacent to the heart and inferior cava, with the help of CT, were confirmed to be the imaging of inferior cava other than hepatic hemangiomas.

CONCLUSION: When the anatomical positions of hepatic hemangiomas are not good enough for diagnosis, the fusion imaging of SPECT/CT is a simple and efficient method for differential diagnosis.

INTRODUCTION

The diagnosis of a number of atypical hepatic hemangiomas in cross-sectional images is also very difficult[1]. Moreover, when the tumor is present in staging or in the follow-up of oncological patients, the differentiation of hepatic hemangioma from hepatic metastatistic diseases is a common clinical question. Contrast-enhanced magnetic resonance imaging (MRI) and multiple helical computed tomography (CT) is also limited to distinguish focal hepatic lesions in some ways[2]. Contrast-enhanced ultrasonography (US) is helpful to confirm the characterization of the focal liver disease. However, the diagnosis is associated with the experience of the surgeon. As regards single-photon emission computed tomography (SPECT), when the anatomical positions of hepatic hemangiomas were not ideal, for example, close to the heart, inferior cava or main hepatic vessels, etc., it may cause some difficulty for diagnosis, because the radioactivity of the ^{99m}Tc-labeled RBC is centralized in the heart, inferior cava, abdominal aorta and main hepatic vessels, and the radioactivity of blood pool is existing from the start. Thus, it is difficult to detect hepatic hemangioma, which is close to the above-mentioned structure, especially tiny ones.

A method, SPECT/CT, which can localize the hepatic lesions accurately will be helpful to diagnose this kind of hepatic hemangioma. The imaging of ^{99m}Tc-labeled red blood cell scintigraphy through SPECT is non-invasive and highly specific, able to avoid invasive method or biopsy. Meanwhile, when the anatomical position is not ideal, close to heart, inferior cava, main hepatic vessels, abdominal aorta, upside of right kidney, the diagnosis accuracy is improved owing to the locating function of the CT.

MATERIALS AND METHODS

Objects

Fifty-four patients who were suspected for hepatic hemangiomas found by US, CT, and or MRI, and were examined by SPECT/CT from April 26, 2001 to July 15, 2004 in Beijing Hospital. Their average age was 49.15±13.78 years. Among them, 31 were men with an average age of 50.38±15.36 years; 23 were women with an average age of 47.36±11.22 years. The oldest was 91 years old and the youngest was 27 years old.

Acquisition methods

First, the patients were required to take 400 mg of perchlorate potassium. Thirty minutes later, 10 mg of pyrophosphate dissolved in 2 mL of water for injection was administered into one patient. Thirty minutes later again, 740 MBq of $Na^{99m}TcO_4$ was also administered intravenously by bolus injection. The imaging was obtained using the SPECT/CT (Hawkeye, General Electronic Medical System).

Hepatic blood perfusion imaging

The patients were laid on the table and the detector was placed at front-back imaging position or back-front one. The field of vision included parts of heart, abdominal aorta, liver, spleen, and kidney. The SPECT was equipped with low-energy parallel hole general collimator or high-resolution collimator. The energy peak was 140 keV, the width of the energy window was from 15% to 20%, and the matrix 128×128. When $Na^{99m}TcO_4$ was injected through elbow vein by bolus, the acquisition was carried out immediately at the speed of 2 s/frame, totally 30 frames.

Planar hepatic blood pool imaging

The static imaging was obtained at 5, 10, 15, and 20 min after intravenous injection. The delayed imaging was obtained from 1.5 to 2 h after injection, and 4-6 h if necessary.

Planar imaging: The patients were laid on the table. The detector was placed at the front-back and back-front position, or in the position where hepatic lesions were able to be shown clearly. The detectors were equipped with low-energy parallel hole general collimator or high-resolution collimator. The energy peak was 140 keV, the width of the window 20%, and the matrix 256×256. The count was set up 500 K/frame in advance.

Fusion imaging

The hepatic blood pool cross-sectional imaging was acquired and together with CT scanning after 40 min of bolus intravenous injection. The X-ray transmission scanning, which needed 0.8 min, was obtained firstly with the matrix of 384×800 to identify the liver position. Then X-CT acquisition, which needed 10.8 min, was followed with matrix of 256×256, zoom of 1.105, 10 mm per layer, totally 40 cross-sections. After transmission process, the detector automatically came back to the start position. Then SPECT acquisition over 360° was performed with the matrix of 128×128, zoom of 1.28, 20 s/frame, and 6°/frame. The technique of automatic human body contour was applied to making detector get closer to the patient's body.

Images reconstruction

The SPECT images were reconstructed from the raw data by filtered back projection using a HANN filter (filter parameter: 0.85). The CT data were reconstructed using nuclear medicine workstation (eNTEGRA, General Electronic Medical System). Then the matching emission and transmission were fused to form the fusion images.

Standard of diagnosis

The standard of diagnosis is that an increase of blood pool activity within a liver lesion is typical of hemangioma. And in the CT scanning, the density of the lesion is low and even. The images were read by experienced physicians, who have worked in the department of nuclear medicine for at least 5 years. The results were recorded as hepatic hemangioma or not.

RESULTS

Of the 54 patients, 31 (57.41%) were diagnosed as hepatic hemangioma patients by SPECT/CT and were not taken for further examination. The diameter of hepatic lesions was from 1 to 9 cm. Twenty-three patients (42.59%) were excluded from the hepatic hemangioma, because their hepatic lesions did not meet the characterization of the hepatic hemangioma. Among them, 9 patients lost contact with us, the 13 patients' were diagnosed as hepatic cancer, and one as hepatic cyst.

Of the 31 patients, the anatomical positions of the hepatic hemangiomas in 8 patients (25.81%) were not ideal. Among them, the hepatic lesions of three patients' were close to abdominal aorta (Figures 1A and B and 2A), that of four patients to inferior cava, that of one patient to heart (Figure 2B). Under these conditions, it was difficult to diagnose by only using SPECT. In SPECT/CT fusion imaging, CT was able to locate the position of focal radioactivity accumulation region, and at last diagnosed it as hepatic hemangioma.

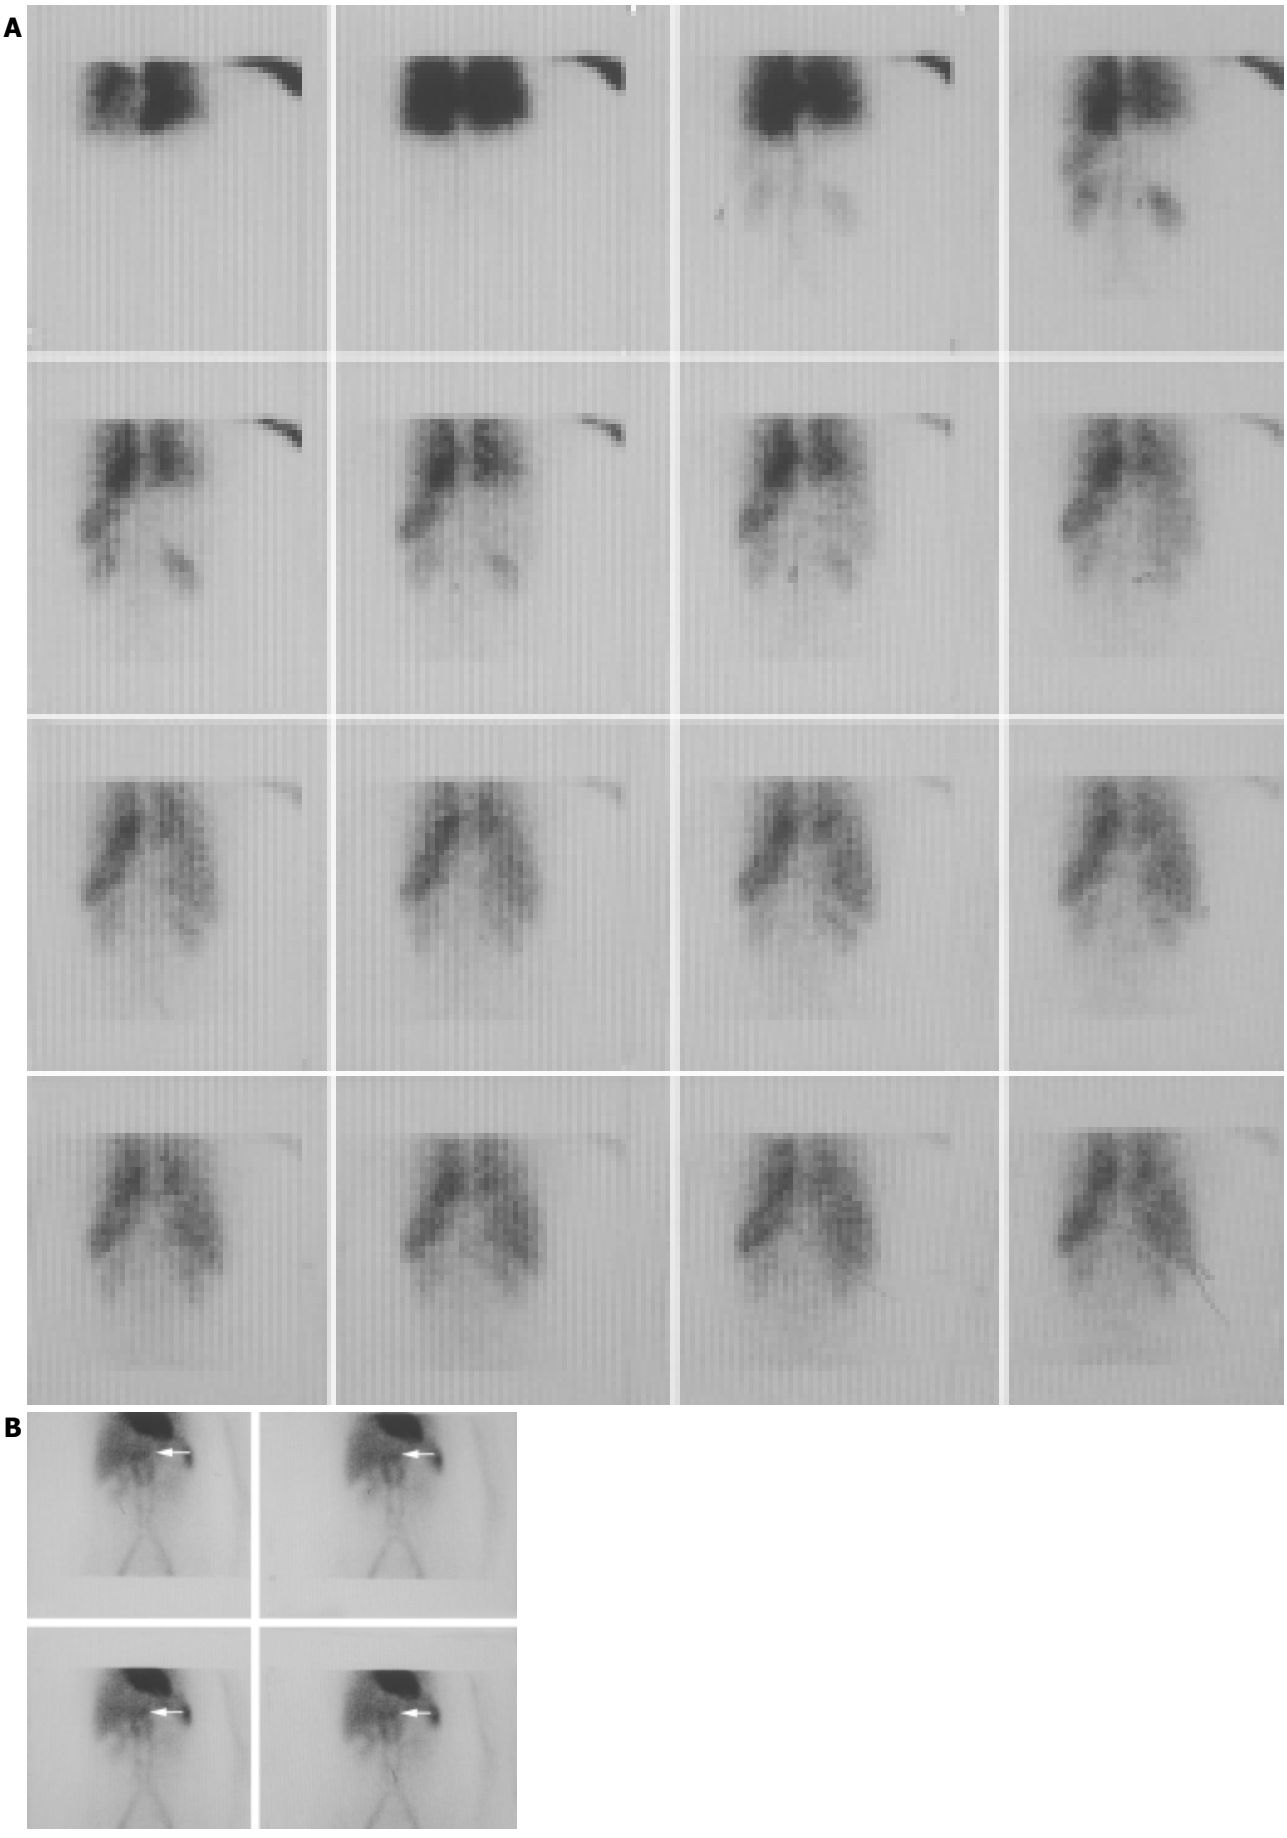
In the research, there are six round-like regions with high radioactivity, close to the heart and inferior cava in six patients on the brim of the liver. The CT showed that they were in the inferior cava. Finally, hepatic hemangioma was excluded (Figure 2C).

DISCUSSION

As a benign tumor, the hepatic hemangioma most frequently appeared in the liver. The incidence of the disease is about from 2% to 7% of the liver lesions. The hepatic hemangioma is classified as capillary and cavernous hepatic hemangioma. The former is not common, and able to change to the other. Thus, the majority is cavernous hepatic hemangioma.

As a non-invasive and highly specific method for diagnosing hepatic hemangioma, the ^{99m}Tc-labeled RBC scintigraphy can avoid invasive imaging or biopsy. And thanks to the application of SPECT, the sensitivity of the method is improved obviously. However, when the diameter of hepatic lesion is less than 1.3 cm, the sensitivity of SPECT is quite low. When the diameter is less than 1 cm, false negative appeared. And when the larger hepatic lesions (diameter more than 2.5 cm) with the bad anatomical positions, close to the heart, inferior cava or main hepatic vessels, *etc*., the diagnosis is difficult in a way, especially tiny hepatic hemangiomas. As reported by Birnbaum *et al*.[3], the hepatic lesions of 18 patients, whose hepatic hemangiomas were adjacent to the above-mentioned positions, 6 of the patients were not able to find them out. As reported by Schillaci *et al*.[4], 24 patients were sceptical of suffering from hepatic hemangiomas. Of them, six patients' anatomical position were not ideal; three patients' were close to main hepatic vessel, and two close to inferior cava, one close to heart. When SPECT/CT was carried out, with the help of CT, four were diagnosed as hepatic hemangioma, two were excluded from the hepatic hemangioma. In this research, about 25.81% patients' anatomical position was not ideal. When SPECT/CT was applied, with the help of CT, finally hepatic hemangioma was diagnosed.

The functional information from the SPECT combining with the anatomical information from the CT is able to solve the problem that anatomical position of hepatic hemangioma is not ideal. CT can accurately locate the lesion of radioactivity concentration region. Several years ago, a new apparatus was discovered. It combined the rotatable double-detectors camera γ with low-dose X-rays tube. The



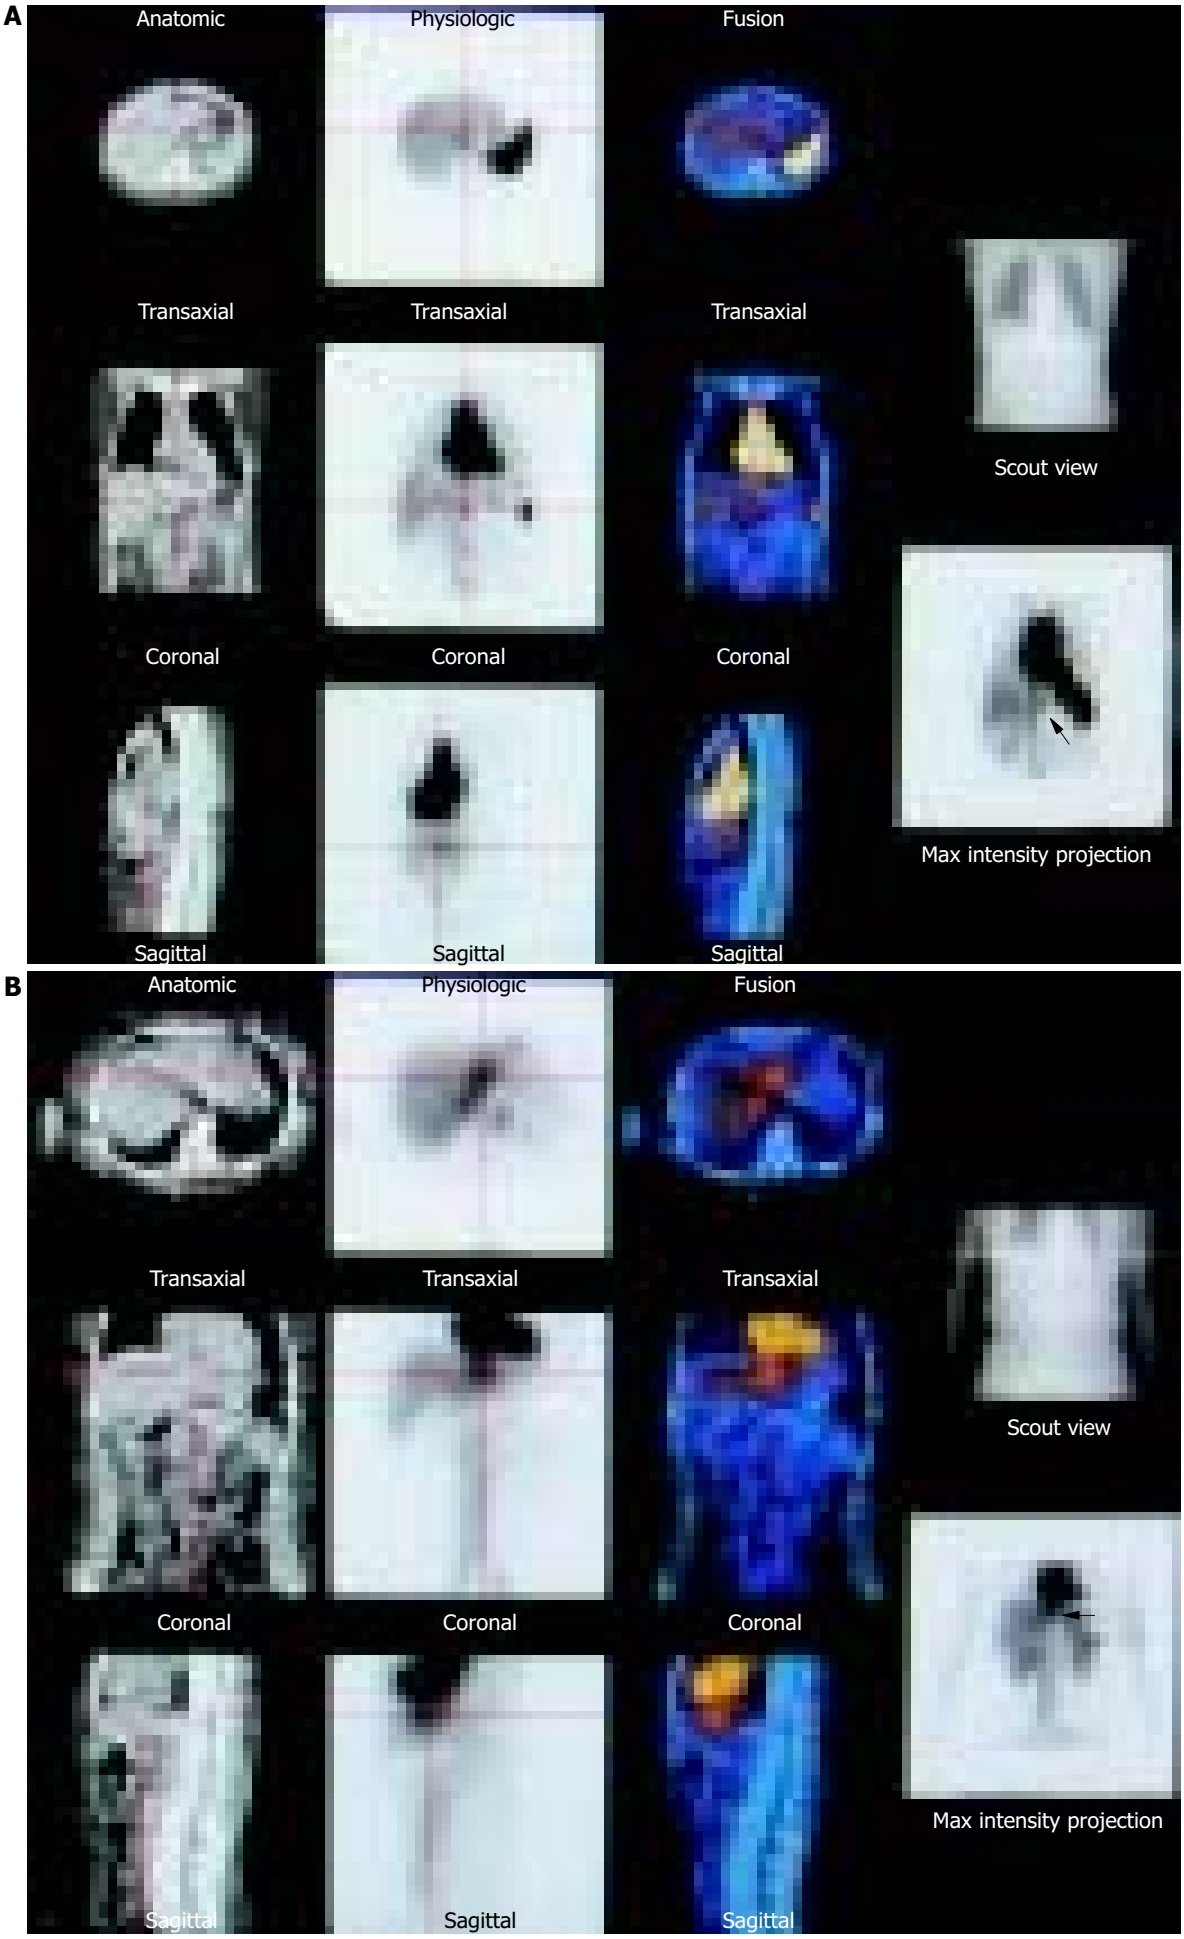


Figure 1 Female, 46 years old. US showed that there was a lesion in the left liver with the size 3.6×2.3 cm^2. The function of liver was normal. SPECT/CT test was carried out to exclude hepatic hemangioma. **A:** The hepatic blood perfusion imaging. The abnormal focal accumulation of the radioactivity was not shown obviously; **B:** The radioactivity accumulation of the focus (pointed by the red arrows) in the left liver was a little higher than the normal liver tissue.

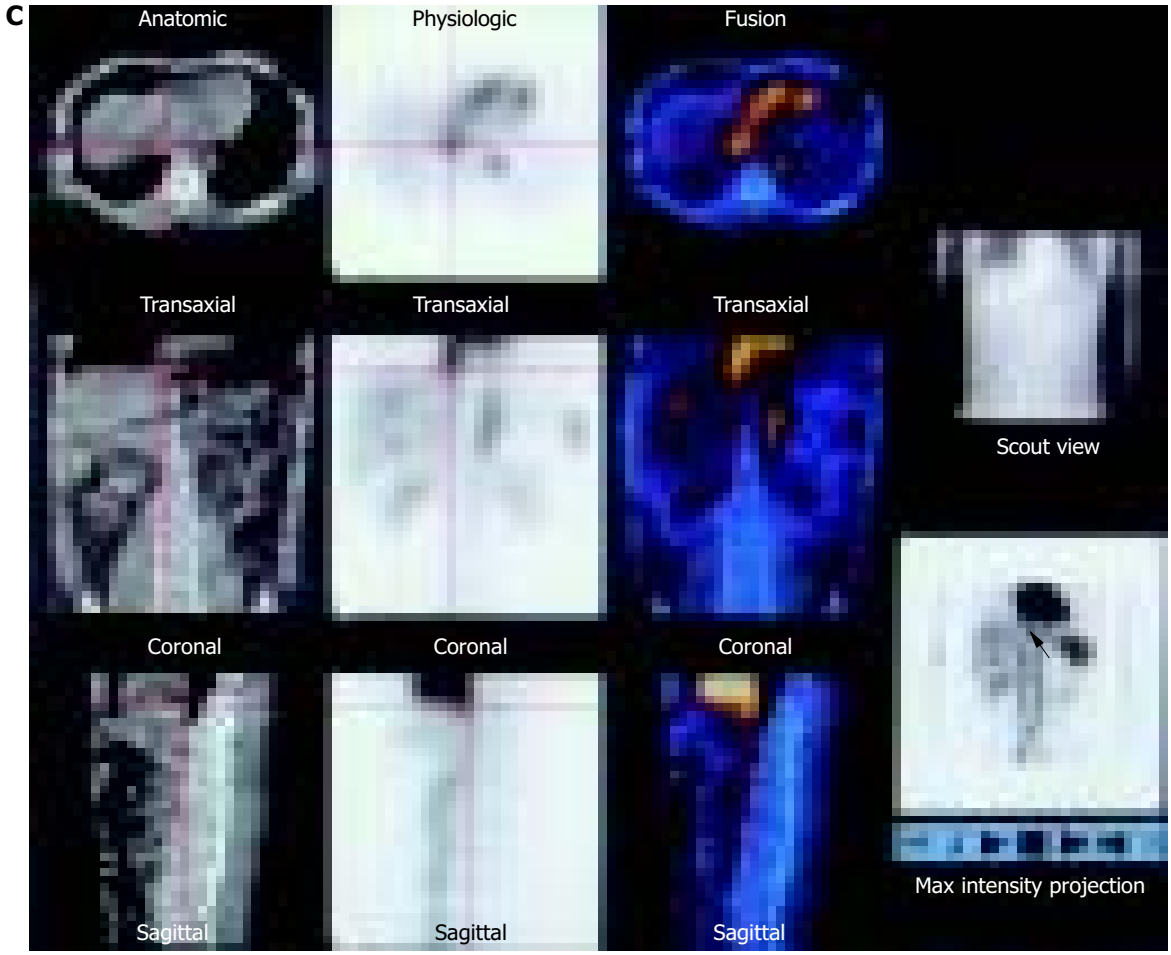

Figure 2 The round-like radioactive accumulation region (pointed by the red arrow) was just on the abdominal aorta. If fusion imaging was not obtained, then to decide whether it was abdominal aorta or hepatic hemangioma would have been difficult. As shown in the CT of fusion imaging, the focus (the red cross) was located in the left liver, but not in abdominal aorta, thus diagnosed as hepatic hemangioma. Female, 39 years old. A lesion in the liver with the diameter of 4 cm was found in the physical examination by US. It might be a hepatic hemangioma. SPECT/CT was performed for differentiation (**A**). The hepatic lesion (pointed by the red arrow) situated adjacent to the heart, whose abnormal radioactive concentration was a bit lower than the heart. The CT showed that the lesion (the red cross) was located in the left liver. The diagnosis was a left hepatic hemangioma. Male, 43 years old. The US showed a few lesions in the liver. They were sceptical of hepatic hemangiomas to go through SPECT/CT examination (**B**). The abnormal focal radioactive concentration region of left liver (pointed by the red arrow) was not only close to the heart, but also close to the inferior cava. The CT indicated that it was a part of the inferior cava (the red cross), and exclude the possibility of hepatic hemangioma. But other three round-like radioactive accumulation regions in the right liver were diagnosed as hepatic hemangiomas (**C**).

camera γ/CT machine would obtain SPECT and CT images respectively. The projection of X-ray was helpful to find the location of the radioactivity concentration focus. This was SPECT/CT fusion imaging. The SPECT/CT was used to diagnose hepatic hemangioma with the following advantages.

A. CT can accurately locate the position of radioactivity accumulating focus theoretically. However, the quality of the present CT in SPECT/CT is not very good. Under some conditions, it is very difficult to indicate the position accurately. But it is believed when multiple helical CT is used in fusion imaging in the future, the position of the hepatic lesions will be located accurately. Moreover, it may reach the function of diagnosis CT but not only in locating the position of the disease.

B. When hepatic lesions are detected by CT scanning, the hepatic colloid imaging may not be necessary. The colloid imaging is mainly used to find out the lesion of the liver. But CT is more superior to the hepatic colloid imaging in this respect. Its sensitivity is much higher than the hepatic colloid imaging. Therefore, when hepatic lesions are detected by CT scanning, the hepatic colloid imaging is not necessary.

C. Fusion imaging can be attenuation-corrected by X-ray. Therefore, the quality of the images would be improved. Because of the high quantity of information of X-ray, especially when the injected dose of ^{99m}Tc-labeled RBC is comparatively low and the patient is fat, the quality of the images will be improved obviously.

D. Improving the accuracy of diagnosis. Typical characterization of hepatic hemangioma is that its density is even and low by general CT scanning. The worth of common CT is limited. Usually it indicates the position of hepatic lesions, which is radioactive accumulation region. It provides anatomical information for hepatic hemangioma. SPECT can provide the functional information for pathological changes. Functional information coordinates with anatomical information, in this way the accuracy of diagnosis is improved.

Furthermore, it is worth paying attention to that, when

inferior cava passes by the liver, and enters right heart, a great majority can form a round-like radioactive accumulation region on the brim of the liver (Figure 2C). Under the condition, with the help of CT, the radioactive concentration region may be seen under the heart, link with the inferior cava and out of the liver. If it is, then hepatic hemangioma can be excluded. If it is not and the, the focus is in the liver, the diagnosis of hepatic hemangioma could be made.

Abstract

AIM: To evaluate the daily high-dose induction therapy with interferon-α2b (IFN-α2b) in combination with ribavirin for the treatment of patients who failed with interferon monotherapy and had a relapse, based on the assumption that the viral burden would decline faster, thus increasing the likelihood of higher response rates in this difficult-to-treat patient group.

METHODS: Seventy patients were enrolled in this study. Treatment was started with 10 MU IFN-α2b daily for 3 wk, followed by IFN-α2b 5 MU/TIW in combination with ribavirin (1 000-1 200 mg/d) for 21 wk. In case of a negative HCV RNA PCR, treatment was continued until wk 48 (IFN-α2b 3 MU/TIW+1 000-1 200 mg ribavirin/daily).

RESULTS: The dose of IFN-α2b or ribavirin was reduced in 16% of patients because of hematologic side effects, and treatment was discontinued in 7% of patients. An early viral response (EVR) was achieved in 60% of patients. Fifty percent of all patients achieved an end-of-treatment response (EOT) and 40% obtained a sustained viral response (SVR). Patients with no response had a significantly lower response rate than those with a former relapse (SVR 30% *vs* 53%; $P = 0.049$). Furthermore, lower response rates were observed in patients infected with genotype 1a/b than in patients with non-1-genotype (SVR 28% *vs* 74%; $P = 0.001$). As a significant predictive factor for a sustained response, a rapid initial decline of HCV RNA could be identified. No patient achieving a negative HCV-RNA PCR at wk 18 or later eventually eliminated the virus.

CONCLUSION: Daily high-dose induction therapy with interferon-α2b is well tolerated and effective for the treatment of non-responders and relapsers, when interferon monotherapy fails. A fast decline of viral load during the first 12 wk is strongly associated with a sustained viral response.

INTRODUCTION

Chronic infection with hepatitis C virus (HCV) is the main cause of chronic hepatitis, liver cirrhosis and hepatocellular carcinoma worldwide, more than 2% of the world population are chronically infected with this virus[1,2]. Until introduction of the nucleoside analog ribavirin, standard therapy for chronic hepatitis C was the monotherapy with interferon-α (IFN-α). The initial data published on the efficacy of IFN-α monotherapy demonstrate that about 50% of patients who have achieved a biochemical end-of-treatment response (ETR) have a relapse within the first 6 mo after cessation of treatment[3], only about 6% of patients with genotype 1 and/or high viral load can achieve a sustained viral response (SVR)[4].

Antiviral combination therapy with IFN-α and ribavirin can lead to significant response rates in treatment-of naive patients with chronic hepatitis C; however, sustained response rates for patients with no former response after IFN-α monotherapy are still low (12-16%)[5,6]. Furthermore, recent introduction of pegylated interferons has not resulted in a substantial increase in response rates among non-responders with a SVR rate being 14-27% after IFN-α monotherapy[7-9]. In order to increase the sustained response rate, it is important to decline the viral load during the initial weeks of antiviral therapy because IFN-α dose administered is directly related with the decline of HCV RNA[10-13].

The aim of the present study was first to evaluate the efficacy as well as safety and tolerability of a high-dose IFN-α2b induction therapy in combination with ribavirin

in patients who failed with interferon monotherapy and had a relapse. Further, the data were analyzed for potential predictive factors for a viral response in this subgroup of patients.

MATERIALS AND METHODS

Patients

A total of 70 patients (49 males/21 females) with chronic hepatitis C (elevated ALT, HCV RNA positive) who failed IFN-α monotherapy (group A, $n = 44$) or had a relapse (group B, $n = 26$), were enrolled in the study. Other inclusion criteria included hemoglobin level >120 g/L, white blood cell count >2.5/nL, platelet count >80/nL, and normal bilirubin, albumin and creatinine levels. Written informed consent was obtained from all patients. Exclusion criteria were decompensated liver cirrhosis (Child-Pugh B or C), autoimmune hypo- or hyperthyroidism, neuropsychiatric disorders, cardiovascular disease, HIV infection or infection with other hepatitis virus or other causes of liver disease, and pregnancy.

Seventy percent of all patients were infected with genotype 1a/b, 7% with genotype 2a/c, 20% with genotype 3a and 3% with genotype 4. Pre-treatment quantitative HCV RNA levels were determined using the Roche Cobas Amplicor v2.0 test. In 71% of patients a liver biopsy was performed and the degree of inflammation and fibrosis was estimated according to the Ishak-Knodell score. More details are listed in Table 1.

Table 1 Baseline characteristics of patients

	All patients	Group A (non-responder)	Group B (relapser)
Male (%)	70	80.5	59
Mean age	40.4	39.6	41.8
Genotype 1 (%)	70	75	57
Serum ALT (U/L)	70±2	67±6	75±10
Viral load[1] (%)			
<2 Mio copies/mL	37	39	35
>2 Mio copies/mL	63	61	65
HAI score[2] (%)			
HAI score (0-1)	72	68	77
HAI score (3-4)	28	32	23

[1]Quantitative HCV-PCR was measured in 48 patients pre-treatment. [2]Liver biopsies of 50 patients (22 relapsers/28 non-responders) were analyzed.

Study design

This study was carried out as an open, randomized, multicenter study (three centers).

Patients were treated first with 10 MU IFN-α2b daily for 3 wk. After the induction phase, patients received 5 MU IFN-α2b TIW for 21 wk. If a negative HCV RNA PCR result was obtained, treatment was continued for the remaining 24 wk with 3 MU IFN-α2b TIW. Ribavirin was added at 1 000-1 200 mg (according to body weight of > or <75 kg) at treatment wk 4 until wk 48 (Figure 1). The concept of a delayed onset of ribavirin was based on the observation that in the initial phase of antiviral therapy ribavirin has no significant effects on viral kinetics[14,15]. Thus the drug was given at a later time point to ameliorate side effects during the IFN high dose induction period. For severe adverse events other than anemia, interferon dosage was decreased (10 MU>5 MU or 5 MU>3 MU) or stopped if the actual dose was 3 MU. For anemia (<100 g/L), ribavirin dose was lowered to 600 mg/d, and discontinued if hemoglobin concentrations fell to <85 g/L. If severe leuko- or thrombocytopenia (white blood cell count <1 500/μL, platelet count <40 000/μL) occurred, interferon medication was stopped.

During the IFN-α2b high-dose induction phase, all patients were evaluated for tolerance, safety and treatment response twice weekly, while for the further follow-up patients were seen at wk 4, 8, 12, 18, 24, 36 and 48. At each visit, hematological, biochemical and HCV RNA testing was done.

When the treatment was completed, all patients were followed up for 48 wk.

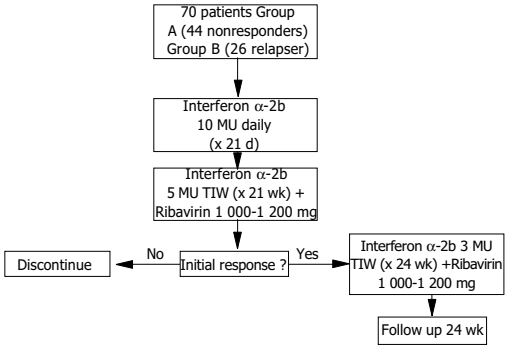

Figure 1 Trial profile of group A (non-responder) and group B (relapser).

Definition of response

Biochemical response was estimated after 12 wk of therapy and defined by a normalization of primary elevated ALT values. Undetectable serum HCV RNA at wk 24 during therapy was the criterion for an initial virological response. Virological end-of-treatment response was defined by a negative testing for HCV RNA at wk 48. If HCV RNA was still undetectable 24 wk after completion of the treatment, a virological sustained response was achieved.

Statistical analysis

The primary end point of the study was the comparison of virological response rates in relation to the prior response to the initial IFN-α monotherapy (non-responder *vs* relapser). Secondary parameters were differences in virological response rates in relation to genotype (genotype 1 *vs* non-1-genotypes) and viral kinetics (estimated after 12 wk of treatment). All safety and efficacy analyses were based on an intention-to-treat basis for all patients who received at least one dose of study medication. Statistical analysis was performed using χ^2 and Fisher's exact test (SPSS for Windows 10.0; SPSS, Inc., Chicago, IL).

Ethical aspects

According to the Declaration of Helsinki, a positive ethics

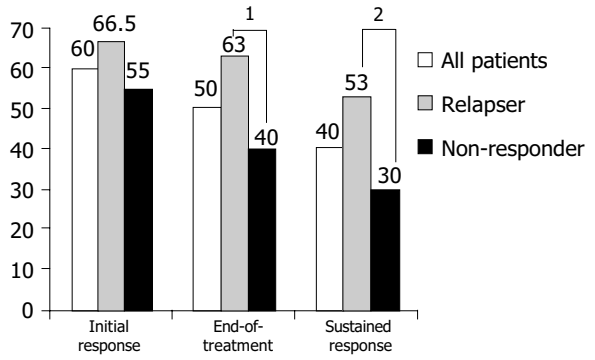

Figure 2 Response rates in relation to former response after IFN-α monotherapy. ^1P = 0.05; ^2P = 0.049; χ^2 test.

committee approval was obtained. Patients were only included in this study after giving their written informed consent.

RESULTS

In 5 patients (7%), therapy was discontinued because of side effects such as insomnia, myalgia and fatigue (three patients) or because of a significant increase (>5×ULN) in alanine aminotransferase levels (two patients). The IFN-α dosage was reduced in seven patients (10%) because of severe neutropenia (<1 500/μL). Average IFN-α induced a mean neutropenia of 2 695±629/μL and a mean thrombopenia of 119.700±31.500/μL. Hemolytic anemia as a common side effect of ribavirin leads to a mean hemoglobin decrease of 3±14.8 g/L in all patients. In four patients (5.7%), ribavirin was reduced because the hemoglobin value was persistently lower than 100 g/L.

At wk 24, a biochemical response was observed in 85% and an initial virological response was achieved in 60% of all patients. Ten percent of patients had a break-through phenomenon after a previous negative HCV RNA PCR in serum in the first 24 wk of therapy. An end-of-treatment response (EOT) was achieved in 50% of all patients. During the follow-up, 10% of patients experienced a relapse. Accordingly, an overall sustained response (SR) of 40% was obtained. Patients with no primary response had a significant lower response rate than those with a former relapse (SVR 53% *vs* 30%; P = 0.049 (χ^2 test; Figure 2)). Likewise, genotype 1a/b showed a significantly lower response rate than other genotypes (28% *vs* 74% for genotypes 2 and 3; P = 0.001 χ^2 test; Figure 3).

To estimate the effect of a fast decline of viral load as a potential predictive factor for a viral response especially in former non-responders, HCV-RNA was analyzed after 12 wk of therapy in 40 patients. An early loss of HCV RNA level was significantly (P = 0.001; Fisher's exact test) associated with higher sustained response rates as all patients with a late negative HCV RNA testing (>12 wk of therapy), experienced a breakthrough or relapse during further follow-up. In contrast, 65% of all patients with a rapid drop of HCV RNA level and a negative PCR result at wk 12, finally experienced a sustained viral response (Table 2). No correlation between the observed decline of viral load and the result of previous treatment (relapse or non-response) or initial viral load could be demonstrated in this small subgroup in the present study.

DISCUSSION

Therapy of patients who failed with IFN-α monotherapy and had a relapse remains a difficult issue though the advances have been achieved with the introduction of ribavirin combination therapy as well as the introduction of pegylated interferons. Retreatment of this patient group with standard doses (TIW) of interferon plus ribavirin especially in non-responders or patients infected with genotype 1 was largely ineffective, resulting in SVR of 12-16%[5,6]. Even when treated with the pegylated interferons-α2a or -α2b, the sustained response rate was between 14% and 27%[7-9].

Many studies have shown the importance of a rapid initial decline of viral load in obtaining a better response rate[10,11]. Higher INF-α dosage is correlated with a faster decline of the viral load[12,13]. Based on these observations, this study using an induction therapy with 10 MU IFN-α daily was designed. To reduce the extent of expected side effects, ribavirin was subsequently added at the end of the IFN-α induction phase (end of wk 3).

The interferon induction phase with 10 MU IFN-α2b daily for over 3 wk was safe and at least moderately tolerated. Treatment was discontinued only in 7% of patients, interferon or ribavirin was reduced in 16% of patients, mainly because of hematological side effects. In comparison to other studies using high-dose interferon

Table 2 Response rates in relation to an early viral response in former non-responders after IFN-α monotherapy

Treatment week	"Fast responder" (HCV RNA negative at wk 12, n = 31)	"Slow responder" (HCV RNA negative after wk 12, n = 9)	P
48 (ETR, %)	25 patients PCR negative (81)	3 patients PCR negative (33)	0.012[1]
Follow-up (SR, %)	20 patients PCR negative (65)	0 patient PCR negative (0)	0.001[1]

[1]Fisher's exact test.

induction therapy in combination with non-pegylated interferons[16-19], the sustained response rate in the present study was higher (30% *vs* 6-27%) , perhaps as a result of the higher initial IFN dose or a longer induction period leading to a faster decline in serum HCV RNA level. Another reason for the relatively higher sustained response rate in the present trial may be due to the low dropout rate (7%) in comparison to other treatment schedules (15-21.9%) using a higher dose of INF-α.

The sustained response rate was significantly lower in patients with no former response than in relapsers (30% *vs* 53%; $P = 0.049$). Possible reasons for these observations might be the higher number of patients infected with genotype 1, male gender and a higher Ishak score of 3-4 in the non-responder group. These viral and host characteristics are known as negative predictive factors for the treatment of chronic hepatitis C[18,19]. Independent of these factors other studies have also shown higher response rates in patients with an earlier relapse than in non-responders after INF-α monotherapy[17,20].

All former non-responders with a sustained response had a negative serum HCV RNA at treatment wk 12, which underscores the importance of a fast decline in viral load and may serve as a rationale in using higher initial interferon doses especially in treating non-responders[21-23]. However, in patients with genotype 1, sustained response rates were significantly lower in those with other HCV types. These observations are due to multiple factors, including higher drug effectiveness, a faster free virion clearance rate and possibly an enhanced immunological response in patients infected with non-1 genotype[24].

As one explanation for the differences in viral kinetics between the HCV subgroups, it has been speculated that HCV genotype 1 is not as sensitive to IFN-α as other viral strains[25,26]. As described above and shown in the large registration trials for treatment of naive patients with pegylated interferons[27], an early therapeutic decision regarding the continuation of treatment at 12 wk appears also to be amenable in non-reponders.

At present, pegylated interferons in combination with ribavirin can improve the sustained response rate of about 50-56% in naive HCV positive patients. The subgroup of genotype 1/high viral load patients, however, did not show improved sustained response rates of 30-34% when treated with pegylated interferons. Furthermore, patients who failed the standard interferon and ribavirin therapy did not show significant sustained response rates when retreated with pegylated interferons (SVR 6-12%). Thus, the sustained response rate reported in this study together with good tolerability using a standard daily interferon dose makes this type of treatment a valuable alternative for this difficult-to-treat patient group. An even longer high-dose induction period for more than 3 wk may lead to an even higher sustained response rate, but this might be counterbalanced by a relatively lower tolerability. For a final evaluation of the optimal duration of induction, larger clinical trials are needed.

Abstract

AIM: (1) To compare the prevalence of osteoporosis (*t*-score ⩽-2.5 SD) between stage IV PBC patients, and two groups of age- and sex-matched controls: one with hepatitis C virus (HCV)-related cirrhosis, and the other one consisting of a group of healthy subjects from the general population; (2) to identify the main risk factors for the development of bone loss.

METHODS: Thirty-five stage IV PBC patients (mean age 52.5±10 years), 49 females with HCV-related cirrhosis (mean age 52.9±5.8 years) and 33 healthy females (mean age 51.8±2.22 years) were enrolled in the study. Bone metabolism was evaluated by measuring serum calcium corrected for serum albumin (Ca corr.), 25-hydroxy vitamin D (25-OH vit D), parathyroid hormone, osteocalcin. Bone mineral density (BMD) was assessed at the lumbar spine by dual-photon X-ray absorptiometry.

RESULTS: Osteoporosis was present in 5/35 PBC patients (14.2%) and in 7/49 HCV-related cirrhotic patients (14.3%), without any statistical difference between the two groups. Among healthy control subjects, none had osteoporosis. No difference was found between the three groups in serum parameters of bone metabolism. Univariate analysis showed that menopausal state and low BMI were significantly correlated with osteoporosis. Multivariate regression analysis showed that menopausal status, BMI <23, and old age were independent variables significantly correlated with osteoporosis.

CONCLUSION: PBC in itself has no negative influence on BMD. End-stage liver disease patients carry a disease-specific risk for osteoporosis, but have an effective risk of bone loss in relation to individual potential risk for each patient. A practical message should be taken into account, that is, every effort should be made to prevent osteoporosis when a patient has simple osteopenia, or if it is a woman in or near menopausal age.

INTRODUCTION

Osteopenia is a major complication of end-stage liver disease and a real risk in liver transplant patients[1]. It is also a common clinical problem, however, in association with chronic cholestatic liver disease, particularly PBC, due to predominant female sex and older age[2]. Osteoporosis was recently found in 20% of 176 patients with PBC, occurring 32 times more frequently than expected[3]. Despite the wisdom that osteoporosis is common in PBC than in other types of liver disease, new data are emerging in the literature concerning this field.

In a previous study, including cirrhotic patients evaluated for liver transplantation, we failed to find any significant difference in bone mineral density (BMD) between patients with chronic cholestatic liver disease and cirrhotics of various etiology[4]. Newton *et al*., retrospectively reviewed a large group of PBC patients in Newcastle (UK) and found osteoporosis in 31.2% of cases; none of the patients went on to develop *de novo* osteoporosis during a mean follow-up of 10.1 years[5]. The authors concluded that osteoporosis is not a specific complication of PBC. They had not considered age- and sex-matched controls from the general population or control groups with different types of liver disease. It should also be stressed that PBC is a heterogeneous disease, and usually any PBC study population includes patients with different severity of liver damage ranging from early disease to cirrhotic stage.

The aims of the present study were therefore: (1) to compare the prevalence of osteoporosis between stage IV PBC patients and two groups of age- and sex-matched controls: one with hepatitis C virus (HCV)-related cirrhosis, and the other one consisting of healthy subjects from general population; (2) to identify the main risk factors for osteoporosis.

MATERIALS AND METHODS

Patients

Thirty-five consecutive female stage IV PBC patients (mean

age 52.5±10 years), 49 females with HCV-related cirrhosis (mean age 52.9±5.8 years) and 33 female healthy subjects (mean age 51.8±2.22 years) were enrolled in the study. The clinical characteristics of the three groups are summarized in Table 1. Body mass index was significantly lower in both PBC and HCV-related cirrhosis patients compared to healthy controls ($P<0.05$). All subjects were asymptomatic for bone loss, and none were taking calcium and/or vitamin D supplementation. None of the patients were treated with steroids. Patients with HCV-related cirrhosis have not been previously treated with interferon/ribavirin therapy. The patients were not given hormone replacement. PBC patients were treated with ursodeoxycholic acid [12-15 mg/(kg·d)] twice a day after meals.

The diagnosis of PBC was obtained according to clinical, immunological, and histological grounds. All the patients with PBC has histological stage IV, according to Scheuer's classification[6]. The diagnosis of HCV-related cirrhosis was obtained by clinical, histological, and virological methods, including serum positivity for HCV-RNA by means of PCR assay.

None of the patients were ingesting alcohol. Ethical approval was obtained from the hospital's ethics committee and informed consent was obtained from each patient, prior to their inclusion in the study.

Table 1 Clinical details of the patients

	PBC	HCV+	Control group
Number of patients	35	49	33
Age (mean±SD), yr	52.5±10	52.9±5.8	51.8±2.22
Age at menopause (mean±SD), yr	48.3±4.5	48.5±4.9	47±7.46
BMI (mean±SD)	22.8±3.2[a]	23.4±4.2[a]	25.9±4.29

[a]$P<0.05$ *vs* control group.

Bone density measurement

BMD was assessed by DEXA (Hologic QDR 4500 C, Walthom, MA, USA) at lumbar spine (L2-L4). The manufacturer's reference database was obtained by measuring more than 500 healthy male volunteers at the University of California (San Diego, CA) and at other QDR-1000 installations across the USA. Reference data collected on Hologic systems in Europe, including Italy, have demonstrated a close correlation with US values. In our hands, the long-term (1 year) coefficient of variation *in vitro* with a Hologic phantom is 0.44%; the short-term (1 wk) coefficient of variation *in vivo*, with five consecutive measurements performed in 10 healthy volunteers, is 1.2%. Osteoporosis was defined according to WHO in terms of *t*-score lower than -2.5 SD. The *t*-score was defined as the number of SD above or below the mean BMD for young adult mean value. The *z*-score for BMD was defined as the number of SD above or below the mean BMD for age- and sex-matched normal population.

Biochemical parameters

The following parameters were assessed in all subjects: serum calcium, parathyroid hormone (PTH), osteocalcin (BGP), 25-hydroxy vitamin D (25-OHD). Serum Ca was measured by common automated laboratory methods. Serum calcium corrected for albumin concentration was calculated using the following formula:

Ca corr (mg/dL) = Ca tot (mg/dL)+4-albumin (g/L)

The result was divided by 4 and expressed in mmol/L.

PTH was tested by IRMA (Allegro TM Intact, Nichols Institute, S. Juan Capistrano, CA, USA). This method detects the biologically intact 1-84 amino acid chain of PTH. The normal range is 10-55 ng/L. The coefficient of variation was 3.6% intra-assay and 5.8% inter-assay. BGP was assayed by IRMA (Cis Bio International, Italy). The normal range is 4-26 mg/L. The coefficient of variation was 3.1% intra-assay, and 5.7% inter-assay. 25-OHD was determined by RIA (Incstar Corp, Stillwater, MN, USA). The normal range is 25-150 nmol/L. The coefficient of variation was 5.1% intra-assay and 9.7% inter-assay.

Statistical analysis

Results were expressed as the mean±SD. Student's *t*-test for unpaired data and the linear regression test were used, as appropriate. Logistic regression analysis was used to establish in which characteristics were independently associated with osteoporosis (age, menopausal status, BMI, 25-OHD, PTH, BGP). A P value $\leqslant 0.05$ was considered significant. Analyses were performed with the EPI-Info 6.04 and the Statistical Package for the Social Sciences (SPSS 10.0).

RESULTS

Osteoporosis was present in 5/35 PBC patients (14.3%) and in 7/49 HCV-related cirrhotic patients (14.3%), without any statistical difference between the two groups. No subjects with osteoporosis were identified in healthy female controls. The mean age of patients with osteoporosis was 54.2±55 years, and the mean age of those without osteoporosis was 52.5±8.4 years (P = NS). No difference was found between the three groups in s-Ca. The mean BMD at lumbar spine was lower in both PBC and HCV-related cirrhosis groups compared to healthy controls, without any statistical significance (Table 2). However, *t*-score was significantly lower in PBC group compared to either HCV-related cirrhosis group or control group (-1.55±0.99 in PBC *vs* -0.39±2.65 in HCV+ *vs* -0.29±0.98 in healthy controls, $P<0.05$).

Table 2 Bone metabolism in PBC, in HCV+ patients and in healthy controls

	PBC	HCV+	Controls
BMD (lumbar spine)	0.810±0.130	0.860±0.140	0.972±0.128
t-score ⩽–2.5 SD	–1.55±0.99[a]	–0.39±2.65	–0.29±0.98
z-score	–0.94±1.10[c]	–0.52±1.23	–0.82±1.02
25-OHD (nmol/L)	103.48±58.85[e]	98.38±44.65[g]	49.66±19.72
BGP (mg/L)	8.80±8.7	6.43±11.14	9.56±2.92
Intact (1–84) PTH (ng/L)	39.8±26.3	35±29.78	33.60±11.77
Ca corr albumin (mg/dL)	2.27±0.26	2.32±0.13	2.31±0.14

[a]$P<0.05$ *vs* controls. [c]$P<0.05$ *vs* HCV+. [e]$P<0.05$ *vs* controls. [g]$P<0.05$ *vs* controls.

Serum 25-OH vit D was significantly higher in both PBC group and HCV+ group *vs* healthy controls (103.48±58.85 nmol/L in PBC *vs* 98.38±44.65 in HCV+ *vs* 49.66±19.72 in healthy controls, $P<0.005$). No significant differences in serum BGP and PTH were found between the three groups. Univariate analysis showed that menopausal state and low BMI were significantly correlated with osteoporosis (Table 3). Multivariate regression analysis showed that menopausal status, BMI <23, and advanced age were independent variables significantly correlated with osteoporosis (Table 4).

DISCUSSION

Our results indicate that female patients with end-stage PBC have a similar percentage of osteoporosis than sex- and age-matched controls with HCV-related cirrhosis. However, PBC patients had significantly lower *t*-score compared to age- and sex-matched controls from general population. All types of liver disease are acknowledged and some osteopenia risk factors are common, e.g. cirrhosis, female sex, old age, alcohol consumption, hypogonadism, steroid therapy, impaired conversion to 25-OH vit D, low BMI, vitamin D receptor (VDR) polymorphism, reduced BGP activity[7-14], but certain specific risk factors for osteoporosis exist in chronic cholestatic liver disease, i.e. calcium and vitamin D malabsorption, hyperbilirubinemia, and cholestyramine therapy[15,16]. In our patients, however, vit D status, evaluated by 25-OH vit D serum levels, was similar in the three groups of subjects, as well as serum Ca, and serum BGP. Furthermore, no secondary hyperparathyroidism was found in our cases, suggesting a normal intestinal calcium absorption.

In order to avoid confounding factors such as corticosteroids and alcohol consumption, we have chosen three groups of subjects with the same demographic characteristics (same geographical area, same prevalence of menopausal status, same age) without evidence of bone disease, and without calcium and/or vitamin D supplementation. Multivariate analysis showed that menopausal status, BMI <23, and old age were independent variables significantly correlated with osteoporosis. This finding apparently confirms previous results[4,11,17] in which chronic liver disease *per se*, and not a specific etiology, should be responsible for hepatic osteodystrophy. Osteoporosis has been shown to be significantly associated with postmenopausal status in several studies[18,19]; however, all PBC series include patients with different histological stages. In our study, we included only patients with advanced disease, namely cirrhotic patients.

As far as our results are concerned, the univariate analysis (which included the type of liver disease, menopausal status, 25-OHD, BGP, PTH, BMI >23) showed that both menopause and old age were associated to bone loss in both groups. We did not assay VDR gene polymorphism in these study groups, but there is evidence that VDR genotypes predict lower BMD in general population in different countries[20,21]. As far as VDR gene polymorphism in liver disease is concerned, there is evidence that similar results may be extended also in PBC[9,22]; however, in our knowledge, no other groups of liver disease patients have been tested for VDR gene polymorphism.

Nevertheless, the mean values of serum parameters of bone metabolism (25-OH vit D, BGP, PTH, and Ca corr) in both PBC and HCV-related cirrhosis patients did not show any difference compared to controls. These data suggest that osteodystrophy in end-stage liver disease patients is characterized by a low turnover osteoporosis.

BGP is a bone matrix protein synthesized by osteoblasts is vitamin K-dependent, but we failed to find any correlation between BGP and vitamin K activity measured by prothrombin activity (data not shown). Moreover, no difference was found in prothrombin activity between the two groups of cirrhotic patients.

PTH was assayed by RIA, using an antiserum directed against the mid-region of the hormone. When intact 1-84 PTH was assayed in cirrhotic patients, normal values of PTH levels were found.

In conclusion, PBC in itself has no negative influence on BMD. End-stage liver disease patients carry a disease-specific risk for osteoporosis, but have an effective risk of bone loss in relation to individual potential risk for each patient. A practical message should be taken into account, that is, every effort should be made to prevent osteoporosis when a patient has simple osteopenia, or if it is a woman in or near menopausal age.

Abstract

AIM: To investigate the possible relationships between gastric autoimmune phenomena and clinical presentations of this disorder, in consecutive atrophic body gastritis patients.

METHODS: A total of 140 atrophic body gastritis patients, diagnosed as consecutive outpatients presenting with macrocytic or iron deficiency anemia, or longstanding dyspepsia underwent gastroscopy with antral and body biopsies, assay of intrinsic factor, parietal cells and *Helicobacter pylori* (*H pylori*) antibodies. Gastritis was assessed according to Sydney System.

RESULTS: Parietal cell antibodies were equally distributed in all clinical presentations, whereas the positivity of intrinsic factor antibodies (49/140, 35%) was significantly higher in pernicious anemia patients (49.2%) than in iron deficiency (21.1%) and dyspeptic patients (27.8%). No specific pattern of autoantibodies was related to the clinical presentations of atrophic body gastritis. A positive correlation was obtained between the body atrophy score and the intrinsic factor antibody levels ($r = 0.2216$, $P = 0.0085$). Associated autoimmune diseases were present in 25/140 (17.9%) patients, but the prevalence of autoimmune diseases was comparable, irrespective of the clinical presentations.

CONCLUSION: The so-called hallmarks of gastric autoimmunity, particularly in intrinsic factor antibody cannot be usefully employed in defining an autoimmune pattern in the clinical presentations of ABG.

INTRODUCTION

Atrophic body gastritis (ABG), particularly in association with pernicious anemia (PA), is believed to be an autoimmune disease, due to the presence of autoantibodies to the secretory elements of the gastric oxyntic mucosa and other associated autoimmune disorders[1,2]. Indeed, parietal cell antibodies (PCA) are detected in 60-90%, and intrinsic factor antibodies (IFA) are found in 50-70% of patients with PA[3-7]. In particular, IFA belonging to the IgG class of immunoglobulins, are considered highly specific to patients with PA, since they have rarely been found in the absence of this condition[8,9].

ABG is usually considered synonymous with the presence of PA, a disorder believed to be most common in individuals of north European descent[10]. However, macrocytic anemia is not the only hematological presentation of ABG. It has been reported, that iron deficiency anemia (IDA) should also be taken into consideration as a presentation symptom of ABG[11]. In fact, in 27% of IDA patients without gastrointestinal symptoms, ABG has been identified as the likely cause of IDA[12]. Furthermore, it is well known, that patients with ABG often complain of dyspepsia, even without hematological disorders[13].

It is now apparent that *Helicobacter pylori* (*H pylori*) is involved in the induction of ABG[14]. In fact, it has recently been reported that two-thirds of ABG patients and a large percentage of PA patients present evidence of *H pylori* infection[15,16]. At the same time, it is well established that *H pylori* infection can induce gastric autoimmunity, since the presence of the bacteria leads to the production of antibodies cross-reacting with human gastric mucosa[17,18]. Recently, it has been reported that the progression of the severity of gastric corporal atrophy is inversely correlated with circulating IgG to *H pylori* and positively with the titer of antibodies to parietal cells[15]. Indeed, most of the studies

regarding the role of IFA in ABG and PA date back to the early seventies[4,5,8,9], and were thus performed before a histological consensus classification of gastritis (e.g., Sydney System) was developed, and the role of *H pylori* infection in this condition was recognized. To our knowledge, studies that evaluate the pattern of gastric autoimmune autoantibodies in relation to *H pylori* status and presentation symptoms of atrophic body gastritis are scarce. Thus, the aim of the present study is to investigate the relationships between the main clinical presentations of ABG and gastric autoimmune phenomena in a consecutive series of patients with ABG.

MATERIALS AND METHODS

Patients

We included 140 patients with ABG diagnosed in consecutive outpatients referred to our Gastroenterology Department from the Hematology Department for evaluation of their anemia (n = 122, either macrocytic or iron-deficiency anemia) or attending our department for unexplained long-standing dyspepsia (n = 18), in application of previously reported screening programs[11,19]. The ABG patients with dyspepsia did not show any type of anemia. Patients taking anti-secretory drugs or with a history of previous gastric and/or intestinal surgery were carefully excluded. Other causes of anemia (e.g., myelodysplasia, neoplasia, blood loss, epistaxis, heavy menstrual loss, fecal occult blood positivity, cirrhosis) were also carefully excluded, as previously reported[12]. None of the patients were vegetarians and none presented with disorders associated with the small bowel.

All ABG patients had a detailed initial assessment including fasting gastrin, gastroscopy with gastric antrum and body mucosa biopsies as well as basal and peak acid output to pentagastrin (PAO). A serum sample was taken for detection of antibodies against intrinsic factor, parietal cells and *H pylori*. Anamnestic data were obtained from each patient by a scrupulously detailed clinical interview and, whenever possible by checking medical records, for the presence of associated autoimmune diseases. All patients gave informed consent to the study, which was approved by a local ethics committee.

Diagnosis of atrophic body gastritis The diagnosis of ABG was based on the following criteria: fasting hypergastrinemia, pentagastrin-resistant achlorhydria or hypochlorhydria (PAO lower than 13 mEq/h) and histological confirmation of gastric body mucosa atrophy (see section on histological procedure).

Diagnosis of pernicious anemia PA was defined as a hemoglobin concentration <14 g/dL for men (normal range 14-18 g/dL) and <12 g/dL for women (normal range 12-16 g/dL), mean corpuscular volume (MCV) ⩾100 fL, low level of vitamin B12 (n.v. 190-950 pg/mL), response to vitamin B_{12} therapy, and histological confirmation of gastric body mucosa atrophy, as described elsewhere[11,16].

Diagnosis of iron deficiency anemia Iron deficiency anemia was defined as hemoglobin concentration <14 g/dL for men (normal range 14-18 g/dL) and 12 g/dL for women (normal range 12-16 g/dL), MCV <80 fL (normal range 80-100 fL) and low serum ferritin (normal range 30-180 ng/mL), as previously described[11,12].

Diagnostic investigation

Gastric acid secretion studies PAO (6 μg subcutaneous, Peptavlon, ICI, UK) was determined as previously described[20]. The median reference value for PAO in our laboratory was 31.1 mEq/h (range 13-44.4 mEq/h).

Serological testing Fasting gastrin levels were evaluated by a specific radioimmunoassay using antibody no. 4562 (kindly provided by Professor JF Rehfeld Copenhagen, Denmark), as described elsewhere[20]. Normal values were ⩽40 pg/mL.

H pylori antibodies were detected by competitive ELISA based on a mAb against 64-ku *H pylori* antigen, as previously described[21]. Antibody concentration was expressed as U/mL. Negative values were <450 U/mL.

Pepsinogen I levels were measured using a commercial RIA kit (Pepsik, Sorin, Saluggia, Italy) as previously reported[22]. The normal reference values were 20-80 ng/mL.

Parietal cell antibodies (PCA) were determined on serum using a solid phase immunosorbent assay commercial kit (AUTOSTAT, Cogent Diagnostic Ltd., Edinburgh, UK), as described elsewhere[15,19]. Intrinsic factor antibody (IFA) IgG was determined by an indirect ELISA using highly purified porcine IF (Sigma-Aldrich, Saint Louis, USA) as a target. Microwells were overcoated with 10% normal rabbit serum to avoid nonspecific binding of human IgG. Antibody concentration was calculated by a calibration curve and expressed as arbitrary U/mL. Values >2 U/mL were considered positive for IFA[23].

Histological procedures

All patients underwent upper gastrointestinal endoscopy with three antral biopsy samples (smaller and greater curve, anterior or posterior) and three from the midbody along the greater curve, taken with a standard biopsy forceps[24]. The specimens were immediately fixed in Bouin's solution for 4-8 h, at room temperature, rinsed in 0.1 mol/L phosphate-buffered saline, pH 7.4 and routinely processed to wax. Serial paraffin sections (5 μm) were stained with hematoxylin and eosin for conventional histological evaluation and with Giemsa stain for *H pylori* determination.

Assessment of the degree of gastritis was performed according to the updated Sydney System[25]. The following scores were assigned to each graded variable: 0 for absence and 1, 2, 3, for mild, moderate or severe presence, respectively. Atrophy of gastric mucosa was defined as focal or complete replacement of oxyntic glands by metaplastic pyloric or intestinal glands.

The biopsies were examined independently by two histopathologists, unaware of the clinical data of the patients. In case of any disagreement, the relevant biopsies were re-examined simultaneously by both histopathologists, until an agreement was reached.

H pylori status in ABG patients

H pylori status of ABG patients was evaluated considering both tissue stain and serology, as described elsewhere[15]:

patients were defined as *H pylori* negative/negative (group I) when both histology and serology were negative for *H pylori*, as *H pylori* negative/positive (group II) when *H pylori* was not detected at histology but circulating antibodies to *H pylori* exceeded the reference value, and as *H pylori* positive/positive (group III) when they were found to be positive at histology and circulating antibodies to *H pylori* exceeded the reference values.

Statistical analysis

Data were expressed as mean±SE and/or median (range) and evaluated by appropriate statistical tests (Student *t*-test or Wilcoxon test). Subgroups (percentages) of the population were compared by Fisher's exact test. $P<0.05$ was considered statistically significant.

RESULTS

Clinical presentation of ABG and gastric autoimmunity

ABG patients presenting with PA, IDA, and dyspepsia were not homogeneous as far as gender, age, gastrin and pepsinogen I levels, and body atrophy score were concerned (Table 1). Whereas gender was equally distributed in ABG patients presenting with PA and dyspepsia, ABG patients with IDA were predominantly female. ABG patients with PA were significantly older and had higher levels of gastrin and lower levels of pepsinogen I, compared to those with IDA and dyspepsia. Moreover, ABG patients with PA also had a higher body atrophy score than those with IDA and dyspepsia. However, it is of interest that all ABG patients, regardless of the three clinical presentations, showed comparable stimulated acid secretion values. It is also worthwhile pointing out that the serological levels of vitamin B_{12} were as expected, significantly lower in ABG patients with PA, albeit also the patients presenting with IDA and dyspepsia had median levels of $B_{12,}$ close to the lower normal value. Finally, *H pylori* positivity was significantly lower in the PA group than in the IDA and dyspeptic patients.

Among the 140 ABG patients, associated autoimmune diseases were observed in only 25 (17.9%, 13 females, 12 males, median age 52 years, range 26-76 years), who presented autoimmune thyroid disease ($n = 10$), alopecia ($n = 6$), vitiligo ($n = 5$), psoriasis ($n = 2$), rheumatoid arthritis ($n = 1$) and type I diabetes mellitus ($n = 1$). However, the prevalence of autoimmune diseases was similar in ABG patients, irrespective of the clinical presentations.

As far as gastric autoimmune antibodies are concerned, the prevalence of PCA was equally distributed among the different clinical presentations, whereas the prevalence of IFA positive cases was significantly higher in ABG patients with PA than in those with IDA and dyspepsia ($P = 0.001$). Moreover, in order to establish whether gastric autoantibodies were specifically related to any of the clinical presentations, ABG patients were classified on the basis of their positivity for PCA alone, for IFA alone, and positivity and negativity for both antibodies. However, no specific pattern of autoantibodies was related to the clinical presentations of ABG (data not shown).

Nevertheless, the presence of the "spared" antrum, a typical histological aspect of autoimmune gastritis, was similar in ABG patients presenting with PA and IDA (46.1% and 43.8%, respectively), but lower (22.2%) in ABG patients presenting with dyspepsia, albeit statistical significance was not reached. Moreover, the positivity of PCA and IFA was equally distributed in ABG patients with the "spared" antrum and those with antral involvement (data not shown).

Table 1 Demographic, clinical, biochemical and histological findings and *H pylori* status in 140 patients with atrophic body gastritis (ABG)

Characteristics of ABG patients with positive gastric autoimmune antibodies

Among the 140 ABG patients, 99 (70.7%, 32 males, 67 females, median age 54 years, range 22-83 years) had a positive PCA titer. However, no significant differences were observed between PCA positive and negative ABG patients in any of the following parameters: age, fasting gastrin and pepsinogen I levels, clinical presentation, stimulated acid secretion, and associated autoimmune diseases (data not shown).

In contrast, IFA were positive in 49 of the 140 ABG patients (35%, 18 males, 31 females, median age 58 years, range 26-83). The median level in IFA positive patients was 7.5 U/mL (range 2.1-40 U/mL) *vs* 0.8 U/mL (range 0-1.95 U/mL) in IFA negative patients ($P<0.0001$). Clinical, serological and histological features of IFA positive and negative patients are shown in Table 2. Male/female ratio, age, and the presence of associated autoimmune diseases were similar in IFA positive and negative patients. Among the 25 ABG patients with autoimmune diseases, only 10 (40%) had positive IFA levels: 5 of them with PA, 4 with IDA and 1 with dyspepsia.

Table 2 Demographic, clinical, biochemical and histological findings in 140 patients with atrophic body gastritis (ABG)

	IFA positive	IFA negative	*P*
Demographic and clinical features			
Patients (%)	49 (35)	91 (65)	
Gender (M / F)	18 / 31	31 / 60	NS
Age, yr, median (range)	58 (26–83)	55 (22–78)	NS
Pernicious anemia, *n* (%)	32 (65.3)	33 (36.3)	*P* = 0.0013
Iron deficiency anemia, *n* (%)	12 (24.5)	45 (49.4)	*P* = 0.0042
Dyspepsia, *n* (%)	5 (10.2)	13 (14.3)	NS
Associated autoimmune disease, *n* (%)	10 (20.4)	15 (16.5)	NS
Biochemical features and gastric autoantibodies			
PCA positive[1], *n* pts (%)	39 (80)	70 (77)	NS
Gastrin (pg / mL) median (range)	500 (55–2.500)	405 (49–2.700)	*P* = 0.0579
Pepsinogen I (ng / mlL median (range)	5 (0–72)	10 (0–84)	*P* = 0.0027
Histological features			
Body atrophy score (mean±SE)	2.67±0.09	2.28±0.08	*P* = 0.0028

Antral atrophy score (mean±SE)	1.2±0.13	1.42±0.1	NS
Antrum spared, *n* (%)	22 (44.9)	37 (40.7)	NS
H pylori positive[2], *n* (%)	37 (76)	70 (77)	NS

[1]Parietal cell antibodies, [2]sum of *H pylori* positive patients at histology and at serology. NS = not significant.

Moreover, IFA positive patients had a significantly higher body atrophy score than IFA negative patients (2.67±0.09 *vs* 2.28±0.08, $P = 0.0028$). As far as the antrum was concerned, the presence of antral atrophy and the "spared" antrum as well as its histological score and its presence did not differ between the two groups.

As expected, the median value of fasting gastrin was higher and the median value of pepsinogen I was lower in IFA positive than in IFA negative patients ($P = 0.05$ and $P = 0.002$, respectively). IFA positive patients were more likely to present with PA ($P = 0.0013$ *vs* IFA negative, Fisher's test), while IFA negative patients presented more frequently with IDA ($P = 0.0042$ *vs* IFA positive, Fisher's test), even though 24.5% of IDA patients and 10.2% of dyspeptic patients had positive IFA levels. It is of interest that the distribution of PCA positive patients was similar between the IFA positive and negative patients.

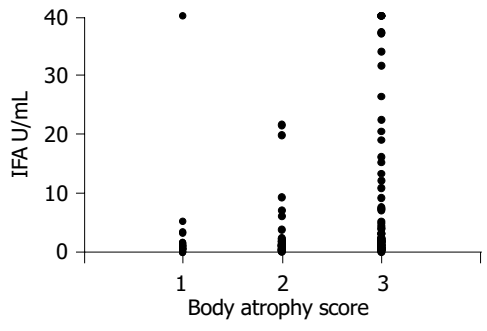

Figure 1 Correlation between histological score of body atrophy and level of intrinsic factor antibodies (IFA) in 140 patients with atrophic body gastritis ($r = 0.2216$, $P = 0.0085$, Spearman rank correlation).

Considering all the 140 ABG patients, there was a positive, statistically significant correlation between the histological score of body atrophy and the IFA levels ($r = 0.2216$, $P = 0.0085$, Spearman rank correlation), suggesting that the progression of oxyntic cell damage could lead to an increase in the production of IFA (Figure 1).

H pylori status and IFA

Among the 140 ABG patients, 33 (23.6%) were *H pylori* negative/negative (group I), 76 (54.3%) were *H pylori* negative/positive (group II) and 31 (22.1%) were *H pylori* positive/positive (group III).

IFA were found to be positive in 12 out of 33 (36.4%) group I patients, in 33 out of 76 (43.5%) group II patients, and in 4 out of 31 (12.9%) group III patients (Figure 2). The proportion of IFA positive patients were significantly higher in groups I and II than in group III (Fisher's test: $P = 0.043$ and $P = 0.003$, respectively). Also the mean level of IFA was significantly higher in groups I and II than in group III ($P = 0.01$ and $P = 0.004$, respectively).

The relationships between IFA positivity, *H pylori* status and clinical presentations observed in ABG patients are shown in Figure 3. The majority of IFA positive ABG

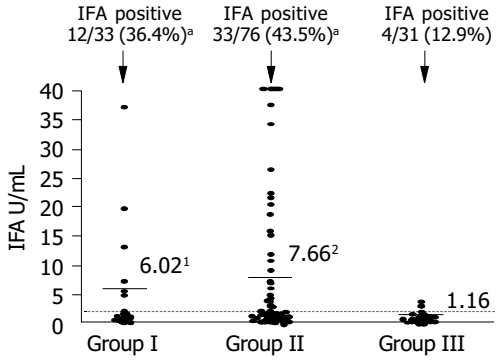

Figure 2 Intrinsic factor antibodies (IFA) in 140 patients with atrophic body gastritis. *H pylori* negative at histology and serology ($n = 33$), *H pylori* negative at histology and positive at serology ($n = 76$), *H pylori* positive at histology and serology ($n = 31$). Broken line indicates cut-off (>2 U/mL positive); bar indicates mean; [1]$P = 0.01$ *vs* group III; [2]$P = 0.004$ *vs* group III; [a]$P<0.05$ *vs* group III, Fisher's test.

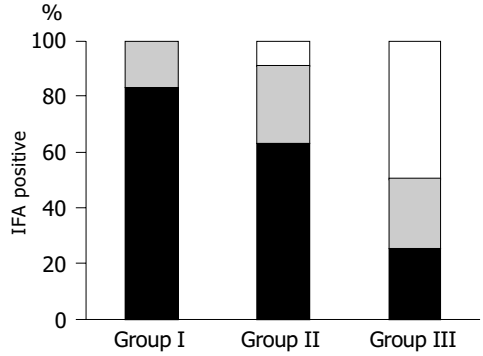

Figure 3 Distribution of clinical presentations of ABG with respect to positivity of IFA and *H pylori* status. *H pylori* negative at histology and serology ($n = 33$), *H pylori* negative at histology and positive at serology ($n = 76$), *H pylori* positive at histology and serology ($n = 31$). Diagonal lines = pernicious anemia; vertical lines = iron deficiency anemia; horizontal lines = dyspepsia.

patients had PA, and most of the PA patients were in the *H pylori* negative group. Albeit, at the same time, the positivity for IFA was not exclusive to PA patients, occurring in a considerable percentage of ABG patients presenting with IDA or even with dyspepsia. ABG patients with these two latter clinical presentations were mainly *H pylori* positive.

DISCUSSION

Two mechanisms are generally considered to induce body mucosa atrophy. On the one hand, the autoimmune pathogenesis of atrophic gastritis is well accepted, and PA is considered as its most characteristic clinical presentation[13,14]. On the other hand, it has been recognized that long-standing *H pylori* infection may induce atrophy of the oxyntic mucosa, which may clinically present with long-standing dyspepsia or IDA[11,15,26].

The main finding from this study is that gastric autoantibodies are present in ABG patients irrespective of the clinical presentations. In fact, the presence of gastric autoantibodies is not exclusive of pernicious anemia, but is also found in ABG patients with iron-deficiency anemia and dyspepsia. In particular, PCA are certainly present in the vast majority of ABG patients irrespective of the clinical presentations. In contrast, the presence of IFA is significantly higher in PA patients (50%), but is also detectable in >20% of IDA and dyspeptic ABG patients. In our opinion, the results obtained are due mainly to the original methodological approach to the diagnosis of ABG, which is based on a screening program for the early detection of this condition in patients with anemia and/or long-standing dyspepsia[11,12]. Thus, the study population comprises a wider clinical spectrum of this condition than in previous studies [8,9], thus avoiding a potential bias due to the *a priori*-selection of the patients. For example, in our study the prevalence of IFA, in all ABG patients, was relatively low (35%), but considering only those with PA, the positivity of IFA reached 50%, which is similar to that described in previous reports[3-7]. In the present study, the classification of ABG patients based on the absence and/or the co-existing positivity and negativity of IFA and PCA failed to identify any specific pattern of gastric autoantibodies related to the clinical presentations of ABG.

Another important finding from the present study was the positive correlation between IFA levels and the histological score of gastric body atrophy in ABG patients, suggesting that progression of the oxyntic mucosa damage leads to an increase in the production of IFA, as previously observed for PCA[15]. Thus, our findings suggest that the positivity of IFA and/or PCA may be an expression of the degree of oxyntic mucosa damage in each patient, rather than a specific hallmark of autoimmunity.

It is of interest, that one-third of the ABG patients with positivity for IFA do not have PA, but present with IDA and dyspepsia. In previous studies, IFA are considered highly specific for PA[8,9] and only appear once when PA develops, thus assigning them a pathogenetic role in this condition[27]. Furthermore, it has been recognized that in PA patients, the co-existence of iron deficiency can occur in up to 20% of patients at initial diagnosis and in another 20% of patients during a 2-year follow-up,[28], indicating that both cobalamin and iron deficiency may overlap during the failure of oxyntic function. On the other hand, in our ABG patients presenting with iron deficiency anemia or dyspepsia, the serum levels of vitamin B_{12} were relatively low (Table 1), suggesting the presence of "latent" pernicious anemia in a proportion of ABG patients. Thus, chronic oxyntic failure may be present with a variable spectrum of hematological disorders depending on the age at onset of the disease, and gender, as observed elsewhere[16,29].

The positivity of IFA, like the positivity of PCA in patients with ABG and PA, together with the association of autoimmune disorders, is considered to be a hallmark of the autoimmune origin of these conditions[1,2]. In our study, <20% of patients with ABG had associated autoimmune disease and <50% of patients with ABG and autoimmune disease were IFA positive, only half of them having associated PA. However, the presence of associated autoimmune disease was similarly distributed in ABG patients with PA, IDA, and dyspepsia. Thus, these findings further highlight that these characteristics, previously considered specific, are not reliable in defining a specific subgroup of patients with autoimmune ABG.

Furthermore, it is well known that autoimmune gastritis has no distinctive histological features[30]. The "spared" antrum is often considered to be associated with autoimmune gastritis, which in fact is generally body-restricted[31]. However, this histological finding is not peculiar to any of the clinical presentations of ABG (Table 1).

Taking *H pylori* infection into consideration, results of this study suggest a possible relationship between the positivity of IFA and the time course of *H pylori* infection (Figure 2). Indeed, at an earlier stage of *H pylori* infection, when the organism is still detectable by tissue staining, the proportion of IFA positive ABG patients and their median level of IFA are significantly lower than that of those patients presenting with a long-standing infection, in whom only immunological memory or even no sign of infection is detectable. These data show that there is a positive correlation between the progression of body atrophy and production of IFA, since it has been reported that evidence of *H pylori* infection disappears parallel to the progression of body mucosa damage[15,32].

In fact, in ABG patients, oxyntic mucosa damage may be triggered by *H pylori* infection[14,33], and may be, as a consequence, exposed to autoantigens on these damaged cells. In animal models, it has been shown that gastric autoimmunity could be the consequence of a local inflammatory response induced by the local expression of pro-inflammatory molecules[34,35]. This hypothesis is supported by the findings of Ma *et al*.[36], who have observed a positive correlation between PCA and *H pylori* antibodies in patients with PA. Furthermore, Claeys *et al*.[37], also showed a positive correlation between antibodies against H^+, K^+-ATPase and antibodies against *H pylori* in patients with PA, suggesting that mixed forms of bacterial and autoimmune gastritis might occur. Recently, it has also been reported that, in genetically susceptible individuals, *H pylori* infection may trigger the development of gastric autoimmunity via molecular mimicry[38]. Thus, these data suggest that the sole

autoimmune origin of ABG may be questionable, and that the role of *H pylori* infection, as an initial trigger of chronic damage to the oxyntic mucosa, should be taken into consideration, regardless of the clinical presentations of ABG.

In conclusion, the so-called hallmarks of gastric autoimmunity, particularly in IFA, cannot be usefully employed in defining an autoimmune pattern in the clinical presentations of ABG.

Abstract

AIM: To study the effects of indomethacin on the isolated transverse and longitudinal rat gastric fundus strips.

METHODS: The strips were suspended in an organ bath containing oxygenated Krebs solution, and contractile responses to electrical field stimulation were recorded on a physiograph in an isotonic manner after administration of cumulative concentrations of indomethacin. The effects of indomethacin on the strips pretreated with K_{ATP} channel modulators, diazoxide and glybenclamide were studied.

RESULTS: Treatment of the transverse strips with indomethacin resulted in a concentration-dependent inhibitory response. In longitudinal strips, biphasic responses were seen, which included a stimulatory response at low concentrations of indomethacin, followed by an inhibitory response at higher concentrations. Diazoxide pre-treatment inhibited the stimulatory response of longitudinal strips. Glybenclamide pre-treatment not only blocked inhibitory effect of the low concentrations of indomethacin on transverse strips, but also increased the amplitude of contractions. Moreover, the drug decreased the amplitude of contractions in longitudinal strips.

CONCLUSION: Responses of the isolated longitudinal and transverse rat gastric fundus strips to indomethacin are not similar, and are influenced by K_{ATP} channel modulators.

INTRODUCTION

Hypermotility of the stomach is proposed to be one of the mechanisms of the ulcerogenic action of indomethacin in rats[1-3]. It has been suggested that the stomach hypermotility plays a key role in the onset of the lesions, and the other factors are involved in the later extension of damage induced by indomethacin[2,4-6]. Ueki *et al*.[3], demonstrated that administration of atropine and 16,16-dimethyl PGE_2 suppressed gastric hypermotility and reduced gastric ulcerations. On the other hand, the K_{ATP} channels have also been shown to play a part in the pathogenesis of indomethacin-induced gastric ulceration[7-10].

In the present work, since our preliminary studies showed that indomethacin has relaxatory effects on the strips, we have studied the effects of different concentrations of indomethacin on contractile response of the isolated longitudinal and transverse rat gastric fundus strips stimulated by the electrical field stimulation (EFS). The effects of diazoxide as K_{ATP} channel opener and glybenclamide as the channel antagonist on the contractile pattern of the stomach were studied as well.

MATERIALS AND METHODS

Male Sprague-Dawley rats (160-200 g) were used. They were fasted overnight and killed by a blow on the head, followed by removal of the stomach through abdominal incision. Longitudinal and transverse strips of the gastric fundus were prepared as previously described by Milenov and Kalfin[11]. The strips were 4-5 mm wide and 15-20 mm long. Not more than four strips were prepared from each stomach. The strips were suspended under 1 g preload in a 20 mL organ bath containing oxygenated Krebs solution (113 mmol/L NaCl, 2.5 mmol/L $CaCl_2$, 4.7 mmol/L KCl, 25 mmol/L $NaHCO_3$, 1.1 mmol/L $MgSO_4$, 1.1 mmol/L KH_2PO_4, and 11 mmol/L glucose at the pH of 7.2). Pre-warmed water (37 ℃) was circulated through the outer

jacket of the tissue bath via constant-temperature circulator pump. The temperature of the Krebs solution in the organ bath was maintained within 37±0.5 ℃. The strips were allowed to equilibrate for approximately 45 min by the change of bath solution every 15 min. After stabilization of the tissue, EFS was applied via two platinum electrodes through which the preparation was surrounded by. Electrical impulses (rectangular waves, 50 V, 20 Hz, 1 ms for 8 s train duration with 100-s intervals between the trains) were provided by a modified stimulator (Harvard 6002, USA). The stimulus resulted in uniform strip contractions which were recorded via isotonic transducer and Universal Oscillograph (Harvard Apparatus, USA).

Cumulative concentrations of indomethacin (3×10^{-7} -2×10^{-4} mol/L) were added to the organ bath for evaluation of effects of indomethacin. In a series of experiments, the strips were pretreated with diazoxide (10^{-4} mol/L) or glybenclamide (4×10^{-6} mol/L) followed, 15 min later, by the administration of cumulative concentrations of indomethacin.

Drugs

All drugs were purchased as pure powder except diazoxide (aqueous solution). Tween 20 was used for the preparation of drug suspensions (indomethacin and glybenclamide). Drug concentrations were adjusted so that the volume of the added drug to the organ bath exceeds not more than 0.2 mL.

Statistical analysis

Each tissue was used for one dose-response curve. This was repeated with eight different tissues. The contractile response of each intact tissue to the EFS was considered as control (100%), and amplitude of the responses to different concentrations of drugs were compared with it. The means and SE for response to each concentration were calculated. Student's *t*-test and two-way analysis of variance with Newman-Keuls post hoc were used to test the statistical significance between different groups. Data were expressed as mean±SE. $P<0.05$ was considered statistically significant.

RESULTS

EFS produced uniform contractile responses in both longitudinal and transverse strips, which lasted for more than 100 min and were abolished following atropine treatment. Vehicle had no effect on contractions.

Strips response to cumulative concentrations of indomethacin

In the transverse strips, administration of cumulative concentrations of indomethacin (3×10^{-7}-2×10^{-4} mol/L) produced concentration-dependent decrease in amplitude of contractile response. The inhibitory effect of indomethacin started from the concentration of 3×10^{-7} mol/L and its maximum effect was obtained at the concentration of 2×10^{-4} mol/L. In the longitudinal strips, indomethacin, at low concentrations (3×10^{-7}-6×10^{-6} mol/L), increased the amplitude of contractile responses. The peak of increase was 14.1±3.14%. With higher concentrations (10^{-5}-2×10^{-4} mol/L), a decrease in contractile response was observed (Figure 1).

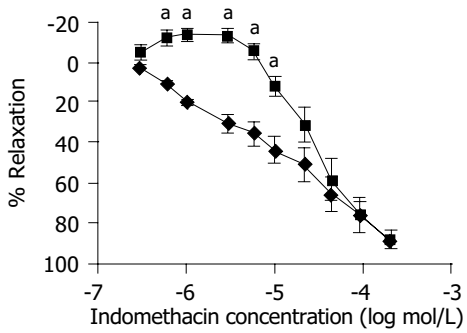

Figure 1 Cumulative concentration-response curves for the effect of indomethacin on EFS-induced contractions of transverse (◆) and longitudinal (■) rat gastric fundus strips. Each point represents the mean±SE of responses observed in eight strips. Relaxations are expressed as percentages of the amplitude of contractions induced in the same strip by EFS before drug treatment. The responses of transverse and longitudinal strips of rat gastric fundus for each concentration of indomethacin were compared. [a]$P<0.05$ *vs* EFS-induced contractions of transverse.

Effects of K_{ATP} channel modulators on responses to indomethacin

Pretreatment with diazoxide (10^{-4} mol/L), a K_{ATP} channel opener, 15 min before indomethacin administration showed no change in the response to indomethacin of transverse strip (Figure 2A). However, in longitudinal strips, "primary contractile response" was abolished and a continuous relaxation was seen following the administration of indomethacin. The concentration-response curve was shifted to the left and down and became similar to the transverse strip responses to indomethacin alone (Figure 2B).

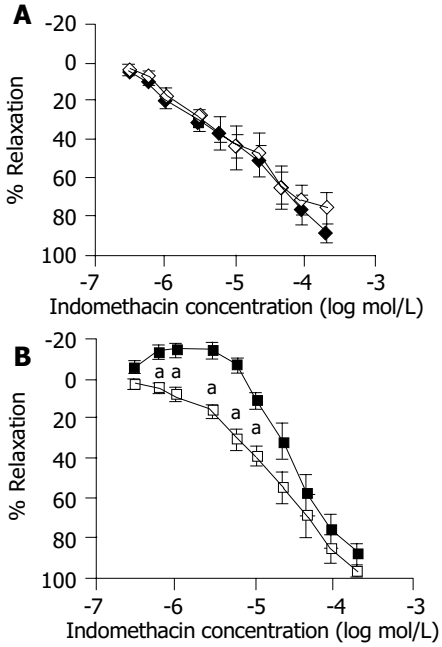

Figure 2 Effect of diazoxide (10^{-4} mol/L) on cumulative concentration-response curves for relaxant effect of indomethacin on EFS-induced contractions of transverse (**A**) and longitudinal (**B**) strips of rat gastric fundus. Each point represents the mean±SE of responses observed in eight strips. Relaxations or early contractions are expressed as percentages of the amplitude of contractions induced in the same strip by EFS before drug treatment. **A**: Responses of transverse strips of rat gastric fundus pretreated with diazoxide (◇) after administration of each concentration of indomethacin compared to saline-treated (◆) strips; **B**: responses of longitudinal strips of rat gastric fundus pretreated with diazoxide (□) after administration of each concentration of indomethacin compared to saline-treated (■) strips. [a]$P<0.05$ *vs* saline-treated strips.

Glybenclamide pre-treatment (4×10^{-6} mol/L) 15 min before indomethacin administration, not only prevented "acute inhibitory response" in transverse strips, but also increased the amplitude of contractile responses to indomethacin at concentrations of 3×10^{-7}-10^{-6} mol/L. The curve shifted to the right and up and became similar to longitudinal strip response to indomethacin alone (Figure 3A). Longitudinal strip responses to indomethacin decreased in the presence of glybenclamide, resulting in a shift to the left and down of the response curve and making the curve similar to the response curve of transverse strip to indomethacin alone (Figure 3B).

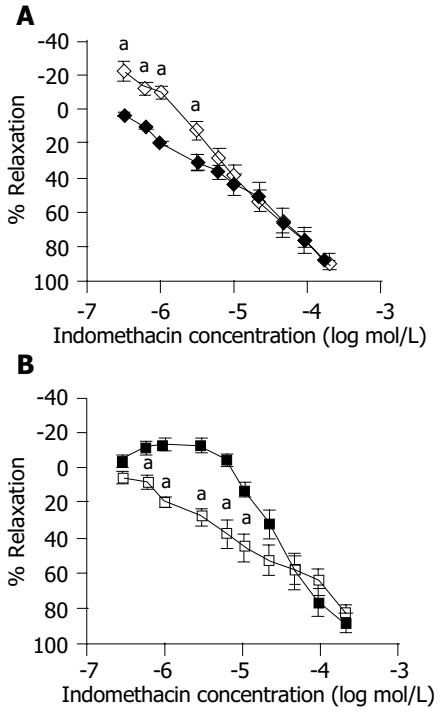

Figure 3 Effect of glybenclamide (4×10^{-6} mol/L) on cumulative concentration-response curves for relaxant effect of indomethacin on EFS-induced contractions of transverse (**A**) and longitudinal (**B**) strips of rat gastric fundus. Each point represents the mean±SE of responses observed in eight strips. Relaxations or early contractions are expressed as percentages of the amplitude of contractions induced in the same strip by EFS before drug treatment. **A**: Responses of transverse strips of rat gastric fundus pretreated with glybenclamide (◇) after administration of each concentration of indomethacin compared to saline-treated (◆) strips; **B**: responses of longitudinal strips of rat gastric fundus pretreated with glybenclamide (□) after administration of each concentration of indomethacin compared to saline-treated (■) strips. $^aP<0.05$ *vs* saline-treated strips.

DISCUSSION

Several mechanisms, including the hypermotility of the stomach, have been proposed to explain indomethacin-induced gastric ulceration[1-4]. Hypermotility may be due to the action of drugs on the CNS, or peripheral effects of indomethacin on the stomach nerves or muscles. In the present study, we have investigated the effects of indomethacin on the contractile responses of the isolated transverse and longitudinal strips of rat gastric fundus to myenteric plexus activation via EFS.

The fact that atropine prevented the EFS-induced strip contractions suggests that the contractions originate, at least in part, from the cholinergic system. According to the present results, the responses of transverse and longitudinal strips to indomethacin were not identical. In the transverse strips, the effect of indomethacin was inhibitory while in the longitudinal strips, the response to indomethacin was dependent on the concentrations of the drug. We observed an increase in the amplitude at the low concentrations, while a decrease in the amplitude at higher concentrations. Takeuchi *et al*.[1,2], and Ueki *et al*.[3], in *in vivo* studies, demonstrated that indomethacin administration resulted in a significant gastric hypermotility. In our experiments, contrary to the hypermotility reported by the aforementioned investigators, we observed relaxation of the strips after indomethacin administration. The reason for this discrepancy may be due to the fact that in the previous published reports, the effects of indomethacin have been studied in the intact animals (*in vivo*) while the present work is an *in vitro* study, independent of humoral and/or neural influences. It is possible that the reported results are the net effect of several different factors; some of them are not limited to the stomach and are systemic effects. Gastric motility is under the control of neural, humoral, and mechanical factors with stimulatory or inhibitory effects on the stomach contractility. The net results of these effects will determine the contractility of the stomach. The strip relaxation may be due to the inhibition of stimulatory prostaglandins (PGs)[12,13], L-type calcium channels[14] or phosphodiesterase 4[15].

The presence of the K_{ATP} channels has been demonstrated in the smooth muscles of the stomach[16]. The difference between the results obtained in transverse and longitudinal strips following indomethacin administration may be dependent on the state of K_{ATP} channels of the tissues. Opening of the channels by diazoxide, in the longitudinal strips, resulted in responses similar to that of transverse strips under indomethacin treatment. On the other hand, the administration of glybenclamide, a K_{ATP} channel antagonist, interestingly, changed the response of transverse strip to a response similar to that of longitudinal strips under indomethacin treatment. Altogether, these results are suggestive of the possible role played by K_{ATP} channels on the effects of indomethacin on the motility of the isolated rat gastric fundus strips.

The stomach is one of the sources of different types of PGs with stimulatory or inhibitory effects on contractility of the organ[17]. It has been known that indomethacin has inhibitory effects on the generation of PGs. On the other hand, the effects of PGs are known to be through their receptors[18]. Some PG receptors are only present in the longitudinal muscles[19]. This also may explain the difference between the results obtained in longitudinal and transverse strips as observed in our present study.

As shown in Figure 3, the stimulatory effect of indomethacin on the EFS-induced contraction of the longitudinal strip was abolished by both diazoxide and glybenclamide. These drugs have an opposing effect on K_{ATP} channels: diazoxide has an ability to open the channels while glybenclamide has an ability to inhibit the channels. Because K_{ATP} channel opener induces relaxation of smooth muscle through hyperpolarization, it is easy to understand the effect of diazoxide. However, glybenclamide causes depolarization through inhibition of K_{ATP} channels and results in activation

of the cell (contraction). Yet, this agent abolished the stimulatory effect of indomethacin on the EFS-induced contraction of the longitudinal smooth muscle. It seems that glybenclamide acts more than a K_{ATP} channel blocker, thus other possible mechanisms for this action of glybenclamide must be evaluated.

In conclusion, the pattern of response of transverse and longitudinal strips to indomethacin is not quite similar, which may be due to the involvement of K_{ATP} channels. However, the overall effect of indomethacin on EFS-induced contractions of the isolated strips of rat gastric fundus is an inhibitory action.

Abstract

AIM: To investigate coping mechanisms, constipation symptoms and anorectal physiology in 80 constipated subjects and 18 controls.

METHODS: Constipation was diagnosed by Rome II criteria. Coping ability and anxiety/depression were assessed by validated questionnaires. Transit time and balloon distension test were performed.

RESULTS: 34.5% patients were classified as slow transit type of constipation. The total colonic transit time (56 h *vs* 10 h, $P<0.0001$) and rectal sensation including urge sensation (79 mL *vs* 63 mL, $P = 0.019$) and maximum tolerable volume (110 mL *vs* 95 mL, $P = 0.03$) differed in patients and controls. Constipated subjects had significantly higher anxiety and depression scores and lower SF-36 scores in all categories. They also demonstrated higher scores of 'monitoring' coping strategy (14±6 *vs* 9±3, $P = 0.001$), which correlated with the rectal distension sensation ($P = 0.005$), urge sensation ($P=0.002$), and maximum tolerable volume ($P = 0.035$). The less use of blunting strategy predicted slow transit constipation in both univariate ($P = 0.01$) and multivariate analysis ($P = 0.03$).

CONCLUSION: Defective or ineffective use of coping strategies may be an important etiology in functional constipation and subsequently reflected in abnormal anorectal physiology.

INTRODUCTION

Functional constipation is a common problem in clinical practice. In the Western population, the prevalence was reported to be as high as 24% in elderly subjects and more commonly among women[1]. We observed a prevalence of 14% of constipation in Asian population[2].

There are growing interests in exploring the role of psychological factors on the pathogenesis of functional constipation. These patients report high levels of emotional distress[3-5]. Patients with functional constipation generally have a higher prevalence of anxiety, depression, and social dysfunction than do normal controls[6,7].

It has been reported that voluntary holding in healthy people can remarkably delay defecation and at the same time slow transit through the ascending colon and the recto-sigmoid tract[8]. This type of mechanism often produces constipation in children, which in some leads to constipation with megarectum-megacolon. This type of constipation can continue into adulthood as an acquired illness behavior[9]. In addition, a recent study[10] demonstrated that general psychosocial function, somatization, anxiety, depression, and feelings about the female role are impaired in women with constipation and are associated with altered rectal mucosal blood flow, which is an indirect measurement of the autonomic function. Furthermore, constipated subjects with slow bowel transit are associated with more psycho-social distress than those with normal bowel transit[11]. These findings suggest that behavior and psychological factors could lead to and be reflected by changes in anorectal physiology.

Drossman *et al*.[12], have proposed that life factors will later influence psycho-social experiences, physiological functioning or susceptibility to developing a functional gastrointestinal disorder, including functional constipation. These psycho-social factors include coping ability and social support and play a role in modulating the effect of stress[13,14]. Coping ability plays an important role in amelioration of the stressful events and behaviors[14]. Penley *et al*.[15], reported that coping ability was correlated with health outcomes.

Despite that psychological dysfunction in constipated patients is well reported, these patients have rarely been

subjected to systematic psychiatric and anorectal physiology study. In addition, their general coping ability has not been investigated. We hypothesized that stresses if not coped will be "internalized" and may lead to symptom expression and different clinical outcomes, as mediated through central nervous system/enteric nervous system pathways. Hence, patients with functional constipation have different coping mechanisms and stress levels from normal subjects, which might contribute to the pathogenesis of functional constipation. We examined this hypothesis by testing the stress level, coping strategies used and anorectal physiology in both constipated patients and healthy subjects.

MATERIALS AND METHODS

The 80 patients in this study were a consecutive group, referred for assessment of constipation. All 80 subjects had been assessed by a gastroenterologist and had chronic constipation, defined by the Rome II criteria as follows: At least 12 wk, which need not be consecutive, in the preceding 12 mo of two or more of: less than three bowel movements per week, straining at stool more than 25% of the time, passage of lumpy or hard stools more than 25% of the time, sensation of incomplete evacuation for more than 25% of the time, sensation of anorectal obstruction/blockage for more than 25% of the time and manual maneuvers to facilitate more than 25% of the time of defecation. In addition, loose stools are not present, and there were insufficient criteria for the diagnosis of irritable bowel syndrome[16]. Patients with associated medical conditions that might result in constipation (i.e. secondary causes) were excluded. In addition, patients with associated psychological illness and/or being followed up by a psychiatrist were also excluded from the present study. Eighteen healthy volunteers were recruited as controls.

The volunteers were recruited through advertisement. They were interviewed by the research nurse about their health status. They did not have any past chronic medical disease including gastrointestinal diseases. They were currently asymptomatic, did not attend any medical practitioners, and had not taken any sick leave or medication over the past 2 mo.

Assessment of bowel transit time

Normal and slow transit constipation were confirmed by X-ray and colonic motility studies performed in all 80 patients, who had been shown to have long-standing severe constipation. Colonic transit time was assessed through the use of radiopaque markers. In brief, four sets of distinctive radiopaque markers of different shapes and size (circle on d 1, semi-cylinder on d 2, dot on d 3 and cylinder on d 4) were ingested by the volunteers on 4 consecutive d. X-ray of the abdomen was taken on d 5 and 7 to assess the mouth to anal transit and segmental colon transit. Transit in the right, left, and recto-sigmoid colon was calculated by adding all markers seen in these regions on d 5 and 7. Slow total colonic transit was defined as >67 h, the mean transit plus 2SD averaged from published studies[17,18].

Rectal sensation

Balloon distension is used to detect the threshold for three common sensations, the first detectable sensation, the sensation of urgency to defecate and the sensation of pain. A commercially available anorectal catheter was connected with a terminal polyethylene balloon (Zinetics: Anorectal Replacement Balloons, one size). The rectal sensation was evaluated by sequentially inflating the rectal balloon with a hand-held syringe using the following volumes: 10, 20, 30, 40, 50, 60, 80, 100, 150, and 200 mL of air. Each inflation was maintained for 1 min after deflation, a rest period of 2 min was allowed before re-inflating the balloon. During this test, the volumes of air inflated were recorded at the following sensations: the first sensation, urge to defecate and the maximum tolerable volume[19].

Questionnaire measures

Psychological well being was assessed by anxiety and depression. The anxiety and depression were assessed by the multiple affect adjective check list (MAACL)[20]. A combined score of anxiety and depression (the MAACL score) was generated by adding anxiety and depression scores.

Coping questionnaire: The coping questionnaires were based on the extended version of Miller Behavioral Style Scale[21,22]. The questionnaire examined the frequency of use of different coping strategies with different controllable (C) and uncontrollable (U) situations. The coping strategies included monitoring, blunting, problem solving, distancing, ventilation, wishful thinking and social support. The questionnaire has been validated and demonstrated previously to have good internal consistency[22]. It was delivered by one investigator [NYHW] to allow consistency.

Outcome measurement: The outcome measurement was measured in terms of the quality of life. The quality of life was assessed by the Short Form 36 (SF-36) health survey questionnaire. The SF-36 is a 36 question survey, which is well tested, valid, and reliable self-report tool developed for use in the Medical Outcomes Study[23,24]. The SF-36 is scored so that higher scores represent better functioning on both the two summary measures and on all eight subscales.

This study was approved by the Ethics Committee of the University of Hong Kong.

Statistical analysis

Comparison between groups was made by Mann-Whitney *U* tests for the demographic, colonic transit and the anal rectal pressures, anxiety and depression scores and the coping scores. Scoring of the SF-36 was performed following the scoring algorithms found in the SF-36™ Health Survey Manual and Interpretation Guideline. The data from the SF-36 were expressed as mean±SE of the means. Spearman's rank correlation was used to assess for correlations between coping strategies, SF-36 and MAACL score. Regression analysis was performed for identifying independent predicting factors for anorectal physiology variables. A stepwise regression analysis was carried out. All statistical analysis was performed using SPSS software.

RESULTS

Demographic characteristics

There were 8 men and 72 women in the patient group and 8

Table 1 Transit time and anorectal physiological assessment in patients and controls (mean±SD)

	Control (n = 17)		Patient (n = 80)		P

Constant sensation / urge	63	20	79	30	0.019
Maximum tolerable volume	95	16	110	38	0.03

men and 10 women in the control group. The mean patient age was 42±16 years (range from 18 to 83 years) and that in the control group was 41±11 years (range from 25 to 64 years) (P = 0.7).

The mean duration of constipation in the patients was 7.2±8 years (range from 1 to 40 years). Sixty-five percent of the patients had straining for more than one quarter of the time, 57% had lumpy or hard stool, 82% had sensation of incomplete evacuation, 47% had anorectal blockade/ obstruction, 78% had fewer than three times of spontaneous opening per week, and 43% need digital evacuation. There were 34.5% patients classified as having slow colonic transit.

Anorectal physiology, anxiety, depression, coping strategies, and SF-36 scores in patients and controls

The readings of transit time and rectal sensation are summarized in Table 1. Transit time, including, left colon, sigmoid-rectal segment, and total colon, differed significantly in patients and controls (Table 1). Constipated patients also differed significantly from controls in the urge sensation and maximum tolerable volume in the assessment of rectal sensation (Table 2).

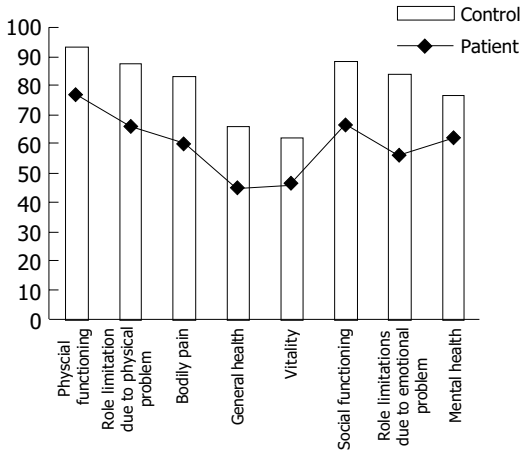

Figure 1 Self assessment of physical and mental health (SF-36) in patients and controls. Mean values of SF-36 scores for patients with constipation (line) compared with normal subjects (bar). Constipated patients differed from the normal subjects in all eight categories. They had decreased physical functioning scores (77 *vs* 93, P<0.0001), role-physical scores (66 *vs* 87, P = 0.009), bodily pain scores (60 *vs* 83, P = 0.001), general health scores (45 *vs* 68, P<0.0001), vitality scores (46 *vs* 62, P = 0.002), social functioning scores (67 *vs* 88, P<0.0001), role emotional scores (56 *vs* 84, P = 0.001), and mental health scores (61 *vs* 76, P = 0.003).

Table 2 Correlation between anxiety/depression (the MAACL score) and the scores of various coping strategies

Coping strategies	Correlation coefficient	P
Monitoring	0.2	0.9
Blunting	-0.05	0.6
Social support	-0.4	0.003
Controllable problem solving	-0.4	<0.0001
Uncontrollable problem solving	-0.3	0.03
Controllable catharsis	-0.3	0.009
Uncontrollable catharsis	-0.2	0.1
Controllable wishful thinking	-0.2	0.1
Uncontrollable wishful thinking	-0.2	0.3
Controllable distancing	0.1	0.7
Uncontrollable distancing	0.002	0.9

Anxiety and depression scores, and hence the MAACL score, differed significantly in patients and controls (34±8 *vs* 26±7 for anxiety score, P = 0.009; 32±7 *vs* 26±7 for depression score, P<0.0001; 66±14 *vs* 52±14 for MAACL score, P = 0.001). Constipated patients also differed significantly from the normal subjects in all eight categories of the SF-36 scores (Figure 1).

The correlation between the MAACL score and the scores of coping strategies are summarized in Table 2. Significant correlation was observed between the MAACL score and social support (P = 0.003), controllable problem solving (P<0.0001), uncontrollable problem solving (P = 0.03), and controllable catharsis (P = 0.009). The scores of coping strategies are summarized in Table 3. Patients with constipation had more frequent use (higher scores) of the 'monitoring' coping strategy than the controls, but no difference in the other coping strategies (14±6 *vs* 9±3, P = 0.001). When patients were stratified according to transit time, those with slow transit type of constipation had less frequent use (lower scores) of the 'blunting' coping strategy than other patients (7±3 *vs* 10±3, P = 0.01). When stratified according to rectal sensation, it was found that the use of the 'monitoring' coping strategy in constipated subjects correlated positively with the balloon volume at the first sensation (P = 0.005), the urge sensation (P =0.002), and the maximum tolerable volume (P = 0.035).

Multivariate analysis for predicting duration of constipation and anorectal physiology

Variables including sex, age, various coping strategies and

Table 3 Coping scores in patients and controls

Coping strategies	Patient (n = 80)		Control (n = 18)		P
	Median scores	Range	Median scores	Range	
Monitoring	14	3-27	9	2-15	0.001
Blunting	8	1-16	9	5-16	0.9
Social support	43	33-56	41	34-51	0.3
Controllable problem solving	6	1-11	6	1-12	0.3
Uncontrollable problem solving	5	1-11	5	1-9	0.8
Controllable catharsis	6	1-12	6	2-10	0.7

MAACL score were entered for the regression analysis for the prediction of symptoms of constipation. It was observed that female sex (P = 0.01) and age (P = 0.002) were the independent predictive variables for symptom of duration of constipation, despite that there were not enough men to comment on the predictive value of gender.

Variables including sex, age, various coping strategies and MAACL score were entered for the regression analysis for the prediction of anorectal physiology. We observed that the more often use of coping strategies of blunting (P = 0.03) predicted slow transit type of constipation. On the other hand, there was no significant independent predictive factor for rectal sensation.

DISCUSSION

High prevalence of emotional distress including anxiety, depression, and social dysfunction in patients with functional constipation has been well reported[6,7]. Our study further supported this observation and the observation was corroborated by objective evidence from anorectal physiology study. Emotional distress can cause physical problems but the reverse is also true: having a physical problem may cause distress. We examined the former link and at a higher level: by hypothesizing that defective coping mechanisms existed in patients with functional constipation and that defective coping mechanism subsequently led to internalization of stress and hence reflected as psycho-somatic disease such as functional constipation. Our study confirmed this hypothesis, showing that defective coping mechanisms existed in these patients and were independent factors for predicting abnormal anorectal physiology.

The present study demonstrated that coping strategies of monitoring and blunting were associated with anorectal physiology. Blunting (information avoiding coping style) has been shown to directly associate with the reporting of symptoms associated with infections like common colds and flu-like symptoms[25]. Similar finding was observed in the current study that blunting was directly associated with the slow transit type of constipation. "Monitoring" or information-gathering coping style was associated with more anticipatory anxiety[26]. Similar finding was observed in our present study that frequent use of monitoring coping strategy was found in constipation patients and associated with larger balloon volume at first sensation, urge sensation and maximum tolerable volume. These ineffective or less use of coping strategies are in accordance with the recent finding that constipated subjects have more social dysfunction and less satisfaction in their sexual life[6]. Testing for both controllable and uncontrollable situations, which were employed in the present study allowed for better assessment of the coping response because uncontrollable life events are better predictive of psychological distress over time[27]. Problem solving and catharsis are strategies that have been used to deal with a variety of stressful situations with different characteristics[15,28] and correlate with health outcomes[15]. Patients with functional dyspepsia have also been reported to have a non-discriminative, action-oriented coping style[29]. Hence we postulated that defective coping mechanism also exists and is an important etiology factor in patients with functional constipation. In addition, the defective coping strategy in the constipated subjects could not be explained by the associated anxiety and depression as there was no correlation observed in the current study between the MAACL score and the coping strategies of monitoring and blunting.

The current study again demonstrated significant anxiety and depression level in constipated patients, which has already been reported previously[2,4-7]. However, it is worth noting that the patients' anxiety and depression scores were relatively higher than individuals in the control group, rather than having absolute high levels in anxiety and depression. SF-36 scale, as a measurement of quality of life, has been demonstrated to be low in patients with functional constipation. This is again further confirmed in our study.

The limitation of our study was that the constipated patients were recruited in the hospital in the present study. Caution should be taken when attempting to generalize the present results to non-consulters. Another limitation was the small sample size of the normal controls. Taking into account the high prevalence of emotional and behavioral abnormalities in general population, a small control group could underestimate the real prevalence of psychological disorders in "healthy" volunteers. Nonetheless, our results suggested the role of defective coping mechanisms as another psychological factor in the pathogenesis of functional constipation. It is possible that failure to cope with stressful situation results in stress internalization and in turn leads to anxiety and other psychological distress. These are in accordance with the findings in this study that coping was associated with both physical and mental well being (SF-36)

as well as anxiety and depression. These distresses may act via the enteric nervous system to inhibit colonic motility and thus prolonged colonic transit, as demonstrated in the present study. This was supported by a recent study[10] demonstrating constipated subjects with psychological abnormality was associated with altered extrinsic gut innervation. Furthermore in cats, it has been demonstrated that stimulation of the pelvic nerves affects colonic contractions[30]. These findings suggest a link between central brain activity, enteric nervous system and gut dysfunction. The current study broadens our knowledge on the pathogenetic mechanisms of constipation and might provide clue to treatment, such as psychotherapy directing at the defective coping mechanisms.

Abstract

AIM: To compare the efficacy and toxicity of a three-step combination therapy with post-operative radiation alone for locally advanced esophageal cancer.

METHODS: Patients with T3-4 and N0-1 esophageal carcinoma from a number of institutions were non-randomly, prospectively enrolled in the study. All patients underwent single-stage curative en bloc esophagectomy. The patients were then assigned into one of two treatment groups based on treatment consisting of either post-operative concurrent chemoradiotherapy (CCRT) with weekly cisplatin 30 mg/m^2 followed by systemic adjuvant chemotherapy (four monthly cycles of cisplatin 20 mg/m^2 and 5-fluorouracil 1 000 mg/m^2 for five consecutive days), or, post-operative radiation alone. The radiotherapy dose was 55-60 Gy for all patients. Primary end-point of this study was to assess the per-protocol patients' improvement of overall survival benefit. Secondary end-point was designed to evaluate both the per-protocol and intent-to-treat patients' outcome of survival.

RESULTS: A total of 60 patients (n = 30 per group) were enrolled in this study. The two groups were generally comparable for demographic characteristics and hematological and non-hematological toxicities. The CCRT with weekly cisplatin was well tolerated, with significantly better overall survival (30.9 mo *vs* 20.7 mo; 95% CI, 27.5-36.4 *vs* 15.2-26.1) and 3-year survival (70.0% *vs* 33.7%; P = 0.003). Low histological grade of tumor (P<0.001) was associated with favorable survival in these locally advanced patients.

CONCLUSION: For locally advanced esophageal cancer, the combination of esophagectomy, post-operative CCRT with weekly cisplatin and systemic adjuvant chemotherapy is well tolerated and effective. A large-scale, prospective randomized trial of this regimen is in progress.

INTRODUCTION

Carcinoma of the esophagus often presents at a locally advanced stage. Even with aggressive surgical resection, however, the reported long-term survival rates remain sub-optimal[1]. From analysis of surgical specimens, it appears that a significant proportion of this disease involves regional lymph nodes[2]. In one inter-group comparison report, the local recurrence rate for complete resection was 31%, and the overall local failure rate was 61%[3]. Besides local recurrence, distant metastases of esophageal cancer are another common type of treatment failure.

Several studies have demonstrated that, compared with single modality treatment, a combination of chemotherapy and/or radiotherapy with surgery can improve local control and reduce distant metastases[4-9]. Although post-operative concurrent chemoradiotherapy (CCRT) is reportedly beneficial in terms of outcome in locally advanced diseases such as cervical[10], nasopharyngeal[11], gastric[12], and colorectal[13,14] cancer, by 1998, the role of this type of treatment in post-operative esophageal cancer remains controversial.

An important concern in multi-modal therapy is the greater prevalence of treatment-related complications. Previous CCRT trials for esophageal cancer were hospital-based and used moderate-high doses of cisplatin and 5-fluorouracil (5-FU) every 3-4 wk during the radiation course. This clinical experience shows that many people are unable to tolerate CCRT, especially after surgery[8,15]. It is important, therefore, to develop an effective but less-toxic CCRT regimen for these patients. In this study, we conducted a non-randomized, prospective, preliminary trial to evaluate the efficacy, toxicity and tolerance of a

postoperative CCRT regimen, using weekly cisplatin as a radiosensitizer. The subsequent systemic adjuvant chemotherapy was also included in this multi-modal treatment strategy to achieve systemic control.

MATERIALS AND METHODS

Study design and subjects

Between July 1999 and June 2002, patients with T3 to operable T4, N0/N1, and M0 thoracic esophageal cancer (TNM system[16]), were prospectively enrolled. Patients with adenocarcinoma of the esophagus were excluded from this study. Experienced pathologists diagnosed all the cancers as squamous cell carcinoma. None of the patients had any prior treatment for their cancer. Written informed consent was obtained from each subject, and the study protocol was reviewed and approved by the institutional review board of studying institutes.

Pre-treatment evaluation included a complete history, physical examination, assessment of ECOG performance status, serum chemistry profile and complete blood cell count, chest radiography, echocardiogram, endoscopy with biopsy, esophagogram with barium enhancement, endoscopic ultrasound, computer tomography, and abdominal ultrasonography. All patients were informed with respect to the differences between the two arms of treatment prior to surgery. This briefing included consideration of adjuvant therapy for the very probable advanced status, the benefits of adjuvant therapy, and unpredictable benefits or side effects from chemotherapy during CCRT. The patients were then non-randomly assigned to a treatment group by a central coordinated office composed with a multi-disciplinary team including chest surgeons, radiation oncologists, medical oncologists, gastroenterologists, and nutritionists after their eligibility was established. Patients were assigned to a treatment group. Grouping was done by cross-referencing.

Surgical intervention

The surgical procedures generally consisted of right-sided thoracotomy for en bloc esophagectomy followed by abdominal and left cervical approach for reconstruction of the esophagus using proximal gastrectomy and gastroesophagostomy via the extrapleural retrosternal route. En bloc resection defined sub-total resection of the esophagus along with bilateral 10-cm margin adjacent soft tissue, including all tissue behind superior vena cava, pericardium, and inferior vena cava, medial to aorta and azygous vein, and in front of the spine. For the upper third tumors, lowest 4-cm margin was accepted in order for later reconstruction. Abdominal dissection included removal of proximal one-third of the stomach, greater omentum, lymph nodes in the porta hepatic around the celiac axis, and retro-peritoneal lymph node-bearing tissue. Only sampling of cervical lymph nodes was done for all patients. All patients underwent remedial resection with a margin negative for malignant cells. Feeding jejunostomy and subclavian venous-access catheters were placed in all patients, as needed, for post-operative nutrition support and replacement of oral drug administration, respectively. All consenting patients were eligible for study if: ECOG performance status<2; serum albumin $\geqslant$30 g/L; serum creatinine level<15 mg/dL; absolute neutrophil count $\geqslant$2 000 cells/μL; and platelet count>10 000/μL. Patients who did not fulfill these criteria were excluded from the study.

Treatment protocol

Adjuvant therapy, consisting of either CCRT or radiotherapy (RT) alone, was begun 2-3 wk after surgery. RT for both groups was delivered by linear accelerator (Clinac® 1800; Varian Associates, Inc, CA) at 6 MV at 320 cGy/min. The initial 40 Gy dose was administered using a conventional appositional two-way technique, followed by a boost of 15-20 Gy using a 3D conformal treatment planning system (Clinac® 600C; Varian Associates Inc, CA). RT was delivered at 1.8 Gy/day for five consecutive days in a given week. Patients lay supine on a customized alpha cradle, with the tumor volume and surrounding nodes included within the RT field with longitudinal and lateral margins of 5 and 3 cm, respectively. The spinal cord dose was limited to 45 Gy.

In addition to RT, the CCRT group received concurrent chemotherapy consisting of six weekly doses of cisplatin (CDDP) (30 mg/m^2 intravenous injection over 2 h, with adequate hydration, mannitol and anti-emetic drugs) completed approximately 1 h prior to RT in the outpatient department. Adjuvant chemotherapy consisted of four monthly cycles of CDDP (20 mg/m^2 per d) plus 5-FU (1 000 mg/m^2 per d) for five consecutive days, beginning 3-4 wk after completion of CCRT. CDDP was administered as a bolus over 30 min, simultaneously started with the 5-FU continuously infused over 16 h, with adequate hydration and anti-emetic drugs.

Dose modification

Toxicity was evaluated using the common toxicity criteria published by the National Cancer Institute[17]. Both CDDP and 5-FU were held if the absolute neutrophil count was <1 500 cells/μL or the platelet count was <75 000 cells/μL. Both chemotherapeutic agents were given at 70% of the initial dose, if the neutrophils were 1 500-2 000 cells/μL or platelets were 75 000-100 000 cells/μL. RT was held only if the neutrophil level was <1 000 cells/μL or platelets were <50 000 cells/μL. For grades 3 and 4 oropharyngeal mucositis or diarrhea, the 5-FU was held until the symptoms improved. It was then restarted at 70% of the initial dose. For grades 3 and 4 renal toxicity, CDDP was held until the creatinine was <1.5 mg/dL. It was administered at 70% of the initial dose thereafter.

Patient follow-up and patterns of failure

Patients were assessed at 3, 6 and 12 mo, and then every 6-12 mo thereafter or more often, if clinically indicated. Evaluation included clinical examination, chest radiography, computed tomography, esophagography, abdominal sonography, bronchoscopy, and nuclear whole-body bone scan. Survival was calculated from the date of surgery to the most recent follow-up contact or to the date of death. The pattern of failure was defined according to the first site of failure evidenced by follow-up examination. Local failure included recurrence of the primary tumor or metastasis to regional lymph nodes. Distant failure included metastasis to any site beyond the primary tumor and regional

lymph nodes. After recurrence, the patients received any salvage therapy that was considered useful.

Statistical analysis

The two treatment groups were compared with respect to base-line characteristics, with the *t*-test and the χ^2 test used for continuous and categorical variables, respectively. Primary end-point was to assess the per-protocol patients' improvement of overall survival benefit. Secondary end-point was designed to evaluate both the per-protocol and intent-to-treat patients' outcome of survival. Estimation of sample size for each group was performed on the basis to detect an improvement in survival over a baseline survival rate (in literatures, about 10-15% in RT group) according to the investigation reported by Freedman[18]. The Kaplan-Meier method was used for the survival analysis[19]. Differences between survival curves were determined using the log-rank test[20]. The Cox multivariate proportional hazards model was utilized for simultaneous analysis to determine the effect of multiple factors on survival, with applying possible covariates from univariate analysis to the multivariate regression. Factors tested for univariate analysis included were performance status, tumor size, tumor location, disease stage, histological features and treatment group. SPSS 10.0 software (SPSS Inc., Chicago) was used for analysis of all the data. Statistical significance was assumed where $P<0.05$.

RESULTS

Patient characteristics

The sample population of 60 patients was evenly divided between the CCRT and RT groups. The most frequent symptom at diagnosis, present in over 90% of individuals, was dysphagia. Other common symptoms included weight loss, vomiting, choking with cough, and chest pain (demographic characteristics presented in Table 1). Both groups of patients received operation for resection of their tumor. Most of them were uneventful during the peri-operative course, except 7 patients had post-operative cervical anastomotic leakage, 4 in CCRT group and 3 in RT group.

Treatment outcome

Median patient follow-up at the commencement of the analysis was 18.0 mo (range 4-40). Patients in the CCRT arm received 5 580-5 940 cGy (mean 5 880 cGy). Of these 30 patients, 15 completed a full course of CDDP during the RT course, 10 had four weekly cycles of full dose CDDP, and 5 had less than four cycles of reduced-dose CDDP. All patients in the CCRT group received the planned dose of RT. After the CCRT, 15 of 30 patients completed the full course of adjuvant chemotherapy, while the others received less than four cycles at a reduced dose. The mean survival for these patients was 31.9 mo, with an estimated 3-year overall survival of 70.0%, and only nine deaths. Local regional failure occurred in 40% of the group and distant metastases in 27%.

Patients in the RT arm received 5 040-5 940 cGy of radiation (mean 5 832 cGy). Twenty-four of 30 patients received the full dose. Six patients went without full planned radiation due to poor tolerance (3/6), minor anastomotic leakage (2/6), and thoracotomy wound disruption (1/6). Mean survival time for the RT group was 20.7 mo, with a median of 11.0 mo for this arm, and 38.0 mo for those still alive at the end of the study period. The estimated 3-year overall survival was 33.7%. Local regional failure occurred in 60% of the group, and distant metastases in 57% (Table 2). The cause of death for all patients after surgery and the metastatic sites are presented in Table 3. A statistically significant difference was demonstrated comparing group survival times ($P = 0.003$, Figure 1).

Variance analysis

Multivariate factor analysis for overall survival revealed that CCRT treatment and tumor cell differentiation were significant predictors (Table 4). Significant and favorable factors for overall survival included CCRT treatment ($P = 0.003$, Figure 1A) and moderate-well differentiation ($P<0.001$, Figure 1B).

Complications and toxicity

The most prevalent treatment-related complications for the subjects were stricture over anastomosis (36%), chronic aspiration (33%), and pneumonia (20%). There were no CCRT-related deaths during treatment, or CT-related deaths during adjuvant chemotherapy administration. Six of the 30 CCRT patients had grade 3 hematological toxicity during

adjuvant chemotherapy, which required treatment modification. In the RT group, there were two treatment-related deaths secondary to upper gastrointestinal bleeding from ulcers. These two patients had grade 3 hematological toxicity, at the time of upper gastrointestinal bleeding. Renal toxicity was less than grade 2 in both groups. The most prevalent of the non-hematological toxic effects were nausea, dermatitis and esophagitis, with the rates comparable for the two groups (Table 5).

DISCUSSION

In comparison to surgery followed by RT alone, surgery with CCRT was associated with longer survival and higher 3-year survival rate. This not only corresponds with the findings of previous non-surgical randomized trials[7,8], but it is also in line with the outcome reported for post-operative combined modality treatment[4,5,15,21]. Most of our patients receiving CCRT had promising outcomes accompanied with acceptable and tolerable toxicity.

In the past, the overall 3-year reported survival rate for esophageal cancer remained below 35%, despite treatment with aggressive resection alone[15,22,23]. The outcome of locally advanced esophageal cancer is even less favorable, however, with no survivors from two samples of patients with either residual microscopic or macroscopic disease with single-modality treatment at 5 years[24-26]. In the study of

Sun *et al*., 44.5% of their patients had regional lymph-node involvement at the time of surgery. As to the treatment of esophageal cancer, a recent report with a systemic review and meta-analysis investigating the impact of neoadjuvant or adjuvant therapy on resectable thoracic esophageal cancer concluded that only surgery could remain the standard[23]. However, a few investigators have reported that adjuvant therapy may be beneficial after resection[4,5,15]. The role of chemotherapy and radiotherapy for locally advanced esophageal cancer still needs to be assessed. Teniere *et al*., have reported that post-operative RT improved local control in their sample, although it did not increase survival[27]. Rice[15] and Saito[21] have reported a significant survival advantage with adjuvant CCRT compared to adjuvant RT. This is in line with our results, where weekly CCRT followed by adjuvant chemotherapy resulted in a better 3-year survival than adjuvant RT alone.

The efficacy of adjuvant chemotherapy has been tested in this investigation because the principal cause of death from esophageal cancer is widespread dissemination. Although the Japanese Esophageal Oncology Group found no survival benefit from two cycles of adjuvant chemotherapy containing cisplatin and vindesine in their 1993 study[28], several years later they reported that two cycles of cisplatin and 5-FU after curative resection improved survival and decreased the incidence of distant and regional-node metastasis[29]. In the current study, four cycles of adjuvant chemotherapy were added to CDDP and 5-FU because the low weekly dose of CDDP during CCRT was included for its local radio-sensitizing effect rather than as systemic therapy. As only 27% of the patients in this arm of the study subsequently developed distant metastases compared to 57% in the RT arm, it seems reasonable to suggest that systemic adjuvant chemotherapy has a role in controlling distant metastasis. For the causes of death, it seemed a higher rate of non-cancer-related death in the RT groups, but most of the non-cancer-related causes were still from poor control of the tumor, local recurrence or distant metastasis. CCRT can get better control of the tumor and related death.

An important concern in CCRT is treatment toxicity. Although combined modality therapy improves outcome, it was reported to be associated with a higher incidence of toxicity. Coia *et al*., have reported a 56% incidence of moderate-severe acute toxicity with combined treatment[30]. Further, Herskovic *et al*., found that CCRT-treated patients had a higher incidence of acute grade 3 (44% *vs* 25%) and acute grade 4 toxicities (20% *vs* 3%) compared with RT alone[7], with only 50% of their sample completing all four cycles of chemotherapy. It may be that the concurrent use of 5-FU and RT in those studies caused significant mucositis and myelosuppression. To reduce toxicity while preserving the radiosensitizing effect of chemotherapy, we excluded 5-FU from the CCRT regimen and used low-dose cisplatin instead. Cisplatin is considered one of the agents most active against esophageal cancer, with single-agent response rate consistently 20% or more[31]. Most of our patients were able to tolerate this regimen during CCRT, with over 80% receiving more than four doses of weekly CDDP during radiotherapy and half tolerating a full course of adjuvant chemotherapy. The only grade 3 or 4 toxicity that occurred was hematological, however, it only affected relatively few patients (20% and 17% in the CCRT and RT group, respectively). Nausea, dermatitis and mucositis of the mouth, pharynx and esophagus were common, but tolerable and reversed after supportive care. Significant renal toxicity was not noted.

To our knowledge, there were no randomized reports that explored the effects and toxicity of post-operative CCRT. One pitfall of the current study is some of the patients receiving adjusted dosage of adjuvant therapy. However, it was for the safety of the patients. From the review of articles, we learned that uniform adjuvant treatments without individualized adjustment would sometimes do harm for patients[23]. Besides, another drawback of current study was non-randomized comparison. Some potential and unmeasured factors that might have influenced patient selection were subjective ones, such as vigor, mental status, ability to cooperate with and consent to treatment protocols, referral and physician bias, and the unblended nature of the treatments. During the process of grouping, our central office had attempted to assign patients through cross-referencing method to avoid selection bias as much as possible. In conclusion, this trial implies the result of superior outcome and reduced toxicity with this combination regimen. Another large-scale randomized, double-blinded clinical trial is in progress to verify the results of this study.

Abstract

AIM: To explore the effect of Gui Zhi decoction on enteric mucosal immune in type II collagen-induced arthritis (CIA) in DBA mice.

METHODS: Eighty DBA/1, weighing 18-22 g, were randomly divided into four groups with 20 in each group: control group, CIA group, treatment groups at high dosage and low dosage (GZH and GZL). CIA was induced by immunization with type II collagen (CII) emulsified with equal complete adjuvant at 0.1 mg CII each mouse. Blood lymphocyte suspension was screened for CD4 and CD8 expression using a flow cytometry, the CD4 and CD8 and secretory IgA (sIgA)-positive cells in enteric lamina propria tested with immunohistochemical staining. Tumor necrosis factor-alpha (TNF-α), interleukin-1 (IL-1)-β, and IL-6 concentrations in serum were assayed with RIA.

RESULTS: Gui Zhi decoction can lower the arthritic scores and decrease the occurrence of arthritis. The CD4, CD8, and sIgA-positive cells in CIA mice are less than in control mice, and in Gui Zhi decoction at high dosage could restore the lowered CD4- and CD8-positive cells in lamina propria, and at both high and low dosages could increase the lowered sIgA-positive cells in lamina propria, even still lower than in normal mice. In periphery, the CD4 cells in periphery are higher in CIA mice than in control mice, and Gui Zhi decoction at high and low dosages could decrease the CD4 and CD8 cells. Also, Gui Zhi decoction at high dosage could decrease the IL-6 and TNF-α concentration in serum.

CONCLUSION: Gui Zhi decoction can lower the arthritic scores and decrease the incidence of CIA in mice, and the mechanism is in part regulating enteric mucosal immune.

INTRODUCTION

Mucosal immune system is an integrated network of tissues, lymphoid and constitutive cells and effector molecules characterized by production of secretory IgA (sIgA), Th1- and Th2-type CD_4 T-lymphocytes responses and CD_8 CTL responses. It functions through protecting the host from infection of the mucous membrane surfaces, on the other hand, it can induct tolerance to the antigen in the food, and now it has become the focus of more and more scientists[1,2].

Gui Zhi decoction is a classical herbal preparation, and functions as regulating Ying and Wei in traditional Chinese medicine. It is commonly used as one of the therapies of rheumatic arthritis and rheumatoid arthritis[3]. While how the Gui Zhi decoction works in anti-rheumatic effect and how the enteric mucosal immune is involved in the mechanism is less clarified.

Collagen-induced arthritis (CIA) is a common animal model for auto-immune disease, special for the research on rheumatoid arthritis, since its pathology and immunology is similar to that in human rheumatoid arthritis[4]. In this paper, the effect of Gui Zhi decoction on enteric immune in CIA mice was explored.

MATERIALS AND METHODS

Animals

Total 80 DBA/1 mice, male, 8-10-wk old with a mean weight of 18-22 g were purchased from Research Institute of Experimental Animals, Chinese Academy of Medical Science. Mice were randomly divided into four groups in average: control group, CIA group, treatment groups at high dosage and low dosage (GZH and GZL). Mice were housed in a temperature-, humidity- and light-controlled environment with free access to rodent chow and water. The light-dark

cycle was 12:12 h with the light phase from 06:00 a.m. to 18:00 p.m. The rodent license of the laboratory (No. SCXK11-00-0006) was issued by National Science and Technology Ministry of China.

Induction of CIA and evaluation of arthritis

Soluble pure type II collagen (CII) was from Dr. Rikard Holmdahl (Lund University, Sweden) and complete adjuvant was purchased from Sigma Corporation, USA. CIA was induced by II collagen, dissolved in 0.1 mol/L acetic acid (2 mg in 1 mL) emulsified with equal complete adjuvant and 0.1 mol/L acetic acid. Each rat in CIA group and treatment group was immunized by injection of mixture (containing 0.15 mg CII) under fur skin at the left sole of the foot. Starting from 14th d after immunization, the degree of arthritis was examined every 2 d. The severity of arthritis was represented as mean arthritic index on a 0-4 scale according to the following criteria: 0 = no edema or swelling; 1 = slight edema and erythema limited to the foot and/or ankle; 2 = slight edema and erythema from the ankle to the tarsal bone; 3 = moderate edema and erythema from the ankle to the tarsal bone; and 4 = edema and erythema from the ankle to the entire leg. Each limb was graded, and thus the maximum possible score was 16 for each animal. A rat or mice with a score of 1 or more was regarded as arthritic.

Treatment of CIA with Gui Zhi decoction

Gui Zhi decoction recipe was a classical one, and consists of Ramulus Cinnamomi, Radix Paeoniae Alba, Rhizoma Zingiberis Recens, and Fructus Jujubae at the ratio of 10:10:7:10:10. The herbal mixtures were extracted by boiling water to the concentration at 1 g/mL. The dosage in GZH was at 30 g/kg (body weight) and in GZL at 8.75 g/kg. All the agents were orally administered in a volume of 0.8 mL/mouse. The animals in normal group and CIA group were administered with the same volume of saline. The admini-strations were conducted that started from 2 wk after the immunization, once a day and lasted for 4 wk.

Immunohistochemistry

The CD4-, CD8- and sIgA-positive cells in enteric lamina propria were tested by immunohistochemical staining method with the test kits. The staining process referred to the manuals for the products. Briefly, on d 36, animals were euthanized under anesthesia, and the mid-section of small intestine were removed and fixed in 10% paraformaline, embedded in paraffin, sectioned at 5 μm, then ice acetone fixed for 10 min. The first antibodies were rabbit anti-rat antibodies, and the second antibodies were goat anti-rabbit antibodies, and the samples were stained with DAB (Sigma, USA) and counterstained with hematoxylin. The positive granules can be observed. The positive granule averages of three samples (6 scopes in each sample) from Q-win DC100 image analysis were used for further statistical analysis.

Peripheral lymphocyte preparation and flow cytometry

The blood was sampled before the animals were killed, and suspended in tubes containing 25 μL heparin (5 000 IU/mL). The erythrocytes were lyzed in a buffer containing 0.84% NH_4Cl at pH 7.4 for 3-5 min. The remaining cells were then washed twice in saline. After washing in saline, the cells were resuspended and fixed in 500 μL saline. Blood lymphocyte suspension was screened for CD4 and CD8 expression using a flow cytometry. The mAbs used for CD4 staining were R-Phycoerythrin-conjugated OX-38 (BD Biosciences Pharmingen) and CD8a staining were Peridinin Chlorophyll-a Protein-conjugated OX-8 (BD Biosciences Pharmingen). Each sample of 0.1 mL peripheral lymphocyte or PP single-cell suspension was incubated for 30 min at 4 ℃ in the dark, with a solution consisting of 6 μL 0.01 mol/L PBS and an appropriate concentration of antibodies. After washing in saline, the cells were resuspended and fixed in 500 μL saline. The cells were then analyzed on a FACSort using the CellQuest software (Becton-Dickinson).

Radioimmune assay

Tumor necrosis factor-alpha (TNF-α), IL-1β, and IL-6 concentrations in serum were assayed using mouse cytokine RIA test kits (Wuhan Boster Biotech Inc., China). The assay was performed in duplicate according to the manufacturer's recommended procedures. The results of the radioactivity count were recorded by an automatic Gamma counter (SN-695B), and expressed as mean±SE of individual rat.

Statistical analysis

Using SPSS 10.0 software, ANOVA was used to determine significance in the data set. Student-Newman-Keuls test was employed for variables between both groups when equal variances assumed and Dunnett's *t*-test for equal variances not assumed.

RESULTS

Scores and incidence changes in different groups

Figure 1A shows the changes of arthritic scores in CIA group and Gui Zhi decoction-treated groups. Figure 1B shows the changes of arthritis incidence, and there is a significant difference in CIA group and Gui Zhi decoction-treated groups. These results demonstrate that Gui Zhi decoction can significantly lower the arthritic scores and decrease the occurrence of arthritis.

Expression of CD4-, CD8- and sIgA-positive cells in enteric lamina propria

The positive expression of CD4, CD8, and sIgA were shown as brown granules in the sections. Most of CD4-positive lymphocytes and sIgA-positive cells were located in lamina propria, and majority of CD8-positive lymphocytes were located in epithelial surfaces. Table 1 shows the positive-stained granules from six scopes under microscope, which represents the numbers of CD4- and CD8-positive cells. The results demonstrate that the CD4- and CD8-positive cells in lamina propria in CIA mice are less than in control mice, and in Gui Zhi-decoction-treated mice at high dosage and they are similar to that in the control mice. The results suggest that the enteric mucosal immunity to some extent was inhibited in CIA mice, and Gui Zhi decoction at high dosage could recover the mucosal immunity.

Table 2 shows that the sIgA-positive cells in lamina

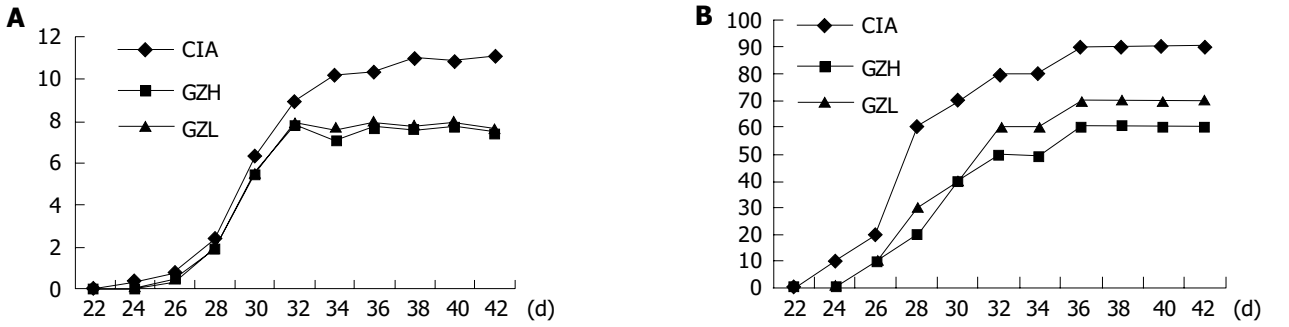

Figure 1 Arthritic scores in the different days after the immunization with CII. From the d 34 after the immunization, the arthritic scores were decreased in the mice treated with Gui Zhi decoction at both high dosage and low dosage (**A**); Incidence of CIA in different groups of mice. Gui Zhi decoction could lower the incidence of CIA (**B**).

propria in CIA mice are less than in control mice, and in Gui Zhi-decoction-treated mice they are similar to that in the control mice, but still lower than in control mice.

The results suggest that the enteric mucosal immunity was inhibited in CIA mice by showing decrease of the CD4 and CD8 cells in enteric lamina propria, and Gui Zhi decoction could recover to some extent the CD4-, CD8- and sIgA-positive cells in lamina propria, and further might recover the inhibition role of mucosal immunity.

CD4 and CD8 cells in periphery

Table 3 shows that the CD4 cells in periphery are higher in CIA mice than in control mice, the CD8 cells in CIA mice are similar to those in control mice. In the mice treated with Gui Zhi decoction at high and low dosages, CD4 and CD8 cells decrease.

DISCUSSION

Lymphoid tissue in the human body is associated with the mucosal system. Mucosa-associated lymphoid tissue includes gut-associated lymphoid tissue, bronchial/tracheal-associated lymphoid tissue, nose-associated lymphoid tissue, and vulvovaginal-associated lymphoid tissue, as the first barrier of the human body, protects the body from antigens entering along mucosal surfaces[5]. Functional disturbance of mucosal system may lead to autoimmune diseases or downregulation of immune function[6,7], which has some similarity with the function of "Ying and Wei" in traditional Chinese medicine.

The gastrointestinal mucosa is a vast interface between the body and the environment; it is the main entry site for many environmental antigens. The influx of multiple antigens through the gastrointestinal mucosa usually results in tolerance. High-dose tolerance is due to T cell deletion or anergy, whereas low-dose tolerance involves activation of TGF-β producing Th2 or Th3 cells. This intolerance effect has been used to try to induce oral tolerance. For instance, pre-treatment with oral bovine type II collagen has proved capable of modulating several models of experimental polyarthritis. Arthritis severity was considerably reduced[8]. Nasal admin istration of 10 μg of CII 15 times had the most prominent suppressive effects, reducing disease incidence by 50% and inhibiting both CII-specific IgG antibody and DTH responses[9].

The enteric immune cells could be considered to be the

effector cells in regarding to deal with food antigen, and also would be the inducer cells with regard to tolerance induction. However, what about the change of enteric immune in autoimmune is not well known. Our group reported a primary result on how Gui Zhi decoction affects on the numbers of enteric mucosal lamina propria CD4-, CD8- and sIgA-positive cells[10,11], and the results suggest that the enteric mucosal immune might involve the pathway of CIA in mice.

In this paper, the results show that Gui Zhi decoction can significantly lower the arthritic scores and decrease the occurrence of arthritis. The CD4 cells in periphery are higher in CIA mice than in control mice, and the results are similar to the previous study. In the mice treated with Gui Zhi decoction at high and low dosages, CD4 and CD8 cells in periphery decrease. The CD4- and CD8-positive cells in enteric lamina propria in CIA mice are less than in control mice, and in Gui Zhi-decoction-treated mice at high dosage they are similar to that in the control mice. The sIgA-positive cells in lamina propria in CIA mice are less than in control mice, and in Gui Zhi-decoction-treated mice they are similar to that in the control mice, but still lower than in control mice, suggesting that the enteric mucosal immunity to some extent was inhibited in CIA mice. The results suggest that the enteric mucosal immunity was inhibited in CIA mice by showing the decrease of the CD4 and CD8 cells in enteric lamina propria, and Gui Zhi decoction could recover to some extent the CD4-, CD8- and sIgA-positive cells in lamina propria, and further might recover the inhibition role of mucosal immunity.

The onset of arthritis in IL-6-/- mice was delayed for 2 wk compared with that in IL-6+/+ mice, and the severity of arthritis, as indicated by the arthritis score, remained significantly lower in IL-6-/- mice during the entire follow-up period (14 wk), although all IL-6-/- mice developed definite arthritis as did the IL-6+/+ mice. These findings suggest that blockade of IL-6 might be beneficial in the treatment of RA[12-14]. IL-1 and TNF-α play dominant roles in mediating the progression of many inflammatory joint diseases, including rheumatoid arthritis in humans, CIA in mice and rats, and adjuvant arthritis in rats. Treating autoimmune arthritic diseases with combinations of anti-IL-1 and anti-TNF molecules will achieve superior efficacy compared to the use of a single class of anti-cytokine agent and may allow for dose reductions that could prove useful in minimizing potential side effects[15]. In this paper, the results show that the IL-6, IL-1β, and TNF-α concentrations are higher in CIA mice than in control mice, and after being treated with Gui Zhi decoction at high dosage, the IL-6 and TNF-α concentration decrease comparing to the concentrations in CIA mice.

In conclusion, Gui Zhi decoction could lower the arthritic scores, and regulate the enteric mucosal immune, and the results indicate that the enteric mucosal immune might involve in the pathogenesis of CIA, and also it might be an important target for anti-rheumatic therapy. However, more detailed studies on how enteric mucosal immune are involved in the pathogenesis of CIA, and how the mucosal immune serves as a pathway for the treatment of CIA need further research works.

Abstract

AIM: To investigate the effects of entero-hepatic bile acid circulation on the inter-digestive migrating myoelectrical complex (MMC) in rats.

METHODS: Thirty-two rats were divided into four groups. Three pairs of bipolar silver electrodes were chronically implanted in the antrum, duodenum and jejunum. Three groups of them were ligated around the upper part of common bile duct (CBD). The experiments were performed in conscious and fasting state. The gastrointestinal myoelectrical activity was recorded. Ursodeoxycholic acid (UDCA) and saline were then perfused into stomachs of two groups with CBD obstruction and the effects of them on the MMC were observed.

RESULTS: A typical pattern of MMC was observed in normal fasting rats. MMC of antral and duodenal origin disappeared temporarily in earlier stage of CBD obstruction. While MMC of jejunum origin appeared. increased MMC cycle duration was seen after 4 d in rats with CBD obstruction. The MMC after CBD obstruction was characterized by an increased duration of phase II-like activity and decreased duration of phase I & III activity. Perfusion into stomachs with UDCA resulted in a shorter MMC cycle duration and a longer duration of phase III of duodenal origin compared to the normal group.

CONCLUSION: Entero-hepatic bile acid circulation initiates inter-digestive MMC of duodenal origin.

INTRODUCTION

Inter-digestive motility has been physically studied intensively[1-3], but mechanism is still unclear. Inter-digestive motility of gastrointestinal tract is characterized by a typical cycling complex of myoelectric activity. The migrating myoelectrical complex (MMC) is a distinct pattern of electromechanical activity observed in gastrointestinal tract during fasting. It serves as a housekeeping role and sweeps residual undigested materials through the digestive tract. Phase III MMC originates at variable sites in the gut from the esophagus to the proximal ileum, especially from antrum and duodenum[2,3].

Previous studies showed that entero-hepatic bile acid circulation and inter-digestive motility should be associated with each other[4]. Bile flow increases during phase II activity and reaches peak just before start of the MMC in the duodenum. It has been thought to exert an important regulatory function on the MMC[5]. Furthermore, phase III MMC plays an important role in the transport of bile acids from the proximal duodenum to the distal small intestine, where bile acids are absorbed for transport back to the liver. But use of different animal species and different methods has led to conflicting results[4-6].

In this article, we describes a new model which was used to further elucidate the role of bile acids in regulating MMC in unrestrained rats without the bias of anesthesia and post-operative influence on gastrointestinal motility. Therefore, the present study aimed to investigate the effects of common bile duct obstruction and UDCA perfusion into stomachs on the inter-digestive myoelectrical activity.

MATERIALS AND METHODS

Animals

Thirty-two healthy Sprague-Dawley rats (20 males and 12 females) weighing 200-250 g were fed with a dry food, with free access to tap water. After fasting for one night, the rats were intraperitoneally anesthetized with sodium pentobarbital (30 mg/kg). The hair on the skull and abdomen was shaved. The surgery was done under strict aseptic conditions. The abdominal musculature and peritoneum were opened through the linea alba. Three bipolar insulated silver electrodes made of Teflon-coated wire (outer diameter 0.5 mm, length 20 cm)

were implanted into the muscular layer of the bowel with a needle as a trocar. One milliliter of the wire was exposed near the implanted end, and the distance between pairs of electrodes should be 2.0-3.0 mm. The electrodes were placed on the gastric antrum 5 mm proximal to the pylorus, the duodenum and jejunum respectively 1 cm and 15 cm distal to the pylorus. The bundled electrode wires were grasped by the clamp through a silastic tube (diameter 2.4 mm), which was then passed through the subcutaneous tunnel from the abdominal incision to the back of the shoulder exit. Furthermore, 24 of them were ligated around the upper part of common bile duct (CBD). During operation, the intestine was kept moist with 9 g/L sterile NaCl solution, and 4 mL of this solution was used intraperitoneally to compensate for intraoperative fluid loss before closure of the abdomen. The abdominal wall was closed in three layers with running Vicryl 4-0 sutures. The rats were kept in a humidified room at 37 ℃ for 2 to 4 h after operation. Then, they were individually housed with free access to water and food. Housing conditions were at 22 ℃, 60% humidity and a 12 h light/dark cycle for 1 wk before experiment.

Gastrointestinal motility recordings

The rats were fasted for 12 h with free access to water. The gastrointestinal myoelectrical activity in conscious rats was recorded by a computerized, multichannel recorder (RM-6280C, Chengdu, China). Myoelectrical activity was sampled at a frequency of 1 kHz. The signals were amplified and bandpass was filtered (above 0.3 Hz and below 100 Hz were cut off). The amplitudes of contractions were recorded as μV.

Experimental procedures

The rats were coded and randomly divided into four groups (groups A, B, C and D), 8 in each. Group A had implanted electrode; group B had implanted electrodes +CBD obstruction; group C had implanted electrodes +CBD obstruction+UDCA perfusion; group D had implanted electrodes +CBD obstruction+saline perfusion. Three days after operation, we started to measure the gastrointestinal motility every day for 3 d. During experiment, the gastrointestinal myoelectrical activity in each rat was recorded for 2 h at least. On the 4th d after operation, before the MMC of duodenal origin recovered, UDCA (Pharmaceutical Factory of Changzhou City) was dissolved immediately before use in 3 mL normal saline at a dose of 20 mg/kg and then perfused into stomachs of one group with implanted electrodes and CBD obstruction. After UDCA was used, the gastrointestinal myoelectrical activity in the rats was continuously recorded for more than 2 h. As a control, normal saline was given in another group with implanted electrodes and CBD obstruction. After the conversion from analog to digital, the signals were stored on optical disk for later analysis.

Statistical analysis

Data are shown for duodenum. All parameters such as MMC cycle duration, duration of phase III, mean amplitude and frequency of phase III were expressed as mean±SD unless otherwise stated. $P<0.05$ was considered statistically significant. One way analysis of variance was performed to compare the means of all variables among groups using software package SPSS 10.0. A comparison was made between two groups using LSD method. Variables could be transformed when they were not coincident with each other.

RESULTS

Inter-digestive and digestive gastrointestinal myoelectrical activity in rats with implanted electrodes

The gastrointestinal motility pattern in rats could mainly be divided into inter-digestive and digestive stage. The inter-digestive stage was characterized by cyclical phase III contractions of the migrating motor complex which occurred in the stomach and duodenum and migrated to the small intestine. The digestive state was characterized by sustained contractions in the gastric antrum and small intestine. In our experiments, a typical pattern of myoelectrical activity in the fasting state appeared gradually in all rats with implanted electrodes about 3 d after operation. The phases of the MMC were as follows: phase I, motor quiescence; phase II, a period of irregular contractile activity; and phase III, a period of rhythmic contractions. The migrating motor complex pattern was disrupted by feeding, and irregular contractions were sustained in the antrum, duodenum and jejunum for 30 min after feeding (Figures 1 and 2).

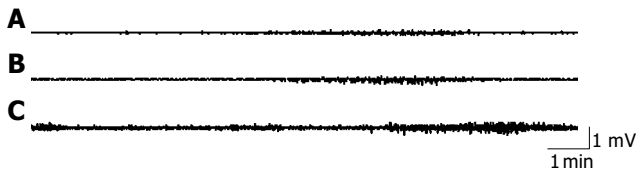

Figure 1 Inter-digestive gastrointestinal motility in antrum (**A**), duodenum (**B**), and jejunum (**C**) of rats with implanted electrodes.

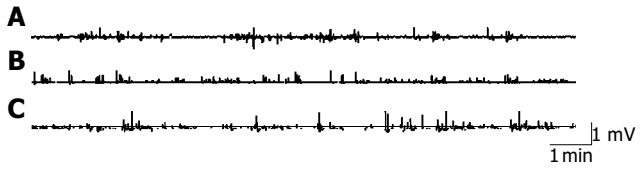

Figure 2 Digestive gastrointestinal motility shows sustained irregular contractions with relatively low amplitude in antrum (**A**), duodenum (**B**), and jejunum (**C**) of rats with implanted electrodes.

Interdigestive gastrointestinal myoelectrical activity in rats with CBD obstruction rats

Early after CBD obstruction regular MMC of duodenal origin disappeared, myoelectric activity was characterized by a continuous, irregular, low amplitude phase II-like activity without migrating activity fronts (Figure 3), while MMC of jejunum origin appeared. On the fourth day after CBD obstruction, MMC of duodenal origin started to recover gradually with a lower frequency. Five days after CBD obstruction, 74% of the MMC originated in the jejunum and 26% of the MMC originated in the duodenum. The MMC cycle duration of duodenal origin in CBD obstruction group was obviously longer than that in the group with implanted electrodes. The increased MMC duration was

mainly caused by increase of phase II-like activity. But the duration of phase III in CBD obstruction group was not significantly different from that of the group with implanted electrodes. There was no statistical difference between the MMC characteristics of jejunal origin in CBD obstruction group and the group with implanted electrodes.

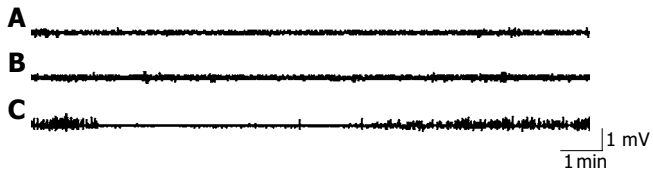

Figure 3 Inter-digestive gastrointestinal myoelectrical activity in antrum (**A**), duodenum (**B**), and jejunum (**C**) of rats with CBD obstruction.

Effects of UDCA on inter-digestive gastrointestinal myoelectrical activity in rats with CBD obstruction

Four days after control recordings were obtained in rats with CBD obstruction and no MMC of duodenal origin was observed. UDCA (20 mg/kg) was dissolved in 3 mL saline and perfused into stomachs of rats. The recording was continued for additional 2 h. The effects of UDCA on the inter-digestive gastrointestinal myoelectrical activity were established after the stomach was perfused with UDCA. Administration of UDCA led to a restart of duodenal MMC. The shorter MMC cycle duration and the longer duration of phase III of duodenal origin were observed. There was no significant difference in the other parameters of MMC of duodenum between the two groups (Figure 4, Table 1). Furthermore, there was no change in the interdigestive gastrointestinal myoelectrical activity of rats with CBD obstruction after normal saline treatment.

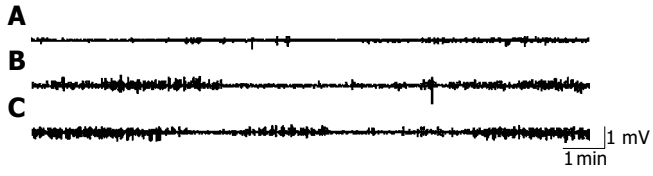

Figure 4 Effects of UDCA on inter-digestive gastrointestinal myoelectrical activity in antrum (**A**), duodenum (**B**), and jejunum (**C**) of rats with CBD obstruction.

DISCUSSION

The gastrointestinal motility pattern in rats can be divided into the inter-digestive and digestive states. The inter-digestive state is characterized by cyclical phase III contractions which occurs in antrum and duodenum and migrates to the small intestine. The digestive stage is characterized by sustained, irregular contractions in antrum and small intestine. These two phenomena were observed in our experiments. The migrating motor complex pattern could be disrupted by feeding.

The regulating mechanism of MMC is not completely understood[7-9]. Previous study showed that entero-hepatic bile acid circulation influences MMC and exerts an important regulatory function on MMC[10-12]. Our experiment showed that when entero-hepatic bile acid circulation was interrupted, spontaneous MMC in duodenum disappeared in early CBD obstruction. MMC originated mostly in the jejunum and migrated to the terminal ileum as a compensating mechanism. The duodenum showed continuous phase II-like activity. During the next 4 d after CBD obstruction, MMC of duodenal origin recovered gradually with a longer MMC cycle duration. The increased duration of MMC was mainly the result of an increase of phase II-like activity. UDCA perfusion into stomach resulted in a shorter MMC cycle duration and a longer duration of phase III of duodenal origin. But normal saline did not influence the MMC in rats with CBD obstruction. The underlying mechanisms for the absence of duodenal MMC during the interruption of entero-hepatic circulation are unknown. The possible explanation is that the development of MMC of duodenal origin is not autonomous but dependent on the stimulation of bile acids to the duodenum or the increased pressure in biliary tract[13]. Nieuwenhuijs *et al*.[14], thought that increased pressure in the biliary tract disrupts MMC early after CBD obstruction and the absence of bile in the duodenum and small intestine lengthens the MMC cycle. Ozeki *et al*.[15], thought that duodenum is not a spontaneous MMC oscillator which keeps resting below its oscillation threshold till a stimulus causes oscillation. However, the resting level of the duodenal MMC oscillator is close enough to its exciting threshold and sometimes may exhibit spontaneous oscillation. Artificial drainage of duodenal bile acids could also lead to increase of MMC cycle and phase II-like activity in healthy volunteers[16]. Thus, stimulation of higher bile acid concentration to the mucosa of duodenum in a short time is the prerequisite for the initiation of duodenal origin MMC[17].

Whether entero-hepatic bile acid circulation and intragastric bile salt infusion influence the MMC is still controversial. Some researchers supported the idea that there are no special effects of bile acids on inter-digestive MMC[18]. Luiking *et al*.[19], did not find any change of gallbladder emptying and small intestinal MMC when they perfused artificial bile into duodenum of healthy volunteers during inter-digestive stage. Van Felius *et al*.[20], found that prolongation of the MMC causes pancreatitis, and ligation of the proximal CBD near the bifurcation does not prolong the MMC, suggesting that pancreatitis influences the MMC cycle and hepatic biliary secretion alone does not play a primary role in the regulation of MMC. Some studies showed that initiation of MMC is closely related to the increasing

speed of bile acids in plasma. This may explain the conflicting results in the above researches[21,22].

Our model is suitable for studying the possible relationship between entero-hepatic bile acid circulation and inter-digestive gastrointestinal motility. At first, we ligated the CBD near the entrance to the duodenum. Almost all the rats died of pancreatitis. Ligation of the proximal CBD did not influence the function of pancreas. Post-operative gastrointestinal myoelectrical motility was measured in conscious state after the rats recovered from operation and could move freely. The advantages of this model are as follows. The surgical procedures are well tolerated by the animals. Experiments can be performed in unrestrained rats without the bias of sedative drugs, anesthesia and stress of operation. Ligation of the proximal CBD does not influence the function of the pancreas.

In conclusion, our model has made it easier and more precise to study the effects of CBD obstruction and UDCA on MMC in unrestrained rats without the bias of anesthetic agents or post-operative effects. Our findings indicate that that the entero-hepatic bile acid circulation initiates the inter-digestive MMC of duodenal origin, which provides a new therapy for patients with gut motility disorders.

Abstract

AIM: To develop a Brown Norway (BN) rat model to determine the potential allergenicity of novel proteins in genetically modified food.

METHODS: The allergenicity of different proteins were compared, including ovalbumin (OVA), a potent respiratory and food allergen, bovine serum albumin (BSA), a protein that is considered to have a lesser allergenic potential, and potato acid phosphatase (PAP), a non-allergenic protein when administered to BN rats via different routes of exposure (intraperitoneally or by gavage). IgG and IgE antibody responses were determined by ELISA and PCA, respectively. An immunoassay kit was used to determine the plasma histamine level. In addition, possible systemic effect of allergens was investigated by monitoring blood pressure.

RESULTS: OVA provoked very vigorous protein-specific IgG and IgE responses, low grade protein-specific IgG and IgE responses were elicited by BSA, while by neither route did PAP elicit anything. In either routes of exposure, plasma histamine level in BN rats sensitized with OVA was higher than that of BSA or PAP. In addition, an oral challenge with BSA and PAP did not induce any effect on blood pressure, while a temporary drop in systolic blood pressure in few animals of each routes of exposure was found by an oral challenge with OVA.

CONCLUSION: BN rat model might be a useful and predictive animal model to study the potential allergenicity of novel food proteins.

INTRODUCTION

Modern biotechnology has resulted in the introduction of a number of new proteins to foods, the potential allergenicity of these new proteins is a major concern in the safety assessment on genetically modified foods. The best known systematic approach for the assessment of the allergenic properties of novel proteins was called IFBC/ILSI decision tree, which was jointly developed by the International Food Biotechnology Council (IFBC) and the International Life Sciences Institute (ILSI)[1]. A universal, reliable and relevant *in vitro* or *in vivo* test to study the sensitizing potential of a new protein is, however, not available. Therefore, it is recommended that the development and validation of a widely accepted animal model should be the most direct approach to determine the sensitizing potential of a new protein. In 2001, FAO/WHO revised this decision tree and developed another one called FAO/WHO 2001 decision tree, in which animal models were included[2].

An ideal animal model should satisfy the following important criteria: sensitization and challenge should preferably be oral; preferably no use of adjuvants; the test animal should produce a significant amount of IgE antibody; the test animal should tolerate most food proteins; clinical reactions should be similar to those seen in humans; antibody responses should be directed to similar proteins as found in patient sera; and the model should be relatively easy to conduct and reproducible both in time and in different laboratories[3]. Several attempts have been made to develop animal models for food allergy research, mainly in mouse, guinea pig, and rats[4-6]. Some drawbacks limited the further use of the guinea pig in food allergy research, including significant differences in immunophysiology, limited knowledge of its immune system, and lack of tools to study its immune system. Studies in mice on oral protein administration without adjuvants readily resulted in tolerance induction[7]. For the rat, there are some advantages including the most commonly used species in toxicity testing, a reasonable amount of knowledge on its immune system, and many tools for immune-related studies. Studies have showed that the Brown Norway (BN) rat is a high-immunoglobulin (particularly IgE) responder strain[8,9].

There is some debate regarding the most appropriate route of administration. In theory, oral administration

appears to be the most attractive and relevant; however, it is well known that exposure of rats to proteins in this way can result in immunological tolerance. While parenteral administration of protein can avoid the development of oral tolerance but can provide a clear indication of inherent ability of proteins to induce IgE antibody responses. Therefore, FAO/WHO recommended that the results from two sensitization routes should be considered. FAO/WHO also suggested that the potential allergenicity of the expressed protein be ranked against well-known strong and weak food allergens and non-allergenic proteins in the animal models.

For these reasons, in the present study, the allergenicity of different proteins were compared, including ovalbumin (OVA), a potent respiratory and food allergen, bovine serum albumin (BSA), a protein that is considered to have a lesser allergenic potential, and potato acid phosphatase (PAP), a non-allergenic protein when administered to BN rats intraperitoneally or by gavage.

MATERIALS AND METHODS

Rats

Male BN rats, 4-6-wk old, were obtained from the Animal Center of the Chinese Academy of Medical Sciences (Beijing, China). The rats were housed in an animal room maintained at 24±1 ℃ and 50±10% relative humidity with the altering 12:12-h light-dark cycle. The animals were housed in stainless-steel wire cages in groups of five and had free access to milk and egg-free diet and water.

Allergens

OVA, a potent respiratory and food allergen, and BSA, a protein that is considered to have a lesser allergenic potential, were obtained from Sigma Chemicals, USA. PAP also purchased from Sigma was used as a non-allergenic protein.

Oral sensitization

Animals were randomly divided into three groups, 10 rats in each group. The rats were exposed by gavage to OVA, BSA, or PAP (1 mg protein/mL tap water; 1 mL/animal) respectively for 6 wk, without the use of an adjuvant. At weekly intervals, blood samples were obtained from the orbital plexus. Blood samples for IgG antibody and reagnic antibody analysis were centrifuged for 20 min at 2 000 r/min to obtain sera. Blood samples for plasma histamine level determination were collected into chilled tubes containing EDTA-K_2 to obtain plasma aliquots.

Intraperitoneal sensitization

Rats were randomly divided into three groups, 10 rats in each group. The animals were exposed intraperitoneally to OVA, BSA, or PAP (100 μg protein/mL tap water; 1 mL/animal) respectively on days 0 and 7. Animals were bled at weekly intervals from d 7 to 42. Blood samples for IgG antibody and reagnic antibody analysis were centrifuged for 20 min at 2 000 r/min to obtain sera. Blood samples for plasma histamine level determination were collected into chilled tubes containing EDTA-K_2 to obtain plasma aliquots.

IgG antibody analysis

Antigen-specific IgG was determined using an ELISA technique. Solution of OVA, BSA, or PAP (10 μg/mL) was bound to a 96-well microtiter plates (100 μL/well) overnight at 4 ℃. The plates were washed thrice with tap water containing 0.5% Tween 20. This was followed by the addition of 100 μL/well PBS containing 0.5% Tween 20 and 2% sheep serum albumin. After 1-h incubation at 37 ℃, the plates were washed and serial dilutions of rat serum were added to the wells and incubated for 1 h at 37 ℃. After washing, 100 μL/well peroxidase conjugated goat anti-rat IgG (H+L) (Zymed, USA) was added. After incubation for 1 h at 37 ℃, the plates were washed again and an enzyme-substrate solution of tetramethylbenzidine (Sigma, 100 μL/well) was added. The plates were developed at room temperature for 10 min. Finally, 100 μL/well of 1 mol/L H_2SO_4 was added. Optical densities were read at 450 nm with an ELISA plate reader. A pre-serum pool was used as negative control. The pooled pre-serum was measured at a 1:4 dilution. The average extinction in negative control wells, to which three times the standard deviation was added, provided the reference value taken to determine the titer in the test sera. Each test serum was titrated starting at a 1:4 dilution, and the reciprocal of the greatest serum dilution giving an extinction higher than the reference value was read as the titer. The titer $>2^5$ was considered as positive IgG antibody responses.

Reaginic antibody analysis

The presence of reaginic antibody was assessed by passive cutaneous anaphylaxis assay (PCA)[7]. Naïve BN rats were shaved on the back and flanks and injected intradermally with 0.1 mL of the test sera in serial dilutions followed 64 h later with an intravenous injection of 1 mL of 1:1 mixture of a solution of OVA, BSA, or PAP (5 mg/mL) and a solution of Evans blue (2% in sterile saline). After 20-30 min, the animals were examined for positive responses. The diameter of dye extravasation at the site of the serum injection was measured. The positive response was considered when a colored spot of at least 5 mm in diameter appeared.

Measurement of plasma histamine level

In order to evaluate the plasma histamine level, blood samples of rat were collected into chilled tubes containing 40 μL of 7.5% potassium ethylenediamine tetraacetic acid (EDTA-K_2) on d 7 after antigen injection or antigen exposure by gavage. After centrifugation, plasma aliquots were collected and frozen at -80 ℃ until use. Plasma histamine levels were determined using an immunoassay kit (IBL, Germany) following the manufacturer's instructions.

Measurement of blood pressure

Before challenge, individual baseline blood pressures were determined on two separate days. Prior to blood pressure measurements, the animals were placed under a heating light (30 ℃) for 20 min. Thereafter, an inflatable pressure cuff was put around the tail and a distal sensor was used to record the systolic blood pressure. The OVA, BSA, or PAP sensitized and control animals were challenged orally with 2 mL of a 5 mg/mL OVA, BSA, or PAP solution or 2 mL of tap water. Blood pressure was recorded at intervals for

over a period of 7 h.

Statistical analysis

Plasma histamine levels were compared among three groups by Student's *t*-test.

RESULTS

IgG antibody responses to antigen

During the whole study of either exposure routes, OVA and BSA provoked protein-specific IgG antibody responses, while PAP did not elicit protein-specific IgG antibody responses (Tables 1 and 2).

Table 1 IgG antibody responses to antigens exposed by oral gavage

Groups	Number of responders on day				
	14	21	28	35	42
OVA	10	10	10	10	10
BSA	5	7	8	8	6
PAP	0	0	0	0	0

Table 2 IgG antibody responses to antigens exposed by intraperitoneal injection

Groups	Number of responders on day				
	14	21	28	35	42
OVA	10	10	10	10	10
BSA	6	8	8	8	7
PAP	0	0	0	0	0

Reaginic antibody responses

Reaginic antibody responses determined by PCA were shown in Tables 3 and 4. Strong OVA-specific IgE antibody responses were provoked, only a limited BSA-specific IgE responders were observed and PAP did not elicit protein-specific IgE antibody responses.

Table 3 Reaginic antibody (IgE) responses to antigens exposed by oral gavage

Groups	Number of responders on day				
	14	21	28	35	42
OVA	8	8	9	9	8
BSA	2	3	3	3	2
PAP	0	0	0	0	0

Table 4 Reaginic antibody (IgE) responses to antigens exposed by intraperitoneal injection

Groups	Number of responders on day				
	14	21	28	35	42
OVA	8	9	9	9	8
BSA	3	4	4	4	3
PAP	0	0	0	0	0

Plasma histamine level

In either routes of exposure, plasma histamine level in BN rats sensitized with OVA was higher than that of BSA or PAP (Tables 5 and 6).

Table 5 Plasma histamine levels (oral sensitization)

Groups	Plasma histamine level (ng / mL)
OVA	44.4±12.5[a]
BSA	29.2±7.8
PAP	27.5±10.4

[a]$P<0.05$ *vs* BSA and PAP.

Table 6 Plasma histamine levels (intraperitoneal sensitization)

Groups	Plasma histamine level (ng / mL)
OVA	64.4±12.5[a]
BSA	36.2±9.6
PAP	30.0±6.9

[a]$P<0.05$ *vs* BSA and PAP.

Blood pressure determination

An oral challenge with BSA and PAP did not induce any effect on blood pressure, while a temporary drop in systolic blood pressure in three animals of each routes of exposure was found by an oral challenge with OVA. Representative results of blood pressure changes induced by OVA via oral sensitization or intraperitoneal sensitization are shown in Figure 1.

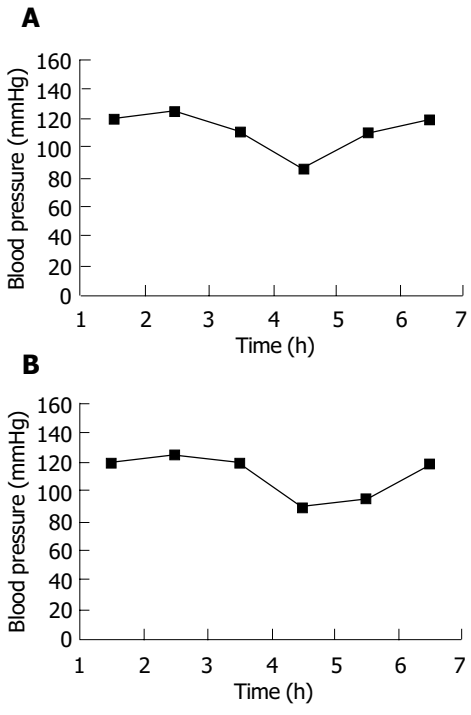

Figure 1 Changes of blood pressure in two representative rats. **A**: Oral sensitization; **B**: intraperitoneal sensitization.

DISCUSSION

Food allergy is an important health issue of growing interest. By definition, food allergy is an adverse reaction to a harmless food or food components that involves an abnormal response of the body's immune system to specific protein in foods. The most common type of food allergy is mediated by allergen-specific IgE[10]. Sensitization is induced by following exposure of the susceptible individual to the protein allergen sufficient to stimulate an IgE antibody response. If the now-sensitized individual is exposed subsequently to the same protein, then antigen cross-links specific membrane-bound IgE antibodies and this in turn causes mast cell degranulation and the release of inflammatory mediators such as histamine, cytokine, and so on, which together initiate the symptoms of food allergy[11,12].

Not all proteins display allergenic potential, despite being immunogenic (able to stimulate IgG antibody responses), proteins appear to differ markedly with respect to their ability to cause IgE-mediated allergic sensitization[13]. Therefore, in this study, IgG antibody response (antigen), IgE antibody response (allergen), histamine level (inflammatory mediators) and blood pressure (systemic challenge effects) were used as parameters to develop the BN rat model.

Collectively, our study has shown that BN rats, bred and raised on a diet free of the antigen to be tested, can be sensitized by daily dosing with the antigen via enteral route or intraperitoneal injection without use of adjuvants. However, there appears to be significant differences between the proteins examined with respect to IgE antibody response. By either route of exposure, OVA provoked very vigorous protein-specific IgG and IgE responses, low grade protein-specific IgG and IgE responses were elicited by BSA, while by neither route did PAP elicit anything. The same phenomenon was described in BN rats sensitized by daily intra-gastric administration of OVA, hen's egg white (HEW) and cow's milk (CM) proteins[14]. In that study, OVA provoked strong antigen-specific IgG as well as IgE responses in almost all rats, while only a limited number of IgE responders were observed in rats with HEW or CM. These results indicate that BN rats demonstrate IgE antibody responses to a comparable selection of proteins upon exposure of different proteins and support that the BN rat may provide a suitable animal model for assessing the allergenicity of novel food proteins and for research on the mechanisms of food allergy. For a more detailed characterization of the rat model developed, additional studies were performed to study the release of inflammatory mediators (histamine) and systemic immune-mediated effects (blood pressure).

Histamine is a potent mediator of numerous biological reactions. In the human organism, it is virtually ubiquitous in tissues and body fluids, being mainly stored in its inactive form in the metachromatic granula of mast cells and basophilic leucocytes. On release, histamine functions as a potent mediator of numerous physiological and pathophysiological processes in nearly all organs and tissues[11,12]. Histamine has been clearly implicated as a primary mediator of "immediate type" allergic reactions (IgE-mediated allergic sensitization). In this study, the plasma histamine level in rats sensitized by OVA was higher than that of BSA and PAP, which is consistent with the results of antigen-specific IgE responses. Also, other mediators such as platelet-activating factor, prostaglandins, leukotrienes and some newly formed cytokines release in anaphylactic reactions have been studied in experimental models.

The possible systemic effect was investigated by monitoring blood pressure. An oral challenge with BSA and PAP did not induce any effect on blood pressure, while a temporary drop in systolic blood pressure in some animals was found by an oral challenge with OVA. Although this effect was observed in only a few animals (around 30%), this low incidence is in agreement with observations from food allergic patients. The results indicate that systemic effects can be induced upon an oral challenge with allergens such as OVA.

In conclusion, although additional studies are needed with more purified strong and weak allergens, non-allergens, and allergenic whole foods, to further validate the developed BN rat model, the results obtained in this study indicate that BN rat model might be a useful and predictive animal model to study the potential allergenicity of novel food proteins.

Abstract

AIM: To examine the sensitivity and accuracy of real-time polymerase chain reaction (PCR) for the quantification of hepatitis B virus (HBV) DNA in semen.

METHODS: Hepatitis B viral DNA was isolated from HBV carriers' semen and sera using phenol extraction method and QIAamp DNA blood mini kit (Qiagen, Germany). HBV DNA was detected by conventional PCR and quantified by TaqMan technology-based real-time PCR (quantitative polymerase chain reaction (qPCR)). The detection threshold was 200 copies of HBV DNA for conventional PCR and 10 copies of HBV DNA for real time PCR per reaction.

RESULTS: Both methods of phenol extraction and QIAamp DNA blood mini kit were suitable for isolating HBV DNA from semen. The value of the detection thresholds was 500 copies of HBV DNA per mL in the semen. The viral loads were 7.5×10^7 and 1.67×10^7 copies of HBV DNA per mL in two HBV infected patients' sera, while 2.14×10^5 and 3.02×10^5 copies of HBV DNA per mL in the semen.

CONCLUSION: Real-time PCR is a more sensitive and accurate method to detect and quantify HBV DNA in the semen.

INTRODUCTION

Human hepatitis B virus (HBV) is the major epidemiological agent of acute and chronic hepatitis, cirrhosis, and hepatocellular carcinoma[1-3]. At present, around 10-15% of individuals (estimated 200 million people) are chronically infected with HBV in China, and HBV-associated hepatocellular carcinoma (HCC) has become the country's second most lethal disease.

One of the major HBV transmission pathways is parenteral[4,5]. HBV is therefore in most cases transmitted to individuals at birth or in the postnatal period by infected mothers, less commonly through close contact with infected fathers, siblings, and relatives during early childhood[2]. In developed countries, sexual transmission plays a major role in infecting individuals[3]. Mother-to-baby vertical transmission gives a large number of HBV carriers in China and other eastern Asian countries. It has also been reported that fetuses become infected in the uterus by their fathers as a result of transmission through sexual contact, although the mothers are negative for any HBV marker[6]. Therefore, the viral load in the semen or vaginal secretions is a very important parameter for safe sex and human reproduction.

Few attempts have been made to monitor HBV viral load in semen or vaginal secretions. Many people, especially in conservative Asian cultures, are reluctant to disclose information on their sexual habits, and unwilling to provide semen or vaginal secretions for epidemiological studies. When semen or vaginal secretions become available for study, they are in far smaller volumes than typical blood samples, and their viral titers are much lower than those of blood samples. These factors have hindered the progress of virological studies of reproduction-related body fluids. Although several methods have been developed for the detection of HBV DNA in semen[7-10], and HBV is routinely monitored when semen is screened for artificial insemination[11-13], the quantitative data produced have been disappointingly small. Southern blot has been used to estimate HBV viral load in semen in a study conducted 15 years ago[7], but no follow-up was made, probably because the work involved would have been tedious, time-consuming,

and possibly of limited accuracy. At present, there are still insufficient virological data to enable the risk factors for HBV infection through semen to be evaluated.

The sensitive quantitative real-time PCR (qPCR) provides an opportunity to investigate the viral load in the semen of HBV patients or carriers seeking assisted reproduction. The qPCR technology has greatly improved the precision of DNA quantification[14-16]. In this paper, we compared two different methods for the preparation of HBV DNA from HBV carriers' semen, and presented a TaqMan technology-based assay to quantify HBV DNA in semen. Our assay is highly sensitive, and theoretically suitable for quantifying most HBV genotypes.

MATERIALS AND METHODS

Sera and semen samples

The study was conducted in patients who were seeking assisted reproduction in Luofu Hospital, Shenzhen, in 2003 and 2004. In accordance with the standard protocols, all patients who received assisted reproduction were systematically screened for serum hepatitis B virus surface antigen (HBsAg), hepatitis B surface antibody (HBsAb), hepatitis B e antigen (HBeAg), and hepatitis B e antibody (HBeAb) with commercially-available enzyme immunoassays (Abbott Laboratories, Chicago, IL, USA). The recommended viral markers including human immunodeficiency virus antibody (HIV Ab), and hepatitis C antibody (anti-HCV) were also detected. Hepatitis B core antibody (HBcAb) was also systematically tested by RIA (Corab; Abbott). Semen HBV DNA was detected by PCR. All patients were tested with liver function tests (including serum alanine aminotransferase, serum albumin and bilirubin) before assisted reproductions were carried out. Five patients were selected for this study. Two patients were positive for HBsAg, HBeAg and anti-HBc, and their serum ALT levels were normal over 6 mo. Two patients presented HBsAb only. One patient with all HBV markers negative (s, e, and c antibody negative; s and e antigene negative) was selected as a control (Table 1). HCV or HIV was not detected by RT-PCR in these patients' sera. Patients were asked not to ejaculate for five days before semen samples were collected. Informed consent was obtained from all patients. Study procedures were approved by the Ethics Committee of Luofu Hospital and the Chinese University of Hong Kong. Each ejaculation was liquefied for at least 30 min at 37 ℃. The sperm concentration and percentage of motile spermatozoa were evaluated by Makler chamber, under a phase-contrast microscope. The serum and semen samples were stored at -20 ℃ until use.

Table 1 HBV status in sera of HBV carriers

Sample	Antigen-antibody test[1]					ALT[2]	Bilirubin
	HBsAg	HBsAb	HBeAg	HBeAb	HBcAb		
1	+	–	+	–	+	39.8	11.7
2	+	–	+	–	+	18.7	7.5
3	–	+	–	–	–	71.7	19
4	–	+	–	–	–	33.8	4.6
5	–	–	–	–	–	18.7	6.2

[1]HBsAg: hepatitis B surface antigen; HBsAb: antibody to HBsAg; HBeAg: hepatitis B e antigen; anti-HBe: antibody to HBeAg; anti-HBc: antibody to hepatitis B core antigen (HBcAg). [2]ALT: alanine aminotransferase. +Represents positive; – represents negative.

Isolation of viral DNA

The spermatozoa in the semen were removed by centrifugation at 3 000 *g* at 4 ℃ for 10 min. Different amounts of each seminal plasma (10, 50, and 200 μL) were used to isolate viral DNA by two methods. Viral DNA was isolated with QIAamp Blood Mini Kit (Qiagen, Germany) following manufacturer's instructions. In the case of a small amount of semen, up to 200 μL of PBS was supplemented to avoid loss of viral DNA. In the phenol extraction experiments, an equal volume of saturated phenol (Sigma, St. Louis, USA) was added to the samples, and vortexed for 1 min. After centrifugation at 13 000 *g* for 10 min, upper layer was transferred to a fresh tube and repeated the extraction with phenol-chloroform (1∶1). Then 0.1 volume of 3 mol/L potassium acetate (pH 5.2), 1 μL glycogen (1 μg/μL, invitrogen), and 2.5 volume of absolute alcohol were added to the extract, and frozen at -80 ℃ for 20 min. The viral DNA was then precipitated by centrifugation at 13 000 *g* for 10 min, and finally resuspended in 20 μL TE buffer. As a control, 200 μL of each serum sample was used to isolate HBV DNA.

Standard HBV DNA

A plasmid containing Chinese HBV genome (pHBV-adr), kindly donated by Professor Yuan Wang[17], was isolated by CsCl purification. The DNA concentration was measured by A_{260} and verified by agarose gel electrophoresis. The copy number was determined by its molecule weight.

Oligonucleotide design

Previously, we used commercial detection kits to quantify HBV DNA in the sera[17]. To develop cheaper reagents and cover more HBV genotypes, we designed a set of primers and probes for this study. Various HBV genotypes undergo rapid mutagenesis because their reverse-transcriptase (RT) lacks proof-reading functions. To obtain specific PCR primers, we aligned over 150 sequences representing all the HBV genotypes, and designed a pair of primers for amplification of the S gene (conventional PCR) and core gene (quantitative PCR). Sequence alignments were carried out with the default settings using the BLAST algorithm (www.ncbi.nlm.nih.gov). Primers were chosen to facilitate amplification of most HBV genotypes. To achieve this goal, degenerated primers were designed. The primer pairs 5'-AGACTCGTGGTGGACTTCTCTC-3' (forward) and 5'-AAGCCA(A/T/C/G)ACA(A/G)TGGGGGAAAGC-3' (reverse) were used for amplification of the S gene in conventional PCR experiments while primers 5'-CCTGGGTGGGAAGTAATTTGG-3' (forward), 5'-TTTTA(A/G)GCCCATATTAACATTGACAT-3' (reverse), and TaqMan probe 5'-FAM-AGACCCA-GCATCCAGGGAATTAGTAGTCAGC-TAMRA-3' were used to amplify core gene fragments in real-time PCR experiments. These primers could target different regions, thereby providing an important cross-check for the results.

Conventional PCR

Conventional PCR was used to detect HBV DNA in sera

and semen. The PCR reactions were set in 20 μL volume containing 100 mmol/L Tris-HCl (pH 8.0), 2.5 mmol/L $MgCl_2$, 1 unit of Taq DNA polymerase (Premega, Wisconsin, USA), 200 μmol/L each of the deoxynucleotide, triphosphates (dNTP), 1 μmol/L each of primers, and 1 μL viral DNA as template in each reaction. Thermal cycling included an initiation step at 94 ℃ for 3 min, followed by 40 cycles at 94 ℃ for 30 s, at 60 ℃ for 30 s, and at 72 ℃ for 60 s. Products were visualized on agarose gels after electrophoresis.

Quantification of HBV viral DNA in serum and semen by real-time PCR

Each 20-μL reaction contained 2 μL of sample extracts (template), 250 nmol/L of the probe, 900 nmol/L of each PCR primer, and 10 μL Master Mix (Roche, New Jersey, USA). PCR was performed using the ABI 7900HT sequence detection system. PCR cycling program consisted of an initial background eliminating step at 50 ℃ for 5 min and a HotStart activation step at 95 ℃ for 10 min, followed by 40 amplification cycles at 95 ℃ for 15 s, and at 61 ℃ for 40 s. The PCR products were further confirmed by electrophoresis loaded in 2% agarose gels. The experiments were repeated twice.

RESULTS

Detection of HBV DNA in sera and semen by PCR

To detect hepatitis B viral DNA in the semen, HBV DNA was isloated from 200 μL of semen using QIAamp blood mini kit. Viral DNA was also isolated from the sera to serve as a control. Conventional PCR was carried out to amplify a 480-bp of DNA fragment. A specific fragment was amplified from viral DNA templates isolated from both sera and semen of HBV carriers (Patients 1 and 2), indicating that hepatitis B viruses existed in the semen of HBV carriers (Figure 1). The bands amplified from serum DNA (lanes 2 and 4) were much stronger than those amplified from semen DNA (lanes 3 and 5), indicating that the viral titers were much lower in semen than in sera. No DNA fragment was amplified from the samples (sera and semen) from the patient with HBsAb only or without any HBV markers (Patients 3-5, data not shown).

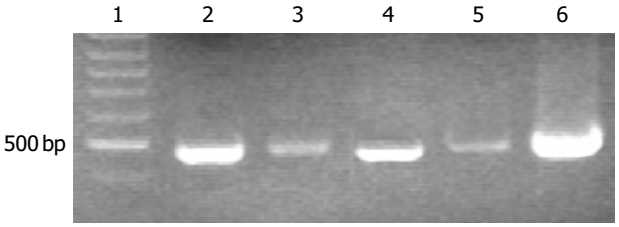

Figure 1 Detection of HBV DNA in sera and semen of HBV carriers by PCR. Lane 1: 100 bp DNA ladder; lanes 2 and 3: sera and semen of patient 1; lanes 4 and 5: sera and semen of patient 2; lane 6: positive control (pHBV plasmid).

Quantification of HBV DNA in sera and semen by real-time PCR

To test the performance of our primers and probes in real-time PCR, we used 10, 10^2, 10^3, 10^4, 10^5, 10^6, and 10^7 copies of HBV DNA[17]. Our results showed that amplification performance was good in all reactions (Figure 2A). A linear relationship was observed between 10 and 10^7 copies of HBV templates (Figure 2B). The viral titers in the sera and semen of patients were further quantified by real-time PCR. The consistent values of the qPCR were obtained by three independent qPCR (Table 2). We detected 7.56×10^7 copies of HBV per mL in the sera, but only 2.14×10^5 copies per mL in the semen of patient 1. Similar results were obtained from patient 2. We observed that the ratio of viral load in semen to sera was 0.3% in patient 1 and 1.8% in patient 2, respectively. The viral DNA isolations with different methods did not result in a statistically-significant difference (Student's *t*-test). As we expected, no viral DNA was detected in the samples from non-infected patients (patient 5) or from the patient with positive HBsAb only (patients 3 and 4).

To validate whether our methods could apply to low-volume semen samples, we isolated HBV DNA from 10, 50 and 200 μL of semen and quantified HBV DNA copies by real-time PCR. Again, all experiments produced consistent results (Table 3), indicating that our methods could indeed be used to quantify HBV DNA with low-volume semen samples.

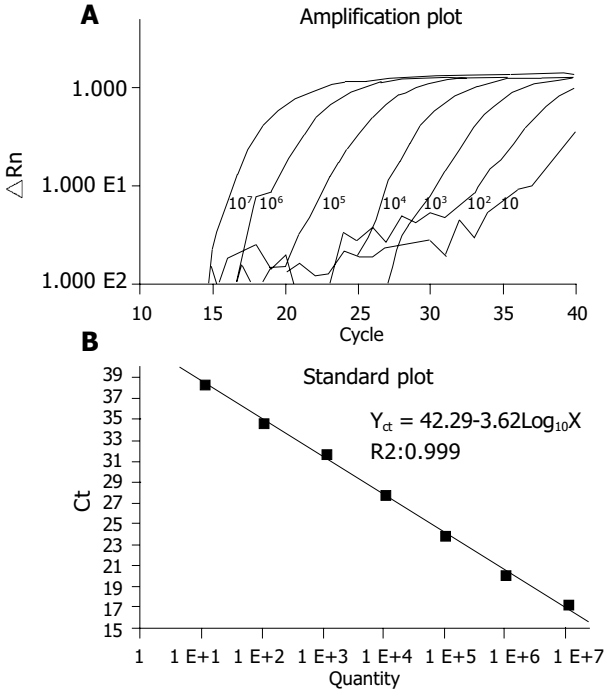

Figure 2 Real-time PCR profile. The amplification profile when 10-10^7 copies of HBV DNA were used (**A**) and standard curve (**B**).

DISCUSSION

In this study, we found that TaqMan technology-based real-time PCR assay could be used to quantify HBV DNA in semen. As this method is highly sensitive and reproducible, and has a wide dynamic linear range, it can be used to monitor HBV viral load in small samples of body fluids.

Table 2 Viral load in sera and semen of HBV carriers

Sample[1]	Method of HBV DNA Isolation	HBV DNA (copies / mL)[2]			Mean	SD[3]
		1	2	3

	Convention	2.38×10^5	2.56×10^5	2.74×10^5

The detection threshold of this assay is 10 copies of HBV DNA per reaction.

Traditionally, HBV in sera is monitored by antigen/antibody test, Dot blot, Southern blot, branched DNA assay, or hybrid capture test[2,18,19]. The minimal template requirement for these assays on blood is at least 7×10^5 copies of HBV DNA per millilter. The threshold of Roche Cobas RT-PCR commercial kit is 400 copies and that of New England DNA kit is around 100 copies. Due to sensitivity limitations, these requirements often give rise to problems in clinical settings. A large portion of HBV patients with undetectable viral antigens or viral DNA often relapse after the cessation of anti-HBV treatments[19], and for this reason real-time PCR has been recently introduced to monitor HBV viral load in sera[18,21]. In this study, we introduced real-time PCR method to quantify HBV DNA in semen of HBV carriers. Possible PCR inhibitors in the seminal extracts may cause false results. To exclude this possibility, we measured viral load from a sample extracted by different methods, as well as by the same method but with a different amount of samples. Our assay produced consistent reproducible results (Tables 2 and 3). These results indicated that this method is highly accurate and reproducible.

Theoretically, our quantification method may be used to quantify HBV DNA with multiple genotypes or mutants. Since HBV genome undergoes fast mutagenesis, the designed PCR primers may not match to a special HBV template or a mutated HBV template with reduced sensitivity. To make our assay applicable to most HBV genotypes, we aligned multiple HBV genome sequences containing most genotypes, and then designed primers targeting the most conserved core region. In addition, we defined the hot spot mutation sites in the HBV genome and designed degenerated PCR primers that could match the natural HBV templates or accumulated HBV mutations during anti-HBV treatment.

The use of TaqMan probe-based real-time PCR to quantify HBV DNA in body fluids has a number of advantages. Firstly, it is highly sensitive and accurate. As shown in Figure 2, as few as 10 copies of HBV template (corresponding to 500 copies of HBV DNA/mL semen) were sufficient to produce a marked amplification profile in the PCR reaction, and a wide linear range from 10 to 10^7 copies of HBV DNA was obtained. Real-time PCR can therefore be used to monitor HBV DNA in small samples of body fluid. Secondly, it has a low background. We noticed that there was no detectable HBV DNA either in the sera of non-HBV-carriers or in the semen of patients 3-5. When reaction and detection are carried out in the same reaction tube, the chance of contamination is greatly reduced. Thirdly, it could produce a very small number of false positive results. Positive results can only be obtained when PCR primers and molecular probes work in a small genomic element simultaneously. The chance of three specific primers targeting any other templates is very low. In our experiment, HBV DNA was not detected in the samples from non-HBV-infected patients. Fourthly, no PCR inhibitors were found in the semen, because consistent results were obtained from different DNA isolation methods. Finally, the method is quick and easy, and has a high throughput. A large number of samples can be simultaneously tested on a 96-well plate within 2-3 h. This is a particularly important consideration in clinical settings. There are about 200 million HBV carriers in China, and doctors need to know the HBV status of patients before medical treatments such as assisted reproduction, surgery, transfusion, and transplantation. These advantages make a popular way of quantifying HBV DNA in body fluids in the near future.

In summary, quantitative real-time PCR is a simple, sensitive, specific, and reproducible assay for the measurement of HBV viral load in semen. The viral load in body fluids, including semen and vaginal secretions, is an important parameter for the estimation of risk factor for HBV transmission through sexual contact.

Abstract

We experienced a very rare complication of colonoscopy, a migration of stiffening tube into the colorectum. We herein introduce a withdrawing method of migrating stiffening tube incidentally inserted into the colorectum. A 65-year-old Japanese woman underwent colonoscopy because of abdominal discomfort. We used stiffening tube to insert the scope to the proximal colon because of her redundant sigmoid colon. When withdrawing the scope, we realized that the tube was fully inside the colorectum. We could not remove the tube instantly, and it reached the splenic flexure, finally. We reinserted the scope through the migrating tube, straightened the scope, and withdrew it holding a slight angle of the scope over the proximal end of the tube. Then, we could safely remove the tube along with the scope through the anus.

INTRODUCTION

Colonoscopy is now performed as a screening exam or as a diagnosing procedure, when the patient has some clinical manifestations of colorectal diseases. Stiffening tube is a useful device sometimes used to facilitate the insertion of colonoscope into the proximal colon[1]. We experienced a very rare untoward event that stiffening tube was fully inserted incidentally into the descending colon, and then drawn out successfully through the anus. We herein introduce the safe and easy withdrawing method.

CASE REPORT

A 65-year-old Japanese woman visited our hospital because of abdominal discomfort. We performed colonoscopy (using the scope: Olympus PCF 240I) with the aid of fluoroscopy. Her sigmoid colon was very long and redundant and made a loop when inserting the scope into the descending colon. We removed the loop after reaching the splenic flexure, and then inserted the stiffening tube (Olympus ST-C6S; about 30 cm in length) over the scope gently. However, it was very difficult to advance the scope into the cecum, because her transverse colon was also long and ptotic.

When withdrawing the colonoscope from transverse colon to descending colon, we realized that the stiffening tube was fully inside the colorectum. The distal end of the tube was inside the rectum, so we removed the scope and firstly tried to grasp the tube by our digits through the anus, but failed. W then inserted the scope again and attempted to grasp by biopsy forceps or grasping forceps, but the stiffening tube migrated gradually into the splenic flexure finally (Figure 1A). We therefore reinserted another stiffening tube along with the scope and tried to connect with the migrated tube according to the previous report[2]. However, we could not connect the two tubes smoothly.

We reinserted the scope through the migrated tube until the proximal end of the tube (Figure 2). After we assured that the scope was straight by fluoroscopy, we made a slight angle of the scope over the proximal end of the tube (Figure 1B). We withdrew the scope very slowly holding the slight angle (Figure 3), and the stiffening tube was successfully removed together from the anus (Figure 1C). There were no mucosal damages after this procedure. She went home without abdominal pain or hematochezia after about 1-h rest.

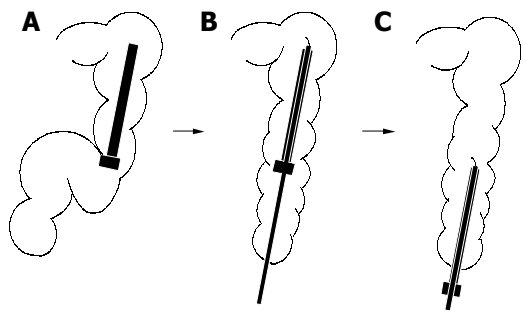

Figure 1 Schema shows our method briefly. **A**: The sliding tube was fully inserted into the descending colon incidentally; **B**: we reinserted the colonoscope through the migrating tube and made a slight angle; **C**: finally, we could remove the tube along with the scope by holding the angle of the scope.

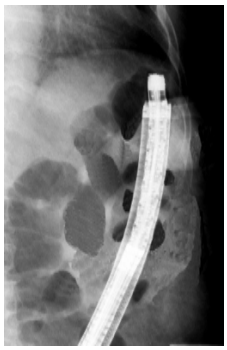

Figure 2 Abdominal X-ray shows that the oral edge of the stiffening tube reaches near the splenic flexure. We reinserted the endoscope through the tube.

Figure 3 We made a slight angle of the scope over the oral end of the stiffening tube and removed the scope gently.

DISCUSSION

Endoscopic examination has now been routinely performed for colorectal diseases or screening. The stiffening tube is an instrument to maintain the sigmoid colon straight, when endoscopists insert the scope into the proximal colon[1]. Colonoscopes have improved in design, and there are many scopes available including the variable stiffness colonoscope[3]. Although the stiffening tube is not necessary when using the variable stiffness scope, they have not spread yet all over the world.

We sometimes used stiffening tube when we have to use other scopes, especially for the patients who are thought to have long and redundant sigmoid colon. Some complications may arise by the insertion of the stiffening tube, for example, bleeding or perforation[4]. We experienced a very rare complication, migration of the stiffening tube into the colorectum. There was only one report of the migration of the tube so far[2]. They successfully drew it through the anus using a balloon-attached endoscope and another stiffening tube. We tried their method, but could not connect two tubes straight. There was also a risk that colonic mucosa was involved between two tubes by this method.

Anyway, straightening is necessary between descending colon and rectum when withdrawing the migrated stiffening tube. So we reinserted the colonoscope through the migrated tube, straightened the scope, and attempted to withdraw the migrated tube together with scope making a slight angle. It is necessary to make sure that there are no mucosal damages, after withdrawing the scope and stiffening tube.

When the stiffening tube was fully inserted into the colorectum, we recommended our method at first, before withdrawing the scope only and leaving the tube inside the colorectum.

Needless to say, it is most important that the distal edge of the tube is always grasped during colonoscopy to prevent complications like this.

Abstract

Peginterferon and ribavirin combination therapy for the treatment of hepatitis C virus (HCV) is well known to be associated with significant adverse effects. Sensorineural hearing loss, that in most cases is unilateral, has been reported as a consequence of therapy with both non-pegylated and pegylated interferon (pegIFN) but is not a well-known adverse effect. We report a 45-year-old Caucasian woman who developed acute sensorineural hearing loss 2 mo after starting therapy with pegIFN-α 2b and ribavirin for the treatment of chronic HCV, genotype 1a. She did not report the hearing loss to the hepatitis clinic until 1 mo, later whereupon therapy was promptly discontinued. Although her serum alanine aminotransferase (ALT) normalized and her HCV-RNA became undetectable after 12 wk of pegIFN and ribavirin therapy, after discontinuation, her HCV-RNA became detectable with significant elevations of serum ALT. Four months after initial discontinuation, the patient re-commenced pegIFN and ribavirin combination therapy. After 44 of 48 wk of therapy, the patient's liver biochemistry has normalized and the HCV-RNA is undetectable. She has not developed worsening of her hearing loss and hearing on the left-side is unaffected. Both patients and physicians should be aware that sensorineural hearing loss may occur with pegIFN therapy. Our experience suggests that re-institution of therapy is not always associated with further hearing impairment.

INTRODUCTION

Chronic hepatitis C affects an estimated 300 million people worldwide, and within Canada, the prevalence is estimated between 0.75% and 1.0% of the general population[1]. Treatment of hepatitis C virus (HCV) with interferon alpha (IFN-α) 2b and ribavirin therapy has been shown to be effective for many years now, with 41-47% of patients achieving a sustained virologic response[2-4]. With the current pegylated interferons (pegIFN) and ribavirin combination, overall sustained virologic response rates are reported to be 54-56%[5-7].

In spite of the current popularity of pegIFN and ribavirin therapy, many reported side-effects with standard IFN-α ARE also seen with pegIFN combination therapy. Flu-like symptoms such as fever, chills, muscle ache, nausea, vomiting, and fatigue are common side effects of treatment. Depression and related symptoms, such as anxiety, irritability, insomnia, and mental confusion, are not rare and may be significant in patients with a previous history. Common hematologic side effects that require monitoring include neutropenia and thrombocytopenia. Withdrawal rates in IFN-based combination studies due to side effects have ranged from 6% to 7%[4,8].

Although IFN-based therapy has been reported to affect any organ system, there have been occasional reports of sudden hearing loss while on IFN therapy[9-14]. We report a case of sudden unilateral hearing loss in a patient with HCV being treated with pegIFN and ribavirin combination therapy. The interesting aspect of our case is that pegIFN combination therapy was re-commenced at the patient's request, despite the reservations of the hepatitis clinic staff.

CASE REPORT

A 45-year-old Caucasian woman with chronic hepatitis C (genotype 1a) acquired 25 years previously after the administration of Rh immune globulin, developed sudden onset of right sided hearing loss 2 mo after beginning therapy with pegIFN-α 2b at a dose of 1.5 μg/kg per week subcutaneously (100 μg/wk) and ribavirin 1 000 mg/d (Pegetron, Schering-Canada, Point-Clare QC, Canada). Before treatment, she had no evidence of decompensated liver disease and her serum alanine aminotransferase (ALT) was 132 U/L (upper limit of normal <36 U/L). At the time of her acute unilateral hearing loss, she had completed a course of antibiotics for an otis media in the left ear. The right-sided hearing loss was described as a sudden onset of deafness followed by marginal improvement such that the

patient could hear a telephone dial tone and low-pitched sounds associated with tinnitus. She was seen in consultation by an otolaryngologist who reported that both middle ears were normal on visual inspection. Audiometric testing performed approximately 1 mo after the acute hearing loss was consistent with severe unilateral right-sided sensorineural loss. The patient's pegIFN and ribavirin combination was discontinued immediately after the patient's disclosure, to the hepatitis clinic, of the unilateral hearing impairment 1 mo after onset and 3 mo after commencement of antiviral therapy. Although her liver enzymes normalized and her HCV-RNA was undetectable (qualitative Cobas Amplicor HCV Test, Roche-Diagnostics Canada, Laval QC, Canada; lower detection limit = 10-15 IU/mL) after 12 wk of therapy, within 2 mo after discontinuation, the HCV-RNA was again detectable and her serum ALT flared to 267 U/L. Symptomatically, her unilateral hearing impairment did not improve further and she was advised not to continue with further anti-HCV therapy. Despite medical advice to the contrary, she re-commenced pegIFN and ribavirin therapy 4 mo after the initial discontinuation. After 44 wk of continued pegIFN and ribavirin therapy, her serum liver biochemistry has remained persistently normal (serum ALT = 16 U/L at mo 9 of therapy) and her HCV-RNA was undetectable at wk 24 of therapy. She has not had any left-sided hearing impairment although her right-sided hearing remains significantly impaired.

DISCUSSION

Side effects of IFN therapy for HCV have been well documented. However, acute sensorineural hearing loss is relatively rarely reported and not well known amongst those who provide treatment for HCV. Several cases were reported of sudden hearing loss in patients with HCV being treated with the previous standard of non-pegylated IFN-α2 therapy[10–13], presumably on the basis of focal small vessel vasculitis. One prospective study of 73 patients reported tinnitus and/or hearing loss in 32 patients (43.8%) during IFN therapy, and audiometry-documented sensorineural hearing loss in 27 cases (36.9%)[14]. These investigators reported that auditory disability frequently developed in the later stages of treatment, but most patients in this report recovered 7-14 d after the discontinuation of therapy.

More recently, Formann *et al*.[9], reported six cases of hearing loss that was associated with the current standard treatment of pegIFN and ribavirin combination therapy. In contrast to the study by Kanda *et al*., these authors reported that hearing loss did not fully resolve after discontinuation of the therapy with pegIFN but also did not worsen on continued treatment. Our patient developed unilateral sensorineural hearing loss that was associated with pegIFN and ribavirin therapy. Therapy was discontinued but subsequently re-instituted at the patient's request. Although the unilateral hearing loss was persistent, it did not worsen on re-treatment and bilateral hearing loss has not occurred.

We believe that sudden hearing loss as a side effect should be discussed, along with the other more commonly known side effects, with patients prior to being treated with standard or pegIFN therapy. We recommend that patients on interferon-based therapies should be monitored during treatment for changes in hearing perception. It remains possible that those who do develop sudden hearing loss can be continued on IFN therapy, if the risk-benefit ratio of treatment dictates.

Abstract

The anti-arrhythmic agent amiodarone (AD) is associated with numerous adverse effects, but serious liver disease is rare. The improved safety of administration of daily low doses of AD has already been established and this regimen is used for long-term medication. Nevertheless, asymptomatic continuous liver injury by AD may increase the risk of step-wise progression of non-alcoholic fatty liver disease. We present an autopsy case of AD-induced liver cirrhosis in a patient who had been treated with a low dose of AD (200 mg/d) daily for 84 mo. The patient was a 85-year-old male with a history of ischemic heart disease. Seven years after initiation of treatment with AD, he was admitted with cardiac congestion. The total dose of AD was 528 g. Mild elevation of serum aminotransferase and hepatomegaly were present. Liver biopsy specimens revealed cirrhosis, and under electron microscopy numerous lysosomes with electron-dense, whorled, lamellar inclusions characteristic of a secondary phospholipidosis were observed. Initially, withdrawal of AD led to a slight improvement of serum aminotransferase levels, but unfortunately his general condition deteriorated and he died from complications of pneumonia and renal failure. Long-term administration of daily low doses of AD carries the risk of progression to irreversible liver injury. Therefore, periodic examination of liver function and/or liver biopsy is required for the management of patients receiving long-term treatment with AD.

INTRODUCTION

Amiodarone (AD) is a cationic, amphophilic, iodinated benzofuran derivative primarily used for the treatment of refractory ventricular tachyarrythmias[1]. Although AD has been used since 1962, it causes various side effects affecting the lung, thyroid gland, cornea, peripheral nerves, and liver[1-3]. In early clinical trials, higher maintenance doses of AD (300-800 mg/d) caused serious side effects in the first year of therapy, and these patients required drug withdrawal[1-6]. In the last two decades, several investigators have shown that daily lower doses of AD (<200 mg/d) are better tolerated but still possess appreciable efficacy in serious cardiac arrhythmias[4-6].

The hepatotoxicity associated with AD is manifested as an asymptomatic and transient elevation of serum aminotransferase[2,3,6-8]. Fortunately, the vast majority of these events are reversible after discontinuation of the medication[2,3,6]. The safer schedule of administration of low doses daily may contribute to reducing the incidence of serious hepatic adverse effects. The histologic appearance of AD-induced liver disease shares several features with that of alcoholic hepatitis. Asymptomatic continuous liver injury by AD may increase the risk of step-wise progression of non-alcoholic fatty liver disease (NAFLD)[7-19]. This implies that severe morphological alterations of the liver may coexist with very mild symptoms in patients receiving long-term treatment with daily low doses of AD. We present herein an autopsy case of AD-induced liver cirrhosis in a patient treated with a low dose of AD daily for 84 mo. We discuss the risk of progression to irreversible liver injury during administration of AD and the value of liver biopsy for patients receiving long-term treatment with a low dose of AD daily.

CASE REPORT

A 85-year-old male with a history of ischemic heart disease

was being treated with AD for continuing symptomatic ventricular arrhythmias. He was admitted with cardiac congestion in December 2001, 7 years after administration of AD had begun. There was no history of alcohol abuse, obesity or diabetes mellitus. Serological screening and PCR examination for hepatitis viruses were all negative. There were no signs of autoimmune hepatitis. His initial dose of AD was 400 mg daily for 17 d, which was then reduced to a maintenance dose of 200 mg daily. The patient had received continuous medication with AD for 84 mo. On physical examination, corneal opacities were found. No skin discoloration or neuronal symptoms were seen.

Serum total bilirubin was 1.2 mg/dL, aspartate aminotransferase 81 IU/L, alanine aminotransferase 35 IU/L, alkaline phosphatase 452 IU/L, gamma-glutamyl transpeptidase 210 IU/L, lactate dehydrogenase 848 IU/L, and prothrombin time activity 59%. Up to that time, no elevation of serum aminotransferase or signs suggesting liver dysfunction had been observed.

The chest radiograph revealed cardiac enlargement and bilateral pleural effusion without findings of interstitial fibrosis. Abdominal ultrasonography showed enlargement of the left lobe of the liver relative to atrophy of the right lobe, and an irregular liver surface. In addition, ascites and mild splenomegaly were seen. An unenhanced computed tomography (CT) scan of the upper abdomen showed an abnormally high density of liver tissue [111.8 Hounsfield units (HU); normal range 30-70 HU] (Figure 1). A percutaneous liver biopsy examination revealed micronodular cirrhosis accompanied by findings of alcoholic liver disease (Figure 2). Fibrous septa containing proliferating bile ductules and neutrophil polymorphs connected adjacent portal areas (Figure 2). Scattered foci of hepatocellular necrosis with neutrophilic infiltration were observed (Figure 2). Electron microscopic observations showed that hepatocytes contained numerous lysosomes with electron-dense, whorled, lamellar inclusions (LI), characteristic of a secondary phospholipidosis (Figure 3). The findings of the CT scan and the liver biopsy indicated that AD-induced liver cirrhosis was responsible for the hepatotoxicity and his poor general condition. Administration of AD was discontinued. The total dose of AD administered over the 84 mo was 528 g.

Initially, withdrawal of AD led to a slight improvement in the serum aminotransferase level and the ascites. The CT density of the liver decreased to 97.2 HU in February 2002, whereas no significant improvement was observed in the size of the liver. Unfortunately, his general condition deteriorated as a result of complications of pneumonia and renal failure. He died in April 2002.

Autopsy was performed on April 22nd, 2002. Microscopically, features affected by AD were observed in the follicular epithelial cells of the thyroid gland and in the liver. Notably, there were no histological findings suggesting AD-induced pulmonary toxicity, which is more common and often more serious than hepatotoxicity, whereas both his lungs revealed congestion with pneumonic foci.

We compared the light-microscopic and electron-microscopic findings for the biopsy (December 2001) and autopsy (April 2002) materials (Table 1). Light microscopy of the autopsy materials also revealed micronodular cirrhosis. The biopsy material showed both microvesicular and macrovesicular steatosis, but the autopsy material showed only microvesicular steatosis. The number of hepatocytes with Mallory bodies was similar to that of the biopsy specimen. We counted the number of lysosomes

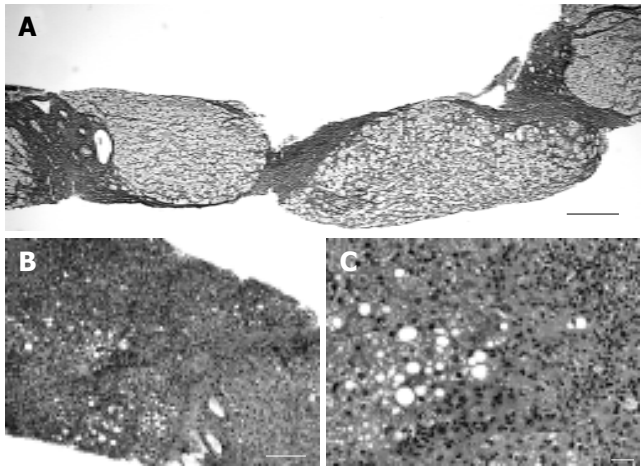

Figure 2 Microscopic features of the liver biopsy specimen. **A**: Micronodular cirrhosis has become established (silver impregnation, scale bar = 200 μm); **B**: Low power view of the liver biopsy specimen (hematoxylin and eosin stain, scale bar = 200 μm). Fatty degeneration and marked fibrosis with inflammatory cell infiltration were observed; **C**: High power view of the liver biopsy specimen (hematoxylin and eosin stain, scale bar = 20 μm). Foci of hepatocellular necrosis and dense fibrosis with neutrophilic infiltration were observed. Hepatocytes showed both the microvesicular and macrovesicular types of steatosis.

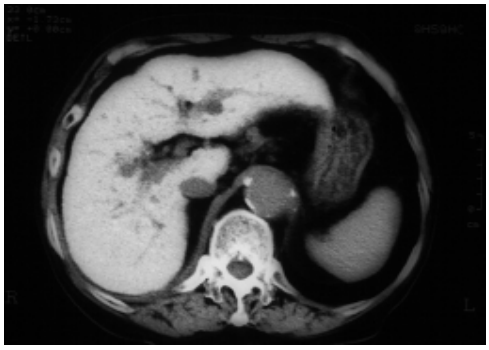

Figure 1 An unenhanced computed tomography (CT) scan of the upper abdomen. The liver has a greatly increased density (111.8 HU).

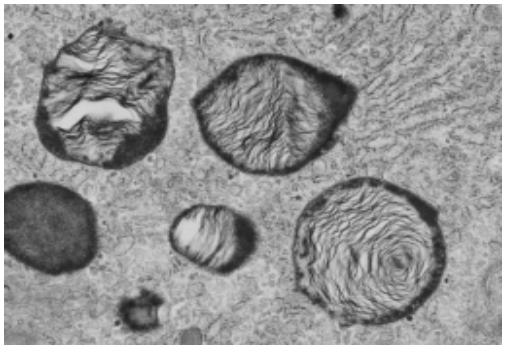

Figure 3 Transmission electron micrograph of the biopsy specimen with lamellated inclusions in the cytoplasm of the hepatocyte (original magnification ×20 000).

with LI relative to the total number of lysosomes in the liver. The incidence was relatively lower in the autopsy specimen compared with the biopsy specimen (Table 1). Unfortunately, we could not assess the tissue concentration of AD.

Table 1 Comparison of CT density and light and electron microscopic findings between biopsy and autopsy specimens of the liver

	Biopsy	Autopsy
CT density (HU)	111.8	97.2
Light microscopic findings		
Nodular formation	Micronodular	Micronodular
Fibrosis	Dense	Dense
Steatosis	Macro / microvesicular	Microvesicular
Infiltration of inflammatory cells	Moderate	Moderate
Electron microscopic findings		
Number of lysosomes with lamellar inclusion / total number of lysosomes (%)[1]	992 / 2 726 (36.4%)	862 / 2 578 (33.4%)

[1]Counts were performed of 10 fields (×18 000) of five blocks for each material.

DISCUSSION

The true incidence of AD-induced liver cirrhosis is obscure, since liver biopsy has not been performed routinely in AD-treated patients. Almost all cases of AD-induced liver cirrhosis have been reported in patients receiving higher maintenance doses[15,16], and only five cases arising from administration of daily low doses have been described in the literature (Table 2)[12-14,18,19]. Some investigators have speculated that the total cumulative dose might be more important in estimating the risk of irreversible liver injury[10,15,16]. The cumulative doses of the patients previously reported ranged from 165 to 213 g, with a duration of treatment of 12-48 mo. The present patient had been treated with 200 mg of AD daily for 84 mo, with a total cumulative dose of 528 g. Even though this dosage is greater than that in previous reports, hepatic abnormalities were not detected during the course of treatment. As asymptomatic progression of liver disease might occur more frequently in patients receiving long-term treatment with AD, periodic examination of liver function and/or biopsy should be performed to detect liver injury. Gilinsky *et al*.[9] described that drug withdrawal was insufficient to restore liver function, if irreversible liver damage had already occurred. Early histological examination for hepatic abnormalities is helpful to warn off irreversible liver changes.

Table 2 Summary of published cases of cirrhosis after long-term administration of daily low doses of AD

No	Reference	Age (yr)	Duration (mo)	Cumulative dose (g)	Outcome
1	Present case	85	84	528	Dead
2	12	76	48	Not described	Dead
3	13	68	13.5	165	Dead
4	14	77	12	202	Dead
5	18	79	33	200	Dead
6	19	83	35	213	Non-fatal

We suggest that genetic background might also be important in determining the risk of progression of NAFLD in patients receiving long-term treatment with AD. It is well known that steatosis and non-alcoholic steatohepatitis (NASH) can be induced by drugs such as tamoxifen, some anti-retroviral agents and AD[20-22]. These drugs inhibit the mitochondrial β-oxidation of fatty acids (causing steatosis) and respiration[20,23]. Inhibition of respiration decreases ATP and also increases the mitochondrial formation of reactive oxygen species (ROS). In hepatocytes, ROS and lipid peroxidation products further impair the respiratory chain, either directly or indirectly through oxidative damage to the mitochondrial genome. Mitochondrial dysfunction can also lead to apoptosis or necrosis, depending on the energy status of the cell. ROS and lipid peroxidation products also activate stellate cells, thus resulting in fibrosis. Finally, ROS and lipid peroxidation increase the generation of several cytokines (TNF-α, TGF-β, and Fas ligand) that play various roles in the pathogenesis of drug-induced NASH[20,23].

Some investigators have postulated that in insulin resistance the combination of elevated plasma concentrations of glucose and fatty acids promotes hepatic fatty acid synthesis and impairs oxidation, leading to hepatic steatosis[20,24,25]. Several polymorphisms in genes related to insulin resistance appear to be associated with the severity of steatosis[25-29]. We examined a few polymorphisms in the *TNF-α*, *HFE*, *CYP2E1*, and *IL-10* genes, but the susceptibility alleles were not present in the patient (data not shown). However, we are now undertaking a genome-wide single nucleotide polymorphism study in patients with drug-induced NASH[20]. Further, several experimental and clinical studies suggest that a number of drugs could be useful for the prevention and/or treatment of NASH. These genetic and clinical approaches may help increase the safety of the long-term administration of AD.

Abstract

Colonoscopic diagnosis of asymptomatic early acute appendicitis is exceedingly rare. Although obstruction of the lumen due to various causes is believed to be the most common physiologic mechanism of acute appendicitis, all of the previously documented cases in the literature have only shown a patent appendiceal lumen with pus flowing into the cecum. We present the case of a patient undergoing colonoscopy for colorectal cancer evaluation with no abdominal symptoms. An obstructed, swollen appendix was seen. The process was probably initiated during the colonoscopy, documenting perhaps the earliest stage of acute appendicitis for the first time. Endoscopic, CT and microscopic documentation of the case is also presented.

INTRODUCTION

Colonoscopic diagnosis of asymptomatic early acute appendicitis is exceedingly rare. Acute appendicitis has been described as a complication of colonoscopy[1-4]. Although obstruction of the appendiceal lumen due to various causes is believed to be the most common physiologic mechanism of acute appendicitis, the few endoscopically documented cases thus far have demonstrated a patent appendiceal lumen with pus flowing out. An obstructed appendix has not been documented earlier in the literature. We describe a case of a patient undergoing colonoscopy for evaluation of colorectal cancer that demonstrated an obstructed, swollen appendix, which is the earliest stage of acute appendicitis.

CASE REPORT

WT is a 53-year-old Caucasian gentleman who presented to our endoscopy suite for colonoscopic evaluation for colon cancer. Pre-colonoscopic evaluation did not reveal any abdominal pain, fever, chills, night sweats, nausea, vomiting, change of appetite, anorexia, hematemesis, diarrhea, constipation, hematochezia or melena. His past medical history was significant only for positive hepatitis C virus antibody. He had no past surgical history. His family history was negative for gastrointestinal cancer and polyps. His physical exam revealed a healthy Caucasian male in no acute distress with normal vital signs. Cardiovascular and pulmonary findings were within normal limits. Abdominal exam revealed normal active bowel sounds in all four quadrants. His abdomen was soft, without any evidence of tenderness or peritoneal signs.

He underwent an uneventful colonoscopy with one diminutive polyp removed with cold biopsy forceps in the ascending colon during the insertion phase. Once the cecum was reached, a mildly erythematous and markedly edematous appendiceal orifice was seen with the appendix bulging into the cecal lumen (Figure 1). The cecum was quickly deflated and the scope was withdrawn.

Figure 1 An obstructed and swollen appendix as seen during colonoscopy.

Surgical consultation was immediately requested. A complete blood count performed following the colonoscopy revealed a WBC count of 11.5 K with 70% segmented neutrophils and no bands.

The patient was admitted to the hospital. Although he felt well initially, later that afternoon he developed some tenderness at McBurney's point. A computed tomography scan of the abdomen revealed an enlarged appendix that was 1.6 cm in total diameter with a thickened appendiceal

wall measuring 6 mm (Figure 2). There were no fluid collections or strands around the appendix.

He underwent an uneventful open appendectomy post-colonoscopy and the intraoperative findings were consistent with mild, early acute appendicitis. Microscopy demonstrated very early, mild, acute appendicitis (Figure 3). There was acute mucosal inflammation with some necrosis, mild acute inflammation of the muscularis mucosa (less neutrophils than are typically seen with appendicitis), and mild acute serosal inflammation. The lumen had some pus in it. No perforation was seen. The patient did well and was discharged the next day.

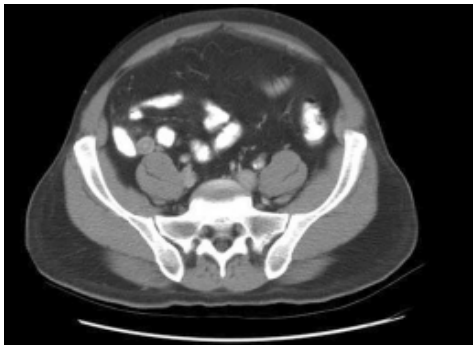

Figure 2 CT scan showing enlarged appendix (1.6 cm) with thickened appendiceal wall (6 mm).

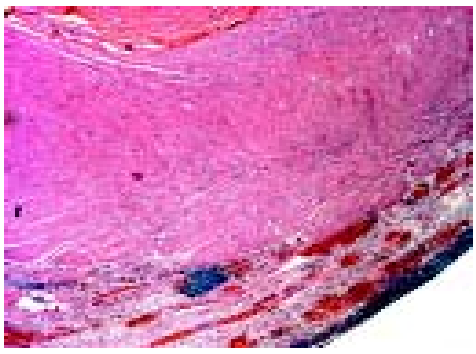

Figure 3 Histopathology of appendix.

DISCUSSION

Our case represents a unique situation of where appendicitis was diagnosed and probably initiated during the colonoscopy, thus documenting perhaps the earliest stage of the pathologic process.

Pathophysiology

Obstruction of the appendix is believed to be the inciting event for the development of acute appendicitis. In young patients, lymphoid follicular hyperplasia is the main cause. This process is either initiated or exacerbated by an infectious event. In elderly patients, obstruction is more likely to be caused by fibrosis, stool, or neoplasia. In endemic areas, parasites as benign as *Enterobius vermicularis* may be the culprit.

Since the only cases reported in literature have showed a patent lumen, it appears that the early obstructed appendix may follow either of the two courses. The appendix may continue to be obstructed which then leads to perforation and abscess formation or rather benign course occurs where the obstruction is relieved as the infection progresses resulting in pus flowing intraluminally into the cecum. This is consistent with the postulate advanced by some authors that some people with acute appendicitis may not have any symptoms, if the pus drains into the cecum and they do not develop serositis. These cases may be self-limiting or result in recurrent or chronic appendicitis[5].

In patients undergoing colonoscopy, the obstruction may occur in the preparation phase during aggressive catharsis or rarely even during the actual procedure. We believe the inciting event in our case may have been that the fecal material was forced into the appendix by the air insufflation, although we do not have any direct evidence. This is supported by the following facts: (1) the symptoms of appendicitis appeared after the colonoscopic diagnosis; (2) WBC count was borderline normal without any left shift; and (3) even though surgery occurred almost 12 h after the colonoscopic diagnosis, a mild acute appendicitis was noted during surgery as well as on histopathology. The other etiologic possibilities include *de novo* or coincidental infection or the irritation by cathartics used for colonic cleansing.

Appendicitis following colonoscopy

Development of acute appendicitis following colonoscopy has been described as a rare complication of this procedure[1-4]. One such case describes an appendiceal colic, due to probable inspissation of fecal material into the lumen of the appendix during insufflation of air in the cecum.

Diagnosis of appendicitis

The diagnosis is primarily clinical with supporting laboratory and CT findings. A false negative rate of about 10-15% still persists although it has declined somewhat with the advent of newer imaging modalities. The role of colonoscopy has been determined to be possibly useful in the diagnosis of appendicitis in patients with symptoms atypical for appendicitis and/or with nondiagnostic imaging studies[5].

There has also been a reported case of a patient presenting with atypical symptoms in whom appendicitis was both diagnosed and treated during colonoscopy by insertion of a catheter into the appendiceal orifice to drain the pus[6]. An elective appendectomy was then performed 5 mo later, after all the symptoms had resolved. The histopathology of the resected appendix showed fibrous thickening of the appendiceal wall correlating with an old inflammatory process, along with changes typical for acute ulcero-phlegmonous appendicitis.

Colonoscopic diagnosis of appendicitis

Colonoscopic diagnosis of acute appendicitis has been reported in the literature of patients with atypical symptoms associated with right lower quadrant pain, and/or non-diagnostic imaging. In one case, a mildly inflamed and erythematous cecum was seen with pus exuding from an edematous appendiceal orifice[7]. Another paper documented an appendix bulging into the cecum with frank pus flowing

from the orifice[8]. Histopathology revealed acute inflammation limited primarily to the lumen and mucosa, which was mostly ulcerated, with an inflammatory infiltrate in the lumen. Earlier, we had described an endoscopic view of appendicitis similar to others[9]. However, the appearance was different from the one we are demonstrating now, i.e., an obstructed/ impacted appendix not previously endoscopically documented in the literature.

Chronic appendicitis has also been diagnosed incidentally by colonoscopy[10,11]. The patient had right lower quadrant abdominal pain for 2 wk prior to colonoscopy. The colonoscopy revealed an inflamed appendiceal orifice. Neither pus nor obstruction was described and it was thought to be low grade appendicitis. She was treated conservatively with a course of metronidazole and discharged. Her symptoms persisted and she gradually became worse over the next 5 wk and an appendectomy was performed. Histology showed an abscess arising in an acquired appendiceal diverticulum and connecting with the lumen of the appendix. The appendix itself showed changes consistent with chronic appendicitis.

In conclusion, we have endoscopically documented for the first time an early obstructive phase of acute appendicitis. Endoscopists need to be aware of the potential for appendicitis during colonoscopy and its appearance, so that prompt appropriate management can be initiated.

Abstract

We report a case of hepatocellular carcinoma (HCC) treated successfully by transarterial chemoembolization (TACE) followed by combination therapy of 5-fluorouracil (5-FU) and pegylated interferon-α (PEG-IFN-α). In the present case, the patient had massive and advanced HCC with a diameter of over 8 cm located in segment 7 (S7) of the liver. Furthermore, the tumor invaded into the major branch of the portal vein (Vp3). After TACE, combined administration of 5-FU and PEG-IFN-α was performed for 5 mo. HCC was totally eradicated and the serum levels of tumor markers were markedly decreased by the treatment. Although it has been reported that the combined use of conventional IFN-α and 5-FU showed striking effects on HCC in some cases, this case may suggest the more promising effect of PEG-IFN-α with a long-lasting effect, in the combined use with 5-FU for the treatment of massive advanced HCC.

INTRODUCTION

Despite the recently innovated treatment modalities including radiofrequency ablation (RFA), hepatocellular carcinoma (HCC) is still one of the most progressive malignancies resistant to the local treatment or chemotherapy. Repeated recurrences often occur due to the multicentric carcinogenesis and intrahepatic metastasis. For the treatment of advanced HCC invading into the major branches of the portal tract, the effectiveness of the combination therapy of 5-fluorouracil (5-FU) and interferon-α (IFN-α) has been reported[1-4]. In the reports, conventional IFN-α has been used as a component of the combination therapy. In the present study, instead of conventional IFN-α, pegylated (PEG) IFN-α was used once a week with continuous infusion of 5-FU for the treatment of advanced HCC and its effectiveness was evaluated.

CASE REPORT

A 74-year-old female had been followed as a diabetes mellitus and chronic hepatitis (non-B and non-C) at Kagawa University Hospital since 1988. The first HCC emerged in S4, S5 and S6 of the liver in 1995. As her hepatic reserve was enough for surgical operation, partial hepatectomy was performed for the multiple HCC. Recurrence of HCC occurred in the middle of 2001, 6 years after the operation. The solitary tumor was detected in S7 of the liver. As it was a relatively small-sized tumor with a diameter of 1 cm, regional treatment by the combination of percutaneous ethanol injection and radiofrequency ablation (PEI-RFA), innovated at our department[5], was performed. The tumorous lesion was totally destroyed by PEI-RFA. Since then she was followed for her liver function and periodically checked for detection of new HCC by blood examination and computed tomography (CT). In January 2002, serum levels of AFP and AFP-L3, tumor markers for HCC, was 13 ng/mL and 4.1%, respectively. Both levels were kept within normal ranges until the end of 2003 and newly developed HCC was not detected by CT or ultrasonography during the period. Both tumor markers suddenly jumped up in March 2004. The levels of AFP reached 555 ng/mL in March and 2 888 ng/mL in June, and AFP-L3 reached 81.7% in April 2004. CT taken in March 2004 showed the development of massive HCC located in S6 and S7 of the liver, with the maximum diameter of over 8 cm. Moreover, HCC invaded into the main branch of the portal vein. The patient was admitted to Kagawa Prefectural Central Hospital for the treatment of HCC. The patient immediately underwent angiography. The angiography clearly showed the massive hypervascular tumor occupying the wide area of the right

hepatic artery (Figure 1A). Furthermore, tumor thrombus was present in the portal tract (Figure 1B). Therefore, in addition to transarterial chemoembolization (TACE) using Farmorubicin (Kyowa Hakko Co., Tokyo, Japan) and gelfoam (Figure 1C), a reservoir for intra-arterial infusion was inserted into the proper hepatic artery (Figure 1D) and the injection port was subcutaneously implanted. From early May 2004, combination therapy of IFN-α and 5-FU was initiated. The patient was treated with subcutaneous administration of PEG-IFN-α-2a (Pegasys, Chugai Pharmaceutical Co., Ltd, Tokyo) and continuous intra-arterial infusion of 5-FU (Kyowa Hakko Co., Tokyo, Japan). Continuous infusion of 5-FU (250 mg/d) was performed for 2 wk with an interval of 2 wk via the implanted reservoir port according to the regimen previously published[2]. PEG-IFN-α-2a (90 μg) was administrated on d 1 of every week. Between May and November, 6 repeated cycles of administration of continuous 5-FU and PEG-IFN-α were performed. No significant side effects were observed. A series of CT examination revealed the marked anti-tumor effect of the combination therapy. Massive HCC in the right hepatic lobe was gradually reduced and the portal tumor thrombus finally disappeared in October 2004, 5 mo after the initiation of the combination therapy. The level of AFP was also decreased to 38 ng/mL in October 2004. No recurrence of HCC has not been detected on enhanced dynamic CT and no elevation of the tumor markers has not been observed so far (Figures 2A-D).

DISCUSSION

HCC is one of the world's most common malignancies, especially in Asia. Despite the advances in diagnostic and therapeutic techniques, HCC often progress to an advance stage regardless of several treatment modalities. RFA technique is one of the promising treatment modalities recently innovated for the treatment of HCC and is used worldwide at present. This newly developed technique appears very effective to induce wider coagulated necrosis rather than percutaneous ethanol injection therapy without major complications, but the efficacy of RFA is limited to relatively small-sized HCC with the maximum diameter of 3 cm or less. Thus, we have developed the combination therapy of PEI-RFA for inducing wider coagulated necrosis[5,6] and for achieving safer treatment of HCC[7]. Nevertheless, recurrences of the tumor after the local treatment often occurs and some of the tumor progress to an advanced stage. For these advanced HCC, chemotherapy alone is not necessarily effective. Recently, combination therapy of some chemical reagents, such as 5-FU and cisplatin, and systemic administration of IFN-α was shown to be effective for the treatment of HCC[1-4]. Indeed, this newly developed therapy could increase the therapeutic effect on HCC that could not be treated by any other therapeutic modalities. However, according to the reports cited above, the response rate including the complete response (CR) and partial response are not necessarily high. Especially, the number of CR cases was extremely small. In the present case, not only the massive tumor but also the tumor thrombus in the major branch of the portal vein was eradicated completely by the combination therapy of 5-FU and PEG-IFN-α. The response to the combination therapy in this case is considered to be CR. Disappearance of massive large-sized HCC of more than 8 cm in diameter as shown in the present case has never been reported. To our knowledge, this case is the first descriptive report of the case with massive HCC

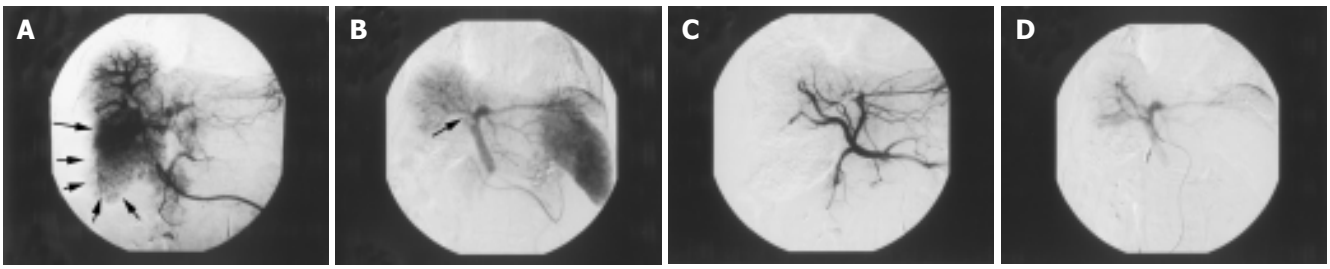

Figure 1 Angiography of the celiac artery before and after TACE was taken on April 15, 2004. Massive tumor stain (small arrow) was exhibited by the celiac arteriography (**A**). Large arterioportal shunt (big arrow) was exhibited above the massive tumor stain. The right branch of the portal vein was not exhibited by the portography (arrow) (**B**). The tumor stain disappeared after the TACE (**C**). The reservoir for intra-arterial infusion was inserted into the proper hepatic artery (**D**).

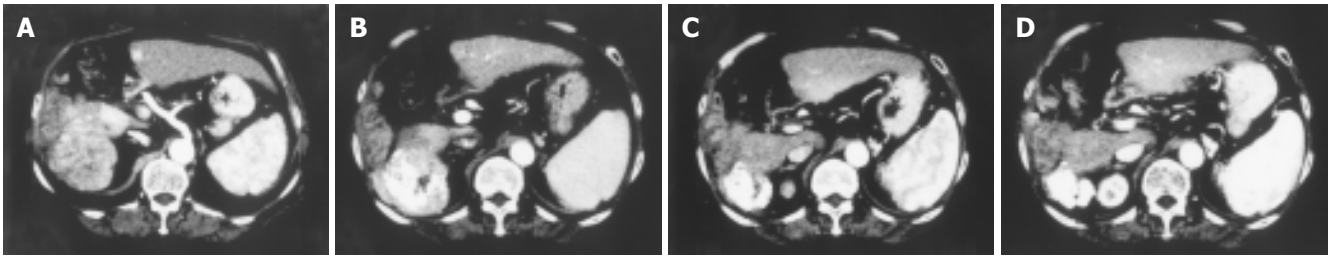

Figure 2 Photographs of enhanced dynamic CT in the time course of the combination therapy of PEG-IFN-α and 5-FU on March 29, 2004 (**A**), June 21, 2004 (**B**), August 27, 2004 (**C**) and October 8, 2004 (**D**). Massive tumor was rapidly reduced during the combination therapy. Only the accumulation of lipiodol remained in the final CT taken on October 8, 2004.

successfully treated with the new combination therapy of systemic administration of PEG-IFN-α and intra-arterial administration of 5-FU. The major difference between the PEG-IFN-α and conventional IFN-α is the retention time of the effect. High concentration of IFN-α in the blood is retained for a week by administration of PEG-IFN-α, whereas high and low concentrations of IFN-α are repeated by turns in the conventional IFN-α treatment. Thus, the present case showing CR to the combination therapy may give us an insight into the promising anti-tumor effects of the combined use of PEG-IFN-α and chemical agents such as 5-FU and cisplatin. Although the study including a large number of patients with advanced HCC is necessary, the combination therapy of PEG-IFN-α and chemical agents may open up a new avenue for the treatment of advanced HCC.

Abstract

Inflammatory bowel disease (IBD) is an idiopathic inflammatory disease of the gastrointestinal tract. The pathophysiology of IBD is probably the result of the complex interaction of genetic susceptibility and environmental influences. There is a well-known risk of thrombosis in patients with IBD. We present the case of a 53-year-old man with ulcerative colitis, who spontaneously developed intracranial sinus thrombosis that was treated with low molecular weight heparin. Literature was searched to assess the frequency and characteristics of cerebral sinus thrombosis in IBD and the role of certain etiopathological factors in such thrombotic patients.

INTRODUCTION

Inflammatory bowel disease (IBD) is an idiopathic inflammatory disease of the gastrointestinal tract. The pathophysiology of IBD is probably the result of the complex interaction of genetic susceptibility and environmental influences. The exact pathogenesis of IBD is unknown. There is a well-known risk of thrombosis in patients with IBD. This pro-thrombotic state seen in IBD has been proposed as a factor contributing to the pathogenesis of IBD, especially in Crohn's disease[1,2]. This conclusion is based on the presence of thrombi in the small vessels of mucosa and submucosa. Furthermore, some IBD patients have been successfully treated with heparin[3-6].

Thromboembolism is a serious complication of IBD patients. The yearly incidence of thromboembolic events in IBD is 13-64/1 000[7,8]. Corticosteroid usage to diminish inflammatory activity and concomitant abnormalities of coagulation cascade such as factor V mutations, protein C and S deficiency, prothrombin gene mutation, hyperhomocysteinemia could increase the risk of thromboembolic complications. On the other hand, some researchers found that the incidence (1.5/1 000 IBD patients per year) of venous thrombosis does not increase in IBD patients and that IBD patients have venous thrombosis earlier in life than non-IBD patients[9].

Deep venous thrombosis and pulmonary emboli are the most common thrombotic complications in IBD. However, cerebral vascular involvement is rare. It was reported that 92 of 7 199 IBD patients suffer from thrombotic complications, 9 of the 92 patients have cerebral vessel involvement[7].

CASE REPORT

A 53-year-old man suffering from abdominal pain, bloody diarrhea (8-10 stools per day) and weight loss (10 kg in the past 3 mo) was admitted to our hospital in April 2003. On admission, his body temperature was 38 ℃. His physical examination revealed no abnormalities except for mild sinusal tachycardia (100 pulses/min). Neurological examination revealed no paralysis and sensory motor disturbances. The blood and stool cultures obtained on his first day of admission did not yield any pathogens. Microscopic stool examination revealed abundant leukocytes and erythrocytes. The stool C. Difficile toxin A assay was negative. Laboratory data showed elevated C reactive protein (CRP) levels and ESR, mild elevations of aminotransferases with ALT/AST ratio >1, mild thrombocytosis (568 000/mm^3) and normochromic anemia with a hemoglobin value of 10 g/L. His colonoscopic evaluation revealed loss of mucosal vascular pattern, granularity and friability of the whole colonic mucosa and widespread pseudopolyps. Histopathological examination of the rectal mucosa showed an abundant infiltration of neutrophils, lymphocytes and plasma cells. Histopathology also revealed cryptitis and crypt abscess in some areas. The patient's ultrasonography and carcinoembryonic antigen (CEA) levels were normal. Hepatotrophic virus (Hepatitis B and C) and autoimmune markers (anti-nuclear, anti-smooth muscle and anti-neutrophilic cytoplasmic antibodies) were negative. Based on these findings, the patient was diagnosed with moderately active ulcerative pancolitis and

started on 4 g of sulfasalazine as anti-inflammatory therapy. Nutritional support was also provided. One week after treatment, his number of times of defecation decreased to 5 stools per day with no blood and the patient was afebrile. CRP levels decreased, thrombocytes were in normal limit but mild anemia persisted. During the second week of therapy the platelet count was 130 000/mm^3. Sulfasalazine was discontinued and 40 mg prednisolone was started. On the third day of corticosteroid treatment, the patient complained of weakness of the right arm and leg. His neurological examination revealed left sided hemiparesis. Motor strength was 2/5 and 4/5 in upper and lower left extremities, respectively. The patient had mild dysarthria. Deep tendon reflexes were brisk. Plantar response in left side was extensive. Cranial CT scan and T2 weighted magnetic resonance imaging showed bifrontal and right parietal infarction (Figure 1). Sagittal MRI venography revealed signal dropout in the superior sagittal sinus and right transverse sinus (Figure 2). We started low molecular weight heparin (LMWH) therapy immediately. The patient also developed focal motor seizures. He became unconscious (Glasgow coma score was 6) 3 d after the first neurological sign. He was on therapy of LMWH and control CT showed no additional abnormality. Laboratory tests for coagulation abnormalities revealed heterozygous factor V Leiden gene mutation. The patient died of pulmonary nosocomial infection and sepsis 2 wk after the onset of neurological findings.

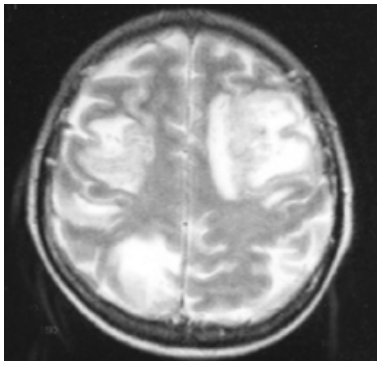

Figure 1 T2 weighted magnetic resonance image demonstrating bifrontal and right parietal lesions consistent with infarctions.

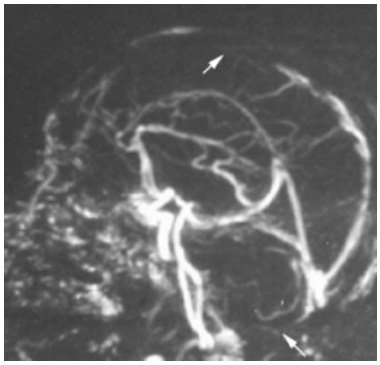

Figure 2 Sagittal MRI venographic image demonstrating signal dropout in superior sagittal sinus (arrow) and right transverse (arrowhead) sinus.

DISCUSSION

Extraintestinal manifestations are common in ulcerative colitis and Crohn's disease occurring in at least 25-40% of patients and can be classified as related to disease activity or not[10]. If secondary systemic effects of therapy on disease and complications are also included, almost all patients have extraintestinal manifestations.

Thromboembolism is a serious complication of IBD patients. Intravascular thrombosis in mucosal blood vessels may play a role in the pathogenesis of IBD. Some studies indicate that heparin may benefit the treatment of IBD[3-6]. There are some conflicting data about the incidence of thrombotic events in IBD patients. The risk factors, relationship between disease activity, corticosteroid use and thrombotic events, incidence of concomitant coagulation disorders and effect of corticosteroid on thrombosis in IBD patients are still not completely understood. Grip *et al.*[9], found that the incidence of venous thrombosis does not increase in IBD patients. However, studies showed that the incidence of thrombotic complications increases in IBD patients[7,8]. These contradictory data may be related to the changing management of IBD patients. Nowadays, IBD patients are less frequently hospitalized and immobilized. This may be the reason why the current incidence of thrombotic complications is lower in IBD patients[9].

Pro-thrombotic factors (anti-cardiolipin antibodies, hyperhomocysteinemia and changes in the lipid spectrum), IBD-induced alterations in plasma and mucosal hemostasis (increased endothelial activation and tissue factor expression, and impaired inhibition of coagulation in IBD), and changes secondary to inflammation have been suggested as the explanatory factors for the high prevalence of thromboembolism in IBD patients. The balance between pro-coagulant and pro-fibrinolytic factors seems to favor plasma hypercoagulability in IBD patients. Inflammation-induced changes in serum, endothelial cells and platelets induce plasma alterations resulting in coagulation activation, whereas coagulation activation induces pro-inflammatory effects, thus providing a looping chain of reactions[11].

van Bodegraven *et al.*[12], studied hemostatic imbalance in active and quiescent ulcerative colitis and found that coagulation and fibrinolytic cascades are activated in active ulcerative colitis and 20% of patients are in remission with a hemostatic imbalance in favor of coagulation. The clinical significance of these phenomena is unknown. Meanwhile previous studies have shown that activated plasma coagulation markers increase in clinically quiescent IBD[13]. Thus, clinical activity of the disease may increase the risk, but it is probably of minor importance.

Hyperhomocysteinemia and coagulation cascade abnormalities in IBD patients have been studied[14-16]. Hyperhomocysteinemia is common in IBD patients but elevated total homocysteine levels do not contribute to the development of thrombotic complications[17].

No correlation is found between hereditary conditions predisposing to thrombosis such as factor V mutation, prothrombin gene mutation, MTHFR mutation, proteins C and S, antithrombin III deficiencies and IBD[18]. Thus, higher prevalence of thrombosis in IBD patients is not due to genetic linkage. Taken together, existing data indicate that

thrombosis in IBD patients is due to multifactors.

Deep venous thrombosis and pulmonary emboli are the most common thrombotic complications in IBD patients, however, cerebral vascular involvement is rare. It was reported that IBD patients are relatively young and have no other relevant risk factors except for IBD[19].

Cerebral venous and dural sinus thrombosis in association with IBD is rare and few cases have been reported[20-24]. Some clinical characteristics of these patients are summarized in Table 1. The frequency of cerebral venous thromboembolic complications in ulcerative colitis patients appears to be greater than that in patients with Crohn's

disease. The superior sagittal sinus and lateral sinuses are commonly involved[25-27]. Less frequently, isolated cortical venous thromboses have been reported[22]. Although one case that present with sagittal sinus thrombosis 10 years after proctocolectomy for ulcerative colitis has been reported, these cerebral venous thrombotic events occur more frequently in patients with active inflammatory bowel disease[28-32]. The most frequent symptoms and signs are headache, paresis, seizures, dysphasia and papilla edema. Approximately 1/3 of patients have some coagulation abnormalities such as FV Leiden mutation, hyperhomocysteinemia, positive anti-cardiolipin antibodies[20,26,27]. The clinical outcome is devastating[33-37].

In conclusion, cerebral venous thrombosis is a devastating complication of IBD, especially, ulcerative colitis. The diagnosis of these patients depends on the demonstration of the thrombus by neuroimaging.

Abstract

Gardner's syndrome is an autosomal dominant disease characterized by the presence of colonic polyposis, osteomas and a multitude of soft tissue tumors. The syndrome may present at any age from 2 mo to 70 years with a variety of symptoms, either colonic or extracolonic. We present a case of a 11-year-old female patient with Gardner's syndrome who presented with a lumbar area desmoid tumor and treated with resection of the desmoid, restorative proctocolectomy and ileal pouch anal anastomosis, A review of the current literature has been performed.

INTRODUCTION

Gardner's syndrome is a rare (1:1 000 000 population in USA) autosomal dominant inherited disorder with a high degree of penetrance characterized by the triad of colonic polyposis, multiple osteomas and mesenchymal tumors of the skin and soft tissues[1-3].

In 1951, Gardner reported the association between surface tumors and colonic polyps that are prone to malignant degeneration[4]. In 1952, Gardner and Plenk described the dominant hereditary pattern of multiple osteomas associated with colonic polyposis[5]. Later that year, Gardner and Richards reported the association of hereditary colonic polyposis and osteomatosis with multiple cutaneous and subcutaneous tumors describing the so-called Gardner's syndrome[6].

It is believed that Gardner's syndrome and familial adenomatous polyposis (FAP) are variants of the same disorder, since they share the same genetic alterations. The fact that Gardner's syndrome is associated with extracolonic manifestations may be explained by a variable penetrance of a common mutation. The disorder is linked to band 5q21-q22, the adenomatous polyposis coli locus (APC gene). More than 1 400 different mutations of this gene have been reported. The specific area of the APC gene that is mutated determines the extracolonic manifestations as well as the number, time frame and malignant potential of adenomatous polyps. Although most cases show familial clustering, one-third of cases occur due to spontaneous mutations. MYH (1p34.3-p32.1) is another gene associated with FAP. In general, the clinical picture of FAP patients with mutations in the MYH gene is milder than those with mutations in the APC gene. The presence of extracolonic manifestations is linked to the vast majority of cases, if not exclusively, to mutations of the APC gene. It is believed that in the pathogenesis of FAP and possibly Gardner's syndrome, environmental factors such as diet, exercise and smoking also play an important role[1,7-11].

The clinical spectrum of disease presentation is variable and often diagnosis is delayed, despite the presence of clues for a significant amount of time. We present the rare case of a 11-year-old girl with Gardner's syndrome that was diagnosed due to the finding of a desmoid tumor on the lumbar area.

CASE REPORT

A 11-year-old female patient presented with a small tumor in the right lumbar area. The patient was afebrile with normal vital signs. Giordano's sign was absent and she had a normal urinalysis, CBC and blood biochemistry. After careful clinical examination, the only abnormal finding was a 4-cm mass on the right lumbar area. The mass was fixed, non-tender and had a bony firm consistency. IVP was scheduled with insignificant findings. Follow up of the tumor growth was advocated for a year before further investigations should take place, but the rapid increase in tumor size lead to a CT scan evaluation of the abdomen and pelvis 3 mo later. A 6-cm tumor of indeterminate quality was revealed originating or adhering to the left latissimus dorsi muscle. After careful medical history was taken again, the patient recalled an episode of hematochezia that had been attributed to hemorrhoids. On colonoscopy, she was found to have numerous polyps carpeting the entire colon and rectum, which was consistent with FAP. The clinical suspicion of Gardner's syndrome was raised. No family history of FAP was evident. A fundoscopic examination was performed showing the typical hypertrophy of the pigmented layer of

the retina. An upper endoscopy was performed revealing normal findings. Subsequently resection of the lumbar tumor was performed via a posterior approach. The pathologist reported a firm tumor with a gritty sensation during transection. On cross section, a glistening white coarsely trabeculated surface was revealed resembling scar tissue (Figure 1A). On microscopic examination, the tumor consisted of eosinophilic or amphophilic spindle-shaped cells embedded within moderate amount of collagen. These cells did not show atypical or hyperchromatic nuclei but some pleomorphism was present (Figure 1B). The final report was that of a desmoid tumor. The next step was a restorative proctocolectomy with ileal pouch anal anastomosis (RPC/IPAA) and mucosectomy. Pathology of the specimen confirmed the diagnosis of FAP (Figure 1C). Colonic polyps proved to be tubular adenomas. The epithelial cells showed moderate differentiation into normal cells although scattered goblet cells could be found. Cellular atypia were manifested by tall cells with pseudostratified nuclei (Figure 1D). No malignant transformation was present.

On discharge, it was recommended that all family members must be evaluated for FAP. Still, the patient was lost to follow-up 2 mo later because of address change.

DISCUSSION

Gardner's syndrome represents a multisystemic disease. Symptoms are usually evident by the 20th year of age, but they may present anytime between 2 mo and 70 years. In general the cutaneous and bone abnormalities develop approximately 10 years prior to polyposis[1,3,12]. However, in our case the polyps were already symptomatic at the time of diagnosis, before the extracolonic manifestation of the disease became evident.

The gastrointestinal manifestations of Gardner's syndrome include colonic adenomatous polyps (tubular, villous, tubulovillous), gastric and small intestinal adenomatous polyps (12% of patients) and peri-ampullary carcinomas (2% of patients). Polyp formation starts at puberty but diagnosis is usually in the third decade, while malignant transformation approaches 100% by the fourth decade of life. The presenting symptoms are anemia, lower gastrointestinal bleeding, cramping abdominal pain, diarrhea, bowel obstruction and mucous discharge. Most of the polyps are small (<5 mm) and therefore difficult to demonstrate on imaging studies. The larger sized polypi may prolapse through the anus or may lead to intussusception or ileus. On colonoscopy, the rectum and whole large intestine appear carpeted by the polyps[1,3,12-14].

Osteomas appear in about half of Gardner's syndrome patients and manifest earlier than polyposis. They may be endosteal or exosteal and demonstrate sclerosis and deformity. The vast majority of osteomas are located on the skull. Since the most commonly affected bones are the mandible and maxilla, many patients present initially to dental surgeons. However, long bones and even phalanges may be affected. A finding of three or more osteomas has been proposed as a screening method for Gardner's syndrome[1,12,15].

The commonest skin manifestations of Gardner's syndrome are epidermoid or sebaceous cysts (66%) and are found on the face, scalp and extremities. They are usually asymptomatic although mild pruritus or signs of inflammation may be evident. Other skin manifestations are fibromas, neurofibromas, lipomas, leiomyomas, and pigmented skin lesions[1,16].

Desmoid tumors appear in 3.5-5.7% of patients and usually appear within 3 years following surgery although they can appear at anytime. Common locations are the incision sites, the abdominal cavity (especially the mesentery) or the retroperitoneum. They are considered as one of the

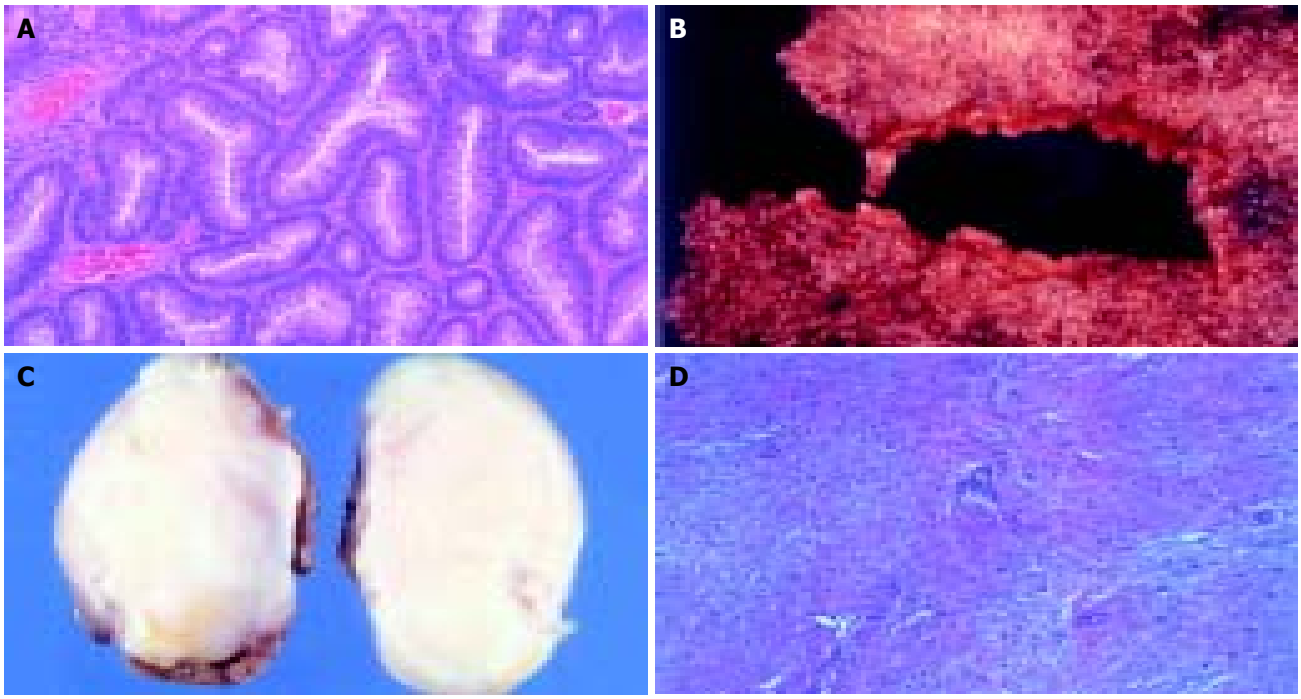

Figure 1 Desmoid tumor. Macroscopic appearance (**A**). Desmoid tumor. Microscopic appearance (HE ×40) (**B**). The resected colon specimen (opened) showing the characteristic carpeting of Gardner's syndrome (**C**). Microscopic appearance of an adenomatous colon polyp (HE ×40) (**D**).

most troublesome manifestations of Gardner's syndrome since they may cause life threatening complications and are usually resistant to treatment[1,17-22]. In our case, the desmoid tumor was the sole manifestation of the disease and with a misleading medical history, diseases of the left kidney and ureter were first considered.

In about 90% of population, hypertrophy of the retinal pigmented layer occurs. Other manifestations of Gardner's syndrome are papillary thyroid cancer (often multicentric), benign intracranial neoplasms such as meningiomas and epidermoid cysts, hepatoma, hepatoblastoma, fibromas, leiomyomas, lipomas, biliary and adrenal neoplasms, osteosarcoma, chondrosarcoma, and in 70% of patients dental disorders (congenitally missing teeth, hypercementosis, odontomas, dentigerous cysts, impacted teeth, supernumerary teeth, fused or unusually long roots and multiple caries)[1-9,12-16].

The diagnosis of FAP and Gardner's syndrome can be made by genetic testing for gene mutations or by the demonstration of multiple colonic polyps during colonoscopy. Genetic testing is the most effective method for demonstrating mutated APC gene in relatives of patients with FAP syndrome[1,23].

Owing to the increased risk of cancer in various organs, patients with FAP/Gardner's syndrome or their relatives should undergo surveillance programs. These include both large bowel and upper GIT surveillance, as well as thyroid and possibly hepatic surveillance too.

Large bowel surveillance is indicated in the following cases:

I Family history of FAP, but no demonstrable mutation

Annual flexible sigmoidoscopy starting from the age of 13-15 till the age of 30. Sigmoidoscopy every 3-5 years from 30 to 60 years.

II Known APC mutation, but patient refuse surgical treatment.

Flexible sigmoidoscopy every 6 mo and annual colonoscopy starting from the age of 10-12. Advise surgery at an age, earlier than 25 years.

III Known FAP following surgery

Annual rectoscopy following ileo-rectal anastomosis (IRA).

Annual proctoscopy following IPAA.

Today no widely accepted upper gastrointestinal tract surveillance program exists. However, all patients with known FAP should undergo an upper GIT surveillance program, due to higher risk of malignancy development in this area. A triennial upper gastrointestinal endoscopy utilizing both direct and side view endoscope has to be performed. In the case of multiple polyps, annual endoscopy is advised.

Annual clinical and ultrasonographic examination of the thyroid gland is mandatory. Hepatic surveillance by ultrasound and AFP level measurement is under investigation[1,23].

Treatment is advised at diagnosis considering the malignant potential of the polyps and due to the fact that 25% of cases presenting with symptoms have cancer. Treatment options include total proctocolectomy and permanent terminal ileostomy, RPC and construction of an IPAA, subtotal colectomy and IRA. Prophylactic resection should be performed before the 25th year of life, ideally between the age of 16 and 20 years. However, patients with a large number of polyps early in life may benefit from an operation at an earlier age, considering the relationship between polyp number and cancer risk. None of these options is ideal and the choice of operation is always a combination of the patient's preference and the surgeon's experience. The first operative option seems to be the safest, since no large intestinal epithelium remains, but the patient must learn to live with an ileostomy. The second option avoids an ileostomy, but is more technically demanding, is associated with greater morbidity and the need for lifetime follow-up, due to the possibility of residual mucosa. The third option should be reserved for those patients whose rectum is relatively disease free (less than 20 polyps). Once thought to result in spontaneous regression of the remaining rectal polyps, this procedure appears to be of questionable efficacy. In our case, we performed the more technically demanding RPC/IPAA after explaining to the patient (and her relatives) the possible choices[1,3,11,24,25].

Owing to the morbidity and mortality associated with the surgical treatment options, there is intensive investigation for drugs that could decrease the malignant potential of adenomatous polyps. In 1983, Waddell and Loughry reported that the rectal polyps of patients with FAP almost disappeared following sulindac administration. Sulindac and other NSAID's have been tested in subsequent clinical studies demonstrating a reduction in the number and size of polyps during the period of their administration. However, the appearance of new polyps as well as the malignant transformation of polyps has been demonstrated in patients on sulindac therapy. In order to avoid the side effects of long-term NSAID administration while maintaining efficacy, researchers have focused on the newer COX-2 inhibitors (celecoxib, rofecoxib) following the demonstration of COX-2 expression in colonic carcinomatous mucosa but not in normal GIT mucosa. A decrease in the polyp size was noted but at higher than usual doses. Currently celecoxib 400 mg/d has granted FDA approval for FAP patients by decreasing the polyps' size, but whether it reduces the malignant potential of them remains to be investigated[11,26].

Non-NSAID substances that have been tested for the prevention of malignant transformation of polyps in FAP patients seem to be of inferior efficacy. These include 5-FU, Vit C, Vit E, calcium, DHA and green tea extract[11].

Treatment options for the cutaneous cysts of Gardner's syndrome are the same as for ordinary cysts. Treatment is indicated for symptomatic cases or for cosmetic reasons. In the same manner, osteomas may require resection if they interfere with function or for cosmetic reasons[1,16].

Treatment of desmoids is generally considered to be a challenge for both the doctor and the patient. Operation is recommended only for symptomatic patients due to common recurrence (up to 80%). Medical treatment consists of sulindac, tamoxifen or toremifene, raloxifene alone or in combination. Doxorubicin, dacarbazine as well as carboplatin, vinblastine and methotrexate have been used in case of aggressive unresectable desmoids. Radiotherapy can also be tried. The treatment plan greatly depends on the location of the desmoid tumor. Mesenteric desmoids tend to involve the mesentery diffusely, altering gross anatomy and can

invade vessels or ureters. Often complex operative procedures have to be employed and recurrence is typical. So a less aggressive medical approach is preferred initially and surgery should be performed in case of failure. Abdominal wall desmoids should be treated surgically since they are easier to be excised and recurrence rates are lower, compared to their mesenteric counterparts[1,17-22]. In our case, we had an unusual occurrence of a desmoid tumor at the muscles of the back. The excisional biopsy raised the clinical suspicion and led to the final diagnosis and treatment. Still, there are no follow-up data to evaluate recurrence.

In conclusion, we presented a case of Gardner's syndrome with an unusual clinical presentation of a desmoid tumor in the left lumbar area that led to the final diagnosis after taking careful medical history. RPC/IPAA was the surgical modality of choice with excellent immediate post-operative results. Even though in our case the patient was lost to follow-up it cannot be over expressed that after the diagnosis of Gardner's syndrome, the patients must be aggressively followed-up, since there is a constant threat to their lives at any age.

Abstract

We report a patient with HBV-related hepatocellular carcinoma (HCC) and refractory ascites who had received a peritoneal-venous shunt (PVS) 1 year before liver transplantation. Urgent surgical intervention following bowel obstruction and failure of immunosuppression therapy. No intestinal obstruction was found during an initial PVS. However, intestinal obstruction developed 2 wk after liver transplantation; and a cocoon abdomen was found upon exploration. This is the first reported case of cocoon abdomen caused by PVS and exacerbated by liver transplantation.

INTRODUCTION

Cocoon abdomen or sclerosing encapsulating peritonitis (SEP) is a rare cause of small bowel obstruction. In this condition, the bowel is partially or totally encased or wrapped by a thick fibrous membrane forming several compartments (cocoons) containing loops of small bowel. SEP usually presents with symptoms of intestinal obstruction, and pre-operative diagnosis is difficult. The pathogenesis of this condition remains unclear; however, it is a form of chronic irritation and inflammation, and may be summarized as primary (idiopathic) or secondarily induced[1]. Here we report a patient with liver cirrhosis and massive ascites who had received a peritoneal-venous shunt (PVS) 1 year before liver transplantation. Thickened parietal peritoneum and fibrotic changes were found during the liver transplantation. After surgery, the patient received treatment with high-dose immunosuppressive agents. Intestinal obstruction developed 2 wk later and this was resolved by surgery.

CASE REPORT

A 64-year-old man received a liver transplantation on August 10, 2003, for decompensated end-stage liver disease caused by hepatitis B, with liver cirrhosis and hepatoma. His pre-transplant history included receiving transarterial embolization of the hepatocellular carcinoma, (HCC) 2 wk before transplantation and a PVS drainage, 1 year before liver transplantation for treating refractory ascites. After the PVS had been performed, the ascites was controlled and the patient was feeding well.

Before liver transplantation, the patient's laboratory data were albumin 3.4 g/dL, total bilirubin 1.9 mg/dL, and prothrombin time 12.3/11.2 s. His Child-Pugh classification was B (score, 8), and he had no history of hepatic encephalopathy. During the liver transplantation, the parietal peritoneum and most of the colonic wall and retroperitoneal liver were observed to be thickened and fibrotic. Hydrocortisone Sod. Succinate (Solu-cortef) (1 000 mg) was administered. After liver transplantation, the patient started to receive immunosuppressive treatment, including Prograf (1 mg twice daily), Solumedrol (40 mg four times daily), CellCept (500 mg twice daily), and we maintained the therapeutic level of Prograf at 10-12 ng/mL. The patient's oral feeding condition was poor; he could not even tolerate semi-liquid diet.

Two weeks after liver transplantation, colicky abdominal pain, vomiting and constipation developed, but no rebounding pain was found by physical examination. Contrasted abdominal computer tomography (CT) revealed a dilated C-shaped region of small intestine over the right lower pelvis, and an adhesion band was suspected to have caused a closed-loop obstruction (Figure 1). Conservative treatment was started, but little improvement occurred and the patient still could not tolerate oral feeding. The patient's abdominal distension increased; repeated plain abdominal radiography showed that the obstructed small bowel loops were enlarged, so we decided on emergency surgery.

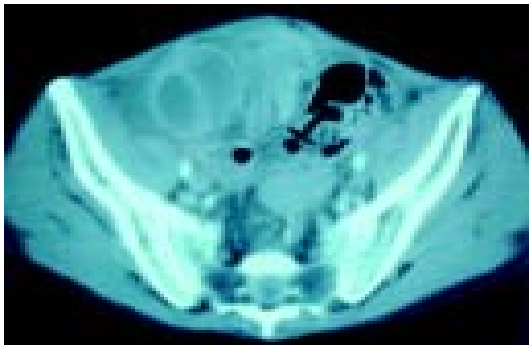

Figure 1 Contrasted abdominal CT revealed a cluster of intestinal loops sacculated in thin, membrane-like sac (black arrow).

Figure 2 Dense thick adhesive sheaths circumferentially wrapping loops of small bowel giving the shape of cocoons in the abdomen (**A**); we excised these fibrous tissues easily using finger dissection (**B**); the serosa was intact and there was no need for bowel resection (**C**).

At laparotomy, we found dense, thick, adhesive sheaths circumferentially wrapping loops of small bowel giving the shape of cocoons in the abdomen (Figure 2). The loops within each cocoon were normal and adherent to each other with avascular fine fibrous tissue; this was easily broken down with finger dissection. The serosa of the bowel was intact. The patient's post-operative recovery was uneventful, and he was discharged 2 wk later.

DISCUSSION

SEP involves entrapment of the intestine in a fibrous sac, resulting in complete intestinal obstruction. It was first described in 1907 by Owtschinnikow[2]. The real causes of SEP are unclear, but it can be classified as primary and secondary forms[1]. Primary (idiopathic) SEP occurs in young women living in warm climates, and is thought to be caused by retrograde menstruation or infection via the Fallopian tubes[3]. Secondary SEP can be classified as systemic caused by local irritants, or as local combined with systemic irritants. The major possible causes include long-term use of β-adrenergic blocking agents, chronic ambulatory peritoneal dialysis, and liver cirrhotic patients after PVS[1,4-6].

If diagnosed before obstruction occurs, the sclerotic membrane can frequently be separated from the small intestine. Successful separation is almost impossible when associated with complete obstruction. Thus, early diagnosis is important.

The clinical picture of cocoon abdomen usually includes recurrent episodes of intestinal obstruction caused by kinking and compression of the intestines within the constricting cocoon. The condition should be suspected in patients with bowel obstructive signs or soft, non-tender abdominal masses. Pre-operative diagnosis of abdominal cocoon is difficult. Plain radiographs and oral contrast studies may show a circumscribed mass of bowel loops with absent or delayed passage of contrast. Ultrasound examination may show a mass of tightly bound small bowel loops surrounded by a thick rim of echo-poor tissue. CT scans might also reveal a mass comprising an encapsulating cluster of dilated small bowel loops with failure of orally taken contrast medium to pass distally.

Beta-blockers, particularly propranolol, have been implicated in the etiology of this condition because they may lead to enhanced collagen production and subsequent fibrosis. Yamamoto *et al*., reported SEP in two patients with liver cirrhosis[5]. Cambria *et al*., and Greenlee *et al*., reported possible associations with the Le Veen shunt. Abul reported the first case of cocoon abdomen in a liver transplant patient[2], but that patient did not receive the Le Veen shunt.

Our patient suffered from liver cirrhosis with massive ascites and received PVS, but he presented with SEP following liver transplantation and developed intestinal obstruction 2 wk later. Although the actual pathogenesis of SEP is unclear, we believe that PVS may be one of the causes. Thus, ascites flow through the PVS and fibrin deposition in the peritoneum may lead to chronic inflammation. Hence, the cause of SEP in this patient may have been a combination of PVS with recurrent spontaneous bacterial peritonitis. Intraperitoneal bleeding may have helped induce this condition. Following liver transplantation, bleeding and manipulation irritation would have exacerbated it[5].

Definitive diagnosis of SEP can only be made at laparotomy. Yamamoto reported successful treatment with total enterolysis and the oral administration of prednisolone[5], and Junor and McMillan reported that immunosuppression has a beneficial effect on SEP in patients with or without a successful transplantation. However, in this patient, even large doses of immunosuppressants were ineffective. Hence, surgery was essential with lysis of the membranes and adhesions. Bowel resection was not necessary. We recommend that SEP should be cleared away during liver transplantation to prevent any following possible intestinal obstruction.

Abstract

Uterine perforation is one of the serious complications associated with use of the intrauterine contraceptive device (IUD). Uterine perforation by IUD can involve several neighboring organs. A case of acute appendicitis was caused by a Multiload Cu 375 IUD inserted previously. This is a rare complication and only fourteen previous cases were recorded in the literature.

INTRODUCTION

Intrauterine contraceptive device (IUD) has been widely used since 1965[1]. Perforation of the uterus by an IUD is a rare and serious complication, occurring in 1/350 to 1/2 500 insertions[2]. Perforation by IUD can involve several neighboring organs such as the bladder, and particularly the intestinal tract[3] resulting frequently in serious complications which require intensive treatment including intestinal surgery. Perforation can occur during insertion or later[4]. Perforation occurring at the time of insertion correlates directly with the skill of the clinician. Delayed onset of symptoms is mostly due to chronic inflammatory reaction of copper-containing IUD. We report a case of acute appendicitis in a 50-year-old woman caused by a Multiload Cu 375 IUD inserted 18 years previously.

CASE REPORT

The patient was a 50-year-old gravida 3 para 3 woman, admitted because of severe lower abdominal pain associated with fever, nausea and vomiting. A Multiload Cu 375 IUD had been inserted, 18 years prior to the present admission and she did not receive regular physical examination after insertion.

On physical examination, the abdomen had decreased bowel sounds and rebounding tenderness mostly in the right lower quadrant. Laboratory data revealed leukocytosis and plain abdominal film showed the IUD to be overlying the right iliac crest (Figure 1). The abdomen was opened through a McBurney incision under the impression of acute appendicitis. The operative finding was the IUD located in the abdominal cavity behind the ileocecal junction and its tip had penetrated the tip of appendix (Figure 2). The whole area was edematous and covered with omentum. No fecalith impaction in appendix was found. Appendectomy was performed and the IUD was retrieved. The patient recovered uneventfully.

Figure 1 KUB showed IUD migration.

Figure 2 Intraoperative photograph showing IUD penetrated the tip of appendix.

DISCUSSION

IUD is generally a safe modality for long-term contraception.

Associated complications are bleeding, infection, ectopic pregnancy and uterine perforation. Uterine perforation is one of the most serious but uncommon complications associated with an IUD[3]. The mechanism of perforation is thought to be the insertion procedure or chronic inflammatory reaction with gradual erosion through the uterine wall[1]. The incidence is influenced by several factors including the timing of insertion, parity, previous abortions, type of IUD inserted, experience of the operator and position of the uterus[4]. Most of the perforations take place at the time of insertion. Delayed onset of symptoms supports secondary migration[1]. The timing of IUD insertion is flexible. Previous studies showed IUD insertion 0-3 mo postpartum increased the risk of uterine perforation as did insertions at 3-6 mo postpartum[4].

In this case, we considered the mechanism of IUD perforation was secondary by gradual erosion through uterine wall due to inserted 18 years prior to the present admission. No fecalith impaction in the appendix was found during operation and we considered that the acute appendicitis was induced by chronic inflammatory reaction of the copper-containing IUD.

Patients with IUD should be alerted about the possibility of its migration. Regular self examination for "missing threads" is useful in the early detection of migration of the IUD. A plain radiograph of the abdomen is usually the initial examination of choice to verify the presence of the IUD in the pelvis. Once found, an ultrasound examination has to be done to determine the location of the IUD relative to the uterus. The treatment of a migrated IUD is surgical, either laparoscopy or laparotomy. Withdrawal of the migrated IUD is advisable even if its migration has not given rise to any clinical symptoms[5] and can avoid further complications like bowel perforation, bladder perforation, or fistula formation[6]. To our knowledge, this is the 15th case of a perforated IUD causing acute appendicitis[7-18].

Abstract

A diagnosis of intestinal diverticulosis is difficult to make pre-operatively because the clinical symptoms are usually non-specific. We report the case of a 70-year-old man who had suffered from three episodes of intestinal obstruction in 1 year. He experienced dull pain and a sensation of fullness over the whole abdomen. The symptoms did not improve after conservative treatment. The presumptive diagnosis was intestinal obstruction, and an exploratory laparotomy found diverticulosis of the proximal jejunum, with an adhesion band formed from the base of one diverticulum. Strangulation of a segment of the jejunum resulted from the internal herniation caused by the band. The band was removed and the proximal jejunum segmentally resected. His postoperative course was uneventful.

Lin CH, Hsieh HF, Yu CY, Yu JC, Chan DC, Chen TW, Chen PJ, Liu YC. Diverticulosis of the jejunum with intestinal obstruction: A case report. *World J Gastroenterol* 2005; 11(34): 5416-5417

http://www.wjgnet.com/1007-9327/11/5416.asp

INTRODUCTION

The incidence of acquired jejunal diverticulosis varies from 0.2% to 1.3% in autopsy studies to 2.3% when assessed on enteroclysis. The clinical presentation is normally asymptomatic and it is usually diagnosed incidentally on laparotomy. Complications may include perforation, hemorrhage, enterolith formation, diverticulitis, and intestinal obstruction. Enterolith formation is the most common complication and intestinal obstruction is rare. An adhesion band, arising from the base of one of the diverticula, may be formed after repeated diverticulitis, and may cause strangulation of the intestine. We report a rare case of diverticulosis of the jejunum with an adhesion band resulting in intestinal obstruction.

CASE REPORT

A 70-year-old male was admitted to our emergency department with dull abdominal pain and no passage of stools for 3 d. He reported a sensation of fullness over the whole abdomen and nausea. He had previously been admitted to our hospital thrice in 1 year with partial intestinal obstruction. An abdominal examination showed a diffuse tympanic sound, with percussion and tenderness over the whole abdomen. Laboratory tests indicated a white-cell count of 4 800/μL, and normal serum sodium (136 mmol/L) and potassium levels (3.8 mmol/L). A plain X-ray of the abdomen showed dilatation of the small intestine, especially in the proximal jejunum (Figure 1A). An upper gastrointestinal (GI) oral contrast study showed multiple diverticula in the proximal jejunum and a mechanical obstruction of the proximal jejunum (Figure 1B). The presumptive diagnosis was partial intestinal obstruction and the patient was admitted. After admission, nasogastric tube decompression was performed. The sensation of abdominal fullness was persistent 3 d later. An exploratory laparotomy revealed minimal clear ascites and diverticulosis of the proximal jejunum and an adhesion band with a dilated proximal jejunum (Figure 2). Segmental resection of the proximal jejunum (20 cm in length) with end-to-end jejuno-jejunostomy was performed. The final pathological diagnosis was diverticulosis of the jejunum with serosal fibrosis, hemorrhage, calcification, and inflammatory change.

The patient had an uneventful post-operative course and was discharged 8 days after the procedure.

DISCUSSION

Diverticulosis of the small bowel (excluding Meckel's diverticulosis) is uncommon, and is found in less than 5% of post-mortem examinations[1]. It is caused by herniation of the mucosa and submucosa through the muscular layer of the bowel wall (false diverticula). Diverticula are usually multiple and occur at the mesenteric border, in contrast to

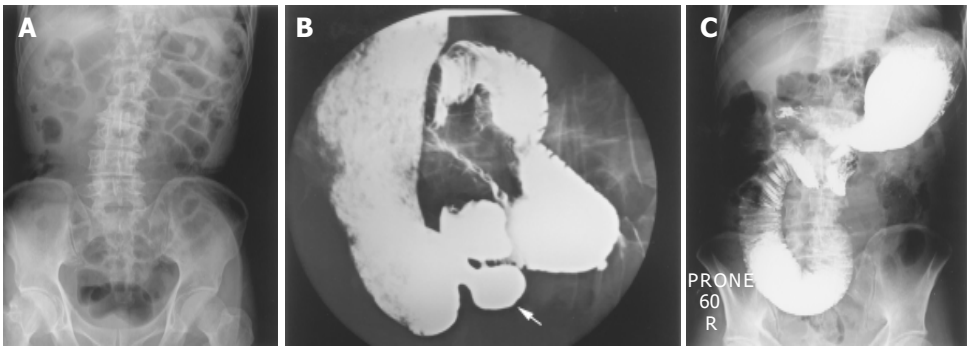

Figure 1 A plain X-ray of the abdomen showing dilatation of the small intestine, especially the proximal jejunum (**A**). **B** and **C:** An upper GI oral contrast study showing multiple diverticula in the duodenum and proximal jejunum (the white arrow, (**B**) and dilatation of the proximal jejunum (**C**).

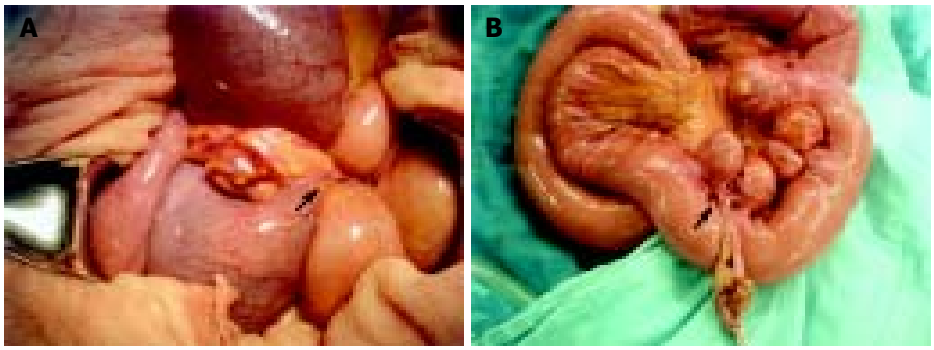

Figure 2 The photograph shows an adhesion band overriding the jejunum (the black arrow), with ischemic changes in the proximal jejunum (**A**). After surgical removal of the adhesion band, we found that the band was connected to one of the diverticula, arising from the mesentery side (the black arrow) (**B**).

the true congenital Meckel's diverticulum. The probable cause of diverticulosis of the small bowel is motor dysfunction of the smooth muscle or the myenteric plexus in the small bowel. If contraction of the affected small intestine is disordered, it may increase the intraluminal pressure, and the mucosa and submucosa would pass through the weakest mesenteric site in the bowel wall[3]. This condition is usually asymptomatic and is found incidentally. Most patients have chronic abdominal pain and a bloated sensation. Complications include hemorrhage, perforation, diverticulitis, and intestinal obstruction. Mechanical intestinal obstruction occurs in 2.3-4.6% of cases of jejuno-ileal diverticulosis, and is reported to be the most frequent complication of jejunal diverticula requiring surgery[3-6]. Previous cases of intestinal obstruction associated with intestinal diverticulosis include distended diverticula, inflammatory mass associated with diverticulitis, stricture or adhesions from recent or past diverticulitis, and intussusception at the site of the diverticulum, most of which are caused by enteroliths[3]. The obstruction is induced by adhesion band rarely, as it occurred in our case.

Lobo *et al*., reported that dynamic intestinal obstruction is the most frequent complication of jejunal diverticulosis necessitating surgery and may be due to enteroliths, adhesions secondary to diverticulitis, volvulus, or intussusception[2].

This is the first report of strangulation of the jejunum caused by a mesodiverticular band in the literature. The band may have formed during recurrent diverticulitis, because it arose from the mesodiverticulum. Although this phenomenon is rare, we should keep in mind that intestinal diverticulosis may induce intestinal obstructions of different kinds, repeat physical examinations and X-ray films are needed and enteroclysis studies or CT scan are helpful in diagnosis. Surgery is indicated for acute abdominal or repeated intestinal obstruction.

Abstract

In this article, we have reviewed the main therapeutic measures for the treatment of Zollinger-Ellison syndrome (ZES). Review of the literature was based on computer searches (Pub-Med, Index Medicus) and personal experiences. We have evaluated all the measures now available for treating patients with sporadic gastrinomas or gastrinomas associated with Multiple Endocrine Neoplasia Type 1, (MEN 1) including medical therapy such as antisecretory drugs and somatostatin analogs (SST), chemotherapy and chemoembolization, and surgical procedures. In ZES patients, the best therapeutic procedure is surgery which, if radical, can be curative. Medical treatment can be the best palliative therapy and should be used, when possible, in association with surgery, in a multimodal therapeutic approach.

INTRODUCTION

The Zollinger-Ellison Syndrome (ZES) represents a clinical, diagnostic and therapeutic challenge. In this paper, we have reviewed the recent advances on this fascinating syndrome. One MEDLINE (PubMed) search, was carried out using only MESH terms with the following strategy: Therapy AND (gastrinoma OR Multiple Endocrine Neoplasia Type 1 OR Zollinger-Ellison Syndrome). No limits were set and 4 369 papers were found. Only those papers *in-extenso* were considered. The authors reviewed all the papers and other papers or chapters in the published book were also manually searched in the references of the papers reviewed, if considered necessary for the present review.

CAUSES

The ZES, as described in 1955, is characterized by peptic ulcers of the upper gastrointestinal tract refractory to medical therapy, diarrhea and severe gastric acid hypersecretion associated with non-beta islet cell tumors of the pancreas[1]. It was later demonstrated that this pancreatic tumor, named gastrinoma, ectopically releases gastrin, which is responsible for the gastric hypersecretion. More than 80% of gastrinomas are localized in the anatomic area called the triangle of the gastrinomas. This triangle includes the convergence of the cystic duct and the common bile duct, the junction of the second and third portion of the duodenum, and the junction of the head and body of the pancreas[2-5]. Most gastrinomas arise from the duodenum (about 75%), whereas they are localized in the pancreas in 25% of cases[4]. Occasionally gastrinomas occur in the ovary, mesentery, liver, bile duct, gastric antrum/pyloric area, renal capsule, and in the jejunum[6,7]. Furthermore, extra-abdominal primary gastrinomas in the heart[8,9] and gastrin-releasing lung tumor causing ZES have recently been described[10].

The structure can be glandular or trabecular, and the cells are round with small nuclei and prominent nucleolus. The cells which produce gastrin are generally well-differentiated and contain the histological markers typical of neuroendocrine tumors, i.e., chromogranin A, neurospecific enolase and synaptophysin. These tumors are positive at immunohistochemistry not only for gastrin but, frequently, also for other peptides, including the pancreatic peptide (PP), somatostatin (SST), the adrenocorticotrophic hormone (ACTH) and the vasoactive intestinal peptide (VIP).

This tumor presents itself at various ages from 7 to 90 years, but the diagnosis is usually made between the ages of 30 and 50 years. There is no clear sex prevalence even if 60% of the patients affected are men[11-14].

Gastrinomas may behave in a benign or malignant manner, but usually, even when malignant, they can be slow growing. Numerous studies support the conclusion that gastrinomas pursue an aggressive growth pattern in 20-30% of cases and an indolent growth pattern in the rest; this seems to be independent of the presence or the absence of positive lymph nodes[3,15,16]. The most common site of metastases are the local lymph nodes, followed by the liver; these metastatic lesions, unlike those of adenocarcinomas, are vascular. Bone metastases are common in advanced disease, probably occurring in the majority of patients[17]. The percentage of patients presenting a malignant form of

sporadic ZES is not clear; some data in the literature report that about 65% of gastrinomas are malignant, but perhaps this is overestimated[18]. Furthermore, it has been suggested that a poor prognosis is associated with the development of ectopic Cushing's syndrome, reported in up to 5% of patients with ZES[19].

The gastrin secreting tumor responsible for ZES is the most common tumor in patients affected by Multiple Endocrine Neoplasia type 1 (MEN 1).

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

MEN 1 is an autosomal dominant inherited syndrome characterized mainly by the development of hyperplasia and/or multiple tumors in the parathyroid, endocrine pancreas, duodenum, anterior pituitary, foregut-derived neuroendocrine tissue, and adrenocortical glands. This syndrome, first described by Wermer in 1954, has a prevalence of 0.2-2/100 000 people/year, even if this is underestimated since, generally, the endocrinopathies which constitute this disease are not adequately classified[20,21]. MEN 1 is associated with inactivating mutations of a tumor suppressor gene (*MEN1*), mapped on chromosome 11q13 in 1988[22]. The MEN 1 gene was sequenced in 1997 and was found to encode for a transcriptional regulator, named "menin"[23]. In MEN 1 patients, one allele of the gene is inactivated by the germline mutation, and phenotype expression occurs with inactivation of the second allele by somatic cellular mutation. Somatic mutations of the MEN 1 gene have also been reported in sporadic forms of endocrine tumors with a variable incidence of 20-30% in the parathyroid, the endocrine pancreas (33% gastrinomas, 17% insulinomas), 25% in lung carcinoids, but less than 1% in pituitary and adrenocortical tumors[24-27].

In clinical practice, it is important to perform genetic analysis in order to diagnose MEN 1, but the diagnosis cannot be excluded with certainty, when a mutation is not found[28]. Therefore, the clinical screening of patients remains a prerequisite for genetic analysis. Screening for MEN 1 is a crucial step in the diagnosis and the management of neuroendocrine tumors, because prognosis and treatment may differ from the sporadic case.

Gastrinoma with ZES is found in 20-61% of patients with MEN 1[29,30]; conversely, MEN 1 is found in 30-38% of all patients with gastrinomas[30-32]. In MEN 1, gastrinomas are mainly localized in the duodenum, they are small and frequently multifocal and may therefore be difficult to detect either by traditional imaging methods or at surgery[33,34].

ZES-MEN 1 is associated with gastric carcinoids, also called ECL-omas (type 2 carcinoids), due to chronic effect of hypergastrinemia on ECL cells. These tumors seem to be found in 13-30% of patients with ZES-MEN 1 and in 0-0.6% of patients without MEN 1[35,36]. ECL-cell tumors in MEN 1 are often multicentric and are generally characterized by a low mitotic index; most of these tumors are less than 1 cm in diameter and are limited to the mucosa and submucosa[37]. The percentage of patients in whom these tumors are invasive is unknown; metastases to local lymph nodes can be observed, but patient survival is usually excellent with tumor persistence for more than 25 years and very few related deaths[38].

CLINICAL MANIFESTATIONS

The signs and symptoms of ZES are primarily due to gastric acid hypersecretion. The most common initial symptom is abdominal pain and 90-95% of patients develop peptic ulcers in the upper gastrointestinal tract. In 36% of cases, the ulcers are multiple or in an unusual site; however, there is a percentage of patients with ZES (from 18% to 25%) who do not have ulcers at diagnosis. The ulcer can appear as a common duodenal ulcer, but it is usually less responsive to therapy with respect to ulcers in patients without gastrinomas. The most common is a single ulcer of the duodenal bulb which can also appear in the second, third, or fourth portion of the duodenum or in the jejunum[39].

Gastroesophageal reflux, present in two-thirds of patients with ZES, can vary from light to severe forms and can be complicated by stenosis or Barrett's mucosa[39]. Diarrhea is the second most common symptom, developing in 50-65% of patients, and can precede, accompany or follow the ulcerous disease; in 7-35%, it may be the only initial symptom[39]. The diarrhea is due to massive acid hypersecretion which activates pepsinogens which are responsible for mucosal damage; in addition, acid inactivation of the pancreatic enzyme and acid damage to enterocytes also contribute to it. Steatorrhea is a result of inactivation of pancreatic lipase by intraluminal acid in the upper small intestine; the low pH also renders some primary bile acids insoluble, reducing the formation of micelles, which are needed for absorption of fatty acid and monoglycerides[3].

DIAGNOSIS

The diagnosis of ZES is based on the finding of elevated fasting serum gastrin associated with gastric acid hypersecretion. Other conditions exist in which gastrin levels can be elevated; these are hypochlorhydria in the course of chronic atrophic gastritis, the prolonged use of proton pump inhibitors or the presence of *Helicobacter pylori* (*H pylori*) infection. When the diagnosis is not completely clear, a reliable test is the measurement of basal acid secretion (BAO) or, alternatively, it can be useful to determine the pH of the gastric juice which can be obtained during endoscopy or through a nasogastric tube. If the gastric pH is >2 in the absence of antisecretory therapy, the patient is hypochlorhydric and, therefore, ZES can be excluded; if the pH is <2 and the plasma gastrin is higher than 1 000 pg/mL, the diagnosis of ZES is certain while, if the pH is <2 and the plasma gastrin concentration is between 100 and 1 000 pg/mL, a secretin test must be carried out[40]. The secretin test is performed by the administration of 2 IU/kg of secretin intravenously in 2 min, after having taken a blood sample in order to perform the basal gastrin concentration; after the injection, blood samples are taken after 2.5, 5, 10, 15 and 30 min. An increase of plasma gastrin >200 pg/mL is diagnostic of ZES. The test can give a false positive result in some patients with Type A chronic atrophic gastritis, but this is identified by measuring the gastric pH[41]. The secretin test can also give a false negative result in 10% of patients with ZES, and this is usually associated with a malignant course of the disease[42]. The calcium test might be of value in those patients in whom ZES is strongly suspected when

the secretin test is negative. There is agreement in the literature that calcium and meal tests are less useful than secretin for detecting ZES.

Imaging techniques

To localize and stage gastrinomas, conventional non-invasive and occasionally invasive diagnostic modalities may be required. At present, the most important study should be somatostatin receptor scintigraphy (SRS) using ^{111}In-pentetreotide with single photon emission tomography (SPECT) scanning[4]. Recent studies demonstrated that SRS allows total body localization study simultaneously at one time, thus allowing detection of liver and distant metastases and it is more sensitive in both localizing the primary gastrinoma and identifying patients with liver metastases than conventional methods such as CT, MRI, US[43]. Unfortunately, SRS detects 30-75% of gastrinomas measuring less than 1 cm, primarily duodenal gastrinomas; a negative scan in the presence of a visible tumor suggests either a poorly-differentiated neuroendocrine tumor or a pancreatic adenocarcinoma[44]. Ultrasonography can detect gastrinomas in 30% of cases and the detection rates are better for lesions greater than 3 cm in diameter and are poor for lesions smaller than 1 cm[45].

Using EUS, the sensitivities as high as 79-82% can be obtained[46,47]. A recent prospective study found a sensitivity of 93% and a specificity of 95% in the localization of intrapancreatic lesions[48]. EUS, in combination with SRS up to 69%, although it may still miss up to 50% of duodenal gastrinomas[49]. Therefore, when a gastrinoma is suspected, endoscopy or EUS should also be performed to identify duodenal as well as pancreatic gastrinomas, especially when multiple lesions are suspected as in MEN 1[33,34].

Regarding CT and MRI, the most recently published series showed that CT with bolus of contrast administration can achieve sensitivities ranging from 82% to 92%[50,51] and MRI, using T1-weighed fat suppression images, has a 91% sensitivity[52,53]. A comparative study demonstrated that MRI is equivalent to dynamic CT. Furthermore, MRI is considered the most sensitive technique for demonstrating liver and bone metastases in patients with neuroendocrine tumors and is recommended for monitoring the response to therapy. However, CT and MRI are both very sensitive and specific methods for demonstrating hepatic metastases and pancreatic tumors, and they show specific advantages in routine tumor staging and monitoring of therapy[54,55].

Functional studies, measuring hormonal gradients by transhepatic portal venous sampling, seem to be more sensitive; however, this method is invasive, and does not lead to the exact location and requires considerable expertise. A modification of the hormonal gradient during angiography has been developed; in brief, secretin is injected intra-arterially selectively into different vessels and hepatic venous samplings are collected and assayed for hormonal gradients. Selective angiography can identify the site of the tumor in up to 75% of cases, but has largely been supplanted by the combination of Octreoscan, EUS and CT[56,57].

In about 20% of patients, a gastrinoma cannot be identified by conventional imaging techniques and SRS[58]. In these cases, during laparotomy, operative techniques such as duodenal transillumination and intraoperative ultrasound can be used[4].

A suggested algorithm for the diagnosis of ZES is reported in Figure 1.

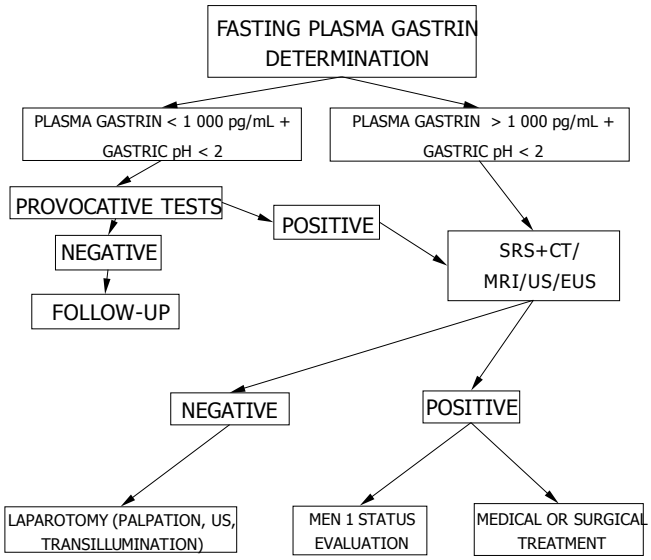

Figure 1 Diagnostic algorithm for Zollinger-Ellison Syndrome. SRS: somatostatin receptor scintigraphy; CT: computed tomography; MRI: magnetic resonance imaging; US: ultrasonography; EUS: endoscopic ultrasonography.

TREATMENT

In patients with ZES, the two main principal therapeutic objectives are to control the gastric acid hypersecretion which causes the most debilitating symptoms (ulcers, diarrhea and dehydration) and to control the growth of the tumor which, even if slow-growing, is able to produce early and diffuse hepatic metastases.

Until the end of the 1970s, the only effective therapy for controlling acid hypersecretion was total gastrectomy. Currently, after the introduction of potent antisecretory drugs, such as H_2 antagonists and proton pump inhibitors, the most important aspect for these patients is the growth of the neoplasm. In fact, half of the patients die from causes related to the tumoral mass and not from the effects of the massive gastric acid hypersecretion[59]. Thus, at present, a large number of treatment options are available for the therapy of patients with ZES: control of the gastric acid hypersecretion; control of the gastrin hypersecretion; surgical resection or cytoreduction of the tumor; control of the tumor size by using chemotherapy or interferon alfa; control of the hepatic metastases with chemoembolization and/or embolization.

Control of gastric acid hypersecretion

If ZES is suspected, it is important, while waiting for the conclusive results of the diagnostic tests, to prevent the complications which could arise. For this reason, it is advised to rapidly start an antisecretory therapy which is usually well-tolerated and without particular contraindications.

Histamine H_2 receptor antagonists

Since proton pump inhibitors have been available commercially,

H_2 receptor antagonists are no longer the drugs of choice for patients with ZES, even if they have actually been proven effective in alleviating the symptoms and healing ulcers in gastrinomas. Ranitidine is the drug of choice among the H_2 antagonists, due to its low side effects and its limited interaction with other drugs. However, despite the first excellent results, long-term studies have shown that the use of these drugs is limited by many factors such as poor control of the gastric acid hypersecretion and sometimes the need for high and frequent doses of the drug[60]. The pharmacological basis of these observations is unknown, even if various possibilities have been suggested, such as a diminished bioavailability due to reduced absorption, an altered metabolism of the drug with increased excretion, the development of tachyphlaxis and the hypersecretory state itself[61]. The poor effectiveness of H_2 antagonists is usually evident in ZES associated with severe gastroesophageal reflux, MEN 1 with hyperparathyroidism and partial gastric resection[62].

Proton pump inhibitors

Omeprazole, the first proton pump inhibitor available, belongs to a new class of drugs which has proven to be safe and effective in controlling gastric hypersecretion in patients with ZES and has completely substituted the use of H_2 antagonists. The PPIs commonly used are omeprazole, lansoprazole, pantoprazole, rabeprazole and esomeprazole[63]. These drugs show differences in pharmokinetics and pharmodynamics, but it is not always clear, if these fine variations have clinical importance[64].

Initial therapy

The goal of ZES therapy is to obtain improvement of the symptoms and healing of the ulcers by controlling the gastric hypersecretion. Various studies have shown that a reliable criterion for the control of the hypersecretion is the reduction of the BAO below 10 mEq/h in the hour preceding the next administration of the drug in cases of uncomplicated ZES and below 5 mEq/h in cases of ZES associated with MEN 1, gastro-esophageal reflux disease or in patients undergoing a partial gastrectomy[2,65].

Using the acute upward dose titration method, widely accepted for establishing the initial dosage of omeprazole, some studies have demonstrated that the average dosage of omeprazole capable of controlling gastric hypersecretion in the majority of patients is between 60 and 100 mg of the drug per day[66]. The only reliable parameter able to demonstrate the absence of damage to the mucosa is the level of acid inhibition when the "steady state" has been reached; therefore, the BAO must be measured every 3-4 wk and the patient should be evaluated by endoscopy and acid secretion analysis at intervals from 3 to 6 mo and, successively, from 6 to 12 mo. The objective of the therapy is not achlorhydria, but a BAO between 1 and 10 mmol/h; if complete inhibition of the acid hypersecretion is seen, the dosage of omeprazole should be reduced by 50% and the patient should be re-evaluated. If the BAO is greater than 10 mmol/h, the dosage of the PPI should be increased gradually and, for doses of omeprazole over 60 mg (or equivalent doses of another PPI), it would be advisable to administer the drug in two divided doses. The lack of control of gastric acid secretion could be a high risk for patients affected by ZES[66,67] and some data in the literature have demonstrated that an initial dose of 20 mg is not able to control the acid secretion and the symptoms linked to the disease[68].

PPI long-term treatment

Many data have been reported on the effectiveness and safety of the PPIs, when these drugs are administered on a long-term basis in patients with ZES. After having established the initial dosage and having monitored the gastric secretion, the long-term maintenance dosages can be reduced significantly in the majority of patients, when control of the gastric secretion is stabilized[69,70]. This can be easily explained by the fact that the effectiveness of omeprazole increases with time[70-72]. In fact, Metz *et al*., have shown that the maintenance dosages of omeprazole can be partially or completely reduced in all patients with ZES, above all in those who are not affected by MEN 1, serious gastro-esophageal reflux or those who have undergone a partial gastrectomy[70]. Some studies have shown that, in the long-term, it is not necessary to increase the dosage of omeprazole; if, however, during the first year, repeated increments in therapy are necessary, it means that the initial dose was inappropriate and there was no progressive development of pharmaceutical resistance[73]. While the H_2 antagonists have demonstrated the phenomenon of tachyphylaxis with prolonged use, only in 10% of patients is it necessary to increase the dose of the PPIs[74]. PPIs have been proven to be safe and effective in the maintenance therapy of patients with ZES for more than 10 years, without any effect of related toxicity[65]. It does not seem that treatment with PPIs in ZES has induced any significant increase in the concentration of plasma gastrin or alterations in the percentage of argyrophil cells[75].

Intravenous PPIs

Patients affected by ZES who are not able to take PPIs orally and who need a therapy which primarily suppresses gastric acid secretion; patients with active peptic ulcer, recent hemorrhage and endoscopic stigmata that puts them at high risk of rebleeding, are candidates to receive PPIs intravenously. Another possible means of administration of solutions prepared with oral PPIs is intragastric, which can be utilized as an alternative to the intravenous route in critically ill patients or in whom esophageal stenosis is present.

Vitamin B12 levels during prolonged treatment with PPIs

During prolonged treatment with proton pump inhibitors, reduced serum levels of vitamin B12, but not of folate, have occasionally been documented[76]. This phenomenon seems to be related to the achlorhydria induced by the drug which, moreover, is not common during therapy with PPIs.

Helicobacter pylori and ZES

Some studies have considered the interactions between ZES, *H pylori* and PPIs, pointing out how the *Helicobacter* infection does not constitute a risk factor for the onset of peptic ulcers in these patients. In fact, the prevalence of *H pylori* infection in these subjects is lower than in the overall population and

is much lower than in patients with common peptic ulcer disease. Indeed long term PPIs therapy in HP-positive patients with ZES may lead to the reduction of parietal cell mass[77].

Control of the hormonal secretion

Somatostatin analogs It is well-known that somatostatin and its analogs are able to reduce gastric acid and serum gastrin levels in patients with ZES, with both short-term and long-term administration[78]. In addition to immediate-release subcutaneous octreotide, other long-acting somatostatin analogs such as lanreotide, which can be administered every 10-14 d, and octreotide LAR, which can be administered every 28 d, are currently available on the market[79,80]. In 1993, Rusniewsky noted an average decrease in serum gastrin of 87% in patients with ZES treated with octreotide subcutaneously for a period of 9–12 mo. It was also seen that octreotide was capable of controlling gastric hypersecretion without an "escape phenomenon" and was able to reduce, and sometimes eliminate, the hyperplasia of the ECL cells when this was present before treatment[81]. In the same period, Bordi reported that prolonged treatment with octreotide is able to significantly decrease the fundic argyrophil cells in patients with a gastric pathology[82].

Thereafter, several studies have shown that treatment with somatostatin analogs has an inhibiting effect on tumoral growth in patients with malignant gastrointestinal neuroendocrine neoplasias, such as pancreatic tumors or carcinoids, and is able to stabilize the tumoral growth in 37-80% of patients; in only a few patients (0-17%), a reduction of the tumor dimensions has been observed[83,84].

Moreover, up to now, only one study on the effectiveness of octreotide in controlling tumoral growth in patients with metastatic gastrinomas has been carried out. In this study, performed on 15 patients, it was shown that, in 53% of these patients with malignant gastrinomas, the tumoral growth progressed, 47% of patients presented stabilization and 6% had a reduction of the tumor size[85]. In patients who responded to treatment, stabilization of the tumor was long lasting and the incidence of side-effects was lower in comparison to the group treated with chemotherapy. In this study, it was concluded that, in gastrinomas, somatostatin analogs are not the drugs of first choice in controlling gastric acid hypersecretion, but are very useful in controlling tumoral growth.

The most common side-effects of somatostatin analogs are gallstones, abdominal pain, diarrhea and pain in the injection site.

Receptor-mediated radiotherapy with ^{90}Y-DOTA-D-Phe1-Try3-octreotide for neuroendocrine tumors has recently been proposed as a palliative treatment; this modality of treatment can, however, cause myelotoxicity and nephrotoxicity[86]. In the past 3 years, several studies have been published on the use of this therapy in neuroendocrine tumors associated with syndromes, using not only ytrium but also lutetium which seems to be less toxic for the kidneys[87]. As regards the therapy for gastrinomas, a regression of metastases in 25% of the patients has been described[88].

As previously reported, long lasting somatostatin analogs have been shown to be capable of reducing the mass of gastric endocrine cells[89]; furthermore, it has been demonstrated that these drugs can inhibit growth in hypergastrinemic experimental models which develop gastric carcinoids[90,91]. This evidence supporting the use of octreotide can be utilized in patients with gastric carcinoids. These data have been confirmed in a recent study of our group which showed the regression of gastric carcinoids associated with ZES-MEN 1 after 1 year of treatment with long acting somatostatin analogs[92].

Control of neoplasia growth

Surgery The role of surgery in the treatment of ZES has evolved considerably from 1955 to now[1]. Initially, the surgical therapy proposed was total gastrectomy with the aim of removing the high levels of gastrin from the target organ[93]; in the past 20 years, improved pharmacological control of gastric acid hypersecretion has eliminated the role of surgery in containing the hypersecretion itself. The availability of PPIs allows us to adequately control the symptoms in all patients with ZES, making the natural history of gastrinomas, the only determining factor in long-term survival[94].

Since adequate medical therapy is able to eliminate the symptoms in all patients and, although it is hard to treat the neoplastic disease with chemotherapeutic drugs, some authors claim that the risks and complications of exeresis of the gastrinoma exceed the actual benefits of this procedure[58]. More recently, however, some others have reported that surgical excision of a gastrinoma has proven highly effective in order to prevent hepatic metastases[93,95]. At present, surgical exploration plays a key role in identifying and removing the primary tumor, and in preventing the onset of liver metastases.

The main objectives of surgery are to stage the tumor, improve survival by removing the malignant tumor and control the acid hypersecretion syndrome. Since the majority of patients with ZES present either with occult disease or with localized disease, the surgeon has to search for and remove the non-localized lesion laparotomically using imaging techniques. Furthermore, intra-operative techniques such as palpation, ultrasonography and transillumination of the duodenal wall can contribute to the identification of pancreatic and duodenal gastrinomas, including lymph nodes and hepatic metastases. It is important to consider that a large percentage of primary occult tumors are found inside the duodenum. Gastrinomas commonly metastasize in the lymph nodes and sometimes arise in this site; hence, the resection of all the lymph nodes in the peripancreatic region is important, even if they do not appear swollen. Exploration of the liver and the rest of the abdomen is also recommended in order to identify possible metastatic disease[96].

It has also been reported that more than 50% of patients are free from disease after surgery and the majority of them remain so for the following 5-10 years[93,95].

Gastric acid hypersecretion caused by hypertrophy of parietal cells can persist, after surgery, despite biochemical evidence of cure; for this reason it is very important for all patients to continue maintenance, antisecretory therapy until the BAO determination is less than 10 mEq/h[97]. In those patients in whom there is a persistence of neoplastic tissue or post-operative relapse, debulking the tumor often leads

to a proven benefit[95].

Liver transplant is characterized by a remarkable morbidity and, for the most part, post-operative immunosuppressive therapy stimulates the relapse of growth of the tumor[98]. A careful evaluation of the data found in the literature shows that a non-carcinoid histotype is present among the exclusion criteria for liver transplants in patients with hepatic metastases and neuroendocrine tumors. In this regard, French authors, in a retrospective study, have pointed out an unfavorable prognosis in patients with non-carcinoid endocrine tumors undergoing a liver transplant[99].

Surgery in ZES associated with MEN 1 The indications for surgery in patients with ZES-MEN 1 are controversial, since previous experience has shown that surgery rarely cures these patients[100,101]. Some authors have carried out an exploratory laparotomy on patients with ZES-MEN 1 in which the tumor, studied using imaging techniques, had a diameter greater than 2.5 cm. A direct relationship between the size of the tumor and the onset of hepatic metastases has been hypothesized and, as in other malignant solid tumors, the effectiveness of the cure is expected to be greater, if the tumors are resected, when they are still small[36,102].

In a recent study, a group of Swedish researchers established that the best surgical procedures include enucleation of the tumor in the head of the pancreas, excision of duodenal gastrinomas together with the removal of the metastasized lymph nodes and, as prophylaxis of tumoral relapse, the combination of these procedures with an 80% subtotal resection of the distal pancreas. It is thought that a more extensive resection of the tumor reduces the risk of the malignant evolution of pancreatic and duodenal tumors[101].

In patients with ZES-MEN 1, hyperparathyroidism is usually present at the moment of diagnosis[103]; therefore, in patients with hypercalcemia, a parathyroidectomy should be performed before any other surgical procedure in order to better control the pathological effects of hypercalcemia. It has been demonstrated that a parathyroidectomy is capable of reducing the fasting serum levels of gastrin and the BAO, and this, therefore, improves the response to the antisecretory therapy[32].

Control of tumor size

Systemic chemotherapy Therapeutic strategies for the management of patients with metastatic gastroenteropancreatic endocrine tumors have to take into consideration the fact that controlling the hormone-mediated symptoms often improves the quality of life, to the point that the patients feel well despite the extensive metastatic disease[104]. At best, chemotherapy has furnished only unclear results utilizing the classical anti-tumoral agents, such as 5-fluorouracil, in controlling metastatic endocrine tumors. Systemic chemotherapy reached a new therapeutic dimension immediately after the introduction of streptozotocin (STZ) into clinical use[105]; there have been several studies on the effects of this drug on metastatic islet-cell tumors which have confirmed the effectiveness of streptozotocin. Despite this, there are a number of acute and chronic side effects, such as serious renal or hematologic toxicity[106]. Various studies have standardized the dosage and administration schedule of streptozotocin and have suggested its combination with other cytotoxic drugs such as 5 fluorouracil (5-FU) and doxorubicin (adriamycin); the combination of STZ and doxorubicin has been superior to other regimens, mainly STZ and 5-FU, and seems to be associated with a 69% objective response lasting for 18 mo and overall median survival of 2.2 years[107].

In a detailed study conducted on 10 patients with metastatic gastrinomas and treated with streptozotocin, 5-fluorouracil and doxorubicin, 4 patients showed a partial response to the treatment, but the survival rate was the same both in the 4 responders and in the 6 non-responders[108]. Another type of chemotherapy proposed is monotherapy with chlorozotocin, a nitrosourea having a composition similar to streptozotocin characterized by less gastrointestinal toxicity but increased myelosuppression or monotherapy with dacarbazine[109].

In conclusion, chemotherapy is not the treatment of first choice in patients with gastrin secreting tumors, but seems to be indicated in rapidly evolving tumors in which the mass of the primary tumor increases more than 25% in a period of follow-up of 12 mo or in which the tumoral symptoms cannot be treated by other means[110].

Interferon In recent years, the validity of interferon has been sustained in neuroendocrine tumors, especially in the carcinoid syndrome. The data in the literature demonstrate that therapy with interferon-alpha leads to the stabilization of the tumor in 20-40% of patients with different gastrointestinal neuroendocrine tumors, including those with metastatic gastrinomas, but it did not result in an increase in the survival rate of these patients[111]. It has been proposed, therefore, that gastrinomas can be treated with chemotherapy and/or interferon when they grow and metastasize[111].

Role of chemoembolization or embolization Selective embolization of the hepatic arteries causes transient and complete ischemia with an objective, symptomatic and hormonal response of 65% and 81%, respectively; this treatment has been demonstrated to be useful in patients with liver metastases from neuroendocrine pancreatic tumors. Unfortunately, only a small number of gastrinomas have been treated with chemoembolization and there are no sufficient data on long-term survival after this procedure. Chemoembolization, which uses a combination of gelfoam and chemotherapeutic agents (streptozotocin or doxorubicin), may determine a notable improvement in the quality of life of the patient and is usually accompanied by a reduction in circulating peptide serum levels and the size of the tumor. However, it has not been clearly demonstrated that the inhibition of tumoral growth improves the survival rate[112-115].

Chemoembolization is an alternative to chemotherapy for progressive liver metastases in patients with gastrinomas.

A suggested algorithm for medical and surgical treatment of ZES is reported in Figure 2.

CONCLUSIONS

Proton pump inhibitors have been used to more drastically inhibit gastrin action on the parietal cells, thus allowing the patient to rapidly return to a normal clinical condition without the need for surgery. If it is possible to eliminate the morbidity

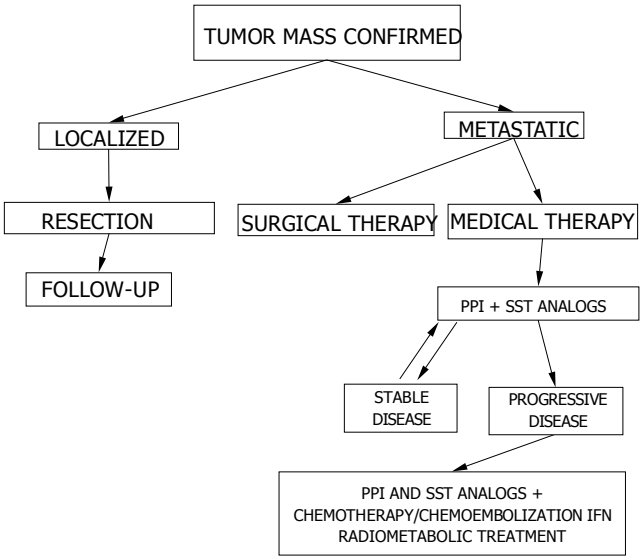

Figure 2 Therapeutic algorithm of Zollinger-Ellison Syndrome. PPI: proton pump inhibitors; SST: somatostatin analogs; IFN: interferon.

and mortality caused by acid hypersecretion, the majority of patients affected by ZES should be able to be maintained in good clinical condition, without symptoms. In ZES, antisecretory drugs have been proven to be safe and effective, without particular side effects over a long period of time, even 15 years or more.

Recent developments in surgical techniques, and pre- and intra-operatory imaging investigation, have permitted the identification and successive resection of more than 95% of gastrinomas. Therefore all localized gastrinomas should be excised, if possible. If hepatic metastases are also present, their enucleation may improve the symptoms and the survival rate as well as facilitate medical treatment. Another possibility is to carry out surgery, only when the tumor is greater than 2 cm in diameter, because these dimensions are associated with a greater risk of metastases in the liver. However, there is some controversy about the surgical approach to gastrinomas associated with MEN 1.

Somatostatin analogs can be useful in reducing gastric acid hypersecretion, serum gastrin and gastric ECL-cells, thus contributing to curing the disease more effectively. Furthermore, thanks to their antiproliferative effects, these drugs are used in treating patients with hepatic metastases and in those affected by ZES-MEN 1 with gastric carcinoids.

Chemotherapy may be particularly indicated in the malignant evolving form, but not in slow-growing tumors or as first choice therapy in gastrinomas.

Embolization and/or chemoembolization may be a palliative procedure for patients with hepatic metastases.

Finally, we would like to emphasize that the choice of treatment must involve a multidisciplinary approach.

Abstract

AIM: To determine the effect of allitridi on cell cycle of human gastric cancer (HGC) cell lines MGC803 and SGC7901 and its possible mechanism.

METHODS: Trypan blue dye exclusion was used to evaluate the proliferation, inhibition of cells and damages of these cells were detected with electron microscope. Flow cytometry and cell mitotic index were used to analyze the change of cell cycle, immunohistochemistry, and RT-PCR was used to examine expression of the $p21^{WAF1}$ gene.

RESULTS: MGC803 cell growth was inhibited by allitridi with 24 h IC_{50} being 6.4 μg/mL. SGC7901 cell growth was also inhibited by allitridi with 24 h IC_{50} being 7.3 μg/mL. After being treated with allitridi at the concentration of 12 μg/mL for 24 h, cells were found to have direct cytotoxic effects, including broken cellular membrane, swollen and vesiculated mitochondria and rough endoplasmic reticula, and mass lipid droplet. When cells were treated with allitridi at the concentration of 3, 6, and 9 μg/mL for 24 h, the percentage of G_0/G_1 phase cells was decreased and that of G_2/M phase cells was significantly increased ($P = 0.002$) compared with those in the group. When cells were treated with allitridi at the concentration of 6 μg/mL, cell mitotic index was much higher ($P = 0.003$) than that of control group, indicating that allitridi could cause gastric cancer cell arrest in M phase. Besides, the expression levels of $p21^{WAF1}$ gene of MGC803 cells and $p21^{WAF1}$ gene of SGC7901 cells were remarkably upregulated after treatment.

CONCLUSION: Allitridi can cause gastric cancer cell arrest in M phase, and this may be one of the mechanisms for inhibiting cell proliferation. Effect of allitridi on cells in M phase may be associated with the upregulation of $p21^{WAF1}$ genes. This study provides experimental data for clinical use of allitridi in the treatment of gastric carcinoma.

INTRODUCTION

Garlic has been used for over 3 000 years in traditional Chinese medicine and is widely used in preventing manifold diseases all over the world. Garlic is the bulb of onion genus lily family plants. Allitridi is a compound extracted from the garlic bulb. It is an important constituent of garlic oil containing diallyl trisulfide (DATS) and diallyl disulfide (DADS)[1,2].

Epidemiological studies indicate that garlic has remarkable antithrombotic, hypolipidemic, hypocholesterolemic and antineoplastic effects. Allitridi has been shown to have anticancer activities, such as inhibiting nitrate reductase, enhancing anticancer activity of macrophages, increasing sensitivity of anticancer drugs[3]. However, its definitive mechanism of anticancer activities has not been established. In this study, human gastric cells MGC803 and SGC7901 were treated with allitridi to study its effect on cell cycle arrest of human gastric cancer (HGC) cell lines MGC803 and SGC7901 and its possible mechanism.

MATERIALS AND METHODS

Cell line and culture

MGC803 was the human gastric mucinous adenocarcinoma cell line and SGC7901 was the human gastric carcinoma metastatic lymph node cell line. These cell lines were grown in RPMI 1640 supplemented with 10% heat-inactivated fetal calf serum, 50 U/mL penicillin and 50 μg/mL streptomycin. The cells were maintained at 37 ℃ in a humidified atmosphere containing 50 mL/L CO_2 and 95% air. Viability of the cells used in these experiments was consistently more than 95%, when evaluated by the trypan blue exclusion method.

Analysis of cell viability

The effect of allitridi on cell growth and viability was determined by counting the number of cells. The cells at a density of 2.5×10^5/mL were seeded onto 24-well plates, and treated with allitridi with different concentrations for 24 h. Cells in control group were also incubated simultaneously. Cell proliferation and inhibition curves were drawn and drug IC_{50} was detected.

Morphological analysis by electron microscope

Cells (1×10^6) were collected after being induced by allitridi at 12 μg/mL for 24 h, washed twice with PBS, centrifuged for 5 min at 1 500 r/min, fixed with 2% glutaral at 4 ℃ and dessicated, embedded in EPON-812. They were then double stained with uranium and plumbum, and observed under transmission electron microscope.

Cell cycle analysis

Flow cytometry was employed to determine the DNA content of these cells. The cells were seeded onto 100-mm dishes and grown in RPMI-1640 supplemented with 10% FCS. After being treated with allitridi at the concentration of 3, 6, and 9 μg/mL for 24 h respectively, the cells were harvested. The cells were trypsinized and washed with D-PBS. The sample was fixed by slowly dropping 2 mL of cold 70% ethanol into the tube and stored at 4 ℃. After fixation, the cells were washed, re-pelleted, and re-suspended in 0.05 mg/mL propidium iodide (Fluka Co.), 100 U/mL RNase (Fluka Co.) in PBS. The sample was incubated at room temperature for 30 min, and analyzed on a FACSCalibur (BD PharMingen). Cell cycle data originally obtained with CellQuest software (BD PharMingen) were re-analyzed using ModFit software (Verity Software House, Topsham, ME, USA). Next, 6 μg/mL allitridi was added to the cultured cells. The induced cells were collected after 24 h. At the same time the negative control was constructed. The cells were smeared and stained with Giemsa dye. The mitotic cells in 1 000 cells were counted under light microscope, and the mitotic index of the cells was calculated.

Analysis of immunohistochemistry

The p21 protein was detected by immunohistochemistry using specific mAb (Maxin Co.). After being treated with allitridi at concentrations of 3, 6, and 9 μg/mL for 24 h, the cells were harvested. At the same time, the negative contrast was constructed. The cells were made into smears and stained using normal S-P immunohistochemical method. Color was displayed with DAB reagent and stained again with hernatein. Results were observed under light microscope. The cells had brown nuclei and plasma was positive.

Semi-quantitative reverse transcription-PCR

The expression of p21 and p16 mRNA was tested by RT-PCR. An aliquot containing 5 μg/mL of RNA was used for the first-strand cDNA synthesis (TaKaRa). In each reaction, 100 μL solution contained 3 μmol/L of random hexamers, 25 mmol/L Tris-HCl, 37 mmol/L KCl, 1.5 mmol/L $MgCl_2$, 10 mmol/L DTT, 0.25 mmol/L dNTP, 40 units of RNAsin, 50 U/mL Super Taq DNA polymerase, and 200 units of reverse transcriptase. The annealing mixture was incubated at room temperature for 15 min, and then incubated in water bath at 41 ℃ for 60 min. The reverse transcriptase enzyme was inactivated by heating the solution to 95 ℃ for 5 min. Thirty cycles of PCR were carried out using the Perkin-Elmer PCR reaction kit and primers, each consisting of denaturation at 94 ℃ for 1 min, annealing at 57 ℃ for 1 min, and extension at 72 ℃ for 2 min. PCR products were separated on 2% agarose gel. Primers used for PCR were p21 sense (5'-GGG GAC AGC AGA GGA AGA C-3') and p21 antisense (5'-CGG CGT TTG GAG TGG TAG A-3'), β-actin sense (5'-GAT TGC CTC AGG ACA TTT CTG- 3') and β-actin antisense (5'-GAT TGC TCA GGA CAT TTC TG-3'). Gene primers were synthesized by Beijing Oake Co.

Statistical analysis

Student's *t*-test was used to compare the difference between control group and allitridi treatment group. The data of cell growth and mitotic index were presented as mean±SD. *P* value less than 0.05 was considered statistically significant.

RESULTS

Allitridi-inhibited proliferation of MGC803 and SGC7901 cells in a concentration-dependent manner

Figure 1 shows the proliferation curves of the cells treated with allitridi at various concentrations. The proliferation of MGC803 and SGC7901 cells inhibited by allitridi was clearly observed in a concentration-dependent manner during the 24-h period. MGC803 cell growth was inhibited by allitridi with 24 h IC_{50} being 6.4 μg/mL. SGC7901 cell growth was inhibited by allitridi with 24 h IC_{50} being 7.3 μg/mL.

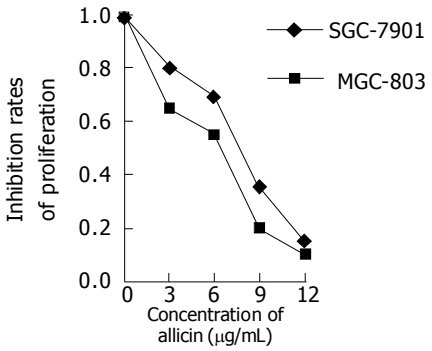

Figure 1 Inhibition of allitridi on MGC803 and SGC7901. Allitridi (3, 6, or 9 μg/mL) inhibited cell growth in a dose-dependent manner.

Morphological observation after allitridi treatment

After being treated with allitridi at the concentration of 12 μg/mL for 24 h, cell morphological change was observed under transmission electron microscope. The ultrastructure showed that the cells were directly killed and broken cellular membrane, swollen and vesiculated mitochondria and rough endoplasmic reticula and mass lipid droplet could be seen. The nuclei had no obvious morphological change or typical apoptosis (Figure 2).

Allitridi-induced cell cycle arrest of MGC803 and SGC7901 cells in M phase

To assess the effects of allitridi on cell cycle progression and population distribution, MGC803 and SGC7901 cells were studied using flow cytometry. A comparison of the cell cycle profiles of allitridi treatment and control cells confirmed the existence of allitridi-induced effects. It was found that 24-h allitridi treatment induced significant cell cycle arrest in G_2/M phase ($P<0.01$) in comparison to

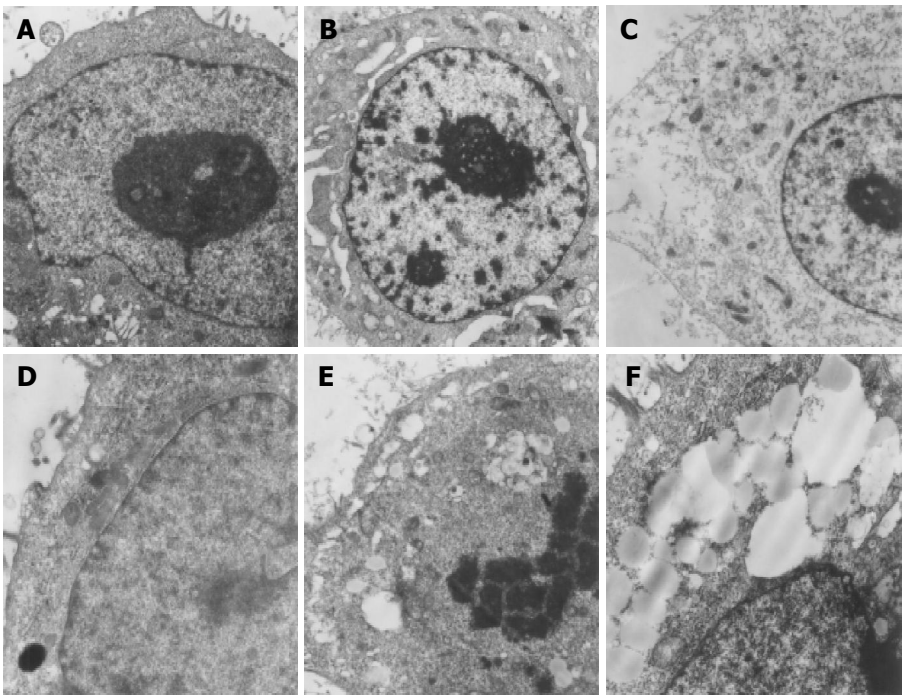

Figure 2 Morphological changes of allitridi-treated MGC803 and SGC7901 cells under electron microscope (×5 000). **A:** MGC803 control cells; **B** and **C:** 12 μg/mL allitridi-induced MGC803 cells; **D:** SGC7901 control cells; **E** and **F:** 12 μg/mL allitridi-induced SGC7901 cells.

untreated cells. Histograms are shown in Figure 3. The percentage of cells in the S phase, G_1, and G_2/M regions are shown in Table 1. After being treated with allitridi at the concentration of 6 μg/mL for 24 h, cell mitotic index was determined. The mitotic index of MGC803 was 316‰ after allitridi treatment, and 21‰ in control group. The mitotic index of SGC7901 was 207‰ after allitridi treatment, and 16‰ in control group. Compared with the control group, the cell mitotic index of allitridi treatment group was much higher (P<0.01), indicating that allitridi caused potential M phase blockage in gastric cancer cells.

Allitridi resulted in increase of p21 expression

The effect of allitridi on p21 protein levels was determined by immunohistochemistry analysis. p21 was not expressed in MGC803 and the SGC7901 cells. However, when MGC803 cells were treated with allitridi at the concentrations of 3, 6, and 9 μg/mL for 24 h, p21 was expressed in high levels, the positive rates of p21 were 28.2%, 29.1%, and 31.8% respe-ctively. Similarly when SGC7901 cells were treated under exactly same as above, p21 expressed in high levels too, the positive rates of p21 were 25.5%, 35.1%, or 39.6%. Figure 4 shows the levels of p21 in MGC803 and SGC7901 cells.

Allitridi upregulated p21^{WAF1} expression

p21^{WAF1} mRNA expressed little in MGC803 and SGC7901 cells. However, we demonstrated that treatment with 6 or 9 μg/mL allitridi did induce upregulation of p21^{WAF1} mRNA in MGC803 and SGC7901 cells. In this study, RT-PCR products of β-actin were used as an inter control. Figures 5A and B show that treatment of MGC803 and SGC7901 cells with allitridi induced an upregulation of p21^{WAF1}.

DISCUSSION

Allitridi containing DATS and DADS is widely used in cancer chemoprevention and anti-cardiovascular disease research[4-6]. Some scholars have reported its protective effects on HGC. DATS can significantly inhibit bacterial nitrosamines. The mechanism is that the constituent of garlic can diminish NO_2, thus preventing the formation of carcinogens[7]. Cellular immune response of patients treated with allitridi shows that the macrophage phagocytotic ability

and lymphocyte transformation percentage are obviously increased in most patients. Cell cycle plays an important role in the modulation of growth of tumor cell, and attention has been paid to preventing unlimited proliferation of tumor cells by cell cycle control[8]. In this study, the proliferation of human gastric cell lines MGC803 and SGC7901 was significantly inhibited after being treated with allitridi at different concentrations. Morphological analysis demonstrated direct cytotoxic effects of allitridi on tumor cells. The cells were detected using flow cytometer in order to examine the distribution of DNA content. The first peak (2C C = haploid DNA content) was produced by the cells in G_1 phase, the second (4C) was produced in G_2/M phase with or without cells in G_1 phase at higher DNA ploidy (tetraploidy, G_{1t}),

and the third (8C) was produced in G_2 phase at higher DNA ploidy (tetraploidy, G_{2t}). The results show that the cells are blocked in G_2/M phase. Furthermore, after allitridi treatment, cell mitotic index was much higher, the cell cycle was blocked just in M phase, indicating that allitridi makes damaged cells stagnate at mitosis phase of cell cycle, and inhibits the proliferation of cells. If this happens, cells re-enter the cycle, otherwise they undergo apoptosis or death. More importantly, allitridi affects M phase of these cells selectively and participates in the regulation of cell cycle, and the blocking effect of allitridi on cells in M phase could be the mechanism of its antitumor effect. Allitridi can be used as a chemotherapeutic agent. Thus, the goal in cancer therapy is to kill cancer cells. Cell cycle control offers a new set of potential target for chemotherapeutic compounds, many of these new agents may be biological modifiers, rather than nonselective cytotoxic agents. The results of the present study reveal that MGC803 and SGC7901 cells have low p21 expression, but allitridi increases the expression of $p21^{WAF1}$ of MGC803 and SGC7901 cells. Completion of the cell cycle requires the co-ordination of a variety of macromolecular syntheses, assemblies, and movements. Negative controls on cell cycle progression are exerted during cell development, differentiation, senescence, and death. These negative controls may play an important role in preventing tumorigenesis. $p21^{WAF1}$ has been implicated as a growth arrest mediator in cell terminal differentiation and apoptosis[9,10]. Regulation of cell cycle progression is orchestrated by CDKs.

$p21^{WAF1}$ is a downstream effector of p53 that mediates cell cycle arrest in G_1 and G_2/M phases. Mechanically, the $p21^{WAF1}$-mediated cell cycle arrest in the G_1 and G_2/M phases has been suggested to include $p21^{WAF1}$-CDK2 and $p21^{WAF1}$-PCNA protein interaction[11]. As we have known, p21 is the cell cycle profiling, when overexpressed it inhibits the CDK4/6-cyclinD complex, leading to cell growth arrest and apoptosis[12], suggesting that many such control points exist within the cell cycle and they play a major role in maintaining the integrity of genome. At least two checkpoints detect DNA damage, one at the G-S transition, the other at the G_2-M transition. In addition, there are mitotic checkpoints, altered expression of cyclins A, B, and CDC2. All potential targets of mitotic checkpoint controls occur in some cancers[13]. Allitridi can upregulate $p21^{WAF1}$. P21 can affect the growth of cells by repressing M phase, and may interact with Cdc2-cyclinB mitosis promoting complex and inhibit its kinase activity; at this point it needs to be further investigated.

In conclusion, allitridi can effectively inhibit the proliferation of HGC MGC803 and SGC7901 cells and upregulate the expression of $p21^{WAF1}$. This study provides experimental data for clinical use of allitridi in treatment of gastric carcinoma.

ACKNOWLEDGMENTS

We are deeply grateful to Dr. Yun-Peng Liu, Director of Department of Internal Oncology, First Affiliated Hospital of China Medical University for providing MGC803 and SGC7901 cells suggestions and reading of the manuscript. We also thank Kezuo Hou for skillful technical inst-ruction.

Abstract

AIM: To investigate the transactivating effect of pre-S2 protein of hepatitis B virus (HBV) and construct a subtractive cDNA library of genes transactivated by pre-S2 protein with suppression subtractive hybridization (SSH) technique, and to pave the way for elucidating the pathogenesis of HBV infection.

METHODS: pcDNA3.1(-)-pre-S2 containing pre-S2 region of HBV genome was constructed by routine molecular methods. HepG2 cells were cotransfected with pcDNA3.1 (-)-pre-S2/pSV-lacZ and empty pcDNA3.1(-)/pSV-lacZ. After 48 h, cells were collected and detected for the expression of β-galactosidase (β-gal). SSH and bioinformatics techniques were used, the mRNA of HepG2 cells transfected with pcDNA3.1(-)-pre-S2 and pcDNA3.1(-) empty vector was isolated, respectively, cDNA was synthesized. After digestion with restriction enzyme *RsaI*, cDNA fragments were obtained. Tester cDNA was then divided into two groups and ligated to the specific adaptor 1 and adaptor 2, respectively. After tester cDNA was hybridized with driver cDNA twice and underwent two times of nested PCR, amplified cDNA fragments were subcloned into pGEM-Teasy vectors to set up the subtractive library. Amplification of the library was carried out with *E.coli* strain DH5α. The cDNA was sequenced and analyzed in GenBank with Blast search after PCR.

RESULTS: The pre-S2 mRNA could be detected in HepG2 cells transfected with pcDNA3.1(-)-pre-S2 plasmid. The activity of β-gal in HepG2 cells transfected with pcDNA3.1 (-)-pre-S2/pSV-lacZ was 7.0 times higher than that of control plasmid (P<0.01). The subtractive library of genes transactivated by HBV pre-S2 protein was constructed successfully. The amplified library contains 96 positive clones. Colony PCR showed that 86 clones contained 200-1 000 bp inserts. Sequence analysis was performed in 50 clones randomly, and the full length sequences were obtained with bioinformatics method and searched for homologous DNA sequence from GenBank, altogether 25 coding sequences were obtained, these cDNA sequences might be the target genes transactivated by pre-S2 protein.

CONCLUSION: The pre-S2 protein of HBV has transactivating effect on SV40 early promoter. The obtained sequences may be target genes transactivated by pre-S2 protein among which some genes coding proteins involved in cell cycle regulation, metabolism, immunity, signal transduction and cell apoptosis.This finding brings some new clues for studying the biological functions of pre-S2 protein and further understanding of HBV hepatocarcinogesis.

INTRODUCTION

Hepatitis B virus (HBV) causes acute and chronic infections of the liver. Acute infections may produce serious illness, and approximately 0.5% terminate with fatal, fulminant hepatitis. Chronic infections may also have serious consequences[1]. In addition to causing acute and chronic hepatitis, HBV is considered to be a major cliological factor in the development of human hepatocellular carcinoma (HCC), one of the most frequent fatal malignancies worldwide, and worldwide deaths from HCC caused by HBV infection probably exceed one million per year[2-4]. Epidemiological studies have demonstrated an approximately 10-fold increase in the relative risk of HCC among HBV carriers compared to noncarriers[5-8].

The precise role of HBV in the etiology of HCC is not well understood. Only occasionally, genes controlling the cell growth and differentiation are disturbed by HBV DNA sequences intergration, but since no common sites of viral DNA integration have been observed, the induction of cell

growth by HBV enhancer or promoter insertion cannot be regarded as a general mechanism of transformation in human HCC. An alternative mechanism of hepatocarcinogenesis could be the activation and/or repression, operated by HBV proteins, of the expression of genes crucial for cell growth regulation. Recent data have showed that some HBV proteins can exert a significant transactivational activity on both viral and cellular promoter[9]. Almost all HBV-associated HCCs studied so far harbor chromosomally integrated HBV DNA[10]. Integrated HBV DNA can encode two types of transcriptional transactivators: the already well studied HBx[11] and the pre-S2 transactivators: LHBs (large hepatitis B virus surface protein) and MHBs^t (C-terminally truncated middle surface protein)[12-14].

Although it is true the transactivator functions are preformed by the LHBs or MHBs^t, on closer inspection, one can easily see that this role is mostly performed by the pre-S region of the envelope protein. This observation naturally leads to the question, whether pre-S protein fragments alone might also have the transactivating role in the absence of the S region. Actually, *in vitro* studies with protease-treated HBV particles showed specific cleavage of pre-S fragments from LHBs, which indicate the presence of protease-sensitive sites within the junction of the pre-S and S proteins[15,16]. So, while the proteolytic cleavage and generation of the free pre-S fragments are quite evident, their biological meanings remain obscure[17-19]. Recently, we have studied the transactivator function of pre-S proteins. In the present study, we showed that pre-S2 protein functions as a transcriptional transactivator, and constructed the subtractive library of genes transactivated by HBV pre-S2 protein, successfully.

MATERIALS AND METHODS

Plasmid construction

The pre-S2 gene was amplified by PCR from the plasmid G376-7 (GenBank number: AF384371)[20-22] using sense (5'- GAT ATC ATG CAG TGG AAC TCC ACC -3') and antisene (5'- GGA TCC TTA GTT CGG TGC AGG GTC -3') primers (Shanghai BioAsia Biotechnology Co., Ltd). As these primers contain *Eco*RV and *Bam*HI (Takara) recognition sites on their respective 5'- ends, the amplified 180 bp PCR fragment was subcloned into the *Eco*RV/*Bam*HI sites of pcDNA3.1(-) vector (Invitrogen), the expression vector, pcDNA3.1(-)-pre-S2 which could direct expression of pre-S2 fusion protein was obtained, then identified by PCR and digested of *Eco*RV/*Bam*HI.

Cell culture and DNA transfection

HepG2 cells were cultured in Dulbecco's modified Eagle's medium (DMEM) containing 100 IU of penicillin and 100 μg of streptomycin per mL, supplemented with 10% (vol/vol) heat-inactivated fetal bovine serum (FBS), at 37 ℃ in a 50 mL/L CO_2 atmosphere. 1.5×10^6 cells were seeded in 35-mm plates 12 h prior to transfection and reached 50% confluence at the time of transfection. Cells were transfected with FuGENE6 Transfection Reagent (Roche), the transfection was carried out with 2.0 μg of pcDNA3.1 (-) empty and pcDNA3.1(-)-pre-S2 plasmid DNA according to the manufacture's protocol, respectively.

mRNA and cDNA isolation

The mRNA from HepG2 cells transfected with pcDNA3.1 (-)-pre-S2 and pcDNA3.1(-) empty vector was isolated by using a micro mRNA purification kit (Amersham Biosciences), respectively, cDNAs were reverse-transcribed from mRNA. Identification was done by PCR with pre-S2-specific primers.

Effect of pre-S2 protein on SV40 early promoter

HepG2 cells were transfected with various concentrations of pSV-lacZ (0.1-1.8 μg) (promega) plasmid DNA, expression of β-gal was detected by using a β-gal assay kit (promega). In pSV-LacZ plasmid, the LacZ gene is under the control of the SV40 early promoter element. The best concentration of pSV-lacZ was selected, HepG2 cells with pSV-lacZ (1.0 μg) and pcDNA3.1(-)-pre-S2 (2.0 μg) were cotransfected as a test group. At the same time, cotransfected with empty pcDNA3.1 (-) (2.0 μg) and pSV-lacZ (1.0 μg) was used as control as control group The cells were collected after 48 h, and the expression of β-gal was detected. Seven separate transfections were present in test and control groups, respectively, and Stata 7.0 program was used to analyze the experimental data.

Suppression subtractive hybridization (SSH)

Genome comparisons was done by suppression subtraction hybridization according to the manufacturer's instructions of PCR-select™ cDNA subtraction kit (Clontech). In brief, 2 μg of mRNA from the tester and the driver was subjected to cDNA synthesis. Tester and driver cDNAs were digested with *RsaI*. The tester cDNA was split into two groups, and each was ligated with a different cDNA adapter. In a first hybridization reaction, an excess of driver was added to each sample of tester. The samples were heat denaturated and allowed to anneal. Because of the second-order kinetics of hybridization, the concentration of high- and low-abundance sequences is equalized among the single-stranded tester molecules. At the same time, single-stranded tester molecules were significantly enriched for differentially expressed sequences. During a second hybridization, the two primary hybridization samples were mixed together without denaturation. Only the remaining equalized and subtracted single-stranded tester cDNAs can reassociate forming double-stranded tester molecules with different ends. After filling in the ends with DNA polymerase, the entire population of molecules was subjected to nested PCR with two adapter-specific primer pairs. After that, secondary PCR products were used as templates for PCR amplification of G3PDH (a housekeeping gene) at 18, 23, 28, 33 cycles to assure subtracted efficiency.

Cloning of subtracted cDNA libraries

Products of these amplified overhangs containing a subtracted cDNA library (6 μL) were ligated into a pGEM-Teasy vector (Promega). Subsequently, the plasmid was transformed into *E. coli* strain DH5α. Bacteria were taken up in 800 μL of LB medium and allowed to incubate for 45 min at 37 ℃ and 225 r/m. after incubation, Bacteria were plated onto agar plates containing ampicillin (100 μg/mL),

5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-Gal, 20 μg/cm^2) and isopropyl-β-D-thiogalactoside (IPTG, 12.1 μg/cm^2) and incubated overnight at 37 ℃. White colonies were selected and identified by PCR. Primers were T7/SP6 primer of pGEM-Teasy vector. After sequencing the plasmids DNA of positive colonies (Shanghai BioAsia Biotechnology Co., Ltd), nucleic acid homology searches were performed using the BLAST (basic local alignment search tool) server at the National Center for Biotechnology Information.

RESULTS

Identification of expression vector

Restriction enzyme analysis of pcDNA3.1(-)-pre-S2 plasmid with *Eco*RV/*Bam*HI yielded two bands: 5 396 bp empty pcDNA3.1(-) and 172 bp HBV pre-S2, cleaved with *Pst*I got only one 5 568 bp band (5 396 bp+172 bp). The plasmid by PCR amplification with pre-S2-sepcific primers got a clear band of the expected size (180 bp, Figure 1). Sequencing the PCR products was correct.

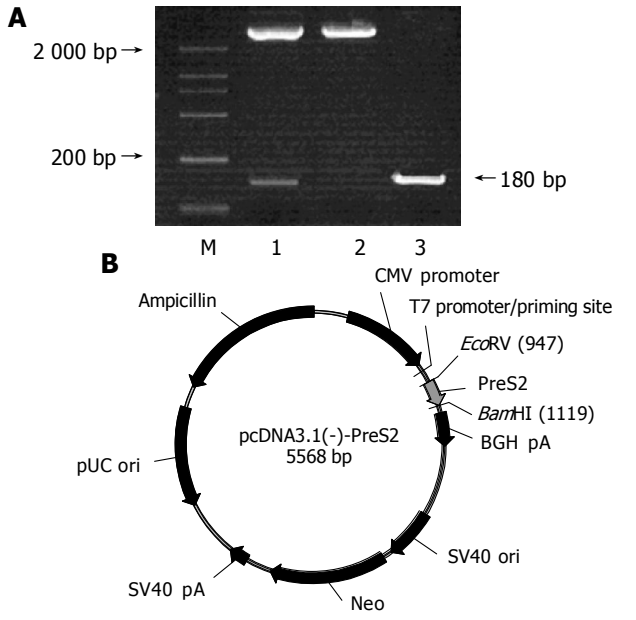

Figure 1 **A**: Products of pcDNA3.1(-)-pre-S2 PCR and restriction enzyme cleaved were eletrophoresed in 2.0% agarose gel. Lane 1: *Eco*RV/*Bam*HI cleaved, lane 2: *Pst*I cleaved, lane 3: production of plasmid PCR, M: DNA marker (2 000 bp). **B**: Structure of expression plasmid pcDNA3.1(-)-pre-S2.

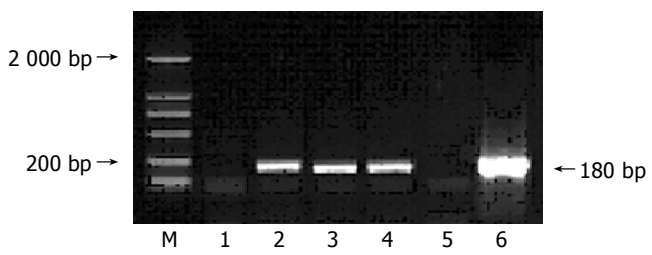

Figure 2 RT-PCR products were eletrophoresed in 0.9% agarose gel. Lane 1: negative control, lanes 2-4: mRNA was isolated from pcDNA3.1(-)-pre-S2 and RT-PCR was performed by three different Oligod T, lane 5: blank control, lane 6: positive control, M: DNA marker (2 000 bp).

Expression of HBV pre-S2 protein

Reverse-transcribed by three different Oligo dT, identification of cDNA by PCR yielded common 180 bp band (Figure 2).

Transactivation of HBV pre-S2 protein on early promoter of SV40

The *A* data about expression of β-gal of the test group (n = 7) was 0.238±0.007. In contrast, the *A* data about that of the control group (n = 7) was 0.034±0.009. Expression of β-gal were 7.0-fold higher when contransfected pcDNA3.1(-)-pre-S2 and pSV-lacZ than when contransfected empty pcDNA3.1(-) and pSV-lacZ. The significant increase of expression of β-gal (P<0.01) was attributed to the transactivating effect of HBV pre-S2 protein on early promoter of SV40, increasing the expression of downstream gene lacZ (Figure 3).

Analysis of the subtraction library

Subtraction efficiency analysis showed that the PCR products of G3PDH in unsubtracted library were visible after 18 cycles, however, 28 cycles were required in the subtracted one for G3PDH to be detected (Figure 4). The abundance of non-differentially expressed gene was effectively reduced, which indicated that the subtraction library had the high subtraction efficiency.

Using SSH technique, we obtained a total of 96 positive clones. These clones were prescreened by using PCR amplification to ensure that only clones with different inserts were subjected to sequencing (Figure 5). Among these clones,

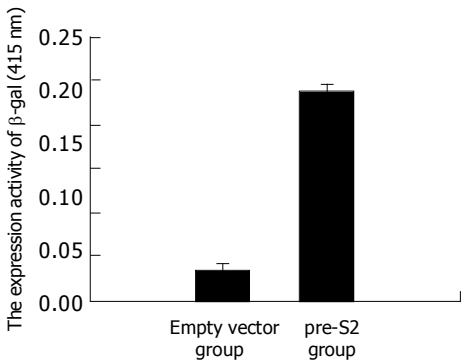

Figure 3 Result of β-galactosidase enzyme analysis. The numbers represent mean±SD of 7 separate transfections.

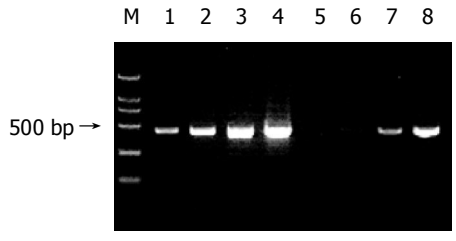

Figure 4 Reduction of G3PDH abundance by PCR-select subtraction. PCR was performed on unsubtracted (lanes1-4) or subtracted (lanes 5-8) secondary PCR products with the G3PDH 5' and 3' primers. Lanes 1, 5: 18 cycles; lanes 2, 6: 23 cycles; lanes 3, 7: 28 cycles; lanes 4, 8: 33 cycles. Lane M: DNA marker (2 000 bp).

eighty-six clones contained 200-1 000 bp inserts. A total of 50 clones from the cDNA library were randomly chosen and sequenced, altogether 25 coding sequences were obtained. Summary of the data is presented in Table 1.

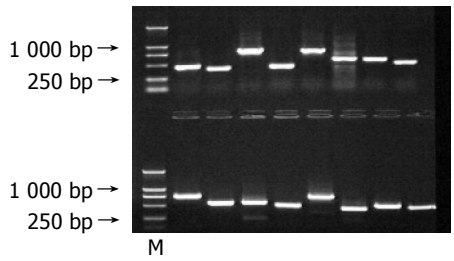

Figure 5 Results of PCR amplification of part clones (17-32). M: DNA marker (2 000 bp).

DISCUSSION

The sequence encoding the pre-S2 transactivators is localized in the HBV surface gene. The surface gene consists of a single open reading frame divided into three coding regions: pre-S1, pre-S2 and S, each starting with an in-frame ATG codon. Through alternate translational initiation at each of the three AUG codons, a large (LHBs, pre-S1+pre-S2+S), a middle (MHBs, pre-S2+S) and a small (SHBs, S) envelope glycoprotein can be synthesized[23-27]. The transactivator function of the surface protein requires the cytoplasmic orientation of the pre-S2 domain (the minimal functional unit) that occurs in the case of MHBs^t and in a fraction of LHBs[28,29]. In contrast, full-length MHBs displays no transcriptional activator function, here the pre-S2 domain directs into the lumen of the endoplasmic reticulum (ER). The generation of functional MHBs^t from MHBs requires deletion of the 3' end of the pre-S2/S gene encoding at least the last 70 amino acids corresponding to the hydrophobic region III of the S domain during the integration process[30]. Deletions of 3' sequences of the pre-S2/S gene generating functional MHBs^t transactivators were found in one-third of the integrates investigated so far[31,32]. This fact and the presence of complete pre-S/S genes in some other systematically studied integrates indicate the biological significance of the pre-S2 transactivators[33].

The transactivator function of the pre-S2 activators is based on the cytoplasmic orientation of the pre-S2 domain, and many reports have demonstrated that the pre-S2 region is sufficient for generation of the transcriptional transactivator function. The pre-S2 domain is PKC-dependent phosphorylated. Moreover, the pre-S2 domain binds of PKC α/β and triggers a PKC-dependent activation of the c-Raf-1/MAPKKK signal transduction cascade, resulting in an activation of transcription factors such as AP-1 and NF-κB. Furthermore, by activation of this signaling cascade, the pre-S2 activators cause an increased proliferation rate of hepatocytes. According to the two-step model of carcinogenesis (initiation/promotion), the pre-S2 activators could exert a tumor-promoter-like function by activation of the PKC/c-Raf-1/MAPKKK signaling cascade: cells harboring critical mutations (initiation) may be positively selected (promotion). Such a multistep process may account for the long latency period in HCC development, but it also leads to the hypothesis that each tumor reflects an individual case[34-37].

We cotransfected HepG2 cells with pcDNA3.1(-)-pre-

S2 and pSV-lacZ and demonstrated that the HBV pre-S2 protein is successfully expressed in transfected HepG2 cells. Expression of β-gal were 7.0-fold higher when contransfected with pcDNA3.1(-)-pre-S2 and pSV-lacZ than when contransfected with empty pcDNA3.1(-) and pSV-lacZ. HBV pre-S2 protein has significant transactivating effect on early promoter of SV40, increasing the expression of downstream gene lacZ. This result indicates that the HBV pre-S2 protein expressed in HepG2 cells retains its biological activity in terms of transcriptional activation, which is consistent with the previous report[38,39].

To get insight into the transactivation mechanism of HBV pre-S2 protein, the SSH was used for identification of transactivating relative target genes of pre-S2 protein, and a subtractive library was set up successfully. Sequence analysis was performed in 50 clones, and 25 coding sequences were obtained. These genes can be divided into 4 groups: (1) The genes involving in cell structure and cell cycle. They possess the important ability to control cell growth, differentiation and adherence, such as ribosomal protein, mitochondrion, nucleophosmin, tubulin, keratin, M-phase phosphoprotein, eukaryotic translation elongation factor, and so on. (2) The genes relating to cell energy or substance metabolism, (i.e., ferritin, albumin, NADH dehydrogenase 2, cytochrome c oxidase II, spermidine/spermine N1-acetyltransferase, 3-alpha hydroxysteroid dehydrogenase, methionine-tRNA synthetase). Bile acids may be important regulators of gene expression in the liver and intestines. Bile acids have been shown to modulate a variety of cellular functions, such as secretion of lipoproteins from hepatocytes and translocation of bile acid transporters to the hepatocyte canalicular membrane[40-42]. Our results indicate that the HBV pre-S2 protein interact with the bile acid-binding protein, maybe it is a way that HBV affect cellular lipid metabolism. (3) The genes involving in the formation mechanism of hepatic fibrosis. alpha-2-macroglobulin (A2M) is a glycoprotein with high molecular weight, which can bind with different proteases, including interstitial collagenases and the other metalloproteases. A2M's proteinase inhibitor effect can inhibit the activity of collagenases, and participate the formation of hepatic fibrosis[43,44]. Laminin (LN) is a kind of serum fibrosis markers, during fibrogenesis LN continuously accumulate in liver tissues and form basement membrane resulting in sinusoidal capillaration[45], the stages of hepatic fibrosis are correlated with the serum levels of LN, so LN can be used in detecting the degree of hepatic fibrosis. The serum levels of LN were elevated from S1 to S4, because of the increase of hepatic fibrosis. Our data suggest that HBV pre-S2 protein may play a role in the progress of liver cirrhosis[46-48]. (4) The genes controlling cell signal transduction and apoptosis. Such as tyrosine 3-monooxygenase/tryptophan 5-monooxygenase activation protein, calmodulin 2, ras-related C3 botulinum toxin substrate 1 (rho family, small GTP binding protein Rac1) (RAC1), Phospholipase A2 (PLA2). PLA2 is a family of enzymes thought to play a key role in inflammation by releasing arachidonic acid for the synthesis of eicosanoids and lysophospholipid for the synthesis of platelet-activating factor and take part in different singaling pathways, including apoptosis and MAPKKK signaling cascade. CPLA2 (cytosolic phospholipase A2) is activated by MAP kinase due to a phosphorylation of serine residue 505[49].

Altogether, we testified the transactivator ability of HBV pre-S2 protein again, and obtained the subtractive cDNA library of genes transactivated by pre-S2 protein with SSH technique, successfully. Furthermore, we brought some new clues for studying the biological functions of HBV pre-S2 protein and and pave the way for elucidating the pathogenesis of HBV infection.

Abstract

AIM: To assess the antioxidant and antifibrotic effects of long-term *Ginkgo biloba* administration on liver fibrosis induced by biliary obstruction in rats.

METHODS: Liver fibrosis was induced in male Wistar albino rats by bile duct ligation and scission (BDL). *Ginkgo biloba* extract (EGb 761, 50 mg/kg·per d) or saline was administered for 28 d. At the end of the treatment period, all rats were killed. Serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactate dehydrogenase (LDH) levels were determined to assess liver functions and tissue damage, respectively. Tumor necrosis factor-α (TNF-α) was also assayed in serum samples. Liver tissues were taken for determination of the hepatic malondialdehyde (MDA) and glutathione (GSH) levels, myeloperoxidase (MPO) activity and collagen content. Production of reactive oxidants was monitored by chemiluminescence (CL) assay. Serum AST, ALT, LDH, and TNF-α levels were elevated in the BDL group as compared to control group and were significantly decreased by EGb treatment.

RESULTS: Hepatic GSH level, depressed by BDL, was elevated back to control level in EGb-treated BDL group. Increase in tissue MDA level, MPO activity and collagen content due to BDL were also attenuated by EGb treatment. Furthermore, luminol and lucigenin CL values in BDL group increased dramatically compared to control and reduced by EGb treatment.

CONCLUSION: Our results suggest that *Ginkgo biloba* protects the liver from oxidative damage following BDL in rats. This effect possibly involves the inhibition of neutrophil infiltration and lipid peroxidation; thus, restoration of oxidant and antioxidant status in the tissue.

INTRODUCTION

Hepatic fibrosis, which is usually initiated by hepatocyte damage, leads to recruitment of inflammatory cells and platelets, activation of Kupffer cells and subsequent release of cytokines and growth factors[1]. These factors probably link the inflammatory processes and oxygen free radicals, which are known to cause tissue fibrosis[2,3].

Accumulation of hydrophobic bile acids during cholestasis leads to generation of reactive oxygen free radicals in the liver[4,5]. Previous studies showed that hepatic mitochondria generate reactive oxygen species when isolated hepatocytes are exposed to hydrophobic bile acids[4,6]. Thus, mitochondrial free radical production may be an important mechanism of cholestatic liver injury and fibrosis[7-9]. Therapeutic attempts with anti-fibrotic drugs are still under investigation[10-12]. Disadvantages associated with anti-fibrotics are toxicity due to chronic administration and reduced therapeutic effect when used in clinical studies. Anti-fibrotics from natural sources may reduce the risk of toxicity and preserve therapeutic effectiveness in clinical usage[13-15].

An extract of the leaves of *Ginkgo biloba* L., a mixture mainly composed of flavonoid glycosides and terpenoides (ginkgolides and bilobalide), has been shown to exhibit a variety of pharmacological actions[16]. *Ginkgo biloba* extract has been reported to be a potent-free radical scavenger and an antioxidant. The leaf extract suppresses platelet aggregation induced by *tert*-butyl hydroperoxide and hydrogen peroxide through its antioxidant action[17]. Furthermore, the extract and its ingredients exhibit an antagonistic effect on platelet-activating factor[18], and inhibitory effect on the expression of inducible nitric oxide synthase and nitric oxide production[19]. They also provide protection in myocardial and brain ischemia/reperfusion injury[20,21].

In the light of these findings, in this study, we investigated the anti-fibrotic and antioxidant effects of *Ginkgo biloba* extract on oxidative damage and liver fibrosis in bile duct-ligated rats.

MATERIALS AND METHODS

Animals

Male Wistar albino rats (200-250 g) were housed in a room at a mean constant temperature of 22± 2 ℃ with a 12-h light-dark cycle, and free access to standard pellet chow and water. The study was approved by the Marmara University School of Medicine Animal Care and Use Committee.

Induction of liver fibrosis

Rats were anesthetized (100 mg/kg ketamine and 0.75 mg/kg chlorpromazine; ip) and the common bile duct was exposed and ligated by double ligatures with suture silk. The first ligature was made below the junction of the hepatic ducts and the second ligature was made above the entrance of the pancreatic ducts. Finally, the common bile duct was resected between the double ligatures[15]. In sham-operated rats, abdominal incision was made without a ligation.

Experimental groups

Ginkgo biloba extract was administered to control (EGb group) and bile duct ligated (BDL+EGb group) rats for 28 d at a daily dose of 50 mg/kg, ip. The sham-operated control (C) and BDL groups received equal amounts of saline for 28 d.

After 28 d of treatment, the rats were killed and trunk blood was collected. Serum samples were used for the measurement of aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactic dehydrogenase (LDH), bilirubin and tumor necrosis factor (TNF)-α levels. Liver samples were taken and stored at -70 ℃ for the measurement of malondialdehyde (MDA) and glutathione (GSH) levels, myeloperoxidase (MPO) activity and collagen contents. Formation of reactive oxygen species in liver samples was monitored by using chemiluminescence (CL) method.

Determination of serum AST, ALT, LDH, bilirubin, and TNF-α levels

Serum AST and ALT levels - as indicators of liver function - and LDH activity - as a marker of tissue injury - were assessed by using commercial kits (Roche Diagnostics, GmbH, D-68298, Mannheim, Germany) in Roche-Hitachi Modular Autoanalyzer (Roche Diagnostics, GmbH, D-68298, Mannheim, Germany)[22]. Serum total bilirubin level was assayed on Bayer Opera Autoanalyzer according to a method described previously[23]. Serum TNF-α level was evaluated by a radioimmunoassay-immunoradiometricassay method by using a commercial kit (Biosource Europe S.A., Nivelles, Belgium). The activity of radioactive assays was measured by gamma counter (LKB WALLAC 1270 RACK Gamma Counter, Canada).

Measurement of liver MDA and GSH levels

Tissue samples were homogenized with ice-cold trichloroacetic acid (1 g tissue+10 mL 10% TCA) in an Ultra Turrax tissue homogenizer. The MDA levels were assayed for products of lipid peroxidation by monitoring thiobarbituric acid reactive substance formation as described previously[24]. Lipid peroxidation was expressed in terms of MDA equivalents using an extinction coefficient of 1.56×10^5 mol/(L·cm) and results were expressed as nanomole MDA per gram tissue. GSH was determined by a spectrophotometric method, which was based on the use of Ellman's reagent[25]. GSH levels were calculated using an extinction coefficient of 13 600 mol/(L·cm) and the results were expressed in micromole per gram tissue.

Measurement of liver myeloperoxidase (MPO) activity

Tissue samples (0.2-0.3 g) were homogenized in 10 volumes of ice-cold potassium phosphate buffer (50 mmol/L K_2HPO_4, pH 6.0) containing hexadecyltrimethylammonium bromide (HETAB, 5 g/L). The homogenate was centrifuged at 30 000 *g* for 10 min at 4 ℃, and the supernatant was discarded. The pellet was then rehomogenized with an equivalent volume of 50 mmol/L K_2HPO_4 containing 5 g/L HETAB and 10 mmol/L EDTA (Sigma). MPO activity was assessed by measuring the H_2O_2-dependent oxidation of *o*-dianizidine·2HCl. One unit of enzyme activity was defined as the amount of the MPO present per gram of tissue weight that caused a change in absorbance of 1.0 per min at 460 nm and 37 ℃[26].

Measurement of liver collagen content

Tissue samples were cut with a razor blade and immediately fixed in 40 g/L formaldehyde in 0.1 mol/L phosphate buffer (pH 7.2) in paraffin and sections of 15-μm thick were obtained. Collagen content was measured according to a method described by Lopez de Leon and Rojkind[27]. The method is based on selective binding of the dyes Sirius red and fast green FCF to collagen and noncollagenous components, respectively. Both dyes were eluted readily and simultaneously by using 0.1 N NaOH-methanol (1∶1, v/v). Finally, the absorbances at 540 and 605 nm were used to determine the amount of collagen and protein, respectively.

Chemiluminescence (CL) assay

Luminescence of the hepatic tissue samples was recorded at room temperature using Mini Lumat LB 9 506 luminometer (EG&G Berthold, Germany) in the presence of luminol or lucigenin, 0.2 mmol/L each. All counts were obtained at 15-s intervals for 5 min and the results were expressed as area under the curve of relative light unit (rlu) for 5 min/mg tissue[28].

Statistical analysis

Statistical analysis was carried out using GraphPad Prism 3.0 (GraphPad Software, San Diego, CA, USA). All data were expressed as mean±SE. Groups of data were compared with an analysis of variance (ANOVA) followed by Tukey's multiple comparison tests. Values of $P<0.05$ were regarded as significant.

RESULTS

As shown in Table 1, serum bilirubin, AST, ALT, and LDH levels were significantly higher in BDL rats compared to controls ($P<0.001$) and EGb administration to BDL group reduced these values ($P<0.001$). In untreated BDL group, serum TNF-α level showed a significant increase compared to that of the sham-operated control group ($P<0.001$). Similarly, BDL-induced rise in serum TNF-α level was significantly reduced by EGb treatment ($P<0.001$, Figure 1).

Table 1 Serum total bilirubin, AST, ALT, LDH and TNF-α levels in control (C), EGb, BDL and BDL+EGb groups

Groups	C (n = 8)	EGb (n = 8)	BDL (n = 8)	BDL+EGb (n = 8)
Total bilirubin (mg/dL)	0.36±0.3	0.35±0.6	10.1±0.6[d]	1.68±0.3[b,f]
AST (mg/dL)	148±16.6	150±12.4	300±18[d]	155±12[f]
ALT (mg/dL)	68±7.3	77±6.1	135±9.7[d]	67±5.7[f]
LDH (U/L)	1 672±240	1 499±219	5 082±225[d]	1 763±226[f]

[b]P<0.01, [d]P<0.001 *vs* control group. [f]P<0.001, *vs* untreated BDL group.

The liver MDA was found to be significantly higher in the BDL group (51.0±3.3 nmol/g; P<0.01) compared to that of the sham-operated control group (32.2±3.1 nmol/g). Treatment with EGb reversed the MDA level (33.8±2.6 nmol/g; P<0.01) back to control level (Figure 2).

The hepatic GSH level showed a marked reduction in the BDL group (0.88±0.07 μmol/g; P<0.001) compared to that of the sham-operated control group (2.1±0.15 μmol/g). Similarly, treatment with EGb reversed this effect (1.8±0.12 μmol/g; P<0.01) (Figure 3).

Liver MPO activity, which was observed to be higher in the BDL group (21.8±2.0 U/g; P<0.01) compared to sham-operated control group (13.8±1.3 U/g) was also attenuated by EGb treatment (13.3±0.7 U/g; P<0.01) (Figure 4).

Hepatic collagen content of the untreated BDL rats (21.3±2.1 μg/mg protein; P<0.01) was found to be significantly higher than that of the control group (12.8±1.4 μg/mg protein). EGb treatment significantly reduced the increase in hepatic collagen content (13.2±1.2 μg/mg protein; P<0.05) to the levels that were close to control values (Figure 5).

Luminol and lucigenin CL values of the liver samples of the BDL group (18.7±1.1 and 38.3±3.2 rlu/mg, respectively) were found to be significantly higher than those of the control group (11.1±1.0 and 14.8±1.1 rlu/mg; P<0.01 and P<0.001, respectively) and EGb treatment reversed these values (12.5±2.0 and 16.1±2.6 rlu/mg; P<0.05 and P<0.001, respectively) (Figures 6 and 7).

DISCUSSION

The present study demonstrates that EGb treatment improved BDL-induced impairment in liver functions and decreased BDL-induced elevations in serum LDH activity and TNF-α levels. Furthermore, increase in hepatic lipid peroxidation, MPO activity, oxidant production and collagen content, and

decrease in GSH levels following BDL were reversed by EGb treatment.

Hepatic fibrosis, characterized by an increased production and deposition of extracellular matrix component accompanies most chronic liver disorders and its presence is a major factor contributing to hepatic failure[29,30]. Although the mechanism of liver fibrosis is not fully understood, activated hepatic stellate cells play an important role in connective tissue synthesis and deposition during fibrogenesis[12]. On the other hand, oxidative stress caused by accumulation of hydrophobic bile acids also have a critical role in fibrogenesis[3,31].

Bile duct ligation (BDL) induces a type of liver fibrosis, which etiologically and pathogenitically resembles the biliary fibrosis in the human beings. Injury to hepatocytes results in the generation of lipid peroxides, which may have a direct stimulatory effect on matrix production by activated stellate cells[8,32]. Liu *et al.*, demonstrated excessive production of superoxide radicals and hydroxyl radicals in blood and liver in rats with obstructive jaundice induced by common BDL[33]. In the present study, BDL caused significant increases in the hepatic MDA level -end product of lipid peroxidation - and EGb treatment prevented the increase in MDA, probably in part by scavenging the very reactive hydroxyl and peroxyl radicals. Moreover, attenuation of the increase in hepatic luminol- and lucigenin-enhanced CL levels by EGb treatment in BDL animals also supports the scavenging ability of the agent.

An extract of the leaves of *Ginkgo biloba L.*, a mixture mainly composed of flavonoid glycosides and terpenoides (ginkgolides and bilobalide), has been shown to exhibit a variety of pharmacological actions. The leaf extract acts as a scavenger of reactive oxygen species, that is, superoxide radical, peroxyl radical and nitric oxide[34-36]. It has been reported that the extract suppresses platelet aggregation induced by *tert*-butyl hydroperoxide and hydrogen peroxide through its antioxidant action[17]. Moreover, the extract and its ingredients (especially ginkgolide C) exhibit a potent antagonistic effect on platelet-activating factor and inhibitory effects on the expression of inducible nitric oxide synthase as well as nitric oxide production[18,19,37,38]. It decreased ethanol- or cold stress-induced gastric injury, protected against cerulein-induced acute pancreatitis and hepatic damage evoked by CCl_4 in the rat[39-42]. It has also been demonstrated that EGb has protective effects on aging liver. Thus, these effects suggest that EGb is beneficial in various cardiovascular, cerebrovascular, and neurological disorders in which oxidants are involved.

GSH, a key antioxidant, is an important constituent of intracellular protective mechanisms against various noxious stimuli, including oxidative stress. On the other hand, reduced GSH, which constitutes the main component of endogenous non-protein sulfhydryl pool, is known to be a major low molecular weight scavenger of free radicals in the cytoplasm[43]. Because of their exposed sulfhydryl groups, non-protein sulfhydryls bind a variety of electrophilic radicals and metabolites that may be damaging to the cells[44]. Huang *et al.*, studied the mitochondrial functions in bile duct-ligated rats and suggested that biochemical and molecular changes are related to oxidative stress in the liver[45]. In accordance with the previous reports, our results also support the notion that depletion of tissue GSH, as observed in the BDL-induced hepatic injury, is one of the major factors that permit lipid peroxidation and subsequent tissue damage. Since administration of *Ginkgo biloba* extract prevented the hepatic GSH depletion, it appears that the protective effect of the extract involves the maintenance of antioxidant capacity in protecting the hepatic tissue against oxidative stress.

Excessive production of hydroxyl radicals in blood and liver has previously been demonstrated by Liu *et al.*, in rats with obstructive jaundice induced by common BDL[33]. It has been demonstrated by various investigators that circulating

proinflammatory cytokines, such as TNF-α, interleukin-1-β (IL-1β) and IL-6, which trigger hepatic injury, were increased, at least in part, by a free radical-mediated apoptotic mechanism. Therefore, it seems reasonable to propose that antioxidants or free radical scavengers counteract the oxidant stress produced by cholestasis. In our study, increased TNF-α levels of BDL rats tended to decrease following the treatment by EGb, also supports the notion that EGb ameliorates oxidative liver injury caused by BDL through its antioxidant effect.

Observations suggest that reactive oxygen metabolites (ROM) play a role in the recruitment of neutrophils into damaged tissue, but activated neutrophils are also a potential source of ROM[46,47]. Although it is not certain whether neutrophil accumulation and activation are the causes or the results of injury, increasing evidence suggests that mesangial cells and neutrophils release chemotactic substances (e.g., IL-8), which further promote neutrophil migration and activation[48]. Several methods have been used to define the role of neutrophils in the tissue injury. MPO, which is an essential enzyme for normal neutrophil function, is released as a response to various stimulatory substances[49]. In the present study, increased hepatic MPO activity due to BDL, which indicates that tissue injury involves the contribution of neutrophil infiltration, was effectively reversed by EGb treatment. Moreover, BDL-induced increase in fibrotic activity, as assessed by hepatic collagen content, was also reduced by EGb treatment. These findings suggest that EGb has an additional protective effect on inflammation-induced production and deposition of extracellular matrix components, which result in hepatic fibrosis.

In conclusion, the findings of our present study demonstrate that *Ginkgo biloba* extract, with its potent free radical scavenging and antioxidant properties, seems to be a highly promising agent in protecting hepatic tissue against oxidative damage and in preventing hepatic fibrosis and dysfunction due to obstructive jaundice.

Abstract

AIM: To assess histochemical expression of KL-6 and its clinicopathological significance in carcinoma of the ampulla of Vater.

METHODS: Ampullary carcinoma tissues were collected from 38 patients who underwent pancreatoduodenectomy or local resection. Tissues were subjected to immunohistochemical analysis using KL-6 antibody.

RESULTS: Positive staining of ampullary carcinoma cells was observed in 26 (68.4%) cases. Staining was not found in the surrounding non-cancer regions of the ampullary tissues. Remarkable KL-6 expression was observed in invasive carcinoma cells in pancreatic and duodenal tissues and in metastatic carcinoma cells in lymph nodes. Positive KL-6 expression was related to lymph node metastasis (P = 0.020), pancreatic invasion (P = 0.016), duodenal invasion (P = 0.034), and advanced stage of TNM clinical classification (P = 0.010). Survival analysis showed that positive expression of KL-6 was related to a poorer prognosis (P = 0.029).

CONCLUSION: The aberrant expression of KL-6 mucin is significantly related to unfavorable behaviors of carcinoma of the ampulla of Vater.

INTRODUCTION

Carcinoma of the ampulla of Vater is a malignancy with a low incidence[1]. Although the prognosis for patients with this cancer is higher than that for patients with cancer arising within the pancreas or common bile duct, the 5-year survival rate after resection is less than 50%[2,3]. Therefore, the mechanism for development of this cancer must be understood to improve the patient's prognosis.

Cell surface sialylation changes dramatically during oncogenesis[4-6]. In several tumors, histochemical studies with sialic acid-binding lectins and antibodies against sialylated carbohydrate antigens showed that aberrant expression of sialylated glycoconjugates may play an important role in tumor progression[7-10]. However, the natures of these glycoconjugates and their clinical application are not yet known.

KL-6 is a type of MUC1 mucin, recognized by a murine mAb, KL-6 antibody, as obtained by Kohno *et al*., from a hybridoma established from the splenocytes of a BALB/c mouse immunized with a human pulmonary adenocarcinoma cell line, VMRC-LCR[11,12]. The epitope recognized by the KL-6 antibody exists in sialylated carbohydrate moieties of the mucin molecule, and this sialylation is essential to the recognition by the KL-6 antibody[12].

Histochemical expression of KL-6 has been observed in malignant tissues in several organs[11,12]. However, little is known about the expression profile and clinical significance of KL-6 in carcinoma of the ampulla of Vater. With due consideration to the importance of sialylation of glycoconjugates in tumor behavior, and that the epitope of KL-6 antibody is a sialylated carbohydrate, investigation of the expression profile of KL-6 in carcinoma of the ampulla of Vater will yield significant pointers in clarification of the mechanisms involved in the development of this cancer. In this study, we performed histochemical analysis of KL-6 in ampullary carcinoma tissues and examined the relationship between KL-6 expression and clinicopathological parameters in carcinoma of the ampulla of Vater.

MATERIALS AND METHODS

Patients

Ampullary carcinoma tissues were collected from 38 patients (22 males and 16 females; median age of 68 years; range of 54-85 years) surgically treated at the Hepato-Biliary-Pancreatic Surgery Division, Department of Surgery, Graduate School of Medicine, the University of Tokyo, between April 1976 and December 2002. All of the patients except one underwent pancreatoduodenectomy, whereas one patient underwent local resection. The size of the tumors varied from 1.0 to 7.5 cm (2.4±1.3 cm, mean±SD). Histopathological examination was performed according to the guidelines of the Japanese Society of Biliary Surgery[13]. The TNM staging system of the International Union Against Cancer was used for TNM classification[14].

Immunohistochemistry

Five-mircometer-thick sections were cut from archival formalin-fixed paraffin-embedded tissue blocks, deparaffinized, and dehydrated through a graded series of ethanol. Endogenous peroxidase activity was quenched with 0.3% hydrogen peroxide/methanol. The sections were incubated at 4 ℃ overnight with KL-6 antibody (Eisai, Tokyo, Japan) diluted to 1:150. The sections were then incubated with biotinylated anti-mouse antibody for 30 min at room temperature followed by development with the biotin-streptavidin-peroxidase complex method, using a commercial kit as per the manufacturer's instructions (Vectastain ABC Elite kit; Vector, Burlingame, CA, USA). 3,3'-Diaminobenzidine was used as the chromogen, and hematoxylin was used as a counterstain. Each tissue sample was microscopically analyzed over its entire area to determine histopathological characteristics. The percentage of cancer cells that were stained of the total number of cancer cells was determined in 10 random microscopic fields of each tissue sample, or using the entire area, if the tissue sample comprised less than 10 fields (magnification ×200). Cases in which more than 10% carcinoma cells were stained were defined as positive.

Statistical analysis

The χ^2 test was used to evaluate the relationship between KL-6 expression and clinicopathological parameters. Survival curves were calculated by the Kaplan-Meier method and compared with results of the log rank test. Differences of $P<0.05$ were considered significant. Statview 5.0J (Abacus Concepts, Berkeley, CA, USA) statistical software was used for data analysis.

RESULTS

Immunohistochemistry

Figure 1 shows immunohistochemical analysis of ampullary carcinoma tissues using KL-6 antibody. Positive staining was observed in 26 (68.4%) of 38 cases. The population of KL-6-positive tumor cells in the cancer regions varied among the samples (mean 49.2%, range 17.0-84.0%). The staining was localized in the tumor-cell cytoplasm and cell membrane in cancer regions (Figure 1A), whereas staining was not detected in the surrounding non-cancer regions of the ampullary tissues. In some cases, the stained materials were also detected along the inner surfaces of glands (Figure 1B). On the other hand, in 12 of 38 cases (31.6%), stained cells were scarce (Figure 1C).

Immunohistochemical analysis was focused on pancreatic and duodenal tissues showing pathological invasion of the ampullary carcinoma cells (Figure 2). Strongly stained carcinoma cells were frequently observed in the invaded areas of pancreatic tissues (Figure 2A), whereas only weak staining was sporadically observed in the surrounding normal pancreatic tissues (Figure 2B). Similarly, strongly stained carcinoma cells were frequently observed in the invaded areas of duodenal tissues (Figure 2C), whereas the surrounding normal duodenal epithelium was scarcely stained by KL-6 antibody (Figure 2D).

In all of the metastatic lymph node tissues tested, strong staining was found in carcinoma cells, whereas staining was not found in the surrounding normal tissues (Figure 3). Staining was not found in metastatic negative lymph node tissues (data not shown).

Clinicopathological and survival characteristics

The relationship between KL-6 expression and clinicopathological characteristics of tumors was examined. As shown in Table 1, positive KL-6 expression was significantly frequent in cases of lymph node metastasis than those without it ($P = 0.020$), in cases of pancreatic invasion than those without it ($P = 0.016$), in cases of duodenal invasion than

Present	26	21 (80.8)	
Absent	12	5 (41.7)	0.016
Duodenal invasion			
Present	30	23 (76.7)	
Absent	8	3 (37.5)	0.034
TNM clinical classification			
III+IV	18	16 (88.9)	
I+II	20	10 (50.0)	0.010

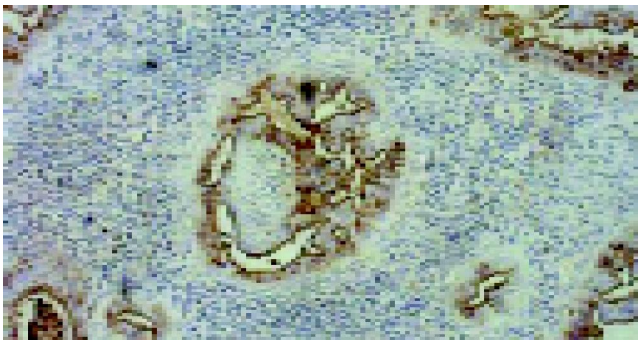

Figure 3 A typical example showing moderately positive staining of KL-6 in carcinoma cells in a metastatic lymph node tissue. Original magnification ×100.

those without it ($P = 0.034$), and in cases classified into III or IV by TNM clinical classification than those classified into I or II ($P = 0.010$). On the other hand, KL-6 expression was not associated with age, sex, histological grade, lymphatic vessel invasion, and venous invasion (Table 1).

The relationship between KL-6 expression and patient survival was then analyzed. As shown in Figure 4, patients showing positive KL-6 expression ($n = 26$) displayed a significantly poorer prognosis than those showing negative KL-6 expression ($n = 12$): 5-year survival rates were 30.8 and 75.0%, respectively, as determined by the Kaplan-Meier method ($P = 0.029$ by the log rank test).

DISCUSSION

Mucins are large extracellular glycoproteins with high carbohydrate content and marked diversity both in the apoprotein and in the oligosaccharide moieties[15]. It has been

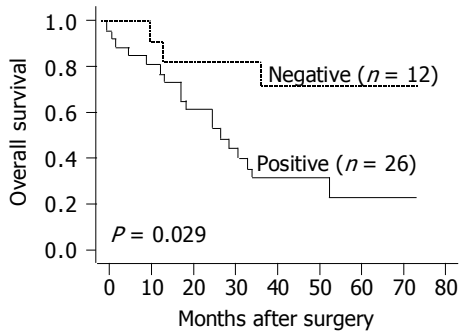

Figure 4 Kaplan-Meier curves for overall survival rates of patients with carcinoma of the ampulla of Vater. Patients with positive (solid line, *n* = 26) and negative (dotted line, *n* = 12) KL-6 expression were followed-up for over 70 mo.

noted that ampullary carcinoma have a heterogeneous mucin expression pattern[16,17] and that overexpression of MUC1 was associated with invasive and metastatic potency of several adenocarcinoma[18-20]. However, the studies on MUC1 expression were mostly done with different antibodies, which recognize different carbohydrate epitopes or the core peptide. This study addresses clinicopathological significance of histochemical expression of KL-6, MUC1 mucin-bearing sialylated carbohydrate epitope recognized by KL-6 antibody, in carcinoma of the ampulla of Vater. Sialylation of tumor cell surface glycoconjugate is thought to contribute to tumor progression and metastasis[7-10]. Furthermore, since sialylated oligosaccharide moieties are exposed on the mucin molecules, KL-6 antibody could effectively recognize the mucin without epitope masking as Cao and Karsten indicated with several antibodies against peptide epitopes of MUC1[21]. Therefore, immunohistochemical detection of KL-6 mucin seems to be a reasonable strategy.

The present data shows that aberrant expression of KL-6 mucin is related to unfavorable behaviors of the carcinoma, such as lymph node metastasis, pancreatic invasion, duodenal invasion, and the advanced stage of TNM clinical classification (Table 1), and poorer prognosis (P = 0.029, Figure 4). Furthermore, remarkable expression of KL-6 was found in invasive carcinoma cells in pancreatic and duodenal tissues and in metastatic carcinoma cells in lymph nodes (Figures 2 and 3). These results suggest that KL-6 mucin might play an important role in unfavorable tumor behaviors, such as invasions and metastasis of carcinoma of the ampulla of Vater.

Several tumor-associated carbohydrate antigens have been identified on mucins[22,23]. Aberrant forms of mucins expressed in cancer cells have been considered to arise as a consequence of the deregulation of expression of enzymes that modify them[15]. The epitope recognized by KL-6 antibody is sialylated carbohydrates included in MUC1 molecule[12], although the detailed structure of the epitope remains to be determined. Among the many types of carbohydrates, sialic acid is vital for cancer growth, since enhanced sialylation is thought to play a role in tumor progression and metastasis[5,24]. Carbohydrate moieties of glycoconjugates are constructed by complex interactions involving a series of glycosyltransferases[25,26]. In our previous study, the aberrant sialylation of glycoconjugates in carcinoma of the ampulla of Vater has been found in histochemical analyses using sialic acid-binding lectins such as *Maackia amurensis* leukoagglutinin and *Sambucus nigra* agglutinin[27]. Therefore, it is postulated that the aberrant expression of KL-6 stems from the aberrant expression of the glycosyltransferase (s) such as sialyltransferase, which participates in the construction of the epitope for KL-6 antibody. Relationship of KL-6 expression to invasions and metastasis has also been suggested in colorectal carcinoma[28,29].

Surgery is still the only option that provides a cure for patients with carcinoma of the ampulla of Vater. Patient outcome after surgery for carcinoma of the ampulla of Vater is better than that for pancreatic cancer or bile duct cancer. However, patients with lymph node metastasis or invasion of carcinoma to adjacent organs including the pancreas or duodenum display a poorer prognosis[30-32]. The present study revealed that positive KL-6 expression was significantly related to lymph node metastasis, pancreatic invasion, and duodenal invasion of ampullary carcinoma. These clinicopathological parameters are recognized as prognostic factors of ampullary carcinoma[30,31]. In particular, the presence of lymph node metastasis, pancreatic invasion, and duodenal invasion was found in 73% (19/26), 81% (21/26), and 88% (23/26), respectively, of KL-6-positive cases. Further, strong staining of KL-6 was frequently found in invasive carcinoma cells in pancreatic and neonatal tissues and in metastatic carcinoma cells in lymph nodes. Therefore, histochemical analyses of preoperatively biopsied tissues using anti-KL-6 antibody might be helpful for the assessment of the development of lymph node metastasis, pancreatic invasion, and duodenal invasion, which would increase a physician's ability to determine operative procedures or predict prognosis for individual patients. Examination with a larger population and a biochemical approach is needed to understand clinical significance of KL-6 expression and biochemical role of carbohydrate moiety of KL-6 mucin in carcinoma of ampulla of Vater.

Abstract

AIM: Vascular endothelial growth factor (VEGF) is a potent mediator of peritoneal fluid accumulation following tumor progression. This study investigated the role of VEGF secreted by cancerous cells in the formation of malignant ascites.

METHODS: VEGF expression was eliminated by knockdown in the pancreas cancer cell-line PancO2 using vector-based short-hairpin type RNA interference (RNAi). Malignant ascites formation in the mouse was analyzed by intraperitoneal injection of PancO2 cells expressing VEGF or with expression knockdown.

RESULTS: The VEGF knockdown PancO2 cell was successfully established. Knockdown of VEGF did not affect cancer cell proliferation *in vitro* or *in vivo*. The volume of ascites following peritoneal expansion of the tumor in VEGF knockdown cells and control cells did not differ statistically in this *in vivo* study. Moreover, the VEGF concentration in the ascites did not differ statistically.

CONCLUSION: Malignant ascites formation might be mediated by VEGF production in noncancerous tissues, such as stromal compartments. An anti-VEGF strategy against malignant ascites could be applied to various tumors regardless of whether they secrete VEGF.

INTRODUCTION

Ascites formation is a critical problem in patients with advanced pancreatic cancer. Vascular endothelial growth factor (VEGF), known as an angiogenic growth factor, is a potent mediator of peritoneal fluid accumulation in tumors. The accumulation of tumor ascites fluid may result from increased permeability of the blood vessels lining the peritoneal cavity. The hyperpermeability of vessels might be mediated by VEGF secreted from tumor cells[1,2]. VEGF antisense plasmid suppresses ascites formation in ovarian carcinoma[3]. VEGF is widely expressed in various normal tissues and many tumors[4,5]. VEGF expression has been detected in both cancer cells themselves and stromal compartments[6-8], raising the question of the relative role of each compartment in VEGF-mediated ascites formation. Recent studies using *RAS*-transformed VEGF-deficient adult dermal fibroblasts or fibrosarcomas generated from VEGF-null *RAS*-transformed mouse embryonic fibroblasts concluded that VEGF production in stromal compartments plays a critical role in tumor angiogenesis[9,10]. However, the role of VEGF in ascites formation in the stroma is poorly understood.

RNA interference (RNAi) is an evolutionarily conserved mechanism of gene silencing. Recently, 21- to 23-nucleotide double-stranded RNA (short interfering RNA, siRNA) molecules have been shown to exhibit specific RNAi characteristics. A plasmid vector expressing siRNA was reported to enable long-term persistence of the silencing effect; a phenomenon termed as 'stable RNAi'[11-13]. This system is a powerful tool for analyzing endogenous gene silencing.

To confirm whether VEGF secreted from cancer cells has a critical role in malignant ascites formation, we used the stable RNAi system to knockdown the VEGF gene in a mouse pancreatic cancer cell line.

MATERIALS AND METHODS

Plasmids

pcDNA-Flag-VEGF expressing vector was constructed as follows: The total RNA was extracted from mouse Colon26 cell using ISOGEN (Nippon Gene, Tokyo, Japan), then the cDNA templates were synthesized from 1 μg of total RNA using the ImProm-II™ Reverse Transcription System (Promega). PCR amplification of mouse VEGFA (191 amino acids) containing Flag sequence was performed using the following two primers: 5'-ATG GAC TAC AAG GAC GAC GAT GAC AAA GAT AAC TTT CTG CTC TCT TGG GTG-3' and 5'-TCA CCG CCT TGG CTT GTC ACA-3'. The PCR product was subcloned into the pCR4Blunt-TOPO vector (Invitrogen, USA), and then *Eco*RI-Flag-VEGF-*Eco*RI fragment was inserted into the *Eco*RI site of the pcDNA vector (Invitrogen, USA).

Plasmid carrying RNAi targeted to VEGF was constructed as previously described[12]. Five 21-nucleotide sequences of the mouse VEGF gene, which had no homology to genomic sequences in a BLAST search, were originally selected using the original algorithm[12]. We designed forward and reverse short-hairpin RNA (Table 1), and both oligonucleotides were annealed to each other (99 ℃ for 2 min, 72 to 4 ℃ for 2 h) and inserted into the *Bsp*MI site of the pcPUR+ U6icassette vector, thereby generating pcPUR+U6-VEGFi.

Cell culture

PancO2 cell line[14] was generated from pancreatic cancer cells derived from C57BL/6 mice, obtained from Dr. Michael A. Hollingsworth, Eppley Institute, University of Nebraska, Omaha, NE, USA. The cells were maintained in Dulbecco's modified Eagle's medium (Sigma, St. Louis, MO, USA) supplemented with 10% fetal bovine serum (Sigma) at 37 ℃ in a 50 mL/L CO_2 atmosphere.

Establishing VEGF knockdown pancreatic cancer cell lines

Stable knockdown cells were established as described[13]. Briefly, the targeting or control vectors were transfected into PancO2 cells using FuGene6 (Roche), and the puromycin-resistant clones or cell pools were selected as stable transfectants. We called stable clones transfected with pcPUR+U6-VEGFi or pcPUR+U6-iRenilla (control vector) as "VEGF-KD" or "VEGF-WT", respectively.

Western blot analysis

Western blot analysis was performed as described[15]. Briefly, cells were lysed in RIPA buffer (50 mmol/L Tris pH 8, 0.1% SDS, 0.5% deoxycholate, 1% NP-40, 150 mmol/L NaCl, 1 tablet complete mini protease inhibitor/10 mL, Roche Diagnostics GmbH, Germany). Next, equal amounts of total cell lysates were electrophoresed and transferred to Pall Fluoro Trans W membrane (Wako, Osaka, Japan). The membranes were incubated with anti-Flag (M2) antibody or anti-β-actin antibody. After washing, the membrane was incubated with horseradish peroxidase-conjugated secondary antibody and visualized using an enhanced chemiluminescence detection system (ECL Advance, Amersham Bioscience, UK).

VEGF measurement by ELISA

To analyze the VEGF production of VEGF-WT and VEGF-KD clones, they were grown in six-well plates with standard medium for 24 h. The medium was replaced with 1 mL of fetal bovine serum-free medium and cells were grown for another 24 h. Then, the VEGF content of the culture supernatants was measured using ELISA (SRL, Japan).

MTT assay

3×10^4 VEGF-KD7 and VEGF-WT cells were seeded in 24-well plates, and the numbers of viable cells were determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay (Sigma, St. Louis, MO, USA) at 24 and 48 h[16]. The absorbance at 570 nm was measured using a microplate reader.

In vivo animal study

C57BL/6 mice were purchased from CLEA (Japan). All procedures involving experimental animals were performed in accordance with protocols approved by the Committee for Animal Research of the University of Tokyo and complied with the Guide for the Care and Use of Laboratory Animals (NIH Publication No. 86-23, revised 1985). 1×10^6 VEGF-KD7 or VEGF-WT cells were injected intraperitoneally into C57BL/6 mice. Ascites accumulation and peritoneal dissemination occurred approximately 2 wk following inoculation of the cancer cells. In this model, the tumor-bearing mice survived for 30-40 d. We weighed the mice every 2-3 d. Twenty-four days after inoculation, some of the mice were anesthetized with pentobarbital sodium (120 mg/kg) and the ascites collected. After centrifuging to remove cancer cells, the volume of ascites was measured. The VEGF concentration was measured using ELISA (SRL, Japan).

Statistical analysis

The data are expressed as mean±SD. Groups were compared using Student's *t*-test. $P<0.05$ was considered statistically significant.

RESULTS

Establishing VEGF knockdown pancreatic cancer cell lines

To study whether VEGF secreted from cancer cells has a critical role in the formation of malignant ascites in pancreatic cancer, we attempted to knockdown the VEGF gene in the mouse pancreatic cancer cell line PancO2. We constructed five plasmids that expressed short hairpin RNAs (as shown in Table 1) targeting the non-isoform-specific common area of VEGF (GenBank locus: NM 009505) under the control of the U6 promoter (pcPUR+U6-VEGFi1-5)[12]. Next, we transiently transfected PancO2 cells with pcPUR+U6-VEGFi1-5 and the Flag-VEGF expression vector, and examined VEGF expression using Western blotting. As shown in Figure 1A, of the five different sites tested, RNAi1-3 proved to be effective for blocking VEGF protein expression, and site 1 was used in subsequent experiments.

To establish stable VEGF knockdown cells, PancO2 cells were transfected with pcPUR+U6-VEGFi1 or

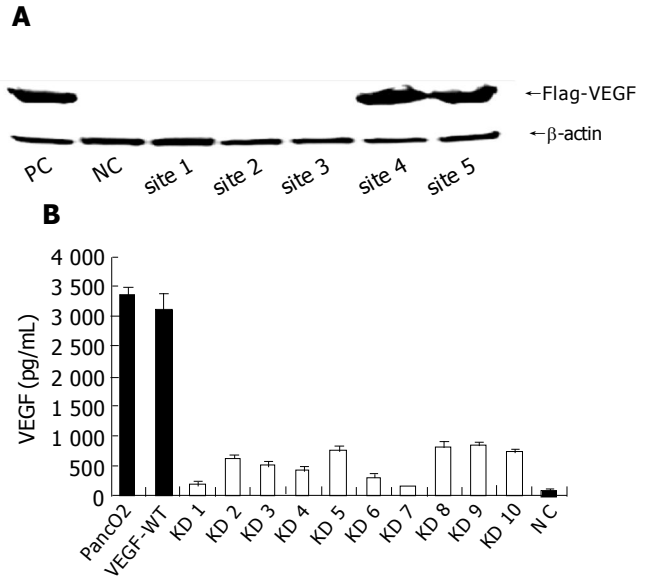

Figure 1 Establishment of VEGF knockdown pancreatic cancer cell lines. **A**: Western blot showing marked reduction of VEGF expression in knockdown cells. Screening of the most effective targeting site for the VEGF gene. **B**: VEGF production of stable knockdown PancO2 cell clones. VEGF-WT and VEGF-KD clones (KD 1-10) were grown in 6-well plates, and the VEGF concentration in culture supernatant was measured using ELISA in triplicates. The growth medium was used as negative control (NC).

pcPUR+U6-iRenilla (control), and incubated with 5 μg/mL puromycin (Wako, Osaka, Japan). Then, we selected puromycin-resistant clones. Parental PancO2 cells, VEGF-WT, and VEGF-KD clones were grown in 6-well plates and the VEGF content in the culture supernatant was measured in triplicates. As shown in Figure 1B, parental cells produced VEGF 3 340±151 pg/mL for 2×10^5 cells/24 h *vs* 3 102±285 pg/mL in VEGF-WT controls. VEGF production was significantly reduced in the pcPUR+U6-VEGFi1 stable clones. VEGF-KD7 produced VEGF (152±16 pg/mL) and was used in subsequent experiments.

Effect of VEGF knockdown on cancer cell growth

To investigate the effect of VEGF knockdown on the cell proliferation potential *in vitro*, 3×10^4 VEGF-KD7 and VEGF-WT cells were grown in 24-well plates. The numbers of viable cells were assessed using the MTT assay. As shown in Figure 2A, there was no statistical difference in cell proliferation between these two cell lines. To study the cell growth *in vivo*, 2×10^6 VEGF-KD7 or VEGF-WT cells were injected into C57BL/6 mice subcutaneously. Small tumors were typically observed, 1 wk after tumor implantation, measured, and the volume was calculated as [(length (mm) ×width (mm)²)]/2. As shown in Figure 2B, the growth of the VEGF knockdown cell line and control cells was not statistically different.

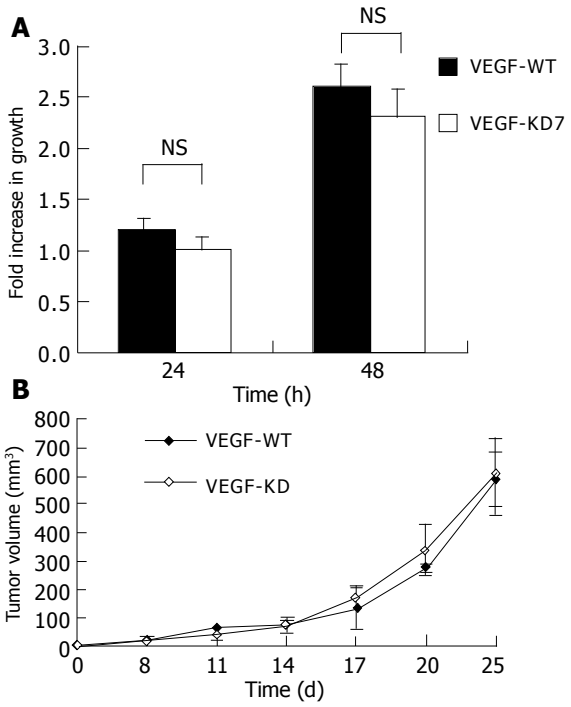

Figure 2 Effect of VEGF knockdown on cell proliferation. **A**: 3×10^4 VEGF-KD7 or VEGF-WT cells were grown in 24-well plates, and the numbers of viable cells were assessed using the MTT assay at 24 (P = 0.082) and 48 h (P = 0.078) (n = 4, mean±SD); **B**: 2×10^6 VEGF-KD7 or VEGF-WT cells were injected into C57BL/6 mice subicutaneous, the tumor size was measured, and the volume was calculated as [(length (mm)×width (mm)²)]/2 (n = 4, P = 0.18, mean±SD).

Effect of VEGF knockdown in the tumor grafted mouse ascites model

Ascites was induced by the intraperitoneal injection of 1×10^6 VEGF-KD7 or VEGF-WT cells into C57BL/6 mice. Ascites accumulation and peritoneal dissemination occurred about 2 wk after cancer cell inoculation. The ascites was bloody in both groups. As shown in Figure 3A, the volume of ascites did not differ between the VEGF-KD7 cell line and control VEGF-WT cells (1.9±0.22 *vs* 1.7±0.16 mL, P = 0.10). Next, we measured the concentration of VEGF in ascites. As shown in Figure 3B, the VEGF tended to be

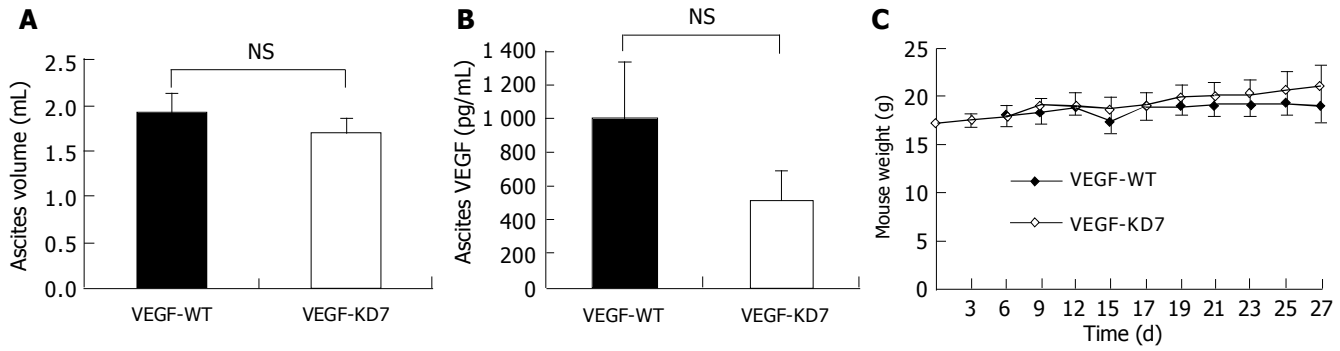

Figure 3 Effect of VEGF knockdown in a tumor grafted mouse ascites model. **A**: The ascites volume of mice inoculated with VEGF-KD7 or VEGF-WT cells (n = 5, P = 0.10, mean±SD); **B**: The VEGF concentration in ascites. VEGF in the ascites was measured using ELISA (n = 4, P = 0.054, mean±SD). **C**: 1×10^6 VEGF-KD7 or VEGF-WT cells were inoculated into mice intraperitoneally and the mice were weighed (n = 8, $P \geqslant 0.05$ in each data point).

lower in the VEGF-KD7 cell line (517±181) compared with VEGF-WT cells (1 001±331), but the difference was not significant (P = 0.054). Both study groups showed extensive macroscopic peritoneal dissemination, but there was no difference in tumor weight between VEGF-KD7 and VEGF-WT cells (0.63±0.15 g *vs* 0.56±0.16 g, P = 0.8). To analyze the systemic effect, the mice were weighed every 2 or 3 d. As shown in Figure 3C, no difference was observed between VEGF-KD7 and VEGF-WT cells. The survival of mice inoculated with VEGF-KD7 or VEGF-WT cells did not differ statistically (35±4.7 d *vs* 38.2±4.2 d, P = 0.29).

DISCUSSION

Pancreatic cancer progression is associated with the accumulation of ascites in the peritoneal cavity. At least three different pathological events cause ascites, i.e., reduced lymphatic drainage from the peritoneal cavity: the obstruction of lymphatic vessels by tumor cells; hyperpermeability of the microvessels lining the peritoneal cavity; and angiogenesis[17]. VEGF contributes to ascites formation by enhancing vascular permeability and promoting new vessel growth[4].

To investigate the role of VEGF secreted from cancer cells in ascites formation following pancreatic cancer progression, we established VEGF knockdown pancreatic cancer cell lines using the stable RNAi method. The stable RNAi system is a useful tool for analyzing endogenous gene silencing[11-13]. Using this system, we were the first to succeed in establishing a VEGF knockdown stable cell line, and to analyze its effect *in vivo*. Others have used VEGF knockdown cells, but their analyses involved *in vitro* experiments[18].

Recent studies using fibrosarcomas generated from VEGF-null *RAS*-transformed mouse embryonic fibroblasts concluded that VEGF production in stromal compartments plays a critical role in tumor angiogenesis[10]. It has also been reported that tumor-infiltrating lymphocytes produce a number of potent angiogenic growth factors, cytokines, and proteases[19]. In another study, we used mouse syngenic colon cancer cells, which do not express VEGF protein *in vitro*, but the levels of VEGF protein expression in the tumor tissues did not differ statistically from PancO2 tumors (data not shown). Although VEGF protein expression was significantly reduced in our VEGF-KD7 cell line *in vitro*, the VEGF concentration in the ascites fluid was not statistically different compared with VEGF-WT cells. During tumor progression, infiltrating cells to the stroma produce a number of potent angiogenic growth factors, cytokines, and proteases. These findings indicate that cancerous compartments, such as the stromal tissues of a tumor, can play a critical role as the scaffold in VEGF production, and VEGF production in tumor tissues is not solely dependent on tumor cells. The accumulation of tumor ascites maybe induced by VEGF-dependent increase of permeability in the blood vessels of the peritoneum, and stromal compartments of the tumor tissue and peritoneum plays a critical role in VEGF-mediated ascites formation.

VEGF is a key mediator of tumor angiogenesis. Recent reports indicate that blocking VEGF is an effective strategy for treating human cancer[20]. The VEGF-specific antibody bevacizumab has anti-vascular effects in human rectal cancer[21]. Malignant ascites formation might be mediated in a cancer cell-type independent manner, and anti-VEGF strategy could be applied to various tumors regardless of whether they secrete VEGF.

Abstract

AIM: To study the distributions and frequencies of intestinal endocrine cells in the C57BL/6 mouse with immunohistochemical method using seven types of specific antisera against chromogranin A (CGA), serotonin, somatostatin, glucagons, gastrin, cholecystokinin (CCK)-8 and human pancreatic polypeptide (hPP) after abdominal subcutaneous implantation of murine lung carcinoma (3LL).

METHODS: The experimental animals were divided into two groups, one is non-implanted Sham and the other is 3LL-implanted group. Samples were collected from six regions of intestinal tract at 28th d after implantation of 3LL cells (1×10^5 cell/mouse).

RESULTS: In this study, five types of immunoreactive (IR) cells were identified except for gastrin and hPP. The regional distributions of the intestinal endocrine cells in the 3LL-implanted group were similar to those of the non-implanted Sham. However, significant decreases of IR cells were detected in 3LL-implanted group compared to those of non-implanted Sham. CGA- and serotonin-IR cells significantly decreased in 3LL-implanted groups compared to that of non-implanted Sham. Somatostatin-IR cells in the jejunum and ileum and CCK-8-IR cells in the jejunum of 3LL-implanted groups significantly decreased compared to that of non-implanted Sham. In addition, glucagon-IR cells were restricted to the ileum and colon of non-implanted Sham.

CONCLUSION: Implantation of tumor cell mass (3LL) induced severe quantifiable changes of intestinal endocrine cell density and the abnormality in density of intestinal endocrine cells may contribute to the development of gastrointestinal symptoms such as anorexia and indigestion, frequently encountered in patients with cancer.

INTRODUCTION

A system using the 3-Lewis lung carcinoma (3LL), a tumor which once arose spontaneously in C57BL/6 mice, is particularly useful because it metastasizes into the lungs. Now, 3LL is considered as one of the widely used type of tumor in the development and study of antitumoral agents[1,2]. C57BL/6 mouse is an inbred black mouse and is probably the most widely used of all inbred strains, though in many ways it seems to be atypical of inbred strains of laboratory mice. This strain of mice is resistant to chloroform toxicity[3], to induction of cleft palate by cortisone, to lethal effects of ozone[4] and to colon carcinogenesis by 1, 2-dimethylhydrazine[5]. In addition, it is also a recommended host for the following transplantable tumors: 3LL, mammary adenocarcinoma BW 10232, melanoma B16, myeloid leukemia C 1498 and preputial gland carcinoma ESR586 T.

Gastrointestinal endocrine cells dispersed in the epithelia and gastric glands of the digestive tract synthesize various kinds of gastrointestinal hormones and play an important role in the physiological functions of the alimentary tract. Until now, the investigation of gastrointestinal endocrine cells is considered to be an important part of a phylogenic study[6] and the endocrine cells are regarded as the anatomical units responsible for the production of gut hormones, and the change in their density would reflect a change in the capacity of producing these hormones[7]. Many studies have

elucidated the regional distribution and relative frequency of different endocrine cells in the gastrointestinal tract (GIT) of the various vertebrates and also the researches or data processing about gastrointestinal endocrine cells in the mouse strains have been widely executed including normal C57BL/6 mouse[8]. The changes of gastrointestinal endocrine cells in some diseases are also well demonstrated. An abnormal density of gastrointestinal endocrine cells was reported in patients with diabetes[7] and proliferation of endocrine cells in the epithelium was detected in pernicious anemia[9]. Some quantitative changes of endocrine cells were also demonstrated in celiac sprue[10] and in pancreatectomy[11]. In addition, changes of endocrine cells in colorectal carcinoma induced by chemicals were demonstrated[12].

In cancer patients, the most frequent and distressing symptoms are gastrointestinal disorder, and Komurcu *et al*.[13], reported that dry mouth, weight loss, early satiety, taste changes, constipation, anorexia, bloating, nausea, abdominal pain and vomiting were 10 most common gastrointestinal symptoms in patients with lung, breast and prostate cancer. In the change of the gastrointestinal endocrine cells with tumor, most of the reports were related to the induction of gastrointestinal endocrine tumor by some chemicals[14,15] or by some diseases[16]. In addition, the composition, number, and types of endocrine cells in the endocrine tumors located in the gastrointestinal tract are well recognized[17-19].

Although nearly one-half of the most frequently reported and most distressing symptoms in patients with cancer are gastrointestinal in nature[13], the study about changes of gastrointestinal endocrine cells was restricted to the region of endocrine carcinoid tissues or nonneoplastic mucosa around the carcinoids. In addition, there was no report dealing with changes of gastrointestinal endocrine cell profiles after subcutaneous implantation of tumor. The objective of this study was to clarify the changes of the endocrine cells in the intestinal regions of C57BL/6 mouse after subcutaneous implantation of 3LL by specific immunohistochemistry using seven types of antisera against chromogranin A (CGA), serotonin, somatostatin, glucagons, gastrin, cholecystokinin (CCK)-8 and human pancreatic polypeptide (hPP).

MATERIALS AND METHODS

Experimental animals

Twenty adult female C57BL/6 mice (6-wk old, 21-26 g of body weight upon receipt) were acquired from the Charles River Laboratories (Yokohama, Japan) and used in this study after acclimatization for 1 wk. Animals were allocated five per autoclaved filter-top cages (Nalgene, Rochester, NY, USA) in a temperature (20-25 ℃) and humidity (50-55%) controlled room during acclimatization periods. Light:dark cycle was 12:12 h and sterilized feed (Samyang, Korea) and autoclaved water were supplied, with free access. Animals were divided into two groups, 3LL-implanted group and non-implanted Sham group. Each of 10 mice was used in this study. All procedures in this study were in compliance with the Animal Welfare Act Regulations (9CFR Parts 1, 2 and 3) and with the Guide for the Care and Use of Laboratory Animals (Institute of Laboratory Animal Resources, 1996).

Implantation of Lewis lung carcinoma (3LL)

Lewis lung carcinoma was maintained as subcutaneous tumor mass. Maintained subcutaneous tumor mass was excised under sterile conditions and single cell suspensions were prepared by collagenase type IV and DNase I (Sigma, USA) in PBS and filtration of the resulting tumor cell suspension through cell strainer (Costar, USA). After counting and adjusting the cell number (1×10^5 cell/mouse), 3LL cell was subcutaneously implanted at abdominal skin with viable tumor cells.

Sampling

After 28 d of implantation, all experimental animals were anesthetized with diethyl ether. For inducing gastric and/or intestinal emptying, animals were fasted for about 24 h. After phlebotomization, samples from six regions of the intestinal tract, the duodenum, jejunum, ileum, cecum, colon and rectum were fixed in Bouin's solution.

Histology

After paraffin embedding, 3-4 μm serial sections were prepared. Representative sections of each tissue were stained with hematoxylin and eosin for light microscopic examination of the normal gastrointestinal architecture.

Immunohistochemistry

Each representative section was deparaffinized, rehydrated and immunostained with the peroxidase anti-peroxidase (PAP) method[20]. Blocking of nonspecific reaction was performed with normal goat serum, prior to incubation with the specific antisera (Table 1). After rinsing with phosphate buffered saline (PBS; 0.01 mol/L, pH 7.4), the sections were incubated in secondary antiserum. They were then washed in PBS buffer and finally the PAP complex was prepared. The peroxidase reaction was carried out in a 3, 3'-diaminobenzidine tetrahydrochloride solution containing 0.01% H_2O_2 in Tris-HCl buffer (0.05 mol/L, pH 7.6). After immunostaining, the sections were lightly counterstained with Mayer's hematoxylin and the immunoreactive (IR) cells were observed under light microscope.

The specificity of each immunohistochemical reaction was determined as recommended by Sternberger[20], including the replacement of specific antiserum by the same antiserum, which had been preincubated with its corresponding antigen.

Frequency

In the restricted view fields on a computer monitor using automated image analysis process (Soft Image System, Germany) attached to light microscopy, IR cells showing immunoreactivities against each antiserum were counted among 1 000 epithelial and intestinal acinar cells. The frequencies of IR cells were calculated as mean±SD of total 10 parts (one filed in each animal) of each intestinal region.

Statistical analysis

Mann-Whitney *U*-Wilcoxon rank sum *W* test (M-W test) was used to analyze the significance of data with SPSS for Windows (Release 6.1.3, SPSS Inc., USA) and the significant values were represented by a and b ($P<0.05$; $P<0.01$).

RESULTS

In this study, five kinds of the IR endocrine cells were detected against CGA, serotonin, somatostatin and CCK-8 in the intestine of C57BL/6 mice regardless of implantation (Tables 2 and 3). However, glucagon-IR cells were restricted to non-implanted Sham and no gastrin- and hPP-IR cells were demonstrated in this study. According to the location of the intestines, different regional distributions and frequencies of these IR cells were observed and these differences are shown in Table 2. Most of these IR cells in the epithelial regions were generally spherical or spindle in shape, while occasionally round in shape cells were also found in the intestinal gland regions. In addition, most of these IR cells showed significant ($P<0.01$ or $P<0.05$) decrease in 3LL-implantation group compared to that of non-implanted Sham group.

CGA-IR cells

CGA-IR cells were observed in the entire intestinal regions of both groups. They were mainly dispersed in the basal portions of intestinal mucosal regions rather than the surface epithelial regions and they were more numerously detected in the small intestine compared to that of the large intestine regardless of implantation of 3LL except for the colon in which CGA-IR cells were more numerously detected than that of the jejunum and ileum (Figures 1A-M). In addition, CGA-IR cells in the colon of 3LL-implanted group that were restricted to the surface epithelium differed from that of non-implanted Sham (Figures 1E, K and L). The frequency of CGA-IR cells in the entire intestinal regions of 3LL-implanted group significantly ($P<0.01$) decreased compared to that of non-implanted Sham (Tables 2 and 3). About 46.56%, 65.88%, 77.42%, 69.86%, 40.14% and 75.00% of CGA-IR cells in the duodenum, jejunum, ileum, cecum, colon and rectum of 3LL-implanted group decreased compared to that of non-implanted Sham, respectively.

Serotonin-IR cells

Serotonin-IR cells were observed in the entire intestinal regions of both groups. These IR cells were dispersed throughout whole gastric mucosa, mainly in the surface epithelium and the intestinal gland regardless of 3LL-implantation (Figures 2A-L). They showed the highest frequency in the rectum of non-implanted Sham and in the colon and duodenum of 3LL-implanted group. The frequency of serotonin-IR cells in the entire intestinal regions of 3LL-implanted group was significantly ($P<0.01$ or $P<0.05$) decreased compared to that of non-implanted Sham (Tables 2 and 3). About 51.32%, 25.41%, 32.79%, 42.28%, 59.86% and 95.24% of serotonin-IR cells in the duodenum, jejunum, ileum, cecum, colon and rectum of 3LL-implanted group were decreased compared to that of non-implanted Sham, respectively.

Somatostatin-IR cells

Somatostatin-IR cells were restricted to the small intestine regions of non-implanted Sham and 3LL-implanted groups. These IR cells were dispersed in the surface epithelium and intestinal gland regions of the mucosa of both groups (Figures 3A-F). The frequency of somatostatin-IR cells in the duodenum of 3LL-implanted group was similar to that of non-implanted Sham (about 5.88% was decreased). However, cells in the jejunum and ileum of 3LL-implanted group significantly ($P<0.01$) decreased compared to that of non-implanted Sham (about 85.25% and 46.15% were decreased, respectively, Tables 2 and 3).

Glucagon-IR cells

A few glucagon-IR cells were restricted to the intestinal gland regions of ileum and colon of non-implanted Sham (Figures 4A and B). However, no glucagon-IR cells were observed in 3LL-implanted group (Tables 2 and 3).

Gastrin-IR cells

No gastrin-IR cells were demonstrated in the entire intestinal regions of non-implanted Sham and 3LL-implanted groups

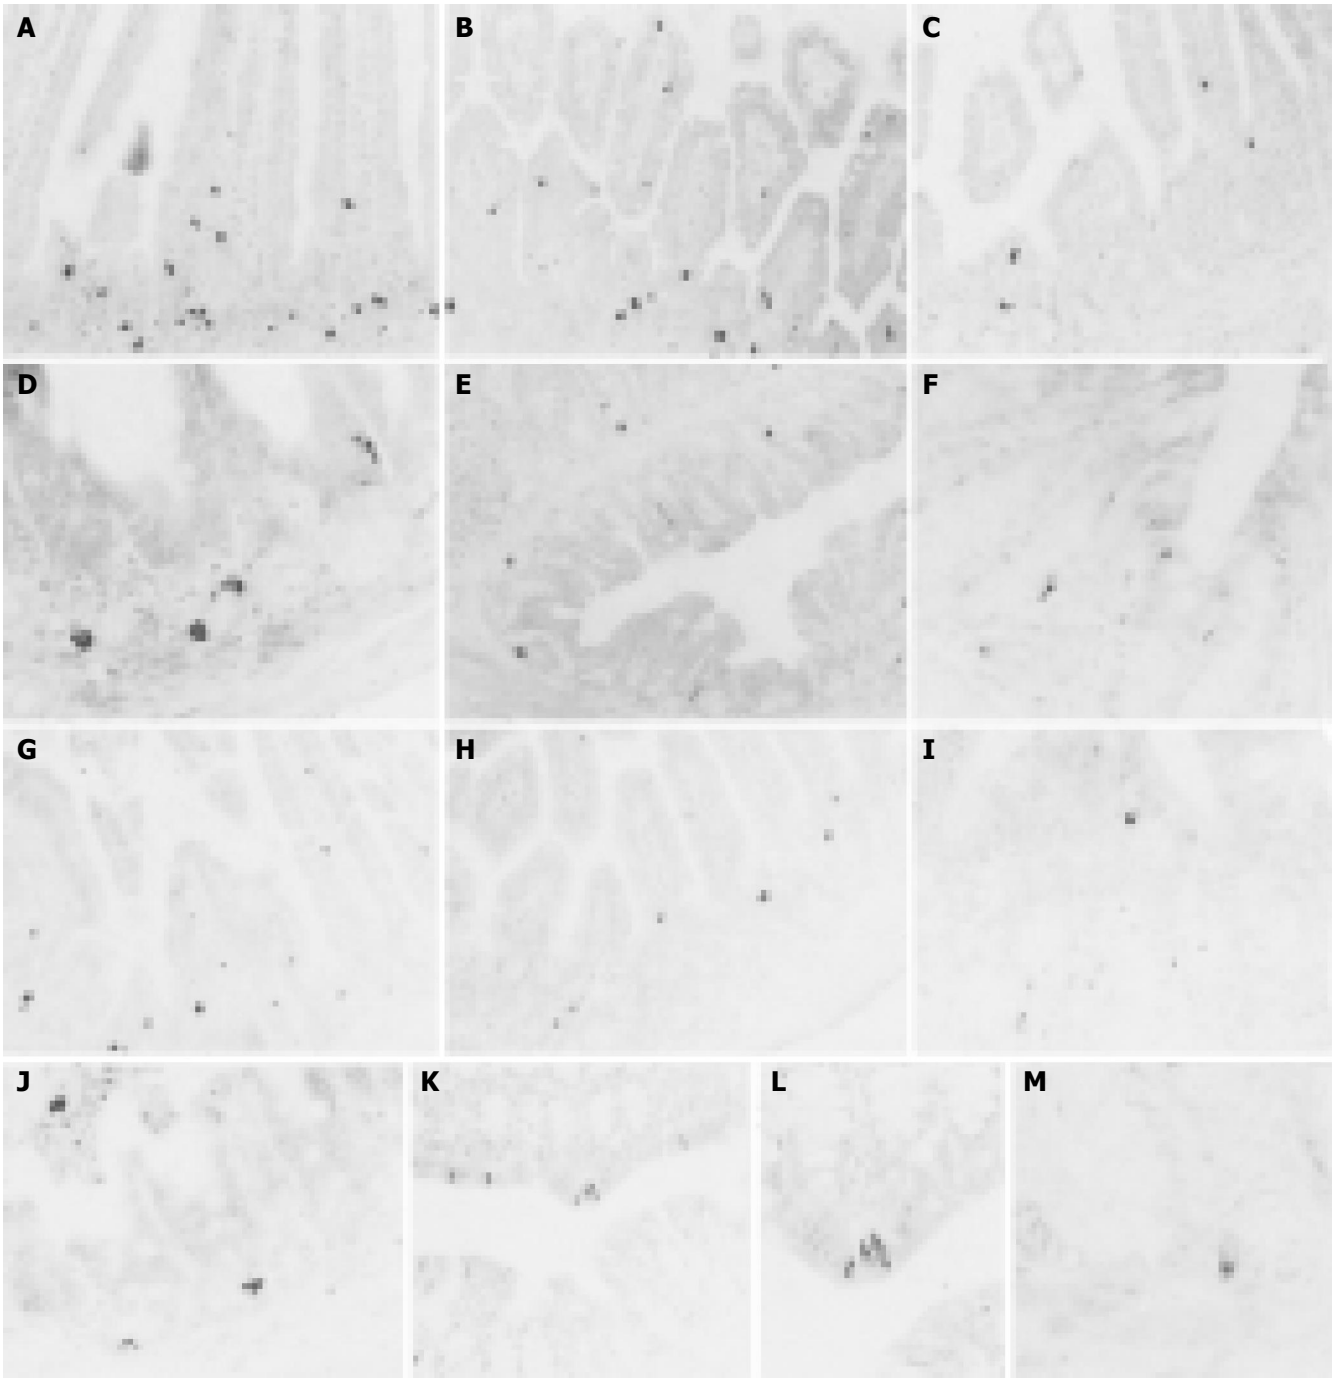

Figure 1 CGA-IR cells of the duodenum (**A**, **G**), jejunum (**B**, **H**), ileum (**C**, **I**), cecum (**D**, **J**), colon (**E**, **K**, **L**) and rectum (**F**, **M**) of non-implanted Sham (**A**-**F**) and 3LL-implanted group (**G**-**M**). In 3LL-implanted group, CGA-IR cells were dramatically decreased in the entire intestinal regions. **A**-**C**, **E**, **G**, **H** and **K**: ×120; **D**, **F**, **I**, **J** and **L**: ×240; **M**: ×480; PAP methods.

(Tables 2 and 3).

CCK-8-IR cells

CCK-8-IR cells were restricted to the duodenum and jejunum of both groups and most of these IR cells were dispersed in the surface epithelium and intestinal gland of the intestinal mucosa similar to that of other IR cells (Figures 5A-D). The frequency of CCK-8-IR cells in the duodenum of 3LL-implanted group was similar to that of non-implanted Sham (about 13.25% was increased). However, cells in the jejunum of 3LL-implanted group were significantly ($P<0.01$) decreased compared to that of non-implanted Sham (about 61.76% were decreased, Tables 2 and 3).

hPP-IR cells

No hPP-IR cells were demonstrated in this study, regardless of implantation of 3LL (Table 2).

DISCUSSION

In the present study, the changes of the endocrine cells in the intestinal regions of C57BL/6 mouse after subcutaneous implantation of 3LL were observed by specific immuno-

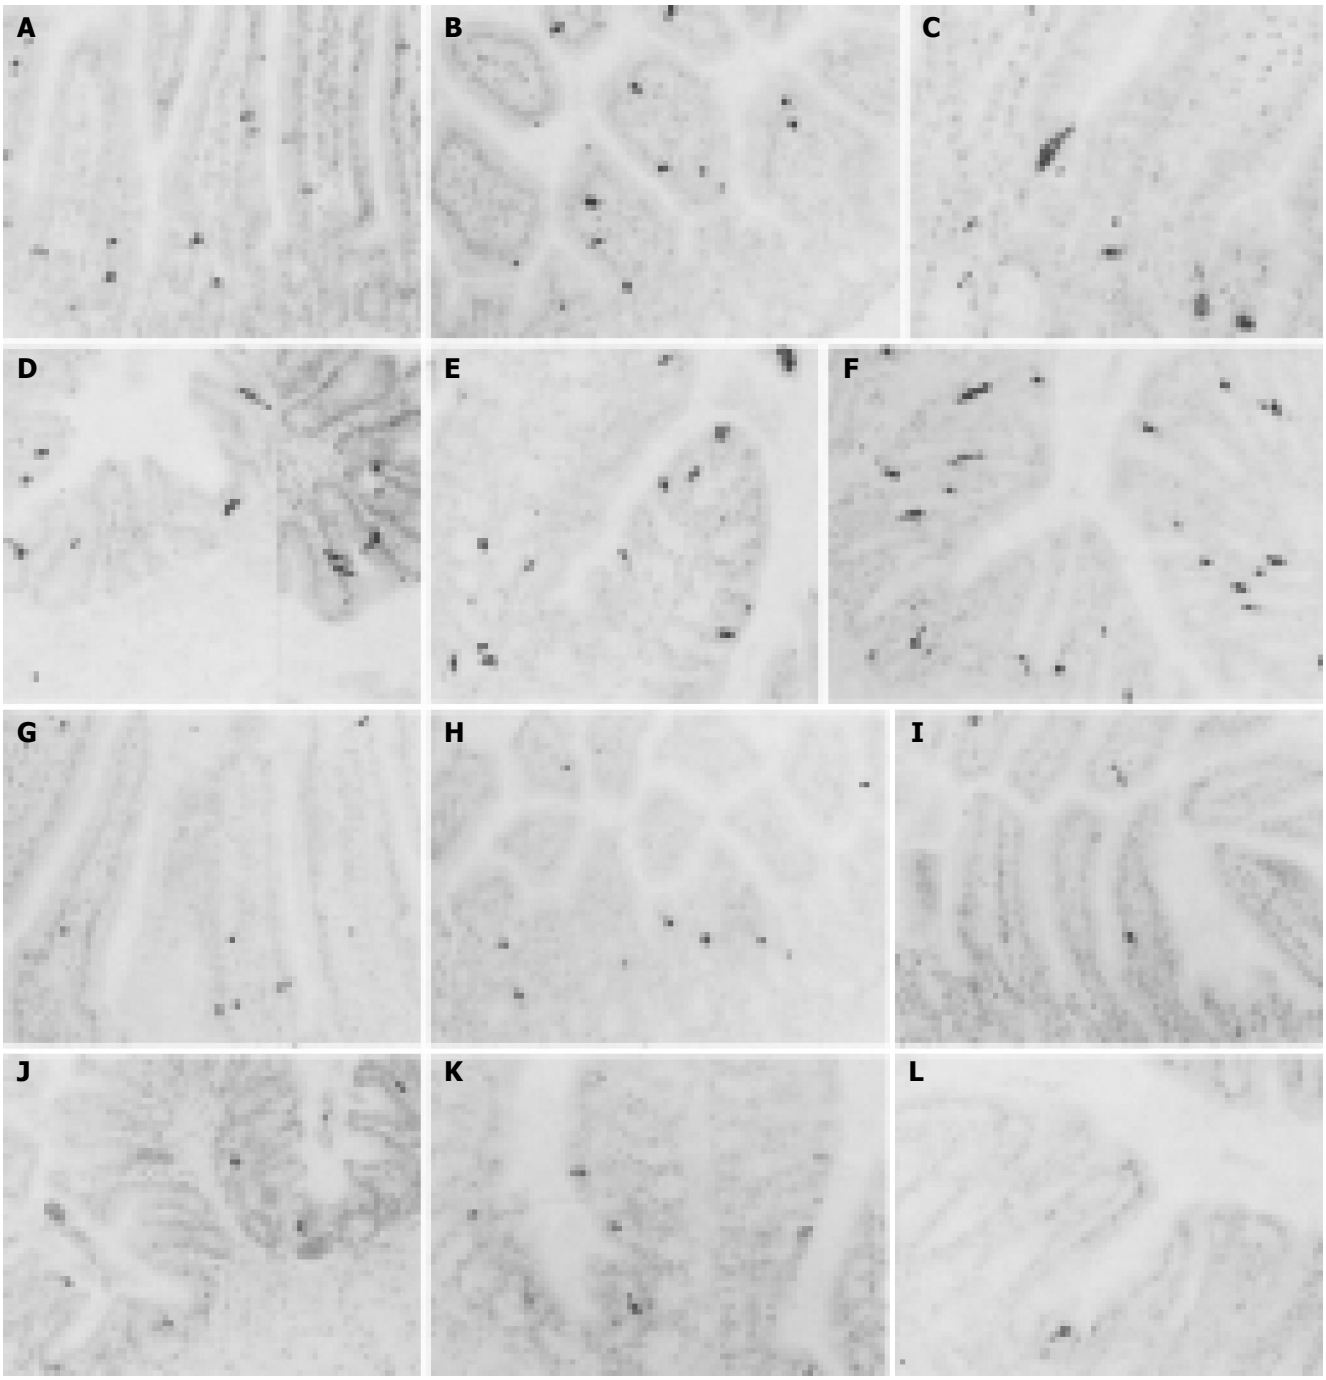

Figure 2 Serotonin-IR cells of the duodenum (**A**, **G**), jejunum (**B**, **H**), ileum (**C**, **I**), cecum (**D**, **J**), colon (**E**, **K**) and rectum (**F**, **L**) of non-implanted Sham (**A-F**) and 3LL-implanted group (**G-L**). In 3LL-implanted group, serotonin-IR cells were dramatically decreased in the entire intestinal regions. **A**, **B**, **D-L**: ×120; **C**: ×240; PAP methods.

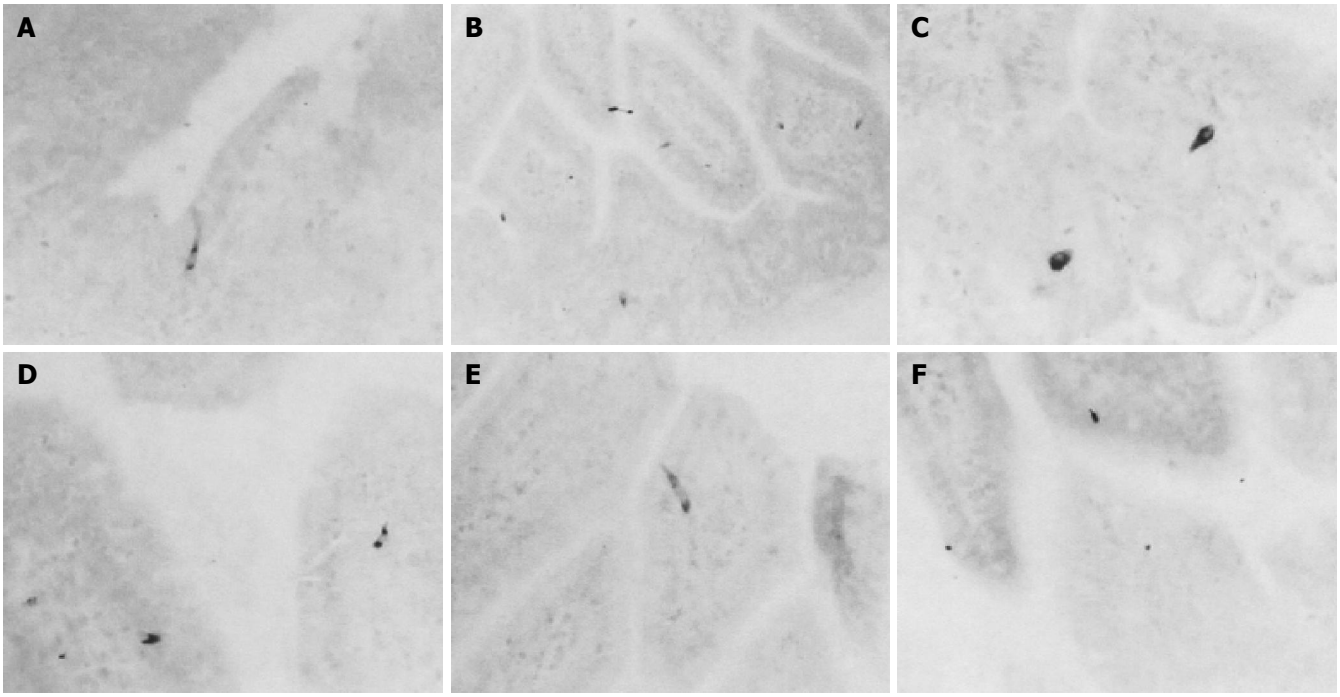

Figure 3 Somatostatin-IR cells of the duodenum (**A**, **D**), jejunum (**B**, **E**) and ileum (**C**, **F**) of non-implanted Sham (**A**-**C**) and 3LL-implanted group (**D**-**E**). In 3LL-implanted group, somatostatin-IR cells were slightly decreased in the jejunum and ileum. **A**, **C**-**F**: ×240; **B**: ×120; PAP methods.

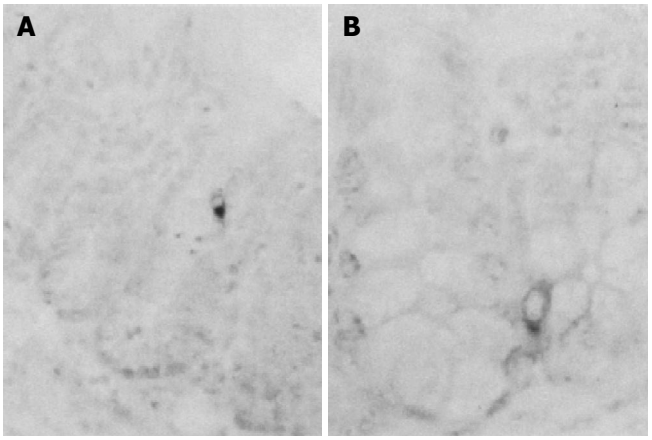

Figure 4 Glucagon-IR cells were restricted to the ileum (**A**) and colon (**B**) of non-implanted Sham. They were located in the intestinal gland regions. **A**: ×240; **B**: ×480; PAP methods.

histochemistry. As results of 3LL implantation, most of IR cells were significantly ($P<0.01$ or $P<0.05$) decreased in the entire intestinal tract except for somatostatin- and CCK-8-IR in the duodenum in which similar cell numbers were detected between non-implanted Sham and 3LL-implanted groups. In the rectum, the most dramatical changes were demonstrated and the most dramatical changes were demonstrated in serotonin-IR cells. These changes might be inducing a gastrointestinal disorder observed in patients with cancer[13].

Chromogranins have been found to occur in a large variety of endocrine organs and cells outside the adrenal medulla, and they have been claimed as common "markers" of all neuroendocrine cells[21]. Although, seldom there were changes of frequency of CGA-IR cells in the GIT of Rodentia, Qian *et al*.[22], reported that decrease of CG-IR cells was demonstrated in the intestine of unilateral cervical

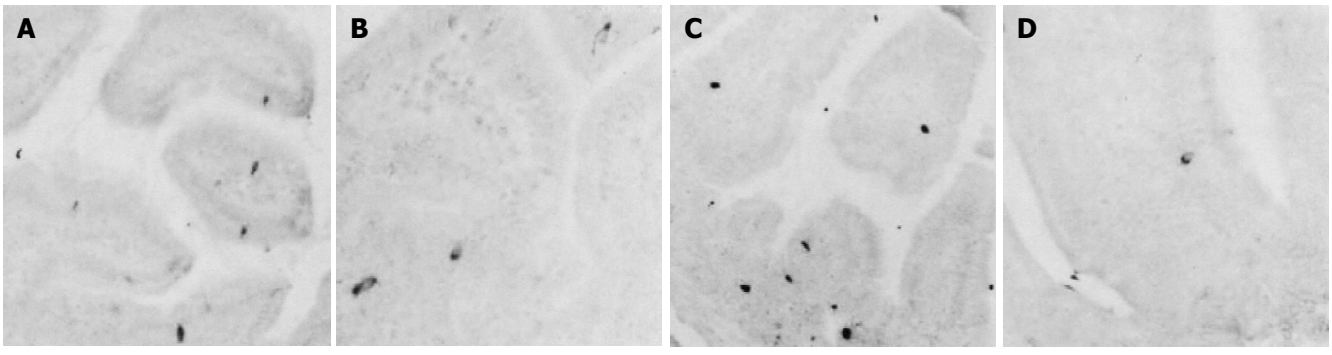

Figure 5 CCK-8-IR cells of the duodenum (**A**, **C**) and jejunum (**B**, **D**) of non-implanted Sham (**A**, **B**) and 3LL-implanted group (**C**, **D**). In 3LL-implanted group, CCK-8-IR cells were decreased in the jejunum. **A**, **C**: ×120; **B**, **D**: ×240; PAP methods.

vagotomized mouse. In addition, increase of CG-IR cells was also demonstrated in the intestine of proton pump inhibitor treated rat[23] and celiac children[24]. According to the previous reports, it is considered that changes of CG-IR cells were possible as a sign of disease and these changes were also considered as results of changes of other endocrine cells because CGs were regarded as a common marker of other endocrine cells[21]. In the present study, CGA-IR cells were remarkably decreased in the intestine of 3LL-implanted groups compared to that of non-implanted Sham.

Serotonin consisted of monoamines widely distributed in the nervous system and gastro-entero-pancreatic endocrine cells and the main functions of serotonin were inhibition of gastric acid secretion and contraction of smooth muscle in the GIT[25]. Serotonin-IR cells were dramatically decreased in the duodenum of diabetic mouse[26] and the number of these IR cells and occupied area were significantly decreased in the damaged gastroduodenal regions of mouse, induced by ethanol[27]. In the present study, among used antisera serotonin-IR cells were most significantly decreased in the entire regions of the intestine. These changes might induce gastrointestinal problems, especially some clinical signs related to gastric motility and gastric acid secretion.

Somatostatin consisting of 14 amino acids was isolated from hypothalamus of sheep for the first time and it could be divided into straight form and cyclic form[28]. This substance inhibits the secretion of the other neuroendocrine hormones[29]. It is known that somatostatin-IR cells show the widest distribution in the whole GIT except for the large intestine of all vertebrate species investigated, including the primitive agnathans with serotonin-IR cells[8]. Somatostatin-IR cells were significantly increased in the cancer adjacent mucosa compared to that of cancer distant mucosa of colorectal endocrine cancer patients[30] and decrease of these IR cells was demonstrated in the duodenal ulcer patients with *Helicobacter pylori*, but they were increased to normal after eradication of *H pylori*[31]. In the present study, somatostatin-IR cells were remarkably decreased in the jejunum and ileum of 3LL-implanted groups compared to that of non-implanted Sham. This decrease of somatostatin-IR cells is considered to have induced somewhat serious problems to gastrointestinal physiology, particularly their functions on the digestive tract.

Glucagon is synthesized in the A cells of the pancreas and regulates serum glucose levels. These IR cells have been demonstrated in various mammals. However, there were no reports dealing with the evidence of changes of glucagon-IR cells in any disease case or in any abnormality induced by any chemical or any manipulation. In the present study, corresponding to that of previous study[8], they were restricted to the ileum and colon of non-implanted Sham. However, no glucagon-IR cells were demonstrated in the intestine of 3LL-implanted group.

Gastrin secreted by intestinal G cell, promotes gastric acid secretion and CCK secreted by intestinal I cell stimulates the pancreatic enzyme secretion. However, gastrin-IR cells in the C57BL/6 mice were restricted to the stomach regions[8] and they were not detected in this study. Enteric CCK-8-IR cells significantly increased in celiac sprue[11]. In the present study, marked decrease of CCK-8-IR cells were demonstrated in the jejunum, after implantation of 3LL and these results induce some gastric disorders. Since PP was isolated from insulin extraction of pancreas at 1961, the regional distribution of PP-IR cells in the mouse strains was relatively well known, but strain-dependant differences existed among mice[8,32]. In the C57BL/6 mice, generally no hPP-IR cells were demonstrated in the GIT[8].

In conclusion, implantation of tumor cell mass (3LL) induce severe quantifiable changes of the intestinal endocrine cell density and the abnormality in density of endocrine cells may contribute to the development of gastrointestinal symptoms such as anorexia and indigestion, frequently encountered in patients with cancer. However, the overall hormone states such as amounts in blood in 3LL-implanted animals were not observed in this study, the exact meaning of the decrease of endocrine cells is unclear. Therefore, to understand the exact relationship between the decrease of GI endocrine cells and gastrointestinal disorder observed in patients with cancer, some quantified study of blood hormone states must be made.

Abstract

AIM: To establish a highly reproducible animal model of acute liver failure (ALF), for assessing the effect of bioartificial liver support system (BALSS).

METHODS: A two-phase complete liver devascularization procedure was performed in eight loco-hybrid pigs. Blood biochemical index and liver biopsy were studied every 2 h after surgery, and survival time was recorded. The BALSS constructed with high volume recirculating technique was a hollow fiber circulating system consisting of a hepatocyte reactor-hollow fiber module inoculated with microcarrier-adhering hepatocytes, and a double pump, heparinized, thermostabilized, micro-capsulized activated carbon-adsorbing plasmapheresis system. Twelve pigs undergoing two-phase surgery were randomized into: control group (perfused without hepatocytes, $n = 6$) and treatment group (perfused with hepatocytes, $n = 6$). Intergroup liver biochemical indexes, survival time, and liver pathological changes were analyzed at regular intervals.

RESULTS: Two-phase surgery was performed in all the experimental pigs, and there was no obvious difference between their biochemical indexes. After 3 h of phase II surgery, ammonia (Amm) increased to (269±37) μmol/L. After 5 h of the surgery, fibrinogen (Fib) decreased to (1.5±0.2) g/L. After 7 h of the surgery, ALT, AST, Tbil and PT were (7.6±1.8) nka/L, (40±5) nka/L, (55±8) μmol/L and (17.5±1.7) nka/L respectively. After 9 h of surgery, ALB and Cr were (27±4) g/L and (87±9) μmol/L. After 13 h of surgery, BUN was (3.5±0.9) μmol/L. All the above values were different from those determined before surgery. Survival time of pigs averaged 13.5±1.4 h. ALF pigs in the other group were treated with BALSS. The comparison analysis between the treated and control animals showed the changes of Tbil, PT, Alb, BUN, Cr, Fib, and Amm ($P<0.01$), but there was no change of ALT and AST. The survival time was statistically different ($P<0.01$), and there was no significant difference in histological changes.

CONCLUSION: The porcine ALF model established by two-phase devascularized surgery is valid and reproducible. The hollow fiber BALSS can meet the needs of life support and is effective in treating ALF.

INTRODUCTION

A highly reproducible animal model of ALF is crucial for assessing the extracorporeal BAL support efficiency. In our investigation, when a two-phase complete liver devascularization surgery was performed, acute loss of compensation for liver functions occurred, and pigs died of acute liver failure (ALF) eventually. Blood samples were collected to analyze biochemical indexes and liver biopsy was obtained for pathologic examinations under light and electron microscope. The survival time of all experimental animals was recorded. Pigs with ALF were treated with the bioartificial liver support system (BALSS) consisting of a hepatocyte reactor-hollow fiber module inoculated with microcarrier-adhering hepatocytes, and a double pump, heparinized, thermostabilized, micro-capsulized activated carbon-adsorbing plasmapheresis system. Pigs with ALF in the other group were treated with BALSS. Compared to the control animals, Tbil, PT, Alb, BUN, Cr, Fib, and Amm in the treated animals changed ($P<0.01$), but ALT and AST did not change. Survival time was statistically different ($P<0.01$), but there was no difference in histological changes.

MATERIALS AND METHODS

Animals and reagents

Twenty 2-3 mo old healthy native hybrid pigs (15-20 kg) purchased from the Animal Center of Sun Yat-Sen University of Medical Sciences were used in the experiment. All the animals received humane care and the study protocols were in compliance with the animal care guidelines established by the First Military Medical University. Twelve grams per

liter alginic acid sodium reservoir, 13 g/L $CaCl_2$ solution, poly-lysine solution, and 0.6 g/L alginic acid sodium solution were kindly provided by the Institute of Molecular Immunology, The First Military Medical University. All other chemicals were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Machines used included Fresenius hemodialysis machine (A2008C, Germany), UF5.5F6 dialyzer (Fresenius Polysulfone, Germany), YT-HP-160 hemoperfusion machine (Yatai Medical Instrumentation Co., Ltd, Ningbo, Zhejiang Province, China).

Animal surgery

Prior to surgery, animals were kept fasting for 12 h, with water available *ad libitum*. Anesthesia was induced with an intra-abdominal bolus of 30 mg/kg pentobarbital (30 g/L). A double lumen catheter was inserted into the right upper limb vein for drug and infusion delivery. Animals received oxygen through nasal catheter intubation. Laparotomy was performed in midline from xiphoideus down to the lower abdomen. After mobilization of the portal vein and right renal vein, 0.25 mg heparin was injected into the portal vein, which was clamped in the middle part with a hemostat, a 15 cm×0.8 cm silica-gel catheter containing 20 g/L heparin saline was introduced into the inferior caval vein with a depth of 2-3 cm from the far-forth end of the right renal vein, and secured. Another end of this catheter was placed in the portal vein toward the far-forth end with a depth of 1.5 cm, then the catheter was secured and opened. When there was no distinct bleeding, the abdominal wound was closed. Thus a portacaval shunt was established end to side. Phase II surgery was performed after 2 d. All the peri-hepatic ligaments were cut. The branches of hepatic artery were transfixed; hepatic artery and gastroduodenal artery were ligated completely. An 18-G catheter was inserted into the left femoral artery for direct blood pressure measurement. After 1, 4, and 7 h of complete liver devascularization, liver biopsies were taken for postoperative histology examination. The operative wound was closed in a single layer. During the surgery, 500 mL 0.9% NaCl and 800 000 U benzylpenicillin were infused. When the animal died, autopsy was practiced, and specimens of liver were taken for histology examination.

Biochemical index assessment During phase II surgery, blood sample was collected before the obstruction of blood liver (0 h) and at regular intervals (every 2 h after phase II surgery) to monitor AST, ALT, Alb, Tbil, Amm, BUN, Cr, PT, and Fib until the pigs died.

Histology examination Under light microscope, liver specimens were trimmed into 5-mm sections, fixed into 100 mL/L formalin, dehydrated with alcohol, embedded with paraffin and sliced up, then stained with HE for observation under light microscope. Under electronic microscope, liver specimens were doubly-fixed with 25 g/L glutaral and 10 g/L osmium acid, dehydrated with acetone, embedded with Epon-812 resin and sliced up by LKB-2088 ultramicrotome, then stained with acetic acid and citromalic acid lead for electronic microscopy with Hitachi-600 transmission electron microscope (Japan).

Survival time record Survival time (from phase II surgery to the death of animal) of all the animals was recorded.

Treatment with BALSS

Porcine hepatocyte preparation Hepatocytes of native hybrid pigs were isolated by the two-step collagenase digestion method[1]. The digested liver parenchyma was suspended in ice cold Hanks-Hepes medium and filtered with gauze and 500 μm of stainless steel mesh. Then, the cell pellet was collected by centrifugation at 50 r/min and washed several times with Hanks-Hepes balanced solution. Viability of the cells was always greater than 90%, as judged by trypan blue exclusion. Isolated liver cells were attached to hydrated microcarriers according to the methods of Demetriou *et al*.[2].

Construction of BAL circulatory system Micro-capsulization of activated carbon was conducted according to the method of Rozga *et al*.[3]. (Figure 1).

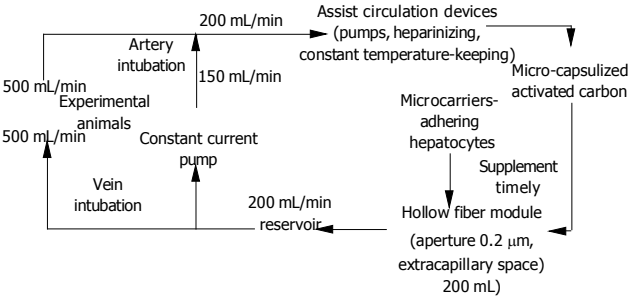

Figure 1 Pattern of BAL circulating system.

System parameters Blood was pumped out from the femoral catheter at a flow rate of 50 mL/min and into a high flux recirculation circuit, and then converged with the recircling blood at a flow rate of 150 mL/min, which was pumped out of the reservoir by constant current pump. The confluent blood was filtrated through the double pumps, heparinizing, thermostabilized, oxygenating, pressure monitoring and micro-capsulized charcoal adsorption devices in order, and then passed through the intracapillary space of the hollow fiber module at 200 mL/min. The extracapillary space of the device was filled with 200 mL of microcarrier-adhering hepatocytes and culture media system (containing 5×10^9 hepatocytes). Solute exchange occurred through the side pore of the fiber. Subsequently, 500 mL of the circling blood flowed into the reservoir and a majority of it (150 mL/min) turned into recirculation through the pump. The rest (50 mL/min of blood) was infused back into the pigs through the femoral vein catheter.

Treatment of ALF with BALSS Twelve experimental pigs were randomized into control group and treatment group (n = 6 in each group). When construction of BALSS was completed, the groups with ALF were treated with BALSS. The control animals were treated with BALSS containing no hepatocytes, but only 200 mL of culture medium, and the treatment group was treated with BALSS containing 5×10^9 hepatocytes in the same volume of culture medium. Analysis of liver biochemical indexes, survival time and morphological changes was carried out to judge the extracorporeal liver support efficiency of BALSS.

Statistical analysis

Results were expressed by mean±SD. Data were analyzed by the *t* test. $P<0.05$ was considered statistically significant.

RESULTS

Establishment of ALF models

Experimental ischemic ALF model was established successfully in eight pigs by two-phase complete liver devascularization surgery. After the obstruction, the average survival time was (13.5±1.4) h.

Biochemical assays After devascularization, Amm increased immediately, followed by a decrease after 9-11 h, and then increased progressively again. Levels of AST, ALT, Tbil, BUN, Cr, and PT increased. Alb and Fib decreased (Table 1).

Histology observation Light microscopy observation: Before the complete liver devascularization (0 h), structure of hepatic lobules was normal, Disse cavity did not dilate, hepatocytes did not swell, and arrayed radiatively around the central vein (Figure 2A). One hour later, structure of hepatic lobules was still normal, so was the linage of hepatocytes. Disse cavity dilated slightly, and hepatocytes were swollen and turbid, while nuclear membrane and nucleoli were still clear (Figure 2B). Four hours later, structure of hepatic lobules was still in existence, so was the frame of hepatic plates. While Disse cavity dilated obviously, central veins caved in and ballooning degeneration occurred in cytolymph. Pyknosis and vanishment of nucleoli occurred as well (Figure 2C). Seven hours after the obstruction, structure of hepatic lobules was in disorder, hepatic plate was dissociated and the arrangement of hepatocytes was disordered, Disse cavity dilated more, ballooning degeneration in cytolymph was more significant, so was the swelling of hepatocytes, chromatin gathered borderly, and there was evidence of lytic necrosis of hepatocytes (Figure 2D). When the experimental animals died of ALF, pathological examinations revealed that hepatic lobules were unrecognized, hepatocytes diminished, hepatic plate dissociated, and obvious extensive piecemeal necrosis of hepatocytes emerged (Figure 2E). Electronic microscopy observation: Before devascularization, the examination of hepatocyte ultrastructures showed that there was abundant glycogen granules in cytolymph, also plenty of endoplasmic reticulum with no dilation and no swelling mitochondria, and mitochondrial cristae were clear, so was mitochondrial membrane, chromatin was symmetrical, nucleoli and nuclear membrane were also legible (Figure 3A). Four hours later, it was obvious that glycogen granules in cytolymph were

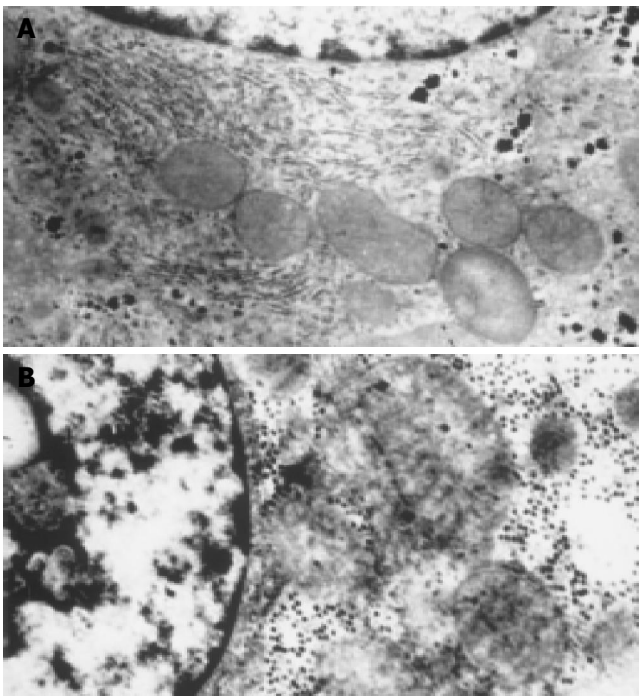

Figure 3 Electronic microscopy observation of hepatocytes at 0 h (**A**) and 4 h (**B**).

homogenized, rough endoplasmic reticulum de-grained, mitochondrion was swollen, and part of it was lysed, mitochondrial cristae blurred, cholangiole microvilli between the hepatocytes significantly diminished, chromatin centralized, nuclei deformed, and pseudo-inclusion bodies in nuclei appeared (Figure 3B).

Treatment with BALSS

Experimental ischemic ALF model was established successfully in 12 pigs by the two-phase complete liver devascularization surgery, and treatment of all the pigs with BALSS was accomplished successfully.

Determination of biochemical indexes Before the complete liver devascularization, the difference in ALT and AST had no statistical significance between the two groups; after the surgery, ALT and AST increased progressively and swiftly in both groups after the surgery, but there was no statistical significance between the two groups (Figures 4A and B). A significant difference in Tbil level emerged between the two groups after 7 h ($P<0.05$), this difference became more significant after 9 h ($P<0.01$, Figure 4C). The significant difference in Alb between the two groups emerged after 3 h ($P<0.05$) and became more significant 2 h later ($P<0.01$, Figure 4D). Amm level increased rapidly in the control animals, but slowly in the treated animals, the difference was significant ($P<0.01$, Figure 4E). The levels of BUN and Cr increased more slowly in both groups as compared to Amm; the difference between the two groups was observed after 5 h ($P<0.05$), and became more significant 7 h later ($P<0.01$, Figures 4F and G). There was no statistical significant difference in PT and Fib between the two groups after 3 h, but the difference in PT tended to be significant 5 h later ($P<0.05$), and difference in Fib was more significant ($P<0.01$, Figures 4H and I).

Morphology observation Liver pathological impairment in the two groups was analogous to the pathological images of ALF model.

Survival time Survival time of the control animals was 11.6-15.1 (averaged 13.17±1.47) h, and that of the treated animals was 18.1-24.4 (averaged 21.33±2.16) h. The difference was significant between the two groups ($P<0.01$).

DISCUSSION

Hepatotoxins, such as alcohol, anaflon, dimethyl-nitramine and D-galactosamine, are used as ALF chemical inducers. But the chemical ALF models induced by hepatotoxin can have much diversity in the changes of biochemical indexes, pathological examinations, mortality rate, and survival time. Thus, it is hard to evaluate the effects of treatments in those models. Also hepatotoxins often impair the internal organs such as kidneys and lungs, thus complicating the causes of death. Surgical ALF models are preferred, especially when a large animal model is established. Since devascularization method to induce canine ALF with two-phase surgery was reported by Rapaport and Gigesin, 1953, the procedure has been modified by the technique of hepatic artery ligation[4-6].

In our experiment, two-phase surgery was performed for liver devascularization. The pigs underwent portal-right renal venous shunt, and 2 d later, hepatic artery, gastroduodenal artery and peri-hepatic ligaments were cut to obstruct blood flowing into the liver. Acute loss of compensation for liver functions was then produced and the pigs died of ALF. We found that this model was simple and easy to operate. The choice of portal-right renal venous intubation shunt instead

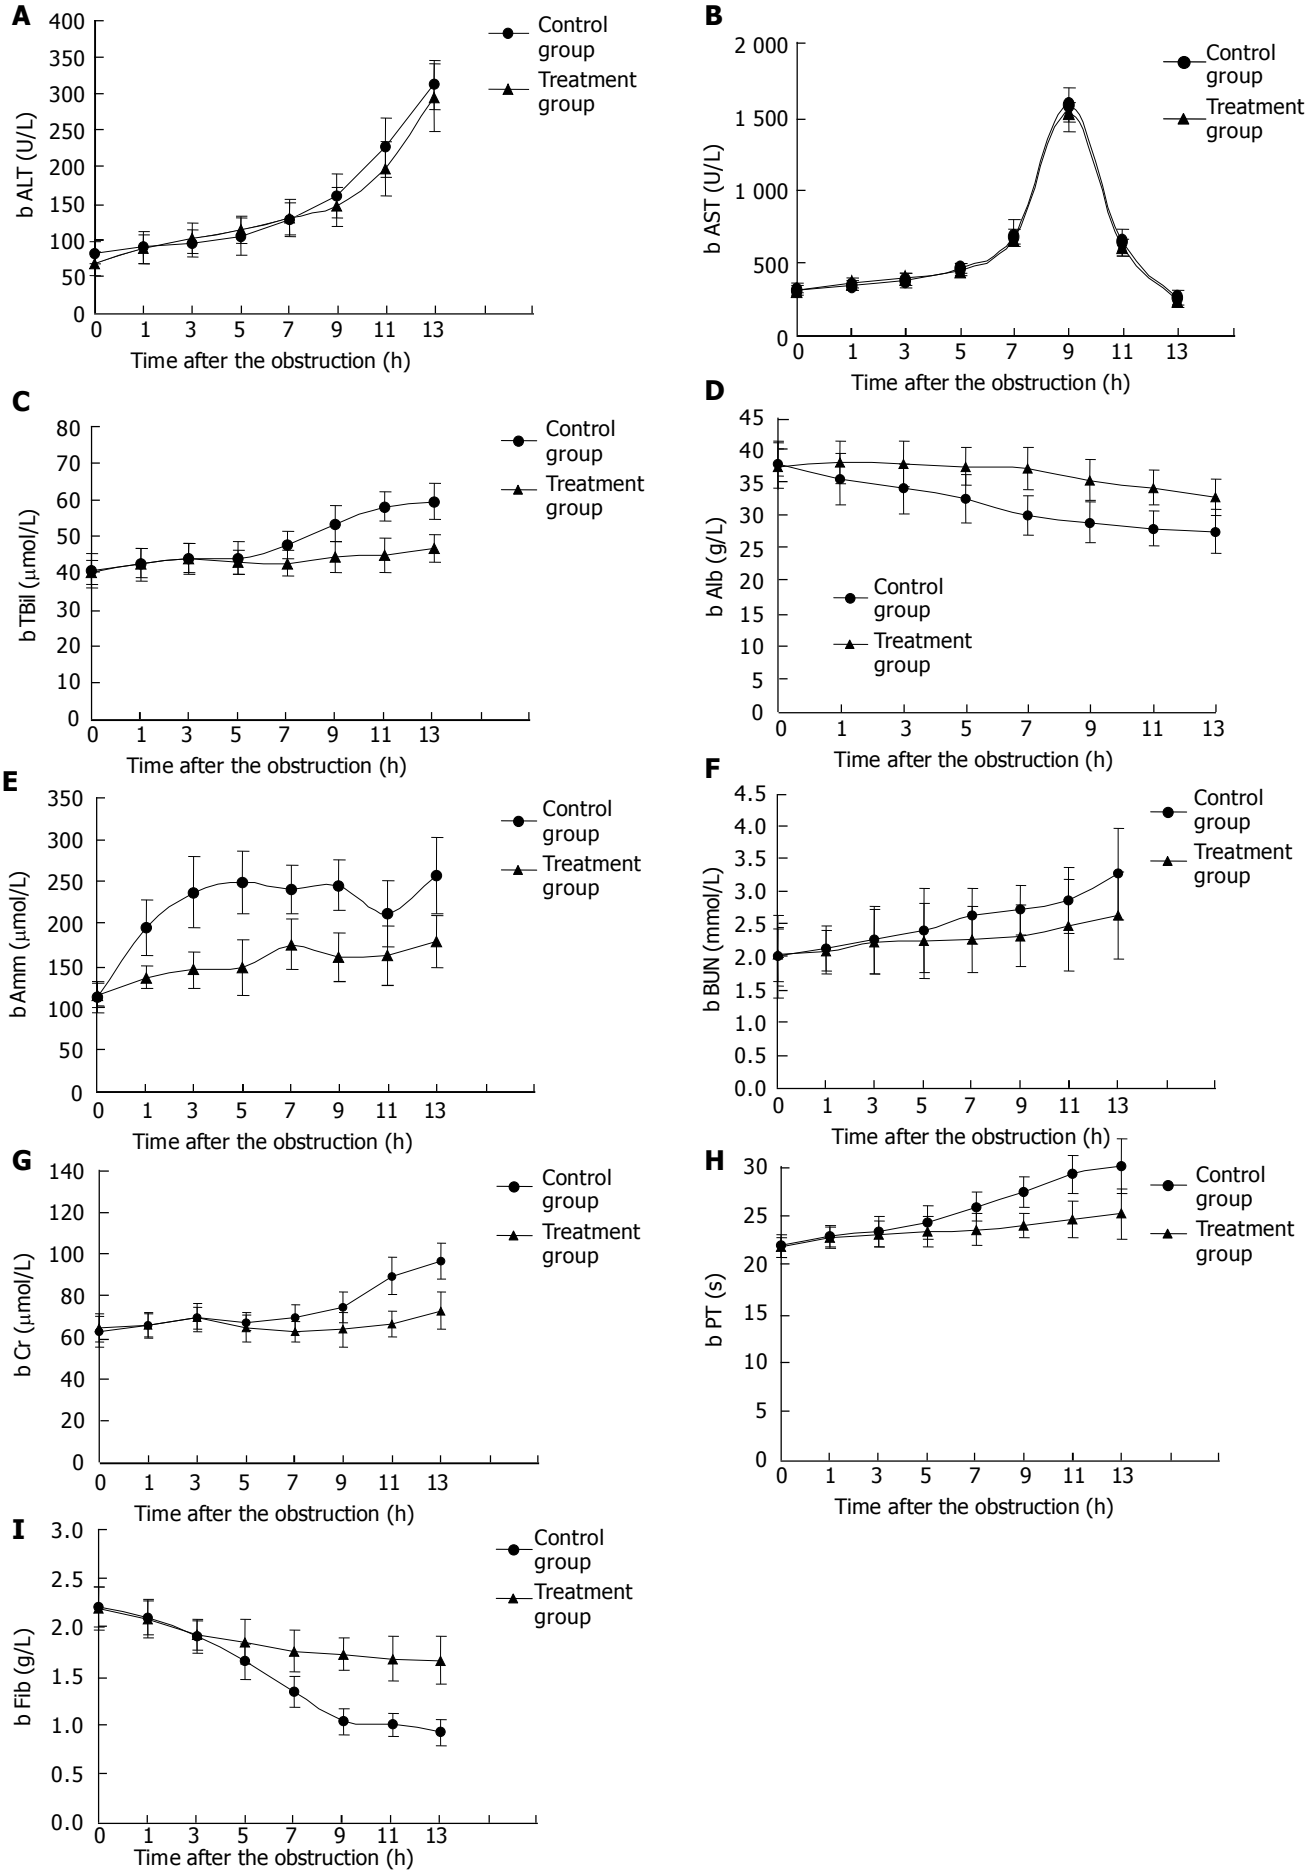

Figure 4 Changes of ALT (**A**), AST (**B**), Tbil (**C**), Alb (**D**), Amm (E), BUN (**F**), Cr (**G**), PT (**H**), and Fib (**I**).

of portal-cava anastomosis reduced the difficulty of the surgery greatly. The blood flowing into liver was obstructed in phase I surgery, which induced ischemia tolerance of the pig. Thus, all the experimental pigs could accept phase II surgery. The model was reproducible. Stable parameters like biochemical indexes and survival time could be obtained, and the success rate of surgery was high. The two-phase surgery could achieve devascularization of liver, while not abruptly diminishing the blood volume in heart, the function of other internal organ was not influenced greatly. The pathologic changes in this model were irreversible, just like the model of total hepatectomy. The key technical point of this ALF model is as follows: The liver rami of left gastric artery and diaphragm artery must be ligated thoroughly during phase II surgery. Because the anatomic structure of porcine liver is similar to that of human beings, the same procedures to obstruct liver rami of human peri-hepatic ligaments were adopted in this study. Portocaval anastomosis is advantageous over portocaval intubation shunt theoretically, but in practice, portocaval intubation shunt is simple and reliable. In the prophase experiments of our study, the metabolism indexes of normal pigs were compared to those of the pigs with their right renal vein ligated. The results indicated that there was no significant difference in Amm, BUN, Cr, and blood sugar fluctuation between the two groups. The time of portocaval intubation shunt was much shorter than that of portocaval anastomosis (just about 5 min). No interference with hemodynamics of portal vein was found in the cases of right renal venous cannulation. The color and luster of bowel were ruddy during phase II surgery, indicating that 0.8-cm caliber of the shunt catheter is advisable.

ALF is a clinical syndrome involving massive hepatocyte necrosis, and resulting in liver function failure and encephalopathy. The death rate of ALF can reach 80%, and there is no specific therapy for it. The introduction of liver transplantation into clinical practice has improved the survival time of patients. However, because of the deficiency in donor liver, about 50% of the ALF patients would die waiting for donors. Since liver has a powerful ability to regenerate, an effective artificial liver assembly has been established to replace the liver functions of ALF patients for a temporary period, till the liver itself regenerates and recovers from acute decompensation. Recently, with advances in cell engineering and material technology, various kinds of large-scale cell culture techniques are used for the study of bioartificial liver, such as microcarriers[7,8], microcapsule coating[9], gelatin embedding[10-12], hollow fiber module[13-15] and spheroid culture[16], *etc*. The BALSS of porcine hepatocyte reactor-hollow fiber module was established and has entered into phase I clinical trials. It has been proven that such a system can yield multifunctions of hepatocytes to support the patients with ALF passing over the crisis. The BALSS can serve as a bridge to liver transplantation[14-18].

The technical characteristics of BALSS are as follows: (1) The microcarrier-adhering hepatocytes and culture media system increase the adsorbing area of hepatocytes greatly. Sufficient contact of cell-matrix or cell-cell is ensured. It is quite helpful to maintain hepatocytes polarity, thus prolonging the stability of hepatocytes. (2) In the circulation loop, high volume recirculating technique is adopted, which facilitates liquor convection greatly, and improves the substrate-product exchange of hepatocytes and the efficiency of BAL circulation. (3) Before the blood is pumped into the hepatocyte reactor, hemoperfusion over charcoal is used to relieve the hepatocyte impairment induced by the toxic substances in blood, thus hepatocyte viability and function can be maintained longer[19,20]. In this study, after devascularization of the liver, ALT increased progressively and swiftly in both groups, but there was no statistical significance between the two groups, suggesting that the degree of hepatocyte impairment is similar in both groups. Since devascularization of the liver in this study was permanent, the impairment of liver function was irreversible. AST could not be determined in treated animals 15 h later. The reason is likely that hepatocyte mitochondria which could not endure hypoxia for a long time reach the peak of disruption about 9 h later, and AST is exhausted gradually. After the experimental pigs died, liver pathological impairment of the two groups was analogous to the pathological image of ALF models, suggesting that the model of ALF established in this study is stable.

During the treatment of BAL, the most impressive result was the fluctuation of Amm. Amm is mainly produced by intestinal bacteria and detoxificated through being synthesized into urea in liver. After the obstruction, Amm level in control animals increased rapidly from (110±17) μmol/L to (240±35) μmol/L 5 h later, while increased slowly from (112±14) μmol/L to (144±34) μmol/L in the treated animals ($P<0.01$), suggesting that the BALSS can detoxify and depress Amm. Similar results have been reported by Chen *et al*. The levels of Tbil, Alb, BUN, Cr, PT, and Fib were significantly different between the two groups 3-7 h later, suggesting that BALSS has some action on bilirubin metabolism.

In conclusion, the BALSS can be used in the treatment of ALF. The results achieved in this study of large animals may contribute to the clinical therapy of ALF with BALSS.

Abstract

AIM: To establish the pig model of pancreatoduodenal transplantation with enteric drainage (ED) and portal venous drainage (PVD).

METHODS: Forty-six hybrid Landrace pigs were divided into two groups (donors and recipients) randomly, and pancreatoduodenal allotransplantation was performed. Donors were perfused via abdominal aorta without clamping the portal venous outflow with UW solution at 80–100 cm H_2O after heparinization. Whole pancreatoduodenal grafts were harvested with segments of abdominal aorta and portal vein, and shaped under 4 ℃ UW solution. Then, end-to-end anastomosis was performed with the donor iliac artery bifurcation Y graft to the recipient superior mesenteric artery and celiac artery. Furthermore, type I diabetes model was made by removal of the recipient pancreas. The venous anastomosis was reconstructed between the donor portal vein and the recipient superior mesentery vein. Meanwhile, end-to-side anastomosis was performed with the donor common iliac artery bifurcation Y graft to the recipient abdominal aorta, and side-to-side intestinal anastomosis was performed between the donor duodenum and the recipient jejunum. External jugular vein was intubated for transfusion. Levels of plasma glucose, insulin and glucagon were measured during the operation and on the 1st, 3rd, 5th, and 7th d after operation.

RESULTS: Pancreatoduodenal allotransplantation was performed on 23 pigs of which 1 died of complication of anesthesia. The success rate of operation was 95.6%. Complications of operation occurred in two cases in which one was phlebothrombosis with an incidence of 4.6%, and the other was duodenojejunal anastomotic leak with an incidence of 4.6%. The level of plasma glucose decreased within 30 min, after removal of pancreas and recovered on the 2nd d after operation. The level of plasma insulin and glucagon increased within 30 min after removal of pancreas and recovered on the 2nd d after operation. Rejection occurred on the 1st d and reached the worst level on the 7th d after transplantation, without change of plasma insulin and glucagon or clinical symptoms of rejection.

CONCLUSION: Pancreatoduodenal transplantation in pigs can treat type I diabetes. ED and PVD can keep the function of endocrine in normal. The technique of pancreatoduodenal transplantation with ED and PVD may pave the way for the further application of pancreas transplantation in clinic.

INTRODUCTION

Pancreas transplantation or combined pancreas-kidney transplantation is a radical therapy method for insulin-dependent diabetes mellitus and its complications. Though immune inhibitors and improvement of surgical technology have achieved obvious improvement of graft functional survival, surgical technology is still one of the important factors contributing to the failure of pancreas transplantation. The rate of it was 7-14% to simultaneous pancreas-kidney transplantation (SPK), 8-23% to pancreas after kidney transplantation (PAK), 10-23% to pancreas transplantation alone (PTA). Since 1995, over 1 000 cases of pancreas transplantation have been done[1]. Surgeons always want to decrease the failure caused by surgical technology, and to perform pancreas transplantation according to the status of anatomy and physiology. To pancreas transplantation, there are two types of exocrine drainage, one is bladder drainage (BD), the other is enteric drainage (ED). There are two types of endocrine drainage, one is systemic drainage (SVD), the other is portal venous drainage (PVD). BD could cause metabolic acidosis, uterine reflux pancreatitis, and urinary bladder stimulation that contributes to mucous erosion, bleeding, urinary tract stricture, etc.; so ED has to be performed after about 25% of BD operations[2]. In SVD cases, insulin and glucagon flow into systemic venous system,

not through the liver first; so it is not good in improving of microvascular lesions[3]. In PVD cases, pancreas glucagonoma can be avoided, and immune intolerance can be induced because the graft antigen goes into the liver directly. The combination of ED and PVD in pancreas transplantation is better to the status of anatomy and physiology. The pig anatomy structure is similar to that of human being, so it is very useful to set up an animal model with combined ED and PVD in pancreas transplantation.

MATERIALS AND METHODS

Experimental animals

Forty-six local Sichuan hybrid Landrace pigs, weighing 25-32 kg, were used as donors and recipients, and were provided by the Pig Institute of Sichuan Agriculture Science Academy. They were fasted for 12 h and forbidden drinking water for 6 h before operation.

Anesthesia and monitoring

Atropine (0.5 mg) and ketamine (15-20 mg/kg) were intramuscularly injected before anesthesia, 0.25% thiopental sodium was intravenously used, ventilation was provided by tracheal intubation. The anesthesia was maintained with 2% procaine and 0.15% succinylcholine chloride. During operation, ketamine, diazepam or fentanyl was sometimes used for better anesthesia; ECG, arterial pressure and SaO_2 were monitored. A trocar was placed in the auricular vein for fluid infusion.

Donor operation

We used anterior abdominal median incision. The stomach was removed, and the end of duodenum was blocked. The proper hepatic artery and common bile duct were ligated and divided. The portal vein was isolated. The superior mesentery artery and vein were isolated and ligated. The jejunum was divided at the site of 5 cm to the superior mesentery artery, the bilateral renal arteries and veins were isolated and ligated. The spleen artery and vein were ligated. Heparin (200 IU/kg) was intravenously injected to get systemic heparinization, 1 000 mL of normal solution (4 ℃) was poured into abdominal cavity. An abdominal aorta cannula was placed, the abdominal aorta was blocked at the site up to the celiac artery, and the in site flushing of fluctuating UW (4 ℃) fluid (about 2 000 mL) was made through the former cannula. The perfusion pressure was 80-100 cm water column. The portal vein was divided, and the end near the pancreas was open, the other end was ligated. The perfusion was stopped when the temperature was down, pancreas became pale, and effluent from the portal vein was clear (Figure 1). The head of pancreas was mobilized to the right of aorta, the tail of pancreas and spleen were mobilized. The aorta was divided above its fork, lumbar arteries derived from the proximal part of abdominal aorta were ligated and divided. The left or right common iliac artery and internal and external iliac arteries were removed.

Modification and storage of donor grafts

The pancreas and duodenum were stored in UW fluid (4 ℃) of a plastic bag, which was placed in a basin containing cold normal solution (Figure 2). The abdominal aorta was opened in the back wall, the peripheral of celiac artery and superior mesentery artery remained as elliptic Carrel patch, whose diameters were 0.5-0.8 cm. The celiac stem cannula and superior mesenteric artery cannula were placed for UW fluid perfusion. The portal vein was modified and 1.5-3.0 cm of it remained. The small blood and lymphatic vessels around the pancreas were ligated one by one. The fat tissue and lymph nodes were removed. The incision of anterior duodenum wall was made for the wash with metronidazole (0.5 g) and amikacin (0.4 g). The length of 20-30-cm duodenum was left for transplantation. An anastomosis was made for the opening of celiac stem and the distal end of external iliac artery, so did for the opening of superior mesenteric artery and the distal end of internal iliac artery. The modified graft was placed in UW fluid (4 ℃).

Figure 1 Pale pancreas after perfusion.

Figure 2 Modified graft for transplantation.

Recipient operation

After anesthesia worked, a cannula was placed in the external jugular vein, an anterior abdominal median incision (18-20 cm) was applied. Then the whole pancreas was removed. The superior mesentery vein and portal vein were exposed. After the anterior part of superior mesentery vein or portal vein was clamped with a vessel nip, whose caliber was similar to the diameter of the proximal end of the donor portal vein, was made. The lacuna was rinsed with normal saline containing heparin. The donor portal vein anastomosis was performed in an end-to-side fashion to the recipient superior mesenteric vein or portal vein

(Figure 3A). The abdominal aorta distal to the renal vein was freed. After the anterior part of abdominal aorta was clamped with a Satinski nip, an incision (1.0-1.5 cm) was made in corresponding part of the recipient anterior abdominal aorta wall. The donor common iliac artery anastomosis was performed in an end-to-side fashion to the recipient aorta (Figure 3B). The blood circulation to the graft was recovered after the former anastomoses were finished, the graft became pink, and its arteriopalmus and peristalsis were restored. The donor duodenum anastomosis was performed in a side-to-side fashion to the recipient jejunum 8-10 cm distal to the recipient Treitz ligament (Figure 3C). After the spleen was removed, the graft was placed in the right part of abdominal cavity.

Postoperation management

After autonomous respiration, steady blood pressure, and normal pulse were recovered, the tracheal intubate was removed. After operation, the recipient pig was forbidden drinking for 24 h, and eating for 2-4 d, and received 1 000-2 500 mL fluid infusion intravenously in those days. During the 1st d after operation, the recipient received the fluid at the ratio of glucose to insulin 1:4, 3 g ampicillin, 0.5 g of metronidazole, 40 mL danshen injection, 500 mL low molecular dextran, and heparin (1 mg/kg). To monitor the graft function status, the plasma glucose, insulin, and glucagon were measured, and pathology examination was performed. Plasma glucose, insulin, and glucagon were measured 30 min after the pancreas was removed, 30 min after blood circulation to the graft was recovered, and on each of the first 7 d after operation. The graft biopsy tissues were obtained on the 1st, 3rd, 5th and 7th d after transplantation. The biopsy tissues were observed by naked eyes and microscope after being stained with HE. The Nakhleh criteria[4] were used as follows:

Criteria for pancreas rejection The score was 0, if no rejection could be seen. The score was 1, if mild rejection could be seen (Lymph cells could be seen scattering in external secretion tissues, especially in tissues among pancreas lobules. The pancreas islet and pancreas duct were normal.). The score was 2, if moderate rejection could be seen (Diffused lymph cells and plasma cells can be seen in pancreas tissue, and local necrosis lesions or small pitch of wrecked granules could be seen. Lymph cells infiltrated in the area around pancreas duct. The structure of islet was normal, sometimes a few inflammation cells could be seen in islet.). The score was 3, if severe rejection could be seen (Much more lymph cells and plasma cells can be seen in pancreas tissue. Sweeping wreck of granules and sometimes pancreas fibrosis could be seen. Islets were wrecked and some or all of them disappeared. Vascular rejection, vessel endothelium inflammation, and fibroid necrosis could be seen.).

Criteria for vascular rejection The score was 1, if lymph cells infiltrated into the area under minority of venous endothelium cells. The score was 2, if lymph cells infiltrated into the area under majority of venous endothelium cells. The score was 3, if lymph cell infiltration and inflammation around the veins could be seen.

Statistical analysis

SPSS10.0 was used for analysis of data.

RESULTS

Success rate of operation

Of the 23 pigs that received pancreas transplantation, only one pig died from anesthesia accident. The survival rate was 95.65%. The longest survival time was 96 d. The operation time of donors was 73.84±6.86 min, and that of recipients was 143.25±18.14 min. There was no warm ischemia, the time of cold ischemia was 117.30±18.02 min. The portal vein anastomosis was 38.30±5.60 min, the time of artery anastomosis was 26.20±2.26 min. Two complications were observed, one was pancreas phlebothrombosis, the other was duodenojejunal anastomotic leak. There was no complication of vessel anastomosis, transplantational pancreatitis, or pancreatic ascites.

Survival of grafts

The graft biopsy tissues were obtained on the 1st, 3rd, 5th, and 7th d after transplantation. There was one case of pancreas infarction. Seventeen cases survived with good blood supply to pancreas.

Graft function after operation

Normal limosis plasma glucose of pigs was 5.22±0.92 mmol/L, plasma insulin was 8.34±2.43 mU/L, plasma glucagon was 177.73±12.11 pg/mL.

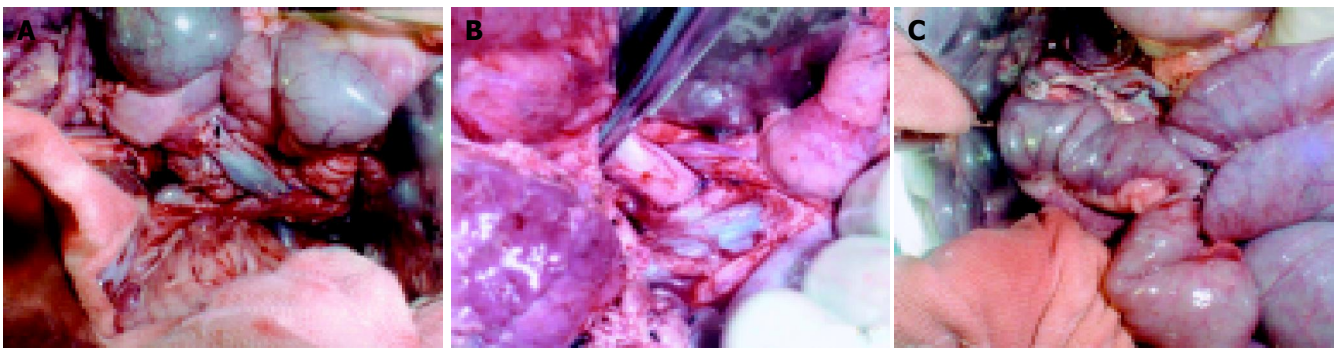

Figure 3 Anastomosis of donor portal vein to recipient superior mesenteric vein (**A**), donor common iliac artery to recipient aorta (**B**) in an end-to-side fashion, and donor duodenum to recipient jejunum (**C**) in a side-to-side fashion.

Pathology of rejection

During the first 3 d after transplantation, mild edema of pancreas could be seen. There were no exudation, congestion, or adhesion of pancreas. Under microscopy, lymph cells and monocytes could be seen in pancreas matrix, not in islet (Figure 4A). During the 5^{th}-7^{th} d, there were mild edema, congestion and adhesion of pancreas. Under microscopy, local or extensive infiltration of lymph cells and monocytes, apoptosis body could be seen (Figures 4B and C). There was separated or small pitch of necrosis of pancreas adrenal cells, extensive infiltration of lymph cells could be seen around small vessels, a few lymph cells could be seen around islets. During the 7^{th}-9^{th} d, the pancreas became more flexible, adhered to peripheral tissues, looked pale, and had good blood supply (Figure 4D). Under microscopy, extensive infiltration of lymph cells and monocytes could be seen in pancreas and around vessels. There were vessel endothelium inflammation and extensive fibrosis of pancreas (Figure 4E). During the 2^{nd}-4^{th} wk after operation, the pancreas glands and islets were replaced by connective tissues. Extensive lymphocyte infiltration could be seen in pancreas (Figure 4F).

DISCUSSION

Our data indicated that the plasma glucose arose 30 min after the pancreas was removed, became normal 2 d after transplantation, and arose again 15-21 d after transplantation. The half life of insulin or glucagon was only 5-10 min, indicating that the graft endocrine function was normal 2 d after transplantation. There was no host plasma insulin or glucagon after the recovery of grafts. It was different from SVD, the plasma insulin and glucagon levels were normal[5,6] indicating that the PVD in pancreas transplantation is better for the treatment of type I diabetes mellitus. To the rejection, our data indicated that mild rejection appeared on the 1^{st} d after operation, and became more serious with the time protracted. At the same time (2 wk after transplantation) plasma glucose, insulin, and glucagon were normal, indicating that we cannot know if there is rejection, or how serious the rejection is, after the operation. More sensitive criterion must be found for clinical work[7]. The length and diameter of pig portal vein are similar to those of human beings[8], setting up of a pig animal model is beneficial in clinical pancreas transplantation with ED+PVD. It was reported that primary ED was associated with a high incidence of early graft

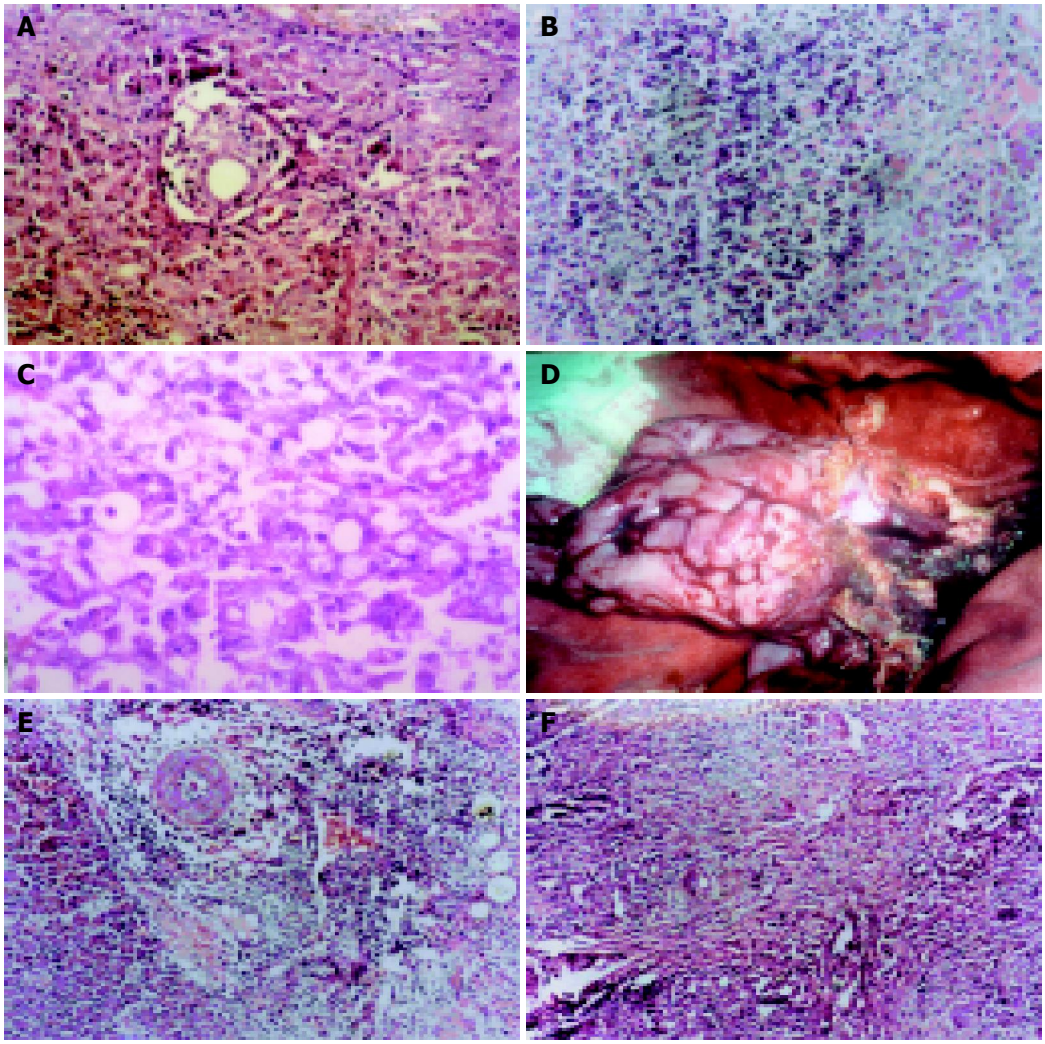

Figure 4 Mild rejection 3 d after operation (**A**) (HE ×200) and moderate rejection 5 d after operation (**B**) (HE ×100), apoptosis body and pancreatic edema 7 d after operation (**C**), pale pancreas with flexible mild edema 9 d after operation (**D**), severe rejection 10 d after operation (**E**), and infiltration of lymphocytes and hyperplasia of connective tissue 21 d after operation (**F**).

thrombosis, a complication that is the major cause of graft loss in PTA recipients[9]. Our data show that only 1/23 had thrombosis of pancreas, no complication of vessel anastomosis was found.

Our pig model of pancreas transplantation was improved on the following aspects[5,10,11]: (1) The outflow of the graft was performed through the anastomosis of donor portal vein to the recipient inferior vena cava. (2) The arterial inflow to the allograft was achieved by a single anastomosis of an aortic patch to the intended target in the recipient. (3) The pancreas exocrine drainage to the urinary bladder was performed through the duodenocystostomy. The present technique has the following advantages. (1) The outflow of the graft was performed through the anastomosis of donor portal vein to the recipient portal vein. It is better to the status of anatomy and physiology. (2) The Y-graft was anastomosed to the recipient abdominal aorta and the blood supply was achieved through it. It is a standard arterial reconstruction of clinical pancreas transplantation[12], because it is good for simultaneous liver procurrent[13]. The allograft was modified, and Y-graft was achieved under the protection of cold preservation solution. It did not prolong warm ischemia[14,15]. (3) The pancreas exocrine drainage to the jejunum was gained through an anastomosis of donor duodenum to the recipient jejunum. So there were no complications in duodenocystostomy, such as metabolic acidosis, uterine reflux pancreatitis, and urinary bladder stimulation that could contribute to mucous erosion, bleeding, urinary tract stricture, etc.[16]. (4) During the operation of blood vessel anastomosis, the abdominal aorta or inferior vena cava was not obstructed completely. Then, during the operation, the disadvantage effect on the recipient blood circulation was lesser.

In conclusion, our pig model is a model with ED and PVD. It is better to the status of anatomy and physiology. Now, more and more clinical pancreas transplantations with ED and PVD are performed[16,17], our pig model of pancreas transplantation can work better for the further study of pancreas transplantation.

Abstract

AIM: To investigate the effect of Jianweiyuyang (JWYY) granule on gastric ulcer recurrence and its mechanism in the treatment of gastric ulcer in rats.

METHODS: Gastric ulcer in rats was induced according to Okeba's method with minor modification and the recurrence model was induced by IL-1β. The expression of vascular endothelial growth factor mRNA (VEGF mRNA) was examined by reverse transcription polymerase chain reaction in gastric ulcer and microvessel density (MVD) adjacent to the ulcer margin was examined by immunohistochemistry.

RESULTS: MVD was higher in the JWYY treatment group (14.0±2.62) compared with the normal, model and ranitidine treatment groups (2.2±0.84, 8.8±0.97, 10.4±0.97) in rats (P<0.01). The expression level of VEGF mRNA in gastric tissues during the healing process of JWYY treatment group rats significantly increased compared with other groups (normal group: 0.190±0.019, model group: 0.642±0.034, ranitidine group: 0.790±0.037, P<0.01).

CONCLUSION: JWYY granules can stimulate angiogenesis and enhance the expression of VEGF mRNA in gastric ulcer rats. This might be the mechanism for JWYY accelerating the ulcer healing, and preventing the recurrence of gastric ulcer.

Dai XP, Li JB, Liu ZQ, Ding X, Huang CH, Zhou B. Effect of Jianweiyuyang granule on gastric ulcer recurrence and expression of VEGF mRNA in the healing process of gastric ulcer in rats. *World J Gastroenterol* 2005; 11(35): 5480-5484
http://www.wjgnet.com/1007-9327/11/5480.asp

INTRODUCTION

Peptic ulcer (PU) is one of the common clinical diseases. The incident rate of PU has been on the rise over the recent two decades[1]. Some latest studies showed that H_2 antagonists and the proton pump inhibitor omeprazole had about 80-100% of healing rate and produced a good therapeutic effect on gastroduodenal ulcer after a 4-8-wk administration. However, gastroduodenal ulcer has 40-80% of recurrent frequency, once the drug is withdrawn within a year. Moreover, *Helicobacter pylori* eradication ameliorates symptoms and improves the quality of lives of patients, but many of them still cannot avoid ulcer relapses[2-4].

The repair of gastric ulcers requires the reconstitution of epithelial structures and underlying connective tissue, including vessels and muscle layers. This complex sequence of events requires a high degree of coordination among different cell types, which is regulated by several factors. Of them, some growth factors, such as vascular endothelial growth factor (VEGF) and the platelet-derived growth factor (PDGF), have received much attention in recent years, because they play a pivotal role in gastric ulcer repair[5]. Previous studies indicated that the Chinese traditional medicine Jianweiyuyang granules (JWYY) can accelerate ulcer healing, improve scar quality, and prevent ulcer recurrence[6,7]. However, the mechanisms responsible for these actions are not fully elucidated. In this study, we examined the microvessel density (MVD) in the ulcer margin by immunohistochemistry and demonstrated the specific expression of VEGF mRNA at the gastric ulcer margin tissue using reverse transcription polymerase chain reaction (RT-PCR). The aim of this study was to determine whether JWYY accelerated ulcer healing by enhancing the expression of VEGF mRNA and angiogenesis.

MATERIALS AND METHODS

Medicine and reagents

JWYY granules were purchased from Hunan Xiangya Pharmaceutical Co., Ltd (No. Z10960018). Ranitidine capsule (purity 98%) was from Hangzhou Sanofi-Synthélabo

Minsheng Pharmaceutical Co., Ltd (No. H33021741). TRIzol reagent was from GIBCO BRL Co., Ltd (MRI, USA). Factor VIII antibody, revert Aid™ first strand cDNA synthesis kit and marker were provided by Fermentas Life Sciences Co. (MBI, Lithuania). DEPC was from Sigma Co. (St. Louis, USA). SABC kit and DAB kit were from Wuhan Boster Biotechnology Co., Ltd.

Animals and ulcer induction

Ninety Sprague-Dawley rats, half male and half female, weighing 180-220 g, were chosen for use in this study. All the rats were obtained from Experimental Animal Center of Xiangya Medical School of Central South University. The rats were kept individually in wire-bottom cages with free access to standard rat diet and water. The animal room was illuminated with a 12-h light-dark cycle. The room temperature was kept at 18-22 ℃ and the humidity at 60-70%. Rats underwent laparotomy under pentobarbital anesthesia.

Ninety rats were divided into six groups: normal group, sham operation group, ulcer model group, ulcer recurrence group, ranitidine group, and JWYY treatment group. Gastric ulcers were induced by a minor modification of the previously described method[8]. In control group, the operation procedures of rats were similar procedures except the application of acetic acid (sham operation).

Rats with healed ulcers were subjected to experiments of induction of ulcer recurrence. The rats in the ulcer model group were killed without treatment with interleukin 1β (IL-1β). The ulcer index, MVD and the expression of VEGF mRNA were measured. Recombinant human IL-1β (1 μg/kg) diluted to 1 mL with isotonic saline was injected intraperitoneally to the remaining animals to induce the ulcer recurrence model[9].

Drug treatment

Each of the rats in JWYY group were treated with a single dose of 0.162 g/(mL·100 g) JWYY granules daily; each rat in the ranitidine control group was treated with a single dose of 5.4 mg/(mL·100 g) of ranitidine daily. Other groups were treated with distilled water.

Tissues preparation

Rats were killed 7 or 92 d later after they received drug treatment or feed, then the gastric walls of rats were removed. A portion of the wall was put into 4% formaldehydum polymerisatum for 1 h to examine the ulcer index by the method designed by us. Another portion of the wall was embedded into the paraffin wax for HE staining. The gastric ulcer margin tissue was removed for MVD and VEGF mRNA expression measurement separately.

Measurement of ulcer index

The length, width, and depth of the ulcer were measured by a compass. The area of the ulcer equals to the width of the ulcer times the length of the ulcer. The ulcer was divided into two grades by its depth more than or less than 2 mm. The ulcer index was classified into 10 degrees[6] (Table 1).

Determination of MVD

The consecutive 5-μm sections were cut and mounted onto glass slides. Sections were stained with HE. The microvessel was examined using immunohistochemistry method with an anti-VIII mouse monoclonal antibody with a dilution of 1:80. Negative controls were detected by PBS substitution for the primary antibodies. All the procedures were carried out according to the manufacturer's instruction.

MVD was evaluated according to the previous method as described by Wang and Liao[10,11]. The stained sections were screened under low power, and five areas with the most intense neovascularization were selected. Microvessel counting of these areas was performed at the ulcer margin (×400). Any brown-stained endothelial cell or endothelial cell cluster was counted as a vessel. Vascular counts of each case were calculated. The mean microvessel count of the five richest vascular areas was taken as MVD.

Determination of expression of VEGF mRNA

Total RNA was isolated from gastric biopsy tissues by using TRIzol reagent according to the manufacturer's instruction.

RT-PCR was performed according to the manufacturer's instruction. RT-PCR reaction mixture containing 2 μL of total RNA, 1 μL oligo (dT)18 (0.5 μg/μL), 9 μL ddH_2O in a tube was mixed gently and then spinned down 3-5 s in a microcentrifuge. The mixture was incubated at 70 ℃ for 5 min and chilled on ice and the drops were collected by brief centrifugation. Four microliters of 5× buffer, 2 μL 10 mmol/L dNTP, and 1 μL (20 U) Rnasin were added to the above collected drops and then the mixture was incubated at 37 ℃ for 5 min. Then 1 μL (200 U/μL) M-MuLV reverse transcriptase was added to the above mixture and incubated at 42 ℃ for 60 min. The reaction was stopped by heating at 70 ℃ for 10 min. The first strand cDNA synthesized was chilled on ice and stored at -20 ℃ until next analysis.

The specific primers were designed by software primer premier 5.0 and purchased from Shanghai DNA Biotechnology Corporation Ltd. The primers for VEGF were 5'-CCTGGTGGACATCTTCCAGGAGTACC-3' (sense) and 5'-GAAGCTCATCTCTCCTATGTGCTGGC-3' (anti-sense), and the size of the amplified fragment conserved in all of the variant spliced forms was 104 bp. PCR products for β-actin were used as a positive control and internal standard. The primers for β-actin were 5'-

Table 1 Method of measuring the gastric ulcer index

Area (mm^2)	Depth	
	<2 mm	>2 mm
0	_	_ (ulcer healing)
1–4	1[1]	2
5–9	2	3
10–14	3	4
15–19	4	5
20–24	5	6
25–29	6	7
30–34	7	8
35–39	8	9
40	9	10

[1]1–10 = grade of the ulcer index.

GAGGGAAATCGTGCGTGAC-3' (sense) and 5'-CTGGAAGGTGGACAGTGAG-3' (anti-sense). The length was 445 bp. PCR was carried out in a final volume of 25 μL reaction mixture containing 9.5 μL ddH_2O, 2.5 μL 10× buffer, 1.5 μL $MgCl_2$, 0.5 μL 10 mmol/L dNTP, 4 μL VEGF primer, 4 μL β-actin primer, 0.5 μL Taq DNA polymerase (1.5 μL) and 2.5 μL cDNA. The final concentration of each primer was 0.1 μmol/L. Amplification conditions included an initial denaturation at 95 ℃ for 5 min, followed by 30 cycles of denaturation at 94 ℃ for 45 s, annealing at 63 ℃ for 45 s, and 1 min extending at 72 ℃, and a final extension at 72 ℃ for 10 min. Negative reaction mixture had no cDNA. PCR products were electrophoretically separated on 1.5% agarose gel in 1× TBE buffer, after which the gel was stained with ethidium bromide (0.5 μg/mL). The PCR instrument was purchased from Perkin Elmer Company.

For quantitative assessment of the PCR products, a computerized video analysis system was used. The results are expressed as the VEGF/β-actin ratio.

Statistical analysis

Results are expressed as the mean±SD. The Student's *t*-test was used to determine statistical significance of differences between two treatment groups. Comparisons of data between groups were performed with analysis of variance followed by *F*-test. $P<0.05$ was taken as significant. Statistical software SPSS10.0 was used in this study.

RESULTS

Effect of JWYY on gastric ulcer recurrence

After rats were induced by acetic acid, ulcers were detected in all rats by macroscopic examination except for the normal and sham operation groups (Figures 1 and 2). Moreover, after rats were induced by IL-1β, no ulcers in the normal and sham operation groups were detected by macroscopic examination (Figure 3). However, as shown in Figures 4-6 and Table 2, 9 of 10 rats in the model recurrence group had a gastric ulcer recurrence. In contrast, only 1 of 10 rats in the model group without IL-1β treatment was observed with ulcer recurrence. Moreover, 8 of 10 rats in the ranitidine group and 3 of 10 rats in the JWYY group with IL-1β treatment had gastric ulcer recurrence.

Expression of VEGF mRNA

In this study, the extracted total RNAs were of high purity (a range of A_{260}/A_{280} of RNA is from 1.807 to 1.913).

The result showed that the expression level of VEGF mRNA in gastric tissues of rats was low in the normal and sham operation groups. However, the expression level of VEGF mRNA in model, model recurrence, ranitidine, and JWYY groups were significantly increased after 7 d of treatment.

As shown in Table 4, the same results of VEGF expression in gastric ulcer were observed in all groups except for the model group after treatment for 92 d. Taken together, JWYY could enhance the expression of VEGF mRNA in gastric ulcer rats.

The result in black figure is considered as the result of the model recurrence group as well as the model group.

Table 4 VEGF mRNA expression in each group (mean±SD)

Group	VEGF mRNA		
	n	7 d	92 d
Normal	5	0.190±0.019	0.186±0.028

DISCUSSION

IL-1β is secreted by monocytes, macrophages, and other inflammatory cells. It can cause acute damage of gastric mucosa[12]. Recently, Watanabe *et al*., have developed a rat model of gastric ulcer recurrence induced by IL-1β and the pathologic characterization is very similar to that of the human chronic gastric ulcer[9,13].

In this experiment, we observed gastric ulcer in all rats after they underwent operation by Okabe's method. Nine of ten healed ulcers in the group treated with IL-1β relapsed in the model recurrence group. In contrast, only 1 of 10 relapsed in the model group and no ulcer was observed in the normal and sham operation groups. Taken together, this model of ulcer recurrence was very successful.

The repair of gastric ulcers is a complicated process. It is associated with the reconstitution of epithelial structures and the underlying connective tissue, including vessels and muscle layers. It has been reported that the recurrence of ulcer is associated with the quality of ulcer healing (QOUH)[14], which is related to angiogenesis. Some studies have shown that several growth factors and their receptors are involved in ulcer healing process. Of those, VEGF has received considerable attention, since it is considered to be the only factor that specifically acts on endothelial cells. The delay of ulcer healing and the poor QOUH may result from the lower expression or absence of some growth factors and their receptors[15,16].

VEGF, previously described as a vascular permeability factor, is a growth factor that is involved in the mucosal protection and the angiogenic response taking place during ulcer healing. VEGF is a peptide which is secreted as dimeric glycoproteins containing characteristic regularly spaced eight-cysteine residues. Multiple isoforms can be generated by alternative splicing of a single gene transcript. VEGF has a variety of effects on vascular endothelium, including the ability to promote endothelial cell viability, mitogenesis, chemotaxis, and vascular permeability. Expression of VEGF and its receptors has been demonstrated in the ulcer margin of the human PU disease. In experimental models of acute gastric damage, the expression of VEGF increases during healing, while the pretreatment of rats with a single dose of oral VEGF may exert a protective effect against acute ethanol damage in the gastric mucosa[17]. Furthermore, the daily administration of VEGF has been found to promote the healing of cysteamine duodenal ulcer in rats by stimulation of angiogenesis and formation of granulation tissue. These data suggest that VEGF might play a dual role in mucosal protection and repair. On the one hand, it might improve mucosal resistance by an increase of vascular permeability that dilutes gastrotoxic agents and reduces the area of the hemorrhagic lesions. On the other hand, it might contribute to the development of the angiogenic response together with other growth factors[5,17]. The recent research findings indicate that the gene therapy with either VEGF or PDGF may be a rapid approach to achieve duodenal ulcer healing[18].

JWYY enhanced the expression of VEGF mRNA by stimulation of angiogenesis in the human gastric mucosa in our study. As a result, it improved the QOUH, accelerated the healing of ulcer and prevented its recurrence.

JWYY granules consist of Chinese thorowax root, pilose asiabell root, white peony root, corydalis tuber, common bletilla tuber, natural indigo, pearl powder and liquorice root. It can soothe the liver and strengthen the spleen, it has anti-spasm and pain relieving effect, stop bleeding, and regenerate muscle, and disperse the visceral heat. Previously, we demonstrated that JWYY accelerated the healing of acetic acid-induced gastric ulcer in rats and had good effect for the PU patients with stagnation of liver Qi and deficiency of spleen Qi syndrome or inharmonic liver and gastric syndrome. At the same time, it could prevent ulcer recurrence[6,7].

In conclusion, our results show that JWYY enhances the expression of VEGF mRNA in gastric ulcer in rats. This may be the mechanism by which JWYY improves the QOUH, and prevents its recurrence in the treatment of PU.

Abstract

AIM: To investigate the functional, morphological changes of the gut barrier during the restitution process after hemorrhagic shock, and the regional differences of the large intestine and small intestine in response to ischemia/reperfusion injury.

METHODS: Forty-seven Sprague-Dawley rats with body weight of 250-300 g were divided into two groups: control group (sham shock $n = 5$) and experimental group ($n = 42$). Experimental group was further divided into six groups ($n = 7$ each) according to different time points after the hemorrhagic shock, including 0th h group, 1st h group, 3rd h group, 6th h group, 12th h group and 24th h group. All the rats were gavaged with 2 mL of suspension of lactulose (L) (100 mg/2 mL) and mannitol (M) (50 mg/each) at the beginning and then an experimental rat model of hemorrhagic shock was set up. The specimens from jejunum, ileum and colon tissues and the blood samples from the portal vein were taken at 0, 1, 3, 6, 12 and 24 h after shock resuscitation, respectively. The morphological changes of the intestinal mucosa, including the histology of intestinal mucosa, the thickness of mucosa, the height of villi, the index of mucosal damage and the numbers of goblet cells, were determined by light microscope and/or electron microscope. The concentrations of the bacterial endotoxin lipopolysaccharides (LPS) from the portal vein blood, which reflected the gut barrier function, were examined by using Limulus test. At the same time point, to evaluate intestinal permeability, all urine was collected and the concentrations of the metabolically inactive markers such as L and M in urine were measured by using GC-9A gas chromatographic instrument.

RESULTS: After the hemorrhagic shock, the mucosal epithelial injury was obvious in small intestine even at the 0th h, and it became more serious at the 1st and the 3rd h. The tissue restitution was also found after 3 h, though the injury was still serious. Most of the injured mucosal restitution was established after 6 h and completed in 24 h. Two distinct models of cell death-apoptosis and necrosis-were involved in the destruction of rat intestinal epithelial cells. The number of goblet cells on intestinal mucosa was reduced significantly from 0 to 24 h (the number from 243±13 to 157±9 for ileum, 310±19 to 248±18 for colon; $r = -0.910$ and -0.437 respectively, all $P<0.001$), which was the same with the large intestine, but the grade of injury was lighter with the values of mucosal damage index in 3 h for jejunum, ileum, and colon being 2.8, 2.6, 1.2, respectively. The mucosal thickness and the height of villi in jejunum and ileum diminished in 1 h (the average height decreased from 309±24 to 204±23 μm and 271±31 to 231±28 μm, $r = -0.758$ and -0.659, all $P<0.001$; the thickness from 547±23 to 418±28 μm and 483±45 to 364±35 μm, $r = -0.898$ and -0.829, all $P<0.001$), but there was no statistical difference in the colon ($F = 0.296$, $P = 0.934$). Compared with control group, the urine L/M ratio and the blood LPS concentration in the experimental groups raised significantly, reaching the peak in 3-6 h (L/M: control *vs* 3 h *vs* 6 h was 0.029±0.09 *vs* 0.063±0.012 *vs* 0.078±0.021, $r = -0.786$, $P<0.001$; LPS: control *vs* 3 h *vs* 6 h was 0.09±0.021 *vs* 0.063±0.012 *vs* 0.25±0.023, $r = -0.623$, $P<0.001$), and it kept increasing in 24 h.

CONCLUSION: The gut barrier of the rats was seriously damaged at the early phase of ischemic reperfusion injury after hemorrhagic shock, which included the injury and atrophy in intestinal mucosa and the increasing of intestinal permeability. Simultaneously, the intestinal mucosa also showed its great repairing potentiality, such as the improvement of the intestinal permeability and the recovery of the morphology at different phases after ischemic reperfusion injury. The restitution of gut barrier function was obviously slower than that of the morphology and there was no direct correlation between them. Compared with the small intestine, the large intestine had stronger potentiality against injury. The reduction of the amount of intestinal goblet cells by injury did not influence the ability of intestinal mucosal restitution at a certain extent and it appeared to be intimately involved in the restitution of the epithelium.

INTRODUCTION

In recent years, it has been made clear that the intestinal tract is one of the earliest organs involved in ischemia-reperfusion injury after hemorrhagic shock. Owing to the increased intestinal permeability with gut barrier injury, the bacteria and lipopolysaccharides (LPS) can enter the systemic circulation through the portal vein and the mesenteric lymph, and result in sepsis and multiple organ dysfunction syndrome (MODS)[1-3]. The intestinal tract, therefore, is regarded as "initiator" of MODS and its potential pathogenicity has been given more attention. Although the recent focus has been on the study of intestinal barrier function, there are a lot of problems to be solved and the exact mechanism about gut barrier function is uncertain[4,5]. The object of this study, based on the model of intestinal ischemia-reperfusion injury in the early phases after hemorrhagic shock, was to observe the intestinal mucosal changes in all process from injury to restitution after hemorrhagic shock and collect more evidences on the function of gut barrier and its influencing factors.

MATERIALS AND METHODS

Experimental animals and grouping

To begin with, 47 adult and healthy Sprague-Dawley rats with body weight of 250-300 g were used (supplied by Experimental Animal Center, Sun Yat-Sen Medical College, Sun Yat-Sen University) and were gavaged with suspension of lactulose (L) (100 mg/each) and mannitol (M) (50 mg/each) dissolved in 2 mL water (Sigma Chemical Company, USA). All rats were randomly divided into two groups: control group (sham shock n = 5) and experimental group (n = 42 each). According to the different time points of the shock resuscitation, the experimental group was further divided into six groups (n = 7 each), namely 0^{th} h group, 1^{st} h, 3^{rd} h, 6^{th} h, 12^{th} h and 24^{th} h group.

Experimental model

Animals were subjected to hemorrhagic shock as previously described[6]. Briefly, the rats were anesthetized with an intraperitoneal injection of 1 200 mg/kg of urethane. A 1.5 cm incision was made, and the common carotid artery and jugular vein were catheterized. The rats were bled to a mean arterial pressure of 40 mm Hg and kept for 60 min and the shock ended, when the initially shed blood volume and partes aequales of saline were reinfused. Following the termination of shock, the animals were killed at 0, 1, 3, 6, 12 and 24 h time points, respectively. Several segments were taken from jejunum, ileum and colon respectively and rinsed with ice-cold normal saline, fixed in 20% buffered formalin and 3% glutaraldehyde. Meanwhile, 1.5 mL of portal vein blood was drawn from each rat, centrifuged and stored at -80 ℃. All urine, except for that of 0^{th} h group, were collected and stored at -80 ℃. The control rats were only anesthetized and catheterized, not bled.

Light and electron microscopic preparations

Tissue samples were prepared for histological examination of lesions. The resected segments of small intestine and colon were opened lengthwise, embedded in paraffin, sectioned (6 μm), and stained with hematoxylin-eosin (H&E) and Alcian blue-safranin O (pH 0.4). The sections were analyzed with a light microscope (Nikon, Tokyo, Japan).

Mucosal specimens of ileum and colon sections were fixed with 3% glutaraldehyde in 0.1 mol/L cacodylate buffer (pH 7.2) for 2 h at 4 ℃. These samples were then washed several times with the same buffer and postfixed with osmium tetroxide for 2 h at 4 ℃. Specimens were washed with 0.1% sodium acetate, stained en bloc with 2% uranyl acetate, dehydrated through ethanol, and embedded in Spurr's low-viscosity resin. Representative areas were sectioned and stained with toluidine blue. The selected fields were trimmed further for ultrathin section and stained with 3% uranyl acetate in 3% ethanol, followed by treatment with Reynolds' lead citrate. Ultrathin sections were examined under a Hitachi H-600 transmission electron microscope.

Histological scoring

The H&E stained sections were coded and evaluated at 40× and 100× by an unbiased observer. Mucosal damage was classified as follows[7]: 0 (normal), 1 (surface epithelium damaged), 2 (<50% mucosa damaged), 3 (>50% mucosa damaged) and 4 (entire mucosa damaged). In each section, multiple readings of mucosal damage were obtained at 500 μm intervals. The mean of these 15-20 readings for each section provided a mucosal damage index for that section.

Quantitative morphometry of intestinal mucosal injury

Mucosal injury was quantitated under light microscope. Specimens were embedded in paraffin, section was cut and stained with H&E. Measurements of villous height in microns (measured from the villous tip to the muscularis mucosa) were made in the control and experimental groups with an objective micrometer. Average value was calculated and documented. All the calculation was done being unaware of the details by an experienced pathologist.

Gut mucosal goblet cell number

Goblet cells were identified by their classical morphology in each small intestine and colon section in all rats. Total goblet cell number was determined along the combined crypt-villi axis of 10 well-oriented crypt-villus units in each small bowel section and 10 well-oriented colonic crypt units, from the crypt base to the luminal surface[8]. To confirm goblet cell numbers identified by morphology, goblet cells in small intestine and colon sections from the same animals were localized using Alcian blue staining. Positive staining with Alcian blue indicates the presence of acid mucins within goblet cells and was quantitated as outlined for morphological assessment.

Permeability determination of small intestine with L/M assay

Urinary L and M concentrations and the L/M ratio were determined using GC-9A high performance gas chromatography with pulsed electrochemical detector. Increased intestinal permeability was defined by a L/M ratio >0.03. Markedly increased intestinal permeability was defined by a L/M ratio >0.10.

Determination of the LPS concentration in portal venous plasma

The LPS concentration in portal venous blood was determined using Limulus test kit II (Medical Science Research Institute, Shanghai); 0.05 mL of Limulus reagent was added to 0.1 mL of plasma pretreated with modified perchloric acid and mixed frequently, then it was water bathed for 25 min at 37 ℃. The solution was added with Limulus tripeptide 0.05 mL again and water bathed for 3 min at 37 ℃, then sodium nitrite, sulfamoyl ammonium and naphthyl ethylidene, each of which was 0.5 mL, were added one by one, and mixed frequently. Using 722-Spectrophotometer (Optical Instrument Station, Shanghai), an *A*-value of absorbance was obtained after shade selection, then the LPS concentration (EU/mL) was obtained from the standard curve.

Statistical analysis

All comparisons were made by analysis of variance with multiple comparison tests. All data were expressed as the mean±SD. Statistical significance was considered to be reached, when *P* value was 0.05 or less. The linear trends were measured by linear correlation coefficients and corresponding tests.

RESULTS

Light microscopic findings

The control specimens showed normal and typical leaf-like villi crypts. In contrast, the specimens from the experimental group after shock resuscitation showed different degrees of structural changes ranging from swelling and degeneration of villous epithelial cells to extensive denudation and collapse of the villi. The severity of the damage was clearly related to the time of resuscitation after ischemic shock. At the beginning after restoration of blood pressure, an increased degree of mucosal injury was observed. The major injury occurred at the 3rd h after shock resuscitation of the small intestine, which was heavily injured. Following tissue restitution, the denuded mucosal surface covered intensively by goblet cells was found at the 3rd h. But the injury was still serious and heavy inflammatory cell infiltration occurred at this time. Mucosal restitution was reestablished in most of the injured area after 6 h, totally completed at 12-24 h. Compared to the small intestine, the injury to the large intestine was less severe (Figure 1).

Electron microscopic findings

Electron microscopic examination of the intestinal mucosa revealed some changes as follows (Figure 2): the apoptosis and necrosis were major injury mode in the intestinal mucosa. There were a lot of enterocytes with the chromatins compacting and segregating against the nuclear envelope between normal appearing cells, and membranes enclosed with cytoplasmic blebs were observed. Some detached cells had characteristic features of apoptosis, but still preserved microvilli and intact mitochondria. The others showed the swelling of mitochondria and endoplasmic reticulum, scarce and lodging microvilli and opening of tight junction among the cells. No apoptotic features were found in control intestinal epithelium except at the tips of the villi.

Thickness of mucosa and height of villi

In the small intestine, experimental groups showed a progressive reduction of the mucosal thickness (jejunum and ileum: r = -0.898 and -0.829 respectively, all P<0.001) and the villous height (jejunum and ileum: r = -0.758 and -0.659 respectively, all P<0.001). The average height of villi significantly decreased from 309±24 μm in the control to 231±28 μm in the 24 h group in jejunum, from

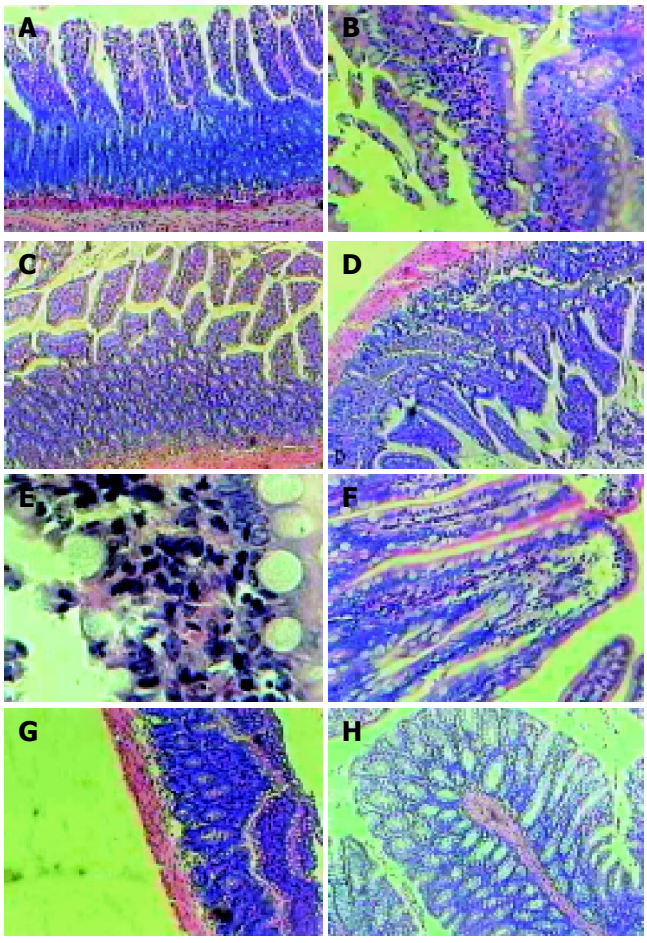

Figure 1 Sections of ileum following ischemia-reperfusion injury after resuscitation of hemorrhagic shock. **A**: Shedding of cell at the tip of the villi is apparent (1 h); **B**: Notes the sloughed epithelial cells detached from the villi and some regions of the villi are destroyed, goblet cells reside throughout the length of the villi (3 h); **C**, **D**: extensive denudation and collapse of the villi and the enterocytes in the upper of the villi had lifted and detached from the villi (3 h); **E**: the tip of the villi was denuded, but some of the goblet cells still remained on the surface (3 h); **F**: Restitution is nearly completed and the area of the villi covered by goblet cells and their number are decreased (6 h); **G**: The restitution of the villi is complete except for the shortening of the villous height and goblet cells cover the villi (12 h). Epithelial cells are lifted off the basement membrane after 1 h. Original magnification: ×40 (**A**), ×100 (**B**, **C**, **D**, **G**, **H**); ×200 (**E**).

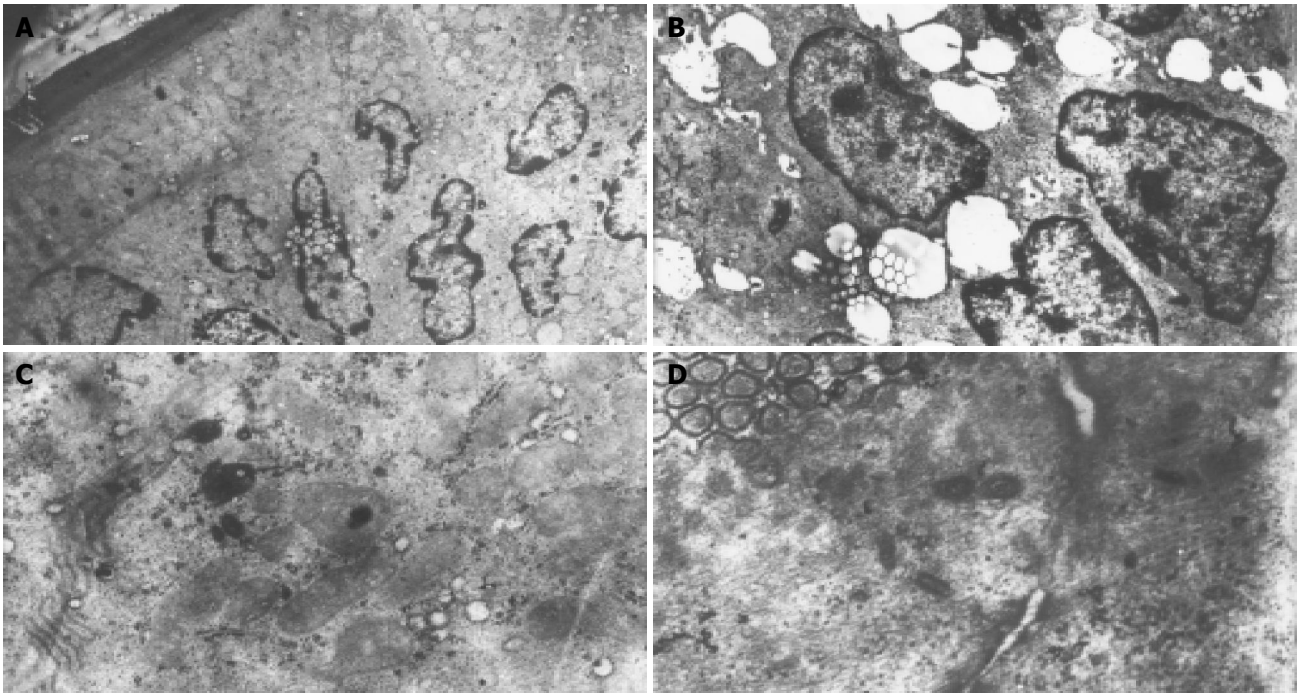

Figure 2 Electron microscopic examination of ileum following ischemia-reperfusion injury after resuscitation of hemorrhagic shock. The apoptosis and necrosis were main manifestation in the intestinal mucosal injury. **A**: Many enterocytes show compaction and segregation of chromatin against the nuclear envelope, but still preserve mcrovilli and intact mitochondria; **B**: Showing the appearance of membrane blebs which cause detachment from the basement membrane; **C**: Some enterocytes show the swelling of mitochondria and endoplasmic reticulum, scarce and lodging microvilli; **D**: the opening of tight junction among the cells. Original magnification: ×2 500 (**A**, **B**), ×4 000 (**C**,**D**).

271±31 μm in the control to 204±23 μm in the 24 h group in ileum. As compared to the control group, the mucosal thickness at 24 h diminished by 25.2%, 23.6%, 23.4% and 24.5% respectively, namely from 547±23 μm to 418±28 μm in jejunum, 483±45 μm to 364±35 μm in ileum. The mucosal thickness of colon was not markedly changed in each time point group ($F = 0.296$, $P = 0.936$, Table 1).

Mucosal damage index in small intestine and colon

Control samples taken from small intestine and colon exhibited a minor grade of damage at each time point group. In the experimental group, the 0th h after shock resuscitation showed moderate damage with the values of the mucosal damage index being 1.4 in jejunum, 1.6 in ileum and 0.6 in colon. The value was significantly elevated in the 1st h group and the 3rd h group with their damage grade being 2.6 in jejunum, 2.8 in ileum and 1.2 in colon, then it dropped gradually at the 6th h (0.8, 1.0, and 0.6, respectively in the above three areas). In the 12th h, all mucosal damage and degradation were nearly closer to that in the control group. For the mucosal thickness change, the damage in colon was significantly less (Figure 3).

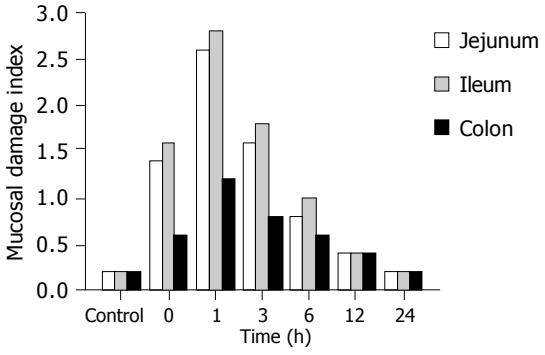

Figure 3 Mucosal damage index in small intestine and colon following resuscitation after hemorrhagic shock. Bars are mucosal damage index, the color represented different sites.

Effect of L/M and the LPS test

Intestinal permeability to macromolecules, as measured by the urinary concentration of L and M, was significantly increased in experimental group rats. The value of L/M was elevated following the time, and reached the peak from 3 to 6 h (0.063±0.012, 0.098±0.011 respectively, $P<0.001$),

then decreased significantly at the 12th h, but was still higher than that in the control group (0.049±0.016, $P<0.001$). The value of L/M was approximate to that of the control group in 24th h group (0.037±0.011, $P>0.05$). The increase and decrease trends of L/M, with 6 h as the turning point, are both of statistical significance (before 6 h: $r = -0.786$, $P<0.001$; after 6 h: $r = -0.767$, $P<0.001$). In general, the change of LPS concentration from portal venous plasma was similar to that of L and M in urine (Table 2 and Figure 4).

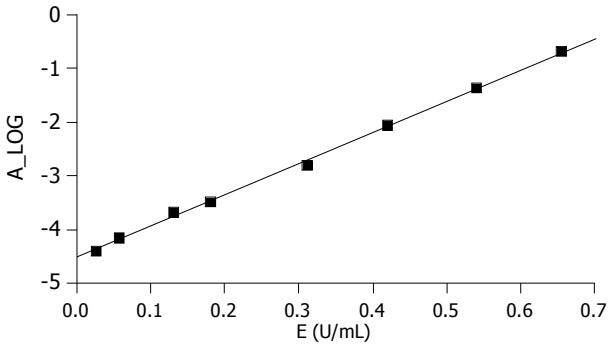

Figure 4 Linear fitness between the standard amount of LPS and absorbance A-value of LPS in portal vein plasma.

Determination of intestinal mucosal goblet cell number

In the experimental group, the number of goblet cells decreased gradually by 35.4% and 20.0% after shock resuscitation, from 243±13 of the control group to 157±9 of the 24th h group in the ileum ($r = -0.910$, $P<0.001$), 310±19 of the control group to 248±18 of 24th h group in the colon ($r = 0$-0.437, $P<0.001$). But the decrease degree in colon mucosa was less than that in the ileum (Table 3).

DISCUSSION

A major function of the gut is to prevent the absorption of toxins, antigens, protease and micro-organisms across the intestinal wall. Epithelial cells cover the surface of the gastrointestinal tract, serving as a barrier between the luminal and tissue compartments[9,10]. Hemorrhagic shock results in a condition of incomplete ischemia of the gut. The ischemia of the small intestine leads rapidly to an impairment of the protective barrier function of the mucosa, and thus the earliest restitution of the mesenteric blood flow is necessary. Although it is evident that circulatory re-establishment is vital in rescuing hypoxic tissues, it is well known that reperfusion would lead to a paradoxical injury. Ikeda *et al*., had reported that the characteristic feature of ischemia/reperfusion injury to the small mucosal epithelium is the detachment of enterocytes from the basement membrane and the apoptosis is regarded as major injury form[11-13]. In this study, two distinct models on cell death-apoptosis and necrosis were involved in the destruction of rat intestinal mucosal epithelium through electron microscopy.

Based on semiquantitative histological examination and the mucosal damage index, we found that the small intestine is more susceptible to ischemia/reperfusion injury than the colon (mucosal damage index: ileum *vs* colon in 3rd h group was 2.8 *vs* 1.2).These data provide probably an explanation for the clinical observation that patients with small intestinal ischemia tend to have worse outcomes than large intestine ischemia. This would also explain why there is a minor injury in the colon. Allopurinol, a competitive inhibitor of xanthine oxidase, is more effective in diminishing the exacerbation of injury in the small intestine after reperfusion because of the level of xanthine oxidase being much higher in the small intestine than that in the colon. However, the exact mechanism why the injury in colon was less severe than in the small intestine is not totally clear. Inherent anatomical structure and biological function of large intestine would be the principal factors against injury.

Repair of intestinal mucosa is called as restitution, where epithelial cells near the wound rapidly flatten, extend with lamellipodia and migrate to form an intact epithelial barrier[14]. The present study suggests that goblet cells were involved in the process of restitution of the small intestine subjected to superficial ischemia/reperfusion injury. Accumulation of goblet cells observed at villous tips by light microscopy in our study seems to be the mode of rapid mucosal repair as restitution. Masuda *et al*.[15], reported, in the recent study, that no incorporation of 5-bromodeoxyuridine (BrdU) was found in the goblet cells covering the villus tips indicating that the accumulation of goblet cells was not due to cell proliferation[16,17].

The decreased number of goblet cells could be an explanation for the reason they participate in the process of the intestinal mucosal restitution. Goblet cells reside throughout the length of intestine and are responsible for the production and maintenance of the mucous blanket by synthesizing and

secreting mucins which can protect the intestinal mucosal epithelium from damage by preventing bacteria and toxin from accessing the underlying mucosa[18-20]. Goblet cells can discharge mucins in response to reactive oxygen species, inflammatory mediators and LPS[21,22]. By means of increasing mucins production and secretion, goblet cells play a function against intestinal injury. A goblet cell has only a time of secretory course from its differentiation to death, so overexpression of mucins will result, when there is a decrease in number. The present study suggests that the mucins were upregulated at sites of gastric and intestinal mucosa injury[23]. On the other hand, intestinal mucosal atrophy would be associated with a reduction in the number of goblet cells.

Maintenance of the intestinal barrier function depends on the integrity of cellular plasma membrane, tight junctions as well as the elaboration of endothelial and epithelial secreting products[24]. Ischemia/reperfusion injury of the gut after hemorrhagic shock lead to epithelial injury and increased intestinal mucosal permeability LPS are the major outer surface membrane components containing in almost all Gram-negative bacteria and act as extremely strong stimulators of tissue damage[25]. LPS flowing across the basement membrane into the lamina propria and portal vein indicated loss of the gut barrier function, while it was difficult to detect LPS from portal vein clinically. The metabolically inactive tracers L and M used in this study can determine whether and when an increase of intestinal permeability occurred in severe stress and how the degree of permeability increase correlated with the severity of initial injury. In the hemorrhagic shock setting, an increase in the L/M ratio corresponding to increased intestinal permeability was observed in rats. The intestinal mucosal injury exactly induced a marked increase of intestinal permeability (L/M>0.10). At the same time, the degree of mucosal damage index and histological alteration in initial injury (in 3rd h group) correlated with the increase in intestinal permeability (including L/M ratio and concentration of LPS). But, there was no significant positive correlation between the morphometric alteration and the degree of increased intestinal permeability. The degree of intestinal mucosal injury did not appear to be consistent with the value of L/M and LPS in urine and plasma. After the restitution had been reestablished, the intestinal permeability was still increased (L/M = 0.039±0.016; LPS 0.15±0.045, $P<0.05$). It means that the developing of leakage of intraluminal markers was behind the morphological alteration. This also suggested that the restitution on the injury mucosa did not achieve its completely normal condition. Complete repair of injury mucosa takes several days because it concerns a process involving mitosis[26,27].

In conclusion, the gut barrier was subjected to ischemia/reperfusion injury after hemorrhagic shock. Damaged intestinal mucosal cells showed two distinct models of cell death-apoptosis and necrosis. The injury of gut barrier resulted in an increase in permeability to intraluminal substances. It is uncertain whether there is a correlation between the morphological alteration and the degree of increased intestinal permeability. The morphological alteration after intestinal mucosal injury cannot reflect the function of gut barrier. On the other hand, goblet cells appear to be intimately involved in restitution of the epithelium. The decreased number of goblet cells perhaps represent the increasing consumption of the goblet cell itself and its secreting products. Compared to the small intestine, the large intestine has stronger potentiality against injury.

Abstract

AIM: To study the protective effect of non-mitogenic human acidic fibroblast growth factor (FGF) on cardiac oxidative injury *in vivo*.

METHODS: Ventricular cardiomyocytes were isolated from 1- to 3-d-old neonatal SD mice and cultured in Dulbecco's minimum essential medium supplemented with 15% fetal bovine serum under an atmosphere of 50 mL/L CO_2-95% air at 37 ℃, as well as assessed by immunocytochemical assay. We constructed the cardiomyocyte injury model by exposure to a certain concentration of H_2O_2. Cellular viability, superoxide dismutase (SOD) activity, leakage of maleic dialdehyde and anti-apoptosis effect were included to evaluate the cardiac protective effect of non-mitogenic human acidic FGF.

RESULTS: Over 50% of the cardiomyocytes beat spontaneously on the 2nd d of culture and synchronously beat after being cultured for 3 d. Forty-eight hours after plating was completed, the purity of such cultures was 95% myocytes, assessed by an immunocytochemical assay. Cellular viability dramatically decreased with the increasing of the concentration of H_2O_2. Non-mitogenic human acidic FGF showed significant resistance to the toxic effect of H_2O_2, significantly increased the cellular viability as well as the activity of SOD, and dramatically decreased the leakage of maleic dialdehyde as well as the cellular apoptosis rate.

CONCLUSION: Hydrogen peroxide shows strong cytotoxicity to the cultured cardiac myocytes, and non-mitogenic human acidic FGF shows strong cardio-protective effect when exposed to a certain concentration of H_2O_2.

INTRODUCTION

Fibroblast growth factor (FGF) is a family of at least 21 structurally and functionally relevant polypeptides characterized by a high affinity of heparin[1]. Acidic FGF found mainly in the brain and retina as well as in the cardiac tissue is also a multifunctional protein, which has many effects including mitogenesis and non-mitogenesis effects.

Studies indicate that intracoronary, intrapericardial, or myocardial administration of FGFs in chronically ischemic canine and porcine hearts can stimulate angiogenesis, a process to minimize infarct size and improve cardiac function[2]. At the same time, though there are some promising results in animal model trials, it produces acute negative inotropic effects on adult cardiac myocytes resulting from alterations in intracellular Ca^{2+} homeostasis[3]. Many people wonder if there would be a potential danger of stimulating the growth of tumor, since NIH-3T3 fibroblasts transfected to express constitutively a secreted form of FGF-1 that becomes tumorigenic[4,5]. FGF-1 behaves as a tumorigenic factor in the NBT-II bladder carcinoma cell model[6].

According to the function and structure of human aFGF, by the method of gene engineering, we removed the part of gene related to mitogenesis, eliminated or reduced the power of mitogenesis, and found it was expressed in

Escherichia coli. We isolated the non-mitogenic human fibroblast growth factor (nm-haFGF) protein, and justified them by mAb of human FGF. Our relevant research results showed that, after modifying the structure of gene and protein, modified haFGF reduced its mitogenetic effect, and preserved its other bio-effects including anti-apoptosis effect, cardio-protective effect, etc.[7]. In this paper, we isolated and cultured the primary cardiomyocytes from 1- to 3-d neonatal SD mice, and observed the pharmacological cardio-protective effect *in vivo*.

MATERIALS AND METHODS

Drugs and reagents

Nm-haFGF was recombined in our experiment laboratory. DMEM, fetal bovine serum (FBS) and trypsin were purchased from Hyclone Co. (UT, USA). Cell death detection kit and immunocytochemical assay kit were purchased from Boster Co. (Wuhan, China). 3-[4,5-Dimethylthiazol-2-yl]-2, 5-diphenyltetrazolium bromide (MTT) was obtained from Sigma (St. Louis, MO, USA). Superoxide dismutase (SOD) and maleic dialdehyde (MDA) were purchased from Jiancheng Bioengineering Institute of Nanjing, China.

Animals

Sprague-Dawley (SD) rats (1-3 d old) were purchased from the Animal Center of Sun Yat-Sen University.

Neonatal mouse primary cardiomyocyte culture

The procedure of culturing ventricular cardiomyocytes from neonatal mice was established by modifications of the previously described methods[7-10]. One- to three-day-old neonatal mice were euthanized by cervical dislocation. Hearts were removed aseptically from the mice, the ventricles were retained, and kept in Hanks' balanced salt solution (HBSS) without Ca^{2+} and Mg^{2+} (in g/L: 0.4 KCl, 0.06 KH_2PO_4, 8.0 NaCl, 0.35 $NaHCO_3$ and 0.06 $Na_2HPO_4 \cdot 7H_2O_2$, pH 7.2) at 4 ℃. The ventricles were washed thrice with HBSS and minced into small fragments and washed twice again during mincing. The cells were dissociated at 37 ℃ for 8 min in enzyme solution (0.8 g/L trypsin in HBSS without Ca^{2+} and Mg^{2+}, pH 7.2), the ventricle tissue was churned by the magnetic stirring (100 r/min) during the digestion. The cells released after the first digestion were discarded, whereas the cells after subsequent digestion were added to an equal volume of cold HBSS with Ca^{2+} and Mg^{2+} (in g/L: 0.14 $CaCl_2$, 0.4 KCl, 0.06 KH_2PO_4, 0.047 $MgCl_2$, 0.049 $MgSO_4$, 8.0 NaCl, 0.35 $NaHCO_3$, 0.05 Na_2HPO_4, and 1.0 D-glucose, pH 7.4) until all cardiac cells were isolated (six times). The resulting mixture was centrifuged for 8 min at 200 r/min, and the cells were resuspended in the FBS-MEM (MEM supplemented with 150 mL/L FBS, 100 U/mL penicillin, and 100 μg/mL streptomycin). To exclude the nonmuscle cells, the isolated cells were first plated in tissue culture dishes at 37 ℃ for 1.5 h in a water-saturated atmosphere of 50 mL/L CO_2-95% air based on the observation that nonmuscle cells attached to the substratum more rapidly. The suspended cells were then collected and plated at a density of 1.0×10^5 cells/cm^2 and incubated under the same conditions as mentioned above.
