For the diagnosis of NAFLD, we used the exclusion of known etiological factors, which are responsible for the liver disease and ultrasound examination. Liver biopsy was not done because the stage and grade of the NAFLD was not of importance in this study and according to Saverymuttu *et al*., ultrasound examinations can accurately identify steatosis with a sensitivity of 94% and a specificity of 84%[22]. Ricci *et al*., also demonstrated that standard ultrasonography may be used for the diagnosis of NAFLD[23].

In NAFLD, most of the liver damage in insulin-resistant and dyslipidemic patients is thought to be caused by accumulation of hepatic triglycerides, and adiponectin might be able to preserve liver function by preventing lipid accumulation in hepatocytes. Adiponectin is also a potent insulin sensitizer and modulates the inflammatory response[2,17,24-26]. In our study, low adiponectin levels in NAFLD patients are compatible with previous studies.

Adiponectin was found to circulate in inverse proportion to IR syndrome such as BMI, fasting glucose and triglycerides[15,25,27,28]. In our study, we also found an inverse correlation between adiponectin levels with BMI, insulin, HOMA, proinsulin and triglycerides.

A recent study showed that adiponectin levels are correlated in healthy humans with various liver function tests such as ALT and GGT[2]. We also found a statistically significant correlation between adiponectin and liver function tests like AST, ALT, and GGT.

This is the first study looking for adiponectin levels in nondiabetic NAFLD patients. Bajaj *et al*., demonstrated a relationship between plasma adiponectin levels with hepatic insulin sensitivity and hepatic fat content in patients with type 2 diabetes, for the first time[14]. Yamamoto *et al*., have reported that adiponectin predicts future IR in a Japanese population in a 2-year follow-up study[4].

In our study, it is remarkable that in males, NAFLD is definitely correlated with low adiponectin levels but the female gender did not show such a correlation. This gender predilection might be due to the correlation of low adiponectin with visceral adiposity in females.

As a summary, adiponectin level is lower in nondiabetic patients with NAFLD in comparison to healthy volunteers. Low adiponectin level might be a predictor of NAFLD especially in male nondiabetics.

Abstract

AIM: To evaluate the agreement between a mAb-based stool test (HP StAR) and the urea breath test (UBT) in monitoring (*H pylori*) infection after eradication therapy.

METHODS: Patients with discordant results on UBT and Hp StAR underwent endoscopy with biopsies for rapid urease test, culture, and histology to confirm *H pylori* status.

RESULTS: Among 250 patients (50±14 years), 240 (96.0%) had concordant UBT and Hp StAR tests with a significant correlation between DOB and *A* values ($R = 0.87$; $P<0.0001$). The remaining 10 (4.0%) patients had discordant tests (positive Hp StAR and negative UBT) with the Hp StAR inaccurate in five cases (false positive) and UBT inaccurate in the other five cases (false negative). The "maximal expected" sensitivity, specificity, +PV, -PV, +LR, and -LR were 91%, 100%, 100%, 97.4%, ∞, and 8.2 respectively, for the UBT, and 100%, 97.4%, 91%, 100%, 38.8, and 0, respectively, for the Hp StAR. Overall accuracy for both tests was 98%.

CONCLUSION: Both the UBT and the Hp StAR are equally accurate in monitoring *H pylori* infection. Nowadays, the choice of the "best" non-invasive *H pylori* test in the post-treatment setting should be done not only in terms of diagnostic accuracy but also in view of cost and local facilities.

INTRODUCTION

Several non-invasive methods of testing for *Helicobacter pylori* (*H pylori*) have been developed and routinely used in clinical practice. They are based on: (1) the detection of ^{13}C- or ^{14}C-labeled CO_2 in expired air as a result of *H pylori* urease activity (^{13}C- or ^{14}C-UBT)[1,2], (2) the detection of antibodies in serum (serology)[3], saliva[4], and urine[5], and (3) the detection of *H pylori* antigens in stool[6]. Until now, the UBT has been considered to be the most reliable non-invasive test for the diagnosis of *H pylori* infection with an overall accuracy approaching 95% in both untreated and treated patients[7]. However, concerns regarding the cost of ^{13}C-urea, the radiological hazards of ^{14}C-urea, and the local availability of either mass spectrometers or β-counters induced clinicians to search for new alternative tests. Serological tests have been extensively used in the past but the diagnostic accuracy is no longer adequate to justify their clinical use. Stool antigen tests have proven to be reliable in the diagnosis of *H pylori* infection. In the previous years, mAb-based stool tests have been developed and introduced in clinical practice[8,9]. Sensitivity values ranged from 88% to 99% in pre-treatment setting and from 89% to 100% in post-treatment setting[10]. Concerning the specificity, values ranged from 92% to 99% in pre-treatment setting and from 95% to 100% in post-treatment setting[10]. The encouraging results obtained with mAb-based stool tests in post-treatment setting raise an important question: should the UBT be still considered on either clinical or economical ground as the most suitable non-invasive test for monitoring *H pylori* infection after treatment? Aim of this prospective, controlled, single-center study was to evaluate the agreement between the UBT and a commercially available mAb-based stool test in patients after *H pylori* eradication treatment in order to determine which of the two tests should be recommended in clinical practice.

MATERIALS AND METHODS

Consecutive outpatients, who were referred to our Center for non-invasively monitoring *H pylori* infection after a first-line or a second-line eradication treatment, were considered for recruitment into this study. Patients were prospectively interviewed on past medical history, smoking habits, and alcohol intake. Exclusion criteria were treatment with antibiotics, H_2-receptor antagonists, bismuth, or PPI in the 4 wk preceding the study, previous gastric surgery, severe renal or liver diseases, and malabsorption syndromes. All patients gave their informed consent to participate and the study was approved by the Ethical Committee of our institution.

Study design

At 4-6 wk after completion of eradication therapy, patients underwent both ^{13}C-UBT and antigen stool test. The UBT was performed with 75 mg ^{13}C-urea. Breath samples were taken before and 30 min after ingestion of the urea. The ^{13}C-enrichment in breath was determined by IRMS. The UBT was considered positive if the d-value over baseline (DOB) at 30 min was >5‰. On the same day of UBT, patients collected stool from the toilet paper or bowl into an airtight container. Stool specimens were analyzed for *H pylori* antigen using a sandwich-type enzyme immunoassay (Hp StAR, DakoCytomation, Milan, Italy), as described by the manufacturer. The results were analyzed by spectrophotometry. The absorbance was read at 450 nm and expressed as optical density (*A*). Specimens with absorbance values >0.19 were considered positive. Patients with concordant tests did not undergo further investigation. Patients with discordant tests were endoscoped with multiple biopsies (three from antrum and three from corpus) for rapid urease test (Cp-test, Yamanouchi, Milan, Italy), culture (Biomerieux Pylori, BioMerieux, Marseille, France), and histology (H&E and Giemsa).

Patient sample size

In the post-treatment setting, a sensitivity and specificity of 94% and 95% for the UBT and 95% and 98% for mAb-based stool tests have been reported[7]. Consequently, 4% and 1.2% of patients are expected to show a false positive or negative result on UBT, respectively, as compared to 1.6% and 1.0% of patients on stool test. In our study, the percentage of patients with discordant UBT and stool test was expected to range from 2.6% (5.2-2.6%) to 7.8% (5.2+2.6%) with a mean value of 5.2%. We assumed that at least 10 patients with discordant results would have been sufficient to evaluate the agreement between the UBT and the Hp StAR results. By taking into account a drop out rate of 20% (patients unwilling to undergo endoscopy), we decided that at least 13 patients with discordant results would have been evaluated. Therefore, the minimal sample size of patient population was 250 (13/5.2%).

Statistical analysis

Patients were considered as still infected if at least one of the biopsy-based tests was positive. Conversely, they were regarded as successfully eradicated if all the three tests were negative. Patients were sorted into two groups according to UBT and Hp StAR results: one group with concordant and the other with discordant results. Univariate analysis (*t*-test or χ^2-test) was carried out between the two groups for age, sex, smoking, alcohol consumption, and type of treatment. A *P*-value less than 0.05 was considered statistically significant. Linear regression analysis was carried out in the group of patients with concordant results to search for a significant correlation between UBT and Hp StAR results. Logistic analysis was performed to identify the factors determining discordance of test results. Finally, the "maximal expected" values of sensitivity, specificity, positive and negative predictive values, positive and negative likelihood ratios, and diagnostic accuracy were calculated for UBT and Hp StAR.

Funding

Stool kits were kindly provided by the manufacturer (DakoCytomation, Milan, Italy) who had no role in the collection, analysis and interpretation of the data. There was no other funding source.

RESULTS

Study population

Overall, 266 patients were asked to participate in this study but 16 (6%) refused to collect stool and were not included; 250 patients (50±14 years; range: 17-92 years; 113 males) were enrolled and none of them were excluded from the final analysis because of insufficient stool or breath collection. There were 75 (30%) smokers and 48 (19.3%) subjects reported alcohol consumption of more than 40 g daily. First-line eradication treatments were the "Maastricht therapy" (i.e., PPI with clarithromycin and either amoxicillin or metronidazole for 7 d) in 149 (59.6%) patients[11], and the 10-d sequential therapy proposed by Zullo *et al*., (i.e., PPI and amoxicillin for the first 5 d followed by PPI, clarithromycin, and tinidazole for the remaining 5 d) in 45 (18%) patients[12]. The quadruple therapy (i.e., PPI, bismuth citrate, tetracycline, and metronidazole for 7 d) was the second-line treatment used by the remaining 56 (22.4%) patients who were still *H pylori* positive after one course of the standard "Maastricht therapy".

UBT and stool test results

UBT and Hp StAR were concordant in 240 (96%) patients (189 negative and 51 positive) and discordant in the remaining 10 (4%, Table 1). All 10 patients tested positive on Hp StAR and negative on UBT. All patients with discordant results agreed to undergo endoscopic examination. After endoscopy was done, 5 out of 10 (50%) patients were classified as *H pylori* positive, and 5 (50%) *H pylori* negative. Compared with the gold standard biopsy-based tests, the Hp StAR was inaccurate in five cases (five false positive) and the UBT in the other five cases (five false negative). No coccoid forms were detected in the five patients with negative UBT and positive Hp StAR.

The absolute values of sensitivity and specificity for UBT and Hp StAR were not calculated since all patients, including those with concordant UBT and Hp StAR tests, would have undergone endoscopy with multiple biopsies.

Table 1 UBT and Hp StAR results in study population. Biopsy-based tests were performed only in patients with discordant UBT and Hp StAR results

Pts	DOB (POS>5)	*A* (POS>0.19)	Histology	Culture	RUT	Hp status

Pt47	4.24	0.23	POS	NEG	POS	POS
51 pts	6.81–86.15	0.23–2.93	np	np	np	POS

However, we extrapolated the "maximal expected" sensitivity, specificity, positive and negative predictive values, and positive and negative likelihood ratios (Table 2). The diagnostic accuracy for both tests was 98% (95%CI and 95.8-98.0%).

Both univariate and logistic analyses showed that patients with discordant results were not significantly different from those with concordant results as far as age, sex, smoking, alcohol consumption, and type of treatment were considered.

In patients with concordant results, a significant correlation (DOB = -0.42+14.9×A; R = 0.87, P<0.0001) was found between DOB and A values (Figure 1).

Table 2 Diagnostic accuracy of UBT and Hp StAR

	UBT	Hp StAR
Sensitivity		
Sens = TP/(TP+FN)	91.8 (87.4–91.8)	100 (95.2–100)

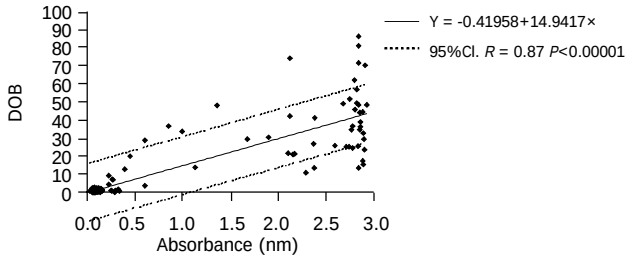

Figure 1 Correlation between UBT and Hp StAR results.

DISCUSSION

The UBT and the Hp StAR test are currently considered to be the only reliable non-invasive tests for monitoring *H pylori* infection[13]. The diagnostic accuracy is reportedly high, although some doubt still exists in the post-treatment setting since non-uniform results on the diagnostic accuracy of the stool test have been reported[14,15]. In a previous work, we found that the UBT and the antigen stool test were discordant or indeterminate in nearly 8% of patients after treatment[16]. This finding was mainly due to a lower diagnostic accuracy of stool test *vs* the UBT with the ratio between false UBT and stool test results of 1:6. The polyclonal antibody of the stool test (Premier Platinum HpSA test, Meridian Diagnostics, Cincinnati, OH, USA) used in that study could have been responsible for this disappointing result.

The present study was designed to evaluate the discordance rate between UBT and stool test results in the post-treatment setting by using a mAb-based stool test. Our results show that the UBT and Hp StAR results are discordant in 4% of patients. Nevertheless, the overall diagnostic accuracy of UBT and Hp StAR is identical (i.e., 98%) with the ratio between false UBT and stool test results of 1:1. Interestingly, we found that the Hp StAR is more sensitive than the UBT in monitoring *H pylori* infection with a higher negative predictive value. This finding is extremely important to assess the true eradication of the bacterium after antibiotic treatment and to definitely reassure patients on treatment effectiveness. Since mAb-based techniques generally have a high specificity, it is unclear why false positive results on Hp StAR test occurred in the post-treatment setting. The principle on which non-invasive *H pylori* diagnostic tests rely are different: the UBT measures a metabolic function of the bacterium (i.e., its urease activity) in the stomach; the Hp StAR detects antigens shed from the microorganism in stool; biopsy-based tests detect the bacterium in gastric mucosal specimens. It would be tempting to speculate that - after eradication treatment - *H pylori* survive in very low concentration in extra-gastric "sanctuary sites" such as dental plaque[17], Merkel's diverticulum[18] or rectum[19] persist in stool even when the other tests become negative. Another reason for the false positivity of the stool test might be due to the fact that it may take a few days for *H pylori* antigens to move from the stomach to the rectum and stay in the rectum for a few more days. Consequently while the UBT becomes negative, their stool could be still positive.

mAb stool tests are available as either laboratory-based or in-office-based[20] diagnostic tests. Both tests have

shown - at least in the post-treatment setting - a diagnostic accuracy comparable with the UBT. Moreover, in-office stool tests have also the advantage of being suitable for the use at the doctor's office affording physicians to prescribe eradication therapy even during the same visit[20]. Consequently, we believe that the UBT should not be regarded as the most suitable non-invasive test for monitoring *H pylori* infection when compared with stool test. The choice of the best non-invasive *H pylori* test after treatment should be done not only in terms of diagnostic accuracy but also after careful evaluation of costs and local facilities. In this regard, monoclonal-based stool tests seem to be more cost-effective than the UBT. In fact, spectrophotometers are generally more available locally and cheaper than IRMS which also require appropriate technical setting to guarantee optimal ^{13}C-measurements and accurate UBT results[21]. Moreover, for some patient subgroups, such as infants[22], elderly[23] or handicapped people, and in some specific clinical conditions, such as gastrointestinal bleeding[24] or severe obstructive respiratory diseases, the stool test seems to be more suitable than the UBT.

Another interesting finding of our work is the high significant correlation between UBT and stool test results. Since several investigators have shown a correlation between UBT results and intragastric bacterial load, it could be hypothesized that mAb-based stool test results give also a semiquantitative measure of bacterial load in the stomach[25]. Further studies comparing stool tests results with histological data are warranted to confirm this finding.

In conclusion, both breath and mAb-based stool antigen tests are reliable non-invasive tests for monitoring *H pylori* infection. In comparison with the UBT, the Hp StAR seems to be more sensitive and cost-effective in the post-treatment setting and more appropriate in non-cooperating patients and in some clinical conditions such as gastrointestinal bleeding or difficult breath collection.

Abstract

AIM: The HBeAg negative form of chronic hepatitis B (CHB) predominates in the Mediterranean area and has a rising frequency in Europe and North America. At present there are three approved therapies for patients with CHB: interferon-α (IFN-α), lamivudine and adefovir dipivoxil. Unfortunately, none of these drugs are effective in achieving a sustained response in patients with HBeAg negative CHB. Therefore, new therapeutic approaches have been examined. Our aim was to investigate the efficacy of combination treatment of IFN-α and lamivudine compared to lamivudine monotherapy, after 24 mo of administration in HBeAg-negative hepatitis B patients.

METHODS: Fifty consecutive patients were randomly assigned to receive IFN-α-2b (5 MU thrice per week, $n = 24$) plus lamivudine (100 mg daily) or lamivudine only ($n = 26$) for 24 mo. Patients were followed up for further 6 mo. The primary outcome was the proportion with sustained virological response (undetectable serum HBV DNA concentrations) and or sustained biochemical response (transaminase levels within normal range) at 30 mo (6 mo after the end of therapy). Secondary end-points were timed from initial virological (biochemical) response to VBR (BBR, respectively) and the emergence of YMDD mutants across the two arms.

RESULTS: Five of twenty-four (21%) patients in the combination arm *vs* 3/26 (12%) in the lamivudine arm had sustained response (i.e., normal serum transaminase levels and undetectable HBV DNA by PCR assay) 6 mo after treatment discontinuation. A reduction in the emergence of YMDD mutants and in the development of virological breakthroughs was observed in patients receiving combination treatment (10% *vs* 46%, $P = 0.01$ and 14% *vs* 46%, $P = 0.03$, respectively). Time from initial virologic response to virologic breakthrough (VBR) was greater among initial responders receiving combination treatment compared to those receiving lamivudine (22.9 mo *vs* 15.9 mo, respectively; $P = 0.005$).

CONCLUSION: Our results demonstrate that IFN-α plus lamivudine combination therapy did not increase the sustained response, compared to lamivudine. However, combination therapy reduces the likelihood of VBR due to YMDD mutants and prolongs the time period until the breakthrough development.

INTRODUCTION

The HBeAg negative form of chronic hepatitis B (CHB) predominates in the Mediterranean area and has a rising frequency in Europe and North America. The HBeAg negative CHB is characterized by frequent exacerbation of hepatitis, which probably increases the risk of cirrhosis, hepatocellular failure, and hepatocellular carcinoma[1].

At present there are three approved therapies for patients with CHB: interferon-α (IFN-α), lamivudine, and adefovir dipivoxil. Unfortunately, none of these drugs are effective in achieving a sustained response in patients with HBeAg negative CHB[2-6]. Therefore, new therapeutic approaches have been examined. Combination of antiviral drugs with different mechanisms of action or prolongation of treatment periods[7-10] have been reported with controversial results[11,12]. The aim of this study was to investigate the efficacy of combination treatment of IFN-α and lamivudine compared

to lamivudine monotherapy, after 24 mo of administration in HBeAg-negative hepatitis B patients.

MATERIALS AND METHODS

Study design and patient selection

This was a multi-center open-labeled randomized controlled clinical trial, comparing IFN-α-2b 5 MU (Shering-Plough, Athens, Greece) t.i.w. plus oral lamivudine (GSK, Athens, Greece) 100 mg/d *vs* oral lamivudine 100 mg/d, for 24 mo. Randomization was performed centrally, using lottery cards.

Between January 2000 and May 2001, 50 consecutive adult patients with HBeAg-negative CHB fulfilling all the inclusion criteria were enrolled in the study. Adult patients were eligible if they met all the inclusion criteria: (1) HBsAg positive, anti-HBe positive and HBeAg negative serology for at least 6 mo before enrollment, (2) serum HBV DNA concentrations $>10^5$ copies/mL, (3) elevated alanine transaminase (ALT) activity (at least 1.5 times the upper normal limit) in three separate monthly occasions within the last 6 mo before randomization and (4) liver biopsy with evidence of chronic hepatitis within 12 mo before entering the study. The last patients enrolled ended their follow-up in December 2003.

Patients were excluded if they had antibodies against HIV or hepatitis C or D viruses, had decompensated liver disease (Child-Pugh score >8) or had previously received liver transplantation. We also excluded patients who had been treated with any antiviral drug other than IFN and those who had received immunosuppressive therapy within 6 mo before participation. Patients with active alcohol consumption (>50 g/d) or suspected hepatocellular carcinoma (by real-time ultrasonography and elevated α-fetoprotein) were also excluded. The study protocol conformed to the ethical guidelines of the Declaration of Helsinki and all patients gave informed consent.

Follow up and definitions

Clinical examination and routine laboratory tests were performed every 2 wk during the first 3 mo of treatment and every month thereafter. Compliance was monitored at each visit by assessing the number of used drugs. Laboratory tests included complete blood count, ALT, aspartate transaminase (AST), amylase, alkaline phosphatase, γ-glutamyl transpeptidase, creatinine, and prothrombin time. Serum HBV DNA and α-fetoprotein were evaluated every 6 mo, until the end of the follow-up period (30 mo). Potential side effects were recorded at each visit. All treated patients were followed up for additional 6 mo after they stopped their treatment.

We regarded as initial virologic response the clearance of serum HBV DNA by PCR, and as initial biochemical response the decline of transaminase levels to normal in two consecutive determinations. We considered as virologic breakthrough (VBR) the reappearance of detectable serum HBV DNA by PCR after an initial virologic response, and as biochemical breakthrough (BBR) the increase of ALT or AST levels to greater than 1.5 times the upper normal limit after an initial biochemical response[13]. The primary outcome was the proportion with sustained virological response (undetectable serum HBV DNA concentrations) and/or sustained biochemical response (transaminase levels within normal range) at 30 mo (6 mo after the end of therapy). Secondary end-points were timed from initial virological (biochemical) response to VBR (BBR, respectively) and the emergence of YMDD mutants across the two arms.

Laboratory assays

Serum ALT, AST, albumin, bilirubin, prothrombin time, and α-fetoprotein levels were measured by standard laboratory procedures. HBsAg, HBeAg, anti-HBe, anti-HBc, anti-HCV, anti-HDV, and anti-HIV titers were measured using commercially available microparticle enzyme immunoassays. Serum HBV DNA viral load levels were determined using AMPLICOR HBV MONITOR (Roche Diagnostics Systems, NJ, USA). The test incorporates a known amount of synthetic internal standard (IS), which is co-amplified. After amplification, a colorimetric reaction determines the amplified products. The HBV/IS ratio for each test specimen is compared against a standard curve and the HBV DNA viral load of the tested samples is calculated from the standard curve in copies per milliliter. The detection limit of this assay according to the manufacturer is 400 copies/mL[14].

YMDD mutants were evaluated at baseline and on any occasion of VBR. The YMDD motif of tested serum samples was determined by a line probe assay (INNO-LIPA HBV DR, Innogenetics NV, Belgium). DNA extraction, subsequent HBV polymerase region amplification, detection, and readout were performed according to the manufacturer's instructions[15].

Statistical analysis

The analyses were performed according to the intention-to-treat (ITT) principle, considering dropouts as failures for the primary endpoint. We used the last observation carried forward (LOCF) approach, where the last available measurement is imputed for missing values. We also performed secondary analyses excluding dropouts ("per protocol" analyses). We compared baseline characteristics between the two arms using Mann-Whitney or χ^2 tests, as appropriate. Dropouts across the two arms were compared with Fisher's exact test. HBV DNA values below detection (<400 copies/mL) were imputed to 399 copies/mL for the analyses. HBV DNA concentrations were log-transformed for normality. Univariate and multivariate logistic regressions were used to address possible relationships between baseline characteristics and the primary outcome. Time from initial virologic (or biochemical) response to VBR (or BBR, respectively) as well as time to YMDD emergence were explored with Kaplan-Meier analyses and multivariate Cox proportional hazards models. In all multivariate analyses (logistic regressions and Cox models), we considered as covariates the treatment allocation arm, age, gender, baseline transaminase level, baseline logarithm of HBV DNA, prior IFN therapy, histology activity index (appropriately coded with dummy variables), and presence of cirrhosis at baseline. Selection of covariates for the final models was performed with backward elimination based on likelihood ratio criteria. Serial measurements of ALT, AST, and log HBV DNA concentrations were compared employing repeated measures analysis of variance, using the Huynh-Feldt adjustment whenever sphericity assumptions

were violated. *P* values <0.05 were considered as statistically significant. All *P*-values were two-tailed. Analyses were performed in SPSS 10.0 (SPSS Inc., Chicago, IL, USA) and STATA 8.2 (STATA Corp., College Station, TX, USA).

RESULTS

Study population and baseline characteristics

During study period, 50 consecutive adult patients with HBeAg-negative CHB fulfilling all the inclusion criteria were randomly assigned to lamivudine plus IFN (n = 24) and to lamivudine monotherapy (n = 26, Figure 1). The baseline characteristics of the two arms were similar with respect to demographic and clinical features (Table 1). Twenty-eight patients had previously been treated with IFN-α: 6 had not responded and 22 had relapsed after discontinuing treatment. Three patients in the lamivudine plus IFN-α arm *vs* none in the lamivudine arm dropped out by the 10th wk (exact $P = 0.10$). None of the patients were dropped due to protocol violations.

Table 1 Baseline characteristics

	IFN-α+lamivudine (n = 24)	Lamivudine (n = 26)	*P*
Age (median, IQR)	53 (47, 60)	58 (41, 66)	0.36
Male (%)	15/24 (63)	18/26 (69)	0.62
ALT, median (IQR)	79 (57, 100)	59 (52, 94)	0.24
AST, median (IQR)	59 (51, 89)	60 (40, 94)	0.43
$\log_{10}$(HBV), median (IQR)	6.1 (5.2, 7.2)	5.9 (5.2, 6.6)	0.72
Previous IFN-α therapy (%)	13/24 (54)	15/26 (58)	0.80
Cirrhosis[1] (%)	11/24 (45.8)	13/26 (50)	0.7

IFN: interferon; IQR: interquartile range. *P*-values were derived from Mann-Whitney and χ^2 tests as appropriate. [1]Ishak classification, fibrosis 5 or 6.

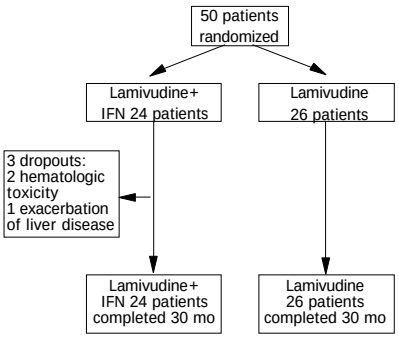

Figure 1 Outline of the trial.

Virologic response -virological breakthrough

In ITT analyses, 5/24 (21%) patients in the IFN-α plus lamivudine arm *vs* 3/26 (12%) patients in the lamivudine monotherapy arm had sustained response to therapy at 30 mo. Hence, the combination therapy was not more likely to lead to sustained response at the end of the follow-up period (rate ratio, RR = 1.81 [95%CI: 0.48-6.76]). The results were essentially the same for per protocol analyses (RR = 2.06 [95%CI: 0.56-7.65]). None of the patients cleared HBsAg at 30-mo study period. Univariate and multivariate logistic regression analyses did not identify a statistically significant relationship between any of the baseline characteristics and sustained response at 30 mo.

The mean log HBV DNA was not different across the two arms over time (P = 0.26; Figure 2A). The proportion of patients with serum HBV DNA below detection by ITT-LOCF for every assessment is shown in Figure 2B. In per protocol analyses, the proportion of patients who lowered their viral concentrations below detection was 21/21 = 100% *vs* 19/26 = 73% at 6 mo; 21/21 = 100% *vs* 20/26 = 77% at 12 mo; 20/21 = 95% *vs* 17/26 = 65% at 18 mo; and 18/21 = 86% *vs* 13/26 = 50% at 24 mo of treatment, between combination and monotherapy, respectively. In the combination arm, all patients except for the three dropouts had an initial virologic response during the first 6 mo of therapy. In the lamivudine arm, an initial virologic response was observed in 24/26 (92%) within the first 12 mo (19 patients by 6 mo, and 5 patients by 12 mo). The remaining two patients in the lamivudine group did not clear HBV DNA; however, their viral load concentrations dropped by at least 2 log during the first 12 mo of treatment.

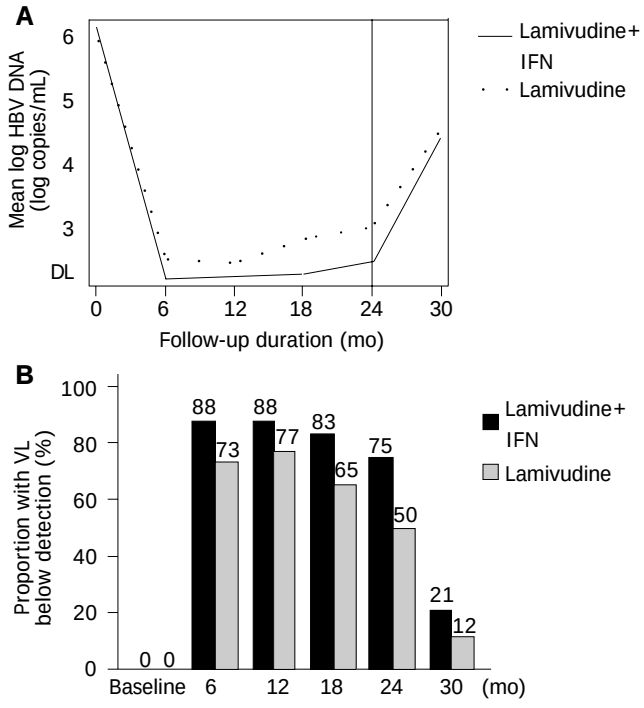

Figure 2 Virological course. A: Treatment was administered up to 24 mo (vertical line). The trajectories of the mean log HBV DNA viral load are similar between the two groups. The following 6 mo were the follow-up period. B: Proportion of patients with viral load below detection (by ITT). DL: Detection limit; IFN: interferon-α; mo: months; VL: HBV DNA viral load concentrations.

During 24 mo therapy, VBR were observed in 3 (14%) of the 21 patients with an initial virological response in the combination arm and in 11 (46%) of the 24 patients in the lamivudine arm respectively (P = 0.03). Time from initial virologic response to VBR was significantly greater among the 21 initial responders in the IFN-α plus lamivudine arm compared to the 24 initial responders in the lamivudine arm (Figure 3; log-rank P = 0.005). The mean time to

VBR was 22.9 mo (95%CI: 21.5-24.2) *vs* 15.9 mo (95%CI: 12.7-19.2), respectively. At the onset of VBR, median serum HBV DNA concentrations were similar between the two groups ($P = 0.10$). Furthermore at the onset of VBR, serum HBV DNA concentrations exceeded 100 000 copies/mL in only two patients, but became greater than 100 000 copies/mL in five more patients with at least 6 mo treatment after VBR.

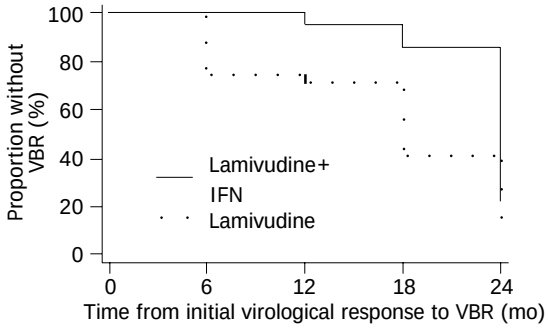

Figure 3 Combination treatment delayed the VBR compared to lamivudine monotherapy among patients who had lowered their HBV DNA concentrations below detection. IFN: interferon-α.

Biochemical response -biochemical breakthrough

Median ALT and AST values were statistically significantly lower in the IFN-α plus lamivudine arm compared to lamivudine monotherapy during the treatment period ($P = 0.04$; Figure 4). The proportion of patients with transaminase levels within normal range (per protocol analyses) was 14/21 = 67% *vs* 12/26 = 46% at 6 mo, 18/21 = 86% *vs* 21/26 = 81% at 12 mo, 19/21 = 90% *vs* 19/26 = 73% at 18 mo, 19/21 = 90% *vs* 16/26 = 62% at 24 mo and 6/21 = 28% *vs* 5/26 = 19% at 30 mo of follow-up for the two arms, respectively. All patients who cleared the serum HBV DNA at 30 mo had normal transaminase levels (complete response).

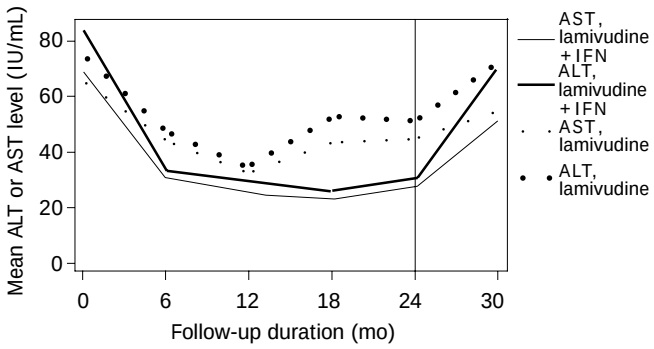

Figure 4 Biochemical course. Mean transaminase levels per assessment time. Layout as per Figure 2. IFN: interferon-α.

BBR was developed in seven patients with an initial biochemical response, two in the combination arm and five in the lamivudine arm respectively. None of the patients with BBR in both groups developed clinical signs of decompensation. At the onset of BBR, transaminase level exceeded 400 IU/L (>10 times the upper normal limit) in two patients receiving lamivudine monotherapy. Elevation of bilirubin to abnormal levels was observed in one of these patients. During BBR period, transaminase levels remained abnormal in all patients. Lamivudine therapy was continued in all patients with BBR in both groups. None of the patients with BBR received other anti-viral treatment. Combination therapy tended to delay BBR for a longer time period after the initial biochemical response, compared to those on lamivudine only. However, this was not formally statistically significant (Figure 5; log-rank $P = 0.18$). Similarly, time from initial biochemical response to BBR was not significantly dependent on any of the covariates in the multivariate Cox models.

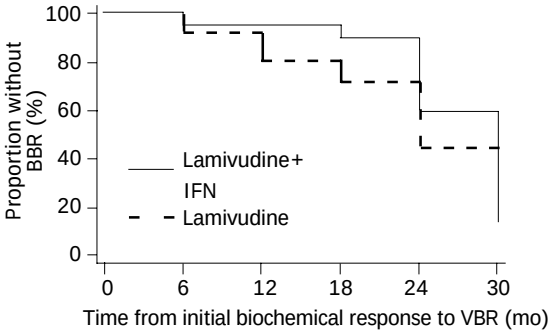

Figure 5 Combination therapy tended to delay BBR. IFN: interferon-α.

Genotypic analyses

None of the patients had YMDD mutants at baseline. YMDD mutations were detected in two of the three patients with VBR in the combination arm (one had the M552I mutant and the other the L528M+M552I mutant strains). In the lamivudine arm, YMDD mutants were detected in all 11 patients with VBR (three patients with VBR had the L528M+M552V mutant; three the L528M+M552I; two the M552I; and three the M552V mutant strains) and in one of the two patients who had detectable serum HBV DNA at all measurements (L528M+M552I mutant strains). Overall, the frequency of emergence of treatment of YMDD mutations in this study was 2/21 (10%) in the IFN-α plus lamivudine arm and 12/26 (46%) in the lamivudine arm (exact $P = 0.01$). The mean time to YMDD emergence was significantly longer in the combination arm compared to the monotherapy arm (23.7 mo [95%CI: 22.9-24.5] *vs* 21.5 mo [95%CI: 19.7-23.3], respectively, Figure 6; log-rank $P = 0.013$).

Adverse events

Three patients in the IFN-α plus lamivudine arm discontinued IFN-α because of hematologic toxicity in two cases and severe exacerbation of liver disease in one case. All 21 remaining patients in this arm reported minor side-effects. All patients tolerated lamivudine monotherapy very well throughout the study period.

DISCUSSION

Our results confirmed our initial hypothesis. The data presented

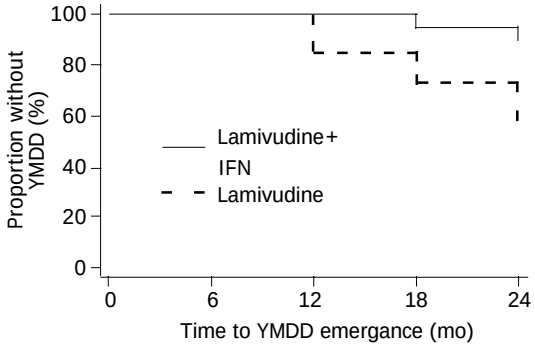

Figure 6 Time to YMDD emergence. IFN: interferon-α.

clearly suggest that 2 years treatment with the combination of IFN-α plus lamivudine induces higher rates of biochemical and virological response, reduces the possibility of YMDD mutations and delays the development of VBR in patients with HBeAg negative form of CHB.

This is the first study to suggest that the combination of IFN-α plus lamivudine may reduce and delay the VBR phenomenon during the treatment period. The only available evidence that this might happen comes from studies showing that the combination treatment is associated with a reduction in YMDD emergence[8-10] independently of HBeAg status. In accordance with these studies, we have also found a similar reduction in escape YMDD mutants. However, none of these studies have shown that this might be followed with a difference in VBR. The explanation might be attributed to the longer duration of treatment in our group of patients. As shown, the difference between the two groups of our patients became evident after 12 mo of continuous treatment. In favor of the above hypothesis is also the fact that in none of the studies conducted so far patients have been treated with the combination of IFN-α with lamivudine for a period longer than 12 mo.

It has been shown that the VBR phenomenon is usually associated with treatment failure[16,17]. It has therefore been anticipated that the reduction in the VBR may be associated with an increase in the number of patients with sustained response to treatment. However, we did not observe a difference in sustained response between the two groups of patients studied. According to our results, any kind of prolongation of remission does not appear to secure sustained remission of the disease. The reason of this phenomenon is difficult to understand. Perhaps in HBeAg negative form of CHB, the longer duration of infection is associated with a higher number of infected hepatocytes which may need longer duration of treatment in order to eradicate the virus[18]. Another possible explanation might be that interferon is not enough to restore the immune responsiveness.

We have identified a tendency in favor of the combination arm regarding sustained response rates at 6 months of follow-up, which did not reach formal statistical significance. If one synthesized findings from the other two relevant controlled trials[19,20] with the results from our trial in a formal meta-analysis, the summary sustained response rate ratio would be 30% greater for the combination arm (rate ratio = 1.28 [95%CI: 0.75-2.19], both by fixed and random effects meta-analysis[21] with no statistical dissimilarity -heterogeneity-across synthesized trials). The summary effect size cannot exclude a twofold difference in the sustained response rate between the two arms. This merely reflects the fact that all relevant trials are underpowered to detect the a posteriori observed differences across the two arms: a trial would have to randomize 440 people in order to be able to detect with 80% power, a difference of 20% *vs* 10% at the 0.05 significance level. For example, an adequately powered trial by Marcellin *et al*.[22], which examined the efficacy of the Pegylated-IFN-α2α in 537 patients with HBeAg negative CHB, was able to identify that the Pegylated IFN-α-2α/lamivudine combination was significantly superior to lamivudine and not different than Pegylated-IFN-α-2α monotherapy.

In our study, we used a sensitive PCR assay for HBV DNA determinations in contrast to less sensitive hybridization assays which were used by previous investigators. At the onset of VBR, only two patients had serum HBV DNA concentrations above 100 000 copies/mL. However, serum HBV DNA increased to levels greater than 100 000 copies/mL in five more patients during the treatment period. Our data are in accordance with those reported by Papatheodoridis *et al*.[16], who observed that only 2/32 patients had HBV DNA concentrations greater than 100 000 copies/mL at the onset of the breakthrough. Therefore, a close serum HBV DNA monitoring by a sensitive PCR assay is necessary in order to recognize the VBR early.

In conclusion, our study clearly shows that the combination of IFN-α plus lamivudine reduces the YMDD mutants and delays VBR, but does not affect significantly the sustained response in HBeAg negative CHB as compared to lamivudine monotherapy. Further well-designed studies are also urgently required in order to explore the mechanism involved in achieving a sustained response in this difficult-to-treat group of patients.

Abstract

AIM: To assess the validity of our selection criteria for hepatectomy procedures based on indocyanine green disappearance rate (K_{ICG}), and to unveil the factors affecting posthepatectomy mortality in patients with hepatocellular carcinoma (HCC).

METHODS: A retrospective analysis of 198 consecutive patients with HCC who underwent partial hepatectomies in the past 14 years was conducted. The selection criteria for hepatectomy procedures during the study period were $K_{ICG} \geqslant 0.12$ for hemihepatectomy, $K_{ICG} \geqslant 0.10$ for bisegmentectomy, $K_{ICG} \geqslant 0.08$ for monosegmentectomy, and $K_{ICG} \geqslant 0.06$ for nonanatomic hepatectomy. The hepatectomies were categorized into three types: major hepatectomy (hemihepatectomy or a more extensive procedure), bisegmentectomy, and limited hepatectomy. Univariate (Fisher's exact test) and multivariate (the logistic regression model) analyses were used.

RESULTS: Postoperative mortality was 5% after major hepatectomy, 3% after bisegmentectomy, and 3% after limited hepatectomy. The three percentages were comparable ($P = 0.876$). The platelet count of $\leqslant 10\times10^4/\mu L$ was the strongest independent factor for postoperative mortality on univariate ($P = 0.001$) and multivariate (risk ratio, 12.5; $P = 0.029$) analyses. No patient with a platelet count of $>7.3\times10^4/\mu L$ died of postoperative morbidity, whereas 25% (6/24 patients) of patients with a platelet count of $\leqslant 7.3\times10^4/\mu L$ died ($P<0.001$).

CONCLUSION: The selection criteria for hepatectomy procedures based on K_{ICG} are generally considered valid, because of the acceptable morbidity and mortality with these criteria. The preoperative platelet count independently affects morbidity and mortality after hepatectomy, suggesting that a combination of K_{ICG} and platelet count would further reduce postoperative mortality.

INTRODUCTION

Postoperative morbidity and mortality remain a challenge following hepatectomy for hepatocellular carcinoma (HCC) of the injured liver[1-5]. Factors affecting morbidity and mortality after hepatectomy include hyperbilirubinemia[2,6], poor indocyanine green clearance[2-5,7], active hepatitis[1,2,5], low preoperative platelet count[6,8], hypoalbuminemia[8], high serum creatinine level[8], major hepatectomy[6,8], excessive blood loss during hepatectomy[4,6,9-11], and perioperative blood transfusion[8,12]. In our department, a hepatectomy procedure has been selected for each patient with HCC mainly based on indocyanine green disappearance rate. Despite this selection method, however, some patients have died of postoperative morbidity.

The aims of this study were to assess the validity of our selection criteria for hepatectomy procedures based on indocyanine green disappearance rate, and to unveil the risk factors for postoperative morbidity and mortality, in order to supplement the selection criteria for hepatectomy procedures for HCC.

MATERIALS AND METHODS

Patient population

From January 1990 to March 2004, 210 consecutive patients underwent partial hepatectomies for HCC in the study department. Eleven patients with concomitant primary malignant tumors in other organs and one with combined hepatocellular and cholangiocarcinoma were excluded. The remaining 198 patients formed the basis of this retrospective study, which included 145 men and 53 women with a median age of 65 years (range: 16-81 years). All patients were Japanese.

Hepatectomy procedures

In the study department, hepatectomy is the standard

treatment for HCC whenever the tumors are considered to be resectable and the patient's condition permits the resection. The hepatectomy procedures examined in this study included nonanatomic hepatectomy (removal of the tumor with a rim of non-neoplastic liver parenchyma) in 66 patients, anatomic monosegmentectomy (removal of 1 Couinaud's segment[13]) in 34, anatomic bisegmentectomy (removal of two Couinaud's segments) in 38, right hepatectomy (removal of Couinaud's segments V-VIII) in 31, left hepatectomy (removal of Couinaud's segments II–IV) in 6, extended right hepatectomy in 15, extended left hepatectomy in 6, and right trisectionectomy (removal of Couinaud's segments IV-VIII) in 2. In the case of combined nonanatomic and anatomic hepatectomies in the same patient, the anatomic hepatectomy represented the hepatectomy procedure for that patient.

The hepatectomies were categorized into three types: major hepatectomy (hemihepatectomy or a more extensive procedure), bisegmentectomy, and limited hepatectomy (monosegmentectomy or nonanatomic hepatectomy). Intra-operative ultrasonography was employed for all patients. Lymph-node dissection of the hepatic hilum was not performed routinely, and only 7 patients underwent this type of dissection. The median operative time was 306 min (range: 100-730 min). The median estimated blood loss was 887 mL (range: 10-14 263 mL).

The selection criteria for hepatectomy procedures based on indocyanine green disappearance rate

In our department, the indocyanine green clearance test[14,15] has been routinely performed preoperatively, in order to assess hepatic functional reserve in patients for whom hepatectomies are planned. After the intravenous injection of indocyanine green (0.5 mg/kg, Diagnogreen; Daiichi Pharmaceutical Co., Inc., Tokyo, Japan), indocyanine green disappearance rate (K_{ICG}) was calculated by linear regression from the plasma indocyanine green concentrations at 5, 10, and 15 min. For the current series, the median indocyanine green retention rate at 15 min was 14% (range: 1-47%; reference range: 10% or less), whereas the median K_{ICG} was 0.136 (range: 0.04-0.243).

The indocyanine green clearance test is useful for estimating hepatic functional reserve in patients with injured livers[2-5,7]. In our department, the selection of a hepatectomy procedure for each patient has depended mainly on K_{ICG}. The selection criteria for this series were $K_{ICG} \geqslant 0.12$ for hemihepatectomy, $K_{ICG} \geqslant 0.10$ for bisegmentectomy, $K_{ICG} \geqslant 0.08$ for monosegmentectomy, and $K_{ICG} \geqslant 0.06$ for nonanatomic hepatectomy (including the enucleation of hepatic tumors).

Laboratory tests before hepatectomy

All patients underwent the following laboratory tests about 1 wk before hepatectomy: blood platelet count (reference range: 16.4-35.4×10^4/μL), serum aspartate aminotransferase (reference range: 8-25 IU/L), serum alanine aminotransferase (reference range: 3-23 IU/L), serum total bilirubin (reference range: 3-9 mg/L), serum albumin (reference range: 41-50 g/L), blood urea nitrogen (reference range: 80-200 mg/L), serum creatinine (reference range: 5-8 mg/L), and prothrombin time (reference range: 81-131%).

Hepatitis B surface antigen and hepatitis C antibody in the serum were detected by radioimmunoassay (Lumipulse II HBsAg; Fujirebio Co., Inc., Tokyo, Japan) and a second-generation ELISA (Lumipulse II Ortho HCV; Ortho-Clinical Diagnostics Co., Inc., Tokyo, Japan), respectively. In the current series, 49 patients tested positive for hepatitis B surface antigen, 100 tested positive for hepatitis C antibody, and 2 tested positive for both. The remaining 47 patients tested negative for both.

Pathologic examination

The resected specimens were submitted to the Department of Surgical Pathology in our hospital for histologic evaluation. Each specimen was examined grossly and microscopically. The cancer stage was determined according to the pathologic tumor-node-metastasis (pTNM) staging system[16]. Cirrhosis in the resected liver was diagnosed microscopically based on the presence of fibrous septa and regenerative nodules. One hundred and six patients were found to be cirrhotic.

Definitions of postoperative morbidity and mortality

Postoperative morbidity was defined as any postoperative complication that lengthened the hospital stay, and included intra-abdominal bleeding (either interventional radiologic technique or reoperation required), hyperbilirubinemia (serum total bilirubin >50 mg/L, persisting for more than 7 d), hepatic encephalopathy, intractable ascites (abdominocentesis required), intractable pleural effusion (either insertion of a thoracic tube or two or more thoracocenteses required), biliary fistula, gastrointestinal hemorrhage, portal vein thrombosis, bowel obstruction (reoperation required), acute renal insufficiency (hemodialysis required), adult respiratory distress syndrome, sepsis, intra-abdominal infection, methicillin-resistant *Staphylococcus aureus* or pseudomembranous enterocolitis, pneumonia, and wound infection. Intra-abdominal infection was diagnosed when either an abscess was detected on imaging or positive bacterial culture of a drainage fluid was identified together with a fever (>38 ℃) without extra-abdominal septic complications. Tumor progression during the hospital stay (one patient) was not treated as a postoperative complication.

Postoperative mortality was defined as any death occurring during the hospital stay for resection of HCC.

Risk factors for postoperative morbidity and mortality

All 198 patients were tested for a total of 20 factors which might influence postoperative morbidity and mortality[17]: age (≤65 years *vs* >65 years), gender, the Child-Pugh classification[18] (A *vs* B+C), cirrhosis (absent *vs* present), hepatitis B viral status (positive *vs* negative for hepatitis B surface antigen), hepatitis C viral status (positive *vs* negative for hepatitis C antibody), blood platelet count (≤10×10^4/μL *vs* >10×10^4/μL), serum aspartate aminotransferase (≤50 IU/L *vs* >50 IU/L), serum alanine aminotransferase (≤46 IU/L *vs* >46 IU/L), serum total bilirubin (≤1.0 IU/L *vs* >1.0 IU/L), serum albumin (≤35 g/L *vs* >35 g/L), blood urea nitrogen (≤200 mg/L *vs* >200 mg/L), serum creatinine (≤10 mg/L *vs* >10 mg/L), prothrombin time (≤70% *vs* >70%), K_{ICG} (≤0.12 *vs* >0.12), the type of hepatectomy (major hepatectomy *vs* bisegmentectomy *vs* limited hepatectomy), operative time (≤300 min *vs* > 300 min), estimated blood loss (≤800 mL *vs* >800 mL),

blood transfusion (transfusion of packed red cells during the operation) (no *vs* yes), and pTNM stage[16] (I *vs* II+III+IV).

Statistical analysis

Medical records were obtained for all patients. Univariate analyses of risk factors for postoperative morbidity and mortality were performed using Fisher's exact test. Multivariate analyses of the risk factors for postoperative morbidity and mortality were performed using the logistic regression model. In this model, a stepwise selection was used for the variable selection, with entry and removal limits of $P<0.1$ and $P>0.15$, respectively. The stability of this model was confirmed using a step-backward and step-forward fitting procedure; the variables identified as having an independent influence on morbidity and mortality were identical with both procedures. The Mann-Whitney test was used to compare the blood platelet counts between patients with postoperative mortality and patients without postoperative mortality. All statistical evaluations were performed using the SPSS 11.5J software package (SPSS Japan Inc., Tokyo, Japan). All tests were two-sided, and the differences with P values lesser than 0.05 were considered statistically significant.

RESULTS

Postoperative complications occurred in 50 patients out of a total of 198 patients, resulting in a postoperative morbidity of 25%. Intra-abdominal infection was the most common complication ($n = 30$), followed by intractable pleural effusion ($n = 18$), wound infection ($n = 9$), gastrointestinal hemorrhage ($n = 9$), methicillin-resistant *Staphylococcus aureus* or pseudomembranous enterocolitis ($n = 8$), pneumonia ($n = 7$), biliary fistula ($n = 7$), hepatic encephalopathy ($n = 5$), intractable ascites ($n = 5$), hyperbilirubinemia ($n = 3$), portal vein thrombosis ($n = 3$), acute renal insufficiency ($n = 2$), bowel obstruction ($n = 2$), sepsis ($n = 1$), intra-abdominal bleeding ($n = 1$), and adult respiratory distress syndrome ($n = 1$).

Seven patients died during their hospital stay, which resulted in a postoperative mortality of 3.5%. Among the seven patients with postoperative mortality, six died of postoperative morbidity and the other died of tumor progression.

Postoperative morbidity and mortality according to the type of hepatectomy procedure

The incidence of postoperative morbidity was 28% (17/60 patients) after major hepatectomy, 32% (12/38 patients) after bisegmentectomy, and 21% (21/100 patients) after limited hepatectomy. The postoperative morbidity incidences for the three types of hepatectomy were comparable ($P = 0.365$).

The incidence of postoperative mortality was 5% (3/60 patients) after major hepatectomy, 3% (1/38 patients) after bisegmentectomy, and 3% (3/100 patients) after limited hepatectomy. The postoperative mortality incidences for the three types of hepatectomy were comparable ($P = 0.876$).

Risk factors for postoperative morbidity

Univariate analysis revealed that the estimated blood loss ($P<0.001$), blood transfusion ($P<0.001$), operative time ($P<0.001$), and blood platelet count ($P = 0.022$) were significantly associated with postoperative morbidity. These four variables entered into multivariate analysis, and the estimated blood loss (risk ratio: 3.935; $P = 0.003$), blood transfusion (risk ratio: 3.704; $P = 0.004$), and blood platelet count (risk ratio: 3.069; $P = 0.010$) remained as significantly independent factors for postoperative morbidity (Table 1).

Risk factors for postoperative mortality

Univariate analysis revealed that the blood platelet count ($P = 0.001$), prothrombin time ($P = 0.005$), and Child-Pugh classification ($P = 0.044$) were significantly associated with postoperative mortality. These three variables entered into multivariate analysis, and the blood platelet count (risk ratio: 12.50; $P = 0.029$) remained as the only significantly independent factor for postoperative mortality (Table 2).

Blood platelet count and postoperative mortality

The blood platelet counts were significantly lower in patients with postoperative mortality than in those without (the Mann-Whitney test, $P = 0.003$, Figure 1). Among the seven patients with postoperative mortality, the patient who died of tumor progression during the hospital stay showed a platelet count of $25.7\times10^4/\mu L$, whereas the other patients who died of postoperative morbidity showed platelet counts of $7.3\times10^4/\mu L$,

Table 1 Risk factors for morbidity after hepatectomy

Variable	Number of patients	Univariate analysis	Multivariate analysis			
		P	β	Risk ratio	95%CI	*P*
Estimated blood loss (mL)		<0.001	1.370	3.935	1.578-9.814	0.003
≤800 (*n* = 91)	8					
>800 (*n* = 107)	42					
Blood transfusion		<0.001	1.309	3.704	1.520-9.009	0.004
No (*n* = 94)	9					
Yes (*n* = 104)	41					
Operative time (min)		<0.001	-	-	-	-
≤300 (*n* = 96)	13					
>300 (*n* = 102)	37					
Blood platelet count ($\times10^4/\mu L$)		0.022	1.043	3.069	1.287-6.250	0.010
≤10 (*n* = 49)	19					
>10 (*n* = 149)	31					

CI: confidence interval.

Table 2 Risk factors for mortality after hepatectomy

Variable	Number of patients	Univariate analysis	Multivariate analysis			
		P	β	Risk ratio	95%CI	*P*
Blood platelet count (×10⁴/μL)		0.001	2.520	12.50	1.302-125.0	0.029
≤10 (*n* = 49)	6					
>10 (*n* = 149)	1					
Prothrombin time (%)		0.005	1.476	4.367	0.812-23.81	0.086
≤70 (*n* = 24)	4					
>70 (*n* = 174)	3					
Child–Pugh classification		0.044	-	-	-	-
A (*n* = 173)	4					
B+C (*n* = 25)	3					

CI: confidence interval.

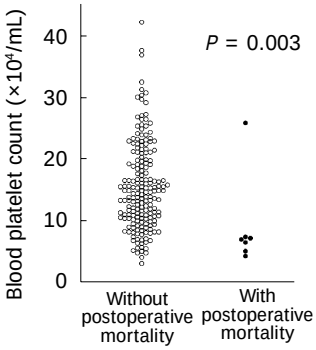

Figure 1 Patients with postoperative mortality had lower platelet counts than those without (the Mann-Whitney test, $P = 0.003$). The platelet counts were 8.9±7.5×10⁴/μL (mean±SD) in patients with postoperative mortality, whereas they were 15.4±7.0×10⁴/μL (mean±SD) in those without postoperative mortality. [1]This patient showed a platelet count of 25.7×10⁴/μL and died of tumor progression, and not of postoperative morbidity, during the hospital stay.

7.1×10⁴/μL, 6.9×10⁴/μL, 6.4×10⁴/μL, 5.0×10⁴/μL, and 4.2×10⁴/μL. Thus, no patient with a platelet count of > 7.3×10⁴/μL died of postoperative morbidity, whereas the postoperative mortality was 25% (6/24 patients) among patients with platelet counts of ≤ 7.3×10⁴/μL ($P<0.001$).

DISCUSSION

The indocyanine green clearance test has been reported to provide a reliable selection criterion for hepatectomy procedures for patients with resectable HCCs[2-4]. In the current series, a hepatectomy procedure was selected for each patient mainly based on K_{ICG}. As a result, both the postoperative morbidities and mortalities became comparable among the three types of hepatectomy. Although major hepatectomy is considered to be a high-risk treatment option for HCC patients with poor hepatic functional reserves[7,10,19], in our patients it resulted in an acceptable morbidity (28%) and mortality (5%). The above suggests that our selection criteria for hepatectomy procedures using K_{ICG} are generally valid. We regret, however, that some patients died of postoperative complications in spite of these selection criteria for hepatectomy procedures. This has prompted us to conduct the current study.

A low preoperative platelet count is related to portal hypertension and its resulting hypersplenism, hepatic fibrosis, and unfavorable indocyanine green clearance test results[20-22]. Jarnagin *et al.*[6], and Poon *et al.*[8], have documented the fact that a low preoperative platelet count is associated with a higher incidence of postoperative mortality. Bennett and Blumgart have stated, "We are cautious when planning resections in patients with counts less than 100 000/μL"[23]. Poon and Fan have also affirmed that cirrhotic patients with platelet counts of less than 10×10⁴/μL should not be considered for major hepatectomy[24]. Among various factors affecting perioperative mortality, the preoperative platelet count is clinically relevant, because it is readily available before surgery.

In this series, a hepatectomy procedure was selected for each patient based on K_{ICG} values, and a low preoperative platelet count (≤ 10×10⁴/μL) was the strongest independent factor for postoperative mortality; no patient with a count of >7.3×10⁴/μL died of postoperative complications, whereas the mortality was high (25%) among those with counts of ≤ 7.3×10⁴/μL. This suggests that the combined use of K_{ICG} and the preoperative platelet count would further reduce postoperative mortality in patients with HCC.

The estimated blood loss and blood transfusion also independently affected the postoperative morbidity in the current series. Recent evidence suggests that blood loss is associated with increased postoperative morbidity and mortality[4,6,9-11]. Blood transfusion is also related to the recurrence of HCC[25-27]. In order to reduce blood loss, adequate and wide exposure of the operative field is essential[25]. During parenchymal transection, intermittent use of the Pringle maneuver[28,29], the use of developed modalities[30-33], and a lowering of the central venous pressure[34-37] are important. Meticulous surgical techniques are required to minimize blood loss. Only experienced surgeons should perform hepatectomies for HCC of cirrhotic liver.

The current study has limitations, such as the retrospective nature of the study and the small number of patients. However, we feel that these limitations did not significantly influence the outcome of the study, because the differences between the groups were too marked to have resulted from these biases.

In conclusion, we believe that the selection criteria for hepatectomy procedures based on K_{ICG} are generally valid

because of the acceptable morbidity and mortality with these criteria. The preoperative platelet count independently affects morbidity and mortality after hepatectomy, suggesting that a combination of K_{ICG} and the platelet count would further reduce postoperative mortality in patients with HCC.

Abstract

AIM: To evaluate the feasibility of a new clinical rating scale for a standardized assessment of cirrhosis-associated neuro-psychiatric symptoms.

METHODS: Forty patients with liver cirrhosis (LC, with or without low-grade hepatic encephalopathy) were investigated using a clinical neuro-psychiatric rating scale based on a comprehensive list of neurological, psychomotor, cognitive, affective, behavioral symptoms, and symptoms of disturbed bioregulation.

RESULTS: The analysis revealed that the majority of cirrhotic patients showed, besides characteristic neurological symptoms of hepatic encephalopathy, various psychomotor, affective and bioregulatory symptoms (disturbed sleep and sexual dysfunction). Patients were impaired in the following subscales: sleep and biorhythm disorder (75.0% of patients), Parkinsonoid symptoms (25.0%), affective symptoms (17.5%), and psychomotor retardation (12.5%). The increase of total neuro-psychiatric clinical score was significantly associated with the degree of hepatic encephalopathy.

CONCLUSION: This study suggests that a substantial number of patients with LC and low-grade hepatic encephalopathy manifest various clinical neuro-psychiatric symptoms. The use of a rating scale, which explores clinical dimensions of hepatic encephalopathy, would improve the management of patients with LC.

INTRODUCTION

Patients with liver cirrhosis (LC) and hepatic encephalopathy frequently demonstrate various neuro-psychiatric symptoms and deficits[1-3]. The pathophysiology, natural history, and prognosis of cirrhosis-associated neuro-psychiatric deficits are not completely established and the data on this issue are controversial[4-7]. Recent studies have shown that these deficits are associated with changes in metabolic brain patterns[8-11] and can fluctuate correspondingly to the current ammonia level. On the other hand, long-term persistence of these symptoms after liver transplantation has been reported[12-14] and the neurodegenerative nature of this disorder has been suggested[15].

Mild forms of cirrhosis-associated encephalopathy include minimal hepatic encephalopathy (MHE) and grade I hepatic encephalopathy (grade I HE). Patients with grade I HE manifest minor symptoms of motor dysfunction and with attention and concentration deficits[16-18]. MHE is diagnosed in patients who demonstrate deficits in attention and visuomotor coordination[1,4,7,17], but otherwise show no evident or only transient neuro-psychiatric symptoms. Besides, cirrhosis-associated neurological symptoms, such as asterixis, tremor, Parkinsonoid symptoms and bradykinesia, patients with low-grade hepatic encephalopathy frequently demonstrate bioregulative (disturbed sleep and sexual dysfunction), behavioral and affective symptoms[2,18,19]. The adequate clinical neuro-psychiatric evaluation of patients with LC remains difficult, because, in part, neuro-psychiatric symptoms associated with LC are multiform and sometimes subtle and also because, in part, there are no available clinical diagnostic tools adjusted to investigate this group of patients. The previously used Brief Psychiatric Rating Scale[18], which was initially designed for the monitoring of chronic psychiatric patients does not allow sufficient assessment of slight and moderate symptoms and does not include specific cirrhosis-

associated neurological, psychomotor, and cognitive symptoms. Combination of several available clinical rating scales adjusted for other clinical disorders would inevitably lead to unreasonable extension of the investigation procedure, which is not always possible in patients with LC.

The purpose of this study was to explore the feasibility of a comprehensive clinical rating scale for the evaluation of frequency and severity of neuro-psychiatric symptoms in patients with low-grade hepatic encephalopathy. A multidimensional clinical neuro-psychiatric rating scale was developed based on previous findings and clinical experience. The scale includes neurological, psychomotor, affective, behavioral, and bioregulatory symptoms and allows a global evaluation of the neuro-psychiatric state of the patients with emphasis on symptoms characteristic of LC.

MATERIALS AND METHODS

Patients

Forty patients with LC at the out-patient clinic of the Department of Gastroenterology of Innsbruck Medical University, who were listed for liver transplantation, were considered to be eligible for this study. Prior to inclusion, patients underwent a comprehensive hepatologic work-up and gave informed consent. The following exclusion criteria were applied in this study: (1) clinical or laboratory signs of inflammation, gastrointestinal bleeding, anemia, electrolyte abnormalities, or renal insufficiency; (2) overt hepatic encephalopathy (persistent or episodic, clinical grades II-IV); (3) abuse of psychotropic substances; (4) known major psychiatric disorders, as defined by DSM-IV classification; and (5) less than 6 mo of complete alcohol abstinence. The severity of cirrhosis was assessed as follows: Child A (n = 6); Child B (n = 30); and Child C (n = 4). Table 1 shows clinical and demographic data of the patients.

Table 1 Clinical and demographic characteristics of patients with LC

	No. of patients	Percent
Age (mean±SD)	54.77±10.06	
Men/women	28/12	70.0/30.0
Etiology		
Hepatitis C	14	35.0
Alcohol-associated	16	40.0
Autoimmune	4	7.5
Cryptogenic	2	5.0
Hepatitis B	2	5.0
Hepatitis C and hepatocellular carcinoma	1	2.5
Polycystic liver disease	1	2.5

Clinical neuro-psychiatric rating ACIND and psychometric tests

The clinical neuro-psychiatric examination focuses on the symptoms frequently found in patients with LC[2,21] and contains the following clusters of symptoms: neurological symptoms, symptoms of psychomotor retardation, cognitive symptoms, affective symptoms, behavioral alterations, symptoms of sleep, and bioregulatory disorder.

Neurological symptoms, such as asterixis, postural tremor, adiadochokinesia (pronation-supination of both forearms), upper limb dysmetria, dysarthria, oculomotor deficits (nystagmus and altered smooth gaze pursuit) and gait ataxia, are assessed using a standard neurological investigation. The evaluation of psychomotor retardation is based on the assessment of psychomotor change (non-interactiveness and retardation parts)[21]. Cognitive deficits and affective symptoms as well as behavioral changes and bioregulatory deficits (disturbed sleep and sexual dysfunction) are assessed using a semi-structured clinical interview based on the AMDP system[22]. Depending on the nature of symptoms, the evaluation is based either on patient's reporting or rater's clinical assessment (Table 2, Appendix 1). The intensity of symptoms, defined as a combination of frequency and severity, is uniformly assessed as follows: absent (0); slight (1 score point); moderate (2 score points); and severe (3 score points). This rating scale was arbitrarily named as assessment of cirrhosis-associated neuro-psychiatric deficits (ACIND).

The ACIND rating scale was designed in order to evaluate several possible syndromes by combining the symptoms into subscales as follows: Parkinsonoid syndrome (rigidity [obligatory symptom]; facial and head hypomobility, bradykinesia and adiadochokinesia); ataxia (dysmetria, dysartria, adiadochokinesia, gait ataxia, oculomotor deficits [without muscular rigidity]); cognitive impairment (memory decline, attention deficits, concentration deficits, as well as apperception and acalculia); psychomotor retardation (bradykinesia, facial and head hypomobility, delayed verbal responses, reduced speech velocity [without muscular rigidity]); affective symptoms (depressive mood [obligatory symptoms], loss of interest, anhedonia, feeling of loss of feeling, energy deficit, affective lability); as well as sleep and biorhythm disorder (recurrent drowsiness, impaired sleep initiation, increased daily sleep, interrupted sleep). The diagnosis of the impairment on a subscale is based on a cut-off average score point (ASP, Appendix 1). The calculation of the ASP is performed as follows: $ASP = \Sigma / n$ (Σ, sum of all score points; n, the number of symptoms within a subscale). Patients with the ASP 1.0 and higher are arbitrarily assessed as being impaired in the corresponding subscale. The total clinical neuro-psychiatric score is calculated as a sum of score points in all symptoms with a possible maximum of 96 score points. The clinical investigation based on the ACIND rating scale (duration 10-20 min) was performed by a trained neuropsychiatrist and was applied prior to the administration of psychometric tests.

The psychometric test battery included trail-making tests A and B (TMT A and TMT B[23,24]) as well as the digit symbol test (DST). The age-adjusted percentile scores based on a large population data were used in order to calculate a cumulative visuomotor index defined as the sum of percentile scores for TMT A, TMT B, and DST. Visuomotor impairment was assessed using 1.5 z-score cut-off (visuomotor index <10.57), based on age-adjusted control group of 34 healthy subjects (mean visuomotor index 19.95, SD = 6.25). Patients without obvious symptoms of grade I hepatic encephalopathy and regular psychometric performance (visuomotor index >10.57) were assigned with absent HE (grade 0 HE; n = 14). Patients without clinical symptoms but with reduced psychometric performance (cumulative index below 10.57) were diagnosed with MHE (n = 11). Patients with apparent

Table 2 Frequency of neuro-psychiatric symptoms in patients with LC

	Neuro-psychiatric symptoms	Mode of assessment	Cumulative percent of patients showing slight, moderate, or severe symptoms		Percent of slight symptoms
			%	95%CI

CI: confidence interval; r: evaluation by rater; s: assessment based on patient's self-report.

clinical symptoms of cerebral dysfunction but without somnolence and disorientation were diagnosed with grade I hepatic encephalopathy (grade I HE; n = 15).

Statistical analysis

The comparison between the subgroups of patients (grade 0 HE, MHE and grade I HE) with regard to the total ACIND score was performed using non-parametric statistics (Mann-Whitney U test and Wilcoxon matched-pairs test) and one-way ANOVA. The confidence intervals of the frequency of neuro-psychiatric symptoms were analyzed using the statistical assumption of standard binomial distribution. For data processing and statistical analysis, the SPSS 11.5 software package was applied.

RESULTS

The analysis of neuro-psychiatric findings showed a high rate of different neuro-psychiatric symptoms in patients with LC. Table 2 presents the frequency of neuro-psychiatric symptoms expressed as the percentage of patients showing a corresponding symptom, as well as the 95% confidence intervals (CI). Adiadochokinesia, bradykinesia, memory and attention deficits as well as recurrent drowsiness, energy deficit (lack of drive), reduction of working ability, sexual dysfunction and impaired sleep were the most frequent symptoms in this study, although these symptoms were only slightly pronounced in a majority of patients. Recurrent drowsiness, reduction of working ability and sexual dysfunction were in some patients reported as moderate or severe (Table 2).

Patients with LC showed various intensities of neuro-psychiatric symptoms and ranged in total ACIND scores from 0 to 56. For the whole group of patients, the mean ACIND score was 22.95 score points (SD = 12.43). Figure 1A presents the percentage of LC patients in respect with different ranges of the total ACIND score and shows that LC patients most frequently ranged between 21 and 30 total ACIND score points and that 77.5% of patients in this study ranged between 10 and 40 score points.

The frequency of symptoms in different ACIND subscales is presented in Table 3. The percentages of the LC patients demonstrating in average one or more score points per symptom in a particular subscale are listed. Symptoms of biorhythm and sleep disorder were the most

Table 3 Percentage of patients impaired on different ACIND subscales

Subscales	Symptoms	Percentage of impaired patients (95% CIs)
Sleep and biorhythm	Recurrent drowsiness, impaired sleep initiation, interrupted sleep, increased daily sleep	75.0 (58.80-87.31)
Parkinsonoid	Rigidity[1], bradykinesia, adiadochokinesia, facial and head hypomobility	25.0[3] (12.69-41.20)
Cognitive	Memory decline, impaired apperception, concentration deficits, impaired calculation, attention deficits	25.0 (12.69-41.20)
Affective	Depressive mood[1], loss of interest, anhedonia, feeling of loss of feeling, energy deficits, affective lability	17.5 (7.34-32.78)
Psychomotor[2]	Bradykinesia, facial and head hypomobility, reduced speech velocity, delayed verbal responses	12.5 (4.19-26.80)
Ataxia[2]	Dysmetria of upper extremities, oculomotor deficits, adiadochokinesia, dysarthria, gait ataxia	12.5 (4.19-26.80)

[1]Obligatory symptom; [2]patients showing muscular rigidity are excluded; [3]patients with average 0.75 or more score points per symptom are included.

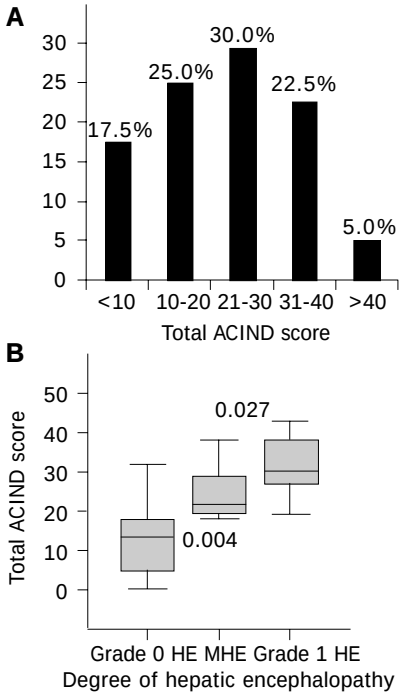

Figure 1 A: Clinical neuro-psychiatric symptoms in patients with LC; B: Box plot and Mann-Whitney *U* test with *P*-values showing the association between total ACIND score and the degree of hepatic encephalopathy (grade 0 hepatic encephalopathy, MHE, and grade I hepatic encephalopathy).

frequent (75.0%). Parkinsonoid syndrome, with rigidity as an obligatory symptom, was diagnosed in 10 patients out of 40 (25%). Cognitive impairment was found in 25% of patients. The average score on this subscale correlated significantly with the cumulative visuomotor index (Spearman's correlation: $r = 0.400$, $P = 0.021$). Depressive symptoms were found in 17.5% of patients. Both ataxia and psychomotor retardation scores were increased in 12.5% of patients.

The increase of the total ACIND score was significantly correlated with the degree of hepatic encephalopathy (Figure 1B). We observed a mean total ACIND score of 12.5 (SD = 9.1) in patients with grade 0 HE, 23.3 (SD = 9.0) in patients with MHE and 32.4 (the highest score, SD = 9.4) in patients with grade 1 HE. One-way ANOVA test demonstrated a highly significant ($P<0.001$) difference among the three subgroups of patients according to the degree of HE (grade 0 HE, MHE, and grade I). Also, the differences between the subgroups were found to be statistically significant, as proven by Mann-Whitney *U* test: grade 0 *vs* MHE ($P = 0.004$) and MHE *vs* grade I ($P = 0.027$).

DISCUSSION

This study provides a systematic description of the neuropsychiatric profile of patients with LC, including affective, behavioral, and bioregulatory symptoms and continues the investigation line of previous studies reporting various neurological, cognitive and psychomotor symptoms associated with LC[4,25-28]. A new clinical rating scale, i.e. ACIND, is proposed for the systematic assessment of the neuropsychiatric state of patients with LC. ACIND uniformly assesses a wide range of neuro-psychiatric symptoms and, due to retrospective evaluation of symptoms, is particularly sensitive for transient and subtle symptoms associated with LC. Since ACIND directly explores clinical dimensions of hepatic encephalopathy, there is a particular advantage in comparison to psychometric tests, which merely measure psychomotor performance.

Our data have shown that patients with LC frequently manifest mild neurological and psychomotor symptoms, such as adiadochokinesia, bradykinesia, and dysmetria of upper limb movements, which are consistent with previous reports on movement disorder in patients with LC[13,29,30]. Although, patients with hepatic encephalopathy grade II were not included in this study, a high rate of minor clinical symptoms of movement disorder was detected. Dysfunctions of basal ganglia, cerebellar pathways as well as in different cortical regions have been recently found to underlie neurological and psychomotor abnormalities in patients with LC and low-grade hepatic encephalopathy[9,30-35]. In our study, a bradykinetic syndrome was associated with Parkinsonoid symptoms in 25% patients (10/40). These findings support previous suggestions on the importance of Parkinsonoid syndrome in cirrhotic patients[13,30,36]. Some patients in our sample (12.5%) showed psychomotor slowing, which was associated with ataxia symptoms and not with crucial Parkinsonoid symptoms. This finding supports the suggestion of multifactorial genesis of bradykinesia in patients with low-grade hepatic encephalopathy[29].

A substantial number of our patients demonstrated a variety of affective symptoms. Depressive mood, energy deficits, loss of interest, feeling of loss of feeling, anhedonia, and social withdrawal were frequent, although in most cases slightly pronounced. These findings are in agreement with those recent reports that found affective symptoms in patients with LC[2,18,38]. Several factors may cause the occurrence of affective symptoms in patients with LC. First, a chronic disease, such as LC, is possibly associated with a high degree of impairment and might be *per se* a factor leading to the

development of a depressive syndrome. On the other hand, all patients in this study suffered from advanced LC and were challenged by indispensability of liver transplantation during several weeks or months prior to the neuro-psychiatric investigation. The inclusion in the liver transplantation waiting list requires substantial adjustment of everyday life and includes the possibility of being called for transplantation at any time. These conditions may also lead to the development of chronic adjustment disorder associated with the up-coming liver transplantation. Recent data supporting this assumption have shown manifest symptoms of post-traumatic stress disorder in a substantial number of LC patients after liver transplantation[39]. Furthermore, specific cirrhosis-associated biological mechanisms might also be responsible for the development of affective symptoms in patients with LC. Recent animal studies as well as investigations in humans have shown that acute and chronic hyperammoniemia can alter brain monoamine metabolism and cause disturbances of dopamine and serotonin neurotransmission[40-42]. Although current data on this issue are not sufficient and, to some degree, controversial, it can be assumed that metabolic brain dysfunction could lead to increased vulnerability for the development of affective symptoms in patients with LC. The high prevalence of depressive symptoms in our sample underlines the substantial demand on systematic screening of patients with LC with respect to affective symptoms.

Various cognitive symptoms, such as attention and memory deficits, have been previously reported in LC patients[37]. Our data were consistent with these findings and showed that 25% of LC patients reported increasing impairment of cognitive functions during the course of their illness.

Sleep and biorhythm dysfunction is an important clinical finding in our sample and has been reported earlier[19,43]. Disturbances of vigilance regulation have been supposed to be associated with a direct toxic effect of increased ammonia concentration, as well as with alterations in glutamine, dopamine, and serotonin neurotransmission occurring in low-grade hepatic encephalopathy[44].

Seventy-five percent of our patients reported sexual dysfunction. Previous reports suggest that an altered metabolism of steroid hormones in patients with LC could be responsible for sexual dysfunction in both men and women suffering from LC[45,46].

Our data demonstrate that clinical rating scale ACIND shows considerable sensitivity with respect to the degree of hepatic encephalopathy, which points toward its validity of clinical assessment of neuro-psychiatric deficits in patients with LC. Follow-up investigations of patients with LC after liver transplantation as well as further investigations including neuroimaging methods are needed to clarify the mechanisms underlying clinical neuro-psychiatric symptoms in LC.

Taking into account that the application of ACIND was not intended to substitute the established methods of investigation of cerebral dysfunction in LC, we suggest that the systematic use of a multidimensional clinical rating would profoundly improve the management of patients with LC.

ACKNOWLEDGMENTS

We are thankful to Mrs. Simone Auffinger and Mr. M. Mattedi for their technical assistance and to Dr. G. Kemmler for his support with statistical analyses. This study was partially supported by Dr. Kolasssa and Merz (Vienna).

Abstract

AIM: To investigate the effect of *Helicobacter pylori* (*H pylori*) infection on Bax protein expression, and explore the role of *H pylori* in gastric carcinogenesis.

METHODS: *H pylori* was assessed by rapid urease test and Warthin-Starry method, and expression of Bax protein was examined immunohistochemically in 72 patients with pre-malignant lesions.

RESULTS: Bax protein was differently expressed in intestinal metaplasia and gastric dysplasia, and showed 63.99% positivity. The positivity of Bax protein expression in *H pylori*-positive gastric precancerous lesions (72.3%) was significantly higher than that in *H pylori*-negative gastric precancerous lesions (48.0%, $\chi^2 = 4.191$, $P<0.05$). *H pylori* infection was well correlated with the expression of Bax protein in gastric precancerous lesions ($r = 0.978$, $P<0.01$). After eradication of *H pylori*, the positivity of Bax protein expression significantly decreased in *H pylori*-positive gastric precancerous lesions ($\chi^2 = 5.506$, $P<0.05$). In the persisting *H pylori*-infected patients, the positivity of Bax protein expression was not changed.

CONCLUSION: *H pylori* infection may be involved in the upregulation of Bax gene, which might be one of the mechanisms of *H pylori* infection-induced gastric epithelial cell apoptosis. *H pylori* might act as a tumor promoter in the genesis of gastric carcinoma and eradication of *H pylori* could inhibit gastric carcinogenesis.

Key words: *Helicobacter pylori*; Bax protein; Gastric precancerous lesions

INTRODUCTION

Helicobacter pylori (*H pylori*) is a Gram-negative bacterium that infects the human stomach and plays an important role in the pathogenesis of chronic gastritis and peptic ulcer diseases. In addition, epidemiological and clinical studies have consistently identified an association between infection with *H pylori* and subsequent development of gastric cancer[1]. Chronic and persistent infection with *H pylori* is considered to be one of the earliest steps in gastric carcinogenesis. *H pylori* has recently been classified as a group I carcinogen by an International Agency for Research on Cancer Working Group. In the Correa model of human gastric carcinogenesis, *H pylori* has been found to be involved in the evolution of the gastric tissue from normal to superficial gastritis, multifocal atrophic gastritis, intestinal metaplasia, and gastric dysplasia, and finally to adenocarcinoma[2-5]. However, the mechanisms underlying the carcinogenic potential of *H pylori* have not been completely understood as yet.

Our previous studies indicated that cell proliferation and apoptosis were essential events in the cellular turnover of gastric tissue. *H pylori* infection was associated with increased apoptosis. Abnormal regulation of apoptosis may play an important role in the pathogenesis of gastric carcinoma. Bax gene is an important apoptosis-regulatory gene. To the author's knowledge, the relationship between *H pylori* infection and Bax protein expression is still unclear. Hence, we conducted this study to investigate the effect of *H pylori* infection on Bax protein expression, and explore the role of *H pylori* in gastric carcinogenesis.

MATERIALS AND METHODS

Subjects

Seventy-two gastric antral biopsy specimens were taken from 51 patients with intestinal metaplasia and 21 patients with dysplasia referred for upper gastrointestinal endoscopy in Southwest Hospital from 1994 to 1996. Informed written consent was obtained from each patient for the upper gastrointestinal endoscopy and biopsy procedures. The patients who had undergone previous gastric surgery or were known to be taking nonsteroidal anti-inflammatory drugs, corticosteroids or prostaglandin analogs, which may damage the gastric

epithelium or impair the normal gastric cytoprotective response to injury, were excluded from this study. Moreover, the patients who had taken antibiotics or other anti-*H pylori* medications, such as a bismuth compound or a proton-pump inhibitor within the previous one month, were also excluded. This study was approved by the Research Ethics Committee of South-west Hospital. *H pylori* infection was assessed by rapid urease test and immunohistochemical method (Warthin-Starry stain). *H pylori* infection was defined when both rapid urease test and immunohistochemical staining were positive. The patients with *H pylori* infection were treated for 14 d with a triple therapy consisting of colloidal bismuth subcitrate, amoxycillin and metronidazole. One month after the end of triple therapy, the patients underwent the same investigations performed at entry. Eradication of infection by the triple therapy was considered successful when both the rapid urease test and immunohistochemical staining were negative.

Histology

Biopsy specimens were fixed in formalin and embedded in paraffin. The sections (4-μm thick) were stained with hematoxylin and eosin for histological evaluation and identification of *H pylori*. Histological evaluation and identification of *H pylori* were assessed at different times to ensure that the different grades were not influenced by each other.

All biopsy specimens were independently and blindly examined by two expert pathologists who were unaware of clinical, endoscopic, serological, and functional data of the patients. When discordance was found, the samples were re-examined by the two pathologists together using a double-headed microscope, and the grading obtained on this occasion was used for the analysis.

Immunohistochemistry

For each case, 4-μm-thick serial sections were cut from paraffin-fixed specimens, mounted on acid-cleaned glass slides, and heated at 55-60 ℃ for 60 min. Slides were dewaxed and rehydrated, then the endogenous peroxidase activity was inhibited by incubation with 30 mL/L H_2O_2 in methanol for 5 min at room temperature. To reduce non-specific background staining, slides were incubated with 50 mL/L normal goat serum for 10 min at room temperature. To enhance immunostaining, sections were treated with an antigen-retrieval solution (10 mmol/L citric acid monohydrate, pH 6.0, adjusted with 2 mol/L NaOH) and heated thrice in a microwave oven at high power for 5 min. Slides were incubated with primary rabbit antihuman Bax polyclonal antibody (1:50 dilution, Santa Cruz, USA) for 30 min at 37 ℃. A biotin–streptavidin detection system was employed with diaminobenzidine as the chromogen. Slides were washed twice with PBS and incubated with the linking reagent (biotinylated anti-immunoglobulin) for 10 min at 37 ℃. After rinsing in PBS, the slides were incubated with the peroxidase-conjugated streptavidin label for 10 min at 37 ℃, followed by incubation with diaminobenzidine and H_2O_2 for 10 min in darkness. The sections were then weakly counterstained with hematoxylin. With each batch of test samples, a positive control consisting of a tissue section from tonsil was evaluated. In addition, negative controls were prepared for each sample using an irrelevant antibody of the same isotype as the primary antibody.

The degree of Bax protein immunopositivity was evaluated semiquantitatively. Four hundred tumor cells were counted in random fields from representative areas of the lesions, and the immunoreactive cells were roughly assessed and expressed as percentages. The scoring system tested was: <10% (negative, -); 10-25% (low positivity, +); 26-50% (moderate positivity, ++); >50% (high positivity, +++).

Statistical analysis

Data were analyzed with the STATA package for Windows. The categorical variables were analyzed using χ^2 test or Fisher's exact test. Correlation between *H pylori* infection and Bax protein expression was assessed using the logistic regression. $P<0.05$ was considered statistically significant.

RESULTS

H pylori infection was identified by rapid urease test and an immunohistochemical staining. *H pylori* infection was detected in 68.62% (35/51) patients with intestinal metaplasia and 57.14% (12/21) patients with gastric dysplasia. There was no significant difference in *H pylori*-infection rate between intestinal metaplasia and gastric dysplasia.

The Bax protein immunoreactivity appeared brown or dark brown, which was mainly located in the cytoplasm, and a few specimens simultaneously expressed Bax protein in the cell nucleus of gastric epithelium (Figure 1). Bax protein was differently expressed in intestinal metaplasia and gastric dysplasia, and its positivity was 63.9%. The positivity of Bax protein expression in *H pylori*-positive gastric precancerous lesions (72.3%) was significantly higher than that in *H pylori*-negative gastric precancerous lesions (48.0%, $P<0.05$). *H pylori* infection was well correlated with the expression of Bax protein in gastric precancerous lesions ($r = 0.978$, $P<0.01$, Table 1). One month after the end of triple therapy, 37 patients became *H pylori* negative, while 10 patients were still infected. After eradication of *H pylori*, the positivity of Bax protein expression significantly decreased in *H pylori*-positive gastric precancerous lesions (42.3% *vs* 70.3%, $P<0.05$). In the persisting *H pylori*-infected patients, the positivity of Bax protein expression was not changed.

Table 1 Relationship between *H pylori* infection and Bax protein expression in gastric precancerous lesions

H pylori	*n*	Bax protein expression				Positive rate (%)
		-	+	++	+++	
Positive	47	13	15	10	9	72.3[a]
Negative	25	13	6	4	2	48.0

[a]$P<0.05$ *vs* negative.

DISCUSSION

The development of gastric carcinoma involves a multistep process from chronic gastritis to atrophy gastritis, intestinal metaplasia, and gastric dysplasia. It has been shown that atrophic gastritis with intestinal metaplasia and dysplasia significantly increased the risk of gastric carcinoma, and *H pylori*-induced gastritis is significantly more pronounced in gastric carcinoma

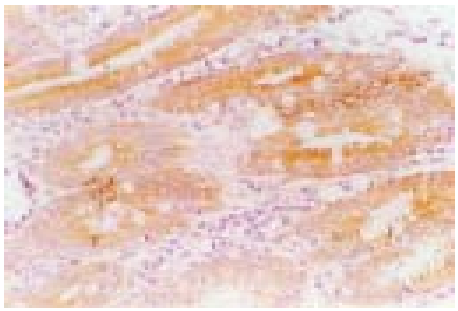

Figure 1 Staining of Bax protein located in the cytoplasm of gastric epithelium of intestinal metaplasia (SP ×200).

patients. Cell proliferation and apoptosis are essential events in the cellular turnover of gastric tissues. Not only excessive cell proliferation, but also abnormal apoptosis occur in the process of gastric carcinogenesis. The excessive cell proliferation and/or decreased cell apoptosis seem to be the biological basis of gastric carcinogenesis[5-8]. *H pylori* infection is an established risk factor for gastric cancer, and has been classified as a group I carcinogen[1,2]. Our previous studies demonstrated that *H pylori* infection not only increased gastric epithelial cell proliferation, but also induced apoptosis of gastric epithelial cells. *H pylori* infection brings about disorders between gastric epithelial cell proliferation and apoptosis, thereby increasing the risk of gastric carcinogenesis[4,7]. Although it is fairly well accepted that *H pylori* infection plays a significant role in gastric carcinogenesis, the exact mechanisms through which *H pylori* increases gastric epithelial cell proliferation and apoptosis are not completely understood to date.

Genetic control of apoptosis and cell survival play a crucial role in tumor growth. Among the molecules related to the apoptotic process, Bcl-2 family proteins are important and critical regulators in a variety of physiological and pathological contexts. Bcl-2 and Bax are members of the Bcl-2 family. Bcl-2 prevents cells from death through a variety of mechanisms, whereas overexpression of Bax protein increases the susceptibility of cells to apoptosis. Although Bax and Bcl-2 have different functions, they share similar structures. Bax is a homolog protein of Bcl-2 and possesses two conserved regions, BH1 and BH2 that appear to be important for Bax/Bcl-2 binding. Bax and Bcl-2 may form homodimers (Bax/Bax, or Bcl-2/Bcl-2) or heterodimers (Bax/Bcl-2). The ratio of Bcl-2 to Bax proteins appeared to control the relative sensitivity or resistance of many types of cells to apoptotic stimuli[9,10]. The Bcl-2 protein has been shown to prevent apoptosis and may play an important role in the regulation of gastric cancer growth. In this study, we have examined the relationship between *H pylori* infection and Bax protein expression in the precursor lesions of gastric cancer. Bax protein was differently expressed in intestinal metaplasia and gastric dysplasia. The positivity of Bax protein expression in *H pylori*-positive gastric precancerous lesions was significantly higher compared to the *H pylori*-negative gastric precancerous lesions. *H pylori* infection was well correlated with expression of Bax protein in gastric precancerous lesions. After eradication of *H pylori*, the positivity of Bax protein expression significantly decreased in *H pylori*-positive gastric precancerous lesions. However, in the persisting *H pylori* infected patients, the positivity of Bax protein expression was not changed. Thus, our results demonstrated that *H pylori* infection might increase Bax protein expression in intestinal metaplasia and gastric dysplasia, suggesting one of the mechanisms of *H pylori*-induced gastric epithelial cell apoptosis. However, the mechanism for the stimulation of Bax protein accumulation is still unknown and is not resolved by this study. Several studies have suggested that *H pylori* produces various toxins, and gastric mucosa can increase some cytokines, nitrous oxide synthase and oxygen radicals released after *H pylori* infection. At the same time, *H pylori* infection can lower the gastric antioxidant ability. All those factors damage DNA or enhance the susceptibility of DNA damage and gene mutation[11-12].

In conclusion, *H pylori* infection seems to be responsible for genomic instability in a subset of cases of *H pylori*-positive chronic atrophic gastritis and precancerous lesions like metaplasia and dysplasia. Our study suggests that patients with precancerous lesions should receive treatment for eradication of *H pylori*, which may correct the abnormal expression of Bax protein, reduce gastric epithelial-cell proliferation and apoptosis, thereby decreasing the subsequent risk of gastric carcinogenesis. Additional epidemiological studies need to elucidate whether prevention of gastric cancer is possible with the eradication of *H pylori*.

Abstract

AIM: To investigate the effects of isolation stress on mouse with liver cancer and possible associated mechanisms.

METHODS: Transplantable murine hepatoma22 (H22) model was used to evaluate the effects of social isolation stress on murine liver cancer. Mice were immunized with sheep red blood cell (SRBC) and intraperitoneally inoculated with H22 cell, then divided into two groups, one reared individually as group (I) and the other reared in groups as group (G). Titer of antibody to SRBC and interleukin 2 (IL-2) in serum was monitored. The survival time of mouse with liver cancer was observed.

RESULTS: The titer of antibody to SRBC in group (G) was 1:24.5 and that in group (I) was 1:11.2. There was a significant difference between these two groups (t = 2.60, P = 0.02). A significant difference in IL-2 concentration was observed between group (G) (39.6 ng/L) and group (I) (47.1 ng/L, t = 2.14, P = 0.046). The survival time in group (G) (16.5 d) was markedly longer than that in group (I) (13.2 d, t = 3.46, P = 0.002).

CONCLUSION: Our study suggests that survival time of the mouse bearing H22 tumor is affected by the social isolation stress and the associated mechanism may be the immunological changes under the social isolation stress.

INTRODUCTION

In humans, stressful life events have been shown to play a role in increased cancer risk and metastasis[1-3]. However, a number of studies have reported little or no support for the association among stressful life events, coping, biological changes, and cancer progression. The complex relationships between psychosocial stressors and the progression of cancer are difficult to investigate in humans because a number of issues, such as the stage of treatment in which the patients are examined as well as tumor and host factors, may affect interpretation of the data. Animal models allow investigation of the relationship among stressors, coping mechanisms, and tumor growth under more controlled conditions. In animals, psychosocial stressors such as housing condition and psychological stressors such as forced restraint and rotation have been shown to affect tumor growth rates or metastasis of both transplantable and chemically induced tumors[4,5].

There are now some evidences in animals and humans that psychological stress may affect many aspects of the integrative network among the central nervous system, endocrine system and immune system. The complex effects of psychological stress on the interactions among these three systems have been subject to study in the developing field of psychoneuroendocrinoimmunology. There is a large body of literature on the effects of psychological stress on immune function in humans[6-8]. Supposing that immunological changes play an important role in the survival time of mouse with liver cancer under the social isolation stress, we designed this experiment to understand the association among isolation stress, immunological response, and survival time of mouse with liver cancer.

MATERIALS AND METHODS

Animal management

Mice (KM strain, 18-22 g) were used for this study. All mice were offered the same commercial diet and tap water *ad libitum* in a temperature-controlled (22 ℃) holding room.

Immunization with SRBC

Each male mouse was injected intraperitoneally with 0.2 mL of 200 mL/L sheep red blood cell (SRBC). On the 10^{th} d, blood samples were obtained by decapitation and sera were prepared by routine methods.

Inoculation with tumor cell

After 2 d, male mice were inoculated intraperitoneally with liver cancer cells (5×10^4 cells/mouse) obtained from murine hepatoma22 (H22).

Grouping

One male mouse with two females, avoiding aggression, was reared in the same cage (21 cm×32 cm×14 cm) with wood shavings for group (G) or society group. One male

mouse reared individually in each cage to induce stress by isolation condition for group (I) or isolation group. Half of them were used to detect immunological parameter on the 10th d and the other half were used to observe survival time.

Detection of anti-SRBC antibody[9]

Normal saline (25 μL) was added in each cup of microtiter plate, and then was the sera (25 μL) in the first cup, followed by doubling dilution. After incubation with 10 mL/L SRBC (25 μL) for 1 h at 37 ℃, titers of the antibody were determined by the maximum dilution when the cells form a continuous carpet on the base of the cup.

Detection of interleukin-2 (IL-2)

Concentrations of IL-2 in sera were measured with ELISA kit (Jingmei Biotech Co., Ltd). All the procedures and conditions were consistent with the instructions of the kit.

Statistical analysis

Using Student's *t*-test with statistics package SPSS10.0, the differences in the survival time and titers of anti-SRBC antibody as well as concentration of IL-2 from isolation and society mice were evaluated. Differences were considered statistically significant at *P* values <0.05.

RESULTS

Survival time of mouse with liver cancer is shown in Table 1. There was a significant difference in survival time between the two groups ($P<0.01$).

Table 1 Survival time of mice of two groups (mean±SD)

Groups	*n*	mean±SD (d)	*t*	*P*
Society	12	16.5±2.7	3.46	0.002
Isolation	12	13.2±1.9		

Quantities of anti-SRBC antibody are shown in Table 2. The titers were converted to logarithms for analysis. We observed a significant difference in anti-SRBC antibody titers between the society and the isolation groups ($P<0.05$).

Table 2 Titers of anti-SRBC antibody

Groups	*n*	Titers	Ig, mean±SD	*t*	*P*
Society	10	1:24.5	1.39±0.38	2.60	0.02
Isolation	10	1:11.2	1.05±0.16		

Quantities of IL-2 in sera are shown in Table 3. Serum IL-2 of the mice in the society group was significantly lower compared to the isolation group ($P<0.05$).

Table 3 Concentrations of serum IL-2

Groups	*n*	mean±SD (ng/L)	*t*	*P*
Society	10	39.6±6.3	2.14	0.046
Isolation	10	47.1±9.1		

DISCUSSION

The effects of psychic factors on somatic diseases and rehabilitation have been more and more appreciated. Several clinical reports have demonstrated that psychic influences work on human bodies mainly through immune system[10-12]. However, many interfering factors in experiments on humans, especially on psychic activities, impair the rigor of the results, and retard further studies. Therefore, we used mice for this experimentation.

Ever since the introduction of the concept of the "animal model" into psychiatric medicine, various experimental models have been applied to clinic oncology trying to reveal the different effects of various psychic states on patient with cancer[4,5,13,14]. Mice are social or gregarious animals; so living alone will leave stressful effects on mice, while living in a society with appropriate sex ratio will not[15]. Our results showed that survival time of mouse with liver cancer in the society group was significantly longer than that in the isolation group ($P<0.01$, Table 1), suggesting that survival time of the mouse bearing H22 tumor was affected by the isolation stress.

Stressor-induced changes in hormones and cytokines have been demonstrated in various studies[6-8]. Our results revealed that the immune response to SRBC of mice in the isolation group was significantly lower than that of the mice in society group ($P<0.05$, Table 2), while IL-2 showed the opposite change ($P<0.05$, Table 3). Thus, differential immune activity in mice in the different experimental housing conditions could alter survival time of mouse with liver cancer.

IL-2 is an important immunoregulatory factor[16,17]. In our experiment, the average serum level of IL-2 in the isolation group mice was obviously higher than that in society group mice, which might be due to the compensative increase of IL-2 to maintain the necessary immune response under stress of social isolation. Even in animal models, data are complex, factors such as the type of tumor, strain or the species have been shown to influence results, and the mechanisms underlying the differential biological change under the stress may also be mediated in survival time of liver cancer. However, further studies are needed for the detailed psychoimmunological pathway and regulation.

Abstract

AIM: To analyze the clinical features, management, and outcome of treatment of patients with primary intestinal and colonic non-Hodgkin's lymphoma (PICL).

METHODS: A retrospective study was performed in 37 patients with early-stage PICL who were treated in our hospital from 1958 to 1998. Their clinical features, management, and outcome were assessed. Prognostic factors for survival were analyzed by univariate analysis using the Kaplan-Meier product-limit method and log-rank test.

RESULTS: Twenty-five patients presented with Ann Arbor stage I PICL and 12 with Ann Arbor stage II PICL. Thirty-five patients underwent surgery (including 31 with complete resection), 22 received postoperative chemotherapy or radiotherapy or both. Two patients with rectal tumors underwent biopsy and chemotherapy with or without radiotherapy. The 5- and 10-year overall survival (OS) rates were 51.9% and 44.5%. The corresponding disease-free survival (DFS) rates were 42.4% and 37.7%. In univariate analysis, multiple-modality treatment was associated with a better DFS rate compared to single treatment (P = 0.001). While age, tumor size, tumor site, stage, histology, or extent of surgery were not associated with OS and DFS, use of adjuvant chemotherapy significantly improved DFS (P = 0.031) for the 31 patients who underwent complete resection. Additional radiotherapy combined with chemotherapy led to a longer survival than chemotherapy alone in six patients with gross residual disease after surgery or biopsy.

CONCLUSION: Combined surgery and chemotherapy is recommended for treatment of patients with PICL. Additional radiotherapy is needed to improve the outcome of patients who have gross residual disease after surgery.

INTRODUCTION

Primary intestinal and colonic non-Hodgkin's lymphoma (PICL) is an extra-nodal gastrointestinal (GI) lymphoma, which is less common than gastric lymphoma. In fact, the clinical features and treatment of patients with the disease in these two locations are different. Patients with PICL generally have a lower survival rate than those with gastric lymphoma and the best management is yet to be developed [1]. The role of surgery, chemotherapy, and radiotherapy in patients with PICL has not been defined. This study was to evaluate the clinical features, management and outcome of patients with PICL.

MATERIALS AND METHODS

During the period between 1958 and 1998, 37 patients with early-stage PICL were treated in our institution. Staging was based on physical examination, blood cell count, blood chemistry, chest X-ray or chest computed tomography (CT), ultrasonograms or CT of the abdomen. Some patients whose tumor was located in the colon or rectum underwent colonoscopy and biopsy or received an air-contrast barium enema. Bone marrow biopsy was performed for 22 patients. All diagnoses were confirmed by histology showing non-Hodgkin's lymphomas (NHLs). Immunophenotyping was performed in 34 patients, all showing B-cell origin. PICL was staged using the Ann Arbor classification system and graded according to the National Cancer Institute's Working

Formulation.

Surgery included tumor plus partial intestine or colon resection and tumor resection only. The chemotherapy regimens consisted of cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP); bleomycin, epirubicin, cyclophosphamide, vincristine, and prednisone (BACOP); or cyclophosphamide, vincristine, and prednisone (COP). Treatment ranged from 1 to 9 courses (median, 5 courses). Radiotherapy was administered to the whole abdomen and the whole pelvis in 11 patients, to the whole pelvis or lower abdomen in 3 patients (1 patient had rectal, 1 had ascending colonic, and 1 had ileocecal lymphoma). No details were available for one patient. The median abdominal dose was 40 Gy (range, 26-45 Gy), and the median pelvic or lower abdominal dose was 40 Gy (range, 26-50.5 Gy). ^{60}Co γ, 6 MV X, or 8 MV X-rays were used to deliver irradiation. The dose per fraction varied from 1.5 to 2.0 Gy.

Follow-up evaluation included patient history, physical examination, blood cell count, blood chemistry analysis, reviews of chest X-ray films, and abdominal ultrasonograms, air-contrast barium enema, and/or endoscopic evaluation, CT of the abdomen. We obtained follow-up data from the hospital charts, reports from the local hospitals mailed to our hospital, forms filled in by patients and their local physicians, or telephone calls. OS was calculated from the date of treatment to death or to the date of last contact. DFS was calculated from the date of treatment to the date of disease relapse. Kaplan-Meier method was used to calculate the duration of survival, the difference in survival between groups was compared by log-rank test.

RESULTS

Clinical features

Patients including 27 males and 10 females ranged in age from 5 to 68 years (median, 42 years). The primary sites of tumor involvement were the ileocecal region in 20 patients, the ascending colon in 9, the ileum in 4, the rectum in 3, and the jejunum in 1. The median tumor size was 6 cm, ranging 1.8-22 cm. The most frequent symptom was abdominal pain (n = 26, 73%), for which five patients required emergency surgery, followed by abdominal mass (n = 17, 46%), intestinal bleeding (n = 8, 22%), and bowel obstruction (n = 2, 5%). According to the National Cancer Institute Working Formulation, PICL was classified in 24 patients as high-grade, low-grade in 7, and unknown in 6. Twenty-five patients had stage I PICL and 12 had stage II PICL based on the Ann Arbor staging system.

Treatment

Thirty-five patients underwent surgery (Table 1). Thirteen patients who underwent a complete tumor resection had surgery alone, 22 patients received postoperative chemotherapy and/or radiotherapy (Table 1). Two patients with rectal tumors had biopsy during colonoscopy: one received chemotherapy alone and the other received chemotherapy plus radiotherapy.

Table 1 Surgical and post-surgical treatment of 35 patients with PICL

Characteristics	*n*
Surgery result	
Complete resection	31
Gross residual disease	4
Post-surgical treatment	
Complete resection plus radiotherapy	8
Complete resection plus chemotherapy	6
Complete resection plus chemotherapy and radiotherapy	4
Incomplete resection plus chemotherapy	2
Incomplete resection plus chemotherapy and radiotherapy	2

Outcome

The median follow-up time was 17 mo for all patients and 45 mo for the surviving patients (range, 2-164 mo). The 5-year OS rate was 51.9%, the 10-year OS rate was 44.5%. The 5-year DFS rate was 42.4% and the 10-year DFS rate was 37.7% (Figure 1). Among the 21 patients who had relapse, 13 had loco-regional relapse, 4 had relapse at distant sites, and 4 had relapse at both loco-regional and distant sites. Among the 16 patients who received salvage therapy, 6 survived for 2, 3, 11, 71, 74, and 91 mo respectively, after disease relapse. Among the 14 patients who died, 12 died of lymphoma, 1 of cerebral arterial rupture, and 1 of hepatic failure due to hepatitis.

Univariate analysis showed that multiple modality treatment (surgery plus chemotherapy, surgery plus radiotherapy, surgery plus chemotherapy and radiotherapy, chemotherapy and radiotherapy) achieved a higher DFS rate than single

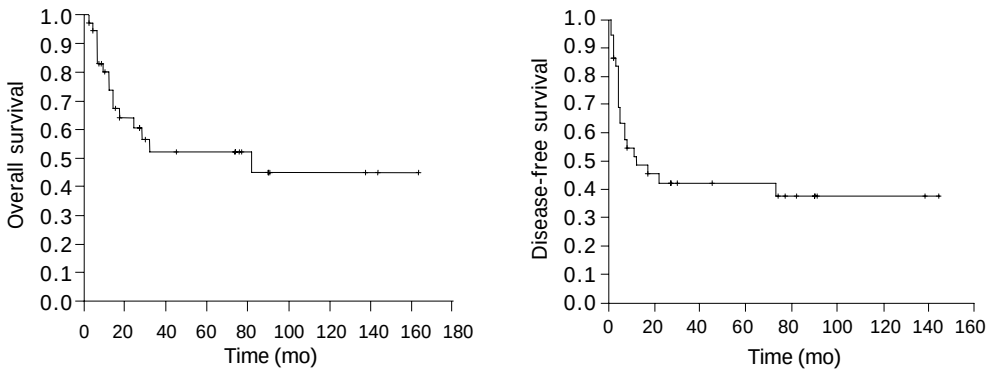

Figure 1 OS and DFS curves for 37 patients with early stage primary intestinal and colonic lymphomas.

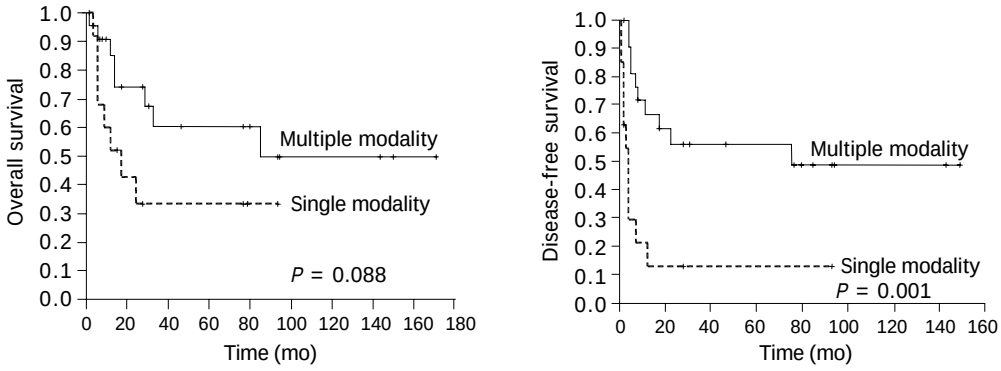

Figure 2 OS and DFS curves for 37 patients stratified by treatment.

modality therapy (surgery and chemotherapy alone, $P = 0.001$, Figure 2), and a higher OS rate than single modality therapy but the difference was not significant ($P = 0.088$). Other factors including age, tumor size, histology, tumor site, stage, and extent of surgery had no significant correlation with survival probability (Table 2).

In respect to the 31 patients who underwent complete tumor resection, there was a significant difference in DFS rates between patients who received chemotherapy and those who did not. The 5-year DFS rates were 68.6% and 27.2% respectively, being in favor of the chemotherapy group ($P = 0.031$). The 5-year OS rate was 70.0% for patients treated with chemotherapy and was 45.3% for patients without chemotherapy ($P = 0.062$, Figure 3). Postoperative radiotherapy tended to improve DFS but not OS. The 5-year DFS rates were 54.6% and 34.0% ($P = 0.087$), while the 5-year OS rates were 54.1% and 51.4% for patients with and without radiotherapy, respectively ($P = 0.831$).

Among the four patients with gross residual tumors after surgery and the two patients who underwent biopsy only, three patients received combined chemotherapy and radiotherapy and three patients received chemotherapy alone. The three patients who received chemotherapy alone had relapse 5, 12, and 22 mo after treatment and died of lymphoma 12, 17, and 28 mo after treatment. However, the three patients who received additional radiotherapy besides chemotherapy had no evidence of relapse 45, 91, and 144 mo after treatment.

DISCUSSION

This retrospective analysis of 37 patients with PICL showed the clinical features of PICL. It was reported that primary intestinal lymphoma accounts for 18.9-62.2% of all primary GI NHLs, and the most frequent sites of origin are the small bowel or ileocecal region, followed by the colon, rectum, and duodenum[2,3]. Most are classified as high-grade NHL. The main symptoms are pain, occult loss of blood or macroscopic bleeding, palpable abdominal mass, bowel

Multiple modality	23	57.8 (10)		61.9 (8)	

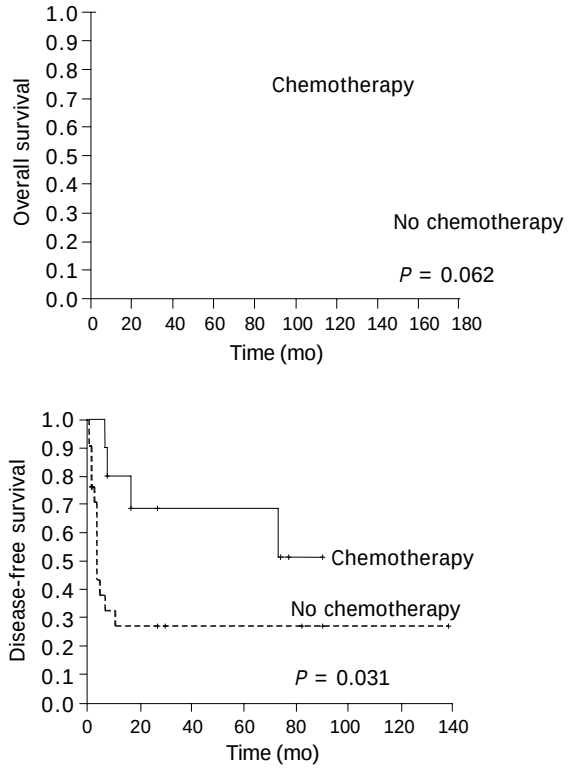

Figure 3 OS and DFS curves for 31 patients after complete surgery stratified by chemotherapy.

obstruction, and perforation. These symptoms occur more frequently in patients with intestinal NHL than in those with gastric NHL, and emergency surgery is necessary for some cases[4,5]. Prognostic factors include advanced disease stage[6], intestinal perforation[7,8], high grade histology[9], and T-cell lymphoma[10,11], which are associated with a lower survival rate. In our study, no patients had T-cell lymphoma. Due to the small number of patients, we did not detect any influence of stage, histological subtype, or sites of origin on the survival time.

Surgery plays an important role in the treatment of PICL. Emergency surgery is required in some cases to reduce the risk of complications and to improve the symptoms such as obstruction or bleeding. Most importantly, surgery can improve the survival of patients with PICL. It was reported that surgical resection is the only statistically significant prognostic variable for patients with intestinal lymphoma[12]. The favorable effects of debulking surgery (partial or complete resection) on OS and DFS were also emphasized[13]. It was reported that the 5-year survival rates were 46% and 0% for patients after radical resection and non-radical resection, respectively[14]. Jinnai *et al*.[15], found that the 5-year survival rate was 44.2% for patients with malignant lymphoma after curative resection, while none survived 5 years after non-curative resection. In our study, surgery was the primary treatment for almost all patients except for two patients with rectal tumor, and the 5-year OS rate was 51.9%. The extent of surgery did not affect survival, because all patients after incomplete surgery received chemotherapy or radiotherapy, or both, suggesting that multiple-modality treatment confer a superior survival advantage over surgery alone or chemotherapy alone.

Chemotherapy significantly improved the DFS rate of patients after complete surgical resection in our study, which is consistent with the reported findings[16]. The efficacy of surgery-chemotherapy combination has been confirmed by other studies[17-19].

In conclusion, surgery is the primary diagnostic and treatment modality for PICL, chemotherapy is necessary for improving the survival of PICL patients, and radiotherapy affords additional benefits to patients with gross residual disease after surgery.

Abstract

AIM: To study the growth inhibitory effects of ATP on TE-13 human squamous esophageal carcinoma cells *in vitro.*

METHODS: MTT assay was used to determine the inhibition of proliferation of ATP or adenosine (ADO) on TE-13 cell line. The morphological changes of TE-13 cells induced by ATP or ADO were observed under fluorescence light microscope by acridine orange (AO)/ethidium bromide (EB) double stained cells. The internucleosomal fragmentation of genomic DNA was detected by agarose gel electrophoresis. The apoptotic rate and cell cycle after treatment with ATP or ADO were determined by flow cytometry.

RESULTS: ATP and ADO produced inhibitory effects on TE-13 cells at the concentration between 0.01 and 1.0 mmol/L. The IC_{50} of TE-13 cells exposed to ATP or ADO for 48 and 72 h was 0.71 or 1.05, and 0.21 or 0.19 mmol/L, respectively. The distribution of cell cycle phase and proliferation index (PI) value of TE-13 cells changed, when being exposed to ATP or ADO at the concentrations of 0.01, 0.1, and 1 mmol/L for 48 h. ATP and ADO inhibited the cell proliferation by changing the distribution of cell cycle phase via either G_0/G_1 phase (ATP or ADO, 1 mmol/L) or S phase (ATP, 0.1 mmol/L) arrest. Under light microscope, the tumor cells exposed to 0.3 mmol/L ATP or ADO displayed morphological changes of apoptosis. A ladder-like pattern of DNA fragmentation was obtained from TE-13 cells treated with 0.1-1 mmol/L ATP or ADO in agarose gel electrophoresis. ATP and ADO induced apoptosis of TE-13 cells in a dose-dependent manner at the concentration between 0.03 and 1 mmol/L. The maximum apoptotic rate of TE-13 cells exposed to ATP or ADO for 48 h was 16.63% or 16.9%, respectively.

CONCLUSION: ATP and ADO inhibit cell proliferation, arrest cell cycle, and induce apoptosis of TE-13 cell line.

INTRODUCTION

Extracellular ATP and adenosine (ADO) are important signaling molecules in both intracellular and extracellular microenvironments of cells. Though the regulatory control is exerted by ectonucleotidases, which maintain its low physiologic concentrations, extracellular ATP may reach high concentrations when released exocytotically from various cell types such as neurons, platelets, basophils, and mast, or when released nonexocytotically from damaged cells[1]. Since the pioneering work of Rapaport and Fontaine[2,3] showing the anticancer activities of extracellular adenine nucleotides on tumor, inhibitory effects of extracellular ATP have been described in the majority of cells and tissues studied so far, including human histiocytic leukemia cell line U-937[4], macrophages[5], mouse neuroblastoma cell line N1E-115[6], pancreatic cancer cells[7], endothelial cells[8], pulmonary artery endothelial cells[9], colorectal carcinoma cells[10], prostate carcinoma cells[11], murine dendritic cells, etc.[12-16]. But in other cell lines, such as human ovarian tumor cells and breast tumor cells, ATP shows opposite effects[17,18]. Recently, Maaser *et al*.[19], reported that extracellular nucleotides inhibit growth of moderately differentiated human esophageal cancer cells. However, the effects of ATP on poorly differentiated esophageal cancer cells have not been reported. In this study, we observed the growth inhibitory and apoptotic effects of ATP and its final metabolite, ADO, on poorly-differentiated human TE-13 esophageal cancer cells.

MATERIALS AND METHODS

Drugs and reagents

ATP, ADO, acridine orange (AO), ethidium bromide (EB), 3-(4,5-dimethyiazol-2-yl)-2, 5-diphenyl tetrazolium bromide (MTT) were purchased from Sigma. RNase, SDS, proteinase K, trypsin and agarose were from Sino-American Biotec Co., RPMI 1640 medium was from GIBCO, and fetal bovine serum (FBS) was from Hangzhou Sijiqing Biotec Co. ATP and ADO were dissolved in sterile PBS, and stored at -20 ℃.

Cell culture

Human esophageal carcinoma TE-13 cells, obtained from Japanese Cancer Cell Database, were cultured in RPMI 1640 medium supplemented with 100 mL/L FBS, 100 U/mL penicillin, and 100 μg/mL streptomycin at 37 ℃ in a humidified CO_2-controlled (50mL/L) incubator.

MTT assays

The cell viability was determined by MTT assay[20]. TE-13 cells in exponential phase of growth were harvested and seeded in 96-well plates (Costar, USA) at a density of 10 000 cells/well, and cultured for 24 h. ATP or ADO (0.01, 0.03, 0.1, 0.3, and 1 mmol/L), and control (PBS) were added into the wells and incubated continuously for 48 or 72 h at 37 ℃ with 50 mL/L CO_2. The drugs were added daily and replaced with fresh medium every 2 d. A 20-μL sample of MTT solution (5 g/L dissolved in PBS) was added to each well and the plates were incubated at 37 ℃ for 4 h. The supernatant was discarded and 150 μL dimethylsulfoxide was added to dissolve the blue insoluble MTT formazan produced by mitochondrial succinate dehydrogenase. The absorbance was measured at 492 nm in a spectrophotometer (Zhengzhou Bosai Biotech Co., ht2010), and the negative control well contained only the medium. The percentage of viable cells was calculated as the relative ratio of their absorbances to the control. All determinations were performed in quadruplicate and each experiment was repeated at least thrice.

Morphological assessment of apoptotic cells induced by ATP or ADO

Morphological assessment of apoptotic cells was performed using the AO/EB double staining method[21]. TE-13 cells in exponential phase of growth were harvested and seeded in a 25-mL cultured flask. The cells were incubated for 24 h at 37 ℃ with 50 mL/L CO_2, and then treated with 0.3 mmol/L ATP or ADO for 48 h. Freshly isolated TE-13 cells (1×10^6) were harvested in an Ependorf centrifuge tube, centrifuged for 5 min at 1 000 r/min and suspended in PBS containing fluorescence dye AO/EB (both AO and EB were at the concentration of 100 mg/L in PBS). The cells were prepared, and dropped on slides. The morphology of the cells was observed under fluorescence light microscope (UFX-II; Nikon, Japan) and photographed.

Agarose gel electrophoresis of DNA[22]

After treatment with ATP or ADO (0.1, 0.3, and 1 mmol/L) for 72 h, TE-13 cells (1×10^6) were harvested in an Ependorf centrifuge tube and washed twice with PBS. The cells were resuspended in a cell lysis buffer (50 mmol/L Tris-HCl buffer, 20 mmol/L EDTA, pH 8.0, 1% SDS) and then mixed by vortexing briefly. After the cells stood for 30 min on ice, proteinase K was added at a final concentration of 0.25 g/L. The cell lysates were incubated at 37 ℃ overnight in a water bath, and RNase was added at a final concentration of 0.5 g/L and incubated at 37 ℃ for 1 h. The lysates were mixed with an equal volume of Tris-saturated phenol–chloroform (1:1, v/v) and mildly shaken for 30 min, and the mixture was centrifuged at 3 000 r/min for 10 min at room temperature to separate the aqueous phase from the organic phase. Extraction of each aqueous phase was repeated using the Tris-saturated phenol-chloroform-isopropanol (25:24:1, v/v/v) mixture, and the aqueous phase was further extracted with an equal volume of chloroform. Mixing with 2 volumes of ice-cold ethanol and 0.1 volume of 3 mol/L NaAc precipitated DNA in the final aqueous phase. At this point, the mixture could be stored overnight. DNA was recovered by centrifugation at 13 000 *g* for 20 min in an Ependorf centrifuge tube. The supernatant was discarded, the DNA pellet was washed once with 70% ethanol, air-dried, and then redissolved in an appropriate volume of deionized distilled water and electrophoresed for 3 h at a constant voltage of 60 mV on an 1.8% agarose gel containing 0.5 mg/L EB, using an electrophoresis buffer (40 mmol/L Tris/acetate buffer, 1 mmol/L EDTA, pH 8.0). Each DNA sample contained bromophenol blue as a front-running dye. Ladder formation of oligonucleosomal DNA was made visible by an ultraviolet transillumination and photographed using a gel imaging system (PE Co., USA).

Determination of apoptosis by flow cytometric analysis

After the cells were incubated with different concentrations of ATP or ADO for 48 h, they were harvested by centrifugation, washed with ice-cold PBS once and fixed in 70% ethanol at 4 ℃ overnight. The cells were then washed once with ice-cold PBS and resuspended in PBS (pH 7.4) containing 0.5% pepsin, 5 mg/L EB and RNase at room temperature for 30 min. Finally, cells were analyzed by flow cytometry on a FACS420 (Becton Dickinson Corporation, USA), equipped with an argon ion laser (488 nm), using the HP-300 Consort 30 software to determine percentage of the apoptotic cells and the proportion of cells in G_0/G_1, S, G_2/M phases of cell cycle. The proliferation index (PI) of cells was calculated by the following formula:

$$PI\ (\%) = ([S+G_2/M]/[G_0/G_1+S+G_2/M])\times100\%.$$

Statistical analysis

The data shown were mean values of at least three independent experiments and expressed as mean±SD. Statistical comparisons were made by ANOVA. $P<0.05$ was considered statistically significant.

RESULTS

Inhibitory effects of ATP or ADO on TE-13 cell proliferation

The proliferation of TE-13 cells was significantly inhibited in a dose- and time-dependent manner, by 0.01-1.0 mmol/L of ATP or 0.3-1.0 mmol/L of ADO for 48 h of incubation, as well as 0.01-1.0 mmol/L of ADO for 72 h of incubation. The inhibitory fraction of TE-13 cells exposed to ATP and ADO for 48 and 72 h was 59.6% and 46.5%, and 80.5% and 74%, respectively (Figures 1A and B). The IC_{50} of TE-13 cells exposed to ATP or ADO for 48 and 72 h was 0.71 or 1.05 mmol/L, and 0.21 or 0.19 mmol/L, respectively.

Effects of ATP or ADO on cell cycle and proliferation index (PI) of TE-13 cells

The cell cycle phase and PI value of TE-13 cells changed when exposed to ATP or ADO at the concentrations of 0.01, 0.1, 1 mmol/L for 48 h. The proportion of cells in

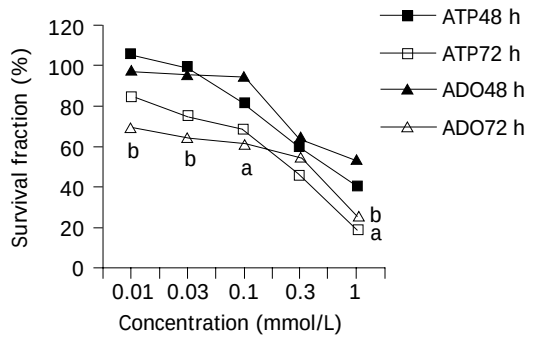

Figure 1 Effects of various concentrations of ATP or ADO on survival fraction of TE-13 cells. [a]*P*<0.05, [b]*P*<0.01 *vs* 48 h groups.

the S phase of cell cycle significantly increased, and that of the G_0/G_1, G_2/M phases and PI value did not alter after sustained incubation of TE-13 cells with ATP (0.1 mmol/L). In contrast, when exposed to ATP or ADO at the concentration of 1 mmol/L, the proportion of cells in the G_0/G_1 phase of cell cycle significantly increased, while that in the S phase of cell cycle and PI value significantly decreased. In accordance with cell proliferation results, neither the cell cycle phase nor PI value changed when exposed to ATP or ADO at the concentration of 0.01 mmol/L. The proportion of cells in G_2/M phase when exposed to ATP at various concentrations did not alter, but that significantly decreased when exposed to ADO at the concentration of 1 mmol/L. These results showed that ATP and ADO inhibited the cell proliferation by changing the distribution of cell cycle phase via either S phase delay (ATP, 0.1 mmol/L) or G_0/G_1 phase delay (ATP and ADO, 1 mmol/L, Table 1 and Figures 2A and B).

Table 1 Effects of ATP or ADO on PI value of TE-13 cells (*n* = 3, mean±SD)

Concentration (mmol/L)		PI (%)
ATP	0	37.57±2.02
	0.01	39.17±3.65
	0.1	31.24±1.04[a]
	1.0	28.69±1.33[a]
ADO	0	36.85±1.15
	0.01	29.91±1.78
	0.1	32.34±3.39
	1.0	21.76±5.20[b]

[a]*P*<0.05, [b]*P*<0.01 *vs* control group.

Morphological changes of TE-13 cells induced by ATP or ADO

Under fluorescence light microscope, the tumor cells exposed to 0.3 mmol/L ATP or ADO displayed morphological changes of apoptosis by AO/EB double staining, such as cell shrinkage, chromatin condensation, cell nuclear fragmentation, cell nucleolus disappearance, increased nuclei fluorescence or labeled orange or red-orange color (Figures 3A-C).

Agarose gel electrophoresis results of TE-13 cells induced by ATP or ADO

By agarose gel electrophoresis, a ladder-like pattern of DNA fragmentation was obtained from TE-13 cells treated with 0.1-1 mmol/L ATP or ADO, indicating that ATP or ADO induced apoptosis of TE-13 tumor cells (Figures 4A and B).

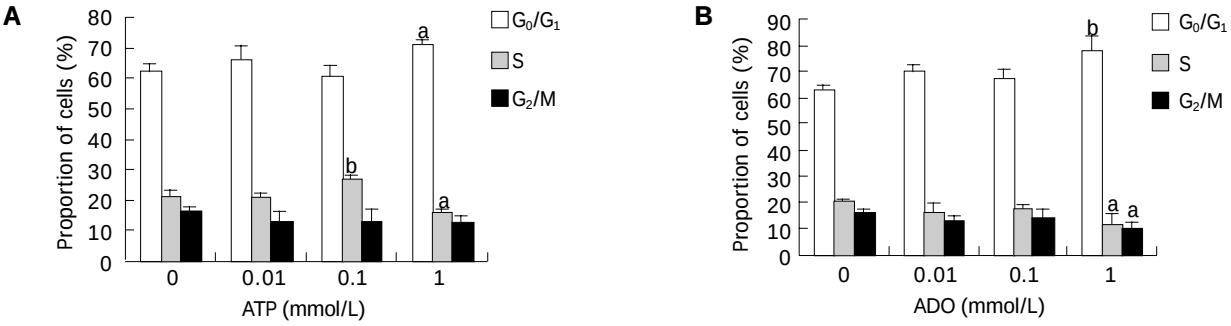

Figure 2 Effects of ATP (A) and ADO (B) on cell cycle of TE-13 cells (*n* = 3). [a]*P*<0.05, [b]*P*<0.01 *vs* 0 mmol/L.

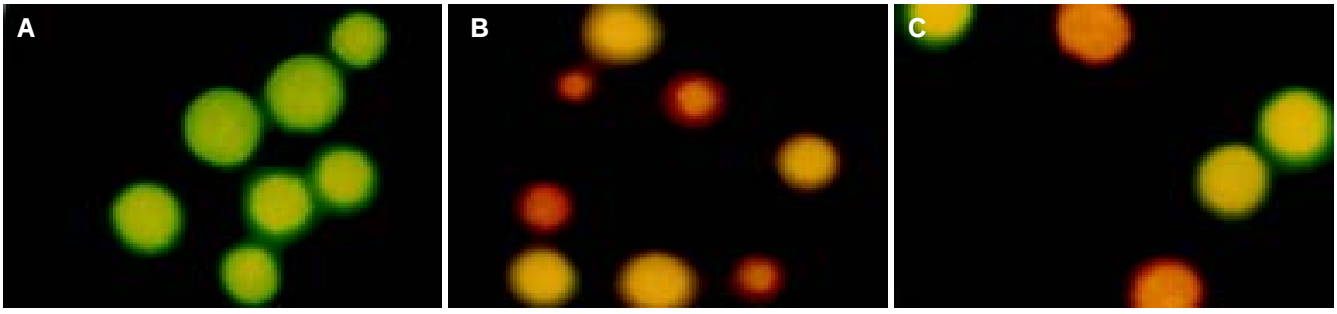

Figure 3 Fluorescence micrographs of TE-13 cells incubated for 48 h without treatment (A) and treated with ATP (B) or ADO (C) (×400).

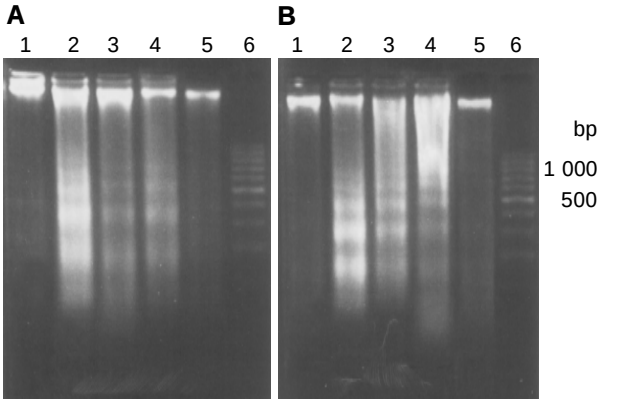

Figure 4 Agarose gel electrophoresis of DNA extracted from apoptotic TE-13 cells treated with ATP (A) or ADO (B) for 72 h. Lane 1: control; lanes 2-5: 1, 0.3, 0.1, and 0.03 mmol/L, respectively; lane 6: marker.

Apoptotic rate of TE-13 cells induced by ATP or ADO

ATP or ADO induced apoptosis of TE-13 cells in a dose-dependent manner at the concentration between 0.03 and 1 mmol/L for 48 h. The apoptotic rate of TE-13 cells treated with ATP or ADO was markedly higher than that of the control. The maximum apoptotic rate of TE-13 cells exposed to ATP or ADO (1 mmol/L) for 48 h was (16.6±1.1)% or (16.9±1.2)%, respectively (Table 2 and Figures 5A-C).

Table 2 Apoptosis of TE-13 cells induced by extracellular ATP or ADO (n = 3, mean±SD)

Concentration (mmol/L)		Apoptotic rate (%)

DISCUSSION

ATP and related compounds are widespread transmitters for extracellular communication in many cell types. By coupling to specific purinergic receptors, ATP is involved in a large variety of cellular functions. Receptors for purines and pyrimidines (P receptor) are divided into two major classes termed as ADO or P1 receptors at which ADO is the principal natural ligand, and P2 receptors at which ATP, ADP, UTP, and UDP are the principal natural ligands. To date four P1 receptor subtypes have been identified (A1, A2a, A2b, and A3), all of them are coupled to G proteins with distinct tissue distribution and pharmacological properties. The P2 receptors are divided into two families: the ligand-gated ion channels (P2X) and the G protein-coupled receptors (P2Y)[23-25]. ATP can inhibit cancer growth, induce apoptosis in various tumor models[26-30]. Both growth inhibition and programmed cell death are mediated by ionotropic P2-receptors and metabotropic P2-receptors[10,19]. Here we provide evidence that extracellular ATP induces apoptosis and causes cell cycle arrest in poorly differentiated human squamous cancer cells of the esophagus, and ADO plays an important role in them.

Recently, Maaser *et al*.[19], studied the effects of ATP and ADO on moderately differentiated esophageal cancer Kyse-140 cells, and found that ATP (100-500 μmol/L) inhibits cell growth, causes a delay in the S phase of cell cycle, and induces apoptosis. However, ADO has no contribution to the antiproliferative and apoptotic action of Kyse-140 cells. In our study, both ATP (0.1-1 mmol/L) and ADO (0.03-1 mmol/L) inhibited growth of TE-13 cells, caused cell cycle arrest in S phase (ATP, 0.1 mmol/L) or in G_0/G_1 phase (ATP or ADO, 1 mmol/L). The reasons why our results did not accord with those of Maaser *et al*.[19], may be due to the different kinds of esophageal cancer cell line and different concentrations of ATP used in our study. Additionally, a positive correlation between S-phase fraction and the response to anticancer agents has recently been documented[31]. Hence, in addition to the antiproliferative action of ATP on its own, possible synergistic effects of ATP and anticancer drugs should be investigated.

Besides its cell cycle interfering effects, ATP or ADO was shown to induce apoptosis in esophageal cancer TE-13 cells as assessed simultaneously by morphological study, agarose gel electrophoresis, and flow cytometry analysis. After being exposed to various concentrations of ATP or ADO for 48 or 72 h, TE-13 cells displayed a series of apoptotic vents, such as chromatin condensation, fragment nuclei, apoptotic body, apoptotic peak in the flow cytometry imaging

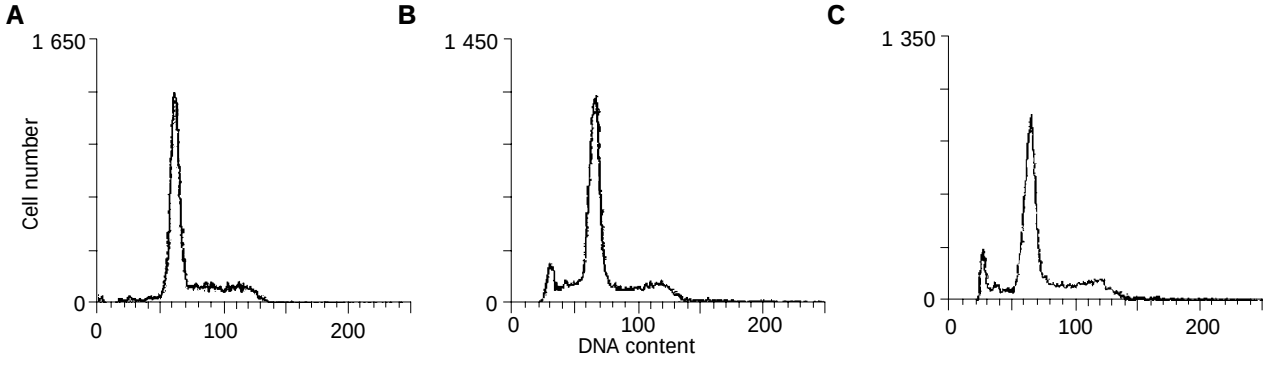

Figure 5 ATP- or ADO-induced apoptosis of TE-13 cells detected by flow cytometry in control (A) and treated with ADO (B) and ATP (C) for 48 h, respectively.

as well as DNA ladder. ADO is the final metabolite of ATP, and the result of ADO contributing to the growth inhibition and apoptosis suggests that the above effects of ATP might be partially related to its metabolite, ADO.

In conclusion, extracellular ATP inhibits cell growth, causes cell cycle arrest, and induces apoptosis. These actions might be partially related to its metabolite, ADO. Although the average concentration of nucleosides in plasma and other extracellular fluids is generally in the range of 0.4-6 μmol/L, these values can increase at sites of vascular inflammation and platelet degranulation[32]. Taken together, to further investigate the effects of ATP on tumor cells may provide an innovative treatment strategy for esophageal cancer.

ABSTRACT

AIM: To determine the prognostic significance of isolated tumor cells (ITCs) and lymph node micrometastases in gastric cancer.

METHODS: Hematoxylin and eosin-stained slides of lymph node dissections of 632 consecutive gastric cancers were reviewed. Cytokeratin immunostaining was performed in 280 node-negative cases and 5 cases indefinite for lymph node metastases. Lymph node metastases were divided into ITCs, micrometastases, or macrometastases, according to the sizes of tumor deposits in largest dimension. ITCs were further classified into four groups according to metastasis pattern.

RESULTS: Lymph node metastases were identified by immunostaining in 58 of 280 node-negative cases (20.7%) and were not significantly associated with patient survival (P = 0.3460). After cytokeratin immunostaining, 196 cases were classified as pN1, which consisted of 20 cases with micrometastases detected by immunostaining (pN1mi(i+)), 34 cases with only micrometastases (pN1mi), and 142 cases with pN1 with one or more macrometastases (pN1). Cases with pN1mi and pN1mi(i+) had a significantly better prognosis than the cases with pN1 (P = 0.0037). ITCs were found in 38 of these 58 cases, and could be divided into four groups: 12 cases with only a single cell pattern, 7 cases with multiple individual cells, 5 cases with single small cluster, and 14 cases with multiple small clusters. Among these four groups, cases with ITCs of multiple individual cell pattern showed the worst survival (median survival: 28 mo, P<0.0001).

CONCLUSION: Both size and pattern of lymph node metastases can give prognostic information on the survival of gastric cancer patients.

INTRODUCTION

The most important prognostic factor in patients with gastric cancer is the presence of a regional lymph node metastasis[1]. Some patients with histologically node-negative gastric cancer will die as a result of local or distant tumor recurrence, even though their primary tumor is curatively resected. Adjuvant chemotherapy benefits some patients with node-negative gastric cancer, but the treatment of all node-negative patients is unnecessary, as most node-negative patients will never have recurrence after surgery. Therefore, additional markers would be helpful for predicting patients at risk of a poor prognosis.

For the above purpose, histological evaluations of multiple serial sections of lymph nodes at many levels have been undertaken by several investigators[2,3]. Although serial sectioning can increase the detection of occult lymph node metastases, it is also labor-intensive and expensive for routine diagnostic practice. Furthermore, a single cell or minute cluster cannot be detected even by an expert pathologist. Recent advances in immunohistochemistry and molecular biology allow the identification of discrete and occult tumor cells, which are undetectable by standard hematoxylin and eosin (HE) staining, in the lymph nodes of patients with breast[4,5], esophageal[6,7], and colorectal cancers[8,9]. Many investigators have correlated patient prognosis with the presence of metastases detected by immunostaining, but controversy remains over the importance of single cell or cluster of cancer cells in regional lymph nodes.

Recently, regional lymph node metastasis was further classified into isolated tumor cells (ITCs), micrometastases, or macrometastases according to the size of tumor deposits in largest dimension in patients with breast cancers[10]. ITCs are defined as single cells or small clusters not greater than 0.2 mm in largest dimension, usually with no histologic

evidence of malignant activity. Cases with only ITCs are designated as pN0(i+) and categorized into pN0 by AJCC[10]. Single cells and small ill-defined clusters in lymph node metastasis, classified as ITCs, are not uncommon in gastric cancer, since cancer cells in diffuse type cancer frequently loose intercellular adhesion molecules, which represents a critical event of the metastatic cascade[11-13]. However, the clinical importance of size or pattern of metastatic tumor deposits in lymph node metastases is not defined in gastric cancer patients. To clarify the prognostic impact of ITCs and micrometastases on regional lymph nodes, we investigated 632 consecutive gastric cancers resected during one year in the aspect of number, size, and patterns of lymph node metastases and examined their clinical significance.

MATERIALS AND METHODS

Specimens

The files of 659 surgically resected primary gastric cancer cases examined at the Department of Pathology, Seoul National University College of Medicine over a period of 1 year (January 1, 1995-December 31, 1995) were examined in order to evaluate their lymph node metastasis status. Of these 659 cases, 632 cases (95.9%) were available for slide review and immunohistochemical staining of lymph nodes. The series consisted of 280 cases of pN0 stage, 183 cases of pN1 stage, 113 cases of pN2 stage and 56 cases of pN3 stage. Mean age of the patients was 54.5 years, and 92.9% of the patients had undergone curative resection (R0 according to the AJCC guideline). The study included 409 advanced gastric carcinomas and 223 early gastric carcinomas. No patient had received preoperative chemo- or radiotherapy. Glass slides were reviewed to determine histologic types according to WHO classification[11]. The clinical outcomes of the patients were followed from the date of surgery to either the date of death or December 1, 2000, resulting in a follow-up period ranging from 1 to 72 mo (mean: 55 mo). Those cases who lost their follow-up and those who ended in death due to a cause other than gastric cancer were regarded as censored data during survival rate analysis.

Review of HE-stained slides of lymph node dissection

HE-stained slides of lymph node dissection of 632 consecutive gastric cancers (31 421 lymph nodes) were reviewed. In contrast to original report, metastatic nodules in the fat adjacent to a gastric carcinoma without evidence of residual lymph node tissue were regarded as regional lymph node metastases by the AJCC guideline. Lymph node metastases were subdivided into three groups according to the AJCC guidelines using the maximum size of tumor deposit, i.e., ITCs are not greater than 0.2 mm in diameter, micrometastases are greater than 0.2 mm but not greater than 2 mm in diameter, and macrometastases are greater than 2 mm in diameter[10]. Lymph nodes with ITCs were not regarded as lymph node metastases, and cases with only micrometastases (not greater than 2 mm in diameter) were classified as pN1mi.

Immunohistochemistry

Immunohistochemical staining was performed on 280 gastric cancer cases (9 604 lymph nodes) without regional lymph node metastasis (pN0) by conventional HE staining, and on an additional 5 cases, who were originally reported as pN1 but were indefinite for metastasis by reviewing HE-stained slides. A single serial section (4 μm) was cut from each paraffin block, deparaffinized and dehydrated. Immunostaining with antibodies against cytokeratin (mAb anti-human cytokeratin clone MNF116, DAKO, Glostrup, Denmark) at 1:100 dilution was performed using a streptavidin peroxidase procedure after an antigen retrieval process using microwaves. Cells were considered to be occult lymph node metastases, if they were immunoreactive mainly in their cytoplasmic membranes, were found within the substance of the lymph nodes and were morphologically consistent with cancer cells. Immunohistochemically detected lymph node metastases were also subdivided into three groups: ITCs, micrometastases, or macrometastases, according to the size of tumor deposits in the largest dimension. Tumor deposits in lymph nodes with histologic evidence of malignant activity, such as gland formation or stromal reaction, were defined as micrometastases even if they were smaller than 0.2 mm in maximum dimension. ITCs were subdivided into four groups according to metastasis pattern (single cell, multiple individual cells, single cluster and multiple clusters, Figure 1). The number of lymph nodes containing tumors and the total number of tumor cells or clusters in a lymph node were recorded.

Statistical analysis

Either the χ^2 test or Fisher's exact test (two-sided) was performed to determine the correlation between lymph node metastasis and clinicopathologic parameters. Survival curves were estimated using the Kaplan-Meier product-limit method, and the significance of differences between survival curves was determined using the log-rank test. Results were considered to be statistically significant when *P* values were less than 0.05. All statistical analyses were conducted using the SPSS 11.0 statistical software program (SPSS, Chicago, IL, USA).

RESULTS

Reclassified pN stage after immunohistochemistry and reviewing HE-stained slides

Occult lymph node metastases were identified by cytokeratin immunostaining in 58 (20.7%) of 280 cases or in 157 of 9 604 lymph nodes (1.63%), which were originally reported as pN0. Of the 58 cases with positive occult lymph node metastasis, macrometastasis was found in one case, micrometastases in 19 cases (pN1mi(i+)), and ITCs in 38 cases (pN0(i+)). Four cases, who were originally reported as pN1, were reclassified as pN0, and one case was reclassified as pN1mi(i+) after cytokeratin immunostaining.

The pN stage, after immunostaining for cytokeratin and reviewing HE-stained slides, was reclassified as pN0 in 264 cases, pN1 in 196 cases, pN2 in 113 cases, and pN3 in 59 cases. The reclassified pN stage was found to be significantly associated with patient survival (Figure 2A).

Subgroups of pN1

One hundred and ninety-six cases with pN1 were subdivided

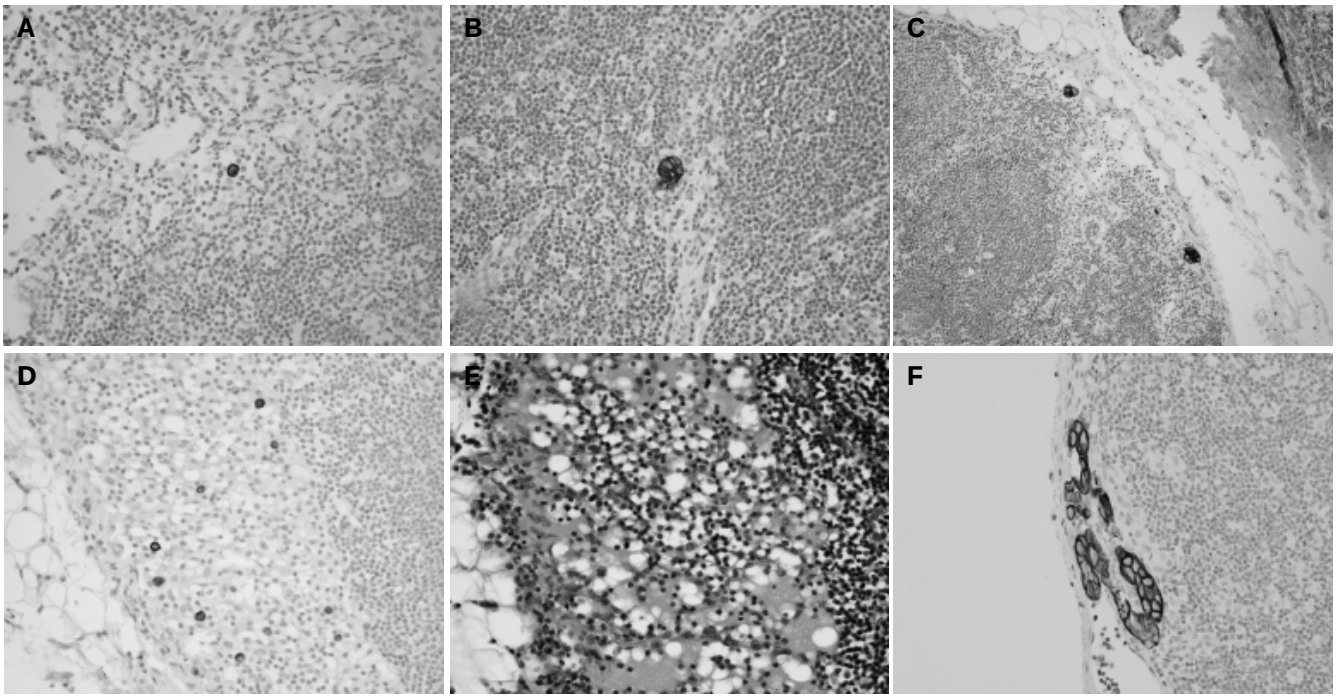

Figure 1 Immunohistochemical staining against cytokeratin. A: Single cell only (×400); B: single small cluster (×400); C: multiple small clusters (×200); D: multiple individual cells (×400); E: HE-stained slides of multiple individual tumor cells in lymph nodes (the same area of D, ×400); F: micrometastasis (×400).

into three groups: 20 cases with pN1mi(i+), 34 cases with pN1mi, and 142 cases with pN1 with one or more macrometastases. Cases with pN1mi, including pN1mi(i+), showed a significantly better prognosis than the 142 cases with macrometastases ($P = 0.0037$, Figure 2B). Furthermore, pN1mi detected by HE staining only was significantly associated with better survival than macrometastases ($P = 0.0218$, Figure 2C). No significant difference was observed between the survival of cases with pN1mi(i+) and pN1mi ($P = 0.3305$, Figure 2B). When compared to pN0(i-) cases, pN1mi cases showed significantly poorer survival ($P = 0.0104$, Figure 2C), but pN1mi (i+) and pN0(i-) cases did not show a survival difference ($P = 0.6738$).

Isolated tumor cells (ITCs)

Cases with lymph node metastases detected by immunohistochemistry (pN0(i+) and pN1(i+)) did not show a different survival when compared to cases without lymph node metastases ($P = 0.3460$, Figure 2D). Patients with immunohistochemically detected metastases had poorly differentiated adenocarcinomas more frequently than those without metastases ($P = 0.019$, Table 1).

Four groups of ITCs included 12 cases with a single cell pattern, 7 cases with multiple individual cells, 5 cases with a single cluster and 14 cases with multiple clusters. Among them, cases with multiple individual cells showed the poorest survival (median survival: 28 mo, $P<0.0001$, Figure 2E),

and had poorly differentiated non-solid type adenocarcinomas with infiltrative border. Lymphatic invasion was not found in these cases. Histologically, cytokeratin-positive individual cells were found in the sinus of lymph nodes, and these could not be recognized by routine HE staining (Figure 1). In four of seven cases with multiple individual cells, the maximum number of tumor cells in a single lymph node exceeded 20 (Table 2), and prognosis was grave especially in these four cases. By Cox regression analysis, the pattern of metastasis was found to be a significant prognostic factor independent of pT stage and histologic type (P = 0.018, Table 3). Two of the seven patients with multiple individual cells had stage IV disease, and the pattern of multiple individual cells was associated with poor survival even after the patients with stage IV disease were deleted (P = 0.0018, Figure 2F).

Thirty-five of thirty-eight cases with ITCs had one to five positive metastatic nodes. The remaining cases had six or more positive metastatic nodes (9, 11, and 19 metastatic lymph nodes, respectively). Cases with ITCs in six or more lymph nodes showed a significantly poorer prognosis than those with ITCs in 1-5 lymph nodes (P<0.0001, Figure 2G).

DISCUSSION

When examining gastric cancer and related material, the pathologist aims to achieve as simply and reliably as possible, a comprehensive diagnosis and prognosis of therapeutic relevance. The routine histologic examination of lymph nodes has long been the gold standard for identifying metastases to regional lymph nodes resected as part of the staging procedure for tumors in diverse locations, including the stomach. However, this method has an inherent limitation, the potential for sampling error. Serial sectioning has been employed to scrutinize metastases[14], but it is impractical for routine surgical pathology practice. In this study, we performed immunohistochemical staining against cytokeratin on routine sections in the cases with original diagnosis of pN0. We found that micrometastases or macrometastases were overlooked in 20 of 280 node-negative cases (7.14%), and ITCs were found in 38 cases (13.6%).

The prognostic impact of lymph node metastases detected by immunohistochemistry remains controversial in gastric cancer. Some authors have reported an insignificant correlation between lymph node metastasis detected by immunostaining and patient survival[15-17], but others have reported a significant impact on patient survival[18-21]. In contrast to previous reports, we subdivided lymph node metastases according to the size of tumor deposits, and then subdivided cases with ITCs into four groups according to the pattern of tumor deposits. In this large scale study, lymph node metastases as detected by immunostaining were not significantly associated with patient survival.

Ishida *et al*.[21], have classified lymph node metastases into five groups according to the pattern of metastasis (single cell *vs* cluster), but did not analyze the implications on patient survival. Fukagawa *et al*.[17], demonstrated that the pattern of micrometastases (single cell *vs* cluster) does not affect the survival curve. In the present study, ITCs were classified into four groups: single cell, multiple individual cells, single cluster, and multiple clusters. Among ITCs, only cases with multiple individual cells comprised the poor prognosis group. Tumors with a pattern of multiple individual cells showed non-solid poorly differentiated type adenocarcinoma and had infiltrative border. Although the pattern of multiple individual cells was very uncommon (7 of 280 pN0, 2.5%), this pattern had a significant impact on patient survival and showed a distinct histologic feature. Therefore, cytokeratin immunostaining is recommended in node-negative gastric cancers especially in non-solid poorly differentiated type adenocarcinoma with infiltrative border, to identify occult metastasis with multiple individual cell pattern.

According to the cancer staging of AJCC, micrometastases are defined when the size of tumor deposits in largest dimension is greater than 0.2 mm and not greater than 2 mm in diameter, and cases in which only micrometastases are detected are defined as pN1mi in breast cancer. However, in previous reports on gastric cancer[17-21], micrometastases are defined as lymph node metastases detected by immunohistochemistry, not according to the size of tumor deposits. In the present study, micrometastases were defined according to cancer staging method recommended by AJCC. Cases with pN1mi including pN1mi(i+) showed a significantly better prognosis than cases with pN1 with macrometastases ($P = 0.0037$), and pN1mi by only HE staining was also significantly associated with better survival than macrometastases ($P = 0.0218$). Therefore, we recommend that pN1mi should be defined in gastric cancer as is currently done in breast cancer. Furthermore, the survival of patients with pN1mi(i+) was not significantly different from that of patients with pN0. Therefore, we also recommend classifying pN1mi(i+) separately from pN1mi.

Several lines of evidence support the interpretation that keratin-positive cells in lymph nodes represent metastatic carcinoma, though occasional normal constituents of lymph nodes may be stained positively for cytokeratin. Other than cancer cells, undesirable cytokeratin has been reported both in plasma cells[22,23] and in interstitial reticulum cells[22,24]. Cytokeratin-positive metastatic cells have an epithelial morphology, in contrast to the dendritic process appearance of keratin-positive reticulum cells. Plasma cells show weak and cytoplasmic expression of cytokeratin and have their characteristic features. Cells are considered as occult node metastases only when they show strong and membranous expression of cytokeratin, reside within the substance of the lymph nodes, and exhibit epithelial morphology.

In conclusion, immunohistochemical staining against cytokeratin can detect occult metastases in regional lymph nodes of patients with gastric cancer, and the presence of immunohistochemically detected ITCs does not affect patient survival, except for a subset of cases with metastasis of multiple individual cells. pN1mi or pN1mi(i+) is distinct from pN0 or pN1 in the aspect of patient survival. Therefore, the size and pattern of lymph node metastases can provide prognostic information in gastric cancer.

ABSTRACT

AIM: To characterize the expression and genomic amplification of decoy receptor 3 (DcR3) in hepatocellular carcinoma (HCC) and to evaluate the role of DcR3 in apoptosis.

METHODS: We examined 48 cases of HCC for DcR3 expression by RT-PCR and DcR3 gene amplification by quantitative genomic PCR. DcR3 protein was detected by immunohistochemistry. Terminal deoxynucleotidyl transferase-mediated dUTP digoxigenin nick and labeling (TUNEL) was used to identify the apoptosis cells in tissues. Primary hepatoma cell culture and MTT test were used to evaluate the protection against FasL- and chemical-induced apoptosis by DcR3 expression.

RESULTS: DcR3 mRNA overexpression was detected in 60% HCC (29/48) patients. The occurrence of HCC was not associated with amplification of the gene. One sample base substitution was found in three sites as a sequence in Genbank. The expression of DcR3 in HCC was associated with the apoptotic index (0.067±0.04 *vs* 0.209±0.12, $P<0.01$), size of mass, stage, and infiltration or metastasis (41.2% *vs* 71.0%, 40% *vs* 75%, 51.8% *vs* 84.6%, $P<0.05$). DcR3 expression could protect hepatoma cells against apoptosis induced by FasL, but not by chemicals.

CONCLUSION: These data suggest that in addition to gene amplification there may be another mechanism underlying DcR3 overexpression. The effect of overexpression of DcR3 on the apoptosis of cancer cells may have direct therapeutic implications for the management of HCC.

INTRODUCTION

DcR3, a member of the tumor necrosis factor receptor superfamily, is amplified and overexpressed in various human cancers as a negative regulator of Fas-mediated apoptosis[1-3]. It was reported that DcR3 can bind to LIGHT and FasL[4-8]. Therefore, DcR3 may act as an inhibitor of LIGHT-induced tumor cell death by blocking LIGHT interaction with its receptors. DcR3 is characterized by a soluble cognate receptor for both LIGHT and FasL/CD95L[9,10]. LIGHT and FasL mediate apoptosis, which is the most common physiological form of cell death and occurs during embryonic development, tissue remodeling, immune regulation, and tumor regression. Abnormalities in FasL and LIGHT system can result in a number of human pathological conditions such as tumor. The cause of DcR3 overexpression in human cancers remains unclear, but its value in tumor escaping from apoptosis and immune surveillance of organism is worthy of special remark.

In contrast, no data are available regarding the expression and amplification of DcR3 gene in HCC. We found that there was a high DcR3 protein level in serum of patients with HCC. In the present study, we examined 48 cases of HCC for DcR3 gene expression by RT-PCR and DcR3 gene amplification by quantitative genomic PCR. The expression of DcR3 protein was detected by immunohistochemistry. *In situ* TUNEL was used to identify the apoptosis cells in tissues of HCC. Primary hepatoma cell culture and MTT test were used to evaluate the role of DcR3 expression in protection against FasL and chemical-induced cell death. The findings in our study suggest that in addition to gene amplification there may be another mechanism underlying DcR3 gene expression. The effect of overexpression of DcR3 on the apoptosis of cancer cells may have direct therapeutic implications for the management of HCC, which remains a major unsolved health problem throughout the world.

MATERIALS AND METHODS

Quantitative genomic PCR

Quantitative genomic PCR was performed as previously described[2,11]. Genomic DNA was isolated from fresh tissues of HCC. Quantitative PCR was carried out by a lightcycler. Primers for DcR3 were designed using an intron sequence to avoid amplification from DcR3 mRNA. The DcR3-specific primers were 5'-CTTCTTCGCGCACGCTG-3' (sense) and 5'-ATCACGCCGGCACCAG-3' (antisense), and the fluorogenic probe was 5'-FAM-ACACGATGCGTGC-TCCAAGCAGAA-TAMARA-3'. The beta-globin primers were 5'-ACCCTTAGGCTGCTGGTGG-3' (sense) and 5'-GGAGTGGACAGATCCCCAAA-3' (antisense), and the

fluorogenic probe was 5'-FAM-CTACCCTTGGACCCA-GAGGTTCTTTGAGTC-TAMARA-3'. For each run, DNA isolated from normal matched tissues was used for comparison.

RT-PCR analysis

For RT-PCR analysis, total RNA was isolated using Trizol (Life Technologies, Inc.) from the tumor and its adjacent normal tissues of 48 HCC cases. RNA was converted to cDNA by reverse transcription and amplified for 35 cycles by PCR. Primers used for amplification of the DcR3 fragment were according to the RNA sequence of DcR3. Beta-actin was used as an internal control for RNA integrity. The DcR3-specific primers were 5'-TCCACCGCGCCACTACAC-3' (sense) and 5'-ACGGCACGCTCACACTCC-3' (antisense). The beta-actin specific primers were 5'-TTCCAGCCT-TCCTTCCTGG-3' (sense) and 5'-TTGCGCTCAGG-AGGAGCA AT-3'(antisense). PCR products were run on 2% agarose gel, stained with ethidium bromide, and visualized by UV illumination. RT-PCR product of one sample was sequenced to show reliability of the reaction.

Immunohistochemistry

HCC tissues were obtained from the Surgical Department of the Second Affiliated Hospital of Zhejiang University. Four micrometer-thick formalin-fixed and paraffin-embedded sections were deparaffinized and treated in microwave with citrate buffer, pH 6.0 (three times each for 5 min) for antigen retrieval and incubated for 15 min in 30 mL/L H_2O_2 Tris-buffered saline (TBS), pH 7.4 to block endogenous peroxidase activities. The sections were then incubated for 10 min at room temperature with blocking solution. Each section was incubated with anti-DcR3 antibody diluted 1:5000 for 30-60 min at room temperature. Bound antibodies were detected with the peroxidase-labelled streptavidin-biotin method, and stained with diaminobenzidine. Counterstaining was performed with Mayer's heamatoxylin, and the sections were mounted.

As a negative control for DcR3 protein expression, the primary antibody was replaced by normal non-immune rabbit serum. There were no known normal tissues expressing DcR3 protein, and no positive control was set up in the DcR3 immunostaining.

In situ TUNEL

HCC tissues were obtained from the Surgical Department of the Second Affiliated Hospital of Zhejiang University. Four micrometer-thick formalin-fixed and paraffin-embedded sections were deparaffinized and treated in microwave with citrate buffer, pH 6.0 (three times each for 5 min) for antigen retrieval and incubated for 15 min in 30 mL/L H_2O_2 TBS, pH 7.4 to block endogenous peroxidase activities. Each section was incubated with TUNEL reaction solution (Roche) for 60 min at 37 ℃, and washed three times with PBS. The signal translation solution was added to the slides for 30 min at 37 ℃. After being washed three times with PBS, each section was stained with freshly prepared diaminobenzidine. Counterstaining was performed with Mayer's heamatoxylin, and the sections were mounted.

As a negative control for *in situ* TUNEL, the TUNEL reaction solution was replaced by TBS. As a positive control, a slide (Roche) in the kit was used together with the samples.

FasL-induced apoptosis and drug-induced cell death of hepatoma cells

Hepatoma cells were obtained from patients with HCC who underwent surgery for tumor resection. After tumor removal, the tissues were placed immediately in petri dishes, minced mechanically, and digested by collagenase (3 h, 37 ℃). Subsequently, the dissociated cells were filtered through 100 μm of cell strainers to remove tissue debris. After centrifugation and lysis of erythrocytes by treatment with hypotonic water, the hepatoma cells were washed and resuspended in full medium (CAM).

The hepatoma cells were cultured with serum-free CAM in 96-well plates. A total 5×10^4 cells were seeded per well. Then 3 ng/mL FasL and ADM, MMC, and GEMZAR of 4-, 1- and 0.25-fold drug concentrations respectively were used to detect the cytotoxic effect on primary hepatoma cells. Each concentration and blank control were put in three parallel wells. The hepatoma cells were co-cultured with FasL or drugs in serum-free CAM for 5 d. The survival rate of the cells was detected with MTT method.

Statistical analysis

Results were expressed as mean±SE. Differences between groups were examined for statistical significance using analysis of variance (ANOVA) and *t*-test. $P<0.05$ was considered statistically significant.

[redacted]

We report that DcR3 mRNA is overexpressed in a substantial percentage of HCC, and that this overexpression can occur in the absence of detectable DcR3 gene amplification. In a case of sequence analysis, three base differences in the DcR3 gene of HCC were identified. The expression of DcR3 in HCC shows a relationship with the apoptosis index of the tissues of cancer. We also demonstrate that the hepatoma cells expressed DcR3 are protected from FasL-induced apoptotic cell death, but not the cell death induced by chemicals.

Relationship between clinical data and DcR3 mRNA expression

The mean age of cancer patients was 58.3±14 years. The clinical and pathological features of the total 48 cases were collected and summarized. The relationship between the DcR3 mRNA expression and the clinical and pathological features was analyzed. DcR3 mRNA expression in HCC showed a relationship with size of the mass, TNM stage and infiltration or metastasis of the tumor ($P<0.05$), but no relationship with membrane of the tumor, cancer embolus, and number of the tumor nodes (Table 1).

Overexpression of DcR3 mRNA and protein in HCC

Twenty-nine of 48 HCC cases were positive for DcR3 mRNA expression (Figure 1A). The ratio of positive expression was 60.4% (29/48). No positive expression was detected in adjacent normal tissues. As the level of DcR3 mRNA appeared to be elevated in HCC, we investigated

Table 1 Relationship between DcR3 mRNA expression and clinical and pathological features of HCC (n = 48)

Features	n	DcR3 mRNA expression (%)	P
Size of mass			
≤5 cm	17	41.2 (7/17)	<0.05
>5 cm	31	71.0 (22/31)	
Number of node			
Single	32	53.1 (17/32)	>0.05
Multiple	16	75 (12/16)

Negative	38	60.5 (23/38)	>0.05
Positive	10	60 (6/10)	
TNM stage			
Stage I, II	20	40 (8/20)	<0.05
Stage III, IV	28	75 (21/28)	
Infiltration or metastasis			
Negative	35	51.4 (18/35)	<0.05
Positive	13	84.6 (11/13)	

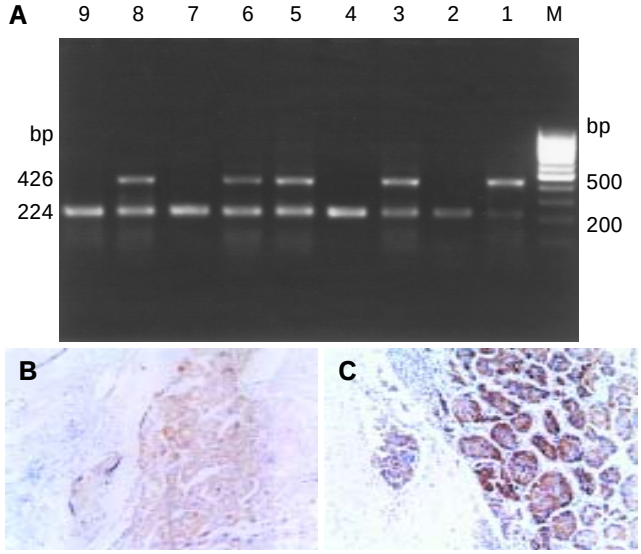

Figure 1 DcR3 gene expression in nine representative HCC samples. A: DcR3 gene mRNA expression detected by RT-PCR. Lanes 1,3,5,6, and 8: positive mRNA expression; lanes 2,4,7 and 9: negative expression. B, C: DcR3 protein expression detected by immunohistochemistry. (Magnification 100×).

whether it was true for DcR3 at the protein level. The expression of DcR3 protein was detected in five cases of HCC by immunohistochemistry. An obvious positive staining signal of DcR3 protein was detected in three out of five HCC cases (Figures 1B, and C). RT-PCR showed positive signals only in cancer cells. Furthermore, we found a high DcR3 protein level in serum of HCC patients by ELISA with anti-DcR3 antibody.

DcR3 overexpression without DcR3 gene amplification

DcR3 gene amplification was proposed to be the mechanism for DcR3 overexpression to promote tumor survival in lung and colon cancer. To determine whether DcR3 overexpression was due to gene amplification, quantitative PCR was carried out on genomic DNA from all the patients, with the relative number DcR3 gene copies determined by normalization of the beta-globin gene. Unexpectedly, the amplification was 2-fold higher only in 7 of 48 tumors patients than that in 29 of 48 tumors patients with positive DcR3 mRNA expression. Among the 29 HCC cases with postive DcR3 mRNA expression, the amplification was 2-fold higher only in six cases. From the result of sequence analysis, we found accidentally that there were three bases different from the DcR3 mRNA sequence in GenBank (Figure 2).

Table 2 Survival rate of hepatoma cells cultured in chemicals with different concentration (mean±SE)

	ADM	P	MMC	P	GENZAR	P
4×	51±0.2		44.6±0.19		52.2±0.17	
1×	72.7±0.18	<0.01	64.8±0.16	<0.01	66.7±0.17	<0.01
0.25×	82.6±0.17		81.8±0.16		77.9±0.18	

Apoptosis index and DcR3 mRNA expression in HCC

In situ TUNEL was used to identify the apoptosis cells in 29 tissue specimens of HCC. The apoptosis index was calculated by counting the positive cells in five visual fields under light microscope at 400-fold magnification. DcR3 mRNA positive expression was detected in 19 out of 29 HCC cases. The apoptosis index of the 29 HCC cases ranged from 0.021 to 0.362. The apoptosis index of the 19 patients with positive DcR3 mRNA expression was significantly lower than that (0.067±0.04) of the 10 patients with negative DcR3 mRNA expression (0.209±0.12) (P<0.01).

Expression of DcR3 protected hepatoma cells from FasL-induced apoptosis

Hepatoma cells of 19 HCC cases were studied. After treatment with FasL, the cell survival rate (CSR) of 10 HCC cases with DcR3 mRNA expression (83.7%±0.18) was significantly higher than that of another eight HCC cases without DcR3 expression (62.2%±0.16) (P<0.01).

From 0.25- to 4-fold drug concentrations, the hepatoma cell death induced by ADM, MMC, and GEMZAR had a positive relationship with the drug concentration (Table 2, P<0.01). But the effect of three drugs between hepatoma cells with positive and negative DcR3 mRNA expression had no significant difference (Table 3, P>0.05).

[illegible]

DcR3 gene is mapped on chromosome 20q13.3, a region known to be associated with gene amplification and rearrangement in human cancer[12,13]. Numerous reports have shown genomic amplifications of 20q13 in breast[14], gastric[15], colon, and lung[12] tumors and neuroblastomas[16]. Pitti *et al*.[1], found that the DcR3 gene is amplified in approximately half of human lung tumors and human colon adenocarcinomas and that DcR3 receptor overexpression might also occur, conferring growth advantage on tumor cells by blocking FasL-induced cell death. In this paper, we demonstrated DcR3 mRNA and protein overexpression in HCC. From the result our data, we found that there were only 20.7% (6/29) genomic amplifications in HCC with positive DcR3 mRNA

Table 3 Comparision of hepatoma cell death induced by chemicals between groups with negative and positive DcR3 expression (mean±SE)

	Survival rate of hepatoma cells					
	4-fold	*P*	1-fold	*P*	0.25-fold	*P*

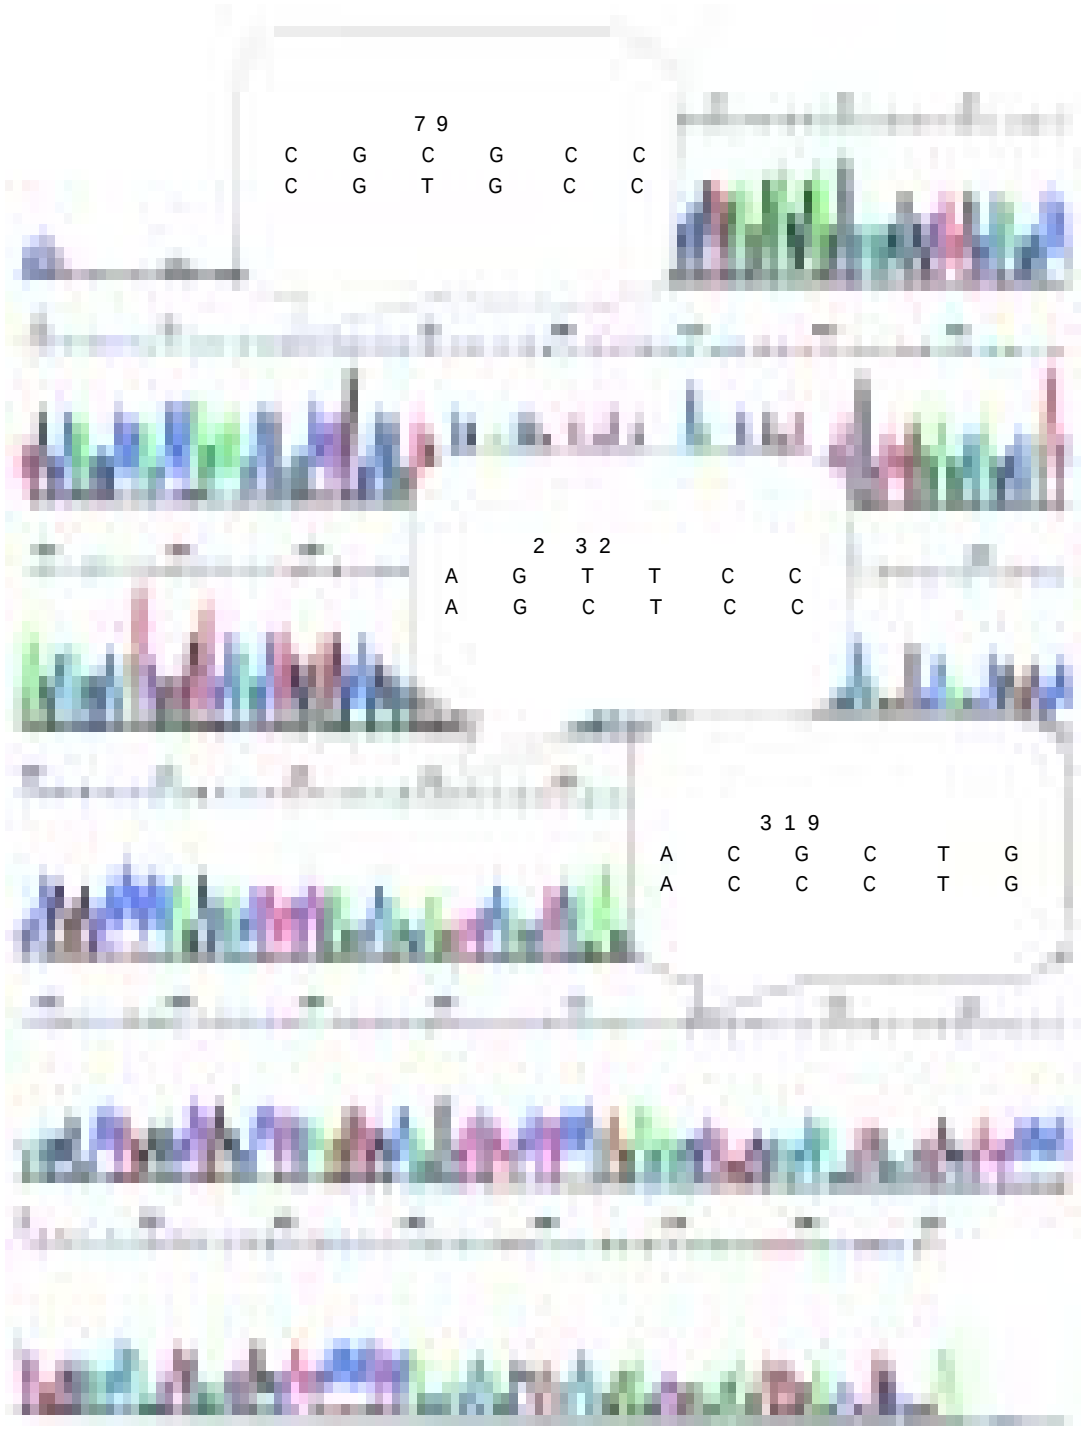

Figure 2 Sequence of DcR3 gene mRNA in HCC detected by sequencing RT- PCR product.

expression, suggesting that overexpression of DcR3 gene occurs without genomic amplification. Bai *et al*.[2], examined DcR3 genomic DNA, mRNA, and protein levels in a series of human gastrointestinal tract tumors and found that DcR3 gene is overexpressed in a substantial number of tumors in which gene amplification could not be detected by fluorescence *in situ* hybridization or quantitative genomic PCR. The identification of tumors with high-level DcR3 overexpression but no significant gene amplification raises the possibility that DcR3 protein overexpression might be an early event in oncogenesis, possibly driving selection of gene amplification. The cause of nongenomic DcR3 overexpression remains unclear. From the result of sequence analysis, we found accidentally that there were three bases different from the DcR3 mRNA sequence in GenBank. The base difference might represent a point mutation or a gene polymorphism in HCC. The meaning and mechanism of the base differences in HCC remain unclear and still need further work.

Since DcR3 is a soluble protein, it can be easily detected in serum with DcR3 antibody. The protein overexpression is likely to be the eventual choice of diagnostic method for DcR3. We found a high DcR3 protein level in serum of the HCC patients by ELISA with anti-DcR3 antibody. Although the diagnostic value of DcR3 protein still needs an overall evaluation, at least it can be used as an auxiliary diagnostic method in combination with other methods for HCC.

Fas-induced apoptosis plays a role in the hepatic pathology of Wilson's disease, in which Fas and FasL are induced in hepatocytes overloaded with copper[17,18]. Bai *et al*.[2,19-21], used an model of copper-induced hepatocellular injury to test whether expression of DcR3 could protect cells from apoptosis and found that DcR3 might indeed plays a physiologically important role in the regulation of apoptosis. In this study, we found that DcR3 mRNA expression in HCC showed a significant relationship with the apoptosis index. Patients with a positive DcR3 mRNA expression had a low apoptosis index compared to those with a negative expression. The difference in apoptosis index between positive and negative DcR3 mRNA expression groups showed a statistic significance. suggesting that DcR3 protein on apoptosis shows its therapeutic value of down-regulating DcR3 overexpression by genetic or immunotherapeutic means.

Abstract

AIM: To determine the expressions of inducible nitric oxide synthase (iNOS) and matrix metalloproteinase-9 (MMP-9) in hepatocellular carcinoma (HCC) and to investigate the relationship between iNOS and MMP-9 expression and their effects on angiogenesis and progression of HCC.

METHODS: In this study, we examined iNOS, MMP-9, and CD34 expression in specimens surgically removed from 32 HCC patients and 7 normal liver tissues by immunohistochemical staining. Meanwhile, microvessel density (MVD) was determined as a marker of angiogenesis by counting CD34-positive cells.

RESULTS: The positive rates of iNOS and MMP-9 expression were 71.88% (23/32) and 78.13% (25/32) in HCC. MMP-9 expression was significantly correlated with tumor size, capsule status, TNM stage, and risk of HCC recurrence ($P = 0.032$, $P = 0.033$, $P = 0.007$, and $P = 0.001$, respectively). There was also a significant relationship between iNOS expression and capsule status and risk of HCC recurrence ($P = 0.049$ and $P = 0.004$, respectively), but no correlation between iNOS expression and tumor size and TNM stage. There was a positive association between MVD and TNM stage and risk of HCC recurrence ($P = 0.037$ and $P = 0.000$, respectively). The count of MVD was significantly different in different iNOS and MMP-9 immunoreactivity groups ($F = 17.713$ and 17.097, $P = 0.000$ and $P = 0.000$, respectively). The examination of Spearman's rank correlation coefficient showed that there was a significant positive correlation between MVD and iNOS, MMP-9 immunoreactivity ($r = 0.754$ and 0.751, $P = 0.000$ and $P=0.000$, respectively). There was also a significant association between MMP-9 and iNOS expression in HCC ($P = 0.010$).

CONCLUSION: Nitric oxide (NO) produced by iNOS could modulate MMP-9 production and therefore contribute to tumor cell angiogenesis and invasion and metastasis in HCC. The strong expression of iNOS and MMP-9 in HCC may be helpful in evaluating the recurrence of HCC, predicting poor prognosis. For patients with strong expression of MMP-9 and iNOS, the optimal treatment scheme needs to be selected.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a highly vascular tumor characterized by a propensity for vascular invasion and distant metastasis. Angiogenesis is a prerequisite for tumor growth and metastasis[1]. In the process of invasion and metastasis of tumor cells, destruction of the extracellular matrix (ECM) is an essential initial step. Among the enzymes responsible for ECM degradation, several studies have shown a critical role played by matrix metalloproteinases (MMPs)[2]. MMP-9 (gelatinase B, 92-ku type IV collagenase) is capable of degrading the main components of the ECM, types IV and V collagen and gelatin[3-6]. Thus, its activities are closely related to the angiogenesis and invasiveness and metastasis of tumor cells[7,8]. However, it is secreted by cells as an inactive form, proMMP-9, which is then activated through an enzymatic cascade involving the generation of plasmin by urokinase-type plasminogen activator (u-PA)[9-12].

Nitric oxide (NO) is an important bioactive agent and a signaling molecule and may contribute to the pathogenesis of cancer[13]. Three distinct isoforms of NOS catalyze the formation of NO. Endothelial nitric oxide synthase (eNOS) and neuronal nitric oxide synthase (nNOS) are constitutively expressed in different tissues, whereas inducible nitric oxide synthase (iNOS) is related to a high-output pathway and is responsible for various pathological processes[14]. Although overexpression of iNOS has been demonstrated in various human neoplasms, such as colorectal cancer[15], pancreatic

cancer[16], and breast cancer[17], its exact function in tumor biology is complex and remains to be fully defined. During the initiation of tumor growth, natural killer cells and macrophages kill tumor cells by a NO-mediated mechanism[18]. However, NO may also suppress the antitumor defense, promote tumor angiogenesis and blood flow in the tumor neovasculature, and enhance tumor growth, invasion and metastasis[18]. Recently, investigators have tended to attribute NO-mediated stimulation of invasiveness to an alteration in the balance between the productions of MMPs and TIMPs[19-21]. Since NO has been assessed for the ability to upregulate u-PA in endothelial cells of post capillary venules during the process of NO-mediated stimulation of angiogenesis[22], the u-PA can convert plasminogen to plasmin, which can activate numerous MMPs.

There is evidence that NO produced by iNOS enhances the activity of MMP-9[19-21]. Both iNOS and MMP-9 expression have been reported to be increased in bone and joint disease and cardiovascular disease[23-25]. However, the relationship between them in tumors has been very seldom studied. To determine the role of iNOS and MMP-9 in HCC, we compared their expressions by the immunohistochemical method.

Materials

Thirty-two patients (24 males and 8 females, ranging in age from 16 years to 69 years, mean 53 years) who had undergone curative hepatectomy for HCC at the Second Hospital, Jilin University, and Tumor Hospital, Jilin Province, between May 2001 and October 2002 were involved in this study. As controls, seven normal adult liver specimens were wedge biopsies obtained during surgeries from patients with rupture of liver and cavernous hemangioma of liver. Of the 32 patients, 21 were positive for hepatitis B surface antigen (HBsAg), while 11 were infected with neither hepatitis C virus nor HBV. Five patients showed tumor thrombi in the portal vein, 3 patients showed lymph node metastasis in the porta hepatis, 14 patients showed microsatellite nodules. The patients were regarded as a high-risk group for HCC recurrence, if any one of the following factors existed: lymph node metastasis of the porta hepatis; tumor thrombi in the portal vein; surrounding the primary tumor two or more microsatellite tumor nodules were present in the same lobe of liver, or the microsatellite tumor nodules scattered over the two or more liver lobes. Eighteen cases were in high recurrence-risk group and 14 cases in low recurrence-risk group. The histological grade of malignancy was classified according to the criteria of World Health Organization. There were 17 cases of G1, 9 cases of G2, and 6 cases of G3. The degree of TNM classification was decided according to the general rules for the clinical and pathological study of primary liver tumor. One patient was staged I, 15 patients were staged II, and 16 patients were staged III. None of our patients received preoperative treatments, such as chemotherapy or embolization therapy. The resected surgical specimens were fixed in 10% buffered formalin and embedded in paraffin. Four-micrometer-thick sections were prepared for H&E and immunohistochemical staining.

Methods

Immunohistochemistry Immunostaining was performed according to the avidin-biotin-peroxidase complex method. Sections were dewaxed in xylene, and dehydrated in ethanol, and then heated at 98 ℃ in EDTA-retrieved solution for the antigens. Endogenous peroxidase was blocked by 3% hydrogen peroxide for 60 min at room temperature. The samples were incubated for 20 min at room temperature with a protein-blocking solution containing 5% normal horse serum and 1% normal goat serum. Subsequently, slides were incubated with primary anti-iNOS rabbit polyclonal antibody (Boster Bio, Wuhan) at 1:200 dilution for 60 min at room temperature, mouse anti-human MMP-9 mAb (Maixin Bio, Fuzhou) at 1:200 dilution overnight at 4 ℃, rat anti-mouse CD34 mAb (Maixin Bio, Fuzhou) at 1:100 dilution for 2 h at room temperature. Slides were then treated with a biotin-conjugated secondary antibody for 30 min followed by incubation with peroxidase-conjugated streptavidin for 60 min at room temperature. All steps were followed by washing in PBS. Finally, the sections were stained with a freshly prepared diaminobenzidine solution for 5 min and then counterstained with Mayer's hematoxylin. For CD34 staining, counterstaining was not done. As a negative control, PBS was used instead of the primary antibody. Known immunostaining-positive slides were used as positive controls.

Evaluation of iNOS and MMP-9 expression

Two independent observers screened all sections as semiqu-antitative evaluation of iNOS and MMP-9 immunostaining. The immunoreactive score was determined by the sum of intensity and extension of staining[26]. The intensity of staining was scored on a scale of 0-3, in which 0, negative staining; 1, weakly positive staining; 2, moderately positive staining; and 3, strongly positive staining. The extent of distribution of positive cells was estimated on a scale of 0-3, in which 0, negative or positive staining in 1-5% of cells; 1, positive staining in 6-25% of cells; 2, positive staining in 26-50% of cells; 3, positive staining in 51-100% of cells. The combined staining score (intensity+extension) $\geqslant$2 was considered as positive staining. The diagnosed grades accorded to the sum of two scores, -: 0-1; +: 2; ++: 3-4; and +++: >5.

Quantification of MVD

Microvessel density (MVD) was evaluated by two independent observers who were blinded to the patients' clinicopathologic data after sections were immunostained with anti-CD34 antibodies according to the procedure described by Weidner *et al*.[27]. In all tumors collected, the density of microvessels was higher in the peripheral tumor tissue close to the margin than in the central areas. Therefore, the peripheral tissue sections were used for counting of microvessels. Any brown-stained endothelial cells or endothelial cell clusters that was clearly separated from adjacent microvessels, tumor cells, or other stromal cells were counted as one microvessel. For MVD estimation, at low power magnification (×40 and ×100), the tissue sections were screened and five areas with the highest vessel density (hot spots) were selected. Microvessel counts of these areas were performed at a high power field (×200, the surface area of every vision

field being 0.708 mm^2) and the maximum microvessel count of the five richest vascular areas was taken as the MVD.

Statistical analysis

Qualitative data were expressed as the number of cases and quantitative data as mean±SD. These data were analyzed with the SPSS (version11.5) software. The qualitative data were compared using χ^2 test and Fisher's exact test, and the quantitative data were compared using one-way analysis of variance and independent sample *t*-test. Correlation between factors was evaluated using the Spearman's rank correlation coefficient. $P<0.05$ was considered statistically significant.

RESULTS

Correlation between MMP-9 and clinicopathologic parameters in HCC

The incidence of positive MMP-9 expression in cases with their tumor being more than 5 cm, their tumor capsules being not integral or their tumor without capsules was significantly higher than that in those with their tumor measured either less than or equal to 5 cm in diameter and their tumor capsules being integral ($\chi^2 = 5.283$ and $\chi^2 = 5.258$, $P = 0.032$ and $P = 0.033$, respectively). The incidence of MMP-9 expression was also significantly higher in high-risk group for HCC recurrence and TNM III stage group than in low-risk group for HCC recurrence and TNM I-II stage group ($\chi^2 = 11.160$ and $\chi^2 = 8.680$, $P = 0.001$ and $P = 0.007$, respectively). At the same time no significant correlation was demonstrated between the expression of MMP-9 and other parameters, such as sex, age, ascites, hepatitis B, cirrhosis of liver, value of AFP, and grade of histology (Table 1).

Correlation between iNOS and clinicopathologic parameters in HCC

The positive immunohistochemical staining for iNOS in cases with their tumor capsules being not integral or their tumors without capsules was significantly higher than that in those with their tumor capsules being integral ($\chi^2 = 4.652$, $P = 0.049$). The iNOS immunoreactivity was significantly higher in high-risk group for HCC recurrence than in low-risk group ($\chi^2 = 10.043$, $P = 0.004$). But there was no significant difference between iNOS expression and each of the parameters such as sex, age, value of AFP, TNM stage, tumor size, grade of histology, hepatitis B, cirrhosis

of liver, and ascites in HCC (Table 1).

CD34 expression and its relationship to clinicopathologic parameters in HCC

No CD34 staining was found in the sinusoids of seven healthy liver tissues. In HCC tissues from 32 cases, sinusoid-like tumor vessels reacted intensively with anti-CD34 (mean±SD, 71.53±21.19; range, 31-126), and the positive staining of CD34 distributed with a diffuse pattern or an intensive cluster pattern and was defined as the buffy zonale staining on the cell membrane (Figure 1). In nonmalignant tissue, anti-CD34 stainings were confined to vessels of the portal triad with weak staining in few of the sinusoids at the periportal area in case of cirrhosis or chronic hepatitis. There was a significant difference in MVD between TNM III stage group (79.25±18.08) and TNM I-II stage group (63.81±21.78, t = 2.182, P = 0.037). There was also a significant difference in MVD between high-risk group for HCC recurrence (82.56±17.29) and low-risk group (57.36±17.19, t = 4.100, P = 0.000). But no significant association was noted between MVD and other clinicopathologic features (Table 1).

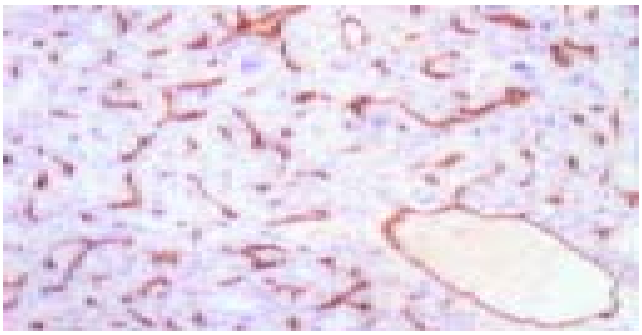

Figure 1 Immunohistochemical staining for CD34 in HCC (×100).

Relationship between iNOS, MMP-9 and MVD in HCC

As shown in Table 2, tumors were divided into three groups based on the degree of immunoreactivity. Along with the increase of immunoreactivity grades, the incidence of iNOS and MMP-9 expression enhanced gradually. The count of MVD was significantly different in different iNOS and MMP-9 immunoreactivity groups (F = 17.713 and 17.097, P = 0.000 and P = 0.000, respectively). The examination of Spearman's rank correlation coefficient showed that there was a significant positive correlation between iNOS, MMP-9 immunoreactivity and MVD (r = 0.754 and 0.751, P = 0.000 and P = 0.000, respectively).

Table 2 Relationship between MVD and MMP-9, iNOS staining intensity in HCC (mean±SD)

Degree of staining	n	iNOS	n	MMP-9
–	9	49.33±11.24	7	48.57±14.62

[b]P<0.01 *vs* degree of staining (–), [d]P<0.01 *vs* degree of staining (++).

Correlation between MMP-9 and iNOS expression in 32 HCC tissues

There was no MMP-9 staining in the normal liver tissue. MMP-9 immunoreactivity was detected in 25 (78.13%) of 32 HCCs. MMP-9 was mainly localized in cytoplasm and cytoplasmic membranes and its staining was detected in vascular endothelial cells, bile ducts, HCC cells, and stromal fibroblasts (Figures 2A and B). iNOS was expressed weakly in healthy liver tissue and mainly localized in tumor

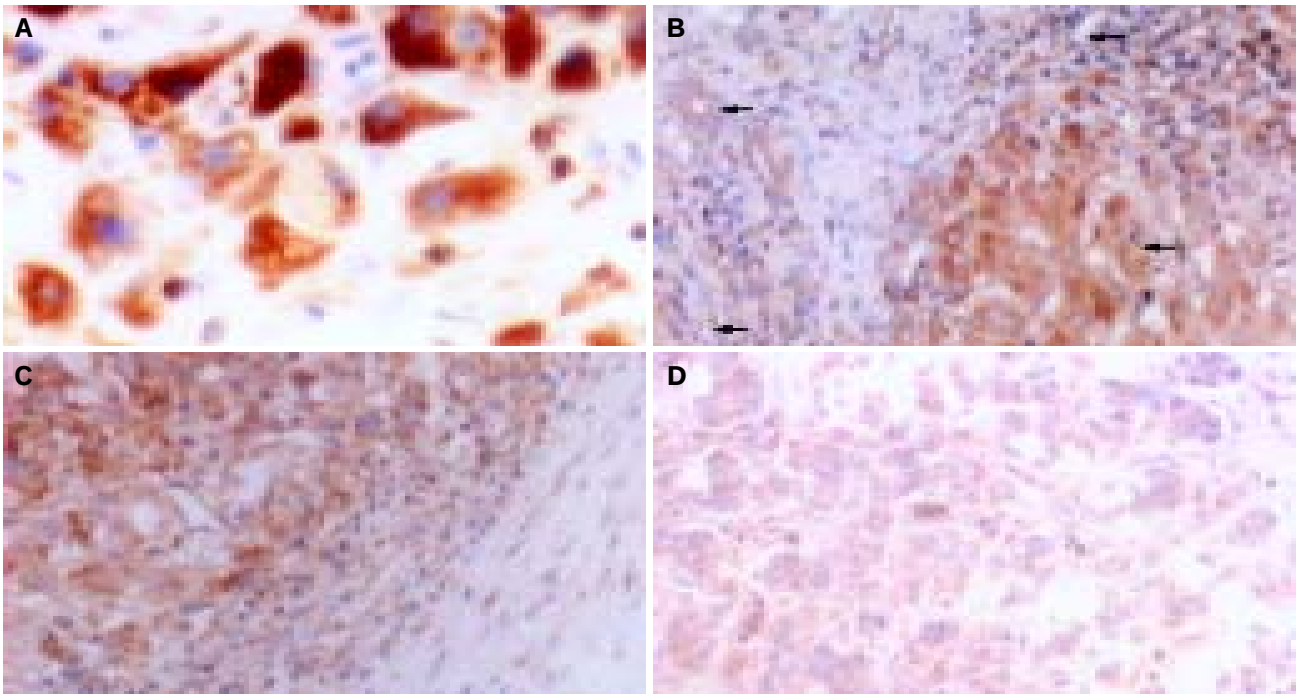

Figure 2 Immunohistochemical staining for MMP-9. A: MMP-9 in cytoplasm and cytoplasmic membranes in HCC (×400); B: MMP-9 in vascular endothelial cells, bile ducts, HCC cells, and stromal fibroblasts (arrow heads from top to bottom) within HCC (×200); C: MMP-9 expression in neighboring capsule of HCC (×200); and D: weak expression of MMP-9 in central areas of HCC tissues (×200).

cytoplasm with a diffuse distribution pattern and a granular pattern. It was also found in cell membranes occasionally. There was no expression of iNOS in tumor nuclei or interstitial cells (Figure 3A). The common characteristics of MMP-9 and iNOS expression were that their stainings were more frequent in tumor cells localized in the anterior borders of invasion or neighboring capsules of tumor tissues (Figures 2C and 3B) than in those cells in central areas (Figures 2D and 3C) and that they displayed various degrees of intensities and inter-tumor heterogeneity. There was a significant correlation between MMP-9 and iNOS expression ($\chi^2 = 8.052$, $P = 0.010$, Table 3).

DISCUSSION

HCC is the fifth most common malignant disease in the world, causing almost one million deaths annually[28]. Surgical resection is the only proven cure for HCC, yet over 80%[29] of patients with HCC undergoing hepatectomy develop new tumors in the residual livers within 2 years. Further investigation of the pathological and biological factors of HCC in relation to recurrence and metastasis using molecular biology techniques will provide promising strategies for treatment and prevention of cancer invasion.

MMP-9 plays a key role in cancer invasion and metastasis by digesting native type IV collagen, which is a major structural component of basement membranes, since increased MMP-9 levels have been observed in various tumors such as HCC[30], bladder carcinoma[33], head, and neck cancer[19]. There is a trend toward a higher proportion of active MMP-9 with an increasing invasiveness of tumor cells. Our immunohistochemical study showed that the expression of MMP-9 was negative in the 7 normal liver tissues, and positive in 25 (78.13%) of 32 HCC tissues, suggesting that MMP-9 is produced by tumor cells. The strong staining in the marginal areas of tumor tissues suggests the close involvement of MMP-9 in the digestion of ECM. Moreover, positive staining of some fibroblasts and endothelial cells with anti-MMP-9 antibody suggests a participation of these cells in degradation of the ECM. The incidence of MMP-9 expression was significantly higher in high-risk group for HCC recurrence and TNM III stage group than in low-risk group and TNM I-II stage group, suggesting that overexpression of MMP-9 plays an important role in the progress of HCC, and that MMP-9 protein may serve as a marker for invasiveness and metastasis of HCC. These results are similar to the results reported by Arii *et al*.[30], and Hayasaka *et al*.[31]. In contrast to their study, there was also a significant correlation between MMP-9 expression and tumor size and capsule status of HCC. Both MMP-9 mRNA and activation of latent type of MMP-9 are significantly correlated with capsular infiltration of tumor[32]. Durkan *et al*.[33], reported that MMP-9 staining is associated with tumor size. Therefore, the above data further indicate that MMP-9 plays an important role in the dispersion of HCC cells and may accelerate the growth of tumors by enhancing angiogenesis of tumors.

MVD is an important indicator to reflect the level of tumor angiogenesis[34]. The result of our study revealed that there was a positive association between the extent of neovascularization and the clinicopathologic characteristics related to aggressiveness, such as TNM stage and risk of recurrence, indicating that the MVD reflects the potentiality for HCC recurrence and metastasis. We also found that the MVD was statistically different in different MMP-9 immunoreactivity groups. There was a significant positive relationship between MMP-9 and MVD, the higher the MMP-9 expression, the higher the MVD. MMP-9 plays a vital role in the turnover of basement membrane collagen types IV and I, which exert a crucial effect on the formation of new capillary sprouts and neoangiogenesis. Based on the above facts, we speculate that MMP-9 expression may initiate angiogenesis and promote vascularization.

A large body of clinical and experimental data suggest that NO plays a promoting role in tumor progression and metastasis[35-37], though a few reports indicate that the presence of NO in tumor cells or their microenvironment may exert deleterious effects on the tumor cell survival and consequently their metastatic ability[13]. In the current study, we found that iNOS was expressed weakly in healthy

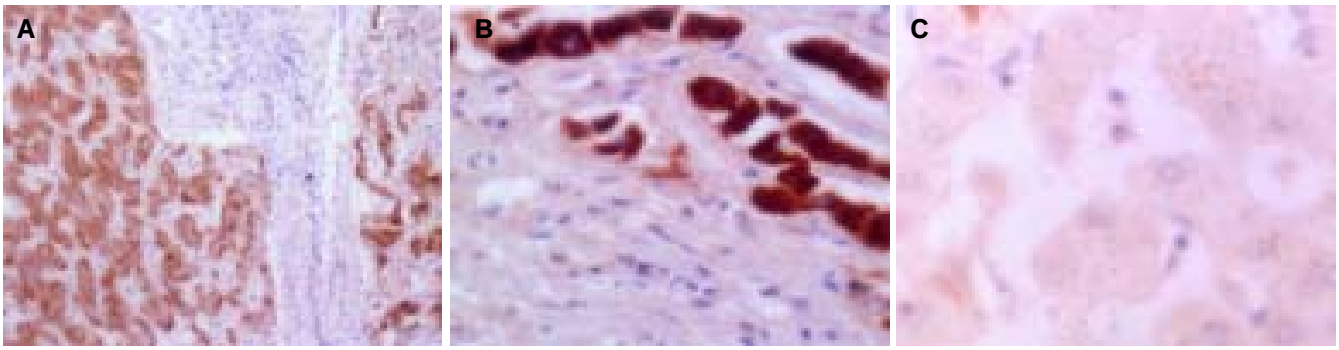

Figure 3 Immunohistochemical staining for iNOS. A: iNOS expression in tumor cytoplasm (×100); B: strong expression of iNOS in neighboring capsule of HCC tissues (×400); and C: weak expression of iNOS in central areas of HCC tissues (×400).

liver tissues, suggesting that iNOS is associated with the physiological function of normal liver tissues. The expression of iNOS showed strong cytoplasmic staining in cancerous cells but not in tumor nuclei and interstitial cells, suggesting that NO is produced by HCC cells and directly or indirectly influences the fate of HCC cells. Here, we also demonstrated that the rate of iNOS expression in cases with their tumor capsules being not integral or their tumors without capsules was significantly higher than that in those with their tumor capsules being integral. The expression of iNOS in high recurrence-risk group was significantly higher than that in low recurrence-risk group, indicating that iNOS positivity is upregulated along with the biological aggressiveness of HCC lesions. It seems more likely that iNOS may increase the viability and infiltrative potential of HCC.

In this study, the count of MVD was statistically different in different iNOS immunoreactivity groups, the higher the iNOS expression the higher the MVD. NO has been implicated in all processes of angiogenesis in a manner consistent with a pre-angiogenic phenotype[38]. iNOS-transfected human colon adenocarcinoma DLD-1 cells have a higher vessel density and a higher growth rate *in vivo* than parental cells in mammary tumor model, suggesting that NO is a key mediator of C3L5 tumor-induced angiogenesis in NOS inhibitor-treated mice[39]. Therefore, the above data further indicate that local NO production by iNOS in HCC cells is able to enhance angiogenesis. It was reported that MMP-9 can also facilitate angiogenesis[40]. In this study, we found that there was a significant association between MMP-9 and iNOS. Both MMP-9 and iNOS positive expressions were more frequent in tumor cells localized in the anterior borders of invasion or neighboring capsules of tumor tissues and were associated with the capsule status and the risk of HCC recurrence, demonstrating that the effect of iNOS on angiogenesis can promote metastatic potential as well as tumor invasiveness by inducing HCC cells to produce MMP-9. To evaluate the mechanism, further investigations are needed.

In conclusion, there is a significant positive correlation between MMP-9 and iNOS expression, suggesting that NO produced by iNOS modulates MMP-9 production and therefore contributes to tumor cell angiogenesis, invasion, and metastasis in HCC. The strong expression of iNOS and MMP-9 in HCC may be helpful in evaluating the recurrence of HCC, predicting poor prognosis. For patients with strong expression of MMP-9 and iNOS, the optimal treatment scheme needs to be selected.

Abstract

AIM: To study the anti-hepatoma efficiency of arsenic trioxide (As_2O_3) in the treatment of experimental rat hepatocellular carcinoma (HCC) induced by 2-acetamidofluorene (2-FAA) and to elucidate the possible mechanisms.

METHODS: SD rats (2 mo old) had been fed with 2-FAA for 8 wk to induce HCC, and then they were treated with As_2O_3 or matrine. On d 29, the rats were killed and the liver was weighed and liver tumors were counted. The histological changes of liver tissue were observed under microscope, and the cellular dynamic parameters were studied by flow cytometry. Immunohistochemistry (two-step method) was used to observe the expression of vascular endothelial growth factor (VEGF) and micro-vessel density (MVD) on consecutive sections. The pathological parameters were also analyzed, the levels of serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin (TBi), and direct bilirubin (DBi).

RESULTS: The number of liver tumors decreased significantly in groups treated with As_2O_3, especially in medium-dose (1 mg/kg) group (t = 2.80, P<0.01). As_2O_3 caused HCC cell death via apoptosis; necrosis was seen and apoptosis was common when the dose was 1 mg/kg. Proliferation index decreased sharply in medium-dose (1 mg/kg) group (7.87±4.11 *vs* 24.46±6.49, t = 2087, P<0.01), but not in 0.2 mg/kg group. However, S-phase fraction decreased dramatically in both groups, it reached the bottom level only when the dose was 1 mg/kg compared with control (0.40±0.13 *vs* 3.01±0.51, t = 2.97, P<0.01), and it was obviously accompanied with accumulation of cells in G_0/G_1 (G_0/G_1 restriction). The expressions of VEGF and MVD in medium-dose (1 mg/kg) group were significantly lower than normal saline group (0.63±0.74 *vs* 2.44±0.88, P<0.05; 15.75±3.99 *vs* 47.44±13.41, t = 2.80, P<0.01). Compared with normal saline group, medium- and low-dose groups As_2O_3 and matrine lowered the levels of ALT in serum (61.46±9.46, 63.75±20.40, 61.18±13.00 *vs* 108.98±29.86, t = 2.14, P<0.05), but had no effect on the level of serum AST, TBi, and DBi.

CONCLUSION: As_2O_3 had inhibitory effect on growth of experimental HCC in rats induced by 2-FAA, but had no obvious effect on normal hepatic cells. The mechanisms may involve decrease of cell division, accumulation of cells in G_0/G_1 phase, apoptosis of tumor cells, and inhibitory effect on angiogenesis through blocking VEGF.

INTRODUCTION

Hepatocellular carcinoma (HCC), with the highest malignancy and worst prognosis, is a common digestive tumor[1]. In recent years, there have been many clinical drugs for the therapy of HCC patients who cannot tolerate operation, such as tamoxifen[2], flutamide[3], lipiodol for embolism[4], but the results were so far unsatisfactory. Arsenic trioxide (As_2O_3) has been extensively used for many malignant leukemia tumors and was proved to be effective[5]. Zhang found As_2O_3 inhibited growth of experimental HCC by inducing apoptosis of tumor cells[6]. Si applied matrine for late HCCs and noticed growth inhibition and apoptosis of malignant cells[7]. To elucidate the antineoplastic mechanisms of As_2O_3, we treated experimental HCC in rats induced by 2-acetamidofluorene (2-FAA) with As_2O_3, counted liver tumors, examined liver histological changes under microscope, examined expression of vascular endothelial growth factor (VEGF) and micro-vessel density (MVD) of tumor with immunohistochemistry, studied cellular dynamic parameters by flow cytometry, and also investigated the levels of serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin (TBi), and direct bilirubin (DBi).

MATERIALS AND METHODS

Establishment of HCC rat models

Seventy SD rats from blocked population, about 2-mo old, weighing 140-180 g (supplied by the Experimental Animal

Center of Nantong Medical College), were fed with granules mixed by 0.05% (w/w) carcinogen 2-FAA (from Sigma Company, USA), and kept in constant environment (20 ℃, moisture content 50%). During the 3rd-5th wk, some rats died; 4 wk later some visible gray nodes appeared on the liver surface of the dead by autopsy. Moreover, the number and size of these nodes had an increasing tendency. At the end of the 8th wk, 34 rats were still alive, and they were then fed with normal granules.

Grouping of animals Thirty-four HCC rats were divided randomly into four groups: two groups were injected intraperitoneally with As_2O_3 (produced by Haerbing Yida Pharma AG), diluted with four volumes of normal saline before injection, including medium-dose (1 mg/kg per d) and small-dose (0.2 mg/kg per d) groups; the third group was injected with matrine (4.2 g/kg per d) in the same way; the last was injected with normal saline (1.5 mL/kg per d) similarly. Treatment effects in all groups were observed: group A (with medium-dose As_2O_3 for 4 wk, n = 8); group B (with small-dose for 4 wk, n = 9); group C (with matrine for 8 wk, n = 8); group D (with saline for 4 wk, n = 9). During the experiment, we weighed the rats and then adjusted the dosage each week.

Sampling of liver and serum specimens At the end of the treatment, 34 rats were killed under diethyl ether anesthesia. Blood (4-5 mL) was drawn from heart and serum sample was collected after blood clotting and stored at 20 ℃ until assay. Whole liver was taken out and weighed immediately after rats were killed. After recording the distribution, size, and number of neoplastic nodes on the liver surface, we fixed part of liver tissue in 10% neutral formaldehyde for pathological examination.

Histopathologic and immunohistochemical examination Formaldehyde-fixed liver tissue was embedded in paraffin, cut into 4-μm-thick sections, some were stained with routine hematoxylin and eosin (HE) to observe liver neoplasia and morphological apoptosis under microscope; the others were examined with the immunohistochemical method. Polyclonal antibodies of VEGF and FVIIIRAg were obtained from the Beijing Zhongshan Biotechnology Company Limited. The two-step staining method consisted of the following main procedures: paraffin section was dewaxed and hydrated; tissue antigens were retrieved with microwave; the first antigen was dropped on tissue section, subsequently, which was incubated in a wet box at 37 ℃ for 1 h. After addition of envision reagent, these sections were put into a wet box again at room temperature for 30 min. Between the above-mentioned steps, tissue sheets were washed thrice in Tris-buffered saline (TBS, 0.01 mol/L, pH 7.4). After that, these tissue samples were colored with dolichos bifows agglutinin, cellular nuclei were redyed with hematoxylin and then sealed. In the negative control group, TBS was used as the first antibody, while the positive controls were from confirmed positive tissue specimens.

Buffy granules in cytoplasm were indicative of positive VEGF expression. According to Wang's standards[8], the median percentage of VEGF-positive-stained cells in 10 high power fields (200×) was counted. These medians were divided into five classes: less than 10% was negative (-); equivalent to or more than 10% was positive: 10-25% was +, 26-50% was ++, 51-75% was +++, and 76% or above were ++++. The five classes were respectively graded as 0-4.

MVD count was in accordance with Weidner's method (ref no.). First under low power microscope, the most intensive micro-vessel area in tumor tissues was identified, and then counted under high power (400×). Any buffy-stained endothelial cell or cell tuft, as well as any structure-unconnected micro-vessel branch, which was distinct from the surrounding tumor cells and connective tissues, was regarded as one "micro-vessel", excluding those vessels with muscular layers or a cavity with more than eight RBCs. The average of three counts was MVD of a liver tissue sample, which was checked by two pathological doctors with double-blind method.

Flow cytometric study Single-cell suspension, about 0.2 g, was prepared from fresh liver neoplasm tissue, first washed twice in PBS, cut into fragments with a clipper, and then filtered twice through a 35-μm-pore nylon filter. Cell count ranged from 3×10^5 to 10×10^5 cells/mL per sample. The suspension was spun by centrifugation at the rate of 1 000 r/min for 5 min, and washed in PBS twice. The obtained pellet was fixed by 70% cold ethanol, and then stored at -20 ℃ for 12-18 h. After being spun and washed again as previously described, the fixed single-cell suspension was pipetted into 0.01% RNase solution (Becton Dickinson Corporation) 200 μL, vortex-mixed and incubated continuously at 4 ℃ for 30 min, stained with 50 μg/mL propidium iodide 200 μL (Becton Dickinson Corporation), and then placed in the dark at 4 ℃ for 10 min. The sample was analyzed from 30 min to 3 h after addition of propidium iodide. Flow cytometric analysis was performed with an FACS Caliber flow cytometer (Becton Dickinson Corporation), which was equipped with a 5 W argon-ion laser. The fluorescence intensity of propidium iodide-stained nuclei, excited by blue laser light (488 nm) with 200 mW of light-regulated power, was quantified after filtering through a 457-502 nm nylon blocking filter. Percent coefficient of variation (%CV) was adjusted to less than 4% with glutaral-fixed chicken erythrocyte nuclei (CEN). Two-micron beads function to verify instrument alignment. The modifier for color compensation was corrected with a fluorescence microsphere. A minimum of 1×10^4 stained nuclei was examined through the flow cytometer, and the data were saved in a computer. DNA data were acquired using CELLQuest, and analyzed with ModFit LT™. Normal peripheral blood lymphocytes and normal SD rat liver cells were used as the control samples to identify the staining efficiency of propidium iodide and the channel of diploid cells (G_0/G_1 phase cells). With the G_0/G_1 peak of CEN as an internal standard, both G_0/G_1 and G_2/M peaks of analyzed samples were determined, and then the DNA quantity was calculated. Cell cycle percentages were derived from DNA histograms. The peak of hypodiploid, anterior to the G_0/G_1 peak, was the apoptosis peak. Proliferative index (PI) was equal to the sum percentage of S-phase and G_2/M-phase nuclei to all; the S-phase fraction (SPF) was determined and calculated with the area under the curve between G_0/G_1 and G_2/M peaks.

Serum enzyme determination Serum AST, ALT, TBi,

and DBi total activity were measured by the direct method of nitrobenzenamine.

Statistical analysis

Experimental data were shown as mean±SD. Student's *t*-test, and rank sum test were performed to assess potentially significant differences between individual groups, with STATA 7.0 statistical analysis software. A P value of <5% was regarded as significant when comparing various groups.

RESULTS

General observation during treatment

During the 1st wk, several As_2O_3-administrated SD rats had a short-term sinus tachycardia, which self-recovered after 1 or 2 d. Skin induration could be avoided if injection sites were changed daily. Whether by As_2O_3 or matrine treatment, there was no significant difference between the treatment group and the control, in terms of body weight gain and the weight ratio of liver to body (Table 1).

Table 1 Changes of body and liver weights in SD rats (mean±SD)

Groups	Body weight	Weight gain	Liver weight	Liver weight /body weight
A	272.25±35.51	74.25±20.71	12.475±1.9	3.49±0.40
B	247.56±63.94	58.44±16.99	13.11±3.15	4.42±0.60
C	253.00±28.63	58.25±24.01	12.54±1.132	4.08±0.50
D	258.22±49.99	40.44±40.15	11.89±1.59	4.24±1.00

Morphological changes In contrast to the normal, HCC rat liver was gray, and hard, both volume and weight increased; slight hemorrhage and necrosis could be found on liver cross section; multiple nodes were distributed unevenly on liver surface, mostly 1-6 mm in diameters, one 9 mm-diameter node was found in the control group; the nodes were widespread on part of liver lobes, more evidently in the saline group; bulky tumor nodes appeared more frequently in the control groups. On the contrary, less node-widespread liver lobes and smaller tumor nodes were found in As_2O_3-treated rats (Table 2).

At the end of 4-wk treatment, five rats in group A and three rats in group B had no visible liver tumor nodes; while in the control group, all rats had widespread nodes on liver lobes and only one had sparsely distributed nodes on liver lobes (Figures 1A and B). Visible neoplastic nodes and node-widespread liver lobes in group A were less than those in groups B (P<0.05) and C (P<0.01), there was no significant difference between groups B and C.

Table 2 The number and distribution of tumor nodes on rat liver

Groups	*n*	2–4 mm diameter nodes	>4 mm diameter nodes	Liver lobes with diffuse nodes
A	8	0 (0)	1 (0.125)	0 (0)
B	9	50 (5.56)	9 (1)	17.5 (1.94)
C	8	137 (15.22)	13 (1.44)	29 (3.22)
D	9	223 (24.778)	49 (5.444)	39 (4.333)

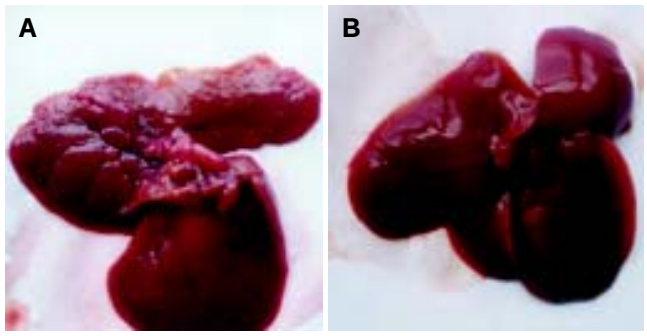

Figure 1 Gross changes of rat's liver after treatment. A: The control group (4 wk after NS injection); B: The treatment group (4 wk after medium-dose As_2O_3 injection).

Pathological examination Under microscope, all 2-FAA-induced HCC rat liver tissues had hepatic cell degeneration, oval cell proliferation, and inflammatory cell infiltration. There were more extensive infiltrations of inflammatory cells in control groups. Whereas in group A, these pathological changes were comparatively slight: there were fewer infiltrating inflammatory cells, more regenerated nodes, partly abnormal differentiated cells, and fewer carcinoma nodes (Figure 2A). There were more apoptotic cells in As_2O_3-treated tumor tissues, which were shrunk and separated from other surrounding cells, round or oval in shape, and had complete cellular membrane; chromatin of apoptotic cells was condensed, edge-gathered or broken, and formed into intra-cellular nucleosomes of different sizes; acidophilia of shrunk cytoplasm was raised; no infiltrating inflammatory cells were seen near apoptotic cells (Figure 2B).

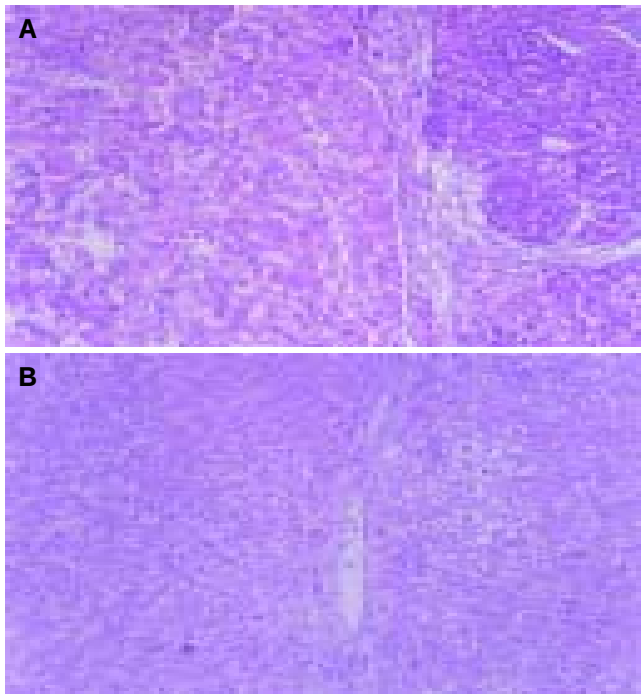

Figure 2 Pathological changes after treatment. A: The control group (4 wk after NS injection, HE×20); B: The treatment group (4 wk after medium-dose As_2O_3 injection, apoptotic cell observed).

Distribution of cell cycle phases The mean percentages of SPF, G_2/M phase, and PI of the 4-wk As_2O_3 group were less than those of the control ($P<0.05$), while G_0/G_1 phase mean ratio increased insignificantly ($P>0.05$, Table 3, Figures 3A and B).

The apoptotic rate in liver tumor tissues By means of DNA content assay, an obvious hypodiploid peak, before the G_0/G_1 peak, was called the apoptotic peak (Figures 3A and B). There was a significant increase in the apoptotic rate of the 4-wk As_2O_3-treated group compared with that of the control ($P<0.01$).

Levels of serum enzymes Compared with the control, serum ALT level of the 4-wk-treated groups was decreased ($P<0.05$), while AST, TBi, and DBi activity differed insignificantly ($P>0.05$, Table 4).

Immunohistochemical staining results Widespread brown cytoplasmic granules were VEGF positive, chiefly distributed inside tumor tissues and near the vessel endothelial cells (Figure 4A). In group A, more rats showed + to ++ degree VEGF signals, while four of eight rats were VEGF negative; in the control groups, more signals were from ++ to +++, with no negative expression (Figure 4B). There was a weakened intensity of VEGF in group A rats in comparison with the control and C groups ($P<0.05$, Table 5), but the difference was insignificant in all treatment groups ($P>0.05$), except for group A.

Vessel endothelial cells of tumor tissues, exhibited by FVIIIAg staining, formed into irregular micro-vessels, in the shapes of cluster and germination, which distributed unevenly, more intensively at the edge of tumor tissues (Figure 5A). As_2O_3 administration obviously inhibited neovascularization of liver tumor (Table 5, Figure 5B).

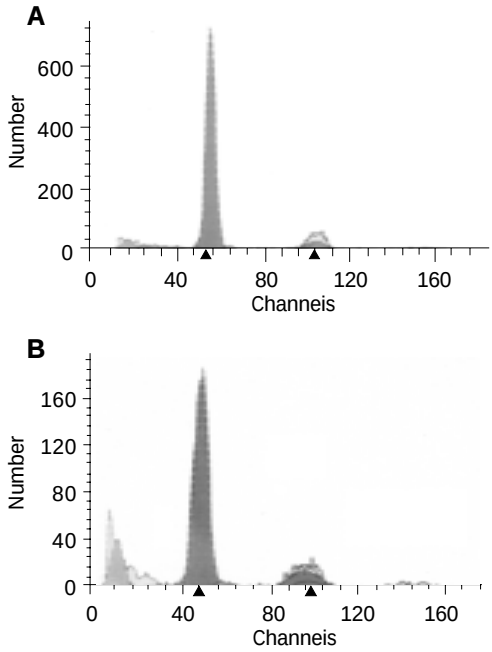

Figure 3 Changes of cell cycle phases after treatment. A: the control group (4 wk after NS injection); B: The treatment group (4 wk after medium-dose As_2O_3 injection, obvious hypodiploid peak).

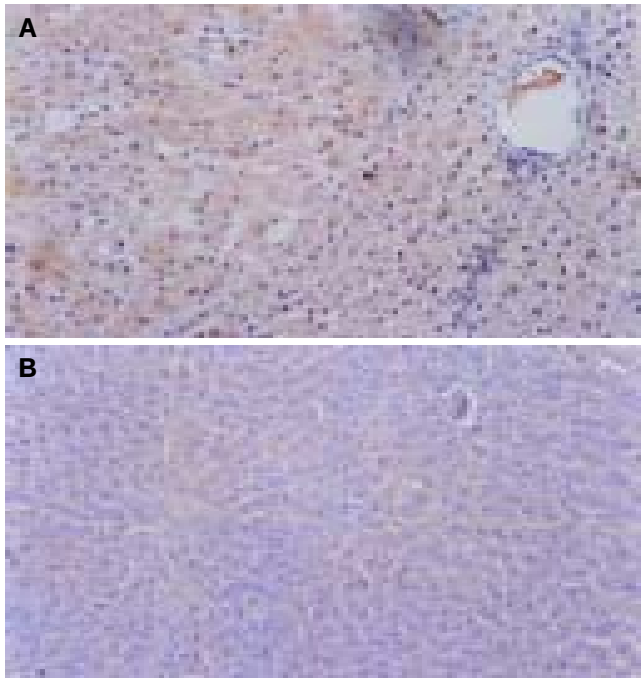

Figure 4 VEGF-positive signals after treatment. A: the control group (4 wk after NS injection, ×20); B: The treatment group (4 wk after medium-dose As_2O_3 injection, ×20).

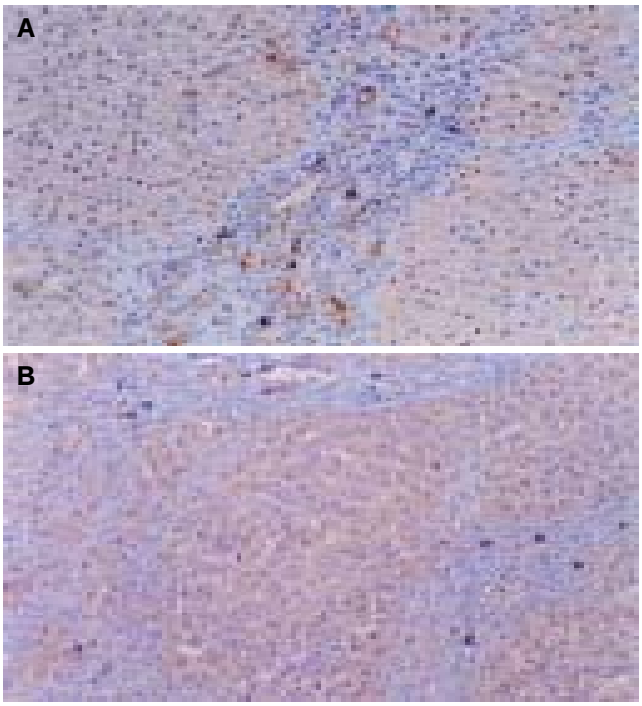

Figure 5 Micro-vessels by FVIIIAg staining after treatment, ×20. A: The control group (4 wk after NS injection); B: The treatment group (4 wk after medium-dose As_2O_3 injection).

DISCUSSION

The antineoplastic mechanisms of As_2O_3 are not yet clear. There are probably five major pathways: (1) inducing apoptosis of tumor cells[6,9-11]; (2) restraining the metastasis of HCC[12]; (3) effecting immunity of liver tumor cells[13]; (4) inhibiting angiogenesis through blocking VEGF; (5) having synergistic anti-hepatoma effect combined with chemical drugs.

PI and SPF often indicate the proliferation of tumor cells. In our study, the distribution of cell cycle phases showed cell proliferation tended to be inhibited after 4-wk of As_2O_3 administration. SPF, G_2/M phase, and PI all decreased ($P<0.05$), whereas G_0/G_1 phase increased insignificantly. More cells were blocked in G_0/G_1 phase. It is implied that As_2O_3 is able to prevent cells transisting from G_0/G_1 phase to S-phase, inhibiting the growth of tumor cells. In addition, apoptosis of tumor cells promoted by As_2O_3 occurred mainly at 1 mg/kg dose. PI decreased sharply in medium-dose (1 mg/kg) group ($P<0.01$), but not in the other (0.2 mg/kg) group ($P>0.05$). However, SPF decreased dramatically in both groups, suggesting 0.2 mg/kg dose also apparently inhibited synthesizing of DNA of tumor cells, but it was weaker. Therefore, antineoplastic mechanisms of As_2O_3 for HCC may involve the following two ways: inhibition of proliferation and induction of apoptosis of tumor cells.

In recent years, much importance has been attached to the relationship between angiogenesis and neoplasm. It has been confirmed that, solid carcinoma, once its diameter is over 2 mm, has to depend on neovascularization for its growth. It is through the blood vessel network that sufficient oxygen and nutrition are transported to meet the needs of high metabolism and fast proliferation of tumor cells. To some extent, the ability of inducing angiogenesis reflects tumor biological behaviors[14].

Various vessel growth factors act as the media to neovascularization, and VEGF is one of the most important one. Flt-1 and KDR/Flk-1, two receptors of VEGF, only exist in vessel endothelial cells, so VEGF promotes the proliferation of endothelial cells with a high specificity. VEGF can obviously improve the vessel permeability, which play an important role in tumor infiltration and metastasis[14,15]. It is necessary to find an objective and accurate indicator for the neovascularization. Thus, MVD count, which is for this purpose, has become a hot spot. In our study, VEGF and MVD were chosen to reflect the activity of tumor neovascularization. Our experiment showed that inhibitive effect of As_2O_3 on the angiogenesis was through inhibition of VEGF.

Morphological improvement by As_2O_3 in HCC rats could also be explained with its effects on cytokinetics. The number and distribution of liver tumor nodes decreased significantly in the As_2O_3-treated than in the controls, especially in medium-dose (1 mg/kg) group ($P<0.01$). As_2O_3 also lowered VEGF expression and MVD count in rat liver tumor tissues.

Compared with normal saline group, administration of As_2O_3 or matrine lowered the levels of AST in serum ($P<0.05$), but had no effect on the amount of serum AST, TBi, and DBi ($P>0.05$), indicating As_2O_3 has no obvious effect on normal hepatic cells.

In summary, through effective inhibition of proliferation, inducement of apoptosis, and restrain of neovascularization of tumor, As_2O_3 can serve as a new alternative for HCC treatment without serious adverse effects.

Abstract

AIM: To investigate how weight gain after OLT affects the speed of fibrosis progression (SFP) during recurrent hepatitis C virus (HCV) infection of the graft.

METHODS: Ninety consecutive patients (63 males, median age 53 years; 55 with HCV-related liver disease), transplanted at a single institution, were studied. All were followed for at least 2 years after OLT and had at least one follow-up graft biopsy, performed not earlier than 1 year after the transplant operation. For each biopsy, a single, experienced pathologist gave an estimate of both the staging according to Ishak and the degree of hepatic steatosis. The SFP was quantified in fibrosis units/month (FU/mo). The lipid metabolism status of patients was summarized by the plasma triglycerides/cholesterol (T/C) ratio. Body mass index (BMI) was measured before OLT, and 1 and 2 years after it.

RESULTS: In the HCV positive group, the highest SFP was observed in the first post-OLT year. At that time point, a SFP $\leqslant$0.100 FU/mo was observed more frequently among recipients who had received their graft from a young donor and had a pre-transplant BMI value >26.0 kg/m^2. At completion of the first post-transplant year, a BMI value >26.5 kg/m^2 was associated with a T/C ratio $\leqslant$1. The proportion of patients with SFP >0.100 FU/mo descended in the following order: female recipients with a high T/C ratio, male recipients with high T/C ratio, and recipients of either gender with low T/C ratio. Hepatic steatosis was observed more frequently in recipients who, in the first post-transplant year, had increased their BMI $\geqslant$1.5 kg/m^2 in comparison to the pre-transplant value. Hepatic steatosis was inversely associated with the staging score.

CONCLUSION: Among HCV positive recipients, excess weight gain post-OLT does not represent a factor favoring early liver fibrosis development and might even be protective against it.

INTRODUCTION

Re-infection by hepatitis C virus (HCV) after liver transplantation (OLT) for HCV-related liver disease is almost universal, but the degree of necro-inflammatory damage and fibrosis deposition in the liver graft varies[1]. In the majority of cases, recurrent hepatitis C is mild. In up to one-third of OLT recipients with recurrent hepatitis C, however, a more severe course is observed, with progression to frank cirrhosis in less than 5 years[2]. The mechanisms associated with early fibrosis progression in this setting are actively investigated but remain poorly understood.

After liver transplantation, most patients gain weight[3], partly because of better health and freedom from pre-transplant dietary restrictions. As a result, within 2 years after the transplant operation, 60% of liver transplantation recipients are either overweight or obese. The role of excess weight post-transplant as a cardiovascular and metabolic risk factor has been widely addressed[4]: whether it may also contribute to graft damage, however, is unclear. Specifically, it is unknown if, in recipients with recurrent hepatitis C, fibrosis occurs earlier and is more severe when the patient is overweight or obese. This is conceivable, though, since data in immune-competent patients with chronic hepatitis C demonstrate that excess body weight leads to steatosis[5-7], acts as a cofactor for fibrosis progression[5,8,9] and represents an independent risk factor for non-response to antiviral treatment[10]. Independently of HCV infection, obesity may cause non-alcoholic steatohepatitis, a disease potentially capable of evolving toward cirrhosis and end-stage liver disease[11-13].

The present retrospective, longitudinal study aimed to investigate the possibility of a relationship between pre- and post-transplant body mass and fibrosis progression during recurrent hepatitis C. The study population included both

HCV positive and negative OLT recipients, in whom the value of body mass index (BMI) evaluated pre transplant and in the first 2 years post-transplant was related to the staging score measured in follow-up liver biopsies, taking into account other factors (pertaining to donor and host) which might have influenced the progression of recurrent hepatitis C.

MATERIALS AND METHODS

Patients

A total of 194 patients received a liver graft from a cadaveric donor between March 1996 and December 2002, at our institution. Insufficient data were available for 53 patients, who died either in the early post-transplant period or were lost to follow-up. Of the remaining 141 patients, 90 consecutive OLT recipients had a minimum follow-up of 2 years after OLT and had been subjected to at least one liver biopsy obtained not earlier than 1 year after OLT, and were included in the present study. Table 1 shows the demographic and clinical characteristics of the studied population. All were maintained in an immunosuppressive regimen that was either cyclosporine- or tacrolimus-based, associated, in the first few months, to corticosteroids. Cyclosporine dosage was calculated to obtain serum levels (measured 2 h after the drug administration) ranging from 800 to 1 200 μg/L in the first 6 wk after transplant and from 600 to 800 μg/L thereafter. Tacrolimus dosage was calculated to obtain pre-dose serum levels ranging from 10 to 15 μg/L in the first 6 wk after transplant and from 5 to 10 μg/L thereafter. Corticosteroid tapering was completed in 8 mo after the transplant in all except six patients (four HCV positive and two HCV negative). Thirty-two out of fifty-five HCV positive patients received antiviral treatment with interferon plus ribavirin due to recurrence of HCV hepatitis, defined as detectable serum HCV-RNA, serum alanine-aminotransferase (ALT) levels above the upper normal limit, Ishak grading score $\geqslant$2 and no evidence of rejection. Therapy was intended to be maintained for 12 mo. Antiviral treatment was started at a median time of 11.4 mo (range 0.7-75.9) after OLT and was completed in 17 patients. In the remaining 15 patients antiviral therapy had to be stopped prematurely due to adverse effects. Body weight was measured to the nearest 0.1 kg and height to the nearest 1 cm, with study participants wearing only underwear and no shoes. BMI was calculated as weight in kilograms divided by the square of the height in meters; it was measured pre transplant and one and 2 years after transplantation. In patients with ascites, pre-OLT BMI was calculated subtracting from the body weight the amount of ascitic fluid calculated on the basis of an ultrasound evaluation.

Liver histology In follow-up liver biopsies, grading and staging were scored according to the method of Ishak[14]. Fibrosis progression was evaluated annually in the first 4 years after OLT. It was based on the staging score at the corresponding "per protocol" liver biopsy, or, when unavailable, on the closest "on demand" liver biopsy. The speed of fibrosis progression (SFP), expressed in fibrosis units per month (FU/mo), was calculated for each 1-year time interval after OLT. It was obtained dividing the change observed in the fibrosis score at the end of the pertinent interval of time, with respect to either the transplant operation (for the first post-transplant year) or the previous liver biopsy (for the following years), by the number of months elapsed. The sum of micro- and macro-vesicular liver steatosis was calculated in each liver biopsy and graded as absent, $\leqslant$10% or >10%. All histological studies were performed by a single experienced histopathologist (CA).

Table 1 Clinical and demographic characteristics of the studied population

Recipient male gender, *n* (%)	63 (70.0)
Donor male gender, *n* (%)	53 (58.9)
Recipient age at transplantation (yr), median (range)	53 (23-66)
Donor age (yr), median (range)	41 (17-77)
Etiology of liver disease, *n* (%)	
HCV infection	55 (61.1)
HBV infection	12 (13.3)
Alcohol abuse	13 (14.5)
Other, unknown	10 (11.1)
Child–Pugh score pre-transplantation, median (range)	8 (5-14)
Immunosuppressive regimen, *n* (%)	
Tacrolimus-based	69 (76.7)
Cyclosporine-based	21 (23.3)
Antiviral therapy in HCV positive, *n* (%)	32 (58.2)

Categorical variables are expressed as frequencies (%); continuous variables as median (range). HCV: hepatitis C virus.

Statistical analysis

Statistical analysis of data was performed by means of the biomedical statistical software package BMDP Dynamic, Rel. 7.0 (Statistical Solutions, Cork, Ireland). Comparisons of continuous variables from two groups were explored by means of the Mann-Whitney's test. Correlations between continuous variables were performed either using the Spearman rank correlation coefficient or the Pearson product moment after logarithmic transformation of the values. Analysis of variance for repeated measures was employed to ascertain the significance of BMI increase post-OLT with respect to pre-OLT values. Wilcoxon matched pairs signed rank sum test was employed to evaluate modifications of fibrosis progression 2 and 3 years post-OLT in comparison to 1 year post-OLT. The associations between categorical variables were explored by means of the Pearson χ^2 test (in selected cases, with comparison of cross product ratios); if appropriate, the χ^2 test for linear trend was applied. Time-to-event analysis was performed to test whether the function to reach a staging score >2, in HCV positive patients, differed according to gender and BMI recorded pre- and 1 year post-OLT. Stepwise logistic regression analysis with a forward approach was used to evaluate the variables independently associated with a high one year post-OLT SFP. A level of 0.05 (two tailed) was chosen to indicate statistical significance.

RESULTS

BMI pre and post-OLT

BMI values, recorded before OLT, as well as 1 and 2 years post-OLT, are expressed in kg/m^2 and presented as medians (25-75th percentiles). For the entire study population, values were 25.0 (23.0-27.1), 25.4 (23.5-27.5) and 26.0 (23.7-28.4),

respectively (ANOVA for repeated measures, $P<0.05$). Among HCV positive recipients, the corresponding values were 24.7 (23.0-26.6), 25.1 (23.3-27.1) and 25.4 (23.4-28.1), respectively. Among HCV negative recipients, the corresponding values were 25.9 (23.0-28.4), 26.0 (24.0-28.0) and 26.6 (24.2-28.9), respectively. A BMI value $\geqslant$35 kg/m^2 (the limit indicating grade two obesity) was recognized before transplant operation in one HCV positive male recipient, who had a value of 38.4 kg/m^2. While 1 year after OLT, none of the recipients reached a BMI value $\geqslant$35 kg/m^2, 2 years after transplant, one HCV positive recipient had a BMI value of 36.5 kg/m^2 and one HCV negative patient a BMI value of 37.8 kg/m^2. The BMI values recorded pre-OLT and 1 and 2 years post-OLT were not statistically different between HCV positive and negative recipients. Among recipients belonging to both groups, no association was found between the pre-OLT BMI values and the severity of liver disease, calculated as the Child-Pugh score. Similarly, 1 and 2 years post-OLT BMI values did not differ considering the kind of immunosuppressive regimen in use (cyclosporine- or tacrolimus-based) or the rate of corticosteroid tapering (withdrawal completed before or after 90 d from OLT).

Liver histology

The histological follow-up lasted a median of 48 mo (range, 12-102 mo) in the HCV positive group and 30 mo (range, 12-78 mo) in the HCV negative group. A total of 465 follow-up liver biopsies were performed. In the group of HCV positive patients, the liver biopsies performed in a total of 315 patients, with a median number of five biopsies (range, 1-13) for each patient; protocol biopsies were 106/315 (median: two for each patient). In the group of HCV negative recipients, the liver biopsies performed were in a total of 150 patients, with a median number of four biopsies (range, 1-9) for each patient; protocol biopsies were 51 (median: one for each patient). In a median of 27 mo of follow up after OLT (range, 12-66mo), eight patients (8.8%; 6/8 were HCV positive) developed histological cirrhosis. The causes of cirrhosis in the two HCV negative patients were severe *de novo* autoimmune hepatitis and *de novo* HBV infection, respectively. At completion of the first post-transplant year, the median SFP was significantly faster in HCV positive in comparison to HCV-negative recipients: 0.083 (range, 0-0.455) *vs* 0.059 (range, 0-0.250) FU/mo ($P<0.02$). Table 2 shows the associations observed between 1 year post-OLT SFP >0.100 FU/mo and clinical and demographic characteristics of patients. Older donor age and lower BMI value pre-OLT were both significantly associated with faster fibrosis progression in HCV positive but not in HCV-negative recipients.

Figure 1 shows the fibrosis progression rates calculated at 1-4 years after OLT in the HCV-positive recipients. The fastest rate of fibrosis progression was observed during the 1st year after OLT. Later biopsies demonstrated a decrease in SFP with a non linear logarithmic trend ($r = 0.436$, $F = 37.1$, $P<0.0001$). Starting with the 3rd year after OLT, the SFP stabilized. Among the variables reported in Table 2, only a BMI value 1 year post-OLT >27.5 kg/m^2 was significantly associated with fibrosis progression <0.050 FU/mo (8/8 *vs* 18/35; $P<0.02$) in the 2nd year post-OLT. There was no difference in the SFP at 1 and 2 years post-OLT between patients that completed antiviral therapy as scheduled in comparison to those that either were untreated or terminated early interferon plus ribavirin treatment.

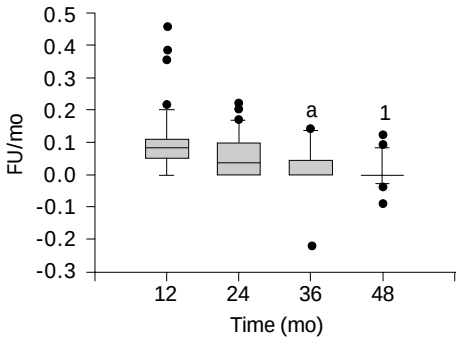

Figure 1 Vertical box plots of fibrosis progression rates in HCV-positive recipients, expressed as FU/mo, at different time points after the transplant operation. Median values, 10th, 25th, 75th, and 90th percentile are reported. Dots indicate outliers. [a]$P<0.005$ in comparison to FU/mo at 12 mo (Wilcoxon matched pairs signed rank sum test), [1]$P = 0.0001$ in comparison to FU/mo at 12 mo (Wilcoxon matched pairs signed rank sum test).

To further explore the relationship between gender and BMI, on the one hand, and fibrosis progression, on the other,

Table 2 Frequencies of patients with a SFP$\leqslant$0.100 FU/mo in the 1st year post-OLT, in relationship with a selection of demographic and clinical variables

	All patients ($n = 90$) FU/mo$\leqslant$0.100 $n = 70$	HCV-positive patients ($n = 55$) FU/mo$\leqslant$0.100 $n = 39$	HCV-negative patients ($n = 35$) FU/mo$\leqslant$0.100 $n = 31$
Recipient male gender ($n = 63$)	53[a]	29	24
Donor male gender ($n = 53$)	40	19	21
Recipient age $\leqslant$55 yr ($n = 54$)	42	19	23
Donor age $\leqslant$45 yr ($n = 54$)	47[d]	29[f]	18
Pre-OLT BMI >26.0 kg/m^2 ($n = 35$)	32[b]	16[c]	16
Tacrolimus therapy ($n = 69$)	56	31	25
Corticosteroid tapering >90 d ($n = 47$)	39	25	14
Diabetes mellitus ($n = 24$)	17	10	7

FU/mo: fibrosis units per month, HCV: hepatitis C virus, BMI: body mass index, [a]$P<0.05$ *vs* recipient female gender, [b]$P<0.02$ *vs* pre-OLT BMI $\leqslant$26 kg/m^2, [d]$P<0.01$ *vs* donor age >45 yr; [c]$P<0.05$ *vs* pre-OLT BMI $\leqslant$26 kg/m^2, [f]$P<0.001$ *vs* donor age >45 yr. P value refers to χ^2.

Table 3 Degree of hepatic steatosis in 105 biopsies performed between 12 and 36 mo after the transplant operation (HCV-positive recipients only), in relationship with a selection of variables

	Steatosis			
	Absent (n = 34)	≤10% (n = 60)	>10% (n = 11)	P
Ishak staging score≤2 (n = 79)	19	49	11	<0.005
Recipient male gender (n = 72)	20	42	10	<0.05
Recipient age≤55 yr (n = 50)	15	28	7	NS
Donor age≤45 yr (n = 65)	19	39	7	NS
BMI increase <1.5 kg/m^2 (n = 76)	29	41	6	<0.05
Recurrent hepatitis C≤1 yr post-OLT (n = 79)	31	41	7	<0.02
Diabetes mellitus (n = 31)	10	18	3	NS

BMI: body mass index, OLT: orthotopic liver transplantation, BMI increase: difference between BMI value 1 yr post-OLT and BMI value pre-OLT. P value refers to χ^2 for linear trend.

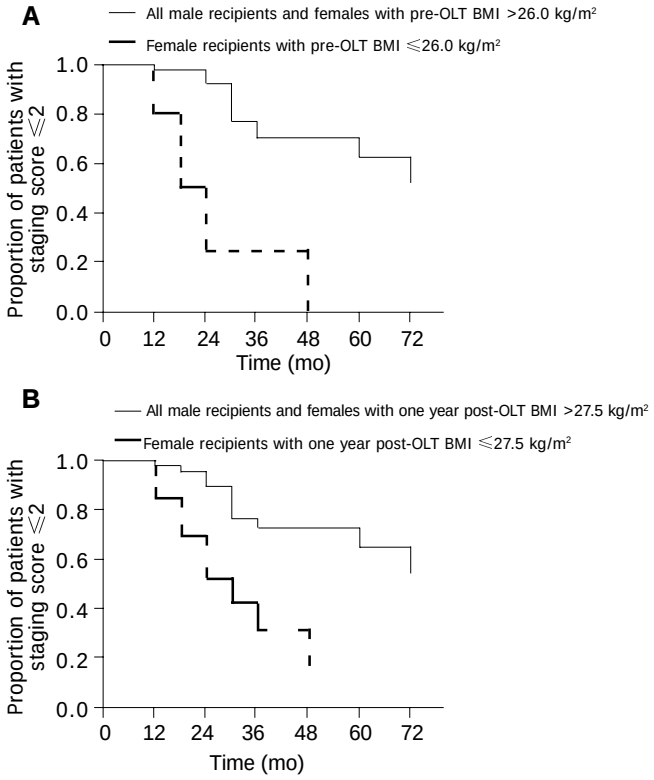

Figure 2 A: Time-to-event analysis to reach a staging score >2. HCV-positive recipients were divided as follows: all the male recipients and those females with pre-OLT BMI value >26.0 kg/m^2 (n = 45, continuous line); females with pre-OLT BMI value ≤26.0 kg/m^2 (n = 10, dotted line). B: Time-to-event analysis to reach a staging score >2. HCV-positive recipients were divided as follows: all the male recipients and those females with 1 year post-OLT BMI value >27.5 kg/m^2 (n = 42, continuous line); females with 1 year post-OLT BMI value ≤27.5 kg/m^2 (n = 13, dotted line).

we categorized OLT recipients as follows: females with BMI pre-OLT ≤26.0 kg/m^2 (group A^{pre}) or ≤27.5 kg/m^2 1 year post-OLT (group A^{post}); males with pre-OLT BMI value ≤26.0 kg/m^2 (group B^{pre}) or ≤27.5 kg/m^2 1 year post-OLT (group B^{post}); recipients of either gender and pre-OLT BMI >26.0 kg/m^2 (group C^{pre}) or >27.5 kg/m^2 1 year post-OLT (group C^{post}). Group A^{pre} showed the fastest SFP 1 year post-OLT, in comparison to group B^{pre} and group C^{pre} (7/10 *vs* 7/27 *vs* 16/18; P<0.002 for linear trend); a similar trend also was found considering 1 year post-OLT BMI and 2 years post-OLT fibrosis progression (A^{post} 6/10 *vs* B^{post} 11/25 *vs* C^{post} 8/8; P<0.02 for linear trend). Time-to-event analysis showed that, in females with lower BMI, the probability to reach a staging score >2 was the highest in comparison to all other recipients; this observation held true either considering BMI values pre-OLT (Figure 2A, Mantel-Cox, P<0.0001) or BMI values 1 year after OLT (Figure 2B, Mantel-Cox, P = 0.0005). Stepwise logistic regression analysis was performed among the predictive variables that, at univariate analysis, were associated, with a P value <0.10, to faster SFP (donor age, recipient gender, type of immunosuppressive therapy, and pre-OLT BMI). A SFP in the 1st year post-OLT >0.100 FU/mo was independently associated with older donor age (improvement of χ^2 11.63, P = 0.001), female recipient gender (improvement of χ^2 5.09, P<0.05) and lower pre-OLT BMI value (improvement of χ^2 4.26, P<0.05).

Post-OLT BMI, blood lipids, and liver steatosis One year post-OLT, having a BMI >26.5 kg/m^2, was found to be associated with a triglycerides/cholesterol (T/C) ratio ≤1 (14/15 *vs* 26/40, P<0.05). In relationship to the recipient gender, a low T/C ratio, i.e., higher serum levels of cholesterol than of triglycerides, was associated both to a delayed (>1 year) hepatitis C recurrence and to a slower post-OLT SFP. Female recipients with a high T/C ratio had the highest proportion of early hepatitis C recurrence and 1 year SFP >0.100 FU/mo, followed by male recipients with high T/C ratio and patients of either gender with low T/C ratio: 4/4 *vs* 11/11 *vs* 28/40 (P<0.05 for linear trend), and 4/4 *vs* 3/11 *vs* 9/40 (P<0.01 for linear trend), respectively.

One-hundred and five liver biopsies were performed in HCV-positive patients along the period of time elapsed between 12 and 36 mo post-OLT. Table 3 shows the relationship between hepatic steatosis and a selection of variables, including the Ishak fibrosis score. Male gender, delayed hepatitis C recurrence, and body weight gain post-OLT were positively associated with steatosis; on the contrary, progression to significant fibrosis was less frequent in the presence of hepatic steatosis.

[redacted]

Post-OLT fibrosis progression in patients transplanted for HCV-related liver cirrhosis has been recently reported to behave not linearly[15], reaching, a sharp increase in the first

2 years, a plateau at the 3rd year after OLT. In the present paper, we confirmed this observation, showing that fibrosis progression during the 1st year after OLT is faster than that observed in the longer follow-up, when the process tends to slow down. Furthermore, early fibrosis progression in the grafts of HCV recipients is confirmed to be related to factors pertaining both to the donor and to the host. First and most importantly, fibrosis progression is affected by the age of donors, in agreement with previous work by several authors who considered an aged donor as the strongest predictor of fibrosis progression in patients with post-OLT HCV recurrence[16]. Second, a novel finding and the focus of the present investigation, early fibrosis progression after OLT appears to be related to the BMI value measured either pre-OLT or post-OLT. The association is not direct, as one might expect, but inverse: the higher the BMI value, the lower is the degree of early fibrosis development. This association is peculiar to HCV-positive patients and was not observed in HCV-negative recipients. Third, the presence of steatosis in the graft, which occurs in association with the increase in BMI, does not predict, as reported in immune-competent patient, a higher fibrosis score. To reconcile these findings with the existing literature, the elements that need to be considered in detail concern the differences that exist between the natural history of HCV infection in immune-competent *vs* OLT patients, and the putative molecular mechanisms of HCV re-infection.

Obesity[5,8,9] and liver steatosis[6,17,18] are recognized factors of liver fibrosis progression in HCV-positive immune-competent patients. Some authors have hypothesized a direct steatogenic effect of HCV, supported by several lines of evidence: the development of progressive hepatic steatosis in transgenic mice expressing the HCV core gene[19], the inhibition of very low density lipoprotein (VLDL) secretion in a transgenic murine model expressing HCV core protein[20], the close relationship between intra-hepatic HCV RNA and development of steatosis[21], and the correlation between hepatic steatosis and hepatic HCV replication in patients infected with HCV genotype 3[22]. Others have investigated the mechanisms involved in the progression of liver fibrosis due to the concomitant presence of steatosis and HCV infection, suggesting that steatosis might contribute to fibrosis through a steatohepatitis-like pathway involving stellate cell activation and peri-sinusoidal fibrosis production[23]. In OLT patients, however, the situation is different. A recent report[24], while confirming that body weight is the best predictor of liver steatosis 12 mo post-OLT, demonstrated that allograft steatosis does not predict the severity of HCV recurrence in HCV-infected patients within the first 12 mo after OLT. The present results converge in the same direction, and suggest, for the first time, that overweight, while facilitates liver steatosis, on the other hand may protect the liver graft, during an initial phase, from the damage due to HCV recurrence. Further data outline the need to be cautious when transposing the information concerning the natural history of HCV in immune-competent patients to the natural history of HCV recurrence post-OLT. For example, female gender, known to be protective against fibrosis in immune-competent patients[25], is on the contrary a negative prognostic factor in the post-OLT setting[26]. The present data showed that, among the patients with the lowest BMI values, female recipients had a SFP faster than the corresponding males. Therefore, one might hypothesize that the stronger susceptibility of female recipients to HCV recurrence could be related, at least in part, to factors affected by the interrelationship between gender and BMI variations, for example the lipid profile.

According to recent studies, several aspects of HCV infection are connected with lipid metabolism and lipid profile modifications. Binding of HCV to cell membrane of hepatocytes is thought to occur via two putative HCV receptors: CD81, a cellular surface protein belonging to the tetraspanin protein super-family, and the low density lipoprotein receptor (LDL-r)[27-29]. The HCV envelope glycoprotein E2 may interact with the CD81 molecule, while HCV or HCV-LDL complexes interact preferentially with the LDL-r[30]. HCV circulates in blood in association with different lipoproteins: early in the course of the infection, the preferential association is with LDL, while later on the association is with high-density lipoproteins (HDL). In accordance, patients with immune-deficiencies present higher HCV RNA titers in the LDL and HDL fractions than the immune-competent counterparts[31]. During the early viremic phase of experimental HCV infection, several genes associated with lipid metabolism are upregulated; interestingly, the fatty acid synthesizing gene is expressed at higher levels among chimpanzees that attain sustained clearance of the virus[32]. Binding and internalization of HCV RNA containing particles seem strictly regulated by lipoproteins: an increase of LDL and other lipoproteins decreases the LDL-r HCV particles interaction[28,33,34] while an upregulation of the LDL-r increases the internalization of HCV[35]. According to a recently proposed model, virions are released by liver cells and may infect other liver cells via LDL-r; free β-lipoproteins may regulate the rate of the infection of liver cells by competing with the virus[29]. Considering altogether these observations, it is tempting to speculate that a particular lipid profile could be associated with a slower kinetic of HCV infection of the hepatocytes and as a consequence a lesser fibrosis progression of the graft. We calculated the ratio between serum triglycerides and serum cholesterol as a proxy index of the balance between VLDL and LDL in the circulation. An association was found between a low T/C ratio and a higher BMI 1 year post-OLT. As previously observed considering the association between BMI and fibrosis progression, the relationships between the value of T/C ratio and both the timing of hepatitis C recurrence and the 1 year fibrosis progression rate were gender-related: females with higher T/C ratio were found to present the fastest SFP. Following this line, one might hypothesize that a low BMI, especially for female patients, could be associated with a lipid profile characterized by reduced serum LDL/VLDL levels. In fact, the relationship between increasing body weight and blood lipid profile is stricter in men than in women[36-38]. Furthermore, we have previously found that recipient's carriage of at least one ε4 allele of the apo-lipoprotein E (an allelic variant associated with higher cholesterol levels) was associated with better histological outcome of recurrent hepatitis C in male, but not in female recipients[39]. An unfavorable lipoprotein profile could possibly enhance HCV infectivity through an

upregulation of LDL-r[40], or decreased interference of LDL at the level of the interaction between HCV and LDL-r[29].

In conclusion, post-OLT overweight in HCV-positive recipients does not represent a factor favoring early liver fibrosis development and could even be protective against it. The explanation of this unexpected finding might reside on the peculiar lipid profile of patients with excess body weight post-OLT, capable to modulate the severity of HCV recurrence and hence the speed at which liver fibrosis develops.

Abstract

AIM: To investigate a pathophysiological role of cathepsin W (CatW), a putative thiol-dependent cysteine protease, which is specifically expressed in cytotoxic lymphocytes, in different types of chronic inflammation of the gastric mucosa.

METHODS: Gastric and duodenal biopsies of patients with *Helicobacter pylori* (*H pylori*)-associated active gastritis (*Hp*, $n = 19$), chemically induced reactive gastritis (CG, $n = 17$), autoimmune atrophic gastritis (AIG, $n = 20$), lymphocytic corpus gastritis (LG, $n = 29$), celiac disease (CD, $n = 10$), and corresponding controls ($n = 24$) were analyzed by immunohistochemistry for the expression of CatW and CD45. Furthermore, immunohistochemical double staining with anti-CD3 and anti-cathepsin was performed for the samples of AIG.

RESULTS: Median values of CatW-expressing cells among CD45-positive immune cells were between 2% and 6% for normal gastric mucosa, CG, and LG, whereas the corresponding value was significantly increased for AIG (24.7%, $P<0.001$) and significantly decreased for HP (0.7%, $P<0.05$). Double staining with anti-CD3 and anti-CatW antibodies revealed that >90% of CatW-expressing cells in gastric mucosa of AIG were T cells. Duodenal mucosa had significantly more CatW/CD45-positive cells than normal gastric mucosa (median: 17.8% *vs* 2%, $P<0.01$). The corresponding proportion of CatW/CD45-positive cells was decreased in CD compared to duodenal mucosa (median: 2.1% *vs* 17.8%, $P<0.05$).

CONCLUSION: The opposite findings regarding the presence of CatW-positive cells in AIG (increase) and CD (decrease) reflects the different cellular composition of immune cells involved in the pathogenesis of these diseases.

INTRODUCTION

Gastritis, by definition, is a histopathological entity characterized by the chronic and active inflammation of the gastric mucosa. The classification of gastritis, according to the updated Sydney system[1], is organized along traditional lines with active and chronic gastritis and includes specific forms of chronic gastritis defined by topography, morphology, and etiology and is graded with the help of a semiquantitative visual scale. The discovery of *Helicobacter pylori* (*H pylori*) has dramatically altered the etiological concepts of several gastric diseases. *H pylori* is the major cause of gastritis, gastric ulcer and has been classified as a definite human carcinogen playing a key role in the pathogenesis of gastric cancer and MALT lymphoma[2,3]. The host response to *H pylori* and its bacterial products is composed of T-, B-lymphocytes and plasma cells defined as chronicity of the gastritis. The infiltration of the lamina propria and gastric epithelium by polymorph nuclear leukocytes (mostly neutrophil granulocytes) reflects the activity of the inflammation.

NSAID-associated or bile-induced chemical reactive gastritis, causing 20-30% of gastritis, as well as autoimmune and lymphocytic gastritis (LG) are distinct entities. The presence

of atrophy in the gastric corpus with diffuse atrophy of parietal and chief cells are the main characteristics of autoimmune atrophic gastritis (AIG) together with a hyperplasia of ECL cells. This disease is associated with serum anti-parietal and anti-intrinsic factor (IF) antibodies that cause IF deficiency, which can lead eventually to pernicious anemia in some patients. It has been shown that AIG is associated with infiltration of $CD4^+$ T lymphocytes into the gastric mucosa, where they contribute to tissue destruction and gastric atrophy[4].

Chemically induced reactive gastritis (CG), caused by the use of nonsteroidal anti-inflammatory agents (NSAIDs) or bile reflux, is characterized by regenerative processes that lead to foveolar hyperplasia, mucosal edema, hemorrhage, capillary ectasia, proliferation of ascending smooth muscle fibers, and apical fibrosis. Usually, these lesions exhibit a slight superficial infiltration of lymphocytes and plasma cells. NSAIDs might additionally cause epithelial damage such as erosions and ulcers[1].

LG is a rare form of gastritis. The essential diagnostic feature is the presence of increased intraepithelial lymphocytes (mostly T cells), at least 25 lymphocytes per 100 epithelial cells. In the lamina propria, there are often additional neutrophil granulocytes among lymphocytes and plasma cells at the surface epithelium and within foveolar epithelium[5-7]. LG is believed to represent a special form of Helicobacter-mediated gastritis, mostly found in the corpus and fundus, although *H pylori* is only rarely found morphologically[6,7]. Three different types of LG can be distinguished depending on the endoscopic appearance: LG without typical endoscopic findings, the varioliform gastritis with thickened rugal folds, and Ménétriers disease with prominent rugal folds.

In human beings, the group of thiol-dependent cathepsins comprises 11 different cysteine proteases that are mostly localized in the lysosomal compartment[8]. During the last decade, it has become evident that most of these enzymes in addition to their role in lysosomal protein degradation[9] can mediate or regulate specific processes in various tissues and cell types. These functions include 'limited proteolysis' leading to the activation of granzymes[10], the maturation of hormones[11,12] and the regulation of antigen presentation[13]. As today, there is limited knowledge concerning the role of thiol-dependent cathepsins in gastric physiology and related disorders. Notably, cathepsins B and L were found to be associated with the carcinogenesis and metastasis of gastric and esophageal cancer[14-16]. Furthermore, cathepsins X and K were found to be specifically expressed in gastric epithelium[17], whereas cathepsin W (CatW) was found to be specifically expressed in lymphocyte-like cells within the gastric and intestinal tissue[18]. This finding was in line with the restricted expression pattern of CatW, which is expressed in NK cells and in cytotoxic T cells[19-21]. Although, its enzymatic activity and major function has not been characterized, there are some data supporting a regulatory role of this putative protease in the cytotoxic process for the NK-92 cell model[22]. However, cells from CatW-deficient mice were not affected in their cell-mediated cytotoxicity *in vitro*[23]. The specific association between CatW and cytotoxic cells and the potential involvement of these cells in chronic inflammation, prompted us to investigate the expression of CatW in different types of gastritis.

MATERIALS AND METHODS

Materials

A total of 119 formalin-fixed, paraffin-embedded biopsy specimens from patients suffering from different gastrointestinal disorders were retrieved from the archives of the institutes of Pathology Bayreuth and Magdeburg. The selection was based on clinical and histological evidence of the corresponding diagnosis including *H pylori*-associated chronic active gastritis (n = 19), CG (n = 17), AIG (n = 20), lymphocytic corpus gastritis without endoscopic findings (n = 29) as well as samples of duodenal mucosa of 10 patients with celiac disease (CD). Furthermore, healthy controls of both gastric (n = 14) and duodenal (n = 10) mucosa were examined immunohistochemically. Histological diagnosis was made by hematoxylin-eosin and Warthin-Starry stainings.

Methods

Detection of cathepsin W and CD45 by immunohistochemistry After the removal of paraffin by xylol, two sets of serial sections of all tissue specimens were subsequently dehydrated using increasing concentrations of ethanol. In order to demask the antigens, the samples were boiled thrice in 0.01 mol/L sodium citrate buffer (pH 6.0) for 10 min in a microwave (600 W), and incubated for 30 min at room temperature in 1×staining buffer containing 5% RPMI, 5% FCS, and 0.05% sodium azide in aqua dest (pH 7.4-7.6). The subsequent staining procedure on each one serial slide was performed using the monoclonal anti-CatW antibody CW-401B1 (1:1 000 in 1×staining buffer, 1 h at room temperature) and the Vectastain ABC-AP Kit (Vector, Burlingame) following the manufacturer's instructions. In addition, a matching set of serial sections was stained with anti-CD45 (LCA, DakoCytomation, Glostrup, Denmark). The used antibody is a mixture of two mAbs (2B11 and PD7/26) representing all isoforms (2B11) and the isoform CD45R0 (PD7/26). Immunostaining was performed as described elsewhere[24]. All samples were counterstained with hematoxylin, dehydrated and mounted using DEPEX™ (Serva, Heidelberg, Germany).

Detection of cathepsin W and CD3 by double immunohistochemistry in autoimmune atrophic gastritis To distinguish between CatW-positive-stained natural killer cells and cytotoxic T lymphocytes, a third series of sections of the above used tissue specimens with AIG was pretreated and stained with the anti-CatW antibody and detected with Vectastain ABC-AP Kit as described above. After washing the slides thoroughly in PBS, subsequent staining with the anti-CD3-antibody (1:100; anti-human CD3, A 0452; DakoCytomation, Hamburg, Germany) was performed; marking the CD3-complex of T cells.

For revealing positive immunohistochemical reaction, the iVIEW™ DAB Detection Kit (Ventana, Germany) was used as chromogen substrate, and then specimens were counterstained with hematoxylin and mounted with DEPEX™.

For all immunohistochemical analyses, two persons counted the numbers of stained cells in three independent high-power fields. Mann-Whitney U test was used for group comparison. For all statistical analyses, $P<0.05$ was considered to indicate statistical significance.

Generally, a consistent staining pattern exhibiting CatW-positive cells with a lymphocytic phenotype was obtained in all samples. The tissue specimens of the different chronic gastrointestinal disorders contained various amounts of CatW-expressing cells. In normal gastric mucosa, CatW-expressing cells were rarely detected (0.5±1 cells/field), whereas the different forms of gastritis revealed higher absolute numbers of 4.1-41 cells per observation field (Figure 2). Other immune cells including polymorph nuclear neutrophils, macrophages, and plasma cells as well as epithelial and stroma cells did not express CatW. AIG showed extensive mucosal atrophy, replacement of the oxyntic glands by intestinal metaplastic epithelium and mononuclear infiltrate within the lamina propria with approximately 25% of $CD45^+$ cells expressing CatW (Figure 1C). CD with subtotal villous atrophy and dense inflammatory infiltrate revealed a fraction of about 5% $CatW^+/CD45^+$ cells (Figure 1D). In chronic *H pylori* gastritis, the gastric mucosa contained high absolute numbers of $CatW^+$ cells among the dense infiltrate consisting of $CD45^+$ lymphocytes, macrophages, plasma cells as well as neutrophils (Figure 1E).

Notably, the relative proportion of CatW-expressing cells among the infiltrating leukocytes, determined by CD45, differed remarkably for the investigated types of chronic inflammation (Figure 2). The highest proportion of CatW-expressing $CD45^+$ cells was found in AIG reaching 24.7% (ranging from 8% to 70%). Normal gastric mucosa, which comprised samples without gastritis, revealed a fraction of 2% (ranging from 1% to 5%). The difference between both groups was found to be significant ($P<0.001$). Surprisingly, for CD as another autoimmune-triggered intestinal disease investigated in this study, a significant reduction of the relative number of CatW-expressing cells was observed compared to healthy duodenal mucosa (2.1% *vs* 17.8%, $P<0.05$, Figure 2). Normal duodenal mucosa contained significantly more CatW-positive cells than normal gastric mucosa ($P<0.01$). Furthermore, the proportion of $CatW^+/CD45^+$ cells was analyzed in the specimens with *H pylori*-associated chronic active gastritis. Here, a significant decreased proportion of 0.7% (ranging from 0.5% to 2%, $P<0.05$) compared to normal gastric mucosa was detected (Figure 2).

For the other two chronic gastric disorders (CG and LG) analyzed in this study, the proportions of $CatW^+/CD45^+$ cells were not changed and similar to normal gastric mucosa (Figure 2). CatW was identified in about 6% and 2.2% of the $CD45^+$ cells in CG and LG, respectively.

As exemplarily shown in Figure 3, the double staining permitted a clear classification of the lymphocyte-like infiltrate of the lamina propria in AIG. The great majority (>90%) of CatW-expressing cells represented $CD3^+$ T lymphocytes, whereas $CatW^+$ NK cells ($CD3^-$) were rarely detected. Whereas $CatW^-/CD3^+$ positive T cells were abundantly seen in the samples of AIG, a high proportion of CatW-expressing cytotoxic T cells (CTL) was detected, too. $CatW^+$ NK cells (NK) were only rarely spotted in the lamina propria.

This study revealed two new and important findings. First, it provides evidence that the elevated number of CatW-expressing cells in AIG is a rather specific event for this disease and does not just represent a general phenomenon of mucosal inflammation. Second, data provide evidence that the cellular distribution of CatW is different in peripheral blood and mucosal compartment[25,26].

The elevated number of CatW-positive cells in AIG supports a pathophysiological role of these cells in this type of gastritis as discussed previously[18]. The specific expression pattern of CatW[19-21] and its potential involvement in cytotoxic processes[22] imply an involvement of CatW in Th1-mediated inflammation like AIG. According to the current model of AIG, first, self-antigen-reactive Th1 cells, which express IFN-γ, IL-2 and are capable for transendothelial migration, are activated by self-antigens of gastric mucosa and participate in tissue destruction and resulting inflammation. Second, Th2 cells, being sessile in the draining lymph nodes and activated by the self-antigens released from tissue destruction, support autoantibody production and might develop into memory cells[27]. Although, IFN-γ, which is mainly released by NK cells is one of the predominant cytokines increased in AIG[28-30], there are data implying that NK cells are dispensable for the onset of AIG. In mice models with neonatal thymectomy and subsequent depletion of NK cells, the disease incidence was not changed suggesting that other cells such as $CD8^+$ T cells are the primary source of IFN-γ[31]. Furthermore, it has been shown by several groups that in the experimental mouse model, CD4-positive T cells are mainly responsible for the development of gastric lesions[32-34]. Interestingly, the predominant role of CD4-positive T cells has not been fully confirmed. D'Elios and co-workers showed an association between AIG and Th1-differentiated T cells that possessed cytotoxic activity[35]. Other studies investigating patient-derived samples identified an upregulation of $CD16^+$ and $CD8^+$ cells suggesting a potential role of these cytotoxic cells in human AIG[36,37]. Based on these reports, an interaction of the $CD4^+$ cells with autoreactive $CD8^+$ effector cells might lead to the development of autoimmune gastritis that involves also regulatory T cells[38,39]. Taking into consideration the data from the human disease that showed a predominant involvement of T cells in AIG[35,36], the higher proportion of $CD8^+$ T cell in mucosal compartments[26] and the specific expression pattern of CatW in cytotoxic T and NK cells[21], we assume that in AIG mostly $CD8^+$ T cells contribute to the high proportion of $CatW^+/CD45^+$ cells. By performing double staining immunohistochemistry, we were able to confirm this hypothesis by showing a very low proportion of $CatW^+$ NK cells, whereas the number of CatW-expressing cytotoxic T lymphocytes was increased significantly. This observation supports a specific role of CTLs in the pathophysiological processes of AIG. For comparison, tissue samples of CD, another prototype of T-cell mediated autoimmune disease, were also investigated. Surprisingly, a decrease of the $CatW^+/CD45^+$ cells was determined in CD. This phenomenon is presumably caused by the massive increase of CatW-negative $CD4^+$ T cells, which make up the majority of infiltrating immune cells in this disease[39,40]. The observation, that the absolute number of CatW-expressing cells is significantly higher in normal intestinal samples compared to gastric samples, is in line with the distribution

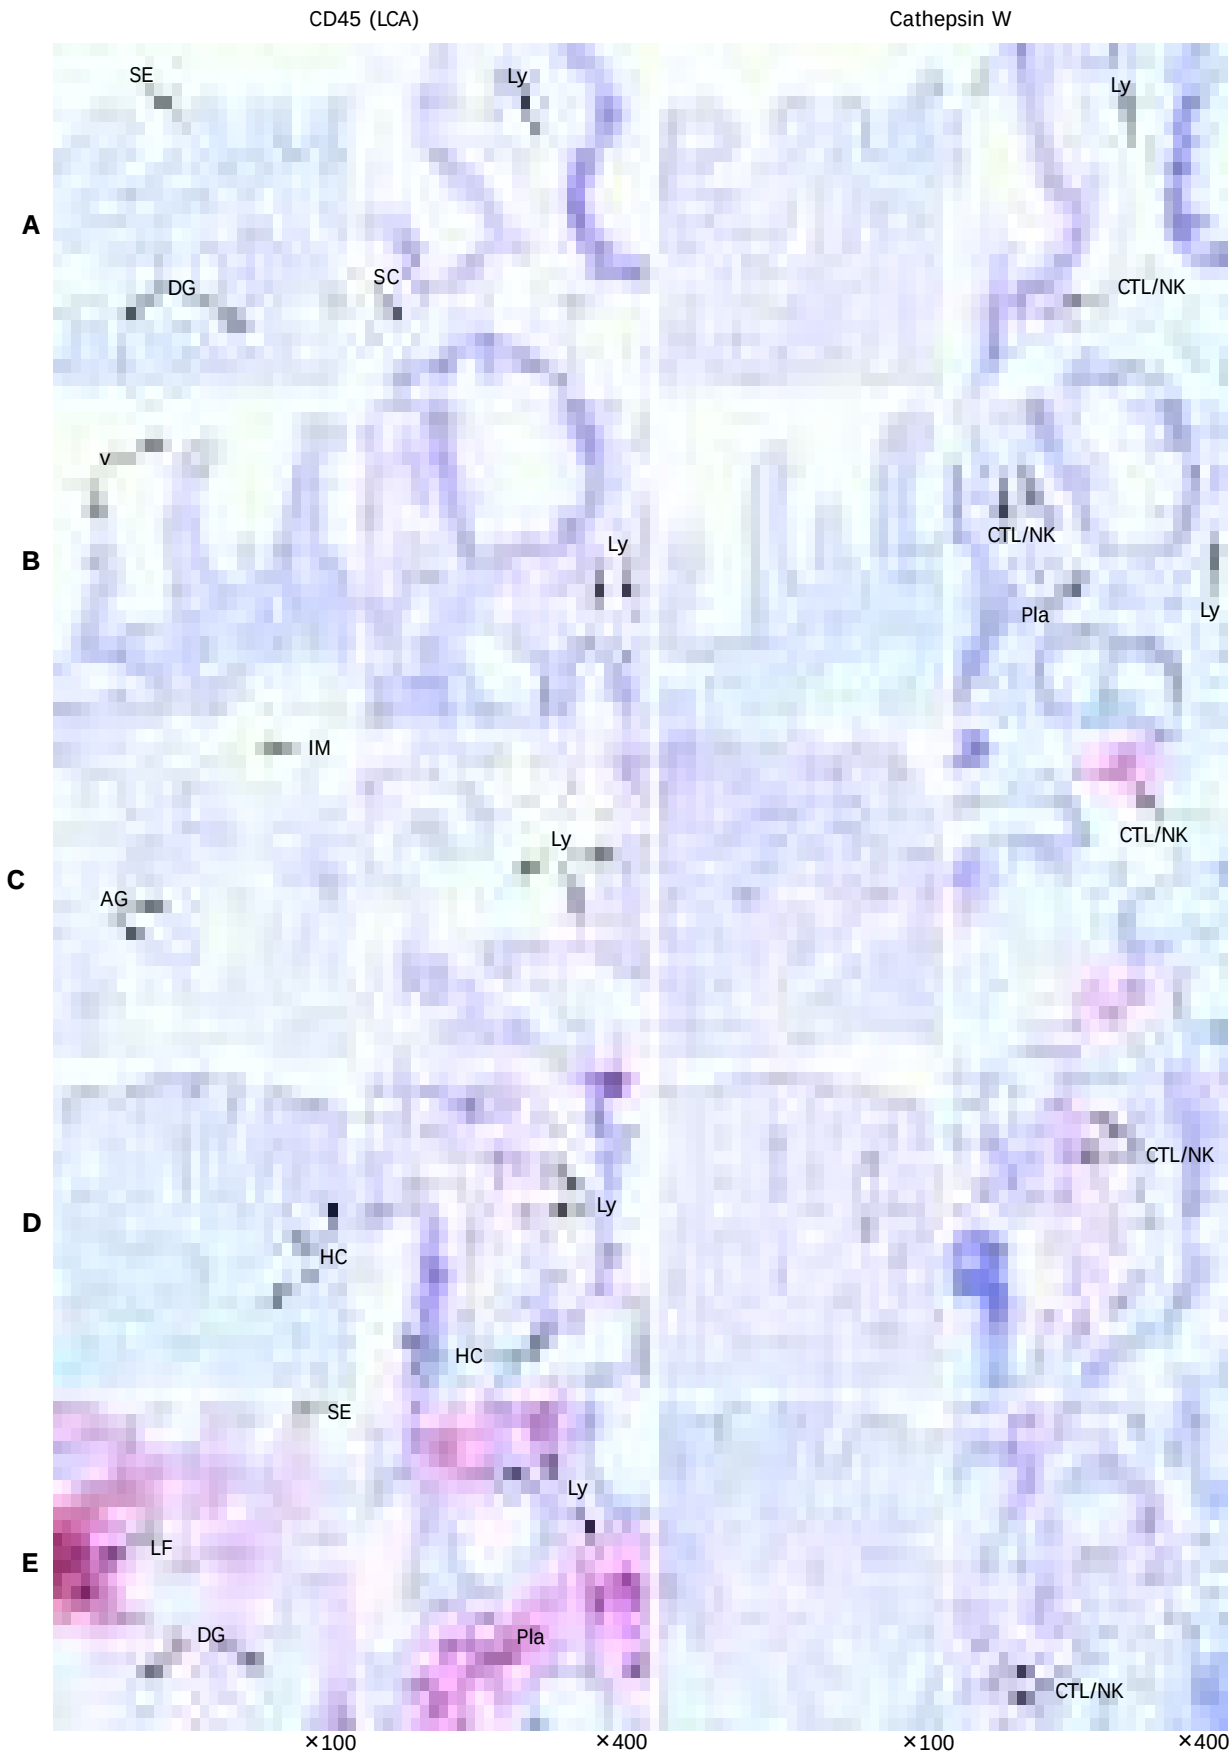

Figure 1 Immunohistochemical detection of CatW in gastrointestinal tissue specimens. The cellular distribution of CatW expression is presented by red staining, whereas the nuclei are counterstained with hematoxylin (blue). The distribution of CD45 (LCA) is shown as brownish staining. The negative controls (using isotype controls) did not reveal any signals (not shown). The tissue samples were as follows: normal gastric mucosa (A), duodenum (B), AIG (C), CD (D) and *H pylori* gastritis (E). AG: Atrophic glands, CTL: cytotoxic T-lymphocyte, DG: deep gastric glands, HC: hyperplastic crypts, IM: intestinal metaplasia, LF: lymph follicle, Ly: lymphocyte, Pla: plasma cell, NK: natural killer cell, SC: stroma cells, SE: surface epithelium, T-Ly: T lymphocyte, and V: duodenal villi.

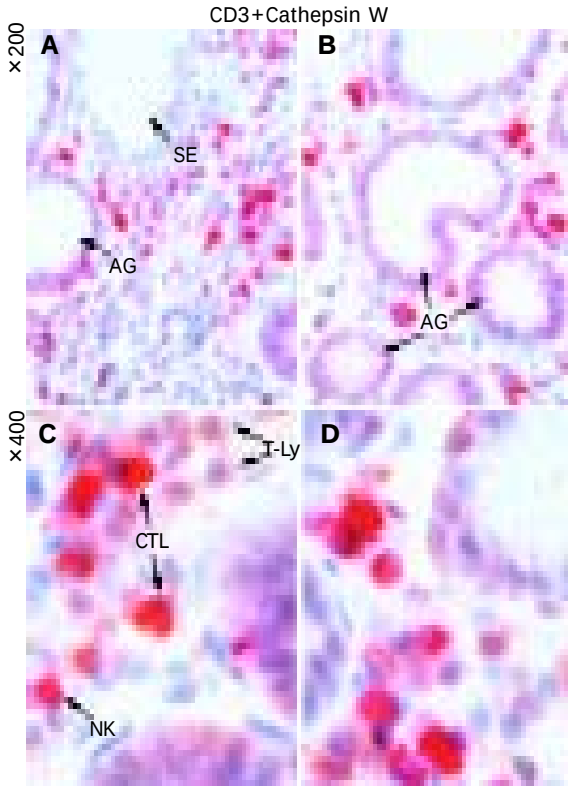

Figure 2 Detection of CatW and CD3$^+$ T cells in tissue specimens of AIG. The immunohistochemical double staining allowed a differentiation of both CatW-expressing cell types as well as a separation of CTLs from the other T cells (T-Ly) among the infiltrating cells of the lamina propria: Whereas CatW$^-$/CD3$^+$ positive T cells could be clearly distinguished by the brownish staining and were abundantly seen in the samples of AIG, an additional cytoplasmic red staining detected the CatW-expressing CTL. The exclusively red staining marked the CatW$^+$ NK cells, which were only rarely spotted in the lamina propria.

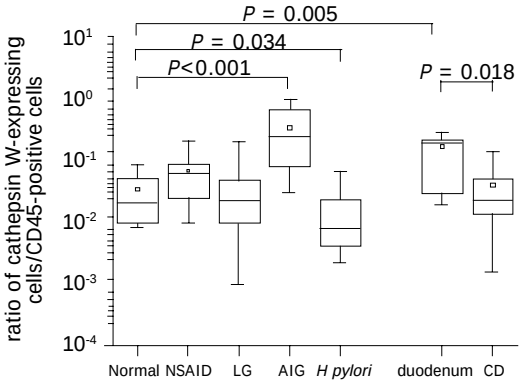

Figure 3 Presence of CatW-expressing cells among infiltrating immune cells in samples of patients with gastritis. The distribution of CatW- and LCA (leukocyte common antigen, CD45)-expressing cells was separately analyzed by immunohistochemistry in serial sections of tissue specimens. The number of CD45-positive cells was considered as 100% presented as a ratio of 1 at the Y-axis. The ratio of CatW$^+$/LCA$^+$ cells illustrates the proportion of CatW-expressing cells among leukocytes present in the gastric/duodenal mucosa. Data are shown as box plot for each group (antral mucosa: normal; chemically induced gastritis: NSAID; lymphocytic gastritis: LG; autoimmune gastritis: AIG; *H pylori*-induced gastritis: *H pylori*; normal duodenum: duodenum; celiac disease: CD). Boxes represent the 25th, 50th, and 75th percentile values (horizontal lines of the box) and means (squares). Mean values of absolute numbers of CatW-expressing cells per observation field were 0.5, 4.1, 4.2, 10.7, and 41 for normal antral mucosa, *H pylori* gastritis, NSAID-associated gastritis, LG and AIG, respectively. Tissue specimens from normal duodenum revealed 16 CatW-expressing cells per field, while samples from patient with CD had 6.3 CatW-positive cells in average per field.

of immune cells in these compartments.

It is well known that *H pylori* leads to an infiltration of neutrophils and a predominant Th1-dominated immune response[41]. The analysis of lymphocytic subsets in chronic gastritis revealed that most of the infiltrating lymphocytes were found to be CD4$^+$ T cells[42], whereas neutrophils and cytotoxic T cells seem to play an important role with respect to the activity of *H pylori* gastritis[43,44]. Furthermore, a significant increase of IL-2 receptor positive cells, including NK cells, was reported in chronic gastritis[44]. Taking into consideration the involvement of different subsets of immune cells in *H pylori*-mediated gastritis, the relative decrease of CatW-expressing cells can be attributed to the massive infiltration of CD45$^+$ leukocytes (CD4$^+$ T cells, B cells, and granulocytes). Although, there is no doubt that these cells in general participate in the immunological response by the secretion of cytokines and mediating cytotoxic effects, the lower numbers of CatW-expressing cells compared to AIG implies that they do not play a predominant role in the pathogenesis of *H pylori* gastritis[17].

No differences in the CatW$^+$/CD45$^+$ proportions for the CG and LG were detected compared to healthy controls. These findings are in line with the pathogenesis of both types of gastritis. NSAIDs, as the most common cause of CG, lead primarily to an inhibition of cyclooxygenases that subsequently leads to lower levels of prostaglandins and thromboxane and less lymphocytic infiltration compared to *H pylori* gastritis and AIG[45,46]. Therefore, CG showed normal numbers or only a minor increase of inflammatory cells, mostly being lymphocytes and plasma cells, in the mucosa[1]. Since the typical histological picture includes only a slight amount of inflammatory cells, the minimal presence of CatW-expressing cells, comparable to healthy gastric mucosa, is in concordance with these studies.

As the name implies, LG is characterized by the presence of large numbers of mature lymphocytes infiltrating the surface and foveolar epithelium[7]. Based on the guidelines, 25-40 intraepithelial lymphocytes per 100 epithelial cells are necessary for this diagnosis. Intraepithelial lymphocytes comprise mostly suppressor T cells showing cytotoxic ability through production of TIA1 and granzyme B[7,47]. The unchanged CatW$^+$/CD45$^+$ proportion in LG obviously corresponds to the normal fraction of CatW-expressing cells among the physiological infiltrate of inflammatory cells in gastric mucosa. It is notable that LG is thought to be related to *H pylori* infection, as shown by their improvement after eradication[6], indicating that LG may represent an atypical host immune response to this infection, even if *Helicobacter* is only rarely found morphologically[5,6].

The numeric differences of CatW-expressing cells and the differences of the relative portion of CatW-expressing cells among infiltrating CD45$^+$ leukocytes in the investigated types of chronic gastroduodenal inflammation imply a distinct involvement of cytotoxic cells expressing CatW in the pathogenesis among these diseases. Whereas CatW-expressing CTLs seem to contribute to the pathogenesis of AIG and to a lesser extent in *H pylori*-associated gastritis, the low

absolute and relative numbers of CatW-positive cells in the inflammatory infiltrate in CG and LG suggest that CatW-expressing cells do not play a major role in these diseases.

The identification of CTL as the predominant CatW-expressing cell type in gastric mucosa, as shown for AIG, supports the idea that the CatW-expression pattern might differ between certain subpopulations of cytotoxic cells. This hypothesis is further supported by the recent finding that cytotoxic cells of gastric mucosa can express an alternatively spliced isoform that has not been detected in peripheral NK cells so far[48].

Abstract

AIM: To determine whether ischemic preconditioning (IP) affects the development of edematous cerulein-induced pancreatitis and to assess the role of cyclooxygenase-1 (COX-1), COX-2, and heat shock protein 70 (HSP 70) in this process.

METHODS: In male Wistar rats, IP was performed by clamping of celiac artery (twice for 5 min at 5-min intervals). Thirty minutes after IP or sham operation, acute pancreatitis was induced by cerulein. Activity of COX-1 or COX-2 was inhibited by resveratrol or rofecoxib, respectively (10 mg/kg).

RESULTS: IP significantly reduced pancreatic damage in cerulein-induced pancreatitis as demonstrated by the improvement of pancreas histology, reduction in serum lipase and poly-C ribonuclease activity, and serum concentration of pro-inflammatory interleukin (IL)-1β. Also, IP attenuated the pancreatitis-evoked fall in pancreatic blood flow and pancreatic DNA synthesis. Serum level of anti-inflammatory IL-10 was not affected by IP. Cerulein-induced pancreatitis and IP increased the content of HSP 70 in the pancreas. Maximal increase in HSP 70 was observed when IP was combined with cerulein-induced pancreatitis. Inhibition of COXs, especially COX-2, reduced the protective effect of IP in edematous pancreatitis.

CONCLUSION: Our results indicate that IP reduces pancreatic damage in cerulein-induced pancreatitis and this effect, at least in part, depends on the activity of COXs and pancreatic production of HSP 70.

INTRODUCTION

Various organs including the heart[1], brain[2], kidney[3], liver[4], skeletal muscle[5], and stomach[6] respond to brief exposure to ischemia with an increase in resistance to severe ischemia, and this phenomenon is called ischemic preconditioning (IP). Also, the protective effect of IP has been found in the pancreas against ischemia/reperfusion-induced pancreatitis[7]. However, no study so far has been undertaken to determine whether IP is also able to prevent the acute pancreatic damage induced by other primary non-vascular factors.

Cyclooxygenase (COX), the key enzyme for prostaglandin synthesis, exists in two isoforms as COX-1 and COX-2[8]. COX-1 is constitutively expressed in most tissues and has been suggested to mediate the synthesis of prostaglandins required for physiological functions and maintenance of organ integrity. COX-2 is undetectable in most tissues in normal condition, but is highly inducible by cytokines, mitogens, and endotoxins, and is responsible for an increased production of prostaglandins during inflammation[8]. However, it was reported that both COXs contribute to gastric mucosal defense[9]. Inhibition of COXs activity by nonselective nonsteroidal anti-inflammatory drugs leads to induction of gastric ulcers and delays the healing of gastric mucosa[10,11], while the selective inhibition of COX-2 delays gastric ulcer healing[12]. The role of COX-2 in pancreatic pathology is unclear. Studies performed by Song *et al*.[13], and Ethridge *et al*.[14], with mice have shown that pharmacological inhibition of COX-2 or

COX-2 gene disruption reduces the severity of pancreatitis and pancreatitis-associated lung injury. On the other hand, our own study has shown that inhibition of COX-2 abolishes the protective effect of hepatocyte growth factor (HGF) against cerulein-induced pancreatitis[15].

Heat shock proteins (HSPs) are cytoprotective molecules that help to maintain the metabolic and structural integrity of cells. HSPs are induced by a variety of stresses, including heat, free radicals, and toxins[16]. In the pancreas, HSPs have been shown to provide the protection against cerulein-[17,18] and arginine-induced[19] acute pancreatitis. However, it is not investigated whether IP interacts with HSPs and what is the biological consequence of this potential interaction in the development of cerulein-induced pancreatitis.

The present study was to determine the effect of IP on the development of acute cerulein-induced pancreatitis, to evaluate the role of COX-1 and COX-2 in pancreatic IP, and to assess the effect of IP on the pancreatic synthesis of HSP 70.

[illegible]

Animals and treatment

Studies were performed on male Wistar rats weighing 180-220 g and following the experimental protocol approved by the Committee for Research and Animal Ethics of Jagiellonian University. Rats were fasted for 18 h before final experiment, but they had free access to drinking water. Animals were housed in cages with wire mesh bottoms at normal room temperature in 12-h light–dark cycle.

Experiments were carried out in the following experimental groups (10 animals in each group); (1) sham-operated control group; (2) IP group; (3) sham-operated group treated with resveratrol (Cayman Chemicals, Ann Arbor, MI, USA, 10 mg/kg, intragastrically (i.g.) 1 h before sham operation); (4) sham-operated group treated with rofecoxib (Vioxx, Merck Sharp & Dohme Idea Inc., Glattbrugg, Switzerland, 10 mg/kg, i.g. 1 h before sham operation); (5) sham-operated group with cerulein-induced pancreatitis; (6) IP group with cerulein-induced pancreatitis; (7) sham-operated group with cerulein-induced pancreatitis and treated with resveratrol (10 mg/kg, i.g. 1 h before sham operation); (8) cerulein-induced pancreatitis group treated with rofecoxib (10 mg/kg, i.g. 1 h before sham operation); (9) IP group with cerulein-induced pancreatitis and treated with resveratrol (10 mg/kg, i.g. 1 h before IP); (10) IP group with cerulein-induced pancreatitis and treated with rofecoxib (10 mg/kg, i.g. 1 h before IP).

IP of the pancreas was performed under ketamine anesthesia (50 mg/kg i.p., Bioketan, Biowet, Gorzów Wlkp., Poland). After longitudinal laparotomy, the celiac artery was clamped twice for 5 min at 5-min intervals. In sham-operated rats, longitudinal laparotomy and mobilization of the pancreas without the clamping of any artery was performed.

Thirty minutes after IP or sham operation, acute pancreatitis was induced by cerulein (Takus, Pharmacia & Upjohn GmbH, Erlangen, Germany) i.p. five times at 1-h intervals at a dose 10 μg/kg per injection. Animals without induction of acute pancreatitis were treated with 0.9% NaCl i.p. at the same time as cerulein.

Determination of pancreatic blood flow

After the last injection of cerulein or saline, animals were anesthetized with ketamine and the abdomen was opened. The pancreas was exposed for the measurement of pancreatic blood flow by a laser Doppler flowmeter using PeriFlux 4001 Master monitor (Perimed AB, Järfälla, Sweden), as described previously[20]. Pancreatic blood flow was measured in five different portions of the pancreas. The area of laser emission of the probe was about 1 mm^2, while the depth of measurement reached about 3 mm. Data were presented as percent change from control value obtained in sham-operated rats injected with saline.

Determination of serum lipase activity and serum interleukin-1β and interleukin-10 concentration

Immediately after measurement of pancreatic blood flow, the abdominal aorta was exposed and blood was taken for determination of serum lipase activity and serum interleukin-1β (IL-1β) and IL-10 concentration. Serum lipase activity was determined with a Kodak Ectachem DT II System analyzer (Eastman Kodak Company, Rochester, NY, USA) using Lipa DT slides (Vitros DT Chemistry System, Johnson & Johnson Clinical Diagnostic, Inc., Rochester, NY, USA). Serum lipase activity was expressed as units per liter. Serum IL-1β and IL-10 concentrations were measured in duplicate, using appropriate BioSource Cytoscreen rat kits based on a solid phase sandwich ELISA (BioSource International, Camarillo, CA, USA). Concentration of IL was determined from standard curves for recombinant IL-1β or IL-10, respectively. Serum IL-1β or IL-10 concentration was expressed as picogram per milliliter.

Determination of serum poly-C specific ribonuclease activity

Poly-C specific ribonuclease activity was determined using Warsaw and Lee's procedure[21], employing polycytydylic acid (poly-C) as a ribonuclease substrate, as described previously in detail[22]. Poly-C specific ribonuclease activity was expressed in units per liter.

Protein extraction and analysis of pancreatic HSP 70 expression by Western blot analysis

Shock-frozen tissue from rat pancreas was homogenized in a lysis buffer (100 mmol/L Tris-HCl, pH 7.4, 15% glycerol, 2 mmol/L EDTA, 2% sodium dodecyl sulfate (SDS), 100 mmol/L D,L-dithiothreitol) by the addition of 1:20 dilution of aprotinin and 1:50 dilution of 100 mmol/L phenylmethylsulfonyl fluoride. Insoluble materials were removed by centrifugation at 12 000 *g* for 15 min. Approximately 50 μg of the total protein extract was loaded on SDS-polyacrylamide gels and run 40 mA, followed by transfer on nitrocellulose membrane (Protran, Schleicher & Schuell, Germany) by electroblotting. Bovine serum albumin (30 g/L, Sigma-Aldrich, Germany) in Tris buffered saline (TBS)-Tween-20 buffer (137 mmol NaCl, 20 mmol Tris-HCl, pH 7.4, 0.1% Tween-20) was used to block filters for at least 1 h at room temperature. Specific primary antibody against HSP 70 (mouse monoclonal, 1:200 dilution; Stressgen Biotechnologies Corp., Canada) or β-actin (mouse monoclonal, dilution 1:5 000; Sigma-Aldrich, Germany) was added to the membrane, followed by an anti-mouse-IgG or anti-mouse IgG horseradish

peroxidase-conjugated secondary antibody (dilution 1:20 000; Promega, WI, USA) dissolved in 1% non-fat milk in TBS-Tween-20 buffer. Incubation of primary antibody was followed by washing thrice with TBS-Tween-20 buffer for 10 min. Incubation of the secondary antibody was followed by five washes for 10 min. Immunocomplexes were detected by the SuperSignal West Pico chemiluminescent kit (Pierce, USA). Thereafter, the developed membrane was exposed to an X-ray film (Kodak, Wiesbaden, Germany). Comparison between different treatment groups was made by determining the HSP 70/β-actin ratio of the immunoreactive area by densitometry.

Determination of pancreatic DNA synthesis

The rate of DNA synthesis in samples of pancreatic tissue was determined as described previously[23]. Briefly, the minced pancreatic tissue was incubated at 37 ℃ for 45 min in 2 mL of medium containing 8 μCi/mL of [^{3}H]thymidine ([6-^{3}H] thymidine, 20-30 Ci/mmol; Institute for Research, Production and Application of Radioisotopes, Prague, Czech Republic). The incorporation of [^{3}H]thymidine into DNA was measured by counting DNA containing solution in a liquid scintillation system. DNA synthesis was expressed as [^{3}H]thymidine disintegrations per minute per microgram DNA (dpm/μg DNA).

Histological examination

Samples of pancreatic tissue for histological examination were fixed in 40 g/L formaldehyde, embedded in paraffin and sections were sliced and stained with hematoxylin and eosin. Slides were examined by two experienced pathologists without the knowledge of the treatment given (four slides per animal). The histological grading of edema was made using our scale ranging from 0 to 3: 0 = no edema, 1 = interlobular edema, 2 = interlobular and moderate intralobular edema, and 3 = severe interlobular and intralobular edema. Hemorrhage was graded: 0 = absent, 1 = 1-2 foci per slide, 2 = 3 to 5 foci per slide, 3 = more than 5 foci per slide. Leukocyte infiltration was graded: 0 = absent, 1 = scare perivascular infiltration, 2 = moderate perivascular and scare diffuse infiltration, 3 = abundant diffuse infiltration. Acinar necrosis was graded: 0 = absent, 1 = less than 15% of cells involved, 2 = 15–35% of cells involved, 3 = more than 35% of cells involved. Grading of vacuolization was based on the percentage of cells involved: 0 = absent, 1 = less than 25%, 2 = 25-50% and 3 = more than 50%.

Statistical analysis

Results were expressed as mean±SE. Statistical analysis was carried out by one-way analysis of variance followed by Tukey's multiple comparison test using GraphPadPrism (GraphPad Software, San Diego, CA, USA). $P<0.05$ was considered statistically significant.

[illegible]

Morphological features of pancreatic tissue

The pancreas of saline-treated sham-operated rats showed no tissue alteration macroscopically and at light microscopic level (Table 1). Exposure to IP combined with treatment with saline caused the mild interlobular edema and minimal vacuolization of acinar cells in cases 4 and 5, respectively. Rest of the animals exposed to IP and treated with saline did not show any histological alterations. Administration of the COX-1 inhibitor - resveratrol - in saline-treated animals did not affect pancreatic tissue morphology. Treatment with combination of the COX-2 inhibitor - rofecoxib - plus saline had no effect on pancreatic histology or caused mild interlobular edema. Administration of cerulein caused acute edematous pancreatitis in all rats that were tested (Table 1). The pancreas was grossly swollen and enlarged with a visible collection of edematous fluid. At light microscopic level, moderate or severe interlobular and intralobular edema was accompanied with moderate perivascular and scare diffuse inflammatory leukocyte infiltration. Vacuolization was observed in 25-50% of acinar cells. Additionally, in few cases, one or two foci of hemorrhages per slide were found. IP applied prior to cerulein-induced pancreatitis reduced histological signs of pancreatic damage such as pancreatic edema, inflammatory infiltration, and vacuolization of acinar cells. Also, administration of resveratrol or rofecoxib in combination with cerulein slightly reduced the cerulein-evoked pancreatic damage. In animals with IP applied prior to cerulein, inhibition of COXs abolished the beneficial effect of IP. This effect was especially pronounced after administration of rofecoxib and pancreatic damage was similar to that in animals treated with cerulein alone (Table 1).

Effect of ischemic preconditioning, resveratrol, and rofecoxib on serum lipase activity in rats without or with cerulein-induced pancreatitis

In sham-operated saline-treated rats, serum lipase activity reached 61.5±3.5 U/L (Figure 1A). IP, applied without

induction of acute pancreatitis, did not affect serum lipase activity. Also, administration of the COX-1 inhibitor - resveratrol - or the COX-2 inhibitor - rofecoxib - had no effect on serum lipase activity in rats treated with saline. Administration of cerulein caused more than sevenfold increase in serum lipase activity, when compared to that of saline-treated control rats. IP markedly reduced the cerulein-evoked increase in serum lipase activity by 37% ($P<0.001$). Also, administration of resveratrol or rofecoxib reduced serum lipase activity in animals with cerulein-induced pancreatitis ($P<0.01$ or $P<0.05$, respectively). The effect of these blockers of COX on serum lipase activity was weaker than the effect of IP, but was still statistically significant. In contrast, administration of resveratrol or rofecoxib in combination with IP significantly abolished the IP-evoked reduction in serum lipase activity in animals with cerulein-induced pancreatitis ($P<0.001$). However, serum lipase activity in these animals was still lower than that in animals with cerulein-induced pancreatitis and treated with resveratrol or rofecoxib alone (Figure 1A).

Effect of ischemic preconditioning, resveratrol, and rofecoxib on serum concentration of IL-1β and IL-10 in rats without or with cerulein-induced pancreatitis

In control sham-operated rats treated with saline, the serum IL-1β concentration was 69.9±3.1 pg/mL (Figure 1B). IP or treatment with resveratrol or rofecoxib alone had no effect on serum IL-1β in rats without induction of acute pancreatitis. In sham-operated rats, cerulein caused more than threefold increase in serum IL-1β concentration and this increase was significantly diminished by IP ($P<0.001$). Lower but still significant reduction of serum IL-1β was also observed when administration of cerulein was combined with pretreatment with resveratrol ($P<0.05$). Administration of rofecoxib alone tended to reduce the cerulein-evoked increase in serum IL-1β concentration, but this effect was not statistically significant. Pretreatment with resveratrol or rofecoxib in animals with IP significantly reversed the

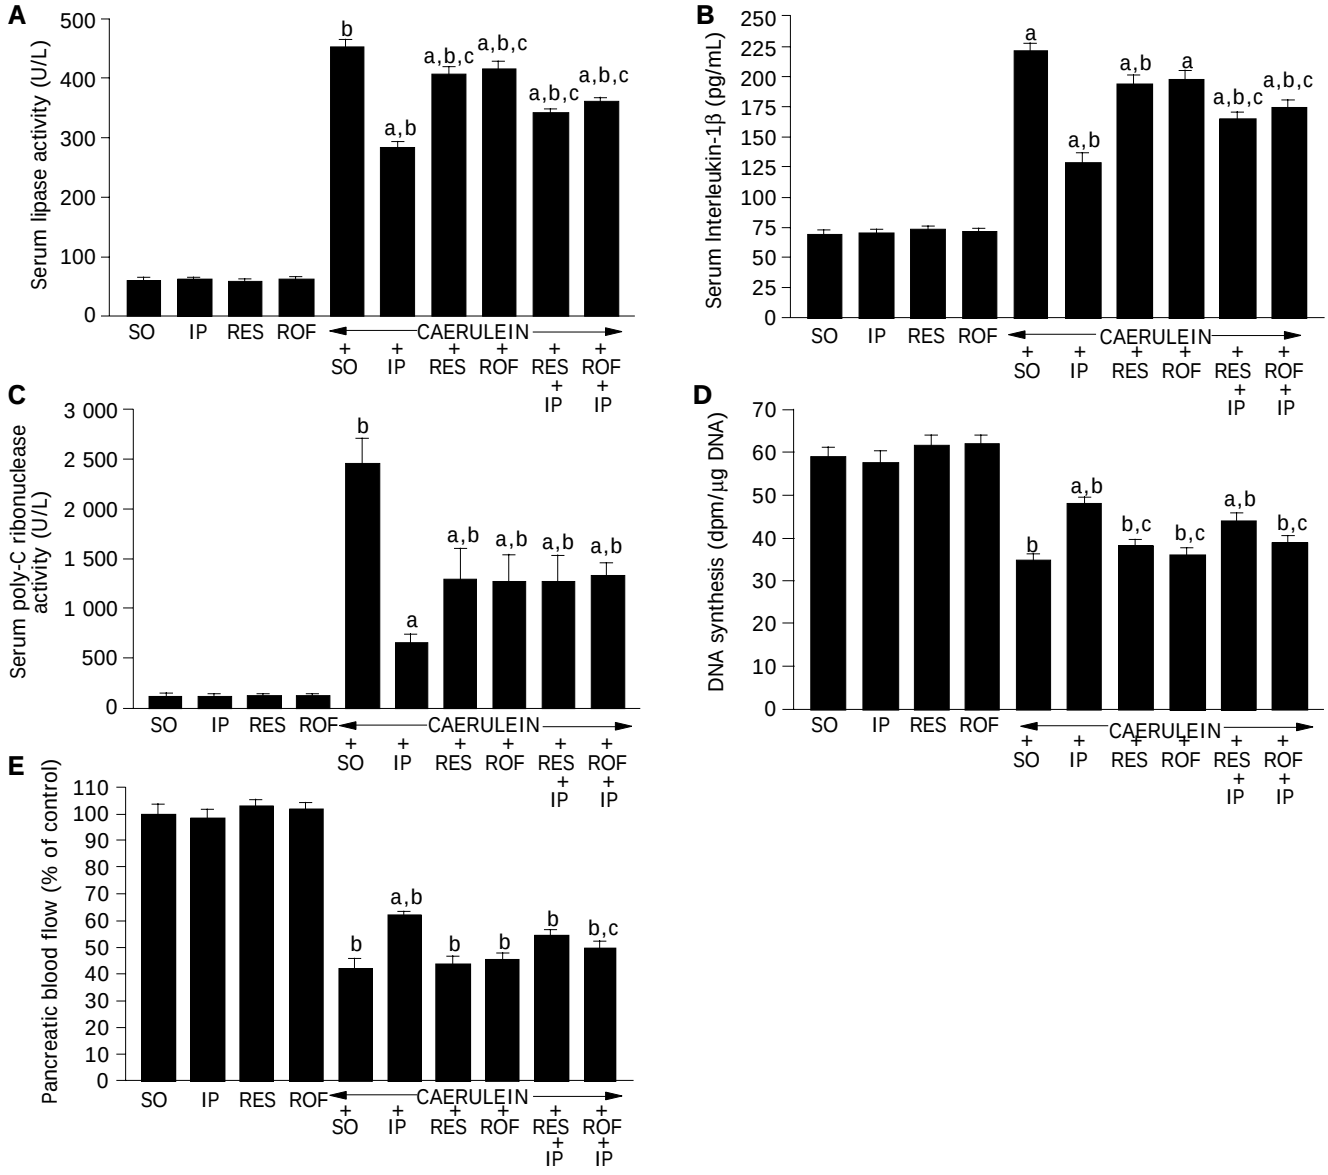

Figure 1 Effect of sham operation (SO), IP, resveratrol (RES) or rofecoxib (ROF) applied alone or in combination on serum lipase activity (A), IL-1β (B), poly-C ribonuclease (C), pancreatic DNA synthesis (D), and pancreatic blood flow (E) in rats with or without cerulein-induced pancreatitis. [a]$P<0.05$ *vs* sham-operated rats treated with cerulein alone, [b]$P<0.001$ *vs* sham-operated saline-treated control (SO), [c]$P<0.05$ *vs* rats exposed to IP and treated with cerulein.

IP-evoked decrease in serum IL-1β concentration in animals with cerulein-induced pancreatitis (P<0.001, Figure 1B).

In control sham-operated rats treated with saline, the serum IL-10 level reached 73.0±5.0 pg/mL (data not shown). Neither IP nor resveratrol or rofecoxib or cerulein applied alone or in their combination significantly affected the serum IL-10 concentration.

Effect of ischemic preconditioning, resveratrol, and rofecoxib on serum activity of poly-C ribonuclease in rats without or with cerulein-induced pancreatitis

In saline-treated sham-operated control rats, serum poly-C ribonuclease activity reached 125±25 U/L (Figure 1C). IP or administration of resveratrol or rofecoxib did not affect serum poly-C ribonuclease activity in animals without induction of acute pancreatitis. Cerulein-induced pancreatitis caused nearly 20-fold increase in serum poly-C ribonuclease activity and this effect was strongly and significantly inhibited by IP (P<0.001). Also administration of resveratrol or rofecoxib reduced the cerulein-induced increase in serum activity of poly-C ribonuclease, but the effect of these blockers of COX was weaker than that of IP (P<0.001). Combination of resveratrol or rofecoxib plus IP decreased the serum poly-C ribonuclease activity in cerulein-treated rats to the similar values as administration of resveratrol or rofecoxib in sham-operated rats with cerulein-induced pancreatitis (Figure 1C).

Effect of ischemic preconditioning, resveratrol, and rofecoxib on pancreatic DNA synthesis in rats without or with cerulein-induced pancreatitis

In saline-treated sham-operated control rats, pancreatic DNA synthesis reached 59.0±2.3 dpm/μg DNA (Figure 1D). IP as well as administration of resveratrol or rofecoxib did not affect pancreatic DNA synthesis in animals without induction of acute pancreatitis. In animals with cerulein-induced pancreatitis, pancreatic DNA synthesis was significantly reduced, reaching 34.7±1.6 dpm/μg DNA (P<0.001). IP significantly attenuated the pancreatitis-related reduction in pancreatic DNA synthesis (P<0.001). Resveratrol or rofecoxib given alone did not affect pancreatic DNA synthesis in animals treated with cerulein. Pretreatment with resveratrol tended to reduce the pancreatic DNA synthesis in animals treated with a combination of IP plus cerulein, but this effect was not statistically significant. In contrast, pretreatment with rofecoxib significantly reduced the pancreatic DNA synthesis in animals treated with IP plus cerulein (P<0.05).

Effect of ischemic preconditioning, resveratrol, and rofecoxib on pancreatic blood flow in rats without or with cerulein-induced pancreatitis

IP or treatment with resveratrol or rofecoxib did not affect pancreatic blood flow in rats without administration of cerulein (Figure 1E). Administration of cerulein for 5 h significantly reduced pancreatic blood flow by 58% when compared to that of saline-treated sham-operated control rats (P<0.001). Exposure to IP significantly reversed the cerulein-induced fall in pancreatic blood flow (P<0.001), whereas resveratrol or rofecoxib given alone had no effect on pancreatic blood flow in animals with cerulein-induced pancreatitis. Pretreatment with rofecoxib significantly abolished the IP-induced improvement of pancreatic blood flow in animals with pancreatitis (P<0.05).

Effect of ischemic preconditioning and cerulein-induced pancreatitis on synthesis of HSP 70 detected by Western blot

Figure 2 shows the effect of IP and cerulein-induced pancreatitis on the production of HSP 70 in the pancreatic tissue. In sham-operated control animals with an intact pancreas, the synthesis of HSP 70 was weak and the ratio of HSP 70 over β-actin reached a value of 0.11±0.01. IP or induction of acute pancreatitis by cerulein significantly increased the ratio of HSP 70 over β-actin in pancreatic tissue reaching 0.31±0.01 and 0.74±0.02, respectively (P<0.05 and P<0.001, respectively). The highest ratio of HSP 70 to β-actin in pancreatic tissue was observed in animals treated with combination of IP plus cerulein.

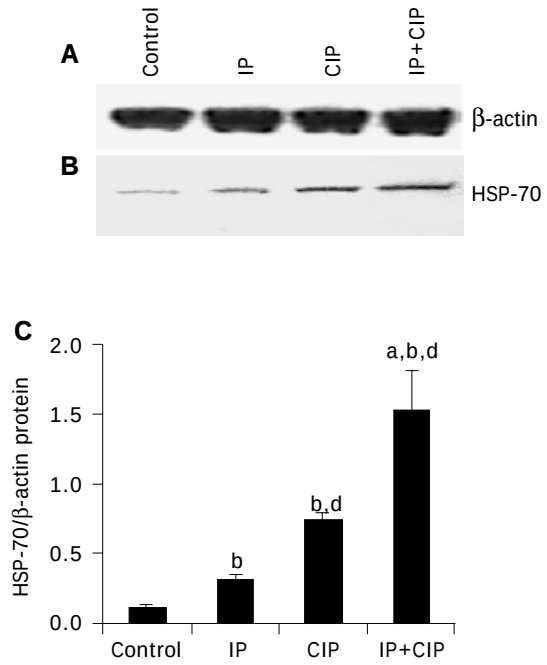

Figure 2 Representative Western blot analysis of β-actin protein (A) and HSP 70 (B), and the ratio of HSP 70 over β-actin protein (C) in pancreatic tissue of sham-operated control rats (lane 1), rats exposed to IP (lane 2), sham-operated rats with cerulein-induced pancreatitis (CIP, lane 3), and rats with IP applied prior to cerulein-induced pancreatitis (IP+CIP, lane 4). [b]P<0.001 *vs* sham-operated rats treated with cerulein alone (CIP), [a]P<0.05 *vs* sham-operated saline-treated control, [d]P<0.001 *vs* rats exposed to IP without induction of acute pancreatitis (CIP).

DISCUSSION

Our present study showed for the first time that: (1) IP could reduce the pancreatic damage in cerulein-induced acute pancreatitis; (2) IP and cerulein-induced pancreatitis could increase synthesis of HSP 70 in the pancreas and combination of these two factors could stimulate the production of HSP 70 to the highest extent; (3) inhibition of COXs, especially COX-2, could reduce the pancreatoprotective effect of IP against cerulein-induced pancreatitis.

Protective effect of IP against pancreatic damage evoked by cerulein was manifested by improvement of the biochemical and histological parameters. Exposure to IP prior to induction of acute pancreatitis significantly reduced the cerulein-evoked increase in serum lipase and poly-C ribonuclease activity, and serum concentration of pro-inflammatory IL-1β. A close relationship was found between the IP-evoked decrease in biochemical signs of pancreatitis and the improvement of pancreatic DNA synthesis, and pancreatic blood flow, as well as the reduction in histological score of pancreatic damage. Morphological features showed a decrease in pancreatic edema, vacuolization of acinar cells, and leukocyte infiltration of pancreatic tissue.

The increase in serum lipase activity is a well known manifestation of acute pancreatitis with high sensitivity and specificity[24]. Pancreatic-type poly-C specific ribonuclease is one of the few direct markers of severe pancreatic injury and pancreatic necrosis[21,25]. In our present study, acute pancreatitis was evoked by stimulation of pancreatitis by overdose of cerulein. This procedure leads to the development of mild edematous acute pancreatitis without pancreatic necrosis[26,27]. However, also in this case, we observed increase in serum activity of poly-C specific ribonuclease, suggesting that serum activity of pancreatic-type poly-C ribonuclease is not specific for severe pancreatic injury and pancreatic necrosis, and that serum activity of this enzyme increases in all types of acute pancreatitis, whereas severity of acute pancreatitis affects only the degree of poly-C ribonuclease activity in the serum. This discrepancy between our data and reports of Warshaw and Lee[21] or Naskalski *et al.*[25], may also be a result of species differences. On the other hand, our finding that IP applied before induction of acute pancreatitis reduced serum poly-C ribonuclease activity provides an additional support for the protective effect of IP on the pancreas in cerulein-induced pancreatitis.

In our present study, IP applied alone did not significantly affect pancreatic DNA synthesis. Induction of acute pancreatitis by cerulein caused a reduction in the pancreatic DNA synthesis, which is in agreement with previous observations[28,29] and may be considered as an index of pancreatic damage. In rats with induction of pancreatitis, IP attenuated the pancreatitis-evoked fall in pancreatic DNA synthesis. This observation brings the additional support for the concept that IP enhances resistance of the pancreas against tissue damage.

Our present observation that IP reduced pancreatic damage in cerulein-induced pancreatitis confirms and extends our previous finding that exposure to IP could protect the pancreas against damage evoked by severe ischemia followed by reperfusion[7]. These data suggest that IP, causing a mild damage, enhances resistance against pancreatic damage independently to the etiology of acute pancreatitis. This hypothesis is also supported by the observation that exposure to other mild damaging factors such as bacterial lipopolysaccharides[30], grapefruit-seed extract[22], or low doses of capsaicin[31] exhibits protective effect against acute pancreatitis.

The role of COX-2 in acute pancreatitis is unclear. Previous experimental studies on mice[13,14] have shown that pharmacological inhibition of COX-2 or COX-2 gene disruption ameliorates the severity of pancreatitis and the pancreatitis-associated lung injury. In contrast, in the rat model of pancreatitis, Foitzik *et al.*[32], have found some beneficial systemic effects of COX-2 inhibition on acute pancreatitis, such as an improvement of renal and respiratory function, but they have not observed any significant effect of COX-2 inhibition on histological score of pancreatic damage or plasma level of trypsinogen activation peptides. In our present study, blockade of COX-1 or COX-2 significantly reduced serum lipase and serum poly-C ribonuclease activity, as well as decreased pancreatic edema and inflammatory infiltration in morphological features in animals with cerulein-induced pancreatitis. The new and important finding of the present study is that inhibition of COXs, especially COX-2, reduces the protective effect of IP against pancreatic damage evoked by cerulein. This observation indicates that activity of COX-2 is necessary for the beneficial effect of IP. The involvement of COX-2 in IP effects on the pancreas is similar to that observed after treatment with HGF. Serum concentration of HGF is increased in patients with acute pancreatitis, and the HGF level reflects the clinical severity of pancreatitis and organ dysfunction[33,34]. Also experimental studies have shown the increase in plasma HGF level and tissue HGF overexpression in acute pancreatitis[35,36]. On the other hand, administration of antibodies that neutralize HGF aggravates the organ dysfunction and increases apoptosis in the course of acute pancreatitis[35], whereas treatment with HGF reduces pancreatic damage in cerulein-induced pancreatitis[37]. These data indicate that HGF is not a pro-inflammatory factor, but a result of pancreatic damage in acute pancreatitis and the elevation of HGF level plays a role of self-defense mechanism, limiting the intensity of inflammatory process. It was reported that inhibition of COX-2 abolishes the protective effect of HGF against acute pancreatitis[15]. Our present study showed that inhibition of COXs, especially COX-2, reduced the protective effect of IP against damage evoked by cerulein. These findings taken together suggest that pancreatoprotective effects evoked by IP and HGF involve similar but not strictly the same mechanisms. In contrast to the administration of HGF[37], exposure to IP did not increase the serum level of anti-inflammatory IL-10.

Another finding of our present study is the observation that cerulein-induced pancreatitis and IP increased pancreatic synthesis of HSP 70 and these two factors applied together caused maximal induction of HSP 70 synthesis in the pancreas. HSPs are highly conserved cytoprotective proteins that are induced by a variety of stresses including hyper- and hypothermia, toxin, heavy metals, and free radicals[16]. Previous studies demonstrated that both thermal and non-thermal stresses protect against cerulein-induced pancreatitis and prevent trypsinogen activation in the pancreas and this effect is mediated by HSP 70[38]. HSPs have also been shown to provide the protection against arginine-[19] and taurocholate-induced[39] pancreatitis. The potential protective mechanisms of HSPs on pancreas include stabilization and refolding of damaged proteins, resistance of cells to apoptosis or necrosis, decrease in the level of pro-inflammatory cytokines, antioxidant effects and interference with intra-acinar zymogen activation[16,38,40]. Our present results are consistent with the

previous studies showing an increase of HSP 70 at the mRNA and protein level after induction of cerulein-induced pancreatitis[41]. The major finding is, however, the observation of the further increase in HSP 70 synthesis in rats with IP, which indicates that the protective effects of IP could be mediated via this HSP.

In conclusion, exposure to IP reduces pancreatic damage in cerulein-induced acute pancreatitis and this protective effect of IP, at least in part, depends on COXs activity and production of HSP 70.

Abstract

AIM: To investigate the precise roles of CAR in CCl_4-induced acute hepatotoxicity.

METHODS: To prepare an acute liver injury model, CCl_4 was intraperitoneally injected in $CAR^{+/+}$ and $CAR^{-/-}$ mice.
RESULTS: Elevation of serum alanine aminotransferase and extension of centrilobular necrosis were slightly inhibited in $CAR^{-/-}$ mice compared to $CAR^{+/+}$ mice without PB. Administration of a CAR inducer, PB, revealed that CCl_4-induced liver toxicity was partially inhibited in $CAR^{-/-}$ mice compared with $CAR^{+/+}$ mice. On the other hand, androstanol, an inverse agonist ligand, inhibited hepatotoxicity in $CAR^{+/+}$ but not in $CAR^{-/-}$ mice. Thus, CAR activation caused CCl_4 hepatotoxicity while CAR inhibition resulted in partial protection against CCl_4-induced hepatotoxicity.There were no differences in the expression of CYP2E1, the main metabolizing enzyme for CCl_4, between $CAR^{+/+}$ and $CAR^{-/-}$ mice. However, the expression of other CCl_4-metabolizing enzymes, such as CYP2B10 and 3A11, was induced by PB in $CAR^{+/+}$ but not in $CAR^{-/-}$ mice. Although the main pathway of CCl_4-induced acute liver injury is mediated by CYP2E1, CAR modulates its pathway via induction of CYP2B10 and 3A11 in the presence of activator or inhibitor.

CONCLUSION: The nuclear receptor CAR modulates CCl_4-induced liver injury via induction of CCl_4-metabolizing enzymes in the presence of an activator. Our results suggest that drugs interacting with nuclear receptors such as PB might play critical roles in drug-induced liver injury or drug-drug interaction even though such drugs themselves are not hepatotoxic.

INTRODUCTION

Drug-induced liver injury is a clinical-relevant problem[1-3], and investigation of mechanisms of drug-induced liver injury is therefore of pharmacological and clinical importance. Animals induce drug-metabolizing enzymes to detoxify xenochemicals, including therapeutic drugs[4-6]. However, paradoxically, this can often result in bioactivation of toxic drugs and cause liver injury[4-6]. Thus, drug-metabolizing enzymes are a two-edge blade and have very crucial roles in drug-induced liver injury.

Recent studies indicate that the nuclear receptor constitutive androstane receptor (CAR) is a key regulator of drug-metabolizing enzymes such as cytochrome P450 (CYP)[7-9], UDP-glucuronosyltransferase (UGT)[10,11] and multidrug resistance-associated protein (MRP)[12,13]. CAR has also been reported as a key regulator for bile acid[14] and bilirubin liver injury[11,15,16]. As a cellular defense mechanism against toxicity and carcinogenicity, induction of and metabolism by CYPs usually leads to increased detoxification and elimination of xenobiotics[4-6]. The nuclear receptor CAR is implicated as an essential factor that mediates this inducible activation of drug-metabolizing enzymes[7-9]. CAR, acting as a heterodimer with the retinoid X receptor, binds to a nuclear receptor-binding site NR1 within the 51-bp phenobarbital-responsive enhancer module and activates genes such as CYP2B in response to phenobarbital (PB)-type inducers[7-9]. Expression analysis of hepatic genes in $CAR^{-/-}$ mice has also revealed that CAR is a key regulator of a group of xenochemical-metabolizing enzymes that include the CYP2B and CYP3A subfamilies[17]. Thus, CAR is closely associated with the regulation of drug-metabolizing enzymes. Because of its regulating roles for drug-metabolizing enzymes, CAR is thought to play an important role in the development of drug-induced liver injury.

Carbon tetrachloride (CCl_4) was once used widely as a solvent cleaner, anesthetic agent, and degreaser both for industrial and home use[18-20]. However, the high incidence of liver and renal problems following administration led to

discontinuation of its use. CCl_4 is used as a model drug for the study of hepatotoxicity in acute and chronic liver failure[18-20]. CCl_4 is metabolized by CYP2E1, CYP2B, and possibly CYP3A, to form the trichloromethyl radical, CCl_3*[18-20]. CCl_3* can bind to cellular molecules (nucleic acid, protein, and lipid), impairing crucial cellular processes. This radical can also react with oxygen to form the trichloromethylperoxy radical CCl_3OO*, a highly reactive species. Thus, the metabolites of CCl_4 cause the hepatic injury in the CCl_4 acute liver injury model. Inducers of drug-metabolizing enzymes, such as PB or dichlorodiphenyltrichloroethane, are also known to cause severe liver toxicity with CCl_4[18-20].

The nuclear receptor CAR has recently been shown to mediate the effects of PB and other PB-like inducers[21] and to act as a key regulator of drug-metabolizing enzymes[21-23]. However, the precise relationship between CAR and CCl_4-induced liver injury is not fully understood. We investigated the mechanism of CCl_4-induced acute liver injury and the roles of CAR in drug-induced liver injury using $CAR^{-/-}$ mice *in vivo*.

MATERIALS AND METHODS

Materials

PB was purchased from Sigma Chemicals Co. (St. Louis, MO, USA). 5α-Androstan-3δ-ol (androstanol) was purchased from Steraloids (Newport, RI, USA). CCl_4 was purchased from Kanto Chemistry (Tokyo, Japan). The total glutathione quantification kit was purchased from Dojindo Molecular Technologies Inc. (Gaithersburg, MD, USA).

Animals and treatment

$CAR^{-/-}$ and $CAR^{+/+}$ mice used in this study were generated as described previously[24]. The background strain contained 98% of the C3H/HeNCrlBR markers by microsatellite analysis[24]. All mouse work was performed in accordance with the guidelines for animal care and use established by Gunma University Graduate School of Medicine. Germline transmission of the disrupted allele was detected by PCR[17]. Mice were injected intraperitoneally with the indicated concentration of CCl_4 dissolved in olive oil at 8-10 wk of age and were killed, and their sera and livers were collected at specified time points. PB was administered in H_2O at a dose of 100 mg/kg body weight for 12 and 36 h before CCl_4 administration. Androstanol was administered in olive oil at a dose of 100 mg/kg body weight for 1 h before CCl_4 administration. For control mice, 100 μL of H_2O or olive oil per 25 g of body weight was injected. Serum alanine aminotransferase (ALT), total bilirubin, and blood urea nitrogen (BUN) levels were measured with an auto-analyzer at each point. Liver tissues were fixed in 40 g/L formaldehyde, embedded in paraffin and stained with hematoxylin-eosin. At a magnification of ×40, 10 areas of centrilobular necrosis were measured in a blinded fashion for each group using NIH Image 1.62 software (National Institute of Health, MD, USA). The index of centrilobular necrosis was scored as follows: area of centrilobular necrosis divided by whole area.

Reverse transcription-polymerase chain reaction

Total RNA extraction from liver and subsequent synthesis of first-strand cDNA were performed using TRIzol reagent (Invitrogen, Carlsbad, CA, USA) and SuperScript™ preamplification system (Invitrogen, Carlsbad, CA, USA), respectively. cDNAs were amplified using the following sets of primers: CYP2B10 mRNA, 5'-AAAGTCCCGTGGCAACTTCC-3' and 5'-CATCCCAAAGTCTCTCATGG-3'; CYP3A11 mRNA, 5'-CTCAATGGTGTGTATATCCCC-3' and 5'-CCGATGTTCTTAGACACTGCC-3'; GSTpi, 5'-CTTGCTCAAGCCCACTTGTC-3' and 5'-ATGGGACGGTTCACATGTTC-3'; CYP2E1, 5'-GGATGAATATGCCCTACATG-3' and 5'-TGATGGGCAGCAGGTCTCAT-3'. β-actin mRNA level was also measured as an internal control. One-twentieth of each cDNA synthesized from 5 μg of RNA was subjected to PCR. PCR was performed using Taq DNA polymerase (Promega, Madison, WI, USA) with TaqStart antibody (Clontech, Palo Alto, CA, USA) at 95 ℃ for 60 s, 55 ℃ for 60 s, and 72 ℃ for 60 s. The amplified DNA was separated on a 1.5% agarose gel and visualized with staining by ethidium bromide. The expected sizes of the amplified cDNA were 340, 423, 468, and 486 bp for CYP2B10, CYP3A11, CYP2E1, and GSTPi, respectively.

Hepatic glutathione concentration

Total hepatic reduced glutathione concentration was determined by the total glutathione quantification kit (Dojindo Molecular Technologies Inc.). Each liver was excised and homogenized with 5% trichloroacetic acid, and centrifuged at 4 ℃, 2 000 r/min for 15 min. The supernatant was used for total glutathione assay using the total glutathione quantification kit according to the manual provided by the manufacturer.

Statistical analysis

All experimental data are shown as mean±SD. Differences in serum ALT levels and the index of centrilobular necrosis were determined by one-way factorial analysis of variance for each group. The level of significance for all statistical analyses was set at $P<0.05$.

RESULTS

Phenobarbital pretreatment induces CCl_4 toxicity in $CAR^{+/+}$ mice

$CAR^{+/+}$ and $CAR^{-/-}$ mice were administered a 25-mg/kg dose of CCl_4 by intraperitoneal injection ($n = 6$ per treatment group) and the ALT level was measured at 24 h (Figure 1A). The serum levels of ALT increased following CCl_4 administration in both groups ($P<0.001$). The level of ALT was slightly higher in $CAR^{+/+}$ mice than in $CAR^{-/-}$ mice ($P<0.001$). There were no significant changes in the serum levels of total bilirubin and BUN in both groups (data not shown). $CAR^{+/+}$ and $CAR^{-/-}$ animals pretreated with PB (12 and 36 h before CCl_4 administration) were then administered the same dose of CCl_4. PB pretreatment caused marked elevation of ALT in $CAR^{+/+}$ mice. The $CAR^{-/-}$ mice showed some elevation of ALT with PB pretreatment, but the level was less than that in wild-type mice. The difference of ALT levels became clear between $CAR^{+/+}$ and $CAR^{-/-}$ mice with pre-treatment by PB ($P<0.001$). PB alone and control mice did not show such an elevation of ALT.

Histological changes associated with CCl_4 toxicity

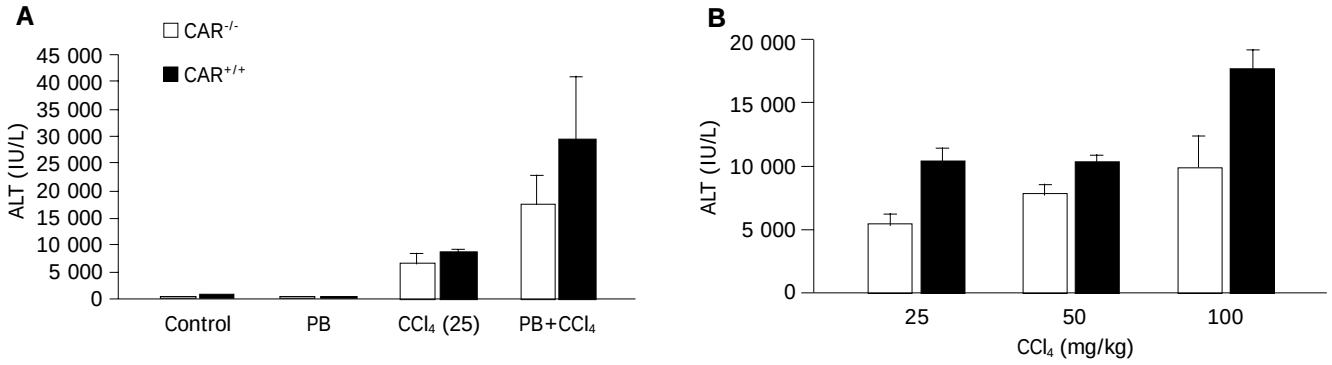

Figure 1 A: PB pretreatment induced CCl_4 toxicity. $CAR^{+/+}$ or $CAR^{-/-}$ mice were administered a 25-mg/kg dose of CCl_4 by intraperitoneal injection with or without PB pretreatment (n = 6 per treatment group). Serum was collected and ALT levels were measured after 24 h. The ALT level was slightly higher in $CAR^{+/+}$ mice than in $CAR^{-/-}$ mice with CCl_4 treatment (P<0.001). The difference in ALT levels became clearer between $CAR^{+/+}$ and $CAR^{-/-}$ mice with pre-treatment by PB (P<0.001). B: Dose dependency of CCl_4 toxicity. $CAR^{+/+}$ and $CAR^{-/-}$ mice were given 25-, 50-, or 100-mg/kg doses of CCl_4. Blood samples were collected 24 h later, and serum ALT levels were measured (n = 4). $CAR^{-/-}$ animals were significantly less sensitive than $CAR^{+/+}$ mice to CCl_4 toxicity (P<0.001). Data are mean±SD.

$CAR^{+/+}$ or $CAR^{-/-}$ mice were administered a 25-mg/kg dose of CCl_4 by intraperitoneal injection with or without pretreatment with PB (n = 6 per treatment group). Liver sections from each treatment were examined by hematoxylin and eosin staining. Liver samples from all treated animals were analyzed but representative histology is presented in Figure 2A showing marked centrilobular necrosis. The extent of the necrotic area with CCl_4 in the $CAR^{+/+}$ liver was slightly larger than that in $CAR^{-/-}$ mice. PB pretreatment caused extensive centrilobular necrosis in $CAR^{+/+}$ mice compared with $CAR^{-/-}$ mice. The indices of centrilobular necrosis (Figure 2B) in $CAR^{+/+}$ mice and $CAR^{-/-}$ mice treated with CCl_4 alone were 17.44±1.02 and 13.11±1.41, respectively (P<0.001). The indices of centrilobular necrosis in $CAR^{+/+}$ mice and $CAR^{-/-}$ mice treated with PB plus CCl_4 were 39.08±2.10 and 26.33±2.33, respectively (P<0.001).

Dose dependency and time course of CCl_4 toxicity

$CAR^{+/+}$ or $CAR^{-/-}$ mice were treated with 25-, 50-, or 100-mg/kg CCl_4 by intraperitoneal injection (n = 4 per treatment group). Five and twenty-four hours later, the mice were killed and blood samples were collected (Figure 1B).

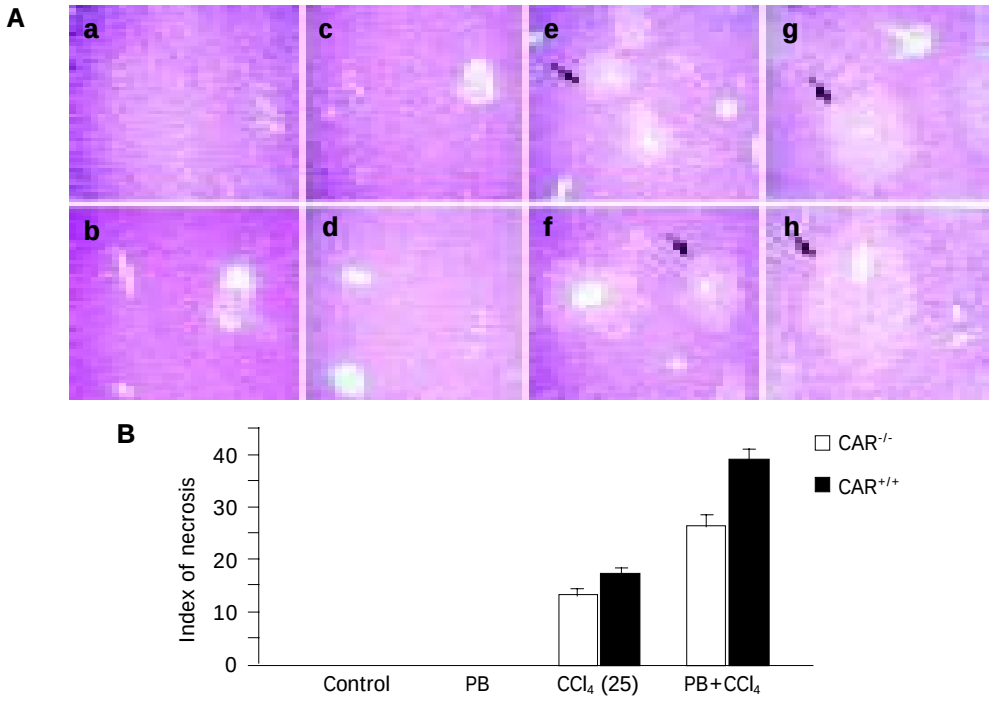

Figure 2 Histological changes associated with CCl_4 toxicity. A: Histological findings in the liver; (a) $CAR^{-/-}$ mice, control; (b) $CAR^{+/+}$ mice, control; (c) $CAR^{-/-}$ mice, PB; (d) $CAR^{+/+}$ mice, PB; (e) $CAR^{-/-}$ mice, CCl_4; (f) $CAR^{+/+}$ mice, CCl_4; (g) $CAR^{-/-}$ mice, PB plus CCl_4; and (h) $CAR^{+/+}$ mice, PB plus CCl_4. Liver sections from each treatment were examined by hematoxylin and eosin staining. Liver samples from all treated animals were analyzed, but only representative histology is presented. The extent of the necrotic area in the $CAR^{+/+}$ liver was larger than that in $CAR^{-/-}$ mice. PB pretreatment caused extensive centrilobular necrosis in $CAR^{+/+}$ mice. The arrows indicate centrilobular necrosis. Magnification, ×100. B: The indices of centrilobular necrosis in $CAR^{+/+}$ mice and $CAR^{-/-}$ mice. The indices of centrilobular necrosis were higher in $CAR^{+/+}$ mice than that in $CAR^{-/-}$ mice with PB pretreatment. The index in $CAR^{+/+}$ mice treated with CCl_4 plus PB was significantly increased. The index of centrilobular necrosis was scored as follows: area of centrilobular necrosis divided by whole area. Data are mean±SD.

No elevation of ALT was observed at 5 h (data not shown). At 24 h, ALT was significantly elevated and dose dependency was observed in CCl_4 toxicity in both groups of mice. The serum ALT concentrations of $CAR^{-/-}$ mice were lower than those of the $CAR^{+/+}$ mice ($P<0.001$). Thus, $CAR^{+/+}$ mice were apparently more sensitive to CCl_4 liver toxicity compared with $CAR^{-/-}$ mice.

Hepatic mRNA levels of CCl_4-metabolizing enzymes

CCl_4 is reported to be metabolized and activated by CYP2E1, CYP2B, and possibly CYP3A, to form the trichloromethyl radical, CCl_3*[18-20]. To evaluate the relationship between CAR and CCl_4-metabolizing enzymes, $CAR^{+/+}$ or $CAR^{-/-}$ animals were treated with a 100-mg/kg PB intraperitoneally ($n = 6$ per treatment group, Figure 3). There were no differences in the basal expression of CYP2E1, the main metabolizing enzyme of CCl_4, between $CAR^{+/+}$ and $CAR^{-/-}$ mice. Among the genes associated with CCl_4 metabolism, PB treatment did not influence CYP2E1 mRNA levels but induced CYP2B10, CYP3A11 mRNAs in $CAR^{+/+}$ mice. On the other hand, no induction of the enzymes CYP2E1, CYP2B10, and CYP3A11 was observed in $CAR^{-/-}$ mice. Thus, PB activated CCl_4-metabolizing enzymes, CYP2B10 and CYP3A11, via CAR. Because CAR is reported to regulate GSTPi, the enzyme that enhances glutathione depletion in acetaminophen toxicity[18-21], GSTPi mRNA, was also measured. GSTPi mRNA was induced by PB in $CAR^{+/+}$ mice stronger than in $CAR^{-/-}$ mice.

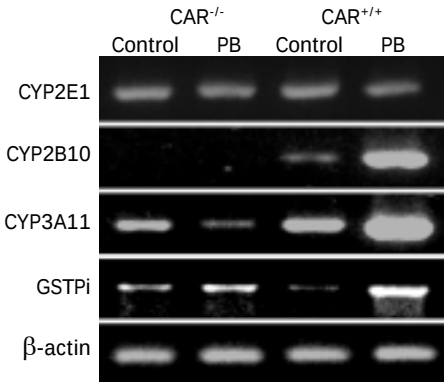

Figure 3 Hepatic mRNA level of drug-metabolizing enzymes with PB treatment. Total liver RNA was prepared from $CAR^{+/+}$ or $CAR^{-/-}$ animals treated with a 100-mg/kg dose of PB by intraperitoneal injection ($n = 6$ per treatment group). Total liver RNA was prepared 12 h after PB treatment and subjected to PCR analysis with the indicated primers in Materials and methods. β-Actin mRNA level was also measured as an internal control. The amplified DNA was separated on a 1.5% agarose gel and visualized with staining by ethidium bromide. The expected sizes of the amplified cDNA are described in Materials and methods.

Hepatic glutathione level

For detoxification, metabolites of CCl_4 such as CCl_3* decreased the amount of reduced glutathione. A decrease of glutathione in the liver reflects increased production of CCl_4 metabolites. Liver samples treated with CCl_4 and/or PB were collected 24 h after each treatment and glutathione levels were measured ($n = 6$ per treatment group, Figure 4). Hepatic glutathione levels in the PB plus CCl_4-treated $CAR^{+/+}$ mice were significantly different from those of the $CAR^{-/-}$ mice ($P<0.001$). $CAR^{+/+}$ mice treated with PB plus CCl_4 showed about a 50% decrease in hepatic glutathione level compared with $CAR^{-/-}$ mice.

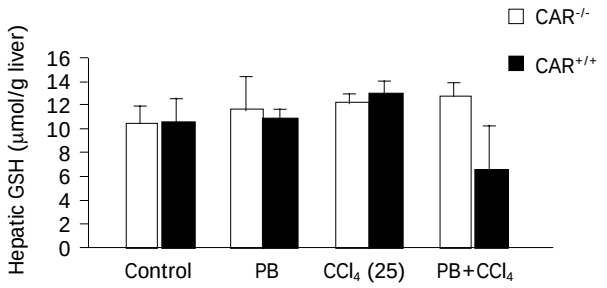

Figure 4 Hepatic glutathione (GSH) level. Liver samples treated with the indicated chemicals were collected 24 h after each treatment and glutathione levels were measured ($n = 6$ per treatment group) using the total glutathione quantification kit. Hepatic glutathione levels in the PB plus CCl_4 treated $CAR^{+/+}$ mice significantly decreased, compared with those of the $CAR^{-/-}$ mice ($P<0.001$). Data are mean±SD.

Androstanol reduced CCl_4-induced hepatotoxicity in $CAR^{+/+}$ mice to the level of $CAR^{-/-}$ mice

$CAR^{+/+}$ or $CAR^{-/-}$ mice were treated with 100-mg/kg CCl_4 intraperitoneally, with or without pretreatment with androstanol (100 mg/kg). Serum ALT levels were measured 24 h later ($n = 6$ per treatment group, Figure 5). Without androstanol, $CAR^{+/+}$ mice treated with CCl_4 showed significantly higher ALT concentrations than did $CAR^{-/-}$ mice ($P<0.0001$). Surprisingly, androstanol reduced the ALT concentration of $CAR^{+/+}$ mice to the level of $CAR^{-/-}$ mice. Liver sections from the same animals, as indicated, were stained with hematoxylin and eosin (Figure 5B). Androstanol pretreatment reduced the hepatic centrilobular necrosis (Figure 5C) of $CAR^{+/+}$ mice to the level of $CAR^{-/-}$ mice. The indices of centrilobular necrosis of $CAR^{+/+}$ mice and $CAR^{-/-}$ mice treated with CCl_4 alone were 33.39±5.04 and 26.49±2.87, respectively ($P<0.001$). With androstanol treatment, the indices of centrilobular necrosis in $CAR^{+/+}$ mice and $CAR^{-/-}$ mice decreased to 23.64±1.89 and 25.15±2.36, respectively ($P = 0.15$). Thus, androstanol, the inverse agonist of CAR, reduced the CCl_4-induced hepatotoxicity of $CAR^{+/+}$ mice to the level of $CAR^{-/-}$ mice.

To evaluate the effect of androstanol on CCl_4-metabolizing enzymes, hepatic mRNA levels were determined with RT-PCR. Androstanol treatment did not influence CYP2E1 mRNA levels but slightly repressed CYP3A11 mRNA in $CAR^{+/+}$ mice as previously reported[25]. Because of low basal expression of CYP2B10 mRNA, the repression of CYP2B10 mRNA by androstanol could not be demonstrated with RT-PCR in $CAR^{+/+}$ mice. However, androstanol was reported to repress the basal promoter activity of CYP2B10 by luciferase reporter assay[26]. On the other hand, no induction or repression of the enzymes CYP2E1, CYP2B10, and CYP3A11 was observed in $CAR^{-/-}$ mice. Thus, androstanol repressed basal expression of CCl_4-metabolizing enzymes, CYP3A11 and may be CYP2B10, via CAR. Androstanol

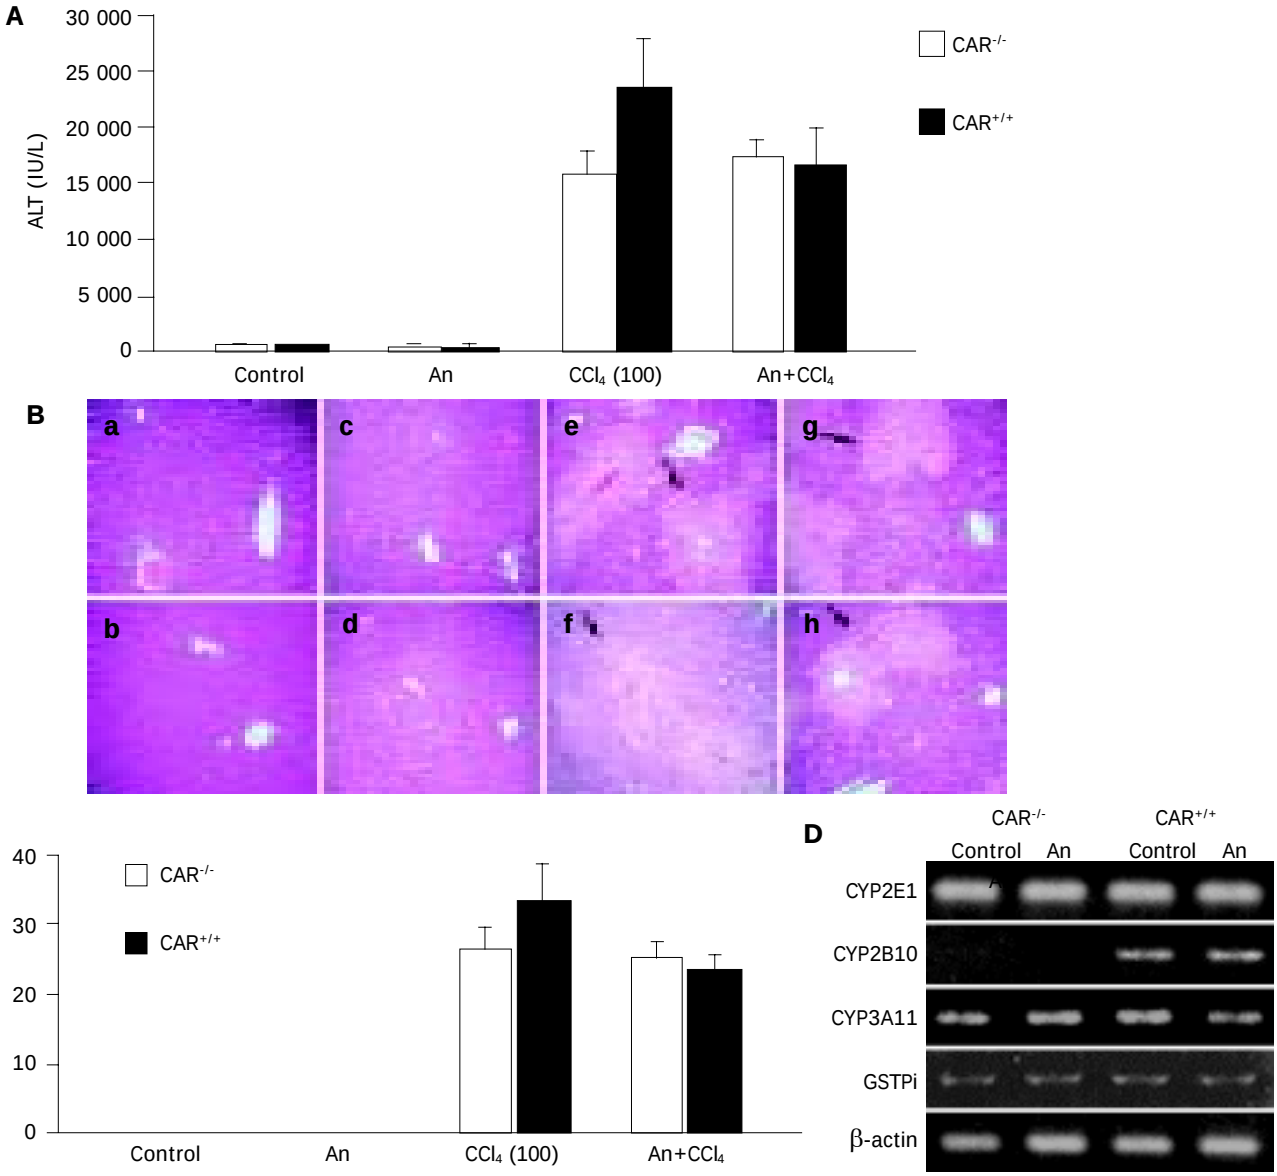

Figure 5 Androstanol prevented CCl_4-induced hepatotoxicity. A: $CAR^{+/+}$ or $CAR^{-/-}$ mice were given a 100-mg/kg dose of CCl_4 by intraperitoneal injection, with or without pretreatment with androstanol (100 mg/kg). Serum ALT levels were measured 24 h later (n = 6 per treatment group). Androstanol-pretreatment reduced the ALT level of $CAR^{+/+}$ mice to the level of $CAR^{-/-}$ mice. An: androstanol. B: Liver sections from the same animals 24 h after different treatments, as indicated, were stained with hematoxylin and eosin. (a) $CAR^{-/-}$ mice, control; (b) $CAR^{+/+}$ mice, control; (c) $CAR^{-/-}$ mice, androstanol; (d) $CAR^{+/+}$ mice, androstanol; (e) $CAR^{-/-}$ mice, CCl_4; (f) $CAR^{+/+}$ mice, CCl_4; (g) $CAR^{-/-}$ mice, androstanol plus CCl_4; and (h) $CAR^{+/+}$ mice, androstanol plus CCl_4. Androstanol pretreatment reduced the hepatic centrilobular necrosis in $CAR^{+/+}$ mice. Arrows indicate areas of hepatic necrosis. C: The indices of centrilobular necrosis in $CAR^{+/+}$ mice and $CAR^{-/-}$ mice. Androstanol-pretreatment reduced hepatic centrilobular necrosis of $CAR^{+/+}$ mice to the level of $CAR^{-/-}$ mice. Data in (A) and (C) are mean±SD. (D) Hepatic mRNA level of drug-metabolizing enzymes with androstanol treatment. Total liver RNA was prepared from $CAR^{+/+}$ or $CAR^{-/-}$ animals treated with a 100-mg/kg dose of androstanol by intraperitoneal injection (n = 6 per treatment group) and subjected to PCR analysis with the indicated primers in Materials and methods. β-actin mRNA level was also measured as an internal control. The amplified DNA was separated on a 1.5% agarose gel and visualized with staining by ethidium bromide. The expected sizes of the amplified cDNA are described in Materials and methods.

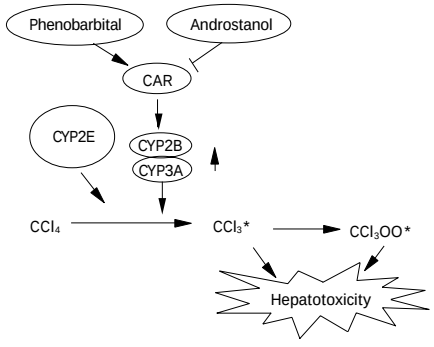

Figure 6 Schematic representation of CAR-mediated CCl_4 hepatotoxicity.

treatment did not influence GSTPi mRNA levels in $CAR^{+/+}$ and $CAR^{-/-}$ mice by RT-PCR.

DISCUSSION

In this study, we showed that CAR partially modulates the CCl_4 toxicity that is associated with induction of some CCl_4-metabolizing enzymes in the presence of agonist. The loss of CAR function results in partial resistance to CCl_4 toxicity. However, the CCl_4 liver toxicity is not fully inhibited in $CAR^{-/-}$ mice and differences between $CAR^{+/+}$ and $CAR^{-/-}$ mice were small in the absence of an inducer, PB. Metabolites of CCl_4 such as CCl_3* and CCl_3OO* are known to cause the

hepatic injury associated with CCl_4[18-20]. CCl_4 is metabolized by CYP2E1, CYP2B, and possibly CYP3A, to form the trichloromethyl radical, CCl_3*[18-20]. The main CCl_4-metabolizing enzyme is CYP2E1 and it is expressed in $CAR^{+/+}$ and $CAR^{-/-}$ mice in the same way. Therefore, CCl_4 liver toxicity occurs despite an absence of CAR. Thus, CYP2B or CYP3A may only have supplementary roles in CCl_4 metabolism in the absence of PB. On the other hand, in the presence of CAR inducers, it results in the induction of CYP2B and CYP3A, and CCl_4 liver toxicity is severe, as seen in $CAR^{+/+}$ mice. Inducers of drug-metabolizing enzymes including PB have long been known to cause severe liver toxicity with CCl_4[18-20]. In this study, we showed that PB activated CYP2B10 and 3A11 via receptor CAR and that it caused the severe CCl_4 liver toxicity (Figure 6). Thus, the xenobiotic receptor CAR will have a mean with the presence of its agonist/antagonist. PB treatment resulted in enhanced CCl_4 liver toxicity in $CAR^{-/-}$ mice although to a lesser degree than that in $CAR^{+/+}$ mice. PB may impact on pathways distinct from CAR to cause CCl_4 liver toxicity. Indeed, cDNA microarray analysis of $CAR^{-/-}$ mice showed CAR-independent genes in response to PB treatment[17]. A total of 138 genes were detected to be either induced or repressed in response to PB treatment, of which about half were not under CAR regulation[17]. Enzymes such as amino levulinate synthase 1 and squalene epoxidase displayed CAR-independent induction by PB[17]. CYP4A10 and CYP4A14 represented the group of genes induced by PB only in $CAR^{-/-}$ mice, indicating that CAR may be a transcription blocker that prevents these genes from being induced by PB[17]. The enzymes having CCl_4-metabolizing activity may be included in these CAR-independent PB response genes.

CAR was also identified as a key regulator of acetaminophen metabolism and hepatotoxicity[27]. CAR regulates GSTPi, the enzyme that enhances glutathione depletion and so promotes acetaminophen toxicity[27-29]. In this study, CAR also induced GSTPi with PB treatment. The metabolites of CCl_4 such as CCl_3* and CCl_3OO* induce hepatotoxicity and expend glutathione and cause a decrease of hepatic glutathione level. In addition, induction of GSTPi expression may cause further depletion of glutathione and severe toxicity in CCl_4-treated mice.

Although CAR acted as a hepatotoxic regulator in this study, CAR could act as a protective manner in other situations[30,31]. PB is a well-established therapy for hyperbilirubinemia in Crigler-Najjar type II patients[30]. CAR has the ability to activate expression of known components of the bilirubin pathway including UGT1A1, OATP2, MRP2, and GSTA1[15]. It was also reported that paralysis by the muscle relaxant zoxazolamine was avoided by pretreatment with CAR activators but was prolonged in $CAR^{-/-}$ mice[21]. Thus, CAR coordinates the induction of metabolic activity and increases elimination of the drugs in a protective manner in some cases.

Transactivation of target genes by CAR can be blocked by the inverse agonist androstanol[32]. Androstanol is reported to not only prevent induction but also to decrease basal expression of CAR target genes including CYP3A11[25]. Androstanol reduced the liver toxicity of $CAR^{+/+}$ mice to the level of $CAR^{-/-}$ mice in this study. This effect of androstanol may result in decrease of the basal expression of CAR target genes including CYP3A11. Androstanol treatment was also reported to decrease the toxicity of acetaminophen[24].

The nuclear receptor CAR has only a small role in CCl_4 toxicity without its agonist/antagonist. However, because of its nature as a xenobiotic sensor, CAR exhibits its ability to the full in the presence of agonist/antagonist. Since some kinds of CAR inducers such as PB and phenytoin are used clinically, CAR may have an important clinical role in drug-induced liver injury or drug-drug interaction. Nuclear receptors regulating drug-metabolizing enzymes such as CAR are a two-edge blade in animals. In some cases, activation of CAR increases production of drug-metabolizing enzymes and increases toxicity. Thus, CAR inverse agonists such as androstanol may have potential for treatment of these kinds of drug-induced liver injury. On the other hand, activation of CAR by appropriate inducers acts in a hepato-protective manner in some cases such as bilirubin toxicity. Conversely, induction of CAR activity reduced the liver injury in these cases.

Thus, a nuclear receptor that regulates drug-metabolizing enzymes is a key factor in drug-induced liver injury. Regulation of CAR activity may be an important clinical strategy for treatment of drug-induced liver injury. Both CAR and nuclear receptor regulating drug-metabolizing enzymes such as pregnane X receptor and peroxisome proliferator activated receptors are thought to be associated with drug-induced liver injury. Activating or inverse agonists for nuclear receptors may provide a clinically useful means to treat drug-induced liver injury.

Abstract

AIM: To evaluate the effects of gliadin on the oxidative environment in the "*in vivo*-like" model of a three-dimensional cell culture system.

METHODS: LoVo cell line (intestinal adenocarcinoma) multicellular spheroids were treated with digested gliadin (with albumin used as a control). Spheroid volumes, cell viability and morphology, lactate dehydrogenase (LDH) release, content of reduced glutathione (GSH) and activity of GSH-related enzymes were examined. The data were statistically analyzed using the Student's *t*-test ($P<0.05$). was considered statistically significant.

RESULTS: Gliadin reduced cell viability (from 20% to 60%) and led to morphological alterations characterized by apoptotic findings and cytoskeletal injuries. LDH activity increased. The content of GSH reduced (-20% *vs* controls), and activity of GSH-related enzymes was significantly inhibited.

CONCLUSION: Gliadin treatment induces an imbalance in the antioxidative mechanism of cells cultured by the three-dimensional technique. This alteration may explain the cell damage directly caused by gliadin and the subsequent morphological abnormalities.

INTRODUCTION

Since Hudson *et al*.[1], first observed the inhibited growth and morphological modifications in different human cell lines induced by gliadin exposure, a number of *in vitro* studies have confirmed the cytotoxicity of the peptide. Gliadin has agglutinating activity on K562 cells (human chronic myeloid leukemia), reduces F-actin content in intestine 407 cells, inhibits cell growth, induces apoptosis and alters redox equilibrium in Caco-2 cells (human intestinal adenocarcinoma), and causes a rearrangement of the cytoskeleton through the zonulin pathway and the loss of tight junction permeability in IEC-6 cells[2].

Three-dimensional cell cultures (multicellular tumor spheroids, MCTSs) were first introduced by Sutherland *et al*.[3], in the early 1970s, and are now considered as an interesting model in biomedical research[4]. Unlike conventional monolayer cell culture systems, MCTSs maintain the specific morphological and biochemical properties of the corresponding *in vivo* tissue, and remain in a differentiated and functionally active state for many weeks, thus making it possible to study the long-term effects of various xenobiotics[5]. We have recently used MCTSs from the LoVo cell line to test gliadin, and have shown that it has a direct cytotoxic effect on cell growth and morphology[6].

Redox equilibrium plays a pivotal role in cell homeostasis, and can affect biological functions[7,8]. Glutathione (GSH), which consists of L-glutamine, L-cysteine and glycine, is the most important low-molecular-weight peptide involved in redox equilibrium. It has a reductive action on the cell environment and neutralizes the reactive oxygen compounds and free radicals formed during metabolism. GSH depletion induces low thiol protein stores, a determinant of cell homeostasis, and triggers cytotoxicity[9,10]. GSH depletion has also been shown in a number of human diseases

(alcoholic liver disease, HIV infection, acute respiratory distress syndrome, and inflammatory bowel disease), and it has been shown that depressed intracellular GSH levels in liver and mammary tissues promote carcinogenesis[11].

The aim of this study was to evaluate the content of reduced GSH and the activity of GSH-related enzymes in LoVo MCTSs treated with gliadin.

[illegible]

Protein digestion

Gliadin was purified from *Triticum aestivum* flour (Hereward cultivar) according to Capelli *et al*.[12]. Bovine serum albumin (BSA) used as a control was purchased from Sigma (Milan, Italy). Pepsin was supplied by Sigma (Milan, Italy) and pancreatin by Merck (Milan, Italy). All the chemicals were of analytical grade. Digestion was performed as previously described[6]: briefly, gliadin was first incubated with pepsin at 37 ℃ for 24 h, and then with pancreatin at 37 ℃ for 3 h, adjusting to pH 8.0.

The digested proteins were analytically controlled by reverse-phase HPLC, size-exclusion HPLC and SDS-PAGE before being freeze-dried and stored.

Cell culture, treatment, volumetric analysis and viability test

LoVo human colon adenocarcinoma cell line (ATCC, Rockville, USA) was maintained in exponential monolayer growth and routinely checked for mycoplasma contamination as previously described[6].

MCTSs were initiated according to Dolfini *et al*.[6], by seeding 2×10^5 cells/mL in 25 mL of complete medium in polycarbonate Erlenmeyer flasks (Corning, Milan, Italy), and incubated in a gyratory rotation incubator. MCTS volumes were evaluated according to Chignola *et al*.[13].

On the 7th d, MCTSs (mean±SD: 220±70 μm) were exposed to digested gliadin (PT-gliadin, 500 μg/mL) or BSA (PT-BSA, 500 μg/mL) in completely renewed medium for further 5 d, and subsequently taken for the evaluation of lactate dehydrogenase (LDH) release, GSH content and GSH-related enzyme activity, and morphological analysis.

MCTS viability was tested (colony-forming assay) by plating a cell suspension obtained after trypsin disaggregation of MCTSs (on the 5th d of treatment at PT-gliadin concentrations of 125, 500, 750, and 1 000 μg/mL, and a PT-BSA concentration of 1 000 μg/mL) in triplicate in six-well plates (500 cells/well). The surviving cell fraction was calculated after 10 d and compared with the plating efficiency of the controls.

Lactate dehydrogenase activity

LDH released from damaged cells was measured in free aliquots of medium from the cell cultures, and cell-free complete medium was included as a negative control.

Briefly, 50 μL of the aliquots of cell supernatants was mixed with 25 μL of LDH reagent (Sigma, Milan, Italy) and incubated at room temperature for 30 min. LDH activity was calculated by measuring the increase in absorbance at 490 nm according to Legrand *et al*.[14], and related to the protein content of MTCSs[15]. LDH activity was reported as percentages of control values.

GSH content and GSH-related enzyme activity

MTCSs were washed with PBS (Sigma, Milan, Italy), and then sonicated and centrifuged. The cytosolic supernatant was used to measure GSH content and activity of the GSH-related enzymes, namely reductase (GSR), peroxidase (GPOX) and GSH-*S*-transferase (GST).

GSH content and enzyme activity were analyzed according to previously described methods[16], and expressed as percentages of control values.

Light and electron microscopy

LoVo cell line MCTS samples were prepared as previously described[6], fixed in 2.5% glutaraldehyde in a phosphate buffer, and then washed in the same buffer. In order to avoid injury or loss of spheroids, they were encapsulated in a solidifying agar solution and small spheroid-containing cubes were routinely processed for transmission electron microscopy (TEM)[17]. The semi-thin (0.5 μm) sections used for light microscopy analysis were stained with toluidine blue, the ultra-thin sections (50-70 nm) used for the ultrastructural study were counterstained with uranyl acetate and lead citrate. The MCTSs were studied for the presence of microvilli and intercellular junctions, and the appearance of nuclei, cytoplasm and intracytoplasmic organelles.

Scanning electron microscopy (SEM) was performed using a Philips mod. XL20 scanning electron microscope. MCTSs were washed twice with PBS, and then fixed in 2.5% glutaraldehyde in a phosphate buffer at 4 ℃ for a minimum of 24 h. At the time of analysis, a representative spheroid sample was recovered, immediately placed on a filter paper, and observed in low vacuum modality at a high voltage of 10 kV.

Statistical analysis

Each experiment was repeated four times. All the data were expressed as mean±SD and analyzed using the two-tailed Student's *t*-test. $P<0.05$ was considered statistically significant.

[illegible]

Volume, viability, and LDH activity in medium

The untreated and control MCTSs (treated with PT-BSA) did not show any statistical difference in terms of diameter ($27\pm7\times10^{-3}$ mm^3 *vs* $26\pm10\times10^{-3}$ mm^3), viability (98% of the colonies formed by untreated MCTSs), LDH release (102% of the activity of untreated MCTSs), or microscopic appearance (data not shown). The volumes of MCTSs treated with PT-gliadin were similar to those of the untreated or control MCTSs (Figure 1), but their viability was 20-50% less than that of the controls and inversely related to PT-gliadin concentrations (Figure 2A). LDH activity in the medium of treated MCTSs was significantly increased by about 30% (Figure 2B).

GSH content and GSH-related enzyme activity

As shown in Figure 3A, the GSH content of treated MCTSs was about 20% less than that observed in the controls ($P<0.05$). The activity of GSH-related enzymes (GSR, GST, and GPOX) was also significantly decreased (by respectively 56%, 34%, and 27%, Figure 3B).

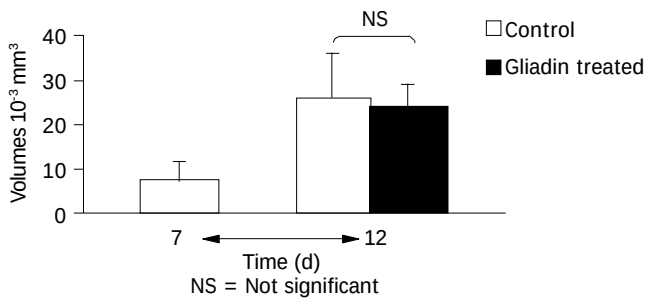

Figure 1 Volumes of MCTSs treated with PT-gliadin.

Morphological analysis

At light microscopy, both the treated and control MCTSs were spherical or oval in shape, but the control cells grew in a solid manner (with pseudoglandular differentiation, and without necrosis or apoptosis), whereas those in PT-gliadin-treated MCTSs showed nucleic displacement, a foamy cytoplasm and loss of cell adhesion: 20-50% had pycnotic nuclei and condensed chromatin (Figures 4A and B).

TEM showed that the control MCTSs had microvilli on their external surface and normal nuclei, cytoplasmatic organelles (rough endoplasmic reticulum, mitochondria,

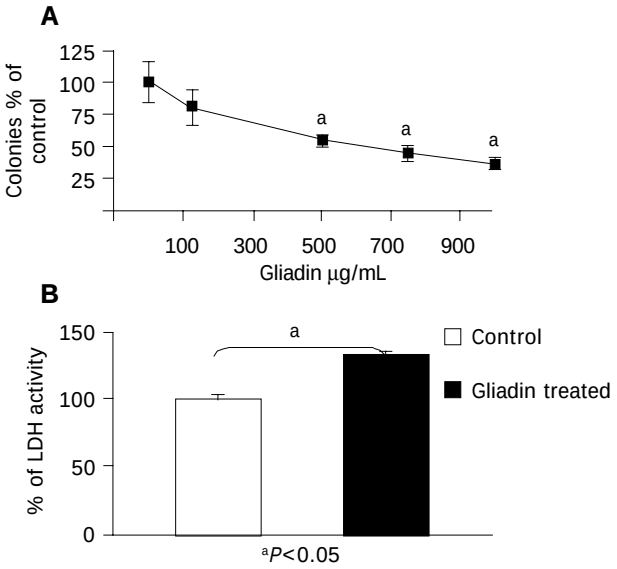

Figure 2 Viability test of MCTSs after treatment with different doses of digested gliadin (A) and lactate dehydrogenase (LDH) activity after gliadin treatment (B).

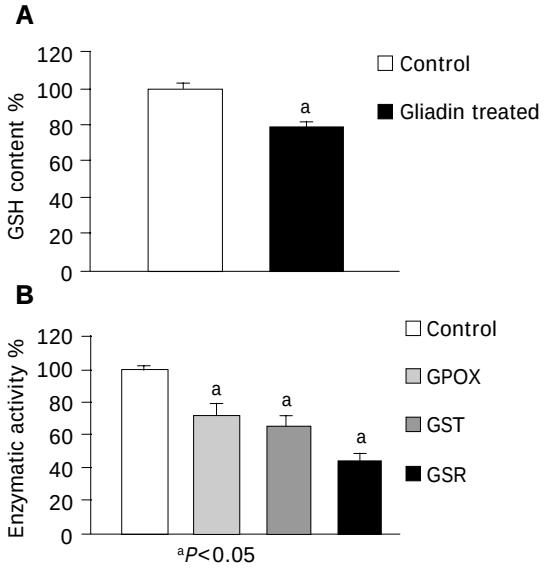

Figure 3 Content of reduced GSH (A) and GSH-related enzyme activity (B) in MCTSs treated with PT-gliadin.

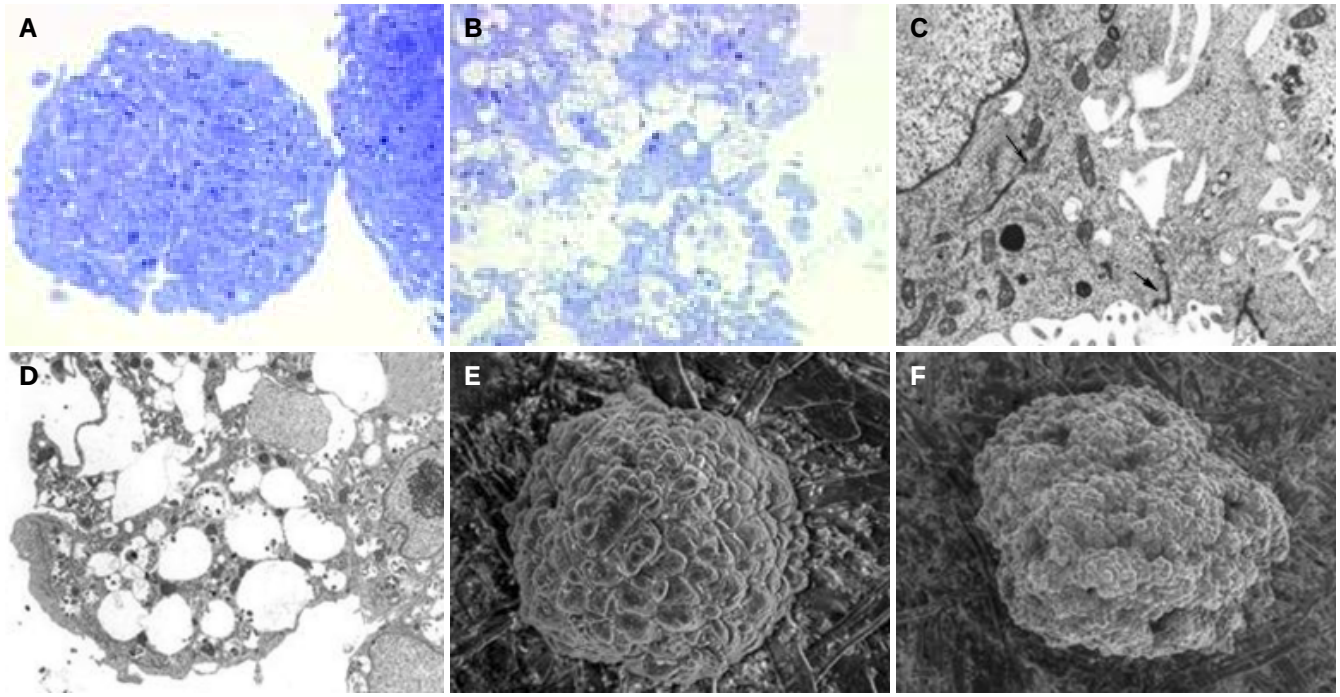

Figure 4 Microscopic analysis of MCTSs treated with digested gliadin or untreated. (A and B) Untreated and gliadin-treated MCTSs with cytoplasmatic vacuoles, (C and D) images of untreated and treated MCTSs, and (E) no holes and blebs on untreated controls, (F) holes and blebs on the surface of treated MCTSs.

Golgi complex, and lysosomes), and cytokeratin tonofilaments. The cells were joined by complexes of tight, intermediate and desmosome junctions. In the treated MCTSs, microvilli disappeared from the cell surface and there were cytoskeletal and tight junction injuries. The cytoplasm contained electron-dense material in numerous phagosomes and frequent vacuoles of various sizes. Some cells showed cytoplasmatic lipid-like droplets and cannibalism (Figures 4C and D).

SEM of the control MCTSs revealed an ovoid or spherical shape with compact cells, which were densely organized and tightly packed together, but clearly distinguishable from each other. The treated MCTSs were irregular in shape with loosely packed cells, and the external surface was focally interrupted by irregularly distributed holes and blebs (Figures 4E, F, and 5).

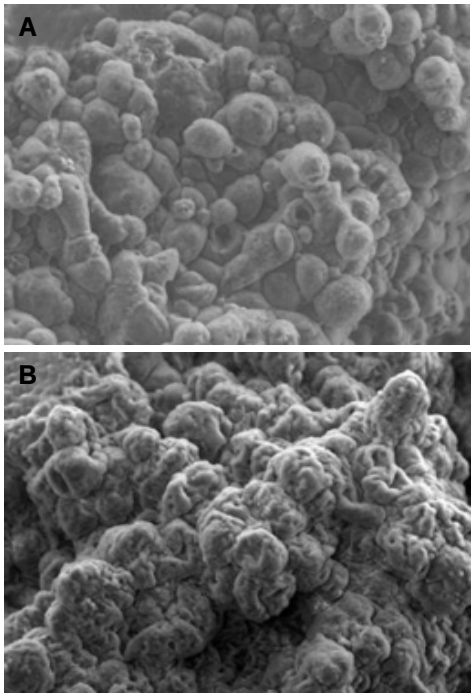

Figure 5 Smooth surface of untreated MCTS (A) and bleb on surface of MCTS treated with digested gliadin (B).

DISCUSSION

Our findings show that gliadin had significant functional and morphological cytotoxic effects on intestinal adenocarcinoma cell line (LoVo) cultured in a three-dimensional model.

Gliadin is a protein characterized by a particularly high proline and glutamine content (respectively 15% and 35% of the residues) that forms a kink in the polypeptide structure that prevents peptidase attack[18].

Over the last few years, a number of studies based on the *in vitro* two-dimensional cell culture system have investigated the cellular effects of gliadin in order to clarify its role in the pathogenetic "puzzle" of celiac disease (CD)[19]. Gliadin alters the cytoskeleton through the network of actin filaments, and damages tight junctions (TJ) by creating leaks in intercellular spaces, and these effects may be responsible for the loss of epithelial permeability and the changes in cell-cell signaling associated with CD[20]. Furthermore, gliadin also has a pro-apoptotic and agglutinating effect, inhibits cell growth and viability[2], and modifies the redox status of Caco-2 cells, thus causing a loss in reductive potential and an increase in the levels of reactive oxygen species[21].

Oxidative balance plays a pivotal role in cell homeostasis, and it has been suggested that its imbalance may be involved in various human diseases (liver diseases, HIV infection, pulmonary diseases, tumors, Parkinson's disease, myocardial ischemia, and inflammatory bowel disease)[9,11]. GSH and its enzymatic machinery represent one of the most important cellular defenses against oxidative agents and harmful xenobiotics. Three enzymes are mainly involved in the GSH cycle: GPOX, which converts peroxides into less dangerous fatty acids, water, and GSH disulfide (GSSG); GSR, which reduces GSSG to GSH in NADPH-dependent reaction; and GST, which is involved in detoxification from xenobiotic compounds[22]. GSH has also been implicated in other cell functions: apoptosis, cell differentiation, prostaglandin synthesis, DNA repair, amino acid transport, enhanced immune response, and enzymatic activation[23].

The reduced GSH content and GSH-related enzyme activity observed in our gliadin-treated MCTSs confirm the dangerous effect of this peptide in an experimental model that maintains some of the biochemical and morphological features of the corresponding *in vivo* tissue[5], and support the hypothesis that relates a deficiency in an oxidable substrate[24]. The disturbed redox equilibrium is associated with the reduced cell viability in treated MCTSs and the alteration in the integrity of plasma membrane, as demonstrated by the leakage of large molecules such as LDH into the medium[25].

These functional alterations affect the morphology of MCTSs and their cells, whose clearly foamy cytoplasm and peripherally displaced nuclei, together with the fact that many are pycnotic with marginally condensed chromatin, support the presence of apoptotic processes[26]. TEM confirmed cell injury by revealing the presence of numerous phagosomes and frequent vacuoles of different sizes in the cytoplasm, as well as intra-cytoplasmic lipid-like droplets. The external ring normally consisting of columnar cells with serrated intercellular TJs and surface microvilli resembling normal enterocyte epithelia was altered in our treated MCTSs, which showed disrupted TJs and microvilli (Figure 4). SEM also showed that the treatment causes a loss of organization in cells contained in the external layer of spheroid, with the formation of hole-like structures and an abundant presence of apoptotic blebs[27].

Although our data cannot explain whether the redox imbalance is due to a resource-consuming mechanism, decreased nuclear expression or protein synthesis (an effect previously associated with gliadin exposure[28]), they clearly demonstrate that gliadin has a direct damaging effect on human intestinal cells. Furthermore, we have confirmed that the three-dimensional cell culture system is a good experimental model for investigating the effects of different peptides, and can therefore be added to the techniques used to study CD.

Abstract

AIM: To determine whether insulin could promote sinusoidal endothelial cell (SEC) proliferation mediated by upregulation of vascular endothelial growth factor (VEGF) in regenerating rat liver after partial hepatectomy (PHx).

METHODS: Adult male Sprague-Dawley rats undergoing 70% PHx were injected with insulin (300 MU/kg) or saline via the tail veins every 8 h after surgery for 7 d and killed at 0, 24, 48, 72, 96, 120, 144, and 168 h after surgery. Proliferation of both hepatocytes and SECs was monitored by evaluating the proliferating cell nuclear antigen (PCNA) labeling index (LI). The expression of VEGF protein was evaluated by immunohistochemistry. The mRNA expressions of VEGF and its receptors Flt-1 and Flk-1 were evaluated by semi-quantitative reverse transcription-PCR.

RESULTS: Insulin markedly increased the expression of VEGF mRNA between 24 and 120 h after hepatectomy compared to controls. Similarly, insulin significantly increased the expression of Flt-1 between 24 and 96 h. However, insulin had no significant effect on Flk-1. Furthermore, the immunohistochemical staining revealed that expression of VEGF protein increased in the insulin groups. Insulin significantly increased the PCNA LI of hepatocytes and SECs compared to controls.

CONCLUSION: Exogenous insulin may promote SEC proliferation with an enhanced expression of VEGF and its receptor Flt-1 in regenerating rat liver after PHx.

INTRODUCTION

Hepatic regeneration is a key step in the recovery process that occurs after various forms of liver injury, including partial hepatectomy (PHx)[1]. The exact mechanism of liver regeneration remains unclear. Several important cytokines and growth factors are involved in the regulation of hepatocyte proliferation[2-6]. Angiogenesis is a fundamental course required for wound healing and regeneration[5]. The liver microvasculature consists of large vessels such as portal and central venules and hepatic arterioles lined with continuous endothelial cells, and sinusoids lined with sinusoidal endothelial cells (SECs) expressing undiaphragmed fenestrations[6]. SECs are the second largest number of resident liver cells, and are vital in supplying nutrients and growth factors to proliferating hepatocytes by the formation of new blood vessels during liver regeneration[5]. Vascular endothelial growth factor (VEGF) is a potent angiogenic factor stimulating the proliferation and migration of endothelial cells, and is also known as a vascular permeability factor[7-9]. The effects of VEGF are mediated through at least two specific receptors, Flt-1 and Flk-1, expressed on the endothelial cell surface[7]. Recent studies have revealed that VEGF stimulates endothelial cell proliferation and plays an important role in the supply of blood to the newly replicating hepatocytes during regeneration[5,7]. Moreover, it is reported that exogenous VEGF can stimulate liver cell proliferation following PHx[5,7,10].

Insulin is a hepatocyte growth modulator, which is essential in liver regeneration, and is transported into the liver during the process of liver regeneration[11]. There is evidence that treatment with insulin contributes to the normal regeneration of liver by decreasing hepatocellular injury and by increasing hepatocyte proliferative capacity[11-13]. In addition, insulin therapy has also been shown epidemiologically as an independent risk factor for the progression of intraocular neovascularization in diabetic retinopathy[13,14]. Yamagishi *et al*.[13], have demonstrated that insulin stimulates the growth and tube formation of human microvascular endothelial cells through autocrine VEGF *in vitro*. Nevertheless the effect of insulin on blood vessels during regeneration after PHx in rats is still unknown.

Based on these studies, we believe that insulin promotes SECs and subsequently liver regeneration by accelerating the expression of VEGF. In the present study, we investigated the expression of VEGF and its receptors, Flt-1 and Flk-1, as well as the expression of proliferating cell nuclear antigen (PCNA) during rat liver regeneration after 70% PHx.

[illegible]

Animals

Adult male Sprague-Dawley rats aged 7-8 wk (180-200 g; from the Center of Animal Laboratory, Wuhan University) were used for all experiments. The rats were maintained in temperature-controlled rooms in a 12-h light/dark cycle with free access to food (standard laboratory chow) and water. Seventy percent PHx was performed by the standard two-thirds PHx under light anesthesia with ether. The animals were randomly divided into two groups: PHx group was injected with insulin (300 MU/kg) in saline via the tail vein of rats every 8 h after PHx for a week, while control group was given saline alone. Five rats in each group were used at each of the eight time points (0, 24, 48, 72, 96, 120, 144, and 168 h after surgery, with a total of 80 animals). All surgeries were performed between 08:30 and 11:30 a.m..

Immunohistochemical examination of VEGF

Anti-VEGF antibody (Santa Cruz Biotechnology Inc., Delaware, CA, USA) was used for the immunohistochemical staining of VEGF on formalin-fixed and paraffin-embedded liver tissue. Briefly, liver tissues excised at designated times after surgery were fixed in 40 g/L formaldehyde solution and embedded in paraffin wax. Sections were cut at 4 μm, mounted on poly-L-lysine-coated glass slides, air dried overnight at room temperature, dehydrated in graded alcohols, and cleared in xylene. The three-step immunoperoxidase method using a LSAB kit (Dako, Copenhagen, Denmark) was performed according to the manufacturer's instructions. Anti-VEGF antibody used was diluted at 1:100 and incubated overnight at 4 ℃.

PCNA labeling index

Immunohistochemical staining of the PCNA was performed using an indirect two-step labeling technique with peroxidase-conjugated IgG (Amersham NA 931, Amersham Life Science, NY, USA). The monoclonal anti-PCNA antibodies were purchased from Amersham Life Science (PC-10). The sections were deparaffinized in xylene and dehydrated by passage through graded alcohol. Endogenous peroxidase was blocked by incubation of the slides with 3% H_2O_2 in methanol for 30 min. After being washed in PBS, 10% normal goat serum (Amersham Life Science) in PBS was applied for 20 min at room temperature. Slides were incubated overnight with monoclonal anti-PCNA antibodies and subsequently exposed to prediluted peroxidase-conjugated IgG for 40 min at room temperature. The peroxidase reaction was developed by incubation in 0.005% H_2O_2 and 0.02% 3,3'-diaminobenzidine tetrachloride. The proliferative activity in the remnant liver was expressed as the labeling index (LI). The LI was the ratio of the number of PCNA positive nuclei of either hepatocytes or SECs to the total number of cells counted. In each liver, the hepatocytes and SECs in 200 consecutive high power fields were counted. In this study, the spindle-shaped sinusoid-lining cells in the open sinusoids were regarded as SECs.

RNA extraction, cDNA synthesis and PCR amplification of different angiogenic factors

About 20 mg liver tissues was immediately flash frozen in liquid nitrogen and stored at -70 ℃ after excision for RNA isolation. Total RNA was extracted with the RNeasy® Mini kit (Qiagen Cat. No. 74104) according to the manufacturer's protocol and eluted in 25 μL RNase-free water. Single-stranded cDNA was synthesized from 8 μL of RNA by the RevertAid™ first strand cDNA synthesis kit (MBI Cat. No. K1621) with random hexamer primers and 3 μL of the product was used for PCR.

The PCR primer pairs are listed in Table 1. Thirty cycles of DNA amplification using a Taq DNA polymerase (recombinant, MBI Cat. No. EP0404) was performed under the following conditions: denaturation at 94 ℃ for 1 min, annealing (β-actin, 52 ℃; VEGF, 60 ℃; Flt-1, 53 ℃; Flk-1, 52 ℃) for 1 min, extension at 72 ℃ for 1 min. Negative controls (cDNA-free solutions) were included in each reaction. β-actin, a house-keeping gene equally expressed in most eukaryotic cells, was used as an external standard and amplified in parallel with different angiogenic factors in all PCR samples.

Table 1 Oligonucleotides used as primers in RT-PCR procedure

Primer	Nucleotide sequence	PCR product lengths (bp)
Rat VEGF	Sense: 5′-ACTGGACCCTGGCTTTACTG-3′	256
Antisense:	5′-ACGCACTCCAGGGCTTCATC-3′ GenBank NM031836	
Rat Flt-1	Sense: 5′-AGGAGAGGACCTGAAACTGTCTT-3′ Antisense: 5′-ATTCCTGGGCTCTGCAGGCATAG-3′[10]	214
Rat Flk-1	Sense: 5′-GTGATTGCCATGTTCTTCTGGC-3′ Antisense: 5′-TCAGACATGAGAGCTCGATGCT-3′ GenBank U93306	337
Rat β-actin	Sense: 5′-TTCCACACACACCAGCTTCG-3′ Antisense: 5′-GGGGTGGTGTGGAGATTTAG-3′ GenBank NM031144	366

Semi-quantification of PCR products

After PCR amplification from 50 μL reaction volume, 10 μL was electrophoresed on 1.5% agarose gel in 1× TBE buffer. The amplified bands were detected by ethidium bromide staining. The intensity of ethidium bromide fluorescence was measured by the Photo Documentation and Imaging System (Bio-1D, VL, France). For quantification of the PCR products from all samples, the samples were evaluated by comparing the PCR product to β-actin.

Statistical analysis

The results were expressed as mean±SD. Statistical analysis was performed for the unpaired data using SPSS11.0 for Windows (SPSS Inc., Chicago, IL, USA). $P<0.05$ was considered statistically significant.

Hepatic VEGF, Flt-1 and Flk-1 mRNA expression

The changes in hepatic VEGF, Flt-1 and Flk-1 mRNA following surgery are shown in Figures 1 and 2. The expression of VEGF mRNA increased after 24 h of 70% PHx, with a peak from 48 to 72 h. Insulin significantly increased VEGF mRNA from 24 to 120 h after hepatectomy compared to controls ($P<0.01$; Figures 1C, D and 2A). Similarly, hepatic Flt-1 mRNA expression increased after hepatectomy. Insulin significantly increased Flt-1 mRNA from 24 to 96 h after hepatectomy compared to controls ($P<0.01$; Figures 1E, F and 2B). Insulin had no significant effect on Flk-1 when compared to controls (Figures 1G, H and 2C).

PCNA labeling index

The PCNA LI was lower than 5% in both hepatocytes and SECs before hepatectomy. However, liver cell proliferation was evident as early as 24 h postoperation. Insulin significantly promoted hepatocyte proliferation from 24 to 120 h compared to controls ($P<0.01$, Figure 3).

Immunohistochemical staining of VEGF protein in remnant liver

Before hepatectomy, there were very few VEGF-positive

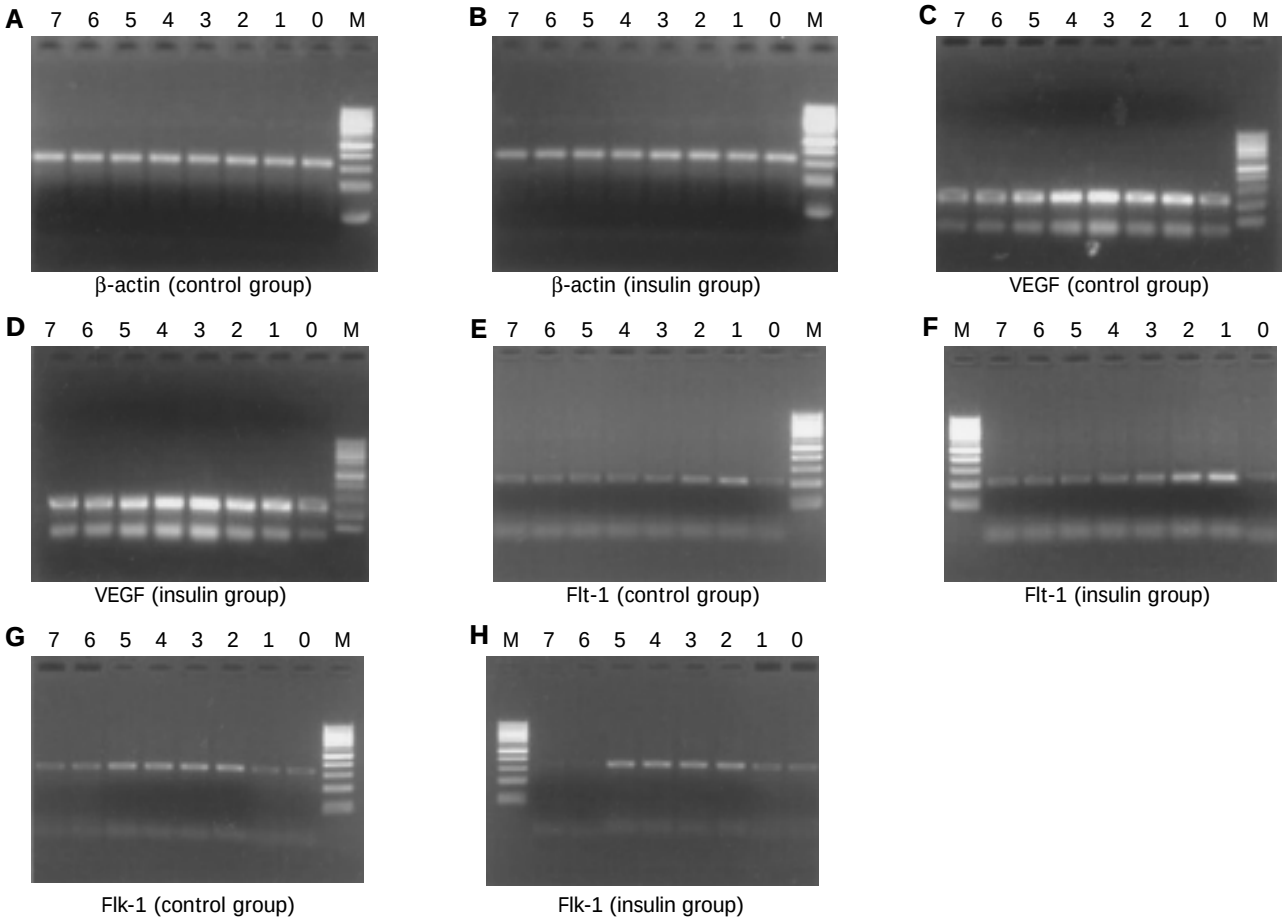

Figure 1 RT-PCR results of VEGF, Flt-1, and Flk-1 mRNA expressions in liver of different groups. M: 100-bp DNA ladder (upper to lower: 1 000, 900, 800, 700, 600, 500, 400, 300, 200, and 100 bp); lane 0: 0 h; lane 1: 24 h; lane 2: 48 h; lane 3: 72 h; lane 4: 96 h; lane 5: 120 h; lane 6: 144 h; lane 7: 168 h.

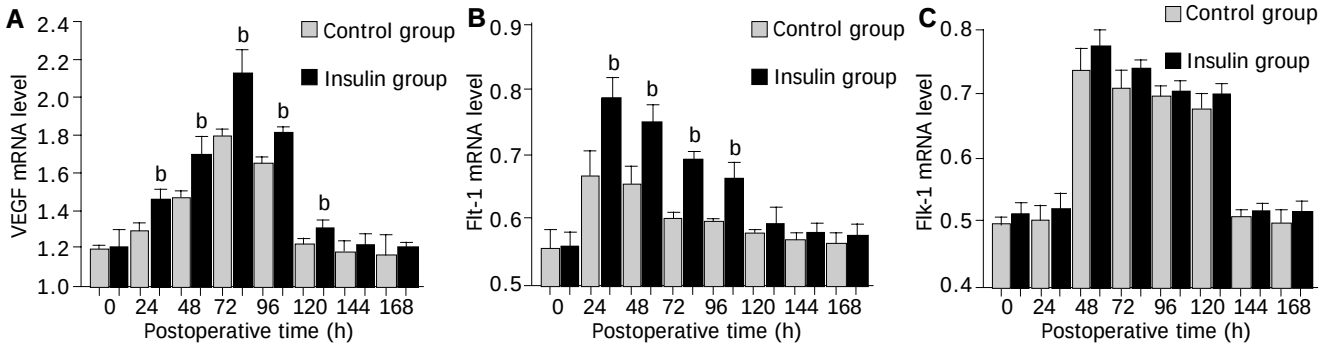

Figure 2 VEGF (A), Flt-1 (B), and Flk-1 (C) mRNA expressions after 70% hepatectomy in rats by RT-PCR.

cells, but increased expression of VEGF was observed 24 h after surgery (P<0.01, Figure 4A). Insulin increased the expression of VEGF, with a peak at 72 h (P<0.01, Figure 4D).

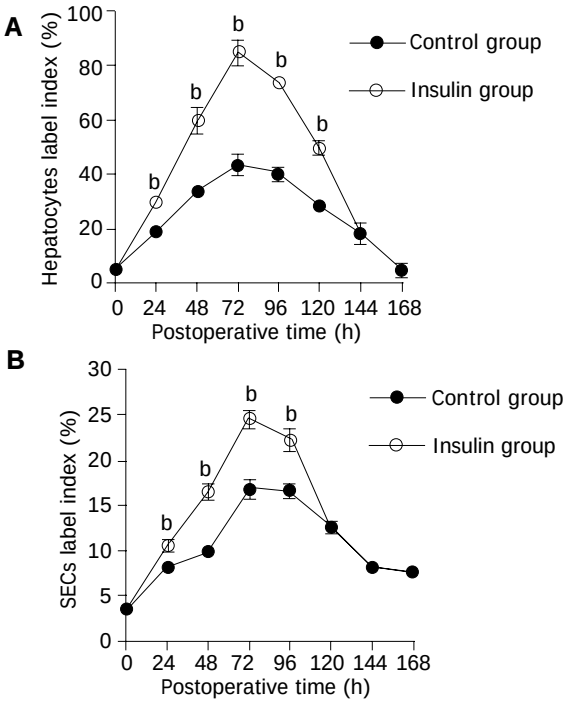

Figure 3 PCNA LI of hepatocytes (A) and SECs (B) after 70% hepatectomy in rats.

DISCUSSION

Liver remodeling following PHx comprises a complex set of events including activation and secretion of numerous factors, cell proliferation, thus finally re-establishing liver architecture[15-19]. Angiogenesis is the integrated process of endothelial cell division, vascular sprouting, and migration from pre-existing cells[20], indicating that SEC proliferation is strongly associated with hepatocyte proliferation during liver regeneration. Liver regeneration involves two processes: liver architecture remodeling and liver cell proliferation. In our study, SECs influenced the regenerative capacity of liver following PHx. Rebuilding the network of blood supply is necessary in liver regeneration. SECs play an important role in the formation of a complex network of blood vessels for remodeling liver architecture following liver resection. Additionally, SECs surround avascular clusters of hepatocytes, subsequently re-establish normal vascular architecture and directly supply nutrition and growth factors to liver cells[6].

The role of VEGF in liver regeneration has been reported[20-25]. SECs have a unique response to growth factors[6-8,18]. Information on the association of angiogenic factors with liver regeneration is available[5,6,18]. VEGF isoform signal has several receptors, including Flt-1 and Flk-1[26-30]. These receptors can operate in a paracrine and cooperative manner with VEGF produced by hepatocytes in regulating SEC growth and subsequent vascularization of the liver[13]. The receptors are structurally similar to members of the platelet-derived growth factor receptor family and consist of an extracellular domain composed of seven immunoglobulin-like motifs, a transmembrane domain, a juxtamembrane domain, a tyrosine kinase that is split by a kinase insert region, and a C-terminal tail. It is uncertain what role each VEGF receptor actually plays in cell signaling during liver revascularization. In some studies, Flk-1/KDR and Flt-1 have been shown to act in unique capacities[6]. These studies have determined that Flk-1/KDR can activate both mitogenicity and motility pathways, whereas

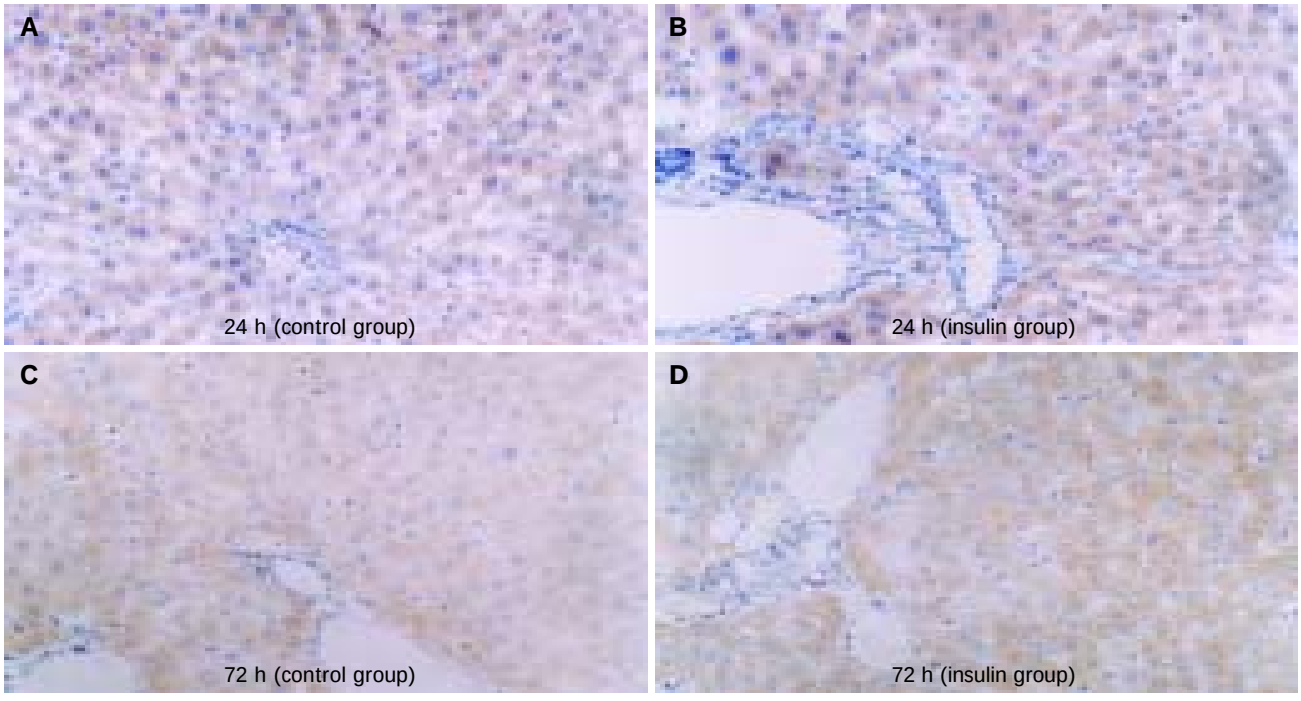

Figure 4 Expression of VEGF protein at 24 h in control group (A) and insulin group (B), at 72 h in control group (C), and insulin group (D).

Flt-1 appears to mediate actin reorganization[6]. Moreover, Flt-1 is induced by hypoxia, which emerges during regeneration, whereas Flk-1/KDR is not[6]. Exogenous $VEGF_{165}$ can stimulate liver cell proliferation following PHx and antibodies to VEGF significantly inhibit hepatocyte proliferation following PHx[5,29]. However, $VEGF_{165}$ does not induce either a motogenic or a mitogenic response in isolated hepatocytes, though Flt-1 is phosphorylated[6,29], indicating that VEGF may stimulate liver cell proliferation by acting on surrounding SECs, which influence hepatocytes by improving nutrient availability or through vascular permeability.

The present study demonstrated that exogenous insulin could stimulate SECs following PHx in rats. Insulin can induce a host of effects on glucose transport and utilization, protein synthesis, and cell proliferation, *etc*.[12].

However, the effect of insulin on blood vessels during regeneration after PHx in rats is still unknown. It has been reported that vascular abnormalities and pathologies are commonly associated with diabetes[31,32]. Jiang *et al*.[25], demonstrated that insulin can stimulate several signaling cascades in endothelial cells and vascular smooth muscle cells by phosphorylating both insulin receptor substrate-1 and -2. The vascular-specific action of insulin may be attributed to the growth factors, especially VEGF, and cytokines of which the expression is regulated by insulin. The exact mechanism underlying insulin-induced VEGF mRNA upregulation in microvascular EC is currently unknown. It was reported that insulin-induced VEGF expression is mediated through the activation of phosphatidylinositol (PI) 3-kinase/Akt being downstream to the insulin receptors[33,34]. It was reported that the activation of PI 3-kinase/Akt pathway can upregulate the expression of hypoxia-inducible factor-1α, a principal factor that causes angiogenesis[34]. Insulin may upregulate the VEGF mRNA through a nuclear factor-κB-mediated pathway, and mAb against VEGF can completely neutralize the proliferation and tube formation of endothelial cells induced by insulin[11,33].

In conclusion, insulin induces expression of VEGF and its receptor after PHx, and promotes liver regeneration besides the traditional metabolic action on hepatocytes.

ABSTRACT

AIM: To investigate whether the routine use of fibrin glue applied onto the hepatic resection area can diminish postoperative volume of bloody or biliary fluids drained via intraoperatively placed perihepatic tubes and can thus lower the complication rate.

METHODS: Two groups of consecutive patients with a comparable spectrum of recent hepatic resections were compared: (1) 13 patients who underwent application of fibrin glue immediately after resection of liver parenchyma; (2) 12 patients who did not. Volumes of postoperative drainage fluid were determined in 4-h intervals through 24 h indicating the intervention caused bloody and biliary segregation.

RESULTS: Through the first 8 h postoperatively, there was a tendency of higher amounts of fluids in patients with no additional application of fibrin glue while through the following intervals, a significant increase of drainage volumes was documented in comparison with the first two 4-h intervals, e.g., after 12 h, 149.6 mL +/-110 mL *vs* 63.2 mL +/-78 mL. Using fibrin glue, postoperative fluid amounts were significantly lower through the postoperative observation period of 24 h (851 mL +/-715 mL *vs* 315 mL +/-305 mL).

CONCLUSION: For hepatic resections, the use of fibrin glue appears to be advantageous in terms of a significant decrease of surgically associated segregation of blood or bile out of the resection area. This might result in a better outcome.

INTRODUCTION

Hepatic resections are considered as a standard intervention in abdominal surgery. Despite this, there is still a remarkable complication rate. In addition to patient-dependent factors, aspects of the surgical technique play a major role, in particular, with regard to the occurrence of postoperative bleeding and bile leakages. A precise dissection is as important as supplements such as hemostatics and tissue glue for the daily surgical practice to avoid complications, e.g., bleeding and biliary segregation from the resection area of the liver.

The aim of the study was to investigate, whether the sealing of the hepatic resection area using biocompatible glue leads to a significant decrease of postoperative release of blood and/or biliary fluid volume, which was measured in the local drainage(s).

MATERIALS AND METHODS

In a pilot study, a comparative non-randomized study of two case series, all consecutive patients with hepatic resections were enrolled with prospective data documentation over a defined observational period until the planned number of individuals was reached (n = 12 per group). Patients were retrospectively (to avoid a study bias) subdivided into two groups with or without sealing of the hepatic resection area using fibrin glue. Patient characteristics are listed in Table 1A.

Hepatic resections were carried out according to standardized technique following anatomically adequate resection margins (segmental resection, bi-/tri-segmental resection or hemihepatectomy) or as atypical hepatic resection with a tumor-free resection margin of minimally 5 mm ("wedge" resection).

Perioperative prophylaxis with antibiotics was performed (2 g of Cefotiam iv., Spizef®, Grünthal GmbH, Aachen, Germany). After explorative laparotomy, definitely exclusion of extrahepatic tumor manifestation and exploration of the hepatic tumor lesion needs to be approached (if necessary including intraoperative ultrasound of liver parenchyma). The liver was mobilized in a typical manner at the "Ligg. triangularia" and "falciforme", a tourniquet loop was placed around the hepatoduodenal ligament. After marking the resection margins, dissection of liver parenchyma was carried out using cavitron ultrasonic surgical aspirator (CUSA) technology. The intraparenchymatic vessels and ducts of the biliary tree were clipped and cut. Bleeding control at the hepatic resection area was achieved by bi- and/or mono-polar electrocoagulation. During the dissection,

Pringle's maneuver (temporary cessation of the blood flow in hepatic artery and portal vein) of maximally 20-min periods was executed to minimize the intraoperative blood loss. Bigger vessels and biliary ducts were ligated. After completion of the hepatic resection, the resection area was repeatedly coagulated (bi- or mono-polar electrocoagulation or infrared coagulation). Depending on the size of the resection area, one (or two) drain (s) was (were) placed into the subhepatic (and subphrenic) space.

According to the aim of the study, the hepatic resection area of the patients was sealed with fibrin glue (Tissucol or Tachocomb seal) or not.

For thrombosis prophylaxis heparin (low dose, low molecular heparin-derivative) was not given for 24 h postoperatively whereas antithrombosis socks were obligatory.

Patients were monitored at the surgical ICU for 24 h postoperatively.

Table 1 Comparison of patient groups with hepatic resection

(A) Patient characteristics.

		Fibrin glue	
		Without	With
Sex ratio			
Patients (*n*)	Male	8	7
	Female	4	6
Mean age (range) (yr)			
	Male	65 (37–77)	68 (41–75)
	Female	55 (44–70)	62 (46–75)

(B) Diagnosis

Diagnosis	Number of patients (sealing with fibrin glue)	
	Without	With
Hepatocellular carcinoma	5	2
Cholangiocellular carcinoma		
Liver metastases	5	9
Adenoma/FNH	2	2

(C) Types of resections

Type of resections	No. of patients (sealing with fibrin glue)	
	Without	With
Hemihepatectomy	4	1
Segmental resection (more than one segment)	4 (3 bisegmental resections)	10 (2 trisegmental and 5 bisegmental resections)
Atypical resection	4	2

Sealing with fibrin glue

Tissucol® (Baxter Deutschland GmbH, Heidelberg, Germany) was applied by spraying it on the hepatic resection area. Tachocomb seal (Tachocomb®, fibrin glue on a collagen fleece, Nycomed, Ismaning, Germany) was applied on the hepatic resection area after moistening it.

In the group of the patients with fibrin glue sealing, 13 patients (6 females and 7 males; mean age 62 years) with hepatic resections enrolled (Table 1A), were compared with a group of 12 subjects (4 females and 8 males; mean age, 60 years) with no fibrin glue application who were enrolled in the same study period.

The diagnoses and types of resections of both groups are listed in Tables 1B and C.

The fluid volumes drained via the intra-abdominally placed drains were documented in 4-h periods in a separate (Table 1D) and additive manner (Figure 1), in total through a time period of 24 h.

Informed consent for hepatic resection was obtained from each patient.

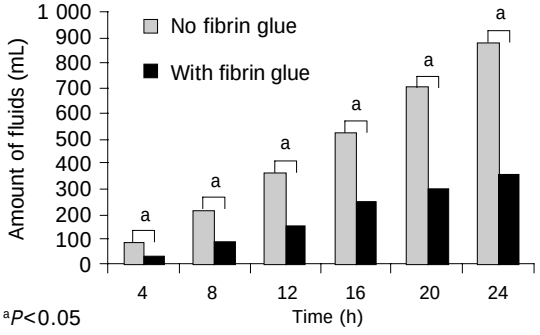

Figure 1 Time course of the mean of the added drain volumes depending on the application of fibrin glue. There was a significant reduction of the segregated amount of fluids in the group of patients in whom sealing with fibrin glue was used. [a]*P*<0.05 *vs* no sealing.

Statistical analysis

In addition to the descriptively statistical presentation of the results (SPSS 10.0 for Windows), fluid volumes of the drains in both patient groups with and without sealing with fibrin glue after hepatic resection were compared by a non-parametric test according to Mann-Whitney (*U* test) as appropriate. A value of $P<0.05$ was considered statistically significant.

RESULTS

The mean age and sex ratio of both patient groups appeared to be comparable. The spectrum and surgical extension of hepatic resections in both groups were similar.

The listed diagnoses demonstrate the patient profile, which is treated in our center of hepatobiliary surgery and varies from primary liver tumors, cholangio- and hepatocellular carcinomas ($n = 2$ and $n = 5$ in the group with and without fibrin glue, respectively), FNH ($n = 2$; no fibrin glue) or hepatocellular adenoma ($n = 2$; no fibrin glue), to metastases of colorectal ($n = 8$ in the group with

fibrin glue *vs* $n = 5$ without) or gastric carcinomas ($n = 1$; with fibrin glue, Table 1B). All patients showed an acceptable preoperative liver function, and no patient showed a postoperative decompensation of liver function.

In the spectrum of resections, there were one right hemihepatectomy, 10 segmental resections (trisegmental resections, $n = 2$; bisegmental resections, $n = 5$; one segment, $n = 3$) and two atypical resections in the patient group with no fibrin glue application *vs* four hemihepatectomies, four segmental resections (bisegmental resections, $n = 3$; one segment, $n = 1$) and four atypical resections in the comparison group with fibrin glue (Table 1C, Figure 2).

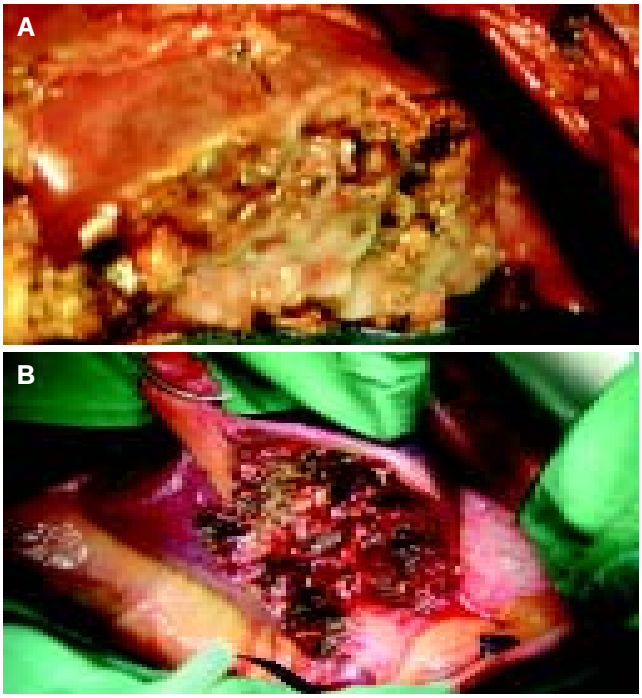

Figure 2 Hepatic resection area after segmental resection. A: With fibrin glue (sealing with Tissucol®). B: Without fibrin glue.

For sealing the hepatic resection area with fibrin glue, Tissucol® was used in 11 patients whereas in two further cases, Tachocomb® was chosen (data not shown).

In none of the patients included in the study, a severe postoperative complication occurred neither as acute nor intermediate problem. The drain fluid was either of serous or bloody-serous nature or serous quality with slight bile impurity. The comparison of the single drain volumes of both groups including the *P* values is shown in Table 1D.

Through the first 8 h postoperatively, there was a tendency of a higher drain fluid volume in the patient group with no fibrin glue, which was indicated by the single (of each 4-h time period) as well as the added amounts of fluids (total volume at specific time points during the postoperative course). Through the following time periods, the segregation increased significantly in this group compared with the first two time periods of 4 h each, resulting in the fact that a significant reduction of the segregated volumes via the drains in the patient group with fibrin glue was observed after 12 h ($P = 0.0059$). This difference became even more distinct through the following time periods up to 24 h ($P = 0.0028$). Figure 1 shows the comparison of the added postoperative amount of fluids drained postoperatively from the hepatic resection area. While the summation of the single drain volumes of the patients with fibrin glue through the 24-h time period shows a linear curve, the curve in the comparison group (no fibrin glue) shows an exponential increase.

Using fibrin glue, a significant reduction of the postoperative drain volume of segregated fluids out of the hepatic resection area was found during the study period of 24 postinterventional hours.

[redacted]

By means of a pilot study, two patient groups with similar demographic and treatment characteristics were compared to investigate whether the application of fibrin glue on the hepatic resection area has a significant impact on the postoperative segregation of fluids via the drains. Using a precise surgical technique with accurate dissection of liver parenchyma, in particular, according to the anatomic margins of the liver segments, with CUSA and a subtle control of bleeding, the complication rate in hepatic resections can be kept low.

The hypothesis was that, by the mean of an additive sealing the hepatic resection area with fibrin glue, the rate of local complications such as postoperative bleeding and biliary fistulas can be reduced. As a first step to prove this hypothesis, the amounts of segregated fluid via the drain(s) was compared between the groups of patients with or without application of fibrin glue on the hepatic resection area despite complete control of bleeding and biliary excretion occurred immediately after accomplishing the resection. It showed a significant difference with lower volumes of segregated fluids after 24 h, indicating a further possible reduction of the surgical risk and complication rate, which can be achieved by the use of fibrin glue. However, the main result of this pilot study needs to be confirmed in a currently ongoing study, in which more patients are being included.

The possible impact of a heparin medication was excluded by the department-specific standard since the continuation of the preoperatively initiated heparin administration for antithrombotic prophylaxis was postponed by 24 h postoperatively according to the duration of the study period[1]. In addition, acetylsalicylic acid-based medication was stopped a couple of days prior to the admission. The pathophysiological background to use postinterventional sealing with fibrin glue is as follows: hepatic resection can lead to an activation of fibrinolysis. Even in the case of a perfect hepatic resection from a technical point of view, postoperative bleeding and segregations of fluids can occur though the resection that was accomplished by leaving a dry hepatic resection area[2]. By the mean of fibrin application, the hepatic resection area can be sealed and, thus, smallest microlesions can be closed. In addition, the fibrin excess can avoid early fibrinolysis.

One limitation of the study might be the possibly varying size of the hepatic resection area but which is, because of the similar spectrum of different types of hepatic resections, almost comparable. In addition, the underlying liver disease

might affect the drain volume, which cannot be satisfyingly clarified in this study, which included only a limited number of patients. Furthermore, following studies need to focus on the composition of the segregated fluid with regard to the content of hemoglobin and bilirubin and the discrimination between the various types of sealing (Tissucol *vs* Tachocomb), which has not been the main focus and can be considered as an acceptable approximation in this pilot study.

From a technical point of view, the fast availability of the fibrin-coated collagen fleece seems to be advantageous as compared with the fibrin glue, which needs to be thawed[3].

There is a varying opinion on the additive use of fibrin glue in several surgical departments. In a Japanese study, 231 hospitals were asked about their routine use in hepatic resections. While in 203 hospitals, CUSA was used for resection (87%), only 135 (60%) applied fibrin glue on the hepatic resection area after the resection[4]. Comparison studies on the use of fibrin glue in hepatic resections were undertaken using animal experiments. The difficulty in the judgment of the fibrin effect was the usage of various additional agents, the different experimental designs, and varying animal strains and species. Davidson showed the advantage of a sealing with fibrin glue and cellulose gauze application after hepatic resections with regard to a tendency of a lower rate of postoperative bleeding using a pig model[5].

Turner has described the advantage of a composition consisting of thrombin and autologous plasma for control of bleeding after hepatic resections in sheep[6]. In addition, Martis has reported the benefit of Tachocomb in hepatic resections of dogs[7].

In conclusion, the presented pilot study in a clinical setting supports the thesis that an additional application of fibrin glue can contribute to the safe postoperative outcome as shown by the impressive statistically significant reduction of the postoperative volumes of segregated fluids via the perihepatic drain (s). Following studies using a prospective randomized study design, in a greater number of patients, and on various aspects such as the postoperative complication rate in patients with and without fibrin glue on the hepatic resection area may result in further facts and arguments for the impact and the beneficial effect of this additional tool.

Abstract

AIM: To examine whether the fasting levels of serum gastrin-17 (G-17) are lower in Barrett's esophagus (BE) patients than in non-Barrett controls.

METHODS: Nineteen patients with BE (presenting with a tubular segment ⩾2 cm long in lower esophagus and intestinal metaplasia of incomplete type ("specialized columnar epithelium") in endoscopic biopsies from the tubular segment below the squamocolumnar junction were collected prospectively from outpatients referred to diagnostic gastroscopy. The controls comprised 199 prospectively collected dyspeptic outpatients without BE or any endoscopically visible lesions in the upper GI tract. Fasting levels of serum G-17 (G-17fast) were assayed with an EIA test using a Mab highly specific to amidated G-17. None of the patients and controls received therapy with PPIs or other antisecretory agents.

RESULTS: The mean and median levels of G-17fast in serum were significantly lower (P = 0.001) in BE patients than in controls. The positive likelihood ratios (LR+) of low G-17fast to predict BE in the whole study population at G-17fast levels <0.5, <1, or <1.5 pmol/L were 3.5, 3.0, and 2.8, respectively. Among patients and controls with healthy stomach mucosa, the LR+ were 5.6, 3.8, and 2.6, respectively. In the whole study population, serum G-17 was below 2 pmol/L in 15 of 19 BE patients (79%). The corresponding prevalence was 66 of 199 (33%) in controls (P<0.001). The G-17fast was 5 pmol/L or more in only one of the 19 BE patients (5%). In controls, 76 of the 199 patients (38%) had such high serum G-17fast levels (P<0.01).

CONCLUSION: Serum levels of G-17fast tend to be lower in native patients with BE than in healthy controls.

INTRODUCTION

High intragastric acidity inhibits the release of gastrin into circulation from antral G cells, and conversely, low acidity and high intragastric pH enhance this release[1,2]. Amidated gastrin-17 (G-17) is the biologically active main gastrin fragment, and G-17 is a gastrin compound secreted nearly entirely from the antral G cells[3-5]. It is conceivable that fasting levels of G-17 (G-17fast) in serum or plasma reflect indirectly the intragastric acidity. Correspondingly, it is conceivable that low serum levels of G-17 occur particularly in patients with acid-related diseases.

Gastroesophageal reflux disease is one of the most important acid-related diseases[6]. Patients with Barrett's esophagus (BE) are a subgroup of reflux patients in whom the refluxed acid gastric juice is a factor causing mucosal damages in the lower esophagus, and at the esophagogastric junction[7-9]. Some studies indicate that the prevalence of BE ranges from 0.5% to 5.0% in patients undergoing upper-GI endoscopy for dyspepsia, and from 12% to 15% in patients with gastroesophageal reflux disease and reflux symptoms[10-13].

In the present study, we investigated whether the serum levels of G-17 are lower in patients with BE than in non-BE controls.

MATERIALS AND METHODS

Patient and control series were collected prospectively in 2002 in Helsinki University Central Hospital (HUCH), Jorvi Hospital, Espoo, Finland, from patients who were referred to diagnostic gastroscopy for dyspeptic or reflux-type symptoms.

Patient series

The patient series consisted of 19 subjects with a BE diagnosed by endoscopy and histology. All had a Barrett's segment 2 cm or more in length in the lower columnar, tubular esophagus.

Of the available 19 patients, 14 were males and 5 females. The mean age was 60±12 years. Three of the nineteen BE patients (16%) had *Helicobacter pylori* (*H pylori*)-related gastritis. In one of these three patients, gastritis was strongly antrum dominant, and this patient showed moderate atrophy and intestinal metaplasia in the antrum. The histopathology was evaluated by biopsies from antrum and corpus (at least two biopsies from each site), and by the principles of the updated Sydney System. The biopsy specimens were stained with HE and Alcian blue (pH 2.5)-PAS methods and modified Giemsa for *H pylori*.

Control series

The control series consisted of 199 patients without any visible endoscopic lesions in the upper GI tract. Of the 199 patients, 71 were males and 128 females. The mean age was 54±15 years. Altogether, 94 patients (47%) had chronic *H pylori*-related or autoimmune chronic gastritis, or atrophic gastritis. The rest had normal and healthy gastric mucosa in gastric biopsies (no chronic gastritis, no *H pylori*, no intestinal metaplasia or atrophy). Of the total number of patients with chronic gastritis, 48 had atrophic gastritis of some grade and type. Advanced (moderate or severe) atrophic gastritis in corpus was found in 23 patients.

Inclusions and exclusions

A patient in the Barrett series was included if he/she had a segment of Barrett's mucosa 2 cm or more in length that was verified by endoscopy and histology of the biopsies taken below the squamocolumnar junction (*z*-line). The biopsies had to show the presence of intestinal metaplasia of incomplete type ("specialized columnar epithelium"), i.e. intestinal metaplasia of type II or III in the Alcian blue (pH 2.5)-PAS-stained sections[14]. In incomplete type of intestinal metaplasia, both goblet cells and columnar epithelium between the goblet cells showed secretory mucins that were stained blue with Alcian blue (pH 2.5)-PAS.

The following patients were excluded: patients with a short segment Barrett (the presence of "specialized columnar epithelium" in biopsies from a segment that is less than 2 cm long); patients with erosive esophagitis, ulcers, or polyps, or those with any endoscopically visible local lesions in stomach or esophagus.

Use of PPIs

Patients and controls with a long-term use of PPIs were excluded from the study, and none of the patients or controls was recorded having used PPI at the time of the diagnosis (information obtained from the patient at endoscopy). Thus, the present BE patients represented the native cases of dyspeptic subjects in whom BE was accidentally diagnosed in a diagnostic endoscopy, and in the subjects who did not receive any effective treatment.

Endoscopy

Diagnostic upper-GI endoscopy was done in all patients and controls. In both patient and control series, two groups were formed: the whole study population that included all patients and controls, and a subgroup of patients and controls in which the histology showed normal and healthy gastric mucosa (updated Sydney criteria) in both antrum and corpus biopsies (no gastritis, no atrophy, no intestinal metaplasia, nor *H pylori*). In the Barrett series, 16 of 19 patients (84%) were classified into the subgroup 2 (subjects with healthy and normal gastric mucosa). In controls, 105 of 199 (53%) subjects were classified into the subgroup 2.

Assay of amidated gastrin-17

G-17 was determined using specific EIA tests (G-17 EIA test kit Cat. No. 601 030, Biohit Plc, Helsinki, Finland) performed in batches of 40 samples on a microwell plate according to the instructions of the manufacturer. The EIA technique was based on measuring the absorbance after a peroxidation reaction at 450 nm. Between the reaction steps the plates were washed in a BW50 microplate strip washer (Biohit Plc, Helsinki, Finland). The absorbances were measured using a microplate reader (BP800 Microplate Reader, Biohit Plc, Helsinki, Finland). For determination of G-17 values, a 2nd order fit on standard concentrations was used to interpolate/extrapolate unknown sample concentrations automatically with the help of the BP800 in-built software (Biohit Plc, Helsinki, Finland).

The monoclonal antibody (Mab) of G-17 in the EIA tests was highly specific. The G-17 antibody used detected only amidated G-17, but no other gastrin molecules or fragments (e.g., glycine extended G-17, a kind gift from Prof. Jens F Rehfeld, Copenhagen, Denmark; human synthetic gastrin-34, G-5024, Sigma; human synthetic gastrin-13, G-0267, Sigma; or cholecystokinin fragment 26-33 amide, C-2901, Sigma) were detected. In immunohistochemistry (formalin-fixed, paraffin-embedded specimens: dilutions up to 10 000), the G-17 antibody stained only antral G cells and glands, not other cells or tissues in stomach, duodenum, small or large bowel, or pancreas. The G-17 EIA results correlated well with those of the G-17 RIA (by the courtesy of Prof. Jens F Rehfeld and Dr. Jens-Peter Gotze, Copenhagen, Denmark).

The G-17 assays from serum samples were done first after an overnight fast (G-17fast) and 20 min after a drink of a glass of a protein-rich juice (Biohit Plc, Helsinki, Finland) in which the protein content corresponded to that in an ordinary beef.

Specificity of G-17 antibody

The specificity of the antibody to G-17 secreted from antral G cells alone has been recently verified[15]. The G-17 assay measured only amidated G-17, and not other gastrin fragments.

Invasive and non-invasive tests for gastritis and atrophic gastritis

In addition to endoscopy and histology, the patient and control series were also classified into those with normal and healthy stomach or into those with non-atrophic or atrophic gastritis by serological tests which applied assays of *H pylori* antibodies, pepsinogens I (PGI) and II (PGII) and postprandial G-17 in serum (GastroPanel, Biohit Plc, Helsinki, Finland). The patients without *H pylori* antibodies and with PGI 50 microg/L, or more or above, were considered to have normal and healthy stomach mucosae.

Ethics

The study was approved by the Ethical Committee of the

Helsinki District University Hospital (HUCH), Helsinki, Finland. The purpose of the study was explained to all patients before taking blood samples, and all patients signed a written consent before enrolment into the study.

Statistical analysis

Non-parametric tests (Wilcoxon-Mann-Whitney test; χ^2 test; SPSS 10.1 Software) were used in the calculations of the significance between the groups. In order to examine the clinical value of low serum G-17 in the diagnosis of BE, the likelihood ratio (LR+) of the positive test result (low G-17fast or G-17prand) between the cases and controls was calculated at arbitrary cut-off levels of G-17. The LR+ indicates a factor by which the pre-test odds of BE has to be multiplied to obtain the post-test odds and, further, the post-test probability of the disease.

[illegible]

The mean and median values of serum G-17fast were significantly lower in patients with long-segment BE than in controls. This was the case both in males and females, or when the analysis was done in the whole study population (all patients and controls), or if the analysis was limited to subgroups of patients and controls with histologically normal and healthy gastric mucosa. The results in the whole study population and among those with healthy stomach mucosa are shown in Figures 1 and 2 in a box-plot form.

In contrast to G-17fast, the serum levels of postprandial G-17 (G-17prand) were significantly lower in BE patients than in controls in the whole study population only but not in the subjects with normal and healthy stomach mucosae (Figure 2).

The positive LR+ of low serum G-17 to predict odds of BE in the whole study population below the arbitrary cut-off levels of G-17fast are presented in Table 1. The corresponding results in the subgroups of cases and controls with histologically normal, healthy gastric mucosa are shown in Table 2. It appears that the LR+ gradually increased with a decreasing concentration of G-17fast. The sensitivity and specificity of low serum G-17fast (<1 pmol/L) to indicate BE in the whole study population were 47% and 89%, respectively.

The study population was also classified into those with normal and healthy stomach mucosae (16 BE patients and 108 controls) and those with gastritis or atrophic gastritis (3 BE patients and 91 controls) by applying the serological tests (GastroPanel, Biohit Plc, Helsinki, Finland). By these tests, the stomach mucosa was healthy when *H pylori* antibodies were not present and the serum pepsinogen I was 50 μg/L, or more. Among the patients diagnosed to have a healthy stomach mucosa by these tests, the LR+s of BE are presented in Table 3. The sensitivity and specificity of low serum G-17fast (<1 pmol/L) to indicate BE were 50% and 82%,

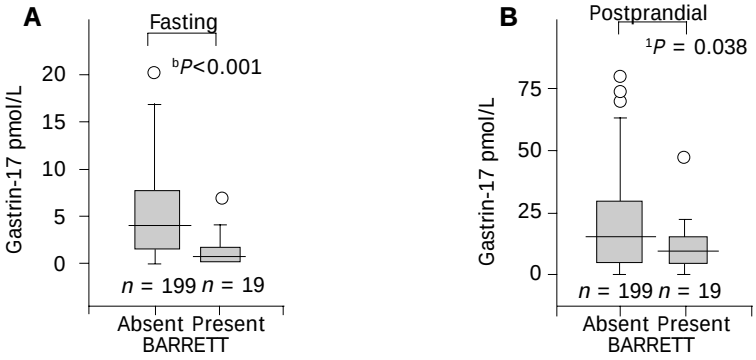

Figure 1 Fasting (A) and postprandial (B) serum G-17 levels in patients with or without long-segment BE in the whole study population. A box plot presentation. The boxes show the central 50% of the cases. The length of the box shows the range within which the center 50% of the values fell. The whiskers show the range of values that fall within 1.5×difference of the values of median from the two hinges of the box. Differences: ^bP<0.001; ^1P = 0.038; non-parametric test (Mann-Whitney *U*). To make the figure clear, the very most extreme outliers are not shown in the pictures.

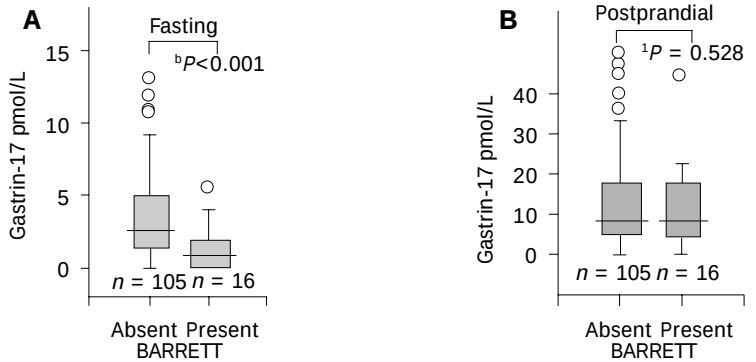

Figure 2 Fasting (A) and postprandial (B) serum G-17 levels in patients with or without long-segment BE among patients and controls with normal and healthy stomach mucosae (no gastritis, no *H pylori*, and no atrophy). A box plot presentation (see Figure 1). Differences: ^bP<0.001; ^1P = 0.528; non-parametric test (Mann-Whitney *U*). To make the figure clear, the very most extreme outliers are not shown in the pictures.

respectively, and at the cut-off level <2 pmol/L 81% and 55%, respectively. The corresponding overall accuracies were 77% and 55%, respectively.

In the whole study population, the G-17fast was very low (<0.5 pmol/L) in 7 of the 19 BE (37%) and 15 of the 199 controls (8%). Correspondingly, the G-17fast was lower than 2 pmol/L in 15 of 19 BE patients (79%) and in 66 of 199 controls (33%, $P<0.001$; χ^2). The G-17fast was 5 pmol/L or more in 1 of 19 BE patients (5%) but in 76 of 199 controls (38%, $P<0.01$; χ^2). In this BE patient, the G-17fast was 5.4 pmol/L.

Three BE patients had *H pylori*-positive chronic gastritis in the biopsy specimens from antrum and corpus. In one of these patients, gastritis was strongly antrum dominant and showed intestinal metaplasia of moderate grade in the antral biopsy specimens. In spite of the presence of gastritis, all three of these BE patients had a low serum level of G-17fast (0.02, 0.6, and 1.4 pmol/L).

Among controls with normal and healthy stomach mucosae (antrum and corpus mucosae were histologically healthy), age and serum G-17fast did not correlate (Pearson correlation 0.05; $P = 0.587$); neither was there any difference in the serum G-17fast between males and females (mean±SD: 4.7±5.7 and 4.1±5.4 pmol/L, respectively).

[redacted]

The present data indicate that the mean and median levels of serum G-17fast tend to be lower in patients with "native" (without previous or ongoing medication, nor previous knowledge of the disease) BE than in controls among outpatients referred to diagnostic endoscopy for dyspeptic symptoms. The BE is associated inversely with the serum level of G-17fast.

An inverse association between the likelihood of BE and serum level of G-17 was seen among the subjects with healthy stomach mucosa (normal gastric histology) and in the whole study population including subjects with gastritis and *H pylori* infection. Several earlier studies have shown that gastric inflammation (gastritis) tends to raise the serum levels of gastrin and other gastric peptides[4,16-18]. In accordance with this, the serum G-17fast levels were higher in the non-BE patients with gastritis than in those without. However, a surprise was that gastritis did not clearly raise the G-17fast concentrations in the present BE patients. Three of the nineteen BE patients had chronic *H pylori* gastritis and all had low serum G-17fast levels that did not differ from those in BE patients without gastritis.

The observations suggest that the inverse relationship between G-17fast and BE is a genuine characteristic of the Barrett's disease itself, and is not a result from gastric inflammation or atrophy, or *H pylori*. The low mean and median levels of G-17fast in BE patients are best explained by assuming that the basal intragastric acidity (basal acid output, BAO) tends to be higher in BE patients than in ordinary dyspeptic patients referred to diagnostic endoscopy. High intragastric acidity may, on the other hand, inhibit the release of G-17 from stomach mucosa, resulting thereby in low serum levels of fasting G-17. In other words, the BE patients may frequently have BAO levels that inhibit the release of G-17 from antral G cells. In two earlier studies, an elevated BAO has been shown to be a characteristic of patients with BE when compared to healthy controls[19,20].

Gastrins themselves have been linked to the pathogenesis of BE in some studies. Gastrins may have direct influences on growth and replication of the metaplastic Barrett epithelium[21], and may impair the esophageal motility and the function of the lower esophageal sphincter[22]. The present study indicates, however, that a low G-17fast in the circulation is a characteristic of BE, and that serum levels of G-17fast above 5 pmol/L are quite rare in BE patients.

Postprandial serum G-17 did not differ between BE and non-BE groups when investigated among subjects with healthy gastric mucosa. This may indicate that the post-stimulation level of serum G-17 does not reflect the intragastric acidity similarly as the fasting level of G-17 (G-17fast). Instead, the G-17prand may merely indicate the number of G cells in the antral mucosa, similarly as the peak acid output and maximal acid output (MAO) are measures of the number and mass of parietal cells in the oxyntic mucosa. Supporting this conclusion, atrophic antral gastritis results in a loss of antral G cells and, consequently, the serum G-17prand levels are low in these patients[23,24].

It was reported that the serum levels of total gastrin are similar in BE patients and controls even though the BAO and MAO are significantly increased[20]. Total serum gastrin was not assayed in the present study. Total immunoreactive gastrin consists of several gastrin fragments of which one-third are G-17 molecules under fasting conditions[25]. The fasting levels of G-17 tend to be very low in normal, healthy subjects in general, and these low G-17 concentrations may be easily eclipsed by other gastrin compounds.

In summary, the present investigation suggests that the serum level of G-17fast tends to be low in native BE patients who are not under PPI medication.

Abstract

AIM: Gene expression profiling provides an unique opportunity to gain insight into the development of different types of gastric cancer. Tumor sample heterogeneity is thought to decrease the sensitivity and tumor specificity of microarray analysis. Thus, microdissection and preamplification of RNA is frequently performed. However, this technique may also induce considerable changes to the expression profile. To assess the effect of gastric tumor heterogeneity on expression profiling results, we measured the variation in gene expression within the same gastric cancer sample by performing a gene chip analysis with two RNA preparations extracted from the same tumor specimen.

METHODS: Tumor samples from six intestinal T2 gastric tumors were dissected under liquid nitrogen and RNA was prepared from two separate tumor fragments. Each extraction was individually processed and hybridized to an Affymetrix U133A gene chip covering approximately 18 000 human gene transcripts. Expression profiles were analyzed using Microarray Suite 5.0 (Affymetrix) and GeneSpring 6.0 (Silicon Genetics).

RESULTS: All gastric cancers showed little variance in expression profiles between different regions of the same tumor sample. In this case, gene chips displayed mean pair wise correlation coefficients of 0.94±0.02 (mean±SD), compared to values of 0.61±0.1 for different tumor samples. Expression of the variance between the two expression profiles as a percentage of "total change" (Affymetrix) revealed a remarkably low average value of 1.18±0.78 for comparing fragments of the same tumor sample. In contrast, comparison of fragments from different tumors revealed a percentage of 24.4±4.5.

CONCLUSION: Our study indicates a low degree of expression profile variability within gastric tumor samples isolated from one patient. These data suggest that tumor tissue heterogeneity is not a dominant source of error for microarray analysis of larger tumor samples, making total RNA extraction an appropriate strategy for performing gene chip expression profiling of gastric cancer.

INTRODUCTION

Gastric cancer is one of the most common malignancies, accounting for almost 10% of new cancer cases diagnosed worldwide[1,2]. However, knowledge about the molecular mechanisms underlying tumor development and progression is limited and molecular features of gastric cancer are not commonly used for diagnosis and treatment.

cDNA and oligonucleotide microarrays are capable of profiling gene expression patterns of tens of thousands of genes in a single experiment. They are an ideal tool to study cancer progression and development and to identify new molecular markers for tumor classification and prognosis. Microarrays have been successfully applied to study various tumors, including gastric cancers[3-13].

Like most solid tumors, gastric cancer consists of many different cell types including endothelium, different types of stromal cells and inflammatory cells. Such tissue heterogeneity is thought to decrease the sensitivity and tumor specificity of the microarray analysis[14-16]. One strategy to overcome the problem of tissue heterogeneity is the use of laser capture microdissection (LCM) for isolation of a defined cell population[17,18], followed by amplification of the RNA for subsequent microarray analysis[19,20]. However, amplification-associated bias may induce considerable changes to the expression profile[15,21]. Depending on both the degree of tissue heterogeneity and the robustness of the microarray analysis protocol, it may therefore sometimes be advantageous to avoid RNA amplification and instead extract total RNA directly from a larger tumor sample.

To assess the influence of gastric tumor heterogeneity on the outcome of the microarray analysis, we measured the variation between gene expression profiles derived from

two RNA preparations extracted from the same gastric tumor specimen.

[illegible]

Gastric tumor samples

Tumor samples from six patients who underwent surgery for gastric cancer at the University Hospital of Dresden were used for microarray analysis. Immediately after gastrectomy, a certified pathologist obtained representative samples of 1 cm^3 from the tumor centers. Special care was taken to avoid tumor necrosis. Tumors were snap-frozen in liquid nitrogen and stored at -80 ℃. To ensure consistency of the study population, only tumors classified as intestinal and T2 by pathology were included in the study[22]. Clinical and histopathological tumor characteristics are summarized in Table 1.

Table 1 Clinical data and histopathological features of gastric cancers included in the study

Tumor number	Age/Sex	Site	Lauren	TNM
1	72/Female	Antrum	Intestinal	T2 N2 G3
2	78/Male	Body	Intestinal	T2 N1 G2
3	81/Male	Antrum	Intestinal	T2 N1 G2
4	75/Female	Antrum	Intestinal	T2 N0 G3
5	76/Male	Cardia	Intestinal	T2 N2 G3
6	76/Male	Cardia	Intestinal	T2 N0 G3

RNA preparation

For RNA isolation, tumor samples were fragmented into smaller pieces under liquid nitrogen using a mortar and pestle. Subsequently, total RNA was extracted from two independent, randomly selected tumor fragments using RNAzol reagent according to the manufacturer's instructions (TelTest Inc., Friendswood, TX). Both extractions (extractions A and B) were processed individually until hybridization on two separate microarrays. To determine the influence of experimental variability, RNA was extracted only once from tumor no. 3 and aliquots of the same RNA preparation were used for further processing.

High-density oligonucleotide microarray analysis

Microarray analysis was performed according to the Affymetrix instructions for eukaryotic sample preparation[23]. In summary, double-stranded cDNA was synthesized from 5 μg of total RNA with oligo$(dT)_{24}$ T7 primer (Affymetrix), followed by *in vitro* transcription of cRNA synthesis using Enzo BioArray High Yield RNA Transcript Labeling Kit (Affymetrix) and the biotinylated cRNA was hybridized to Affymetrix U133A gene chip arrays containing 22 253 probe sets (approximately 18 000 human gene transcripts). The hybridized probe array was stained with streptavidin–phycoerythrin conjugate and scanned by the Affymetrix gene chip scanner.

Statistical analysis

Expression profiles were analyzed using Microarray Suite 5.0 (Affymetrix) and GeneSpring 6.0 (Silicon Genetics). We used the Affymetrix software to identify changes in expression levels between fragments of the same tumor specimen using standard protocols recommended by Affymetrix[24]. For normalization, data from each expression array were scaled, so that the overall fluorescence intensity across each chip was equivalent (average target intensity set at 500). Only relative changes equal or greater than twofold level of expression were considered. For a given gene transcript in any chip-to-chip comparison, Microarray Suite Software generates a "change call" parameter ("Increase" or "Decrease") based on a consideration of signal specificity as well as intensity. In other words, the "change call" is based on an evaluation of the intensities of the signals generated from each gene transcript on one chip relative to the corresponding signal intensities on the other chip. Instances where the signal on the higher intensity chip is falsely elevated are called "Increased" in a comparison between two chips derived from the same target preparation. "Decrease" calls represent instances where the signal on the lower intensity array has been falsely elevated. Consequently we define all "Increase" or "Decrease" calls in a comparison between arrays derived from the same target preparation as false positive. According to the Affymetrix specification, a percentage of "total change" up to 2% between two chips derived from the same hybridization cocktail is acceptable. To confirm results derived by Microarray Suite, GeneSpring was used to perform multiple comparisons between arrays and to generate pairwise correlation coefficients (Spearman correlation) for all arrays.

[illegible]

RNA and hybridization quality control parameters

Extracted total RNA was evaluated on a 2% agarose gel for the presence of 28S and 18S rRNA bands, which were clearly visible in all RNA samples. RNA purity was assessed by UV spectrophotometry. An $A_{260/280}$ ratio >1.9 was achieved in all samples. Total RNA was also used for RT-PCR of a housekeeping mRNA species to assess RNA quality. Human GAPDH (Applied Biosystems Inc., Foster City, CA, USA) was robustly amplified in all cases.

We followed the Affymetrix guidelines for efficient hybridization: Among the 22 253 probe sets, there was a consistent percentage of "present" calls for each of the 12 cRNA samples tested with a median of 50.68 (range 42.9-54.7). No array image showed grossly visible artifacts. The ratio of the 3' probe set to the 5' probe set of the GAPDH internal control gene, which acts as an indicator for overall RNA quality was below three in all cases. RNA and gene chip hybridization quality control parameters are summarized in Table 2.

Intra-tumor variability

Expression profiles from five gastric tumors were used to determine the degree of intra-tumor variability. As shown in Table 3, all gastric cancers demonstrated very little variance in expression profiles between different regions of the same tumor sample. In this case, expression arrays displayed mean pairwise correlation coefficients of 0.95±0.02, in contrast to values of 0.61±0.1 when different tumor samples were compared to each other. In accordance, the variance between two expression profiles calculated with the Affymetrix software

Table 2 RNA and hybridization quality control parameters

Extraction /Tumor number	$A_{260/280}$ ratio	GAPDH CT	Present calls (%)	GAPDH 3′5′ ratio
A/1	2.18	15.86	52.5	1.08
B/1	2.18	15.7	52.3	1.26
A/2	2.09	15.8	49.2	0.89
B/2	2.07	15.6	54.4	1.19
A/3	2.1	15.2	53.5	1.09
B/3	2.1	15.2	52.5	1.08
A/4	2.07	15.5	48.8	0.99
B/4	2.08	15.2	49.8	0.96
A/5	2.15	16.07	51.7	1.95
B/5	2.24	16.15	54.7	1.46
A/6	2.19	16.08	42.9	1.58
B/6	2.13	16.2	45.9	1.34

(percentage of "total change") revealed a remarkably low average value of 1.18±0.78 for comparing fragments of the same tumor sample. This result is even more striking in light of the Affymetrix guidelines, which suggest that a percentage of "total change" up to 2% is tolerable for comparing chips derived from the same hybridization cocktail. In contrast, when we compared tumor fragments from different tumors the percentage of "total change" was 24.4±4.5. As an example, Figure 1 illustrates different analyses results for two regions of the same gastric cancer sample (Figure 1A) and for two different gastric cancer samples (Figure 1B). In conclusion, there is a surprisingly low degree of expression profile variability within all gastric tumor samples studied.

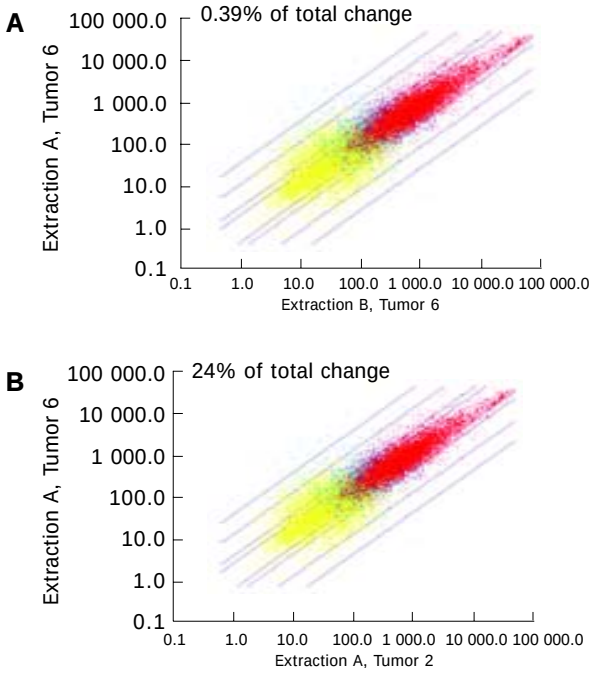

Figure 1 Scatter plots of the expression profiles derived from two different regions of the same gastric cancer sample (extraction A *vs* extraction B from tumor no. 6) (B) and from two different gastric cancer samples (extraction A from tumor no. 6 *vs* extraction A from tumor no. 2). The solid lines indicate 2-, 3-, 10-, and 30-fold expression level differences. Red dots represent gene transcripts detected in both arrays, yellow dots represent gene transcripts undetectable in both arrays, and blue dots represent transcripts detectable in one but undetectable in the other array. Gene transcripts detectable in both arrays (red dots) show a high correlation and thus a low percentage of "total change" for two different regions of the same tumor sample (B), whereas they show a poor correlation and thus a high percentage of "total change" for fragments of different tumors (A).

Experimental variability

During the whole procedure of the microarray experiment, so called experimental variability is generated by multiple factors including chip manufacture, preparation of cRNA, hybridization, washing steps, *etc*. To measure the degree of experimental variability, RNA was extracted only once from tumor no. 3. Subsequently, two aliquots from the same RNA preparation were used for further processing and hybridization on two separate Affymetrix U133A arrays. In this case, gene chip expression profiles differed in only 0.18% of all genes analyzed. Likewise the correlation coefficient was 0.99, respectively. Table 3 summarizes comparison of results from all samples.

Table 3 Comparison results for all tumor samples analyzed

Comparison	Pairwise correlation coefficient	Percentage of "total change"
Tumor 1, extraction A *vs* B	0.96	1.07
Tumor 2, extraction A *vs* B	0.91	2.65
Tumor 3, extraction A *vs* B	0.99	0.08
Tumor 4, extraction A *vs* B	0.96	0.55
Tumor 5, extraction A *vs* B	0.94	1.28
Tumor 6, extraction A *vs* B	0.95	0.39

Tumor no. 3 was used to evaluate experimental variability.

DISCUSSION

Microarray studies on gastric cancer are currently based on two main methods of RNA preparation: the recently developed technique of LCM allows for the isolation of cancer cells and other subpopulations of interest from a heterogeneous piece of tumor tissue. The advantage of microdissection is that it directly focuses on the gastric cancer cells[5,10]. The disadvantage of LCM is at the level of resources and expertise. A certified pathologist is required to select the cells to be microdissected under the microscope, and microdissection itself requires an expensive technology and special training. Furthermore the amount of RNA obtained after LCM is not sufficient for microarray analysis and generally requires amplification. However, the amplification of small amounts of RNA from laser-captured samples is difficult and has been proved to be less reproducible than measurement of unamplified mRNA[15,21]. Even a minor degree of amplification bias might result in a substantial variation to the expression profile.

The approach we used here is based on total RNA extraction with RNA isolated directly from the gastric tumor tissue without the need for subsequent amplification. Hence, the microarray profile reflects all different tissue components present in the tumor. Most gastric cancer microarray studies are based on this method of RNA extraction[3,4,6-9,11-13]. This strategy is less laborious, because it does not require isolation of specific cell types. Moreover, there is usually a sufficient amount of high quality RNA obtained for microarray analysis. However, since the actual proportion of tumor cells in the gastric cancer tissue studied remains unknown, expression profiling based on this strategy may not reliably represent "true" tumor changes. In other words, the level of intra-tumor variability is crucial for the sensitivity and tumor specificity of the microarray experiment. If there is a significant amount of intra-tumor variability, LCM becomes the strategy of choice.

In this study we found an unexpectedly low degree of

expression profile variability within all gastric tumor samples studied. Randomly selected fragments from the same tumor sample displayed a striking similarity in expression profiles, while expression profiles derived from distinct tumor samples differed significantly. These data suggest that tissue heterogeneity is not a dominant source of error for microarray analysis of larger gastric tumor samples, making total RNA extraction an appropriate strategy for performing gene chip expression profiling of gastric cancer.

Our findings are in contrast to a recently published microarray study on human muscle biopsies[25], where tissue heterogeneity was a major source of expression profile variability. This indicates that our results may be exclusive for larger tumor samples and should not be generalized. It might also reflect the influence of study design and appropriate material selection on the outcome of any microarray experiment. We believe that an experienced pathologist who is able to carefully select an appropriate piece of gastric tumor for microarray experiments directly from a large tumor avoiding necrosis and infiltration by normal gastric mucosa is crucial for the quality of our results.

In our study, the degree of experimental variability was only minimal. In the early times of gene chip technology, Mills and Gordon[26] found a substantial level of experimental variability, with an average of 12% increase/decrease calls between the same RNA processed in parallel and hybridized on two Mu11k-A Affymetrix arrays. However, studies using newer, more robust Affymetrix array generations have achieved results consistent with our studies[25,27]. The low degree of experimental variability reflects the inherent advantage of the Affymetrix Gene Chip technology. Due to commercial mass production, they contain a robust series of controls designed to minimize chip-to-chip variation. The availability of standardized protocols together with the use of stringent laboratory quality control parameters also helps to reduce experimental variability.

In conclusion, we assume that gastric tumor expression profiling based on total RNA extraction reliably represents "true" tumor changes. Therefore, total RNA extraction may be the strategy of choice for microarray studies including large gastric cancer samples.

AIM: To examine the effect of acute infection caused by herpesvirus (pseudorabies virus, PRV) on pancreatic ductal secretion.

METHODS: The virulent Ba-DupGreen (BDG) and non-virulent Ka-RREp0lacgfp (KEG) genetically modified strains of PRV were used in this study and both of them contain the gene for green fluorescent protein (GFP). Small intra/interlobular ducts were infected with BDG virus (10^7 PFU/mL for 6 h) or with KEG virus (10^{10} PFU/mL for 6 h), while non-infected ducts were incubated only with the culture media. The ducts were then cultured for a further 18 h. The rate of HCO_3^- secretion [base efflux -$J(B^-)$] was determined from the buffering capacity of the cells and the initial rate of intracellular acidification (1) after sudden blockage of basolateral base loaders with dihydro-4,4,-diisothiocyanatostilbene-2,2,-disulfonic acid (500 μmol/L) and amiloride (200 μmol/L), and (2) after alkali loading the ducts by exposure to NH_4Cl. All the experiments were performed in HCO_3^--buffered Ringer solution at 37 ℃ (n = 5 ducts for each experimental condition). Viral structural proteins were visualized by immunohistochemistry. Virally-encoded GFP and immunofluorescence signals were recorded by a confocal laser scanning microscope.

RESULTS: The BDG virus infected the majority of accessible cells of the duct as judged by the appearance of GFP and viral antigens in the ductal cells. KEG virus caused a similarly high efficiency of infection. After blockage of basolateral base loaders, BDG infection significantly elevated -$J(B^-)$ 24 h after the infection, compared to the non-infected group. However, KEG infection did not modify -$J(B^-)$. After alkali loading the ducts, -$J(B^-)$ was significantly elevated in the BDG group compared to the control group 24 h after the infection. As we found with the inhibitor stop method, no change was observed in the group KEG compared to the non-infected group.

CONCLUSION: Incubation with the BDG or KEG strains of PRV results in an effective infection of ductal epithelial cells. The BDG strain of PRV, which is able to initiate a lytic viral cycle, stimulates HCO_3^- secretion in guinea pig pancreatic duct by about four- to fivefold, 24 h after the infection. However, the KEG strain of PRV, which can infect, but fails to replicate, has no effect on HCO_3^- secretion. We suggest that this response of pancreatic ducts to virulent PRV infection may represent a defense mechanism against invasive pathogens to avoid pancreatic injury.

INTRODUCTION

Pseudorabies virus (PRV) is an α-herpesvirus closely related to the herpes simplex virus (HSV), a well-known human pathogen[1,2]. The natural host of PRV is the pig, but it has a very wide host range including several mammalian families, such as carnivores, ungulates and rodents, but humans are resistant to PRV infection[1]. PRV infection is a multistep process initiated by the receptor-mediated attachment of the virus to the cell surface. Upon entering the cells, the PRV nucleocapsid approaches the nuclear membrane and the viral DNA is released into the nuclei by a poorly understood mechanism. The lytic cycle of the virus is controlled by a transcriptional cascade mechanism[2].

Acute pancreatitis is most commonly associated with

biliary stone and alcoholism. Other causes, including infections, drugs, lipid abnormalities, congenital anomalies, trauma, tumors, and idiopathic form, account for at least 10-20% of the total number of cases[3]. The incidence of pancreatitis may even be higher since the diagnosis of acute pancreatitis may go undetected in many patients. Several viruses have been reported to cause acute pancreatitis, including coxsackievirus B3[4] and B4[5], mumpsvirus[6], varicella[7], hepatitis A[8] and B[9], cytomegalovirus[10], varicella-zoster virus[11] and HSV[12].

We have previously shown that hypersecretion can be observed during the early phase of experimental edematous and necrotizing pancreatitis[13]. However, the source and the role of this hypersecretion are unknown. Either acinar cells and/or the ductal epithelium could be responsible for hypersecretion.

Our aim in this study was to examine the effect of acute infection caused by PRV on pancreatic ductal secretion.

Virus strain

Ba-Dup Green (BDG), a genetically modified replicating strain of PRV, was used in this study. The Bartha virus[14], which is an attenuated live vaccine strain of PRV, was used as the parental virus for the generation of BDG. Two copies of a genetically modified green fluorescent protein (GFP) gene-containing expression cassettes were inserted into the PRV antisense promoter region located in the inverted repeat segment of the virus[15,16]. Ka-EP0lacgfp (KEG) strain of PRV was used as a non-replicating control virus for these experiments. KEG was constructed by deleting the small subunit of ribonucleotide reductase[17] and the early protein 0 (EP0)[18] genes. An expression cassette containing a GFP and a lacZ gene was inserted in place of the EP0 gene[19]. These mutations render the virus incapable of replication in non-dividing cells[19].

Isolation and infection of pancreatic ducts

Small intra/interlobular ducts were isolated from the pancreas of guinea pigs weighing 150-250 g. The guinea pig was humanely killed by cervical dislocation, the pancreas was removed and intra/interlobular ducts were isolated by enzymatic dissociation, microdissection and then cultured at 37 ℃ in 50 mL/L CO_2[20]. Ducts were incubated in McCoy's-based culture medium containing BDG viruses at a dose of 10^7 PFU/mL for 6 h or KEG virus (10^{10} PFU/mL for 6 h), while the non-infected ducts were exposed to culture media only. The ducts were then cultured for a further 18 h as described earlier[20], during which time the ducts seal to form a closed sac that swells due to accumulation of ions and water secretions within the duct lumen[20].

Immunohistochemistry

The immunofluorescent detection of structural viral proteins was performed as follows. Isolated pancreatic ducts were fixed in 40 g/L paraformaldehyde in PBS, pH 7.4 for 1 h at room temperature. Following three rinses in PBS, the ducts were blocked with 10 g/L bovine serum albumin and 1 mL/L Triton X-100 in PBS for 1 h at room temperature. Thereafter, a rabbit polyclonal antiviral antibody (Affinity Bioreagents, Golden, USA) diluted at 1:500 (v/v) in blocking solution was applied for 24 h at 4 ℃. After being washed with PBS, the ducts were incubated with an anti-rabbit antibody conjugated with a red light-emitting dye (Alexa Fluor® 633; Molecular probes, USA) diluted at 1:1 000 (v/v) in a blocking solution for 24 h at 4 ℃. After further washing in PBS, the ducts were mounted on slides using Aqua-Poly/ Mount (Polysciences Inc., Niles, USA). The specificity of immunohistochemical procedure was assessed by simultaneous staining of non-infected ducts. No immunohistochemical labeling was observed in control experiments.

Microscopy

For monitoring virally expressed GFP and immunofluorescence signals, fluorescent images and optical sections of the infected ducts were recorded by a confocal laser scanning microscope (Zeiss, LSM 400).

Measurement of intracellular pH

Cultured ducts were attached, using Cell-Tak, to a coverslip (24 mmol/L) forming the base of a perfusion chamber mounted on a Nikon Diaphot microscope (Nikon UK Ltd, Budapest, Hungary). The ducts were bathed in the standard Hepes solution at 37 ℃ and loaded with the pH-sensitive fluorescent dye 2',7'-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein (BCECF) by exposure to 2 μmol/L BCECF-AM for 20-30 min. After loading, the ducts were continuously perfused with solutions at a rate of 4-5 mL/min. Intracellular pH (pH_i) was measured using a microspectrofluorimeter system (Cairn, Kent, UK). A small area of 5-10 cells was excited with light at wavelengths of 490 and 440 nm, and the 490/440 fluorescence emission ratio was measured at 535 nm. Four pH_i measurements were obtained per second. *In situ* calibration of the fluorescence signal was performed using the high K^+-nigericin technique[21,22]. During calibration, the ducts were bathed in high K^+ HEPES solution and extracellular pH stepped between 5.95 and 8.46.

Determination of base efflux

The intrinsic buffering capacity (β_i) of duct cells was estimated according to the NH_4^+ pre-pulse technique[23,24]. β_i refers to the ability of intrinsic cellular components (excluding HCO_3^-/CO_2) to buffer changes of pH_i. Briefly, pancreatic duct cells were exposed to various concentrations of NH_4Cl, while Na^+ and HCO_3^- were omitted from the solution in order to block the Na^+-dependent pH regulatory mechanisms. β_i was estimated by the Henderson-Hasselbach equation. The total buffering capacity (β_{total}) was calculated from: $\beta_{total} = \beta_i+\beta_{HCO3^-} = \beta_i+2.3\times[HCO_3^-]_i$, where β_{HCO3}- is the buffering capacity of the HCO_3^-/CO_2 system and $[HCO_3^-]_i$ is the intracellular HCO_3^- concentration[24].

Measurement of HCO_3^- efflux

Inhibitor stop method Exposing the ducts to dihydro-4, 4,-diisothiocyanatostilbene-2,2,-disulfonic acid (H_2DIDS, 0.5 mmol/L) and amiloride (0.2 mmol/L) for 5 min caused a marked acidification of pH_i (Figure 2A). This acidification occurred due to inhibition of the basolateral Na^+/HCO_3^- co-transporters and Na^+/H^+ exchangers, which normally

act to transport HCO_3^- into the duct cell from the blood[25,26]. The rate of pH_i acidification after the exposure to H_2DIDS and amiloride could reflect the intracellular buffering capacity and the rate at which HCO_3^- effluxes (i.e., secreted) across the apical membrane via Cl^-/HCO_3^- exchangers and CFTR channels[24,25].

The initial rate of intracellular acidification (dpH/dt), over the first 60 s of exposure to amiloride and H_2DIDS, was calculated by linear regression analysis using 240 data points (four pH_i measurements per second)[24].

Alkali load method Exposing the ducts to 20 mol/L NH_4Cl caused an alkalization of pH_i due to the rapid influx of NH_3 into cells (Figure 3A). Recently, we demonstrated that the recovery of pH_i under these conditions was dependent on the presence of HCO_3^- in the bathing solution, suggesting that it results from HCO_3^- efflux (i.e., secretion) out of the duct cells[24]. In the present study, the initial rate of recovery from alkalosis (dpH/dt) over the first 30 s (120 pH_i measurements) in the continued presence of NH_4Cl was calculated as described previously[24].

The rates of pH_i change measured in these inhibitors stopped and alkali load experiments were converted to transmembrane base flux $J(B^-)$ using the equation: $J(B^-)= dpH/dt \times \beta_{total}$. We denoted base influx as $J(B^-)$ and base efflux (secretion) as $-J(B^-)$.

Solutions and chemicals

The standard Hepes-buffered solution contained (mmol/L) 130 NaCl, 5 KCl, 1 $CaCl_2$, 1 $MgCl_2$, 10 D-glucose, and 10 Na-Hepes. The high K^+ Hepes-buffered solution contained (mmol/L) 130 KCl, 5 NaCl, 1 $CaCl_2$, 1 $MgCl_2$, 10 D-glucose, and 10 Na-Hepes. Hepes-buffered solutions were gassed with 100% O_2 and their pH was set to 7.4 at 37 ℃ with HCl. The standard HCO_3^--buffered solution contained (mmol/L) 115 NaCl, 25 $NaHCO_3$, 5 KCl, 1 $CaCl_2$, 1 $MgCl_2$, and 10 D-glucose. The ammonia pulse solution contained (mmol/L) 95 NaCl, 20 NH_4Cl, 25 $NaHCO_3$, 5 KCl, 1 $CaCl_2$, 1 $MgCl_2$, and 10 D-glucose. HCO_3^--buffered solutions were gassed with 95% O_2/50 mL/L CO_2 to set pH to 7.4 at 37 ℃.

Chromatographically pure collagenase was obtained from Worthington (Lakewood, NJ, USA), culture media from Sigma (Budapest, Hungary). Nigericin (Sigma, Budapest, Hungary) was dissolved in absolute ethanol, H_2DIDS (from Molecular Probes,Eugene, OR, USA) and amiloride in dimethyl sulfoxide (DMSO). CellTak was obtained from Becton Dickinson Labware (Bedford, MA, USA). BCECF-AM was obtained from Molecular Probes (Eugene, OR, USA) and was made up as a 2 mmol/L stock solution using DMSO. The 10-fold concentrated PBS stock solution contained (g/L) 80 NaCl, 2 KCl, 2.4 NaH_2PO_4, 14.4 Na_2HPO_4 (pH 7.2). Chemicals were obtained from Merck (Darmstadt, Germany). Blocking solution contained 10 g/L bovine serum albumin from Sigma (Budapest, Hungary) and 1 mL/L scintillation grade Triton X-100 (BDH Chemicals, Poole, UK).

Statistical analysis

Results were expressed as mean±SE (n = 5 ducts). Statistical analyses were performed using ANOVA. $P<0.05$ was accepted as statistically significant.

Efficacy of viral infection

Two GFP-expressing cassettes were inserted into the PRV genome[15] enabling virus infection to be visualized in both living and fixed cells. Monitoring of GFP expression of BDG was utilized to assess the extent of viral infection of ductal epithelial cells. We observed that BDG virus practically infected all accessible cells of the duct when used at a titer of 10^7 PFU/mL after 24 h (Figure 1A). We used a higher concentration (10^{10} PFU/mL) of KEG virus and found a similarly high efficiency of infection (Figure 1C).

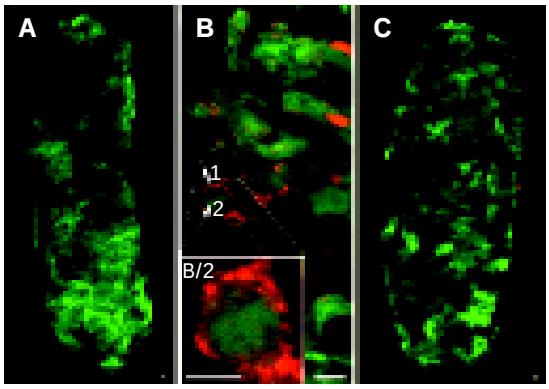

Figure 1 Infection of guinea pig pancreatic ducts with BDG and Ka-EP0lacgfp (KEG). A: Infection of the pancreatic ductal epithelial cells with BDG; B: appearance of viral antigens indicating the productive BDG infection and GFP fluorescence; C: non-virulent KEG strain-produced high efficiency of infection. Scale bars represent 10 μm.

Cytotoxic effect of PRV infection

BDG is a virulent strain; therefore, virus uptake by cells results in the immediate initiation of the lytic viral cycle and the unavoidable death of the infected cells. Productive virus infection was detected in the BDG group by labeling the structural viral proteins by means of immunohistochemistry. The GFP gene was placed under the control of the constitutive human cytomegalovirus immediate early promoter, which conferred a very early expression of the reporter gene. In contrast, viral structural proteins, which are recognized by the anti-PRV antibodies, appeared at a later stage of viral infection[15]; therefore, a shift between the appearance of GFP and immunofluorescence could be observed (Figure 1B). In contrast, in the KEG group, we did not observe any cytopathic effects and could not detect viral antigens. However, GFP expression indicated the presence of the virus within the infected cells (Figure 1C).

Pancreatic ductal bicarbonate secretion

Exposing the ducts to 0.5 mmol/L H_2DIDS and 0.2 mmol/L amiloride caused an acidification of pH_i (Figure 2A), due to inhibition of the basolateral Na^+/HCO_3^- co-transporters and Na^+/H^+ exchangers. The effect of H_2DIDS and amiloride was reversible, removal of the inhibitors caused pH_i to return to the control value. In these series of experiments, we tested whether virus infection affected the net HCO_3^- secretion of pancreatic duct cells. Base efflux was significantly elevated

in the BDG group compared to the non-infected ducts, 24 h after the infection (7.84±1.24 mmol/L B^-/min *vs* 2.2±0.18 mmol/L B^-/min, respectively; $n = 5$). However, no change was observed in the KEG group (2.4±0.32 mmol/L B^-/min; $n = 5$) compared to the non-infected ducts. These data are summarized in Figure 2B.

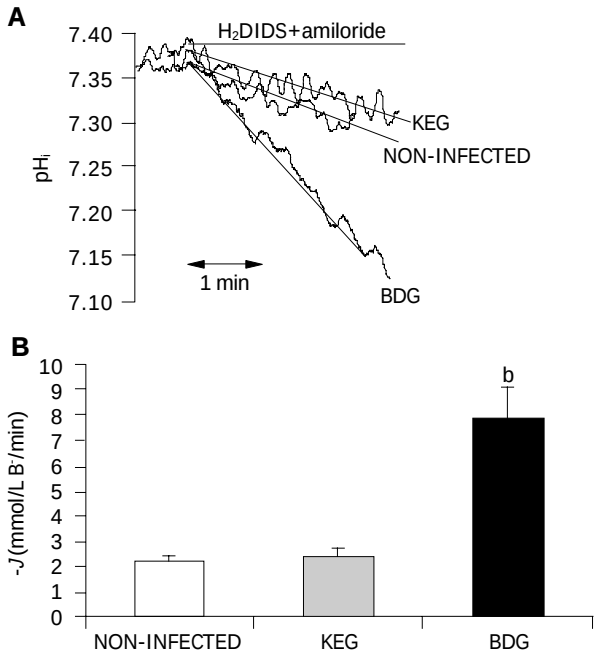

Figure 2 Inhibitor stop method for determining bicarbonate secretion. A: Representative pH_i traces; B: summary of the results obtained using the inhibitory stop method. $^bP<0.001$ *vs* the control (ANOVA).

Exposure of duct cells to 20 mmol/L NH_4Cl induced an immediate rise in pH_i due to the rapid entry of NH_3 into the duct cells (Figure 3A). In this series of experiments, base efflux was significantly elevated in the BDG group compared to the control group 24 h after the infection (160.04±19.16 mmol/L B^-/min *vs* 36.37±1.08 mmol/L B^-/min, respectively; $n = 5$). However, as we found with the inhibitor stop method, no change was observed in the KEG group (39.34±3.49 mmol/L B^-/min, $n = 5$) compared to the non-infected ducts (Figure 3B).

Using the ammonium pulse technique, we also tested whether PRV affected the ability of duct cells to recover from an acid load following removal of NH_4Cl from the superfusate. The transporters most likely to be involved in this process are the Na^+/HCO_3^- co-transporter, the Na^+/H^+ exchanger and the H^+ pump located on the basolateral membrane of the duct cells. No significant change was observed between the PRV infected and non-infected groups (Figure 3A, $n = 5$).

[redacted]

Though the broad spectrum of etiological factors is involved in acute pancreatitis, the pathophysiology of the disease is less understood. Most investigators believe that acute pancreatitis results from an early intra-acinar cell activation of zymogens[26]. Following this early activation, a trypsin cascade occurs in the gland leading to the auto-digestion of acinar cells[26]. However, a possible pathophysiological role of the ductal epithelium has not been investigated. The permeability of the pancreatic ductal epithelium to HCO_3^- and Cl^- is increased by exposure to various bile salts at concentrations within the range normally found in the duodenum[27]. Moreover, *E. coli*-infected bile causes further increases of the permeability of the ductal epithelium to HCO_3^- and Cl^-[27]. Ethanol could induce fluid hypersecretion from guinea pig pancreatic duct cells. Low concentrations of ethanol directly augment pancreatic ductal fluid secretion stimulated by physiological and pharmacological concentrations of secretin (cAMP pathway) and via Ca^{2+} mobilization[28]. The effects of other etiologic factors for acute pancreatitis on pancreatic ductal HCO_3^- secretion have not been characterized as yet.

Viruses can alter ion transport by epithelial cells. Kunzelmann *et al*.[29], reported that parainfluenza virus I (Sendai virus) produces rapid changes in ion transport across tracheal epithelium. The Sendai virus, at concentrations observed during respiratory infections, activates Cl^- secretion and inhibits Na^+ absorption[29] by triggering the release of ATP, which then acts on apical P2Y receptors to produce changes in ion transport[29]. Bacterial infection (e.g., *Pseudomonas aeruginosa* or *Staphylococcus aureus*) triggers mucus and interleukin production[30,31]. Mucus clearance is a primary innate defense mechanism for mammalian airways[32].

In this study, we developed a model to investigate the effect of acute infection with a herpes virus (PRV) on the pancreatic ductal epithelium. Incubating BDG at a dose of 10^7 PFU/mL for 6 h resulted in the infection of the majority

of accessible epithelial cells within the duct. As expected, the virulent PRV strain resulted in a productive infection of epithelial cells, indicated by the appearance of viral antigens. We used two different measures of HCO_3^- secretion (inhibitor stop and alkali load methods) to study the effect of acute PRV infection on pancreatic ducts. Both methods showed that BDG infection stimulated HCO_3^- secretion in guinea pig pancreatic duct by about four or fivefold. However, BDG had no effect on the pH_i recovery after an acid load, suggesting that neither the basolateral Na^+/HCO_3^- co-transporter nor the basolateral Na^+/H^+ exchanger is involved in the hypersecretory effect. We have previously reported that pancreatic hypersecretion is observed during the early phase of acute necrotizing pancreatitis[33]. Furthermore, the early phase hypersecretion is accompanied with a simultaneous decrease in protein output[34], suggesting that the pancreatic ducts are at least in part involved in the change of secretory pattern. In our study, the genetically engineered control virus (KEG) did not evoke hypersecretion in the ductal cells, indicating that the presence of the virus in the cell is not enough to trigger hypersecretion. Hypersecretion was only induced by the BDG virus, which is able to initiate a lytic viral cycle.

Our finding that BDG stimulates HCO_3^- secretion from pancreatic ducts may represent a defense mechanism against invasive pathogens in order to avoid pancreatic injury. We speculate that the stimulated secretion can wash out activated enzymes, viruses and other toxic factors from the pancreas. Moreover, the high efficiency of PRV infection in the pancreatic ductal epithelium may open the possibility for gene transfer and gene therapy of the duct cells using non-replicating or conditionally replicating PRV variants (KEG)[2,19].

Abstract

AIM: Prostaglandin G/H synthase 2 (PTGS2 or COX2) is one of the key factors in the cellular response to inflammation. PTGS2 is expressed in the affected intestinal segments of patients with inflammatory bowel diseases (IBD). In IBD patients, non-steroidal anti-inflammatory drugs, which have been shown to reduce both the production and activity of PTGS2, may activate IBD and aggravate the symptoms. We aimed at examining genetic variants of *PTGS2* that may be risk factors for IBD.

METHODS: We genotyped 291 individuals diagnosed with IBD and 367 controls from the Dutch population for the five most frequent polymorphisms of the *PTGS2* gene. Clinical data were collected on all patients. DNA was extracted via normal laboratory methods. Genotyping was carried out using multiplex PCR followed by the Invader Assay and the 5' exonuclease assay (TaqMan). New polymorphism screening was performed by pre-screening with denaturing high-performance liquid chromatography, followed by fluorescent sequencing.

RESULTS: Allele 5209G was weakly associated with Crohn's disease (odds ratio [OR] 1.63, 95% confidence interval [CI] 1.03-2.57), and allele 8473T with ulcerative colitis (OR 1.50, 95%CI 1.00-2.27). The haplotype including both alleles showed a strong association with IBD (OR 13.15, 95%CI 3.17-116.15). This haplotype, while rare (-0.3%) in the general population, is found more frequently in patients (3.5%).

CONCLUSION: Our data suggest that this haplotype of *PTGS2* contributes to the susceptibility of IBD.

INTRODUCTION

Risk factors for inflammatory bowel diseases (IBD) include several environmental and genetic exposures. Diet, tobacco smoking, and childhood diseases or poor hygiene have been identified as risk factors for IBD, with some important differences between ulcerative colitis (UC) and Crohn's disease (CD)[1-3]. Caucasians have been shown to be at higher risk than non-Caucasians, with North-South gradients seen in Europe[4,5].

Familial aggregation of IBD suggests a genetic component in the susceptibility to IBD. One major locus of susceptibility to IBD has been mapped by linkage analysis to chromosome 16, at the *CARD15/NOD2* gene[6-8], which has a role in inflammatory responses, through activation of nuclear factor NF-κB. Two more susceptibility genes have recently been identified[9,10]. Population-based association studies focused on polymorphisms of inflammatory genes, such as genes of the interleukin-1β pathway. Few showed significant associations with some degree of contradiction between studies[11-15].

Key genes involved in the regulation of the inflammatory processes, such as prostaglandin G/H synthase/cyclooxygenase (PTGS/COX), are obvious candidates to look for variants predisposing to IBD. One of the two PTGS isoforms, PTGS2/COX2, is expressed in epithelial cells and mononuclear cells in IBD[4], and it is induced in response to pro-inflammatory cytokines, including interleukin-1β[16-18]. PTGS2 is the rate-

limiting enzyme in the production of prostaglandins. Prostaglandins are thought to be essential in the process of wound healing in the gastrointestinal tract[19]. The use of non-steroidal anti-inflammatory drugs (NSAIDs), which inhibit both the transcription and activity of PTGS2, exacerbates the symptoms in UC[20] and may even activate quiescent IBD[21]. Thus, the expression of PTGS2 in the inflamed intestine might be a protective response within the wound-healing process[22]. Consequently, polymorphisms that change the amount of prostaglandins produced in inflamed cells could cause susceptibility to IBD.

To address this hypothesis, we have studied 145 UC patients, 146 CD patients, and 367 controls from the Dutch Caucasian population, which has a high incidence of IBD[23]. The present study was to search for associations between IBD and common single nucleotide polymorphisms (SNPs) in the *PTGS2* gene.

[illegible]

Samples

The recruitment of cases took place at the Department of Gastroenterology of the VU University Medical Center (VUmc), a referral center for IBD, between April 1992 and September 2000. Patients with indeterminate colitis were excluded from this study. Seventy-five UC patients were females and seventy males, with a median age of 46 years (range 19-89 years). The gender repartition of CD patients was 101 females and 45 males, with a median age of 40 years (range 15-80 years). The control population consisted of 175 healthy individuals who were students or staff at the VUmc, with a median age of 51 years (range 24-88 years). All subjects were unrelated Dutch Caucasians. Genomic DNA was extracted using the DNAzol procedure (Invitrogen).

In order to ensure that the control group was representative of the general population, a second control group was also used, consisting of 192 Dutch subjects (96 males and 96 females). These samples were selected from the European Prospective Investigation on Cancer (EPIC) cohort[24] to provide information on the genetic background in the overall Dutch population. These samples were selected to provide a similar age distribution and sex ratio as the original control group. DNA was extracted from buffy coat using Puregene chemistry (Gentra Systems, Minneapolis, MN, USA). This population-based sample was indistinguishable from the VUmc controls from the point of view of frequencies of *PTGS2* alleles and genotypes (data not shown). We take this as confirmation that both groups were drawn from the general Dutch population, at least from the genetic point of view.

Patient classification

Diagnosis and assessment of maximal extent of IBD were based on endoscopic, histopathological, and radiological criteria[25]. Patients with indeterminate colitis were not included in this study, as they can be categorized as UC or CD only at a later stage. UC patients were subdivided into three groups: proctitis, limited to the rectum (12 cases), left-sided colitis with disease activity up to the splenic flexure (72 cases), and pancolitis (61 cases), extending beyond the splenic flexure. In addition, the patients with UC were subdivided into one group with their colon *in situ* (116 cases), and a second group in which (procto)colectomy had to be performed during the course of disease (29 cases), indicative of severe or intractable disease (i.e., unresponsive to medical therapy). No patient was operated on prophylactic indication. In CD, patients were subdivided according to the Vienna classification[26]. This classification subdivides patients with CD according to age at onset (<40 years [125 cases] or ⩾40 years [21 cases]), disease behavior (non-stricturing, non-penetrating [51 cases], stricturing [63 cases], penetrating [32 cases]) and location of disease (terminal ileum [50 cases], colon [32 cases], ileocolonic [62 cases], or upper gastrointestinal tract [2 cases]). Anatomical classification is defined as the maximal extent of the disease prior to the first surgical procedure, while behavior is assessed at any time during the course of the disease.

SNP selection and genotyping

SNPs were selected from our previously collected data[27] to include those SNPs with a prevalence of greater than 5% in Caucasians. Among the SNPs we studied, the only one with a proven functional role is a SNP located in the promoter of *PTGS2*, at position 926 of GenBank entry D28235 (dbSNP rs20417), which has been shown to affect the expression of *PTGS2* mRNA[28].

The order of samples of patients and controls was randomized in the PCR plates, so that a uniform number of patients and controls could be analyzed simultaneously in each run. EPIC samples were genotyped separately.

Three SNPs were genotyped with the Invader Assay[29]. PCR for the Invader assay (Third Wave Technologies, Madison, WI, USA) was carried out in 25 μL reactions, using the following concentrations: 20 ng DNA, 20 μmol/L dNTPs, 1×Taq Platinum buffer, 1.5 mmol/L $MgCl_2$, 1.25 U Taq Platinum polymerase (Life Technologies, Inc., Gaithersburg, MD, USA), 0.5 μmol/L of each primer. The primers used were as follows (nomenclature of SNPs refers to base numbers in GenBank entry D28235):

PTGS2.401 (rs689465)
401F: AAG GAC TTA GGA CAT AAC TGA ATT TTC
401R: ATG GGT AGT GCT CAG GGA GGA G
PTGS2.3050 (rs5277)
3050F: CGT TGT GAA TAA CAT TCC CTT
3050R: ATT TTT CTT TGA GAA GGC TAA AA
PTGS2.5209 (rs20432)
5209F: ATG ATG TAT GCC ACA ATC TGG CTG
5209R: TTG TCT GGA ACA ACT GCT CAT CAC.

This multiplex reaction was then carried out in a Tetrad DNA Engine PCR machine (MJ Research, Waltham, MA, USA), with the following cycling conditions: 96 ℃ for 5 min, then 30 cycles of 96 ℃ for 30 s, 50 ℃ for 60 s, and 72 ℃ for 10 s, with a final extension of 72 ℃ for 5 min. PCR volumes were then brought up to 150 μL, and Invader reactions were carried out as per manufacturer's instructions. Plates were read in a fluorometer with excitation and emission spectra as recommended by Third Wave.

The SNPs *PTGS2*.926 and *PTGS2*.8473 were tested using the TaqMan assay with MGB chemistry (Applied Biosystems,

Foster City, CA, USA). The assay was carried out in a 10 μL reaction, with 20 ng DNA, 1×TaqMan master mix (Applied Biosystems), 0.1 μmol/L of each primer, and 0.2 μmol/L of each probe. Primer and probe sequences are as follows:
PTGS2.926 (rs20417)
926F: TTA ACT ATT TAC AGG GTA ACT GCT TAG G
926R: CTT CAC CCC CTC CTT GTT TC
926VIC: CCT TTC CCG CCT CT
926FAM: CTT TCC CCC CTC TC
PTGS2.8473 (rs5275)
8473F: ATG CAC TGA TAC CTG TTT TTG TTT G
8473R: GTT TCC AAT GCA TCT TCC ATG A
8473VIC: TGA CAG AAA AAT AAC CAA AA
8473FAM: TGA CAG AAA AAT GAC CAA A

The cycling conditions for these PCR reactions were as follows: 95 ℃ for 10 min, then 35 cycles of 95 ℃ for 15 s, and 60 ℃ (58 ℃ for *PTGS2*.926) for 60 s. Plates were then read in the ABI 7900HT sequence detection system.

Data analysis

For genotype data from the Invader assay, raw intensity counts were corrected with a negative control, and the ratio between the two signals (one color for each allele) was used to call each genotype. For the TaqMan assay, groups of genotypes (homozygote common, heterozygote, and homozygote rare) were determined manually within the SDS software (Applied Biosystems). Each SNP was tested in the control group to ensure that it does not deviate from Hardy-Weinberg equilibrium. Linkage disequilibrium tests were performed using macros developed by the authors in conjunction with the PHASE program[30] to reconstruct haplotype frequencies. Odds ratios (OR) and 95% confidence interval (CI) were calculated in Stata 7.0, using logistic regressions correcting for sex and age in analyzing genotypes at single SNPs. Simple OR were calculated when data consisted of frequencies of alleles or haplotypes in the population. All *P* values reported are two sided. SNPs were tested for effects on splicing using the Delila Server (http://www.lecb.ncifcrf.gov/-toms/delilaserver.html) at the Laboratory of Experimental and Computational Biology of the National Cancer Institute[31].

New polymorphism screening

Individuals termed "at risk" based on association testing (i.e., the 19 cases carrying the haplotype, which includes the two alleles showing increase in risk at SNPs 5 209 and 8 473) were screened for novel polymorphisms using denaturing high-performance liquid chromatography (DHPLC) via the WAVE system (Transgenomic, Omaha, NE, USA). The areas studied were the promoter region, exons 6 and 10, and the 3' UTR. The protocols followed were as published previously[27].

Figure 1 shows a graphical representation of the structure of the *PTGS2* gene. The five major SNPs as well as the polymorphisms discovered as part of this study are depicted. The allele frequencies of the five major SNPs in the control group were 11.4% (*PTGS2*.401), 13.4% (*PTGS2*.926), 14.6% (*PTGS2*.3050), 13.5% (*PTGS2*.5209), and 33.9% (*PTGS2*.8473). All SNPs, except *PTGS2*.3050, were in Hardy-Weinberg equilibrium in the control group. Table 1 shows the genotype counts of the SNPs studied, among cases and controls. The SNP at position 5 209 shows an increase in the carriers of the G allele in cases as compared to controls, with a weak but significant association was found only in CD (OR = 1.63, 95%CI 1.03-2.57, $P = 0.04$). The SNP at position 8 473 shows an increase in the frequency of the T/T homozygote genotype in cases as compared to controls, with an association of borderline significance found only in UC (OR = 1.50, 95%CI 1.00-2.27, $P = 0.05$). No association was seen with the SNPs at position 401, 926, or 3 050, although it should be noted that there is a lack of homozygous rare genotypes at bp 3 050 in the control group, which is the reason for its departure from Hardy-Weinberg equilibrium.

We analyzed differences in genotype counts among the different clinical variables for CD and UC. No statistically significant differences between classification levels were observed (data not shown).

Significant levels of linkage disequilibrium were seen among the most common SNPs in the *PTGS2* gene (data not shown). Table 2 shows the frequencies of haplotypes of the *PTGS2* gene in both IBD patients and controls. The SNP at bp 3 050 was not included in haplotype analysis, as it was not in Hardy-Weinberg equilibrium in the control population, and this has been shown to affect the accuracy of haplotype reconstruction methods[32]. All individuals were genotyped for the SNP at bp 3 050, eliminating the risk that its lack of Hardy-Weinberg equilibrium is caused by bias due to the genotyping technique missing preferentially one genotype. Haplotype frequencies were calculated using all four valid SNPs, and all data are shown. There were no differences in haplotype frequency between the two groups of IBD patients and the controls, except for haplotype AGGT, which shows an OR of 11.9 (95%CI 2.83-105.76, $P<0.00005$, for UC and CD combined). Interestingly, this haplotype includes the two alleles showing an increase in risk at SNPs 5 209 and 8 473. If we consider the haplotype including the 5209.G and 8473.T alleles (by lumping haplotypes

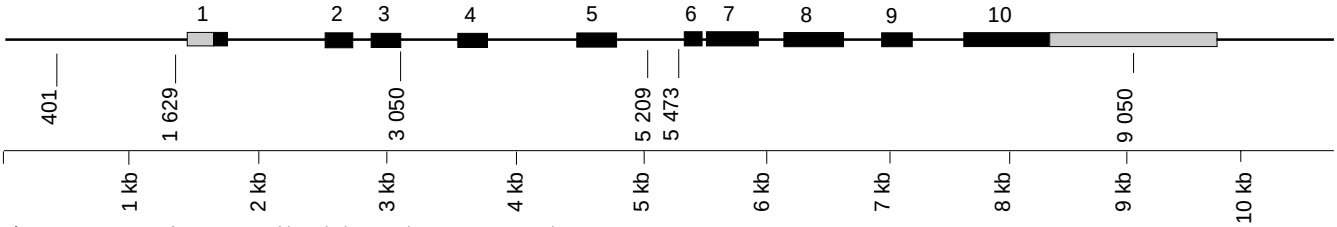

Figure 1 Structure of *PTGS2*. Positions in base pairs as per GenBank sequence D28235. Exons are shown as dark boxes, untranslated regions as light boxes. Vertical lines represent SNPs, with their positions in the sequence indicated.

[1]Numbers may not sum up to the totals of controls or cases due to genotyping failure. All samples that did not give a reliable result in the first round of genotyping were resubmitted to up to three additional rounds of genotyping. Data points that were still not filled up after this procedure were left blank. [2]All ORs are adjusted for sex and age. [3]Heterozygotes and homozygotes for the rare allele have been grouped in order to improve statistical power.

Table 2 *PTGS2* haplotype frequencies and OR for IBD

Haplotype[1]	Controls	UC cases		CD cases		UC+CD cases[2]	
	n (%)	*n* (%)	OR (95%CI)	*n* (%)	OR (95%CI)	*n* (%)	OR (95%CI)[3]
AGTT	471 (64.7)	193 (65.6)	1.00 (ref.)	183 (62.7)	1.00 (ref.)	376 (64.2)	1.00 (ref.)
AGTC	147 (20.2)	55 (18.7)	0.91 (0.64-1.30)	54 (18.5)	0.95 (0.66-1.35)	109 (18.6)	0.93 (0.69-1.24)
GCGC	64 (8.8)	22 (7.5)	0.84 (0.50-1.39)	27 (9.2)	1.09 (0.67-1.75)	49 (8.4)	0.96 (0.63-1.45)
ACGC	25 (3.4)	8 (2.7)	0.78 (0.35-1.73)	7 (2.4)	0.72 (0.31-1.66)	15 (2.6)	0.75 (0.36-1.51)
AGGT	2 (0.3)	10 (3.4)	12.2 (2.97-inf.)	9 (3.1)	11.58 (2.79-inf.)	19 (3.2)	11.9 (2.83-105.76)
Rare[4]	19 (2.6)	6 (2.0)	0.77 (0.31-1.90)	12 (4.1)	1.63 (0.78-3.37)	18 (3.1)	1.19 (0.61-2.29)

[1]The order of SNPs in the haplotypes is *PTGS2*.401, *PTGS2*.926, *PTGS2*.5209, and *PTGS2*.8473. [2]UC and CD combined. [3]ORs are not corrected as they are based on population level haplotype frequencies and are relative to the most common haplotype (AGTT). [4]Rare haplotypes (frequency ≤1% in both cases and controls).

AGGT and GCGT), we observe an increase in its frequency in patients with IBD (0.035, UC and CD combined) as compared to controls (0.003). This increase in frequency yields an OR of 13.15 (95%CI 3.17-116.15, $P<0.00005$, for UC and CD combined).

In order to test the possibility that these positive associations are in reality indicative of linkage disequilibrium with yet undiscovered nearby polymorphisms, we studied by DHPLC the 19 cases who could carry the risk haplotype. Regions of *PTGS2* surrounding the three SNPs, and in addition the promoter region, exon 1 and the UTRs were analyzed. No novel polymorphisms were discovered in the coding sequence of the gene. One SNP was discovered at bp 9 850 (A-G), with a minor allele frequency of lower than 2%. Therefore, we considered it unlikely that polymorphisms other than 5 209 or 8 473 could explain the observed associations.

[redacted]

PTGS2 is a critical enzyme involved in the production of prostaglandins, which are essential in the process of healing bowel wounds. The use of NSAIDs, which inhibit both the translation and activity of PTGS2, can induce a flare-up[21] and actually exacerbate the symptoms of IBD[20]. We hypothesized that polymorphisms in *PTGS2* might influence prostaglandin production in inflamed cells, thus affecting susceptibility to IBD. In this study, we have found a slightly increased risk of IBD associated to *PTGS2*.5209 and *PTGS2*.8473, and a strong association with a haplotype including alleles of these two SNPs.

PTGS2.5209 is in intron 5 of *PTGS2*. *In silico* analysis

of this SNP for splice site mutations[31] reveals that the T-G substitution creates a new splicing acceptor sequence with nearly the same strength as that found in normal splice sites. While this is most probably not enough of a change to exclude completely the normal splicing of exons 5-6, it could cause some "leaking", reducing the amount of normal *PTGS2* mRNA. *PTGS2*.8473, being in the 3' untranslated region (UTR), could affect the stability of *PTGS2* mRNA[33]. In fact, the unusually long 3' UTR plays an important role in determining the half-life of the mRNA. Various proteins bind to it and cause either acceleration or protection of the degradation of the mRNA[34,35].

The associations we have found between CD and *PTGS2*.5209 G/G, and UC and *PTGS2*.8473 T/T are statistically significant, but of moderate importance. We propose that it is the combination of the G allele at *PTGS2*.5209 with the T allele at *PTGS2*.8473, on the same chromosome (GT haplotype), that would have the most influence on disease status.

The association between IBD and the GT haplotype could be due to linkage disequilibrium with another polymorphism that lies nearby. To test this hypothesis, we have analyzed subjects who carry the GT haplotype for the presence of novel functional polymorphisms of *PTGS2*, but this search has not yielded any additional candidates. Linkage disequilibrium with polymorphisms in neighboring genes is not a likely explanation either, as there is no gene mapping of at less than 100 kbp on either side of *PTGS2*.

We are inclined to think that this association is not a finding by chance. First of all, we have found a higher level of linkage disequilibrium between alleles at bp 5 209 and 8 473 in controls than in cases. This could mean that natural selection has exerted pressure toward the disappearance of the GT haplotype, i.e. this haplotype might negatively affect the fitness of individuals carrying it. Additionally, we have observed that this haplotype is virtually absent not only in the Dutch population, but in other Northern European populations as well (Cox *et al*., unpublished data).

These results are the first linking of *PTGS2* to IBD. While the GT haplotype of *PTGS2* is rare, the two alleles that compose it are much more frequent, they both show a modest association with the disease, and could therefore be important for a large proportion of the population. Future steps are to replicate these findings by independent studies, to determine experimentally the extent to which *PTGS2* polymorphisms alter the expression or function of the gene, and to discover genetic or environmental factors that may alter the risk of IBD interacting with *PTGS2* alleles.

ACKNOWLEDGEMENTS

ABSTRACT

AIM: To examine the frequency of antibiotic resistance in Iranian *Helicobacter pylori* (*H pylori*) strains isolated from two major hospitals in Tehran.

METHODS: Examination of antibiotic resistance was performed on 120 strains by modified disc diffusion test and PCR-RFLP methods. In addition, in order to identify the possible causes of the therapeutic failure in Iran, we also determined the resistance of these strains to the most commonly used antibiotics (metronidazole, amoxicillin, and tetracycline) by modified disc diffusion test.

RESULTS: According to modified disc diffusion test, 1.6% of the studied strains were resistant to amoxicillin, 16.7% to clarithromycin, 57.5% to metronidazole, and there was no resistance to tetracycline. Of the clarithromycin resistant strains, 73.68% had the A2143G mutation in the *23S rRNA* gene, 21.05% A2142C, and 5.26% A2142G. None of the sensitive strains were positive for any of the three point mutations. Of the metronidazole resistant strains, deletion in *rdxA* gene was studied and detected in only 6 (5%) of the antibiogram-based resistant strains. None of the metronidazole sensitive strains possessed *rdxA* gene deletion.

CONCLUSION: These data show that despite the fact that clarithromycin has not yet been introduced to the Iranian drug market as a generic drug, nearly 20% rate of resistance alerts toward the frequency of macrolide resistance strains, which may be due to the widespread prescription of erythromycin in Iran. *rdxA* gene inactivation, if present in Iranian *H pylori* strains, may be due to other genetic defects rather than gene deletion.

INTRODUCTION

Helicobacter pylori (*H pylori*) infects the majority of the adult population in developing countries including Iran. The rate of infection in Iranian adults according to serology data is up to 80%[1]. The outcomes include gastritis, peptic ulcers and gastric adenocarcinomas, which are highly prevalent in Iran[2]. Patient compliance with the prescribed medications, presence of pre-existing resistance to the key anti-*H pylori* antibiotics (clarithromycin and metronidazole), final duration of therapy and prescribed dose of antibiotics are all the factors which influence the effectiveness of therapy[3]. Host genetic polymorphisms, i.e. IL-1-511 and CYP450 and CYP2C19, may affect the efficiency of the therapy as well [4]. Antibiotic resistance varies geographically and there is a great need for local studies.

Clarithromycin is recommended as a key component in anti-*H pylori* eradication[5]. In different geographic locations, resistance to clarithromycin differs. In countries with a higher use of macrolides, the rate of resistance to clarithromycin is reported to be proportionally higher[6]. The basis of the resistance is the presence of defined mutations in the *23S rRNA* gene, which results in a decrease in the antibiotic binding to the bacterial ribosome[7-9]. Mutations in the form of A-G transition at nucleotide positions 2143, 2144, and A-C at nucleotide position 2142 have been found to confer clarithromycin resistance in *H pylori* strains[10]. Recently in *H pylori* isolates from northeast China, three new mutation points (G2224A, C2245T, and T2289C) were found to be related to the clarithromycin resistance[11]. Several different PCR-based methods have been developed for the detection of the above-mentioned mutations in order to amplify part of the V domain of *23Sr RNA* gene[12]. The amplified fragments are digested by restriction enzymes, indicating mutations in the positions 2143 and 2144 which yield a high level clarithromycin resistance[10,13]. A2142C is reported to be less frequent and is detectable by PCR using 3'-mismatched specific primers[14,15].

Though most countries include clarithromycin in the prescribed anti-*H pylori* treatment regimens, this drug is infrequently prescribed in Iran due to its high cost.

As regards to metronidazole, the basis of resistance in *H pylori* has been partly associated with inactivation of *rdxA*, the gene encoding an oxygen-insensitive NADPH nitroreductase may be enhanced by mutations in *frxA* gene

encoding a NAD(P)H-flavin oxidoreductase[16].

This study presents the first documented report from Iran on the *rdxA* gene deletion. Frameshift mutations in *frxA* gene were not studied as their frequent occurrence has questioned its reliability as a resistance marker[17].

We have used modified disc diffusion test for primary analysis followed by the described molecular assays to examine resistance among Iranian *H pylori* strains with particular emphasis on clarithromycin and metronidazole.

MATERIALS AND METHODS

Bacterial strains and growth conditions

Gastric antral biopsies were taken from 120 non-*H pylori* pretreated patients (52 males and 68 females, aged 42±20 years) with epigastralgia referring to gastric endoscopy (during 2001-2002) followed by rapid urease test. These patients did not undergo any prior treatment. Urease positive samples were cultured on brucella agar (Merck) supplemented with 5% sheep blood, (6 mg/L) vancomycin (Fluka BioChemika), (5 mg/L) trimethoprim (Fluka BioChemika) and (2 mg/L) amphotericin-B (Gibco) under microaerophilic conditions (85% N_2, 100 mL/L CO_2, 5% O_2) at 37 ℃ for 3-5 d. Single colonies of *H pylori* were then isolated and confirmed for identity according to colony morphology, wet mount, microscopic observation after Gram staining and biochemical analysis (urease and catalase tests).

Disc diffusion susceptibility test

Bacterial resistance to clarithromycin[18], metronidazole[19], amoxicillin, and tetracycline[20] was determined using modified Kirby-Bauer procedure as previously described[21,22]. Suspensions of 4-d-old cultures were prepared in sterile saline to opacity of No. 4 (108 CFU/mL) McFarland standard. Muller-Hinton agar plates supplemented with 5% sheep blood were then inoculated with a swab from the prepared suspension. House-made discs containing 2 μg clarithromycin, 5 μg metronidazole, 10 μg amoxicillin, and 30 μg tetracycline were placed separately on the culture plates for each strain. Plates were then incubated at 37 ℃ for 72 h under microaerophilic conditions generated by Gas Pak jars. The disc diffusion tests were made thrice for each strain. The inhibition zone diameters were measured in millimeters with a ruler. If similar results were observed in two experiments out of three, the isolates were considered susceptible or resistant but as mixed populations. A *H pylori* control strain susceptible to metronidazole (Sydney strain, ss1) was used. The breakpoints with the Mueller-Hinton agar for the inhibition diameters are described in Table 3, briefly: 20 mm for tetracycline, 11 mm for amoxicillin, for metronidazole zones areas; <16 mm resistant, 16-21 mm intermediate and >21 mm susceptible (but in this study isolates in the intermediate and resistant zone were both considered as resistant), for clarithromycin development of any size zone is considered resistant[23].

DNA extraction and PCR assays

Genomic DNA was extracted as previously described[10]. PCR primers used for this study were chosen from published reports with the implementation of the same PCR cycles[10] (Table 1). Primer sets 1 and 2 were designed to detect point mutations in the *23S rRNA* gene responsible for clarithromycin resistance. Set 1 was used to amplify a 1 400-bp PCR fragment following digestion with *Bsa*I produced three fragments of 700, 400, and 300 bp, if the A2143G mutation was present. *Mbo*II digestion of the 1 400-bp fragment produced two 700-bp fragments, if A2142G mutation was present. A 750 and a 850 bp were produced, if A2144G mutations existed[10]. Set 2 was used in 3'-mismatched PCR to obtain a 700-bp-amplified fragment, an indication of the A2141C mutation[15].

For detection of *rdxA* gene deletion, set 3 was used. In this case, the native gene yielded a 850-bp PCR product and its deletion resulted in a 650-bp fragment[24].

Table 1 Primer sets used in this study

Gene	Primers	Expected fragment (bp)	References

Statistical analysis

Data were analyzed by SPSS version 11.0. The Pearson χ^2 test and Fisher's exact test were used to assess the relationships between the results of disc diffusion and PCR/RFLP methods. Standard error of mean for each frequency was determined accordingly.

RESULTS

Primary antibiotic resistance by disc diffusion

According to the disc diffusion test, all 120 strains were sensitive to tetracycline. Of these, 2 strains (1.6%) were resistant to amoxicillin, 20 (16.7%) to clarithromycin and 69 (57.5%) to metronidazole. Five of the one hundred and twenty (4.2% of the strains) showed dual resistance to metronidazole and clarithromycin. Table 2 presents the frequency of single and multiple resistances to the tested antibiotics.

Detection of 23S rRNA mutations via PCR-RFLP

All the DNA samples were positive by the PCR assay for the amplification of the 1 400 bp of *23S rRNA* gene. RFLP analysis pattern showed that 19 out of 120 (15.8%) strains were mutated (Table 2). In this group, 73.68% had the A2143G mutation and 5.26% the A2142G mutations. Moreover, none of the clarithromycin resistant samples showed the A2144G mutation, 21.05% of the samples were positive for the 3'-mismatched PCR, revealing the presence

of the A2142C mutation. Among the 20 clarithromycin resistant strains, only one did not show any of these mutations. None of the sensitive strains were positive for any of the mentioned mutations.

PCR detection of rdxA gene deletion

Among the 69 metronidazole resistant strains (based on antibiograms), only 6 (5% of total) demonstrated 200 bp deletion in the *rdxA* gene (Table 2).

According to the data analysis by the SPSS program, there were no relations between the *23S rRNA* mutations, *rdxA* deletion and antibiotic resistance with age, gender, and cagA status.

Table 2 Frequency of single and multi-drug resistance based on listed methods of detection

Antibiotics	Method of detection					
	Disc diffusion		*23S rRNA* PCR-RFLP		*rdxA* gene deletion	
	n	%	*n*	%	*n*	%
Amoxicillin only	1/120	0.8				
Amoxicillin and metronidazole	1/120	0.8				
Clarithromycin only	15/120	12.5	19/120	15.8		
Clarithromycin and metronidazole	5/120	4.2				
Metronidazole only	63/120	52.5			6/120	5
Metronidazole and amoxicillin	1/120	0.8				
Metronidazole and clarithromycin	5/120	4.2				
Tetracycline	0/120	0				

Table 3 Susceptibility rates of 120 isolates to selected antibiotics by modified disk diffusion method

Antibiotics	Disc content (μg)	Zone size breakpoint (resistance) (mm)	Resistant isolates (%)
Metronidazole	5	16	34.2 resistant 23.3 intermediate
Clarithromycin	2	Any zone	16.7
Amoxicillin	10	11	1.6
Tetracycline	30	20	0

DISCUSSION

Several studies comparing the different susceptibility techniques for *H pylori* have been published, but the results are controversial, as *H pylori* is a very slow growing bacterium with particular growth needs[23,25-28]. The oxygen-dependent metabolism of metronidazole in *H pylori* via several nitroreductases possibly results in great difference in MIC when isolates are tested repeatedly. Nevertheless, strains continue to be classified as resistant or susceptible[25].

As regards to culture-based antimicrobial susceptibility testing (especially to metronidazole), routine methods of agar dilution, disc diffusion, and *E*-test seem to be poorly standardized[29]. Though time consuming agar dilution is accepted as the gold standard and is reported to be highly reproducible in several studies[23,30,31], nowadays, *E*-test is used most frequently as a substitute as it is easier to perform and relatively reproducible[32]. Finally, a cheap and easy way to perform susceptibility testing is via disc diffusion, but no MIC value can be obtained. Recently in UK, susceptibility testing to metronidazole, tetracycline, macrolide, and amoxicillin is performed by the modified disc diffusion method and the results are adequate to determine the resistance rates in a large cohort of patients from a single clinical center whom resistance patterns have been evaluated over time[33]. Then again in a study in France, reproducibility study on randomly selected strains declared that disc diffusion is more reproducible than *E*-test for both clarithromycin and erythromycin[34]. Due to these observations and high cost of *E*-test, modified disc diffusion test was chosen for this study.

Worldwide antibiotic resistance has been carefully reviewed by Megraud[35], and our resistance rate to clarithromycin and metronidazole is comparable to the resistance rate of 50% to metronidazole and 8% to clarithromycin in China[36].

Current regimens for the eradication of *H pylori* in Iran consist of a proton pump inhibitor (omeprazole) or an H_2 receptor blocker (ranitidine), a bismuth salt plus two antibacterial agents, such as amoxicillin, furazolidone/metronidazole or recently clarithromycin[37]. Treatment regimens of 4 or 7 d are unacceptable for *H pylori* infection in Iran, even in the presence of a favorable sensitivity profile[38]. Although the presented data do not support the association with the failure of eradication in our country, according to our results, such rates of resistance to metronidazole and clarithromycin could be the major cause of eradication failure in Iran. For developing countries, the standard triple therapy remains as the best option for the eradication regimen because of its low cost. However, in Iran bismuth triple therapy in the presence of high prevalence of metronidazole resistance has a poor efficacy unless higher doses of metronidazole are prescribed to increase the cure rate of therapy[39].

Our results indicate that making clarithromycin available may not be an effective strategy to improve the eradication rates in Iran, as the level of resistance is already significant. There is a worldwide need for simple and cost effective anti-*H pylori* therapies. Since the effectiveness relates to the level of antibiotic resistance, knowledge of the resistance patterns is essential for choosing empiric therapy. Metronidazole is widely used in Iran because of the prescription in most periodontal and parasitic diseases. Resistance to metronidazole among Iranian patients, as most of the developing countries, is relatively high and this is the major cause of eradication failure in these countries. Thus, the need for a suitable alternative for this drug is highly perceptible and crucial to plan a more effective therapeutic strategy. (OABC) Omeprazole, Amoxicillin, Bismuth, Clarithromycin and (OABF)Omeprazole, Amoxicillin, Bismuth, Furazolidone are both effective in eradicating *H pylori* in countries where metronidazole resistance is a problem. OABF is a good alternative in the face of growing resistance to clarithromycin in developed countries, and is attractive for developing countries where clarithromycin is not readily available and is particularly recommended for Iran[37].

In recent years, *rdxA* gene analysis of the fresh samples showed that the metronidazole resistance is mainly attributed to the mutations in this gene including gene deletion[24]. Antibiogram analysis of our strains demonstrated 57% metronidazole resistance; however, the majority of the metronidazole resistant strains did not show the 200 bp deletion in the *rdxA* gene. One obvious explanation is that the deletion in this gene is not the only defect causing gene inactivation and is not an informative indication of metronidazole resistance in Iranian *H pylori* strains (with ~60% metronidazole resistance). The data are supported by data from Germany[40] and France[16] (with 40-50% metronidazole resistance) and contradicted by data from China[41] and Taiwan[42] (with 50-60% resistance). Due to the reported disparity, it seems that *rdxA* gene mutation is not a suitable marker for molecular prediction of metronidazole resistance. Although *rdxA* gene deletion is not a good resistance indicator, it is only detected in resistant strains and all of the strains with *rdxA* deletion clusterized in specific rapedemes (analyzed by RAPD-PCR), suggesting that they are genetically similar (data not shown). Unlike clarithromycin, metronidazole resistance *in vitro* does not reflect *in vivo* resistance. Other existing genetic defects causing metronidazole resistant phenotypes and the high incurring cost of molecular diagnostic assays lead us to the conclusion that standard culture-based techniques (simple and inexpensive disc diffusion method) remain the recommended method of choice in Iran.

In conclusion, the discovery of such a high rate of resistance to clarithromycin, which is most likely due to the vast consumption of erythromycin in cases of upper respiratory infections, calls for an effective eradication program and disqualifies clarithromycin as an alternative to metronidazole. These results further confirm the essence of continuous monitoring of antibiotic resistance patterns in order to reduce the rate of eradication failure in Iran or any other target population.

Abstract

AIM: To investigate the expression of receptor-binding cancer antigen expressed on SiSo cells (RCAS1) in metastatic lymph nodes from gastrointestinal cancer.

METHODS: Metastatic lymph nodes from gastrointestinal cancer were detected for RCAS1 by immunohistochemical staining and mRNA *in situ* hybridization.

RESULTS: A total of 102 metastatic lymph nodes from bile duct, gastric, colon, and pancreatic cancer were investigated for RCAS1 expression. The immunoreactivity of RCAS1 was identified in 100% of metastatic lymph nodes. Both local and distant metastatic lymph nodes showed RCAS1 expression. On the contrary, specimens of non-cancerous lymph nodes were negative for RCAS1. The result of mRNA *in situ* hybridization was also confirmed by the finding of immunohistochemical staining. RCAS1 mRNA was detected in all tumor cells that metastasized to lymph nodes.

CONCLUSION: All metastatic lymph nodes express RCAS1 in tumor cells at both protein and mRNA levels, and RCAS1 should be used as a complementary factor for identification of metastatic lymph nodes from gastrointestinal cancers.

INTRODUCTION

One of the major factors for the poor prognosis of gastrointestinal cancer patients is lymph node metastasis[1-3]. To indicate the lymph node metastasis, pathologists must carefully identify tumor cells spreading to lymph nodes in each serial section of pathological specimens. The suitable method for the identification of tumor cells in lymph nodes is to stain the specimen with antibody, which highly recognizes the tumor antigen. At this time, the antibody to cytokeratin is widely used for detection of lymph node metastasis from breast cancer[4,5]. However,a current study showed that the sensitivity of cytokeratin to lymph node metastasis from gastrointestinal cancer is low[6].

Recently, receptor-binding cancer antigen expressed on SiSo cells (RCAS1) is recognized as type II membrane protein and secreted as a soluble protein[7,8]. This tumor-associated antigen has been demonstrated in several kinds of gastrointestinal cancer by immunohistochemical study using the specific mouse mAb, 22-1-1. The result of RCAS1 expression was evaluated for the percent incidence in various cancers including gall bladder cancer (70%)[9], cholangiocarcinoma (85.9-96.4%)[10,11], gastric cancer (54.3%)[12], pancreatic cancer (100%)[13], and colorectal cancer (100%)[14]. However, until now, there has been no intensive study about the expression of RCAS1 in lymph node metastasis from gastrointestinal cancer. Therefore, the purpose of the present study was to investigate the expression of RCAS1 at both protein and mRNA levels in lymph node metastasis from gastrointestinal cancer.

MATERIALS AND METHODS

Tissue specimens

Fifteen specimens of non-cancerous lymph nodes and 102 specimens of metastatic lymph nodes from different gastrointestinal cancers (surgically resected in Rajavithi Hospital, Bangkok, Thailand) were collected for RNA investigation and immunohistochemical staining. The study was carried out with the approval of the Ethical Committee of Rajavithi Hospital. Pathological diagnosis and evaluation

were routinely performed.

Immunohistochemical staining

The sections (4 μm) were deparaffinized and immunostained for RCAS1 as described previously[14]. Briefly, the sections were incubated overnight at 4 ℃ with 1:1 000 dilution of 22-1-1 mouse mAb (Medical & Biological Laboratories Co., Ltd.). Biotinylated rabbit anti-mouse IgM (DAKO) was applied to the sections followed by avidin-biotin-peroxidase conjugate (ABC Elite, Vector Labs). The immunohistochemical reactions were developed with freshly prepared 3,3'-diaminobenzidine tetrahydrochloride solution (Histofine SAB-PO kit) and counterstained with hematoxylin. As a negative control, primary antibody was replaced with mouse IgM. The positive cell staining in each slide was identified under a high power field (×400) of Olympus BH2 microscope (field width = 0.5 mm).

RCAS1 mRNA in situ hybridization

Fluorescent probe preparation RCAS1 cDNA fragments from metastatic lymph nodes were synthesized by RT-PCR as described previously[14], using forward primer 5'-ACCTTACTGCCCTCCGTCTA-3' and reverse primer 5'-CTTCTTCATTAGCCGTTGTG-3'. The nucleotide sequence was confirmed with a Model 310 genetic analyzer (PE Biosystems) using a BigDye terminator cycle sequencing kit and used for generating fluorescent probes using Gene Images™ random prime labeling kit (Amersham, Biosciences). Twenty nanograms per microliter of denatured RCAS1 cDNA was mixed with 10 μL of nucleotide mix, 5 μL of primer, and 1 μL of 5 U/μL Klenow enzyme solution. The reaction was incubated at 37 ℃ for 1 h and stored at -20 ℃ until used.

***In situ* hybridization** The specimens were deparaffinized in xylene. The sections were treated with proteinase K for 20 min at 37 ℃ then diluted fluorescent-RNA probe (1 ng/mL with hybridization buffer) was applied onto each specimen. The slides were incubated at 55 ℃ for 2 h. The sections were rinsed with TBS and incubated for 15 min with blocking mixture (10% fetal calf serum). For detection of mRNA, the sections were incubated at room temperature for 30 min with anti-FITC/alkaline phosphatase. The immunoreactions were visualized by incubating the sections at room temperature with substrates and immersed in tap water for 5 min. The slides were counterstained with hematoxylin before observation under a light microscope.

Statistical analysis

Statistical analysis for comparing the expression of RCAS1 in the specimens was performed using SPSS 10.0 for Windows. $P<0.05$ was considered statistically significant.

结果

A total of 102 metastatic lymph nodes from various kinds of cancer were investigated for RCAS1 expression as shown in Table 1. The metastatic lymph nodes were divided into two groups (local and distant metastatic nodes) according to the TNM staging systems. The immunostaining pattern for RCAS1 was observed in the cytoplasm of tumor cells but not in lymphocytes (Figure 1). Most metastatic tumor cells showed a high intensity of RCAS1 immunostaining. The staining level was not related with tumor stage or differentiation status. All sections in negative control (non-cancerous lymph nodes) showed no immunoreactivity. RCAS1 was identified in 100% of metastatic lymph nodes. Interestingly, several primary cancers, which identified RCAS1 expression in some parts of tumor tissues, were found to express RCAS1 in most of the metastatic tumor cells in lymph nodes.

The RCAS1 cDNA of metastatic lymph nodes from various gastrointestinal cancers was determined by reverse-transcription-PCR. The 802 bp product was sequenced and its homology was compared with the RCAS1 cDNA sequence databases present at NCBI GenBank (gi: 13528905). This cDNA fragment started from nucleotide 41 to 842 of RCAS1 cDNA. As demonstrated in Figure 2, the cDNA fragment from metastatic lymph nodes revealed a high similarity throughout the 802 bp in the coding region.

To confirm further the expression of RCAS1 in metastatic lymph nodes, RCAS1 mRNA *in situ* hybridization was performed using the cDNA probes showing a high similarity with RCAS1 cDNA. The expression of RCAS1 mRNA was clearly identified in cytoplasm of tumor cells but not in lymphocytes. Figure 3 represents the typical RCAS1 mRNA expression, which could be detected in cytoplasm of tumor cells and represented the negative signal for RCAS1 mRNA in lymphocytes.

Table 1 RCAS1 expression in metastatic lymph nodes from gastrointestinal cancers

Type of cancer	Total no. of lymph nodes		No. of lymph nodes express RCAS1 (%)
	Local metastasis	Distance metastasis	
Bile duct cancer	10	4	14 (100)
Colon cancer	56	6	62 (100)
Pancreatic cancer	12	2	14 (100)
Stomach cancer	10	2	12 (100)

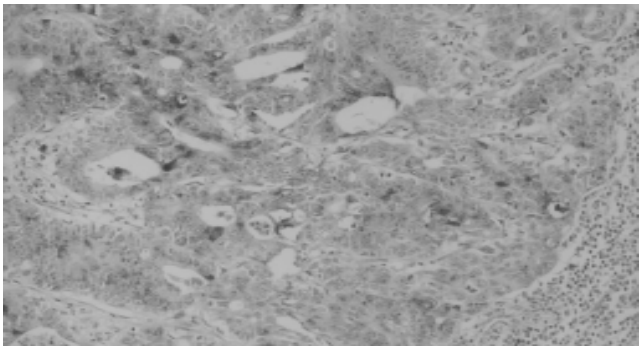

Figure 1 Typical result of immunohistochemical staining of RCAS1 (×200) in metastatic lymph nodes. Expression of RCAS1 was demonstrated both in cytoplasm and on cell membrane of tumor cells.

Figure 2 Nucleotide sequence alignment of RCAS1 cDNA from databases present at NCBI GenBank (gi: 13528905) and RT-PCR products from metastatic lymph nodes. The residues boxed in black indicate positional identity for both sequences. Numbers of nucleotide sequences are indicated on the left and right margins.

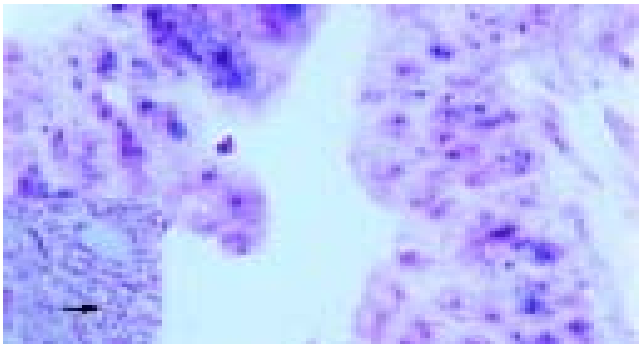

Figure 3 RCAS1 mRNA *in situ* hybridization in metastatic lymph nodes from colon cancer. The positive signal was identified in the cytoplasm of tumor cells. All leukocytes showed negative signal for RCAS1 (as presented in the Figure).

gastrointestinal cancers was first explored at protein level by immunohistochemical staining. The RCAS1 cDNA obtained from metastatic lymph nodes from various gastrointestinal tumors showed high homology with the RCAS1 cDNA sequence databases present at NCBI GenBank (gi: 13528905). This finding increases the reliability of *in situ* hybridization for identification RCAS1 of mRNA expression in metastatic tumor cells.

As suspected, it was expressed in all cases of metastatic lymph nodes. RCAS1 was shown to be a ligand for a putative receptor on immune cells such as T cells and natural killer cells[7-14]. Scientists suggest that RCAS1 may play a protective role in tumor cells against immune surveillance by inhibition of clonal expression and inducing receptor-expressing cell death. It has been previously reported that activated lymphocytes process receptors for RCAS1[7]. Thus, binding interaction between them induces apoptosis of lymphocytes. The mechanism by which tumor cell expressed RCAS1 mediates lymphocyte apoptosis is a main biologic pathway to escape the immune surveillance in both local and distant metastatic lymph nodes.

Although previous results[13,14] have demonstrated the correlation between the staining level and tumor stage or differentiation status, this study did not find any significant correlation between them. Most metastatic tumor cells showed a high intensity of RCAS1 immunostaining. This result may explain why tumor cells expressing RCAS1 metastasize the lymph nodes. The role of RCAS1 in lymph node metastasis needs further study.

Since the expression of RCAS1 is found in gastrointestinal cancers and their metastatic lymph nodes, it can be used as an additional step for identification of the status of lymph nodes.

AIM: To evaluate serum alanine aminotransferase (ALT) activity in a well-characterized group of uncomplicated obese subjects and its correlation with insulin resistance, plasma adiponectin, and leptin concentrations.

METHODS: One hundred and five uncomplicated obese subjects (87 women, 18 men, age 34.3±9.6 years, BMI 39.9±8.3 kg/m^2) were studied. Serum ALT activity was evaluated. Insulin sensitivity was assessed by euglycemic hyperinsulinemic clamp (M index) and fasting insulin. Plasma leptin and adiponectin levels were also measured.

RESULTS: Serum ALT concentration in the whole group of uncomplicated obese subjects was 17.73±6.33 U/L with none of the subjects presenting ALT levels greater than 43 U/L and only 9 (11%) women and 3 (19%) men showed ALT levels >19 and >30 U/L for women and men, respectively. No significant difference was detected in serum ALT levels between severe obese subjects (BMI >40 kg/m^2) and those with BMI <40 kg/m^2 (18.63±6.25 *vs* 17.26±6.02 U/L). ALT was significantly correlated with fasting insulin (r = 0.485, P = 0.02) and triglycerides (r = 0.358, P = 0.03).

CONCLUSION: Serum ALT activity is practically normal in uncomplicated obese subjects, independently of their obesity degree. These findings suggest the role of obesity-related comorbidities and not of BMI as main risk factors for elevated ALT levels in obese subjects.

Overweight and obesity have been reported to be major risk factors for elevated serum alanine aminotransferase (ALT) activity[1,2] and non-alcoholic fatty liver disease (NAFLD)[3-6]. High serum ALT levels have also been proposed as a marker of risk for type 2 diabetes[7,8]. A recent atherosclerosis study showed a significant relationship between ALT activity and insulin resistance[7]. In addition, unexplained ALT elevation has been found to be associated with increased visceral adiposity and other features of the metabolic syndrome[9]. Nevertheless, no studies evaluating serum ALT activity in metabolically healthy obese subjects have been performed. Uncomplicated obesity, as previously shown by our group[10], could be a good model to clarify the influence of obesity *per se* on ALT levels, without the confounding effect of the obesity-related comorbidities.

In this study, we sought to evaluate the serum ALT activity in a well-characterized uncomplicated obese subjects and its possible correlation with insulin resistance, plasma adiponectin, and leptin concentrations.

Patients

We selected 105 consecutive Caucasian uncomplicated obese subjects (body mass index [BMI] >30 kg/m^2) from 600 obese subjects who were referred to our Day Hospital from Rome and surrounding areas between January 2001 and June 2004. The selected subjects had the following features: 87 women, 18 men; age, 34.3±9.6 years (range, 20-55 years); BMI, 39.9±8.3 kg/m^2 (range, 30-80.1 kg/m^2); duration of obesity, 15±5 years (range, 10-30 years). Uncomplicated obesity was defined according to the following parameters: no signs, symptoms and history of liver diseases (alcoholic hepatitis, viral hepatitis, positive serum hepatitis B surface antigen, positive serum hepatitis C surface antibody, auto-immune hepatitis, drug-induced hepatitis, familial metabolic disorders, history of fatty liver during pregnancy, portal hypertension, liver cancer, elevated serum transferrin

Abstract

AIM: To investigate retrospectively the clinical and endoscopic features of bleeding Dieulafoy's lesions and to assess the short- and long-term effectiveness of endoscopic treatment.

METHODS: Twenty-three patients who had gastrointestinal bleeding from Dieulafoy's lesions underwent endoscopic therapy. Demographic data, mode of presentation, risk factors for gastrointestinal bleeding, blood transfusion requirements, endoscopic findings, details of endoscopic therapy, recurrence of bleeding, and mortality rates were collected and analyzed retrospectively.

RESULTS: Hemostasis was attempted by dextrose 50% plus epinephrine in 10 patients, hemoclipping in 8 patients, heater probe in 2 patients and ethanolamine oleate in 2 patients. Comorbid conditions were present in 17 patients (74%). Overall permanent hemostasis was achieved in 18 patients (78%). Initial hemostasis was successful with no recurrent bleeding in patients treated with hemoclipping, heater probe or ethanolamine injection. In the group of patients who received dextrose 50% plus epinephrine injection treatment, four (40%) had recurrent bleeding and one (10%) had unsuccessful initial hemostasis. Of the four patients who had rebleeding, three had unsuccessful hemostasis with similar treatment. Surgical treatment was required in five patients (22%) owing to uncontrolled bleeding, recurrent bleeding with unsuccessful retreatment and inability to approach the lesion. One patient (4.3%) died of sepsis after operation during hospitalization. There were no side-effects related to endoscopic therapy. None of the patients in whom permanent hemostasis was achieved presented with rebleeding from Dieulafoy's lesion over a mean long-term follow-up of 29.8 mo.

CONCLUSION: Bleeding from Dieulafoy's lesions can be managed successfully by endoscopic methods, which should be regarded as the first choice. Endoscopic hemoclipping therapy is recommended for bleeding Dieulafoy's lesions.

INTRODUCTION

Dieulafoy's lesion was first described by Gallard in 1884 and later fully characterized by French surgeon George Dieulafoy in 1896, as an arterial lesion associated with massive gastric hemorrhage. It is described as a minute defect of the gastrointestinal mucosa with rupture of a large submucosal artery into the lumen. Although usually described in the stomach, Dieulafoy's lesions are also described in the rest of the gastrointestinal tract including esophagus[1-3], duodenum[4], small bowel[5], colon[6], rectum[7], and anus[8].

Until a few years ago, surgical treatment was advocated for such lesions because of the inability to recognize the lesion via endoscopy, or because of massive and recurrent bleeding. However, endoscopic therapy has recently become the treatment of choice by many endoscopists, being effective in the majority of cases[9]. The aim of our study was to assess the short- and long-term effectiveness of endoscopic treatment of Dieulafoy's lesions.

MATERIALS AND METHODS

Between January 1994 and December 2003, 936 patients with acute GI bleeding of non-variceal origin were admitted to our endoscopy unit. After resuscitation with intravenous fluids and blood transfusions, emergency endoscopy without preparation was performed within 24 h of the onset of bleeding, using standard video-endoscopes. If there was fresh blood or clots obscuring bleeding lesion, a lavage with a large bore tube (34F) for upper GI bleeding or rigorous

cleansing of the colon with polyethylene glycol solution was performed. ECG, blood pressure, and oxygen saturation were monitored. Twenty-three patients were diagnosed as having Dieulafoy's lesions.

The endoscopic diagnosis of Dieulafoy's lesions was based on the following established criteria: active arterial spurting or micropulsatile streaming from a minute (<3 mm) mucosal defect, visualization of a protruding vessel with or without active bleeding within a minute mucosal defect or normal surrounding mucosa or densely adherent clot with a narrow point of attachment to a minute mucosal defect or normal-appearing mucosa. To avoid possible inclusion of variceal bleeding at either the index episode of bleeding or an episode of recurrent bleeding, all patients with esophagogastric varices were excluded from the study. If Dieulafoy's lesion was diagnosed at emergency endoscopy according to the criteria outlined above, the choice of the endoscopic method of treatment was left to the endoscopist's discretion.

The therapeutic methods used in the first six years of our study were injection of a solution of dextrose 50% plus epinephrine (1:10 000) and ethanolamine oleate, while heater probe treatment and hemoclipping were used in the last 4 years. In the injection group, 1 mL aliquot was injected via a plastic cannula (23-gauge, 5-mm tip) into and around the Dieulafoy's lesion. A limit of 10 mL of mixture per endoscopic session was set. A 3.2 mm diameter heater probe set at 30 J/pulse was used to coat the bleeding vessel. Hemoclip therapy (HX-3L, 5LR-1; Olympus Optical Co., Ltd, Tokyo, Japan) was performed by mechanical clipping of spurting, oozing or visible vessels.

Therapeutic endoscopy was defined as successful if there was no further bleeding from the Dieulafoy's lesion until the withdrawal of the endoscope. After endoscopic treatment, the patients with Dieulafoy's lesion in the upper GI tract were treated with intravenous administration of a standard dose of PPIs. Follow-up endoscopy was performed within 24 h after the initial procedure and at least once within 5 d. Criteria for recurrent bleeding included fresh hematemesis or hematochezia, fresh blood aspirated through the nasogastric tube, instability of vital signs or a reduction of hemoglobin in excess of 30 g/L within 24 h after endoscopic hemostasis. When recurrent bleeding was suspected, immediate endoscopic retreatment was performed. If bleeding persisted after the second intervention, an operation was performed. In order to determine whether new bleeding episodes occurred after discharge, long-term follow-up was carried out by retrieving the medical records from the files, and when necessary by telephone calls to the patients. The patients who underwent surgery were not subjected to long-term follow-up.

Data including age, gender, comorbidities, mode of presentation, hemodynamic parameters, blood transfusion requirements before and after endoscopic therapy, risk factors for gastrointestinal bleeding (such as coagulopathy, use of aspirin or other non-steroidal anti-inflammatory drugs), endoscopic findings, details of endoscopic therapy, complications, recurrence of bleeding, and 30-d mortality were collected (Table 1).

Informed consent was obtained from the patients and/or their relatives. Because this study was a retrospective review, institutional review board approval was not necessary.

Student's *t*-test was utilized to compare the mean values of continuous variables and Fisher exact test was utilized for the comparison of discrete variables.

[illegible]

The study group consisted of 17 male (74%) and 6 female (26%) patients. The mean age was 70.26 years (range 42-84 years). There was a history of hypertension in nine patients, ischemic heart disease in four, heart failure in six, diabetes in two, gout in two, chronic renal failure in one, BII gastrectomy in two, duodenal ulcer in one, and aorto-iliac bypass in one (Table 1).

Melena was present in 11 patients (47.8%), hematemesis and melena in 9 (39%), and rectal bleeding in the remaining 3 patients (13.2%). Mean hemoglobin concentration was 101 g/L (normal 130-160 g/L). Blood transfusion requirements ranged from 1 to 8 U of packed RBC (mean 2.9 U per patient) during hospitalization. There was no significant difference with respect to coagulation parameters in patients who had recurrent bleeding and those who did not.

The Dieulafoy's lesions were located in the stomach in 18 patients (78%, fundus in 6, body in 9, and antrum in 3), in the colon in 3 (Figure 1), in the jejunum in 1 and in the descending duodenum in 1 (Table 1). Eleven patients (47.8%) had active bleeding (oozing in 7 and spurting in 4) at the initial endoscopy. In the remaining 12 patients (52.2%), a non-bleeding vessel was found (Table 1). In a 84-year-old patient with a medical history of heart failure and aorto-iliac bypass, endoscopy revealed two simultaneous Dieulafoy's lesions in the fundus, 2 cm apart. The initial endoscopy was diagnostic in 69% of patients. The mean number of endoscopies required for diagnosis was 1.7 (range 1-3). Failure to diagnose when the appropriate site was evaluated at endoscopy was due to excessive blood on 11 occasions (47.8%) and a missed lesion on 8 occasions (34.7%).

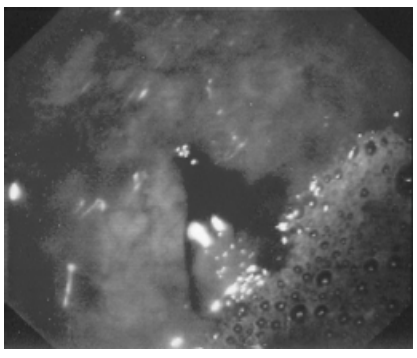

Figure 1 Endoscopic view of Dieulafoy's lesion with oozing in sigmoid.

Ten patients were treated with dextrose 50% plus epinephrine 1:10 000 injection. Mean injection volume was 7.6 mL (range 6-9 mL). Initial hemostasis was achieved in nine patients (90%), but four patients (44%) had rebleeding, which was successfully controlled at repeat endoscopy in one patient, but not in the other three using similar therapy,

Table 1 Clinical characteristics, endoscopic data, and after endoscopic therapy of patients with acute bleeding from Dieulafoy's lesion in GI tract

N	Sex	Age (yr)	Location	Bleeding symptom	Hb g/L	Transfusion (RBC)	Medical history	Endoscopic picture of bleeding	Type of therapy	Hemostasis	Rebleeding	Outcome

EPI, epinephrine solution 1:10 000.

and surgical intervention was required (Table 1). Four patients were treated with injection of ethanolamine oleate and the heater probe respectively, and permanent hemostasis was achieved on a single session (Table 1). The power settings for the heater probe were clearly stated in two patients (30 J in both) and the number of applications ranged from 6 to 8. Among the patients in the hemoclip group, the mean number of hemoclips used was 3.1 (range 2-4). Hemostasis was achieved at the initial endoscopic procedure by hemoclip (Figure 2) in all eight patients. Epinephrine plus normal saline (1:10 000) was used as an useful adjunct when the lesion was oozing or spurting, to slow or stop bleeding prior to hemoclip application or heater probe treatment. Five patients (22%) underwent surgery, four after unsuccessful endoscopic therapy and one because it was impossible to approach the lesion on the posterior wall of the patient's gastrectomized stomach. One patient (4.3%) died of sepsis and multiple organ failure in the postoperative period.

Endoscopic hemoclipping therapy was shown to be generally more effective than injection therapy in terms of the rates of permanent hemostasis (100% *vs* 66.6%, $P<0.01$), recurrent bleeding (0% *vs* 33.3%, $P<0.01$) and surgery (0% *vs* 33.3%, $P<0.01$, Table 2).

In the five patients, who underwent surgery, gastrotomy showed a muscular artery protruding from the mucosa but not ulceration, findings being consistent with Dieulafoy's lesion. Wedge resection was performed and histopathologic examination confirmed the presence of an abnormally large submucosal artery.

None of the patients presented with recurrent gastrointestinal bleeding from Dieulafoy's lesions during a mean long-term follow-up of 29.8 mo (range 2-120 mo). Seven patients died during the follow-up from causes unrelated to the Dieulafoy's lesions or endoscopic procedures.

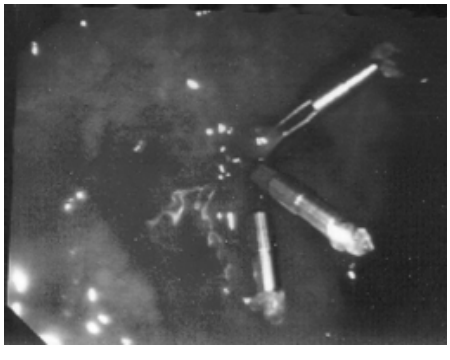

Figure 2 Endoscopic view showing complete closure of a minute mucosal defect with a protruding vessel with three hemoclips.

Table 2 Outcome of endoscopic therapy in injection and mechanical groups, *n* (%)

Parameters	Injection group	Mechanical group	*P*
Initial hemostasis	11 (92.5)	8 (100)	NS
Recurrent bleeding	4 (33.3)	0 (0)	<0.01
Permanent hemostasis	8 (66.6)	8 (100)	<0.01
Operation	4 (33.3)	0 (0)	<0.01

NS, non significant.

DISCUSSION

Dieulafoy's lesion is an uncommon cause of gastrointestinal bleeding, although some authors consider it as an under-recognized entity[1,9]. It is a disease of mainly aged and elderly males[10,11]. Our results with a mean age of 70.3 years and a more pronounced male predominance of 1:3 are consistent with former findings. Though the fact that they have been described in other parts of the gastrointestinal tract, Dieulafoy's lesions are located in the proximal stomach in more than three-fourths of patients[1,2]. Accordingly, in 78% of our patients the lesion was found in the stomach and in 39% in the classic site within 6 cm of the gastroesophageal junction. As in other reports, we identified Dieulafoy's lesions in the colon, jejunum and duodenum. Interestingly, one patient presented two simultaneous Dieulafoy's lesions in the gastric fundus.

The diagnostic yield of the first endoscopy varies from 63% to 92%[9]. Norton *et al*.[12], and Kasapidis *et al*.[13], found that a mean of 1.9 or 1.3 endoscopic sessions is required for diagnosis. In the present study, the diagnosis of Dieulafoy's lesion was established in 69% of patients during the first endoscopy, with a mean of 1.7 endoscopic sessions. A protruding vessel is found in 50% of patients and about two-thirds of patients manifest active bleeding, either as oozing or as spurting[10,11,14,15]. By contrast, in the present study the frequency of active bleeding was low (39%), with the majority of our patients having a non-bleeding visible vessel (61%), though the fact that the comorbid conditions and the mean age of our patients were consistent with former studies.

Some investigators have documented significant diseases in patients with Dieulafoy's lesion[5,10,16,17]. Comorbidity of cardiovascular diseases, diabetes, chronic renal failure and hypertension is present in almost 90% of patients with Dieulafoy's lesion[12]. In more than 40% of patients with Dieulafoy's lesion, the use of medication that influences blood coagulation has also been noted[12,16]. However, other studies have found no association of Dieulafoy's lesion with concomitant disease or the use of medications[14,18]. The results of the present investigation are consistent with the former studies. The significant comorbidity in 17 patients (74%) is likely a reflection of the elderly population studied, since any pathogenic significance remains speculative. Pathologic studies have failed to demonstrate atherosclerosis or aneurismal dilatation of the involved vessel[16,18].

Surgical wedge resection has been the standard treatment of Dieulafoy's lesions in the past[1]. However, its mortality rate is as high as 23%[1]. Since the late 1980s, a variety of endoscopic techniques have been used in the management of Dieulafoy's lesions. Endoscopic hemostatic methods could be divided into three groups: thermal, regional injection and mechanical[9,12,17,19,20]. Each method has both advantages and disadvantages related to the hemostatic mechanism and the technical procedure itself and varying results have been reported. The results of endoscopic hemostatic therapies depend on many and variable factors. The major factors include the level of expertise in performing the endoscopic procedure, coincident clinical risk factors, the use of advanced equipment and the inherent differences in various procedures.

All these factors influence the success of endoscopic outcome, but endoscopic modalities can achieve permanent hemostasis in approximately 95% of patients[9]. The overall lower rate of permanent hemostasis (78%) in our study was due to the low hemostatic effect (60%) of dextrose 50% plus epinephrine injection. It must be emphasized that the osmotic dehydrating and sclerosant effect of hypertonic glucose water (50%) has been reported[21] to be superior than a classic sclerosant agent, like sodium tetradecyl sulfate (15%), in controlling bleeding and rebleeding in patients with advanced liver cirrhosis and gastric variceal bleeding. Therefore, the low rate of hemostasis achieved in our study by dextrose 50% plus epinephrine cannot be explained. A careful search of the MEDLINE database from 1970 to 2003 did not retrieve any report of dextrose 50% plus epinephrine used in the treatment of Dieulafoy's lesions. Thus, the present study seems to be the first report on the use of dextrose 50% plus epinephrine as a therapeutic modality for Dieulafoy's lesions.

In the present investigation, none of the patients treated with heater probe coagulation or ethanolamine oleate injection developed recurrent bleeding. The mechanical method of hemoclips used in our study achieved complete hemostasis in 100% of patients. None of our patients treated with hemoclips had recurrent bleeding, while four patients (33.3%) in the injection group had recurrent bleeding ($P<0.01$, Table 2).

Although the number of patients in our study was small, we believe that the successful management especially by hemostatic clips (Table 2) favors a primary endoscopic approach to Dieulafoy's disease. It must be underscored, however, that an experienced endoscopist is necessary as a Dieulafoy's lesion can easily be overlooked or may be difficult to be approached, as was the case for one of our patients.

Hemoclips are mechanical devices, it must be argued that they cannot eradicate a Dieulafoy's lesion with a large caliber artery as effectively as sclerosant injections or thermal coagulation and that bleeding may recur after this type of treatment. However, in our study no patient had recurrent bleeding after hemoclip treatment during the follow-up period.

In conclusion, endoscopic therapy has become the treatment of choice for Dieulafoy's lesions and the endoscopic hemoclip treatment is effective and appears to be more successful in achieving hemostasis than injection treatment. More definite conclusions require further large controlled studies.

Abstract

AIM: Chronic constipation is a frequent finding in children. In this age range, the concomitant occurrence of megarectum is not uncommon. However, the definition of megarectum is variable, and a few data exist for Italy. We studied anorectal manometric variables and sensation in a group of constipated children with megarectum defined by radiologic criteria. Data from this group were compared with those obtained in a similar group of children with recurrent abdominal pain.

METHODS: Anorectal testing was carried out in both groups by standard manometric technique and rectal balloon expulsion test.

RESULTS: Megarectum patients displayed discrete abnormalities of anorectal variables and sensation with respect to controls. In particular, the pelvic floor function appeared to be impaired in most patients.

CONCLUSION: Constipated children with megarectum have abnormal anorectal function and sensation. These findings may be helpful for a better understanding of the pathophysiological basis of this condition.

INTRODUCTION

Chronic constipation is a frequently encountered symptom in children[1]. Due to a general belief that childhood constipation gradually disappears before or during puberty, this symptom is often underestimated and scarcely taken into consideration. However, recent evidence suggests that up to one-third of the constipated children followed beyond puberty continue to have severe complaints of constipation[2].

The definition of constipation in childhood is also less standardized than in adults; for the latter, in fact, the Rome II criteria[3,4] seem quite accepted and widespread whereas the criteria for children[5] are believed to be too restrictive, in that they might exclude several children with constipation[6].

For practical purposes, childhood constipation may be grossly divided into two groups, represented by functional fecal retention (FFR, most frequent) and slow transit constipation (STC), which also reflect the main pathophysiological abnormalities[7]. In fact, constipation in children is very rarely caused by a colonic motility disorder, as frequently found in adults[8]. Childhood constipation is mostly due to a maladaptive behavior triggered by an unpleasant defecation that in some subjects led to delay further defecation by withholding the stools. These patients, who were different than those with STC, have normal colonic motility[9].

In chronically constipated children with FFR, the abnormal motor activity is often found in the rectum, which may become so dilated that it is unable to generate enough pressure to propel the stools into the anal canal[9]. This megarectum is found in 30-100% of constipated children, depending on the definition used[10-14]. Thus, no uniform definition of megarectum for constipated children is available, it is unknown whether a large rectum is the result or the cause of constipation, and which underlying mechanism is responsible for fecal impaction[15].

Therefore, purpose of the present study was the assessment of chronically constipated pediatric patients with megarectum defined by radiologic criteria.

MATERIALS AND METHODS

Patients

Fifteen constipated children (11 males and 4 females, age 9±0.6 years) entered the study. Average duration of symptoms was 4 years (range 2-8 years). Patients were recruited when they met at least two of the following criteria[16,17]: (1) less than three defecations per week; (2) soiling and/or encopresis episodes more than twice per week; (3) passage of large amounts of feces once per 7-30 d; and (4) presence of a palpable rectal mass. Moreover, barium enema showed the presence of an enlarged rectum

(diameter more than 6.5 cm in the lateral view, as measured on a line extending perpendicular to S_2[18]) in all patients.

On physical examination, all patients had a large amount of soft stool that filled the rectum. Soiling, defined as the loss of a small amount of loose stool in the underwear[17], was present in 3 (13%) patients and encopresis, defined as the loss of a normal amount of stool in the underwear after the age of 4 years (without an underlying organic disorder)[17], was present in 13 (87%) patients. Before performing manometric and rectal compliance determination, a rectal disimpaction schedule was performed in all patients. This schedule consisted of oral osmotic laxatives (lactitol, 5 g/10 kg body weight in two divided daily doses) and tap water enemas given by the parents for a maximum of 7 d. The last enema was given at least 5 h before physiological assessment was done. Rectal digital examination was performed in all patients, to ascertain that an adequate rectal disimpaction was achieved.

Controls

The control group was represented by 12 children (nine males and three females, age 10±0.7 years) with recurrent abdominal pain (RAP) and without rectal fecal impaction. These patients were recruited on the basis of Rome II criteria for RAP[5]: at least 12 wk of: (1) continuous or nearly continuous abdominal pain in a school-aged child or adolescent; and (2) no or only occasional relation of pain with physiological events (e.g., eating, menses, or defecation); and (3) some loss of daily functions; and (4) the pain is not feigned (e.g., malingering); and (5) the patient had insufficient criteria for other functional gastrointestinal disorders that would explain the abdominal pain. All controls had at least one bowel movement per day, and they did not meet the criteria for constipation as defined above.

Methods

Anorectal manometry and tests of rectal compliance were carried out according to a standard technique. Briefly, a commercially available four-lumen pediatric anorectal catheter with terminal balloon (Menfis bioMedica, Bologna, Italy, type 5R-9-100CB), connected via physiological pressure transducers to a low-compliance infusion pump and to a computerized recording system (Dyno Compact System, Menfis) was used.

After recording the rectoanal pressure profile with stepwise withdrawal (1 cm/30 s), the anal resting tone was recorded for 2-5 min with the catheter fixed at the highest pressure point obtained during two pull-throughs. Then, the rectosphincteric reflex was evaluated by inflating and rapidly deflating the catheter balloon with 10, 20, 30, 50, and 100 mL of air. Finally, the sphincteric response to straining was assessed by asking the patients to strain as if to defecate thrice at 1-min intervals.

To test rectal compliance and sensation, a single-lumen PVC catheter (outer diameter 4 mm) with a 7-cm-long cut terminal unstretched condom was used, connected to the above-mentioned pressure transducer and recorder, as previously described[19]. The balloon was placed with its distal portion about 5 cm from the anal margin and, through a syringe equipped with a three-channel stopcock, inflated with 50 mL of air increments every 60 s until the maximum rectal tolerable volume (MRTV) was reached. Rectal expulsion ability was assessed, with the patient lying on the left side, by inserting a well-lubricated Foley catheter in the rectum, then filling it with 50 mL of water and asking the patient to defecate it[20].

Ethical considerations

After careful explanations about the aims of the study, the parents of the children gave written informed consent, and the studies were carried out in accordance with local ethical guidelines, following the recommendations of the Declaration of Helsinki.

Data analysis

All tracings were analyzed in blind by one of the investigators. For anorectal manometry and test of rectal compliance and sensation, the following variables were taken into account[19,21]: (1) maximum basal pressure of the internal anal sphincter, defined as the mean of the highest resting pressures recorded from each of the four ports during the two pull-throughs[19,21,22]; (2) minimum relaxation volume (MRV), defined as the lower quantity of air inflated in the rectal balloon necessary to elicit the rectoanal inhibitory reflex, a drop in pressure >5 mmHg, which represents relaxation of the internal sphincter[23,24]; (3) defecatory sensation threshold (DST), defined as the smallest volume at which the first desire to defecate was reported by the patient[25,26]; (4) response to straining, evaluated by observing whether straining to defecate caused a decrease in intra-anal pressure (normal response) or a paradoxical increase in intra-anal pressure[27]; (5) MRTV, defined as the maximum volume of air that could be infused into the rectal balloon and responsible either for an intolerable urge to defecate, painful distension, or expulsion of the balloon itself[11]; (6) rectal compliance, defined as the intraballoon pressure at 100 mL when inflated intrarectally minus the intraballoon pressure at 100 mL when inflated in open air[28,29]; and (7) rectal expulsion. Without any time limitation, the test was considered abnormal when the patient was not able to expel the balloon (Foley catheter filled with 50 mL of water) and refused further straining attempts.

Statistical analysis

The Kolmogorov-Smirnov test for normality was applied, and showed that the data were not normally distributed. Therefore, comparisons of data between controls and patients were done by means of nonparametric tests. The Wilcoxon rank sum test (two-tailed) and the χ^2 test were applied, where necessary. Values of P less than 0.05 were chosen for rejection of the null hypothesis. Data are expressed as mean±SE.

RESULTS

No differences between groups were found concerning age (9.6±0.7 years in controls *vs* 9.5±0.6 years in patients, $P = 0.10$). Soiling and/or encopresis was found in none of the controls and in 13/15 (87%) patients ($P<0.0001$). Analysis of anorectal physiological variables showed that

the maximum basal pressure of the anal sphincter was significantly higher in controls with respect to the patients (58±3.4 *vs* 31±3 mmHg, $P<0.001$), whereas the MRV was lower in controls (13.3±1.4 *vs* 39±5.3 mmHg, $P<0.001$). Concerning the DST, this was found to be significantly lower in controls compared to that found in megarectum patients (54±4 mmHg *vs* 130±27 mmHg, $P<0.01$). As expected, controls displayed lower values of MRTV compared to the megarectum patients (171±11 mL *vs* 523±68 mL, $P<0.001$) and higher compliance values (18±1.3 mmHg *vs* 10.5±2 mmHg, $P<0.02$).

The response to straining was abnormal in 1/12 (8.3%) controls and in 9/15 (60%) patients ($P = 0.017$); the rectal expulsion test was abnormal in 1/12 (8.3%) controls and in 15/15 (100%) patients ($P<0.0001$).

DISCUSSION

The term megarectum is frequently employed in children with constipation or fecal impaction without any quantification measure, and there are only a few data obtained in groups with more objective definitions[17]. In the present study, we adopted a validated radiological definition, at least for adults and adolescents: the limit of this definition is due to the fact that lesser degrees of megarectum in the pediatric population may have been excluded. However, we had a well-defined group of patients with objective criteria, and we feel that this is important since to the best of our knowledge there are no such reports from Italy.

The comparison of anorectal parameters between patients and controls showed significant abnormalities in the former that displayed lower basal pressures of the anal sphincter and compliance values, whereas higher values were found for MRV, DST, and MRTV. In addition, most megarectum patients had clinical and instrumental evidence of abnormal pelvic floor function.

These results are in agreement with some previous studies[11,30-33], where others were not able to find such differences[16,17,34]. We are at present unable to explain such discrepancies, although patients' selection, severity of symptoms, and assessment methods may be responsible for these differences between studies.

We feel of interest that this group of children with megarectum shares anorectal abnormalities similar to those we found in adult patients with megarectum[19]. In this rather homogeneous group of pediatric patients, the findings seem consistent with similar mechanisms proposed for adults, i.e. that megarectum may be a mechanism for constipation by outlet obstruction[35], as shown by the impairment of anorectal dynamics in such patients. The rectal function, in fact, seems to be severely deranged, as shown by the MRTV recorded in these children, due to an atonic rectum that sometimes adapted to masses of over 800 mL, too large to be defecated. The MRV and rectal sensation were also impaired, with some of the patients needing higher volumes to relax the sphincter and feeling the defecatory stimulus only at high volumes of distension, thereby enforcing the mechanisms leading to further dilatation of the rectal ampulla.

The clinical significance of a dyssynergic phenomenon in these patients is unclear. Previous studies have proposed this phenomenon as one of the main causes of impaired rectal expulsion in megarectum and megacolon patients[36], but other studies have challenged this hypothesis, since rectal emptying may happen against a contracting pelvic floor[37,38]. However, since fecal consistency is likely to influence the efficiency of rectal emptying[39,40], it is possible that the presence of large, hard stools in a megarectum may elicit a dyssynergic pattern.

In conclusion, we described a group of constipated children with well-defined megarectum, and showed that these patients display important abnormalities of anorectal variables and sensation. We feel these findings may be of some interest for a better understanding of the pathophysiological mechanisms of this condition and, possibly, for a more targeted therapeutic approach.

Abstract

AIM: Clinical and experimental data suggest that gut-derived endotoxins are an important pathogenic factors for progression of chronic liver disease. Recently, a C-T (-159) polymorphism in the promoter region of the CD14 gene was detected and found to confer increased CD14 expression and to be associated with advanced alcoholic liver damage. Here, we investigated this polymorphism in patients with less advanced alcoholic liver disease (ALD) and chronic hepatitis C virus (HCV) infection.

METHODS: CD14 genotyping was performed by PCR-RFLP analysis in (a) 121 HCV patients, (b) 62 patients with alcohol-associated cirrhosis (Alc-Ci), (c) 118 individuals with heavy alcohol abuse without evidence of advanced liver damage (Alc-w/o Ci), and (d) 247 healthy controls. Furthermore, serum levels of soluble CD14 (sCD14) and transaminases were determined.

RESULTS: The TT genotype was significantly more frequent in Alc-Ci compared to Alc-w/o Ci or controls (40.3% *vs* 23.7% or 24.0%, respectively). In Alc-w/o Ci, serum levels of transaminases did not differ significantly between patients with different CD14 genotypes. In HCV patients, TT-homozygotes had significantly higher sCD14 levels and sCD14 serum levels were significantly higher in patients with advanced fibrosis or cirrhosis. However, no association was found between CD14 genotypes and histological staging or grading.

CONCLUSION: Considering serum transaminases as surrogate markers for alcoholic liver damage, the CD14 polymorphism seems to exhibit different effects during the course of ALD. Differences in genotype distribution between cirrhotic HCV patients and alcoholics and the known functional impact of this polymorphism on CD14 expression levels further indicate differences in the pathophysiological role of CD14 and CD14-mediated lipopolysaccharides signal transduction with regard to the stage as well as the type of the underlying liver disease.

INTRODUCTION

Individuals affected by chronic liver disease show a broad spectrum of responses to the same etiologic agent. As one cause for this finding and increasing evidence indicates that genetic factors influence the natural history of chronic liver disease[1].

In case of alcoholic liver disease (ALD), early studies have focused on polymorphic forms of enzymes involved in alcohol metabolism[2-4]. Recent studies have shown that genetically determined variations in the inflammatory response contribute to different susceptibility for the development of various liver diseases, notably viral hepatitis[5,6] and ALD[7-10]. These findings together with accumulating clinical and experimental data indicate that the extent of the inflammatory response to the etiological agent is crucial in the pathogenesis of chronic hepatitis C virus (HCV) as well as alcoholic and other liver disease.

Several lines of evidence indicate that bacterial products, primarily endotoxins (lipopolysaccharides; LPS) induce and perpetuate hepatic inflammation. Endotoxin levels are correlated with the severity of ALD in experimental models[11] as well as in patients with chronic liver disease[12], and reducing gut endotoxin alleviates hepatic injury[13]. Endogenous LPS are constitutively produced within the gut by the death of Gram-negative bacteria and are absorbed into intestinal capillaries. In low concentrations, LPS can also be demonstrated in the portal venous blood in healthy

humans[14].

Increased LPS levels have been shown in patients with ALD as well as patients with chronic hepatitis C infection[12,15-17]. Several factors promote endotoxemia in this setting, including increased translocation of endotoxins and reduced hepatic clearance[11,18].

Circulating endotoxin is bound mainly to the LPS binding protein. This complex has a high affinity for the CD14 receptor[19]. CD14 is expressed on mature monocytes and macrophages, such as Kupffer cells[20,21]. Furthermore, hepatocytes as well as activated hepatic stellate cells (HSC) get stimulated by LPS via membrane-bound CD14[20,23].

A soluble CD14 (sCD14) is constitutively present in the circulation, and is apparently derived both from secretion of CD14 and from enzymatically cleaved glycosylphosphatidylinositol-anchored tissue CD14[24,25]. sCD14 is believed to play a key role as an intermediate in the neutralization of LPS under physiological conditions. sCD14 accelerates the transfer between LPS micelles and lipoproteins by acting as a carrier. sCD14 also enhances the release of monocyte-bound LPS, transferring LPS into plasma and into lipoproteins[26]. This results in a decreased cellular response to LPS, such as induction of TNF and interleukin-6 synthesis[27].

Recently, a polymorphism of the CD14 gene (C-T transition at bp -159 from the major transcription start site) was described. This polymorphism is located within the Sp1 transcription factor binding site, known to affect CD14 expression. The T allele promotes CD14 gene transcription as shown in *in vitro* on monocytes[28,29].

Functional relevance of the polymorphism has been suggested in several studies finding an association with myocardial infarction[29,30], ulcerative colitis[31], asthma[32], and chronic spondyloarthropathy[33]. Notably, all these diseases have an inflammatory component.

Recently, Järveläinen *et al*., investigated the frequency of this CD14 polymorphism in autopsy series of Finnish patients with ALD[34]. Interestingly, the T allele was associated with advanced ALD, especially with cirrhosis, but not with steatosis or less advanced stages of fibrosis. A subsequent analysis of a relatively small cohort of 30 patients with primary biliary cirrhosis revealed no significant association of the CD14 polymorphism with the severity of the disease and found no differences in the genotype distribution as compared to healthy controls[35]. Poullis *et al*., analyzed the effect of the CD14 polymorphism on liver function tests and found some evidence indicating that the TT genotype, associated with higher serum levels of sCD14, may offer protection from the development of fatty liver disease[36]. This hypothesis is supported by recent studies indicating an association between sCD14 levels and insulin sensitivity[37,38].

As in ALD in HCV patients, elevated serum levels of endotoxin as well as sCD14 have been reported[12,16,39] but the C-T (-159) promotor polymorphism of the CD14 gene had not been investigated in this group of patients so far.

Here we analyzed the association of this CD14 polymorphism with the histological stage of fibrosis and the grade of inflammation in hepatic tissue of HCV patients, and their corresponding sCD14 serum levels, respectively.

Furthermore, the aim of this study was to verify the association of the CD14 polymorphism with the degree of alcoholic liver damage, previously found in the Finnish study[35], in our cohort of patients with ALD from southern Germany.

[illegible]

Patients and controls

The following groups of patients were studied retrospectively: (a) 121 patients (80 males and 41 females; mean age: 37.2±11.5 years) with chronic hepatitis C (positive for HCV-RNA and anti-HCV) consecutively admitted to the medical department of the University of Regensburg. All patients were negative for hepatitis B surface antigen or antibodies to HIV and none of them had evidence of other types of liver disease. Risk factors for acquisition of hepatitis C infection were previous intravenous drug abuse in 25.6%, receipt of blood or blood products before the introduction of donor screening in 15.7%, and other factors or unknown in 58.7%. Liver biopsies were obtained from all patients before initiation of antiviral therapy (naive patients) by percutaneous Menghini-needle biopsy. In these patients fibrosis and inflammation were graded and staged numerically according to a score proposed by Desmet *et al*.[40], by a single pathologist.

The majority of patients received treatment with interferon-α+ribavirin. For 91 patients, data of qualitative HCV-PCR analysis 3 mo after initiation of antiviral therapy were available.

(b) sixty-two patients with alcoholic cirrhosis consecutively admitted to the medical department of the University of Regensburg (49 males and 13 females; mean age: 53.1±8.9 years). Patients were considered to have alcohol-related cirrhosis, if alcohol intake had been in excess of 100 g/d for more than 10 years and if testing for viral, metabolic, and immune etiologies was negative. Liver cirrhosis was diagnosed based on typical clinical, laboratory, ultrasound, and gastroscopical findings.

(c) one hundred and eighteen heavy drinkers without evidence of liver damage (90 males and 28 females; mean age: 42.5±9.1 years). These unrelated individuals of German descent were recruited from an in-patient abstention program at the Department of Psychiatry of the University of Regensburg. Each subject met the criteria of alcohol dependence according to ICD-10[41]. At the day of admission, several serum parameters were analyzed including transaminases (alanine aminotransferase [ALT], AST, and γ-glutamyl transferase [γ-GT]), and anti-HCV- and HBV-antibodies. Previous and current drinking habits, as well as family history of non-ALDs, and potential previous complications of advanced liver damages as ascites or esophageal varices were examined. Furthermore, within 14 d after admission, a clinical and ultrasound examination of the abdomen was performed.

Only alcohol-dependent subjects with an alcohol consumption of at least 80 g/d for more than 5 years were included. Furthermore, clinical or sonomorphological indications for advanced liver damage and serological evidence of HBV or HCV infection were exclusion criteria.

(d)two hundred and forty seven healthy subjects (119

females and 128 males), genotyped already in a previous study[42], served as controls.

Patients and controls were Caucasians and their geographical origin was southern Germany. Informed consent was obtained from all patients and the study was approved by the local ethics committee.

DNA isolation and CD14 genotyping

Genomic DNA specimens were prepared from 200 μL blood using the QIAamp blood kit following the manufacturer's instructions (Qiagen, Hilden, Germany). The C-T polymorphisms at position -159 of the CD14 gene was analyzed by performing PCR and subsequent restriction fragment length polymorphism analysis. PCR was performed under standard conditions (35 cycles, annealing temperature: 55 ℃) in a total reaction volume of 50 μL containing 2 μL of diluted genomic DNA, using the following pair of primers: forward: 5'-CCG AGA TGT TCC CAG CAC AG-3' and reverse: 5'-CTG CTT TGC TTG TGC CTC TT-3'. PCR products were digested by *Hae*III, and the resulting fragments were separated by electrophoresis in a 2% agarose gel and visualized by ethidium bromide staining. With the -159 T polymorphic base, the recognition sequence 5'-GG/CC-3' is modified to 5'-GG/TC-3', which is not cut by *Hae*III.

Serum sCD14 levels

sCD14 concentrations were analyzed in the serum of 97 patients with chronic hepatitis C infection using a sandwich ELISA following the instructor's manual (Biosource Europe, Nivelles, Belgium).

Statistical analysis

Results are expressed as mean±SD (range), median, or percent. Genotype frequencies are reported with their group percentages. Comparisons between clinical subgroups were made using the Student's unpaired *t*-test. A two-sided χ^2 test was used for comparison of qualitative variables. A P value <0.05 was considered statistically significant.

All computations were performed by using the SPSS-10 for Windows statistical computer package (SSPS, Inc., Chicago, IL, USA).

RESULTS

CD14 genotype frequency in patients with chronic alcohol abuse and controls

Initially, we wanted to confirm the finding of the previous Finnish study by Järveläinen *et al*., indicating higher prevalence of the C-159T promotor polymorphism of the CD14 endotoxin receptor in patients with advanced ALD[34].

CD14 genotyping was performed in patients with chronic alcohol abuse and liver cirrhosis (n = 62), or without clinical or sonomorphological signs of liver cirrhosis (n = 118), respectively. Furthermore, 247 healthy controls were genotyped. Results are summarized in Table 1.

Distribution of the individual genotypes in the control group (CC: 64/247 [25.6%], CT 128/247 [51.8%], and TT: 55/247 [22.3%]) was similar as in cohorts of other healthy individuals in previous reports[36,43,44].

Frequency of the C-159T polymorphism did not differ significantly between alcoholics without cirrhosis and controls. However, in accordance to the study by Järveläinen *et al*.[34], the TT genotype was significantly more frequent in alcoholics with cirrhosis (40.3%), compared to alcoholics without cirrhosis (23.7%; P = 0.020) and controls (22.3%; P = 0.006), respectively.

Comparison of ALT and AST levels between TT-homozygotes and alcoholics with genotype CC or CT revealed no significant differences (42.0±61.0 U/L *vs* 33.6±33.8 U/L, and 34.9±27.9 U/L *vs* 28.2±28 U/L, respectively).

Table 1 Frequency of (-159) CD14 genotypes (%) in patients with chronic alcohol abuse and cirrhosis, compared to alcoholics without clinical or sonomorphological signs of cirrhosis and controls

	CD14 genotype frequency		
	CC	CT	TT
Alcoholics with cirrhosis (n = 62)	5 (8.1%)	32 (51.6%)	25 (40.3%)
Alcoholics w/o cirrhosis (n = 118)	32 (27.1%)	58 (49.2%)	28 (23.7%)
Controls (n = 247)	64 (25.6%)	128 (51.8%)	55 (22.3%)

CD14 genotype frequency in patients with chronic hepatitis C infection

Next we wanted to analyze the frequency of the C-159T CD14 polymorphism in patients with a different etiology of chronic liver disease. Genotyping of 121 patients with chronic hepatitis C infection revealed no significant differences compared to healthy controls (CC: 26/121 [21.5%], CT: 66/121 [54.5%], and TT: 29/121 [24.0%]).

Comparing TT-homozygote HCV patients and HCV patients with genotype CC or CT we found no differences in demographic features such as age (38.0±12.3 years *vs* 37.1±11.4 years) and distribution of sexes (58.6% *vs* 68.5% males), and in the frequencies of potential routes of HCV infection (24.1% *vs* 26.1% i.v. drug users; 17.2% *vs* 15.2% recipients of blood transfusions), serum HCV-RNA levels (2.0×10^6 copies/mL *vs* 1.6×10^6 copies/mL) or frequencies of different HCV-genotypes (58.7% *vs* 66.3% type 1; 34.5% *vs* 25.0% type 2, Table 2). The number of initial virological responders to interferon therapy (no HCV-RNA detectable in the serum, 3 mo after initiation of therapy) did not differ between the genotypes (14/21 [66.7%] *vs* 46/70 [65.7%]).

Moreover and in contrast to patients with chronic alcohol abuse, frequency of TT-homozygotes did not differ between HCV patients with different severity of liver damage (Figure 1). TT-homozygotes were similarly frequent in patients with no or only mild, periportal fibrosis (staging 1 or 2) and HCV patients with more advanced septal fibrosis or cirrhosis (staging 3 or 4), respectively (20/85 [23.5%] *vs* 9/36 [25.5%], respectively).

The frequency of the CD14 genotypes was similar in HCV patients with mild or only minimal hepatic inflammation (grading 1 or 2) and patients with more severe hepatic inflammation or necrosis (grading >2): 14/63 [22.2%] *vs* 15/58 [25.9%], respectively. As in patients with chronic alcohol abuse, the comparison of ALT and AST levels between TT-homozygotes and hepatitis C patients with

genotype CC or CT revealed no significant differences (80.4±65.3 U/L *vs* 80.2±78.1 U/L, and 33.9±20.7 U/L *vs* 36.1±28.7 U/L, respectively).

Table 2 Clinical and biological characteristics of 121 patients with chronic hepatitis C infection according to CD14 –159 genotypes (TT *vs* CC and CT)

Clinical and biological characteristics	All patients	CD14 -159 genotype	
		TT	CC or CT
Age (yr; mean±SD)	37.2±11.5	38.0±12.3	37.1±11.4
Male gender (%)	66.1	58.6	68.5
HCV transmission route (%)			
- i.v. drug use	25.6	24.1	26.1
- Post-transfusion	15.7	17.2	15.2
- Other factors or unknown	58.7	58.6	58.7
HCV genotypes (%)			
- Type 1	64.5	58.7	66.3
- Type 3	27.3	34.5	25.0
- Others than type 1 or 3	8.3	6.9	8.7
Viral load			
(10^6 copies/mL; median)	1.7	2.0	1.6
Initial virological response to anti-HCV treatment[1] (%)	65.9	66.7	65.7

[1]HCV-RNA negative, 3 mo after the start of antiviral therapy; data available from 91/121 patients.

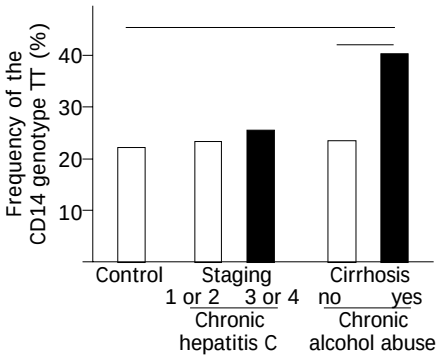

Figure 1 Frequency of the TT genotype at position -159 of the CD14 gene in patients with chronic hepatitis C infection, chronic alcohol abuse, and controls. The TT genotype was significantly more frequent in alcoholics with cirrhosis (25/62; [40.3%]), compared to alcoholics without clinical or sonomorphological signs of cirrhosis (28/118; [23.7%]; $P = 0.020$) and controls (55/247 [22.3%]; $P = 0.006$). In contrast, in HCV patients with no or only mild fibrosis (stage 1 or 2) and patients with prominent fibrosis or cirrhosis (stage 3 or 4) the frequency of the TT genotype was not significantly different (20/85 [23.5%] *vs* 9/36 [25.5%]).

Soluble CD14 serum levels in patients with chronic hepatitis C infection

It has been reported that sCD14 levels were elevated in patients with chronic liver disease[39]. Furthermore, studies investigating sCD14 levels in children recruited from a general population sample or in patients with ulcerative colitis found an association between sCD14 serum levels and CD14 -159 genotypes[28,31].

Therefore, we investigated sCD14 levels in the serum of 87 patients with chronic hepatitis C infection. Mean serum CD14 levels (3.8±0.4 μg/mL) were comparable to previous studies analyzing serum of patients with chronic liver disease[39].

HCV patients with no or only mild, periportal fibrosis, had significantly lower sCD14 serum levels than HCV patients with more advanced septal fibrosis or cirrhosis, respectively (3.5±0.4 μg/mL *vs* 3.8±0.9 μg/mL; $P = 0.004$).

Moreover, TT-homozygote HCV patients ($n = 20$) had significantly higher sCD14 serum levels than HCV patients with -159 CD14 genotype CT or TT ($n = 77$), respectively (3.5±0.4 μg/mL *vs* 3.7±0.7 μg/mL; $P = 0.012$, Figure 2).

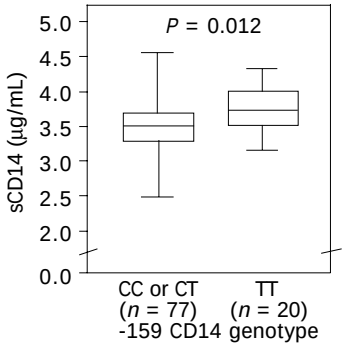

Figure 2 Serum levels of sCD14 comparing TT-homozygote HCV patients and patients with genotypes CC or CT, respectively. Box plots illustrate median values and interquartile distance.

[illegible]

There is a remarkable variation in the course of chronic liver disease in different patients. Recent studies suggest that the natural history of chronic liver disease is influenced by a number of gene polymorphism[1]. These genetic factors could explain the broad spectrum of response of the same etiologic agent seen in these individuals.

Recently, the C-T (-159) polymorphism in the promotor region of the CD14 gene was identified as a risk factor for the development of alcoholic liver cirrhosis in the Finnish population based on autopsy series[34]. The Finnish population has a limited number of founders and is characterized by national and regional isolation[45,46].

The first aim of our study was to re-evaluate the results of this previous study in a cohort of patients with chronic alcohol abuse from southern Germany.

In line with the previous Finnish study[35], the -159 CD14 genotype TT was significantly more frequent in patients with alcoholic liver cirrhosis compared to healthy controls or alcohol-dependent subjects without evidence of advanced liver damage.

Interestingly, serum aminotransferase levels did not vary significantly between patients with different genotypes in the group of alcoholics without evidence of advanced liver damage. Considering serum levels of aminotransferases as surrogate markers for hepatocellular damage, our data are in line with those of Järveläinen *et al*., who also could not find an association between the -159 genotypes and histological steatosis or less advanced stages of fibrosis, respectively[34]. Taken together, these findings indicate that the functional CD14 polymorphism and the associated CD14 expression, respectively, may exhibit different effects during the course of ALD.

On one hand, the CD14 polymorphism has been shown

to affect expression levels of membrane-bound CD14[28,44]. Higher expression levels of membrane-bound CD14 predispose hepatic cells for higher cytokine expression in response to endotoxins and cause increased inflammatory activity[23,47].

On the other hand, the CD14 polymorphism plays a significant role in regulating serum levels of sCD14 as TT-homozygotes have raised levels of sCD14[28,31]. Increased sCD14 can decrease the inflammatory response of monocytes to endotoxin by enhanced clearance[26]. Furthermore, a strong correlation between sCD14 and the endotoxin neutralizing capacity of plasma has been shown[48].

Increased expression of sCD14 in TT-homozygotes may lead to enhanced clearance of portal endotoxin and subsequently low-grade hepatic stimulation. In line with this hypothesis, Poullis *et al*., found the TT polymorphism to be associated with significantly reduced serum levels of ALT and γ-GT[36]. Similarly, Fernandez-Real *et al*., reported an inverse correlation between serum levels of sCD14 and ALT in individuals without known liver disease during routine-checkup visits[38].

These data indicate that the CD14 polymorphism seems to affect two mechanisms with opposite effects on hepatic inflammation by regulating the expression of membrane bound as well as sCD14. During the course of ALD the relative pathophysiological impact of each of these two mechanisms may vary.

Interestingly, there is an association between CD14 expression and the degree of fibrosis[49], and CD14 is *de novo* expressed on HSC during their activation process[23]. These cells are present in acute as well as chronically diseased livers, and there is a positive correlation between the degree of fibrosis and the accumulation of activated HSC[50,51]. Activated HSC synthesize and secrete excessive ECM molecules. In addition, it is recognized that they also play an important role in hepatic inflammation[52], and LPS-mediated NF-κB activation in HSC increases their resistance to apoptosis[23]. Therefore, with progressing liver damage and fibrosis, the number as well as type of CD14-expressing cells varies leading to differences in the LPS effects and CD14-mediated signal transduction.

In summary, the balance between potentially anti-inflammatory effects of sCD14 and proinflammatory effects of mCD14 may shift toward mCD14 during progression of ALD.

This imbalance may be further enhanced by higher endotoxin levels in patients with severe liver damage[11,16,17]. High LPS levels in more advanced liver damage may saturate the scavenger effects of sCD14. Furthermore, higher LPS levels promote hepatic inflammation leading to increased SP1-binding activity[53]. Since the -159 CD14 promotor polymorphism potentially affects binding of the transcription factor SP-1, high LPS levels in more advanced liver disease might promote CD14 expression particularly in carriers of the T-allele.

In summary, this hypothesis could explain that TT genotype promotes fibrosis in late stages of ALD, while in earlier stages pro- and anti-inflammatory mechanisms may be in balance regardless of the genotype.

The second aim of this study was to investigate the role of the -159 CD14 promotor polymorphism in HCV patients.

TT-homozygote HCV patients had significantly higher sCD14 serum levels than HCV patients with -159 CD14 genotype CT or TT, respectively. Moreover, HCV patients with advanced liver fibrosis or cirrhosis had significantly higher sCD14 levels than patients with less advanced stages of liver fibrosis. Similarly, a correlation between sCD14 levels and hepatic fibrosis has been shown previously in patients with ALD[39]. However, in contrast to patients with ALD, liver cirrhosis was not associated with the TT-homozygous state in patients with chronic hepatitis C infection. These findings indicate that the functional CD14 polymorphism and the expression of CD14 may exhibit different effects during the course of ALD and chronic HCV infection.

One explanation for this finding could be different expression patterns of membrane bound and sCD14, respectively, depending on the underlying cause of chronic liver disease. Furthermore, pathophysiological mechanism of viral and ALD may be differently affected by endotoxins, binding of sCD14 or CD14-mediated signal transduction.

It is known that sCD14 reveals inhibitory action on lymphocyte function[54,55]. Hepatic inflammation in HCV patients is characterized by lymphocyte infiltration while in alcoholic hepatitis there is a predominant infiltration with neutrophils. Furthermore, endotoxemia has been shown to exaggerate hepatic inflammation in murine viral infections[56,57] and to be associated with the response to antiviral therapy in HCV patients[58].

The origin of endotoxemia in HCV patients seems to be multifactorial, likely depending on impaired phagocytic functions and reduced T-cell-mediated antibacterial activity[57]. Furthermore, one cannot exclude the passage of LPS from the gut flora to the blood stream, condition owing to altered intestinal permeability, similar as shown in models of ALD[11,18]. In patients with alcoholic cirrhosis, the mean endotoxin concentration was significantly higher than in patients with non-alcoholic cirrhosis and higher endotoxin concentrations were more frequently observed in patients with alcoholic cirrhosis[12]. Therefore, it may be speculated that different LPS levels in patients with ALD and patients with chronic HCV infection may indirectly account for varying pathophysiological effects of CD14-mediated signal transduction.

There are several studies indicating that alcohol potentiates the proinflammatory effects of endotoxins in hepatic diseases. Peripheral blood mononuclear cells or purified monocytes from patients with alcoholic liver cirrhosis, stimulated *in vitro* with LPS, displayed a marked increase of proinflammatory cytokines compared with healthy controls[59]. Furthermore, alcohol was shown to increase the expression of CD14 on Kupffer cells and subsequently increased their responsiveness to endotoxins[60,61]. Interestingly, elegant studies by Järveläinen *et al*., in an animal model indicate that the synergistic effect of endotoxins and alcohol may vary depending on the time of exposure[62].

Finally, as for most genetic association studies, it has to be considered that the single nucleotide polymorphism investigated is in linkage disequilibrium to a different disease-associated genetic variation. Theoretically, this

potential genetic variation may affect particularly the pathophysiology of alcoholics but not viral liver disease. However, the functional relevance of the CD14/-159 polymorphism demonstrated in several studies and the important role of LPS and CD14 signaling in the pathophysiology of chronic liver disease clearly argue against this hypothesis.

In summary, comparison of the frequency of the -159 CD14 genotypes revealed significant differences between the two etiologies of liver diseases investigated in this study. In ALD, the impact of the -159 CD14 polymorphism may vary during the course of the disease, potentially via varying effects of soluble and membrane-bound forms of CD14. It will be interesting to elucidate the importance of this CD14 polymorphism in patients with other underlying liver diseases as non alcoholic fatty or autoimmune liver disease. These studies could potentially lead to therapeutic or prevention strategies selectively for those subgroups of patients that are particularly prone for the pathophysiological effects of gut-derived endotoxins.

ABSTRACT

AIM: To study the prevalence and clinical significance of hyperhomocysteinemia (hHcys), an independent factor for arterial and venous thrombosis, in a group of patients with ulcerative colitis (UC).

METHODS: Fasting homocysteine (Hcys), folate, and vitamin B_{12} serum levels were measured in 40 UC patients and 50 healthy controls. Clinical data regarding UC were gathered.

RESULTS: Median serum Hcys levels in UC patients were similar to those in controls (12.26 μmol/L *vs* 12.32 μmol/L), but the prevalence of hHcys was higher in UC patients than in controls (30% *vs* 10%, $P = 0.028$). UC significantly increased the risk of hHcys (adjusted odds ratio: 4.125; 95%CI: 1.26-13.44). Multivariate regression analysis showed that male sex, folate and vitamin B_{12} deficiency or lower serum values were significant independent predictors of higher Hcys levels in UC patients ($r^2 = 0.4$; $P<0.001$).

CONCLUSION: hHcys is common in UC patients and it is related to folate and vitamin B_{12} deficiency or lower serum values. It would be reasonable for patients with UC to receive folate and vitamin B complex supplements as a prophylactic measure.

INTRODUCTION

The risk for thromboembolic complications is increased in patients with inflammatory bowel disease (IBD). The incidence of arterial and venous thromboembolic disease in patients with ulcerative colitis (UC) and Crohn's disease (CD) has been reported between 1% and 8%[1,2], rising to an incidence of 39% in some autopsy studies[3]. Several studies have shown that a hypercoagulable state involving all components of clotting system exists in IBD[4-6]. This hypercoagulable state may be related to an increased tendency for thromboembolic events and may be linked to the disease pathogenesis through promoting microthrombi formation in intestinal microcirculation[7,8]. The etiology and pathogenesis of the hypercoagulable state in IBD have not been fully elucidated but may be induced through a procoagulant effect of proinflammatory cytokines[9-13] in combination with acquired or genetic defects of clotting factors (protein S, protein C, antithrombin, factor V Leiden, prothrombin mutation 20210A, and antiphospholipid antibodies)[14-16]. Recently, the factor V Leiden has been implicated in the increased risk of venous thrombosis in IBD patients[17-19].

Homocysteine (Hcys) is a non-essential, sulfur-containing amino acid formed during the metabolism of methionine. Mild hyperhomocysteinemia (hHcys), which occurs in approximately 5-7% of the general population, has been proved to be thrombogenic and an independent risk factor for coronary artery disease[20], arterial and venous thrombosis[21-26]. Elevated levels of Hcys may result from abnormalities in metabolism pathways due to inherited abnormalities of the enzymes involved or nutrient deficiencies such as insufficiency of folate and vitamins B_2, B_6, and B_{12}[27,28].

The mechanism by which hHcys promotes thrombosis is uncertain, but it may be related to a hypercoagulatory state due to endothelial dysfunction[28-30].

Vitamin B_{12} and folate deficiency are relatively common conditions in IBD (especially in active disease) through malnutrition, malabsorption or antifolate drugs such as methotrexate and sulfasalazine (SASP). Deficiencies of key nutrients/cofactors in Hcys metabolism pathways (B_2, B_6, B_{12}, and folate) might lead to raised Hcys levels in IBD. The association between IBD and hHcys has been shown

in some recent studies, reporting an increased prevalence of hHcys in IBD (both UC and CD)[31-36].

The aim of this study was to evaluate whether Hcys levels were elevated compared to a group of healthy controls and whether Hcys levels were related to vitamin B_{12} and folate serum concentrations, disease activity, disease extent or history of thrombotic complications.

[illegible]

Patients and control population

Forty patients with UC (20 females and 20 males, mean age 41.65±15.21 years, range 17-71 years) were consecutively recruited from our outpatient clinic between February 1999 and February 2000. Diagnosis of UC was based on standard clinical, endoscopic and histological criteria. A detailed clinical history was taken from each patient regarding current symptoms, activity and duration of disease, extraintestinal manifestations, present medication, smoking status, and thrombotic complications. Patients with significant liver or kidney diseases were excluded. Endoscopy was performed in all patients in order to evaluate endoscopic activity, disease extension and histological confirmation and grading. Blood samples from fasting UC patients were collected. Serum Hcys, folate and vitamin B_{12} levels were determined.

Serum Hcys levels were also measured in blood samples from 50 healthy control subjects (HC) with similar age and gender (25 females and 25 males, age 39.96±14.33 years, range 17-72 years), under similar conditions and in the same laboratory. Healthy control subjects were visitors in the outpatient clinic of Hematology Department and had no known diseases, or any clinical or laboratory evidence of metabolic, neoplastic or inflammatory disease. They also had no history of thromboembolic disease. Patients and healthy controls were from the same geographical area (Northern Greece) and had Greek ancestry. Patients and controls reported that they had no daily alcohol intake above 35 g, and no use of drugs affecting Hcys status (phenytoin, theophylline, and vitamin supplements).

Measurements

Total serum Hcys concentrations were measured by the IMx homocysteine assay, which is a fluorescence polarization immunoassay (FPIA, Abbott Laboratories). Reference serum Hcys concentrations for both men and women were <15 μmol/L. Vitamin B_{12} and folate serum levels were measured by enzymatic immunoassays (ELISA). Reference ranges for vitamin B_{12} and serum folate were >223 pg/mL and >2.8 ng/mL respectively.

Statistical analysis

Descriptive statistics for continuous variables (including means and medians) were calculated. Categorical variables were described using proportions. Odds ratios and the 95%CI for the risk of hHcys in UC patients, as compared to healthy controls, were calculated. Multivariate logistic regression was used to adjust these crude odds for confounding differences in sex. Comparisons of continuous variables between the two groups were made by Student's *t*-test for normally distributed data or by Mann-Whitney *U*-test when data were not normally distributed. Fisher's exact test was used for the comparison of proportions. Pearson's correlation coefficient was calculated to describe the relationship between variables. Multiple linear regression analysis was performed in order to study the influence of individual factors on Hcys levels (treated as continuous variable). Since the concentrations of Hcys, folate and B_{12} were not normally distributed, correlation and regression analysis were performed with log-transformed data. Statistical analysis was performed using the SPSS for Windows package (version 11.0, SPSS, Chicago, IL, USA).

[illegible]

Demographics

The baseline characteristics of the patients and controls are shown in Table 1. There were no significant differences in age between healthy controls and patients, or between sexes or between study groups. There were also no significant differences in duration of disease, disease activity, endoscopic score, disease extent, smoking, and use of medication between sexes in UC group.

Table 1 Epidemiological and clinical data of study subjects

	UC patients (95%CI)	Healthy controls (95%CI)
Subjects (*n*)	40	50
Gender (female/male)	20/20	25/25
Mean age (yr±SD)(range)	41.65±15.21	39.96±14.33
	[36.78–46.52]	[35.89–44.03]
	(17–71)	(17–72)
Mean disease duration (mo±SD)	56.65±63.18	
(range)	[36.44–76.86]	
	(3–216)	
Current smoking (%)	9 (22.5)	
Extent of UC (%)		
Rectum/sigmoid	9 (22.5)	
Left colitis	22 (55.5)	
Pancolitis	9 (22.5)	
Activity of UC (%)		
Active	28 (70)	
Inactive	12 (30)	
Extraintestinal complications (%)	6 (15)	
Thrombotic complications (%)	2 (5)	
Medical treatment		
None	1 (2.5)	
5-ASA	35 (87.5)	
SASP	1 (2.5)	
Steroids	17 (42.5)	
Immunosuppressors (AZA/6-MP)	11 (27.5)	

Homocysteine determination and associations

The median serum levels of Hcys in UC patients were similar to those in controls (12.26 μmol/L [range 7.15-35.8 μmol/L] *vs* 12.32 μmol/L [range 5.97-22.06 μmol/L], $P = 0.518$), but hHcys was more prevalent in UC patients (30% [12/40] *vs* 10% [5/50], $P = 0.028$) than in controls. Male sex had higher median serum levels of Hcys both in HC and in UC groups (Table 2). Logistic regression analysis showed an odds ratio of 3.857 [95%CI: 1.22-12.12] for hHcys in the UC group as compared to healthy controls. Advanced age and

male sex were associated with higher Hcys levels, and there was not any difference in age and sex, but males had significant higher Hcys values in both study groups and we believe that sex might be a significant confounder. The adjusted odds ratio for the sex difference was 4.125 (95%CI: 1.26-13.44).

Table 2 Serum Hcys levels in male and female subjects in study groups

	Hcys (μmol/L)		*P*
	Male	Female	
Controls	13.7 (8.17–22.06)	11.94 (5.97–16.99)	0.005
UC	14 (9.13–35.8)	11.07 (7.15–26.6)	0.011
Total	13.72 (8.17–35.8)	11.87 (5.97–26.6)	0.0003

Values are expressed as medians (range). Comparisons were performed using Mann–Whitney's test.

Serum homocysteine, folate and vitamin B_{12} levels in ulcerative colitis patients

In UC patients, the median serum levels of folate and vitamin B_{12} were 7.2 ng/mL (range 2.4-13.4 ng/mL) and 431 pg/mL (range 195-1 430 pg/mL) respectively. One patient had serum folate below the lower limit (2.4 ng/mL) and two others had normal folate near the lower limit (2.9 and 3.4 ng/mL respectively). All three had high levels of Hcys (the three highest values). One patient had vitamin B_{12} below the lower limit (195 pg/mL) and two others had normal B_{12} near the lower limit (226 and 237 pg/mL, respectively). The patient with low B_{12} and one of the two others had high levels of Hcys. These patients had no overlapping low values for both folate and B_{12} levels. The disease duration, activity, extent, endoscopic severity, medical treatment, and smoking status did not significantly influence Hcys, folate, and vitamin B_{12} levels. There were no significant differences in levels of folate and vitamin B_{12} between sexes.

Predictors of hyperhomocysteinemia in ulcerative colitis

Because the concentrations of Hcys, folate and B_{12} were not normally distributed, correlation and regression analysis were performed with log-transformed data. To directly assess the effect of age, folic acid and B_{12} on Hcys levels, the Pearson correlation coefficients between these variables were determined, as shown in Table 3. A relatively strong inverse correlation was observed between log-transformed serum levels of Hcys and log-transformed serum concentrations of folate (r = -0.466, P = 0.002). To further define the role of folic acid and B_{12} in determining Hcys levels, a multiple regression analysis was performed where log-Hcys was the dependent variable whereas age, gender, log-B_{12}, log-folic acid, smoking and history of thrombosis were the independent variables. Multiple linear regressions revealed the following variables to be significant independent predictors of Hcys levels in UC patients: male sex, folate, and B_{12} deficiency or lower serum values (r^2 = 0.4; P<0.001).

Table 3 Pearson coefficient analysis of variables within UC group

	log-Hcys	Age (yr)	log-folic acid	log-B_{12}
log-Hcys				
Coefficient	1.000	–0.016	–0.466	–0.163
P	0.000	0.920	0.002	0.314
Age (yr)

Homocysteine metabolism in ulcerative colitis patients with previous thrombotic events

Two patients had a history of previous thrombotic events. hHcys was found in one of them. This patient had folate deficiency and the highest value of Hcys. The other one had vitamin B_{12} close to lower normal limit without hHcys.

[redacted]

This study showed that although Hcys levels were similar in UC patients and healthy control subjects, hHcys (serum Hcys ⩾15 μmol/L) was more common in UC patients than in healthy controls (adjusted odds ratio, 4.125; prevalence 30% *vs* 10%). Increased Hcys levels and high prevalence of hHcys in IBD patients have been reported in previous studies[31-36]. In our study, similar findings were observed in this cohort of UC patients with a slightly higher prevalence of hHcys (30%) than in other studies (10-26%)[31,32,35,36].

Our analysis showed that male sex and low serum levels of folic acid and vitamin B_{12} were correlated with high Hcys levels. Multiple regression analysis and Pearson's correlation coefficient showed that serum folic acid was the most significant predictor of Hcys levels. We did not find significant correlation between age, disease activity, medication, smoking status, and Hcys levels in this UC cohort. Chowers *et al*.[33], have observed similar findings in a group of patients with CD.

We did not study the frequency of MTHFR C677T variant in our study groups. In a previous study, Mahmud *et al*.[31], reported that the frequency of the homozygous C677T mutation, which results in slower synthesis of 5-methyltetrahydrofolate, is increased from 7.3% in controls to 17.5% in patients with UC and is related with high Hcys levels especially in folate deficiency status. However, in that study, Hcys levels were also elevated in patients with IBD with no mutation to MTHFR enzyme. The levels of Hcys decreased after folate supplementation, regardless of the fact that the genotype of the mutation was detected or not. It has been suggested that folate status should be addressed in all IBD patients and prophylactic folate supplementation has been recommended to all patients with IBD. In our study, the prevalence of hHcys in UC patients was much higher than the frequency of homozygous mutation of MTHFR as detected by Mahmud *et al*.[31]. The differences between prevalences of hHcys and MTHFR mutant can be explained by the existence of additional factors affecting Hcys levels. Vitamin deficiencies can be a significant

contributing factor as it has been supported by our study and previous reports. The suboptimal vitamin status in IBD patients can be due to a combination of several factors. Folate levels may be low due to either inadequate dietary intake, or increased utilization, or drug effects, mainly SASP[33]. In our study, one patient was receiving SASP and had low folate levels and hHcys. Other studies have conflicting conclusions about the significance of SASP antifolate effects[31,32]. Disease activity may contribute to increased demand for folate due to inflammation, but like Chowers *et al*.[33], we did not find any correlation between disease activity and folate or Hcys levels. Furthermore, Chowers *et al*.[33], found no change in Hcys levels, despite a significant improvement in the disease activity in a group of CD patients. These data point out that an inadequate intake of folate may be the most significant factor affecting folate levels in IBD patients.

The prevalence of thromboembolic complications in IBD patients is higher than that in the normal population, in large retrospective studies 1.3-8% of the patients develop these complications[1,2]. The pathogenesis of thromboembolism in IBD is unknown, but it seems to be multifactorial[37]. In our study we found a high prevalence (2/40; 5%) of thromboembolic events in this group of UC patients. hHcys was found in one of them. There are case reports that hHcys was noted in the test results in IBD patients with thrombosis[38,39]. In our study a correlation between hHcys and history of thrombosis was noted, but the number of patients is too small to supply safe conclusions. Nevertheless high Hcys levels may predispose IBD patients to thrombotic complications in combination with other existing circumstantial or permanent risk factors[37].

In conclusion, UC patients have a higher prevalence of hHcys than healthy controls. hHcys in these patients is related to low folate and B_{12} status but not to disease activity. All UC patients, irrespective of disease activity, are at risk for vitamin deficiencies. It is recommended that all patients should have an assessment of the nutritional status in order for the vitamin deficiencies to be detected and that they should also receive folate and vitamin B complex supplements for protection from complications of HHcys.

AIM: To investigate the relationship between genetic polymorphism of the CD14 promoter and the occurrence of alcoholic cirrhosis and alcoholic pancreatitis, and to challenge the conclusion made earlier that the patients with acute alcoholic pancreatitis and patients with alcoholic cirrhosis of liver are two different subpopulations.

METHODS: Using the polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) method, we determined the polymorphism of CD14 gene and aldehyde dehydrogenase gene 2 (ALDH 2) in 335 alcoholic patients with different organ complications i.e., cirrhosis of liver (n = 100), acute pancreatitis (n = 100), esophageal cancer (n = 82) and avascular necrosis of hip joint (AVN) (n = 53) and 194 non-alcoholic controls in a Chinese group.

RESULTS: The results showed that the carriage of T allele was not different among alcoholic patients with cirrhosis of liver, alcoholic patients with other complication and non-alcoholic controls. On the other hand, the carriage of the C allele was significantly more prevalent for alcoholic pancreatitis than for esophageal cancer (0.79 *vs* 0.60, P<0.001), alcoholic AVN (0.79 *vs* 0.65, P<0.025) and non-alcoholic controls (0.79 *vs* 0.68, P<0.025). Furthermore, when only subjects with ALDH2 1-1 genotype were examined, the C allele frequency was significantly more prevalent for alcoholic pancreatitis than for alcoholic liver cirrhosis (0.82 *vs* 0.69, P<0.025), esophageal cancer (0.82 *vs* 0.61, P<0.01), alcoholic AVN (0.82 *vs* 0.64, P<0.01) and non-alcoholic controls (0.82 *vs* 0.69, P<0.05).

CONCLUSION: The C allele may be associated with some mechanism, which is important in the pathogenesis of alcoholic pancreatitis, and that alcoholic patients with acute pancreatitis and cirrhosis of liver are probably two different subpopulations.

INTRODUCTION

It is well known that alcoholism causes numerous physical complications[1]. However, it is still a mystery why certain organ-specific complications occur only in some alcoholics. Twin concordance studies suggest a contribution by genetic factors. In a large study, consisting of 16 000 male twin pairs, the concordance rate of alcoholic cirrhosis was significantly greater among monozygous (14.6%) than dizygous (5.4%) twins[2]. Later, Reed *et al*., also confirmed the findings in 1996[3]. Based on the above findings, many studies were designed to search for candidate genes that contribute to the susceptibility to alcoholic liver disease (ALD)[4-8]. As we know, the alcohol metabolizing enzymes alcohol dehydrogenase (ADH), aldehyde dehydrogenase (ALDH) and cytochrome P4502E1 are polymorphic at the ADH2, ADH3, ALDH2 loci and the 5'-fling region of the P4502E1[9,10]. Many studies have investigated the differences in these alcohol-metabolizing enzymes to explain susceptibility to alcoholism and to alcohol-induced liver disease[9-12]. The studies have been inconclusive in the linkage of the susceptibility to ALD and polymorphism of alcohol-metabolizing enzymes[13-16].

More recently, accumulating clinical and experimental data indicate that inflammatory responses are involved in the pathogenesis of ALD. Elevated serum endotoxin levels are found in alcoholic patients and in alcohol-treated experimental animals[17,18], as a consequence of intestinal wall leakage, bacterial overgrowth, or reduced phagocytic clearance[19]. Circulating endotoxin is bound mainly to the lipopolysacchride binding protein. This complex has a high affinity for the CD14 receptor, which is expressed on monocytes and macrophages[20]. Binding of the lipopolysaccharide–lipopolysaccharide binding protein complex to CD14 initiates transcription and release of several proinflammatory cytokines, such as tumor necrosis factor-α and interleukin-1β[21].

A polymorphic C/T form at position-159 in the promoter region of the human CD14 gene was recently detected. The polymorphism is within the Spl transcription factor binding site, known to affect CD14 expression. The T variants of the -159 polymorphism promote CD14 gene transcription and cause higher expression of CD14 on monocytes, which seems to lead to an enhanced inflammatory response[22,23]. The T allele has a suggested association with myocardial infarction, which also is known to have an inflammatory component[23,24]. Later, Jarvelainen *et al*., investigated the allele frequency of the CD14 promoter genotype in a Finnish group and found that the T allele was associated with advanced ALD. The T allele confers increased risk of alcoholic liver damage. The TT homozygotes are at a high risk to develop cirrhosis[25]. On the other hand, Koppelman *et al*., reported the importance of the C allele influencing the expression and severity of the atopic phenotype in a Dutch group[26]. The CD14 genotype does not appear to represent a susceptibility gene for the development of atopy, yet it appears to produce a more severe atopic phenotype. Considering the ethnic variations, we conducted a study in a Chinese group to investigate the relationship between genetic polymorphism of the CD14 promoter and the occurrence of alcoholic cirrhosis and alcoholic pancreatitis, two common necro-inflammatory complications in alcoholic patients. Because the preliminary data revealed that the C allele was higher in alcoholic pancreatitis patients, we also included patients with non-alcoholic pancreatitis for comparison. By investigating the polymorphism of CD 14 gene, we also want to challenge the conclusion we made before that the Chinese alcoholic patients with cirrhosis of liver and acute pancreatitis are two different subpopulation[27].

[illegible]

Blood samples were obtained from 335 alcoholic and 194 non-alcoholic patients at the Tri-Service General Hospital in Taipei, from September 2002 to March 2004. Of the 335 alcoholic patients, 100 were diagnosed with cirrhosis of liver, 100 with acute pancreatitis, 82 with esophageal cancer, and 53 with avascular necrosis of the hip joint (AVN), with all instances of the respective diseases deemed to be alcohol-induced. Of the 194 non-alcoholic controls, 77 were diagnosed with gallstone pancreatitis and 117 were non-alcoholic controls that had been admitted to hospital during the same observation period (clinical diagnoses for the controls included peptic ulcer, inguinal hernia, acute appendicitis, bone fracture and acute gastroenteritis). All of the alcoholic patients had consumed in excess of 60 g alcohol per day, on average, for at least 6 years. None of the patients in the non-alcoholic subgroup had a history of alcoholism and consumption of alcoholic beverages was infrequent for these individuals. The 100 patients in the alcoholic cirrhosis subgroup were all negative for serum antinuclear and anti-mitochondrial antibodies, and negative for antibodies to the hepatitis C virus and its RNA (determined using a second-generation test kit, Abbott Laboratories, Chicago, IL, USA) and PCR, respectively. The hepatitis B surface antigen and HBV DNA were negative for all 100 of these patients. All the cirrhotic patients presented with typical sonographic signs suggestive of cirrhosis, and all had endoscopically proven esophageal varices. The distributions of these cirrhotic patients according to Child-Pugh score (A/B/C) were 4/70/26. Liver biopsy was not performed for most cases because of decompensated hepatic function or massive ascites. None of the patients in the alcoholic cirrhosis subgroup had a history of acute pancreatitis. The acute pancreatitis patients presented with typical symptoms and signs, with elevations of serum amylase and lipase at least three-fold normal levels. Abdominal sonography, computerized tomography (CT), and endoscopic retrograde cholangiopancreatography were used for patient evaluation. For the alcoholic pancreatitis subgroup (n = 100), risk factors for the pancreatitis, other than alcoholism, were carefully assessed before being ruled out. Of these 100 patients, 40 had experienced two or more episodes, with mild but persistent elevation for serum transaminases noted among 12 during a 6-mo follow-up period after discharge, indicating the possibility of a coexisting alcohol-induced liver disease. The serum albumin, total bilirubin, prothrombin time and peripheral platelet count for these 12 acute alcoholic pancreatitis patients were within normal limits. No evidence of esophageal varices or congestive gastropathy was noted for any of the 100 patients in this subgroup. All the patients in the alcoholic AVN subgroup had undergone total hip replacement, with diagnosis proven from pathology; for 11 of these, hip-joint involvement was bilateral. None of the 53 patients in alcoholic AVN subgroup had a history of acute pancreatitis. Eleven patients were diagnosed with alcoholic liver disease because of persistently abnormal transaminase levels; however, there was no clinical evidence of cirrhosis. The pathology diagnosis of the patients in esophageal cancer subgroup revealed that 72 of the 82 were squamous cell carcinoma and the other 10 were adenocarcinoma. The 82 patients showed no clinical evidence of liver cirrhosis on abdominal sonography, gastroscopy, and biochemical studies. However, seven of them had mildly elevated serum transaminase levels. None of them had any history of acute pancreatitis. Alcohol consumption histories were obtained using a standard questionnaire. The physician on duty ensured that the informed consent was obtained and the questionnaire was reliably completed by interviewing both the patient and a member of the family, usually the spouse or mother.

DNA isolation and CD14 genotyping

DNA was extracted from WBC pellets, obtained after lysis of the red cells with ammonium bicarbonate. The genotyping of a polymorphism in the promoter region of the CD14 receptor characterized by a C to T transition at -159 was accomplished by restriction fragment length polymorphism analyses. The genomic DNA was amplified using the following primer pair: forward, 5' GTGCCAACAGATGA-GGTTCAC 3'. And reverse, 5' GCCTCTGACAGTTTAT-GTAATC 3'. The PCR was carried out in a final volume of 50 μL, containing 1 mmol/L $MgCl_2$, 0.2 mmol/L of each deoxynucleotide triphosphate, 0.2 μmol/L of each primer, and 1 U Taq DNA polymerase. After an initial denaturation of 5 min at 94 ℃, the samples were subjected to 35 cycles at 94 ℃ for 30 s, 60 ℃ for 30 s, and 72 ℃ for

30 s, with a final extension of 7 min at 72 ℃. The 497-bp product was restricted with Eca 471 (Ava II; Fermentas, Amherst, NY) overnight at 37 ℃. The unrestricted 497-bp product represents the C allele, where a T allele was cut into 144- and 353-bp fragments. The three genotypes were scored after running on a 2.5 % agarose gel. A T/T homozygote was included in PCR as a positive control of digestion.

ALDH2 genotyping

ALDH2 genotyping was determined by our previously published method, using PCR-directed mutagenesis[14].

Statistical analysis

χ^2 analysis was performed to compare the allele frequencies between groups.

□□□□□□□

The patient's age, sex, and alcoholism history are listed in Table 1. The CD14 genotype and allele frequencies for alcoholic and non-alcoholic patients are presented in Table 2. Carriage of C allele was significantly more prevalent in alcoholic pancreatitis than in esophageal carcinoma ($P<0.001$), alcoholic AVN ($P<0.025$), non-alcoholic pancreatitis ($P<0.001$) and non-alcoholic controls ($P<0.025$). When the subjects with genotype CC compared with genotype TT, the CC genotype was more prevalent in alcoholic pancreatitis than in esophageal cancer ($P<0.005$), non-alcoholic pancreatitis ($P<0.005$), and non-alcoholic controls ($P<0.025$).

We also compared subjects with genotype CC *vs* CT and TT (T- *vs* T+). The CC genotype was more prevalent in alcoholic pancreatitis than in alcoholic esophageal cancer ($P<0.001$), alcoholic AVN ($P = 0.005$), non-alcoholic pancreatitis ($P<0.001$) and non-alcoholic controls ($P<0.002$). The CC genotype was more prevalent in alcoholic liver cirrhosis than in alcoholic esophageal cancer ($P<0.05$) (Table 2).

For further clarification of the role of C allele in the development of different alcohol-related complications, we checked the allele frequency of CD14 only in subjects with the ALDH2 1-1 genotype (Table 3). The C allele frequency was significantly more prevalent in alcoholic pancreatitis than in alcoholic liver cirrhosis ($P<0.025$), esophageal cancer ($P<0.01$), alcoholic AVN ($P<0.01$), non-alcoholic pancreatitis ($P<0.001$) and non-alcoholic controls ($P<0.05$). In a subgroup of subjects with genotype ALDH2 1-1, the genotype CC *vs*

Table 1 Age, sex, and alcohol consumption in the different groups

Groups (*n*)	Alcohol consumption			
	Age (yr)	Sex (M/F)	Daily (g)	Duration (yr)
Alcoholic cirrhosis (100)	50.5±12.9	97/3	189±119	25.8±11.6
Alcoholic pancreatitis (100)	40.2±11.7	95/5	143±93	15.8±8.8

Table 4 CD14 polymorphism in alcoholic patients with and without pancreatitis

Group (*n*)	CC	CT	TT	*C	*T
Alcoholics without pancreatitis (235)	89[b,c]	131	15	0.66[a]	0.34
Alcoholics with pancreatitis (100)	59	39	2	0.79	0.21
Alcoholics with genotype ALDH2 1-1					
Alcoholics without pancreatitis (142)	59[g,i]	78	9	0.66[e]	0.34
Alcoholics with pancreatitis (65)	41	24	0	0.82	0.18

C allele frequency, [a]$P<0.005$ *vs* alcoholics with pancreatitis. Genotype CC *vs* TT, [b]$P<0.001$ *vs* alcoholics with pancreatitis. [c]$P<0.05$ *vs* alcoholics with pancreatitis. Genotype CC *vs* CT and TT (T- *vs* T+), C allele frequency, [e]$P<0.005$ *vs* alcoholics with pancreatitis. Genotype CC *vs* TT, [g]$P<0.05$ *vs* alcoholics with pancreatitis. Genotype CC *vs* CT and TT (T- *vs* T+), [i]$P<0.005$ *vs* alcoholics with pancreatitis.

CT and TT (T- *vs* T+) was also more prevalent for the alcoholic pancreatitis than for the alcoholic liver cirrhosis ($P<0.05$), alcoholic esophageal cancer ($P<0.05$), alcoholic AVN ($P<0.01$), non-alcoholic pancreatitis ($P<0.005$) and non-alcoholic controls ($P<0.05$). We did not check CC *vs* TT, and TT *vs* CC and CT in subjects with ALDH2 1-1 genotype because there were no TT homozygous patients in alcoholic pancreatitis group. We also compared alcoholic patients with and without pancreatitis in Table 4. The frequency of C allele was more prevalent for the alcoholic patients with pancreatitis than for the alcoholic patients without pancreatitis ($P<0.005$). Genotype CC was more prevalent for alcoholic patients with pancreatitis than for patients without pancreatitis ($P<0.05$). The genotype CC *vs* CT and TT (T- *vs* T+) was also more prevalent in alcoholic patients with pancreatitis than patients without pancreatitis ($P<0.001$). In subjects with genotype ALDH2 1-1, the C allele frequency was significantly higher in alcoholic patients with pancreatitis than without pancreatitis ($P<0.005$). The CC genotype was more prevalent for alcoholic patients with pancreatitis than patients without pancreatitis ($P<0.05$). And, the genotype CC *vs* CT and TT (T- *vs* T+) was more prevalent in alcoholic patients with pancreatitis than patients without pancreatitis ($P<0.005$).

[illegible]

The genotype distribution of the CD14 promoter polymorphism was unique in that the TT genotype was less prevalent in the Chinese than in the Finnish group (4.8% in Chinese alcoholics *vs* 19.7% in Finnish alcoholics and 7.7% in Chinese non-alcoholics *vs* 16.4% in Finnish non-alcoholics)[25]. In this study, we investigated the genotype distribution of CD14 in alcoholic patients with necro-inflammatory complications, pancreatitis and liver cirrhosis and other complications i.e., esophageal cancer and avascular necrosis of hip joint. We did not confirm the results in Chinese alcoholic patients that the T allele confers increased risk of alcoholic liver damage, reported by Jarvelainen *et al*., in the Finnish group[25]. This indicates that this polymorphism is probably not, at least in the Chinese population, an important factor determining the severity of liver disease in alcoholic patients. But we found that the C allele frequency was significantly higher in alcoholic patients with pancreatitis than alcoholic patients with other complications.

The significant role of the T allele in CD14 promoter region was suggested by two findings: (1) it has been found to confer increased CD14 expression on monocytes[22,23] and (2) an increased risk for myocardial infarction has been observed among individuals who are CD14-promoter TT homozygotes[23,24]. The T allele seems to favor the inflammatory process. On the other hand, Ito *et al*., reported that no association between CD14 genotypes and serum CD14 levels was observed in the Japanese population[28]. Risley *et al*., suggested no significant differences in serum CD14 concentration between Caucasian healthy carriers and noncarriers of the T allele[29]. Furthermore, Fernandez-Real *et al*., also found that there was no difference in CD14 levels among healthy Spanish people with different CD14 genotypes[30]. However, the T/T homozygotes have higher levels of circulating CD14 in a subset of diabetic patients[27]. The CD14 genotype was associated with insulin sensitivity in both Caucasian healthy subjects and type 2 diabetic patients[29]. Taking these together, whether CD14 polymorphism was associated with circulating CD14 levels remains controversial. More functional studies are needed to study the effect of CD14/-159 on promoter activity.

Previous publications discuss the relationship between diseases and the CD14 genotypes and have revealed conflicting results. Hubacek *et al*., found the T allele and TT genotype elevated in Czech patients with myocardial infarction ($n = 178$) if compared with the control subjects, suggesting the -159 C/T nucleotide polymorphism to be a genetic risk factor[23]. In a large study which included 1 793 patients, conducted in Germany by Koch *et al*., data indicated that the -159 C/T polymorphism is not related to coronary artery disease or myocardial infarction[31]. In a Dutch population, Koppelman *et al*., found homozygotes for the C allele had a higher number of positive skin tests and higher total serum IgE levels and subsequently, more allergic symptoms including rhinitis and hay fever, compared with subjects with CT and TT alleles[26]. In our study, we found that the C allele frequency was significantly higher in alcoholic patients with pancreatitis than alcoholic patients with other complications. This difference persisted between alcoholic patients with pancreatitis and alcoholic patients with other complications when compared with CC to TT or T- to T+. This suggested that the C allele may be associated with some mechanism which is important and specific in the pathogenesis of alcoholic pancreatitis.

Previously, we reported that most Chinese alcoholic patients with liver cirrhosis never had an episode of acute alcohol-induced pancreatitis despite the fact that they are older and their daily alcohol consumption is larger than that of pancreatitis patients. Further analysis revealed that the ADH2*1 allele frequency is significantly different between Chinese alcoholic patients with cirrhosis and pancreatitis.

We also suggest that alcoholic patients with these two different complications are two different subpopulations[27]. In this study, we also want to investigate whether the CD14 allele frequency is different between alcoholic patients with liver cirrhosis and alcoholic pancreatitis. Initially when comparing the C allele frequency of CD14 in alcoholic patients with pancreatitis and liver cirrhosis, no significant difference was found in these two groups. As the alcohol-specific complications are considered to be influenced by multiple genes and also because the ALDH2 gene is one of the most important alcohol-metabolizing genes, we evaluated the relationship between CD14 genotypes and different complications only in alcoholic patients with genotype ALDH 2 1-1, the most common genotype in the Chinese alcoholic patients. The result showed that the C allele frequency is significantly different between alcoholic patients with cirrhosis of the liver and alcohol-induced pancreatitis. This further indicated that the C allele is associated with the development of alcoholic pancreatitis and alcoholic patients with cirrhosis and pancreatitis are of two different subpopulations.

Unlike alcoholic pancreatitis patients, those with gallstone pancreatitis share the similar frequency of C allele with general population. This indicates that the increased C allele frequency is specific for alcoholic, but not all types of pancreatitis.

The pathogenesis of alcoholic pancreatitis is not clear. There are several plausible explanations for a possible role of CD14 in alcoholic pancreatitis. CD14 is a multifunctional receptor and may play a role in different biological and pathophysiological processes such as: apoptosis, sepsis and inflammatory disease[32-35]. CD14 on monocytes and polymorphonuclear cells functions as a receptor for lipopolysaccharides, thereby inducing mediator and cytokine release. Thus, CD14 may be involved in a proinflammatory pathway through the release of cytokines.

The reason why alcoholic patients develop different organ complications is still unknown. It seems highly probable that the development of specific complications in alcoholic patients is determined by multiple genes, with most of these still not well understood.

Abstract

AIM: Acute pancreatitis (AP) is a process with variable involvement of regional tissues or organ systems. Multifactorial scales included the Ranson, Acute Physiology and Chronic Health Evaluation (APACHE II) systems and Balthazar computed tomography severity index (CTSI). The purpose of this review study was to assess the accuracy of CTSI, Ranson score, and APACHE II score in course and outcome prediction of AP.

METHODS: We reviewed 121 patients who underwent helical CT within 48 h after onset of symptoms of a first episode of AP between 1999 and 2003. Fourteen inappropriate subjects were excluded; we reviewed the 107 contrast-enhanced CT images to calculate the CTSI. We also reviewed their Ranson and APACHE II score. In addition, complications, duration of hospitalization, mortality rate, and other pathology history also were our comparison parameters.

RESULTS: We classified 85 patients (79%) as having mild AP (CTSI <5) and 22 patients (21%) as having severe AP (CTSI $\geqslant$5). In mild group, the mean APACHE II score and Ranson score was 8.6±1.9 and 2.4±1.2, and those of severe group was 10.2±2.1 and 3.1±0.8, respectively. The most common complication was pseudocyst and abscess and it presented in 21 (20%) patients and their CTSI was 5.9±1.4. A CTSI $\geqslant$5 significantly correlated with death, complication present, and prolonged length of stay. Patients with a CTSI $\geqslant$5 were 15 times to die than those CTSI <5, and the prolonged length of stay and complications present were 17 times and 8 times than that in CTSI <5, respectively.

CONCLUSION: CTSI is a useful tool in assessing the severity and outcome of AP and the CTSI $\geqslant$5 is an index in our study. Although Ranson score and APACHE II score also are choices to be the predictors for complications, mortality and the length of stay of AP, the sensitivity of them are lower than CTSI.

INTRODUCTION

Acute pancreatitis (AP) is a process of acute inflammation of the pancreas, with variable involvement of regional tissues or organ systems. The clinical expression of AP varies from edematous mild AP to severe AP, and is frequently associated with necrosis of the pancreas, a protracted clinical course, organ failure, a high incidence of local complications, and a high mortality rate[1]. Multifactorial scales including the Ranson[2] and Acute Physiology and Chronic Health Evaluation (APACHE II) systems[3] have been used for AP since the 1970s. Balthazar computed tomography severity index (CTSI) was developed since 1990[4]. Computed tomography (CT) with intravenous contrast medium injection is accepted as the imaging procedure of choice: first to document the extent of pancreatic and extrapancreatic acute fluid collections and, second, to detect pancreatic necrosis. These two parameters have been identified as prognostic indicators of the severity of AP. CTSI, based on combined assessment of peripancreatic fluid collections, and the degree of pancreatic necrosis were developed to improve prognostic accuracy. The purpose of this review study was to assess the early predictability of a variety of parameters in AP, such as Ranson, APACHE II, and CTSI. We compared the accuracy of CTSI, Ranson score, and APACHE II score in course and outcome of AP prediction and the prognostic value of CT in the assessment of AP.

MATERIALS AND METHODS

We performed a retrospective review of all 121 patients who underwent helical CT within 48 h after onset of symptoms of a first episode of AP between 1999 and 2003.

Fourteen inappropriate subjects who did not meet criteria of clinical blood data for diagnosis of pancreatitis were excluded, CT was performed without contrast because of renal dysfunction and missing chart in medical records, and we reviewed the 107 contrast-enhanced CT images. Of these, there were 57 males, 50 females, with ages ranging from 21 to 87 years, mean age 56 years. The abdominopelvic CT scans were (HiSpeed CT/I; GE Medical Systems, Milwaukee, WI, USA) acquired from patients after oral administration of 4% iothalamate meglumine (Mallinckrodt, USA) 1 000 mL and intravenous administration of iohexol (Nycoveien, Norway) 100 mL (350 mg/mL); flow rate, 2 mL/s, with a section thickness of 10 mm and a pitch of 1.5. We reviewed the CTSI of their CT images. CTSI is a 10-point scoring system derived by assessing the degree of pancreatic and peripancreatic inflammation (0-4 points), and the presence and degree of pancreatic parenchymal nonenhancement or necrosis (0-6 points)[4]. In addition, we also collected the clinical chart records (temperature, heart rate, mean blood pressure, respiratory rate, etc.) to calculate the APACHE II and Ranson score. Complications, duration of hospitalization (according to Simchuk's study[5], we defined the prolonged length of stay as ≥20 d; short length of stay as <20 d), mortality rate, and other pathology history also were our comparison parameters.

RESULTS

According to Casas's study[6], we classified 85 patients (79%) as having mild AP (CTSI <5) and 22 patients (21%) as having severe AP (CTSI ≥5). We found that the CTSI in all patients was 0-8 points and mean score was 3.7. The mean CTSI in mild group was 1.9±0.4 and that in severe group was 6.1±0.5. In APACHE II score aspect, the mean score among all patients was 9.4±2.4. In CTSI mild AP group, the mean APACHE II score was 8.6±1.9 and that of CTSI severe AP was 10.2±2.1. In Ranson score aspect, the mean score in all patients was 2.7±1.4. In CTSI mild group, the mean Ranson score was 2.4±1.2 and that of CTSI severe group was 3.1±0.8. Complications included pseudocyst formation in 21 (20%) including abdominal abscess in two cases. The CTSI in these patients was 5-8, and the mean score was 5.9. Mean APACHE II score and Ranson score of them were 9.4 and 2.7 respectively. Four patients (3.7%) died because of multiorgan failure and sepsis. They died at 21st, 23rd, 19th, and 12th d after admission. The CTSI of them was 3, 5, 6, and 7 respectively. The APACHE II in these four patients was 6, 7, 7, and 9 and the Ranson score was 2, 2, 2, and 3. The APACHE II and Ranson score in the patient who died but with a CTSI of 3 were not significantly higher than other patients. In the length of stay aspect, 19 patients stayed for over 20 d and the mean CTSI was 5.6. Others stayed for 3-15 d and the mean CTSI was 2.7. By comparison, there is no significant difference of APACHE II and Ranson score in the short length of stay (<20 d) group and prolonged length of stay (≥20 d) group. Mean APACHE II score in short and prolonged length of stay was 8.9 and 9.8 and the mean Ranson score was 2.9 and 2.6, respectively. Comparison of CTSI, APACHE II score and Ranson score in our patients are listed in Table 1.

Table 2 shows the relationship between CTSI and outcomes. These data showed that the CTSI significantly correlated with all outcomes measured. Patients with a CTSI ≥5 was 15 times to die than those CTSI <5, and the prolonged length of stay and complications present were 17 times and 8 times than that in CTSI <5, respectively. AP was due to gallstone in 36 patients (34%), to alcohol consumption in 36 patients (34%), to both causes in 16 patients (15%) and to unknown reasons in 19 patients (18%). In other pathology history aspect, the most popular disease in our patients is diabetes mellitus (DM). Thirty-six patients (34%) were with DM and two of them underwent neuropathy. The mean CTSI in these DM patients was 5.3. Three of the DM patients died and their CTSI were 5, 6, and 7. In addition, AP relapse occurred in 17 patients (16%) and they all belonged to alcoholic type. The mean CTSI of them was 4.2.

Table 1 The comparison of severity, complication, mortality, and the length of stay in CTSI, Ranson score, and APACHE II score

		CTSI[1]	Ranson score	APACHE II score
Severity	Mild	1.9±0.4	2.4±1.2	8.6±1.9

	CTSI <5	86		

DISCUSSION

Predicting the severity and outcome of AP still represents a challenge for the physician. Since the work of Ranson[2] establishing a scoring system of severity for patients with AP, there has been several other scoring systems: Imrie[7], APACHE II[3], and Balthazar CTSI[4] systems were used to assess the severity of disease that had a high sensitivity and positive predictive value (PPV). A milestone achievement in assessing the severity of AP occurred in 1974, when Ranson developed his prognostic signs. He examined the relationship of 43 different measurements made during the first 48 h of treatment, finding 11 variables that significantly correlated with overall morbidity and mortality. Imrie *et al*., later modified Ranson's criteria by removing serum transaminase and adding serum methemalbumin, albumin, and cyclic AMP to Ranson's prognostic variables. However, the Ranson and Imrie criteria cannot be calculated until data from admission and 48 h after admission are compared. Larvin and McMahon[3]

applied the APACHE II score in the setting of AP and found that those with scores >7 were likely to have a severe course. They defined a severe course as the development of major organ system failure and a pancreatic collection. An advantage of the APACHE II score was flexibility, as it could be recalculated at any time during a hospital stay. However, Larvin and McMahon also showed that the APACHE II score had just a 67% PPV at 24 h after admission. They also showed that the APACHE II score was even less accurate for identifying patients with specific complications including peripancreatic fluid collections or major organ failure. Thus, better prognostic tools are needed. The Balthazar CTSI was reported to be of value in identifying patients with severe and fatal outcome, only a few studies have investigated whether CTSI performance is superior to that of the APACHE II or Ranson score in predicting AP outcome. This is the major challenge of this study.

Robert *et al.*[8], demonstrated that the Ranson score in mild AP (defined as the course of the disease was uncomplicated) and in severe AP (defined as organ failure) were 1.9±0.9 and 2.2±0.5. The APACHE II score was 6.9±0.7 and 7.4±0.4 in mild and severe group. In Chatzicostas's study[9], the Ranson score in mild (defined as normal amylase and lipase level) and severe (defined as organ failure and complications) groups were 2.0±1.4 and 2.1±1.6. The APACHE II score was 10.1±0.2 and 9.8±0.6 in mild and severe group. There were no significant differences between these data. According to these data, Robert and Chatzicostas demonstrated that the Ranson score and APACHE II score are not absolute predictors for severity of AP. In our study, we also did not find significant differences of Ranson and APACHE II score in mild and severe groups. So we suppose that our results are similar to Robert's and Chatzicostas's. In addition, in Wilson's study[10], they demonstrated that the patients with Ranson score ⩾3 was always in a severe situation. On evaluation of mean Ranson score in our study, we found that in severe AP it was 3.1±0.8. However, only one-thirds of the patients with severe pancreatitis had Ranson score ⩾3. Compared to Wilson's results, there were still a lot of variability in Ranson score prediction.

Complications are often the major reasons that resulted in the death of AP patients. The management of complications is important to reduce the mortality rate. In our study, we found that the higher CTSI associated with higher complication rate and the CTSI ⩾5 is an index. However, we did not find the same situation in Ranson and APACHE II score. There were no significant differences between mild and severe groups of Ranson and APACHE II score. According to Nicolas[11], they found that complications occurred rarely in Ranson score <3 and APACHE II score <8. In our study, the mean Ranson score and APACHE II score in complications-occurred patients were 2.7 and 9.4. Our APACHE II score result was similar to Nicolas' but in Ranson score aspect, the results showed that the relationship between complications present and Ranson score appeared to involve multiple variables. In the length of stay aspect, we demonstrated that CTSI is a more sensitive predictor than APACHE II and Ranson score. The mean CTSI in short and in prolonged length of stay showed significant difference (2.7 *vs* 5.6). However, there is no significant difference of APACHE II and Ranson score in the short length of stay group and prolonged length of stay group. In Simchuk's study[5], they mentioned that the PPV of APACHE II and Ranson score for the length of stay were 31% and 38%, and the PPV of CTSI was 71%. However, in Fleszler's study[12], they mentioned that APACHE II score is the most appropriate index to predict the length of stay, but they also mentioned that this score requires an arterial blood gas level, which was not available on some patients, thus the practicality of APACHE II is lower than Ranson score and CTSI.

The reported mortality rates for patients with AP vary greatly from 15% to 56%[12]. In Casas's study[6], they demonstrated that CTSI ⩾5 is the index, if the patients are under the danger of death. In Bradley's study[13], their results showed that CTSI >8 is the index for death. In our study, three of the four died patients had a CTSI ⩾5. So we supposed that our results were more similar to Casas's. According to Simchuk *et al.*[5], they mentioned that the CTSI <3 had a 3% mortality rate, whereas patients with a CTSI >7 had a mortality rate of 17%, it is likely 5-6 times mortality rate in CTSI >7 group. From the CTSI definitional value described above, there was still a lot of variability in death prediction of CTSI. According to our results, we demonstrated that the reason resulted in the variability may be the different characteristics of patients. Age, chronic diseases such as DM present or not, alcohol consumption and organ dysfunction all may affect the mortality rate of AP. We found that three of our four died patients had DM and their CTSI were 5, 6, and 7, all of them were alcoholics, and the average age of the four died patients was 55 years. Mortality rate associated with higher CTSI and worse pathological rate, the different characteristics of individual should not be ignored.

In conclusion, the CTSI is a useful tool in assessing the severity and outcome of AP and the CTSI ⩾5 are likely to have a severe course in our study. Although Ranson and APACHE II scores also are choices to be the predictors for complications, mortality and the length of stay of AP, the sensitivity of them are lower than CTSI. In addition, we found that if we are using CTSI to be an indicator for mortality rate, the different characteristics of an individual should not be ignored.

AIM: To study the function of α-fetoprotein (AFP) in SMMC-7721 hepatoma cells.

METHODS: A hairpin siRNA expressing plasmid pSilencer3.0-H1-*afp* was constructed and transfected into SMMC-7721 cells with Lipofectamine 2000. The expression of AFP was monitored by real-time RT-PCR and immunoassays, its effect on SMMC-7721 cell proliferation and cell death was detected by MTT and fluorescence-activated cell sorter (FACS).

RESULTS: The AFP-siRNA expressing plasmid downregulated the expression of AFP obviously (about 34%), and inhibited SMMC-7721 cell proliferation, but did not induce apoptosis.

CONCLUSION: Downregulation of AFP siRNA inhibits proliferation of SMMC-7721 cells, but cannot cause apoptosis.

INTRODUCTION

Primary hepatocellular carcinoma (PHCC) is one of the most common malignancies in the world, with a high fatality rate and a short survival time[1].

α-fetoprotein (AFP) is a major serum protein produced by the liver or yolk sac in mammals and other vertebrates, and is not detectable in normal adults[2]. However, AFP is often elevated to a significant level in association with development of PHCC, and has been defined as an oncofetal antigen[3,4]. The biological role of AFP has been widely investigated. However, the relationship between AFP and PHCC is still unclear. Some recent investigations indicate that human AFP can enhance the proliferation of mouse hepatoma H-22 and human hepatoma SMMC-7721, BEL-7404, or QGY-7703 cells *in vitro*[5]. Similar growth stimulatory effect of AFP at low concentrations has also been found in human hepatoma Hep G_2 cells. These results have an important implication that AFP may function as a hepatoma growth stimulator, thus suppression of AFP gene expression and its biological activities may become a new strategy for the treatment of AFP-associated tumors such as PHCC.

RNA-mediated interference is the inhibition of expression of specific genes by double-stranded RNAs (dsRNAs)[6]. Since short dsRNAs can silence the expression of its homologous gene in mammalian cells, and do not induce nonspecific interferon response, it is widely used in genome and therapy study. Here we have designed a plasmid pSilencer3.0-H1-*afp*, which can express siRNAs in mammalian cells to study the function of AFP and its therapeutic effect on hepatoma cells *in vitro*.

MATERIALS AND METHODS

Plasmid construction

The plasmid pSilencer3.0-H1-*afp* was constructed as previously described[7]. The targeted sequence of AFP gene (GenBank accession no. NM_005030) is 5'-AACTCAGTG-AGGACAAACTAT-3'. Positive and negative technical controls were supplied by Ambion Incorporation, and the positive control plasmid was aimed at GAPDH gene.

Hepatoma cell culture and plasmid transfection

Human hepatoma SMMC-7721 cells were cultured in RPMI-1640 (Invitrogen) supplemented with 10% FCS. Transfection was done with Lipofectamine 2000 (Invitrogen). One day before transfection, SMMC-7721 cells were seeded in the wells of 24-well culture plates, about 7×10^4 cells/well. Before transfection, 1 μg plasmid and 2 μL Lipofectamine 2000 were diluted with 50 μL serum-free Opti-MEM I (Invitrogen) and incubated for 5 min. They were mixed and incubated for 20 min at room temperature,

added to the medium, mixed gently, and then incubated at 37 ℃ for 4 h. The medium was replaced with a new medium and incubated for 12, 24, and 48 h.

Quantitative real-time PCR

For validation of the silencing effect by quantitative PCR, cDNA was prepared from the SMMC-7721 cell line. RT-PCR was carried out using RT and SYBR Green PCR Master Mix (ABI) according to the manufacturer's instructions. RT reaction was performed at 48 ℃ for 30 min. The cDNA was analyzed by real-time quantitative PCR immediately and stored at -20 ℃ until use. Each PCR was carried out in triplicate in a 25 μL volume for 15 min at 95 ℃ for initial denaturing, followed by 40 cycles at 95 ℃ for 30 s and at 60 ℃ for 1 min in the ABI 7000 sequence detection system. Each primer set was first tested to determine optimal concentrations, and products were run out on a 3% agarose gel to confirm the appropriate size. Subsequently, the ABI dissociation curves software was used following a brief thermal protocol (95 ℃ for 15 s and 60 ℃ for 20 s, followed by a slow ramp to 95 ℃) to control their multiple species in each PCR amplification. cDNA from hepatoma cells was used to construct a standard curve for each gene. Values for each gene were normalized to expression levels of actin-β, and then a ratio comparing the expression in negative and positive control, and pSilencer3.0-H1-*afp*-transfected hepatoma cells was calculated. The sequences of the primers used for RT-PCR were as follows: actin-β forward: 5'-CGT ACC ACT GGC ATC GTG AT-3'; reverse: 5'-GTG TTG GCG TAC AGG TCT TTG-3'; GAPDH forward: 5'-CTT CAC CAC CAT GGA GAA GGC-3'; reverse primer: 5'-GGC ATG GAC TGT GGT CAT GAG-3'; AFP forward: 5'-AAA TAC ATC CAG GAG AGC CA-3'; reverse: 5'-CTG AGC TTG GCA CAG ATC CT-3'.

Immunoassay of AFP concentration in supernatant

AFP concentration in the supernatant in each well was determined by chemiluminescence immunoassay according to the manufacturer's instructions.

MTT assays

Eight hours after plasmid transfection, the cells were harvested and replated in 96-well microtiter plates in triplicate at 1×10^4 cells in 0.1 mL medium/well. Twenty microliters of MTT dye (5 mg/mL) was added and incubated for 0, 24, 48, and 72 h respectively. Following 4 h of incubation at 37 ℃, formazan crystals were dissolved in dimethyl sulfoxide (0.1 mL/well). The plates were mechanically agitated for 5 min and the optical density at 540 nm was determined on the microtiter plate reader. Each experiment was done thrice.

Fluorescence-activated cell sorter (FACS) analysis

Forty-eight hours after transfection, cells were harvested by trypsin digestion, washed twice with cold PBS, and resuspended in 1× binding buffer, regulated to the concentration 1×10^6/mL. Then 100 μL was extracted to a new tube, 5 μL PI and 5 μL annexin V-FITC were added, mixed gently, incubated at 25 ℃ for 15 min. Four hundred microliters of binding buffer was added and analyzed within 1 h with FACS.

RESULTS

SiRNAs expressing vector pSilencer3.0-H1-afp could silence the expression of AFP in hepatoma cells efficiently

To specifically deplete AFP in hepatoma cells, we took advantage of the recently developed vector-based siRNA technology. The targeting sequence of human AFP (GenBank accession no. NM_005030) is 5'-AACTCAGTG-AGGACAAACTAT-3'. The vector pSilencer3.0-H1-*afp*, pSilencer3.0-H1-*gapdh* (positive control) and negative control vector were transfected into SMMC-7721 cells, which were cultured for 48 h, then RT-PCR and AFP in supernatant fluid were assayed. Positive control vector pSilencer3.0-H1-*gapdh* could silence the GAPDH efficiently. The inhibition rate of the positive control plasmid and pSilencer3.0-H1-*afp* was 60% and 34% respectively. In order to confirm the inhibitory effect, we assayed the AFP concentration in the supernatant. The AFP level in the supernatant reduced about 40%, 48 h after transfection. These results showed that the expression of AFP in hepatoma cells was downregulated.

MTT assays and FACS

Figure 1A shows that vector pSilencer3.0-H1-*afp* inhibited the proliferation of SMMC-7721 cells obviously compared to the negative control plasmid, and that the suppression effect was most obvious at 32 h. The results of FACS showed no difference between the negative control and pSilencer3.0-H1-*afp*-treated cells (Figure 1B).

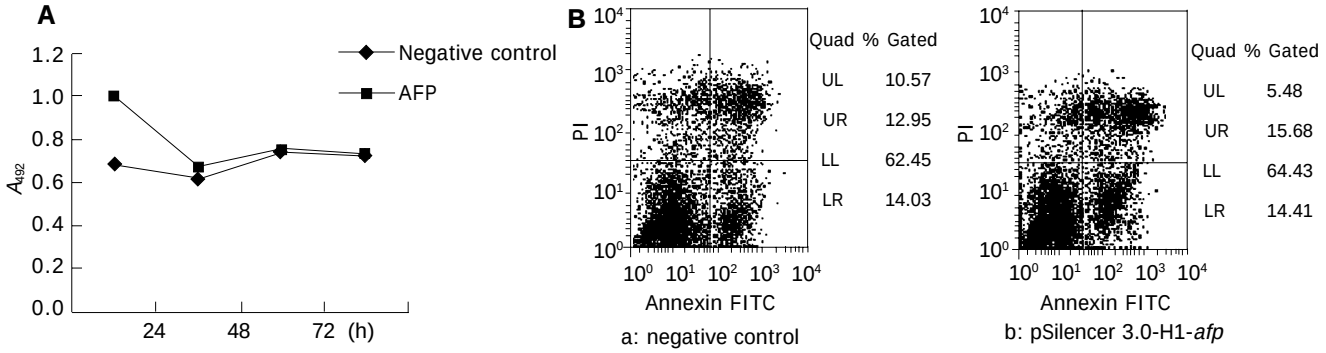

Figure 1 Proliferation (A) and apoptosis (B) of transfected cells. LR indicates the value of cell apoptosis.

DISCUSSION

Since AFP was found in the mid-1950s, this oncofetal protein has been used as a PHCC marker in clinical diagnosis[10]. But its biological activities in mammals still remain unclear. To date, only two functional roles of AFP have been ascertained[10]. In the last decade, the growth regulatory properties of AFP have aroused interests as a result of studies involving ontogenetic and oncogenic growth in both cell cultures and animal models. Particularly, the effect of AFP on the development of experimental tumors in mammals has been investigated *in vivo* with the use of carcinogens[11]. When AFP-treated mice develop larger tumors, they require a longer period for regression and have a significantly higher mortality[10]. Chicken AFP-treated quails develop tumors with shorter latent periods than the untreated quails[8]. The *in vivo* tumor growth stimulation by AFP can be explained by its immunosuppression. Cell-mediated immunity is an important mechanism of host resistance to malignant neoplasms. Recently, anonymous studies found that antihepatoma effects of AFP antisense S-ODNs are more significant in normal mice than in nude mice[10], suggesting that there exists a relationship between AFP and the susceptibility of hepatoma cells to immunity-mediated cytotoxicity. Recent studies indicate that AFP directly stimulates the proliferation of hepatoma cells *in vitro*, independent of its immunosuppression[11].

However, the precise relationship between AFP and PHCC is not clear. AFP is highly expressed in hepatic oval cells during the early stages of carcinogenesis, and high levels of AFP in the fully developed PHCC, or in the serum of the host, are associated with more aggressive behaviors, and increased anaplasia[9]. The present study also demonstrated that silencing the expression of AFP could effectively inhibit the growth of hepatoma cells *in vitro*, suggesting that AFP may play a role in the pathogenesis of PHCC.

The present results indicate that AFP siRNAs expressing plasmid exhibit significant antihepatoma activities *in vitro* by the sequence-specific silencing of AFP gene expression. But the results of FACS have no obvious difference between the negative control and the pSilencer3.0-H1-*afp* treated wells. Therefore, the mechanisms of antihepatoma action of AFP siRNAs expressing plasmid are not through the induction of hepatoma cell apoptosis.

ACKNOWLEDGMENTS

The authors express appreciation to Professor Bing-Yu Mao, Kunming Institute of Zoology, Chinese Academy of Sciences and Senior Lecturer Bin Yu, Sydney University, Australia for their critical revision of the manuscript.

AIM: To explore the interaction models of the cytochrome P-450 (CYP) *1A1 Val* variant and glutathione S-transferase (GST) *M1* null polymorphisms with tobacco smoking in the occurrence of intestinal gastric cancer.

METHODS: A community-based case-control study was conducted in Yangzhong. Subjects included 114 intestinal types of gastric cancer with endoscopic and pathological diagnosis during January 1997 and December 1998, and 693 controls selected from their spouse, siblings or siblings-in-law who had no history of digestive system cancer. Logistic regression was used to estimate the interaction models.

RESULTS: The frequency of the *CYP1A1 Val* variant allele in cases did not differ from that in controls. The OR of *GSTM1* null genotype was 2.0 (95% confidence interval [95%CI]: 1.2-3.1, $P<0.01$). It showed a significant type 2 form of interaction model when both *CYP1A1 Val* variant allele and former tobacco smoking existed (i.e., among the multiplicative effects, the disease risk is increased by the tobacco exposure alone but not by the *CYP1A1* variant alone). The interaction index γ was 2.8, and OR_{eg} (95%CI) was 5.0 (1.9-13.4). *GSTM1* null genotype and former tobacco smoking were significant in a type 4 interaction model (i.e., the disease risk is increased by *GSTM1* null genotype or tobacco exposure alone among the multiplicative effects). The interaction index γ and OR_{eg} (95%CI) were 3.4 and 8.4 (3.4-20.9), respectively.

CONCLUSION: Different interaction models of *CYP1A1 Val* variant allele and *GSTM1* null genotype with tobacco smoking will contribute to understanding carcinogenic mechanism, but there is a need to further investigate in larger scale studies.

INTRODUCTION

Worldwide, gastric cancer is the second in rank overall (798 000 new cases per year), and ranks second in males, fourth in females. It remains the most common malignancy in many countries of the world[1,2], though the frequency of incidence and mortality is declining in almost all populations. Thirty-eight percent of gastric cancer cases occurred in China, where it remains to be most common and is the leading cause of cancer death in both sexes[1]. Yangzhong is among the areas with the highest gastric cancer mortality and incidence rate in south-east of China[3]. The crude mortality rate of gastric cancer changed from 96.9 to 110.9/100 000 during 1991 and 1997, and the average adjusted incidence rate in the same period was over 115/100 000 (unadjusted rate is 155.5/100 000). Previous studies have shown that high incidence rate of gastric cancer is associated with exposure to environmental factors (tobacco, alcohol consumption, and *H pylori* infection), and individual susceptibility[2,4].

Genetic polymorphisms in cytochrome P-450 (CYP) *1A1* and glutathione S-transferase (GST) *M1* genes that metabolize known and potentially carcinogenic environmental exposures may affect enzymatic activities and alter an individual's ability to metabolize pro-carcinogenic and related compounds, which may change the biologic effect of exposures[5]. A large number of studies have examined the role of polymorphisms in *CYP1A1*, *GSTM1*, and cancer risk, including gastric cancer[6-10], but the results are equivocal[11–14]. The interaction between *GSTM1* null genotype and tobacco smoking for the risk of gastric cancer has only been explored in three studies, with inconsistent evidence of departure from a

multiplicative model, possibly because of the small size (70, 91, and 136 gastric cancer cases, respectively), and the gene-environmental interaction (GEI) models best describing the risk of gastric cancer is not clear[6,11,14]. For this reason, we conducted a community-based case-control study in a Chinese population. Genetic polymorphisms in *CYP1A1* and *GSTM1* were analyzed to test the hypothesis that these genotypes have different interaction models with tobacco smoking in the development of intestinal gastric cancer.

[illegible]

Subjects

All gastric cancer patients and controls in this study are Han ethnic Chinese selected from Yangzhong County. Gastric cancer was prevalent in cases diagnosed according to International Classification of Diseases for Oncology IX, code = 151, and classified by the criteria of Laurén[15]. One hundred and fourteen intestinal gastric cancer patients (76 men and 38 women; mean age and SD 59.4±9.9 years) were identified by endoscopic and pathological diagnosis in Yangzhong City Municipal Hospital from January 1997 to December 1998. To reduce misclassification of the histological types, two pathologists reviewed and confirmed all diagnosed cases. Controls were selected from case's siblings (150 male and 140 female) and non-blood relatives (403 spouses and the siblings-in-law, 160 male and 243 female) without digestive tract cancers. Both kinds of controls differed slightly in demographic features, and their results were combined to increase the sample size and decrease type I error. The study was approved by the regional ethics committees of Yangzhong. All participants were given an explanation of the study and informed consent was obtained. Study subjects completed a questionnaire administered by specially trained interviewers through a face-to-face interview. The questionnaire was designed to elicit detailed information on tobacco smoking habit, alcohol drinking habit, family history of cancer, and occupational exposures. Cigarette smokers were defined as subjects who reported smoking of at least one cigarette per day for 1 year or more, or whose accumulated tobacco cigarette consumption was over 18 packs per year. Former smokers were those who had stopped smoking for one or more years before the interview. Cumulative smoking exposure (pack years) was defined as one pack per day for 1 year equals 1 pack years.

CYP1A1 and GSTM1 genotypes

DNA extraction was performed using Puregene DNA isolation kits (Gentra Systems, Minneapolis, MN, USA). PCR-RFLP approach was used to detect the 7th *CYP1A1 Ile/Val* variant at position 4 889. PCR was used to amplify the transcription regulatory region of *CYP1A1* that includes the restriction enzyme recognition site for *Hin*cII. The two allele-specific primers are respectively F5'-TCCT ACCTG-AACGGTTTCTCACCC-3' (T_m = 63.0) and R5'-TTTTTT-TTTTTGAAAGACCTCCCAGG GGTCA-3' (T_m = 65.1) modified from those previously reported[16]. The homozygous null polymorphism of *GSTM1* was determined using a PCR approach as previously reported[16].

Statistical analysis

The relative associations between cases and controls were assessed by crude odds ratio (OR), interaction OR_{eg} and the corresponding 95%CI. Unconditional logistic regression analysis was performed to assess the association between the *CYP1A1 Ile/Val* and *GSTM1* null polymorphism and intestinal gastric cancer after adjusting for confounding factors. All models included as co-variables: gender, age (entered as a continuous variable), living areas (relative lower or higher incidence areas in Yangzhong), education level (years), former tobacco smoking, former alcohol drinking, BMI (weight [kg]/height [m^2]) and family history of cancer. Test of trend was calculated through logistic models based on semi-continuous and dummy variables. A common way to describe the interaction between the effect of an environmental agent and a genetic risk factor is to use a term called interaction index (γ), which is determined by coefficient (β) in a multiple logistic regression model. The coefficient of this interactive term was calculated according to the method of Taioli *et al*.[17]. If the types of interaction belong to multiplicative effects suggested by Khoury and Ottman[18-20], it included several types of interactions. Such as type 1 interaction which means that the disease risk is increased only in the presence of the genotype and the environmental exposure. Type 2 interaction: the disease risk is increased by the environmental exposure alone but not by the genotype alone. Type 3 interaction: the disease risk is increased by the genotype in the absence of the environmental exposure but not by the environment alone. Type 4 interaction means that the disease risk is increased by genotype or environmental exposure alone[18-20]. False positive report probability (FPRP) was used as an index for judging the noteworthy or not noteworthy results at the 0.5 FPRP level among significant GEI results[21]. All data analysis was performed with the SAS package Genmod (SAS Institute, Cary, NC, USA) for the personal computer.

[illegible]

CYP1A1, GSTM1 polymorphisms and risk of intestinal gastric cancer

Compared with controls, patients were significantly older (median age 59 years for cases and 53 years for controls) and with a BMI less than 20. Former tobacco smoking is significantly associated with the risk of intestinal gastric cancer (OR = 2.4, 95%CI: 1.0-5.8). A significant dose-response was observed in relation to increasing gastric cancer risk, especially in 20 pack-years or more smokers (Table 1). The frequencies of *CYP1A1 Ile/Val* and *Val/Val* genotypes in controls were 33.4% and 5.6%, respectively, which showed no significant difference from that in cases (32.1% and 5.4%, respectively). The homozygote null *GSTM1* genotype was observed in 63.4% of cases, which was significantly higher than that in controls (53.5%). The adjusted OR was 2.0 (95%CI: 1.2-3.1).

Interaction models of CYP1A1 and GSTM1 polymorphisms with former tobacco smoking

Among former tobacco smokers with *CYP1A1 Ile* or *GSTM1* present genotypes, the OR_{eg} of intestinal gastric

cancer were 1.8 and 3.5, respectively. With both exposure to tobacco smoking and the *CYP1A1 Val* allele or *GSTM1* null genotype, the OR_{eg} of suffering intestinal gastric cancer increased sharply, 5.0 (95%CI: 1.9-13.4) and 8.4 (95%CI: 3.4-20.9), respectively. The γ were 2.8 and 3.4, respectively, which showed multiplicative effects of type 2 GEI model for *CYP1A1* and type 4 model for *GSTM1* (Table 2).

Assessment of the probability of a potential positive result

A high FPRP (e.g., >0.5) could be a consequence of any combination of a low prior probability, low statistical power, or a relatively high *P* value[21]. We calculated FPRP to assess the probability that a positive result might be false using the observed *P* value or CI for the observed ORs, and to determine whether to consider a significant finding to be noteworthy with the specific prior probability (Table 3). The results showed that the FPRP was less than 0.5 for *GSTM1* null and former smokers, which indicated the most noteworthy finding in the present study even with a prior probability between 0.0001 and 0.00001.

□□□□□□□□□□

A large number of molecular epidemiological studies completed in the past decade have identified the relative etiologic roles of the *CYP1A1 Val* variant allele and *GSTM1* null genotype for cancer risk (including gastric cancer), although some results indicate no overall associations, only specific relationships were found in subgroups, such as in smokers, *H pylori*-infected patients or low consumption of

fruit[6-10]. Other studies have reported contrary findings[11-14]. These inconsistent results might be contributed to ethnically diverse populations involved in studies, different histological subtypes of cases used, and different co-variables categorized the sub-population. Until now, only a few studies discussed interactions between tobacco smoking and the polymorphisms in the occurrence of gastric cancer[6,11,14]. In the present study, we observed some evidence of a relationship between *GSTM1* null genotype and a risk of gastric cancer. Both the *CYP1A1 Val* variant allele and *GSTM1* null polymorphism have statistically significant interactions with former tobacco smoking. The GEI model of *CYP1A1* with smoking belongs to type 2, and *GSTM1* with smoking belongs to type 4 as Khoury and Ottman described. Present study as most molecular epidemiology studies based on multiple comparison corrective procedures is relied on the standard *P* value criterion of 0.05 to define statistical significance without consideration of power or prior probability, which may create a lot of false positives[21]. We further calculated FPRP as one of indices to decide about whether a positive finding in association study can be called "a noteworthy finding" or "deserve of more attention". We confirmed that the interaction between *GSTM1* null and former smokers was the most noteworthy positive finding in the present study even with a prior probability less than 0.0001. The interaction between *CYP1A1 Val* variant allele and former smokers was also a possible noteworthy positive finding with a prior probability less than 0.01 (data not shown). These results suggest that the risk of intestinal gastric cancer was greatly dependent upon both tobacco smoking exposures and susceptibility genes. Only complete smoking cessation may decrease susceptibility to gastric cancer in persons carrying the *CYP1A1 Val* variant allele or *GSTM1* null genotype. The different types of GEI models indicated that the interactions between genes and environmental factors are neither simply gene specific, nor exposure specific, and must be related to the mechanism of action of the gene product and features of exposure leading to gastric cancer.

Although the mechanism for tobacco-related gastric cancer risk is not well understood, tobacco-specific nitrosamines and other nitroso-compounds, plus other carcinogens contained in tobacco and tobacco smoke, are swallowed and may thus be involved in the process of gastric carcinogenesis[22,23]. Among gastric cancer cases, smoking-related DNA-adduct levels were higher in smokers than in non-smokers[24], and a study in China found smoking to be a risk factor for intestinal metaplasia and gastric dysplasia arising from chronic atrophic gastritis[25]. The biological mechanisms responsible for different interaction models observed in our study were not known, but it was possible to speculate that these interaction effects might be a reflection for individuals with and without environmental susceptible genotypes. This analytical approach may be used to determine higher risk individuals and take further preventive measures to decrease cancer risks in these susceptible individuals.

One limit of the study is the small number of subjects in some cells when GEI models were analyzed. The models resulting from the present study might be affected by chance, and need to be identified by more large-scale molecular epidemiological studies. Another potential limit was the

selection of controls, which include case's siblings. This kind of selection might create over-matching because siblings were more likely to have the same genotypes as cases than non-related controls, therefore leading to some loss of statistical efficiency, i.e. larger sample sizes required to attain the same statistical precision[26]. But others consider that the use of sibling controls generally improves efficiency for GEI evaluations[27,28].

In conclusion, our studies identified two kinds of GEI models between the *CYP1A1 Val* variant allele, *GSTM1* null genotype and tobacco smoking. Although the proposed carcinogen metabolism pathway seems a plausible explanation of our findings, further large studies are required to replicate these observations.

ACKNOWLEDGMENTS

We thank Zhaoxi Wang for his excellent technical assistance; thank Professor Regina M Santella for editing the manuscript. We also thank all the doctors for their kind help in collecting the biological samples and epidemiological data. We thank all participants in our study for their cooperation.

ABSTRACT

AIM: To investigate the effect of peroxisome proliferator-activated receptor gamma (PPAR-γ) and its ligand, ciglitazone, on inflammatory regulation of human gallbladder epithelial cells (HGBECs) and to assess the effect of human epithelial growth factor (hEGF) on growth of HGBECs.

METHODS: HGBECs were cultured in media containing hEGF or in hEGF-free media. HGBECs were divided into normal control group, inflammatory control group and ciglitazone group (test group). Inflammatory control group and ciglitazone group were treated with 5 μg/L of human interleukin-1β (hIL-1β) to make inflammatory model of HGBECs. The ciglitazone group was treated with various concentrations of ciglitazone, a potent ligand of PPAR-γ. Subsequently, interleukin-8 (IL-8), IL-6, and tumor necrosis factor-α (TNF-α) concentrations in all groups were measured. The data were analyzed statistically.

RESULTS: HGBECs were cultured in medium successfully. The longevity of HGBECs in groups containing hEGF was longer than that in hEGF-free groups. So was the number of HGBECs. The longest survival time of HGBEC was 25 d. The inflammatory model of HGBECs was obtained by treating with hIL-1β. The concentrations of IL-6 and IL-8 in ciglitazone group were lower than those in inflammatory control group ($P<0.05$). The secretion of IL-6 in inflammatory control group was higher (350.31±37.05 μg/L) than that in normal control group (50.0±0.00 μg/L, $P<0.001$). Compared to normal control group, IL-8 concentration in inflammatory control was higher ($P<0.05$).

CONCLUSION: hEGF improves the growth of HGBECs *in vitro*. Ciglitazone inhibits the inflammation of HGBECs *in vitro* and has potential therapeutic effect on cholecystitis *in vivo*.

INTRODUCTION

The peroxisome proliferator-activated receptor-γ (PPAR-γ) is a member of the nuclear receptor superfamily of ligand-dependent transcription factors[1]. With ligand binding, PPAR-γ forms a heterodimer with the retinoid X receptor-α (RXR-α) and joins to the PPAR response element in promoters of target genes, thus directly regulating their expressions[2]. PPAR-γ plays an important role in cell growth, differentiation, inflammation, and apoptosis. Binding to its ligand, PPAR-γ is associated with the regulation of cardiovascular disease, diabetes, and carcinogenesis[3]. Expression in many kinds of cells such as colon epithelial cells, monocytes, hepatic stellate cells, aortic smooth-muscle cells, thyrocytes, and airway epithelial cells, PPAR-γ gene can regulate their inflammation[4-8].

The commonly used method to elucidate the physiological role of PPAR-γ is to investigate the effects of its well-characterized ligands. The most specific PPAR-γ agonists are thiazolidinediones (TZDs)-insulin-sensitizing drugs including pioglitazone, rosiglitazone, troglitazone, and ciglitazone[9]. Previously, cyclopentenone prostanoids were thought to be the most potent one among the naturally occurring PPAR-γ activators[10]. However, 15d-PGJ2 is proved to be a potent inducer of interleukin-6 (IL-6) and IL-8 production and can be a mediator of inflammatory response recently, but this effect is independent of PPAR-γ activation[11].

In activated macrophages and vascular smooth muscle cells, the agonists of PPAR-γ inhibit the expression of many proinflammatory genes, like inducible nitric oxide synthase (iNOS), tumor necrosis factor-α (TNF-α), IL-6 or metalloproteinase-9. Endothelium lines, the inner surface of blood vessels, and is a primary target for inflammatory

agents. Exposure of endothelial cells to cytokines or bacterial lipopolysaccharide (LPS) induces the secretion of proinflammatory mediators, among them both IL-6 and IL-8 are crucial to acute inflammation[12,13]. IL-6 and IL-8 are produced either by endothelial cells directly or by endothelial cells activated by human interleukin-1β (hIL-1β) and TNF-α[14].

The present study was to investigate whether and how the PPAR-γ agonist, ciglitazone, one of the TZDs, affected the inflammatory regulation of human gallbladder epithelial cells (HGBECs). The effect was assessed by changes of IL-6, IL-8, and TNF-α in media after being treated with ciglitazone and IL-1β in order to determine the potential therapeutic function of PPAR-γ agonists for cholecystitis.

[illegible]

Materials

Dulbecco's modified Eagle's medium (DMEM), antibiotic-antimycotic solution, trypsin-ethylenediaminetetraacetic acid (EDTA) were purchased from Gibco BRL Life Technologies. Epidermal growth factor (EGF), type IV collagenase were purchased from Sigma Chemical Co. hIL-1β was purchased from Roche Biology Co. Ciglitazone was purchased from Cayman Chemical Co. IL-8, IL-6 RIA kit and TNF-α RIA kit were purchased from East Asia Radio-immunology Institution, Beijing, China. The lower detection limit of the assay was 0.3 μg/L for TNF-α, 50 μg/L for IL-6, and 0.2 μg/L for IL-8.

Cell isolation and primary culture

The isolation of HGBECs was processed immediately after its surgical removal. Bile was aspirated through a cannula placed in the cystic duct and the mucosal cavity was washed repeatedly with cold PBS containing 10^5 U/L penicillin and 100 mg/L streptomycin. Subsequently, 15 mL of 2.5 g/L trypsin-EDTA was introduced into the gallbladder and then placed in a sterile glass container immersed in a water bath at 37 ℃ for 20 min. Trypsin treatment led to a clear separation of the lining columnar epithelial cells from the underlying fibrous connective tissue. The cells were further dissociated by agitating in a turbulent stream of culture medium containing the pepsin for 5-10 min. The cell suspension was then centrifuged at 4 000 r/min for 5 min and the pellet was washed twice with DMEM containing 100 mL/L FCS. Subsequently, the cells were counted and tested for viability using concentrated trypan blue solution. In a typical study, >95% of cells would exclude trypan blue. Cells were placed on the Vitrogen-100 coated 24-well culture plate with DMEM containing 100 mL/L FCS, 10 μg/L human epithelial growth factor (hEGF) as test groups. Another 24-well cells were cultured in media without hEGF as control groups. Cell concentration was $(5\text{-}10)\times10^5$/mL. After being incubated for 2 h, media were changed to exclude non-epithelial cells. Media were changed after 48 h and subsequently, the cells were fed every 3 d.

Cells in three wells were digested by 2.5 g/L trypsin/0.1 g/L EDTA and counted every 24 h for 3 d to protract cell growth curve. Cells were studied serially by inverted phase microscopy and immunohistochemical reaction with epithelial keratins.

Cell group and treatment

HGBECs obtained through the above procedure were incubated in DMEM supplemented with 100 mL/L FCS, 10 μg/L hEGF, 10^5 U/L of penicillin, 10 mg/L of streptomycin at 37 ℃ in 50 mL/L CO_2. They were placed into 48-well culture plates in 5×10^5/mL of cell density. Then, they were randomly divided into normal control group, inflammatory control group, test group 1, test group 2, test group 3, and test group 4, among which each group had 8 wells containing 2 mL of media in a well. On the 5th d of culture, media were changed to DMEM without hEGF. Various final concentrations including 10, 20, 30, 50 mmol/L of ciglitazone were added into test groups 1-4, respectively. Cells were incubated in DMEM at 37 ℃ in 50 mL/L CO_2. The cells were treated with ciglitazone and incubated for 24 h, then inflammatory control group and all test groups were treated with the final concentration 5 μg/L of hIL-1β. Media were collected after 2-h incubation for measuring concentration of IL-6, TNF-α, and IL-8 by radioimmunoassay. Cell morphology was studied serially by inverted phase contrast microscopy.

Statistical analysis

The data were analyzed by Student's *t*-test for paired sample, by ANOVA for multiple comparison between groups. The statistical significance of the difference between mean values was determined by the *P* value less than 0.05.

[illegible]

Growth and conformation of cultured cells

HGBECs were cultured successfully in DMEM containing hEGF or without hEGF. In groups containing hEGF, the number of HGBECs reached the peak on the 5th d of culture and maintained for 10-12 d. After 20 d, apoptosis of HGBECs was noted. The longest longevity of HGBECs was 25 d. Compared to hEGF-free group, the growth and number of HGBECs were increased by hEGF (Figure 1).

After 6 h of culture, HGBECs attached to the monolayer were flat and multiangular in morphology. Some of the HGBECs were columnar with vigorous growth (Figure 2A). After 20 d of culture, vacuoles and drawbenches were found in cytoplast.

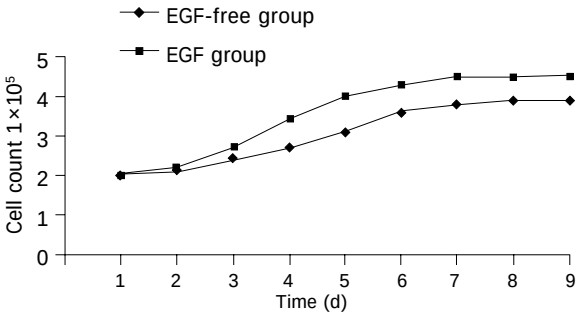

Figure 1 Growth curve of HGBECs.

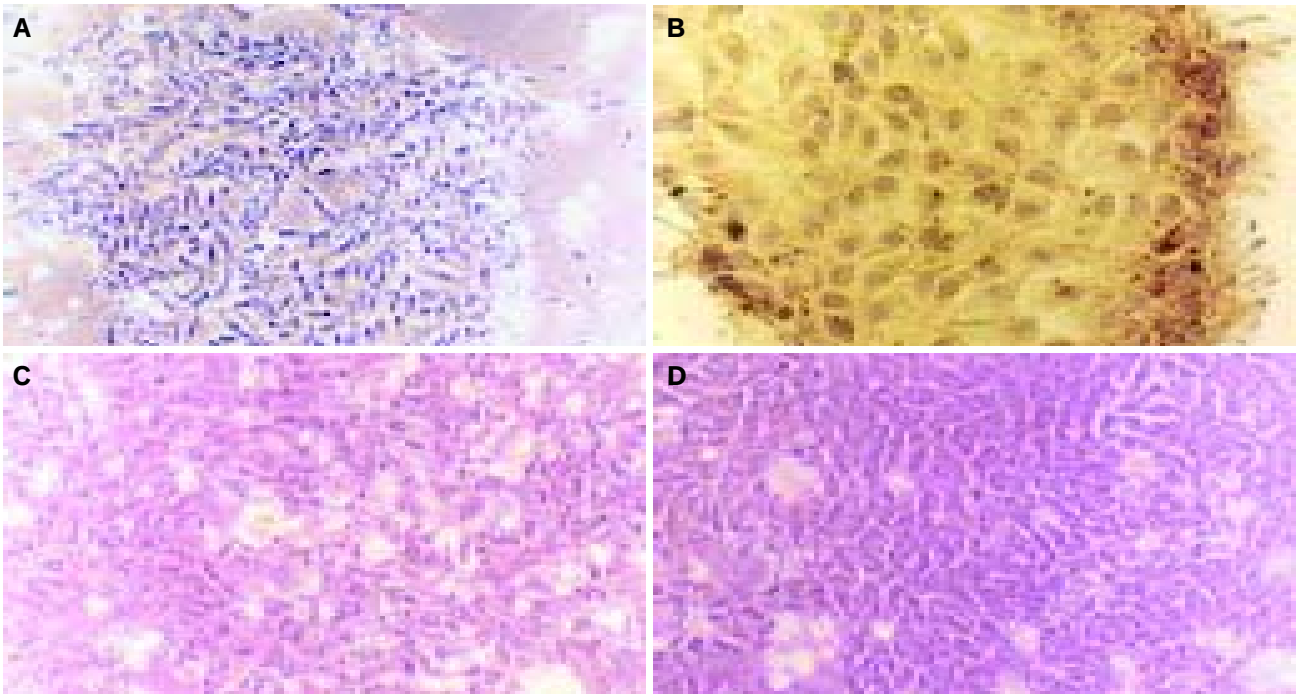

Figure 2 Attachment to monolayer (A), positive response (B), normal shape and structure (C) and edema (D) of HGBEC.

Identification of HGBECs

The cultured cells were identified by immunohistochemistry as keratin CK19. Specific positive reaction that could identify HGBECs was found in the cultured cells (Figure 2B).

Morphology of inflammatory HGBECs and inflammatory model of HGBECs

After HGBECs were treated with hIL-1β for 2 h, inflammatory changes of HGBECs such as swelling, unclear edge and irregular shape were found in test groups and inflammatory control group compared to normal control groups (Figures 2C and D).

Concentration of IL-6, IL-8 and TNF-α

Concentration of IL-6, IL-8 and TNF-α was measured by radioimmunoassay (Table 1). The data of TNF-α concentration were not shown because of its error and dispersion.

Table 1 IL-6 and IL-8 concentration in all groups (mean±SE)

Group	IL-6 (μg/L)	IL-8 (μg/L)
Normal control	50.0±0.00	0.20±0.00
Inflammatory control	350.31±37.05[b]	13.97±0.63[b]
Ciglitazone 10 mmol/L	231.46±39.41[a]	10.94±1.59[a]
20 mmol/L	207.22±26.72[a]	11.74±2.01[a]
30 mmol/L	188.89±29.33[a,d]	9.62±1.71[a]
50 mmol/L	170.46±20.24[a,e]	9.34±2.91[a,e]

[a]P<0.05 *vs* inflammatory control group; [b]P<0.001 *vs* normal control group; [d]P<0.001, [e]P<0.025 *vs* 10 mmol/L group.

[redacted]

The isolation and culture of HGBECs play a crucial role in studying biliary tract and liver disease. HGBECs have been cultured successfully since 1993[15], but its short duration limits the related research about the pathophysiology of biliary tract and liver. hEGF is a potent proliferation-activated factor of epithelial cells[16]. The first part of this study was performed to determine the hypothesis that hEGF could improve the growth of HGBECs. The proliferative activity of HGBECs promoted by hEGF was assessed by calculating the number and the life span of HGBECs, and compared to those in hEGF-free group. Results are in agreement with the hypothesis because hEGF increased the number of HGBECs and prolonged the longevity of HGBECs in which the longest was 25 d (8.2 d in EGF-free group). Also, the effect of hEGF on the growth of HGBECs is in agreement with the light microscopic findings. Thus, HGBECs cultured in medium containing hEGF are beneficial to the biological study of HGBECs.

The discovery that the insulin-sensitizing TZDs-specific PPAR-γ agonists have antiproliferative, anti-inflammatory and immunomodulatory effects has led to the evaluation of their potential use in the treatment of diabetic complications and inflammatory, proliferative diseases in non-insulin-resistant, euglycemic individuals. Apart from improving insulin resistance, plasma lipids and systemic inflammatory markers, ameliorating atherosclerosis and preventing coronary artery restenosis in diabetic subjects, currently approved TZDs that have been shown to improve psoriasis and ulcerative colitis in euglycemic human subjects[17]. In endothelial cells, troglitazone reduces expression of vascular cell adhesion molecule-1 and intercellular adhesion molecule-1, which are adhesion molecules that facilitate monocyte attachment and migration[18].

In addition to their impact on TNF-α and IL-6, IL -8, PPAR-γ agonists have also been reported by Pasceri *et al*.[18], to inhibit other macrophage proinflammatory mediators, including iNOS, gelatinase B, and the macrophage scavenger

receptor-A. PPAR-γ activation suppresses gastric mucosal inflammatory responses to *Helicobacter pylori* (*H pylori*) LPSs, suggesting that pharmacological manipulation of PPAR-γ activation may provide therapeutic benefits in the resolution of inflammation associated with *H pylori* infection[19]. In airway, PPAR-α and -γ (co) agonists might be of therapeutic interest for the regulation of allergic or inflammatory reactions by targeting both regulatory and effector cells involved in the immune response[20,21]. An important step in the monthly turnover of the endometrial lining during the menstrual cycle is the cyclical recruitment and activation of inflammatory cells. The use of PPAR-γ ligands to reduce chemokine production and inflammation may be a productive strategy for future therapy of endometrial disorders, such as endometriosis[22,23].

The mechanism of PPAR-γ and its ligand to regulate cellular inflammation may involve multiple pathways in different kinds of cells and the state of differentiation/ activation of the same source of cells. In macrophages and epithelial cells, the effect of 15 d-PGJ2 is targeted to the NF-κB/I-κB pathway and to the mitogen-activated protein kinase ERK1/2. The role of PPAR-γ activation in tissue factor inhibition by 15 d-PGJ2 is excluded[24]. 15 d-PGJ2 and rosiglitazone rapidly induce the transcription of suppressor of cytokine signalings 1 and 3, which in turn inhibit Janus kinase (JAK) activity in activated glial cells. In addition, Src homology 2 domain-containing protein phosphatase 2, another negative regulator of JAK activity, is also involved in their anti-inflammatory action[25]. Although it is not a direct causal effect, the insufficient PPAR-γ activity contributes to ongoing dysregulated inflammation in pulmonary sarcoidosis by failing to suppress NF-κB[26]. Dendritic cells (DCs), the most potent antigen-presenting cells, involve the anti-inflammatory activation of PPAR-γ. Recent reports showed that activation of PPAR-γ alters the maturation process of DCs, prevents induction of Th2-dependent eosinophilic airway inflammation and contributes to immune homeostasis in the lung[27]. However, conflicting findings on the consequences of PPAR-γ activation on inflammatory responses have led to a confusion regarding the role of the transcription factor in inflammation. Cyclopentenone prostaglandins, synthetic ligand of PPAR-γ, induce apoptosis of human DCs in a PPAR-γ-independent manner. Since these compounds are released during an inflammatory event and show anti-inflammatory properties, they may contribute to the downregulation of DC function through apoptotic cell death[28]. In a murine model of asthma, IL-8 release and activation of NF-κB-responsive reporter gene are inhibited only at micromolar concentrations, suggesting that these effects are not mediated by PPAR[29].

Based on the hypothesis that PPAR-γ expresses in HGBECs and inhibits inflammation of HGBECs, the following part of this study was designed to investigate whether the activation of PPAR-γ inhibited inflammation of HGBECs. IL-1β is a potent proinflammation factor that can induce multiple inflammatory mediators. After being treated with IL-1β for 2 h, HGBECs secreted a higher concentration of IL-6 and IL-8 in media ($P<0.001$). An inflammatory model of HGBECs was achieved successfully and showed a higher concentration of IL-6 and IL-8 in media, and inflammatory morphological changes such as edema and unclear edge in cellular formation. TNF-α, a potent inflammatory mediator, is often produced by white blood cells and smooth muscle cells in the early stage of inflammation. TNF-α could not be detected in the present study because HGBECs did not secrete it.

In vivo, IL-1β, TNF-α, and LPS initiate the secretion of cytokines including IL-6, IL-8, and IL-2. IL-1 can induce inflammation of gallbladder epithelial cells and biliary epithelial cells. Gallbladder inflammation is an early feature of gallstone formation[30]. These findings have been proved by molecular biology at mRNA level[31,32]. Also, these cytokines interact to form a network, which is named as cytokine storm[33]. The storm activates inflammatory cells and mediates inflammatory cell chemotaxis, then causes systemic inflammation. This process is defined as systemic inflammation response syndrome by the Association of American Physician and Critical Care in 1992[34].

PPAR-γ is a nuclear hormone receptor, with a well-established role in adipogenesis and glucose metabolism. Over the past 3 years several laboratories have reported that this protein can influence macrophage responses to a variety of inflammatory stimuli[32]. Immunolocalization of PPAR-γ primarily to colonocytes, especially in the presence of inflammation, strongly suggests that these epithelial cells are the target of PPAR-γ ligands[35-37]. In order to verify that HGBECs could express PPAR-γ and that PPAR-γ could affect the inflammation of HGBECs after binding to the ligand, we investigated the characteristics of PPAR-γ receptor using traditional endocrinological technique to study unknown receptor by binding to known ligand. We noted that ciglitazone with a final concentration of 10-50 mmol/L could suppress the IL-6 and IL-8 gene expression induced by IL-1β in a dose-dependent manner. This is consistent with our experimental hypothesis. Our results suggest that activation of PPAR-γ downregulates inflammation of HGBECs *in vitro*.

PPARs are nuclear receptor isoforms with key roles in the regulation of lipid and glucose metabolism. Synthetic ligands for PPAR-γ promote insulin sensitization in the context of obesity. In this study, ciglitazone showed potential therapeutic effects on inflammation of HGBECs *in vivo*.

Abstract

Multiseptate gallbladder, characterized by the presence of multiple septa dividing the gallbladder lumen, is a very extremely rare congenital anomaly of the gallbladder. On the other hand, anomalous pancreaticobiliary ductal union is also one of the congenital anomalous biliary diseases and thought to be related with choledochal cyst or biliary tract malignancies. In this paper, we describe a unique and first patient of multiseptate gallbladder with anomalous pancreaticobiliary ductal union and a review of the literature. To clarify more characters of the multiseptate gallbladder, examination of a larger patient population will be needed and further studies will be required.

INTRODUCTION

Multiseptate gallbladder is a very extremely rare congenital anomaly of the gallbladder. In the published cases, concomitant biliary diseases of the multiseptate gallbladder were reported as cholecystolithiasis, choledochal cyst, and hypoplasia. On the other hand, anomalous pancreaticobiliary ductal union is also one of the congenital anomalous biliary diseases and thought to be related with choledochal cyst or biliary tract malignancies. Along with the review of literature, reported here is a first patient of multiseptate gallbladder with anomalous pancreaticobiliary ductal union.

CASE REPORT

A 46-year-old Japanese female with gastric carcinoma underwent preoperative examinations at our institution. She had no complaints and her past history and family history were noncontributory. She reported no history of smoking and alcohol. Neither anemia nor jaundice was present. The abdomen was flat and soft. Liver, spleen, and mass could not be palpable. No lymph node swelling was palpated. Plain abdominal X-ray was normal. Laboratory data including tumor makers showed within normal range. Abdominal US and CT suspected septa in the gallbladder and showed neither cholecystolithiasis nor tumor lesion in the gallbladder. EUS demonstrated clearly multiple thin septa of the gallbladder (Figure 1A). ERCP revealed multiple faint septation in the neck portion of the gallbladder and combined with anomalous pancreaticobiliary ductal union. The common bile duct was not significantly dilated (Figures 1B and C).

Total gastrectomy and cholecystectomy were performed. In the macroscopic findings, the resected gallbladder was of normal size with smooth surface. Multiple thin septa were present only at the neck of the gallbladder. Neither tumor nor cholelithiasis was observed (Figure 1D). Microscopically, the septa were lined by typical columnar epithelium containing normal muscular layer of the gallbladder. There were mild chronic inflammation changes with the gallbladder. Pathological findings were consistent with multiseptate gallbladder (Figure 1E).

DISCUSSION

In recent years, congenital malformations of the gallbladder are increasingly diagnosed according to the rapid improvement of the imaging. The congenital malformations of the gallbladder are classified as anomalous forms, abnormal position, and absence. Multiseptate gallbladder is a very rare congenital anomaly form, which was first described by Simon and Tandon[1]. To our knowledge, only 30 cases including our case have been reported in the literature. A review of the cases described a female predominance; 21 of the patients were females. A mean age showed 29.4 years (range 3-70 years), and pediatric patients in four cases[2-5].

Most patients usually present with right upper abdominal pain, epigastralgia, and back pain, only six cases including our case were asymptomatic. Though the symptoms of multiseptate gallbladder patients were relieved after cholecystectomy, histological findings of the resected gallbladder in patients were usually of normal size with smooth surface and not

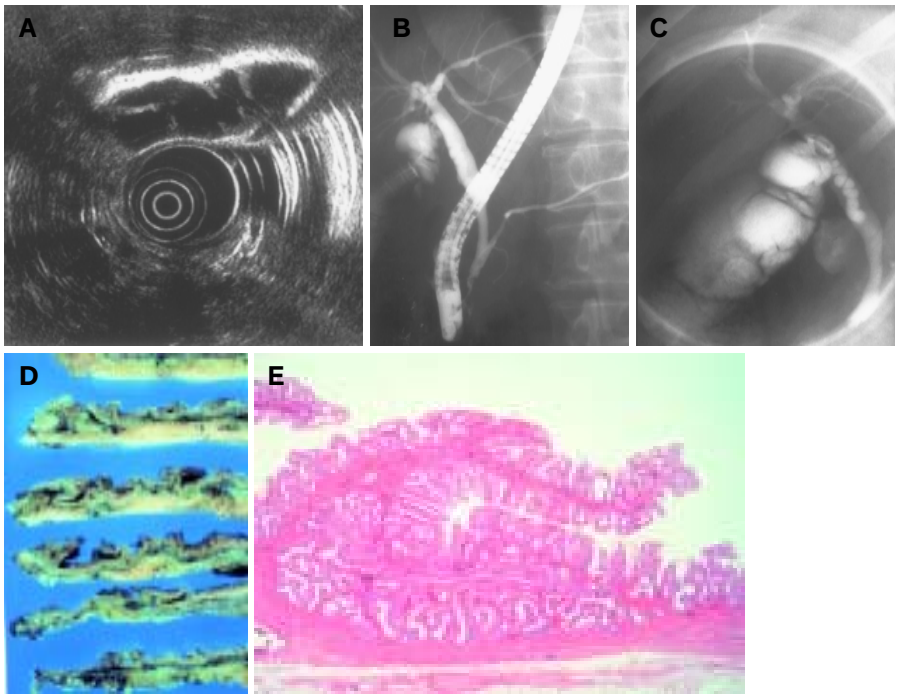

Figure 1 A: Endoscopic ultrasonography of the gallbladder showing multiple thin septa in the neck portion. B: Endoscopic retrograde cholangiopancreatography showing anomalous pancreaticobiliary ductal union. The common bile duct was not dilated. C: Endoscopic retrograde cholangiopancreatography showing multiple faint septation in the neck of the gallbladder. D: Longitudinal resected gallbladder shows multiple thin septa appearance at the neck portion. E: Microscopic findings of the resected gallbladder demonstrate the septa lined by normal typical columnar epithelium containing normal muscular layer (H&E stain, original magnification ×40).

always recognized as acute cholecystitis or cholecystolithiasis, and the exact mechanism of the biliary symptoms of multiseptate gallbladder is unknown. Saimura and co-workers investigated the mechanism of the symptoms of the patients with multiseptate gallbladder using biliary manometry and scintigraphy[6]. According to their study, both biliary manometry and scintigraphy indicated the impairment of the bile flow between the common bile duct and the gallbladder. One of the mechanism of the symptoms of multiseptate gallbladder is considered to be the impairment of the bile flow.

In nearly all literatures, pathological findings of multiseptate gallbladder reveal numerous septa, which consisted of a normal muscularis layer of the gallbladder wall, like a honeycomb appearance. Though the septa usually existed in the whole of the gallbladder, in some cases, the septations were confined to the neck, the body and the fundus alone[2,7,8]. This case presented the multiple septa in the neck portion of the gallbladder.

To make a diagnosis of multiseptate gallbladder exactly, it is important to detect clearly the septa in the gallbladder. Diagnostic imaging modalities for this disease were reported as abdominal US, abdominal CT[9], ERCP[7,10], oral cholecystography, and 99mTc hepatobiliary imaging[11]. In some asymptomatic cases, the diagnosis were made incidentally by abdominal US[3,4,8,12]. This case presented more clearly multiple thin septa in the neck portion of the gallbladder on EUS rather than other imagings. EUS is considered to be a very useful modality for the diagnosis of the cases with partial multiseptation.

Concomitant biliary disease of the patients with multiseptate gallbladder besides our case was reported in six patients; cholelithiasis in two patients[3,13], choledochal cyst in two[5,14], and hypoplasia of the gallbladder in two[15,16]. No cases that coexisted with malignancies were reported in the literature. On the other hand, anomalous pancreaticobiliary ductal union is also known as the congenital malformation of the pancreaticobiliary duct system and is thought to be related to choledochal cyst and biliary tract carcinoma. Though anomalous pancreaticobiliary ductal union is frequently observed in patients with congenital choledochal cyst, the cases without choledochal cyst are recognized to have great malignant potential of the gallbladder[17,18]. In this case, ERCP demonstrated anomalous pancreaticobiliary ductal union without choledochal cyst.

Our case is asymptomatic and has the septations at the only neck of the gallbladder. Besides these unique findings, this present case is the first report of multiseptate gallbladder associated with anomalous pancreaticobiliary ductal union in the world literature. To clarify more characters of the multiseptate gallbladder, examination of a larger patient population will be needed and further studies will be required.

Abstract

The patient was a 57-year-old woman presenting with jaundice as the chief complaint. She began vomiting on July 10, 2003. Jaundice was noted and admitted to our hospital for thorough testing. Tests on admission indicated severe hepatitis, based on: aspartate aminotransferase (AST), 1 076 IU/L; alanine aminotransferase (ALT), 1 400 IU/L; total bilirubin (TB), 20.9 mg/dL; and prothrombin time rate (PT%), 46.9%. Acute hepatitis A (HA) was diagnosed based on negative hepatitis B surface antigen and hepatitis C virus RNA and positive immunoglobulin (Ig) M HA antibody, but elevation of anti-nuclear antigen (×320) and IgG (3 112 mg/dL) led to suspicion of autoimmune hepatitis (AIH). Plasma exchange was performed for 3 d from July 17, and steroid pulse therapy was performed for 3 d starting on July 18, followed by oral steroid therapy. Liver biopsy was performed on August 5, and the results confirmed acute hepatitis and mild chronic inflammation. Levels of AST and ALT normalized, so dose of oral steroid was markedly reduced. Steroid therapy was terminated after 4 mo, as the patient had glaucoma. Starting 3 mo after cessation of steroid therapy, levels of AST and ALT began to increase again. Another liver biopsy was performed and AIH was diagnosed based on serum data and biopsy specimen. Oral steroid therapy was reinitiated. Levels of AST and ALT again normalized. The present case was thus considered to represent AIH triggered by acute HA.

INTRODUCTION

Autoimmune hepatitis (AIH) is a chronic progressive hepatitis characterized clinically by positive anti-nuclear antibody (ANA) and hypergammaglobulinemia, and histologically by portal inflammatory cell infiltration (plasmacyte dominant) and piecemeal necrosis. However, the exact mechanisms of onset are unknown. Based on past reports, AIH appears to be induced by antibody-dependent cell-mediated cytotoxicity, which involves both antibody-mediated and cellular immunity against specific liver antigens on hepatocyte membranes[1]. Several studies have documented the involvement of genetic factors, including human lymphocyte antigen (HLA) types such as DR3 and DR4[2]. Furthermore, cases of AIH have been reported in which viruses causing acute hepatitis such as hepatitis A (HA) virus[3-7], HBV[8] and Epstein-Barr virus[9] have acted as a trigger. We report herein the case of a patient with AIH that appears to have been triggered by acute HA.

CASE REPORT

The patient was a 57-year-old woman with jaundice as the chief complaint.

History of present illness

The patient had been seeing a local doctor for hypertension, with no sign of hepatic pathology. On July 2, 2003, she developed hives and was given fexofenadine hydrochloride. Around this time, she began to feel sick. While she had eaten raw foods within the previous month, she had not eaten raw oysters. Starting on July 10, she began vomiting and visited the local doctor on July 14. Jaundice was noted, and the patient was referred and admitted to our hospital for thorough testing.

Physical findings on admission

The patient was 163 cm tall and weighed 100 kg. She was thus very obese, and although yellowing of the bulbar conjunctiva was noted, no other abnormalities were identified.

Test findings on admission (Table 1)

Aspartate aminotransferase (AST), 1 076 IU/L; alanine aminotransferase (ALT), 1 400 IU/L; total bilirubin (TB), 20.9 mg/dL; prothrombin time rate (PT%), 46.9%; hepatitis B surface antigen (HBsAg) negative; hepatitis C virus (HCV) RNA negative; and immunoglobulin (Ig) M HA antibody positive (titer, 1.9 cut of index). Acute HA was therefore diagnosed. Furthermore, as levels of ANA (×320) and IgG (3 112 mg/dL) were elevated, AIH was suspected. Drug lymphocyte stimulation test (DLST) yielded negative results for fexofenadine hydrochloride. The patient scored 1 point according to the diagnostic criteria for acute drug-induced

hepatic injury established by the International Consensus Meeting (ICM)[10], excluding the possibility of drug-induced hepatic injury. Computed tomography showed no hepatic atrophy, but thickening of the gallbladder wall was apparent, suggesting acute hepatitis (Figure 1). HLA assessment conducted after admission revealed: A24(9); B52(5); B61 (40); DR15(2); and DR9.

Table 1 Labo data on admission

WBC	6900/uL	BS	129 mg/dL
Neutro	60.9%	HbA1c	6.4%
Eosin	3.6%	CRP	1.59 mg/dL
Baso	0.5%	Na	137 mEq/L
Mono	9.1%	K	3.6 mEq/L
Lympho	25.9%	Cl	99 mEq/L
RBC	502×10⁴/uL		
Hb	15.2 g/dL		
Ht	44.7%		
Plt	16.5×10⁴/uL	ANA	320 times
		AMA	-
TP	8.5 g/dL	IgG	3 112 mg/dL
Alb	3.4 g/dL	IgM	234 mg/dL
BUN	11 mg/dL	IgA	631 mg/dL
Cr	0.9 mg/dL		
T-Bil	20.9 mg/dL	IgM HA	+
D-Bil	16.9 mg/dL	HBsAg	-
AST	1 076 IU/L	HCV Ab	-
ALT	1 400 IU/L	CMV IgM	-
PT%	46.9%	EBV IgM	-
LDH	498 U/L		
Γ-GTP	129 IU/L		
ChE	242 U/L	DLST	-

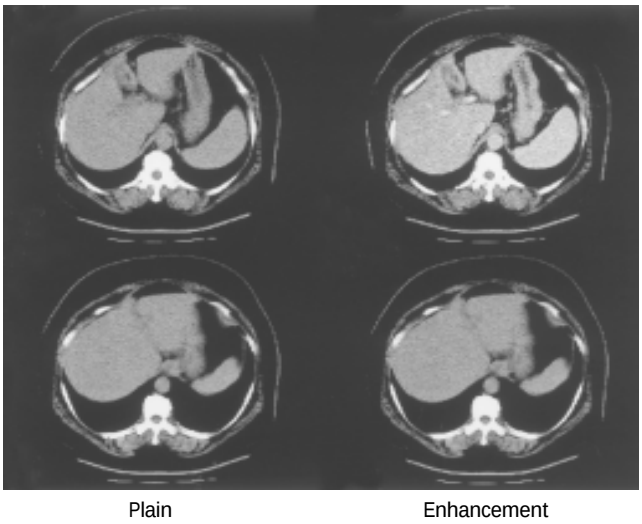

Figure 1 Liver parenchyma is not atrophic. Thickening of the gall bladder wall is also seen. This finding is compatible with acute hepatitis.

Clinical course following admission

Although AST and ALT levels started to improve, TB and PT% deteriorated to 27.5 mg/dL and 40.8%, respectively. To avoid onset of fulminant hepatitis, plasma exchange was performed for 3 d starting on July 17. From July 18, steroid pulse therapy was performed for 3 d, followed by oral steroid therapy. Levels of AST, ALT, TB, and PT% improved. Results of liver biopsy on August 5 confirmed acute hepatitis and mild chronic inflammation (mild fibrous enlargement of portal area was shown in two of eight portal areas and marked inflammatory cell infiltration of liver parenchyma was identified). The patient scored seven points according to international diagnostic criteria for AIH[11], which was thus excluded at this time. Acute HA was therefore diagnosed. At first, 50 mg/d of oral steroid (prednisolone) was administered, with dose reduced by 10 mg/d every week. Levels of AST, ALT, and TB gradually improved, and the patient was discharged while receiving 20 mg/d of steroid. After discharge, dose of oral steroid was reduced by 5 mg/d every week. As the patient also had glaucoma, oral steroid therapy was terminated after 4 mo. Levels of AST and ALT remained low, but began to increase around 3 mo after cessation of therapy. Since IgM HA antibody was negative at this time, AIH was suspected to be based on serum data such as ANA and IgG levels, and liver biopsy was performed on April 13 (Figure 2). AIH was diagnosed, and 600 mg/d of ursodeoxycholic acid was administered. This therapy proved ineffective, and oral steroid therapy (40 mg/d) was reinstated. AST and ALT levels normalized, and dose of oral steroid was gradually reduced. The patient is currently undergoing treatment in an outpatient basis with oral steroid therapy 1 mg/d, and no further elevation of AST or ALT levels has been seen.

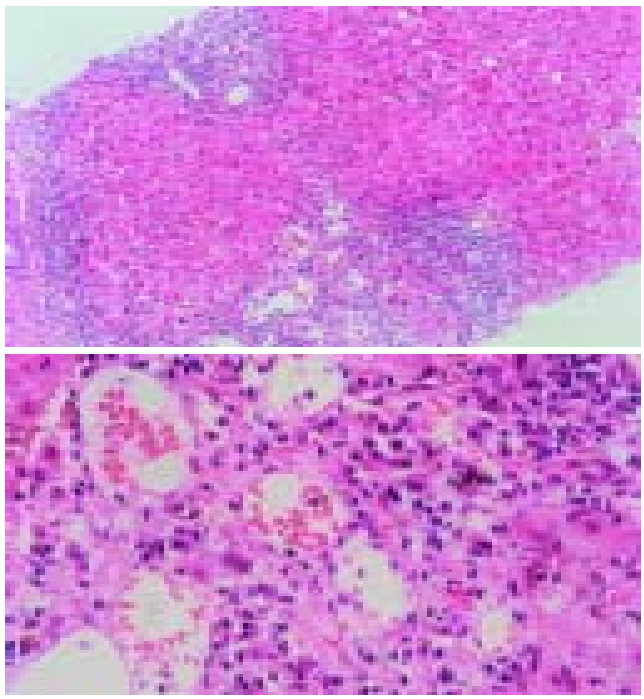

Figure 2 This liver biopsy specimen show the histopathologic appearance of chronic hepatitis. Interface hepatitis is present with bridging fibrosis, which fibrosis connects portal and cetral arreas. However, dominant plasmacyte infiltrates and rossete formation are not present.

[illegible]

On admission, although drug-induced hepatic injury was suspected in the present patient, acute HA was diagnosed due to positive IgM HA antibody. However, since ANA

was ×320 and IgG was 3 110 mg/dL, AIH could not be excluded as a possibility, and we could not be certain that the acute hepatic injury was caused by HA alone. DLST for the prescribed drug was negative, and the patient scored one point according to the diagnostic criteria for acute drug-induced hepatic injury established by the ICM [9]. Drug-induced hepatic injury thus seemed unlikely.

In the present patient, AIH was suspected at the onset of acute hepatitis, and assessment was performed in accordance with the international diagnostic criteria for AIH[11]. However, as the patient scored seven points, AIH was not initially diagnosed. Oral steroid therapy was terminated after 4 mo because transaminase levels remained normal and the patient also had glaucoma. However, transaminase levels again increased 3 mo after terminating oral steroid therapy. Since AIH had been suspected based on serum data such as ANA and IgG, liver biopsy was performed again. At this time, the patient scored 21 points according to international diagnostic criteria for AIH[11], and AIH was thus diagnosed.

While viral infection has been known to trigger AIH, few cases of AIH following acute HA have been described[3-7]. In most of these cases, AIH did not occur at the same time as acute hepatitis, with AIH often occurring several months after the onset of acute HA. According to international diagnostic criteria, the present patient did not display AIH at the time of acute hepatitis. However, since levels of ANA and IgG were high, excessive immune reactions were present. We suspect that these excessive immune reactions may lead to onset of AIH. No studies have investigated AIH during the early stages of acute hepatitis, and excessive immune reactions during acute HA have not been documented. One report documented a case of AIH that occurred after several months of abnormal liver function following acute HA[5]. While immune reactions are not often assessed in acute HA, as was the case with the present patient, excessive immune reactions may occur during acute HA.

Vento and colleagues[3] reported a patient with a deficiency of specific suppressor T cells for asialoglycoprotein receptor who developed type I AIH following subclinical HA, suggesting the possibility that immunological abnormalities including antigen presentations were involved in the onset of AIH following acute HA. HLA typings of patients with AIH triggered by acute HA were compared, but no specific tendencies were identified (Table 2). Since the sample of patients was small, larger subject populations need to be studied in future.

Herein, we presented the case of a patient with AIH that appears to have been triggered by acute HA. Given the existence of such patients and the need for careful follow-up of patients with acute HA, the clinical features of AIH patients after acute hepatitis need to be investigated for early diagnosis of AIH.

[illegible]

Cancer patients usually present a prothrombotic condition. Several clotting-related proteins, such as von Willebrand factor (vWF), presenting higher plasma concentrations in these patients, may play a key role in this process. Moreover, some of those proteins are currently being characterized as response rate and overall survival markers in metastatic colorectal cancer (MCRC). In this comment article, we discuss the last piece of evidence that supports the use of vWF as a prognostic indicator in MCRC patients, provided by a paper recently published by Wang *et al*., in the *World Journal of Gastroenterology*. Summarizing, although vWF should be seriously considered as potential future prognostic and predictive indicator in colorectal cancer, more dynamic and better designed studies in longer series of patients should be conducted before standardizing its universal use among these patients.

Wang *et al*.[1], have recently published an encouraging paper in the World Journal of Gastroenterology regarding the possible and novel use, as a prognostic factor, of vWF plasma levels in MCRC.

As the authors expose, cancer patients often show an imbalance between coagulation and fibrinolysis systems, which results in their prothrombotic condition[2-6]. Several clotting-related proteins, such as vWF, presenting higher plasma concentrations in these patients[7-11], may play a key role in this process. Moreover, some of those proteins are currently being characterized as response rate and overall survival markers in MCRC[12-16].

Accordingly, the data shown by Wang *et al*.[1], seem to indicate that plasma vWF concentrations are increased among colorectal cancer patients and correlate with tumor stage. In addition, those vWF higher levels may be related to significantly poor prognosis of subjects presenting metastasis.

However, although authors are aware of the important variability of vWF levels in humans due to the presence of a variety of diseases like diabetes mellitus, connective tissue disease, cardiovascular dysfunctions, thrombo-embolic events, acute infections, and other conditions like age or gender[17-20], patients suffering any of those illnesses were not apparently excluded from the study nor controlled by those factors in the multivariate analysis.

More strikingly, even though platelets are partially responsible for vascular endothelial growth factor (VEGF) levels[21-25], and VEGF is considered the most potent activator of the endothelium (main vWF producer), neither platelet count nor VEGF levels were measured and included in the statistical analysis.

Other issue that remains unclear in this article is whether the chemotherapy (CMT) regime used (5-fluorouracil alone or in combination with irinotecan, oxaliplatin or capecitabine) in each group of patients could have accounted for the differences observed between the survival curves for individuals presenting vWF$\geqslant$160% and those with levels below that threshold. Thus, in order to avoid the possible bias, the CMT regime administered to each patient should have also been taken into account in the multivariate statistical analysis.

Finally, given the fact that the CMT could catalyze the original risk for progression and death in these patients due to its alleged antiangiogenic effect, measuring vWF concentrations during treatment may modify the prognostic value of this protein.

According to this, in the University Clinic of the University of Navarra, 64 colorectal cancer patients were enrolled from 2002 and 2004. Blood samples were taken dynamically before and after fluoropirimidine-based CMT in 32 patients presenting metastasis, and stored until further

processing. vWF, VEGF, plasminogen activator inhibitor (PAI) 1, D-dimer, fibrinogen levels and platelet count were measured before and after CMT using standardized techniques. Gender, age, ECOG performance status, tumor burden, CMT course, and regime and CEA/CA 19.9 levels were also considered for the statistical analysis. Patients received a median of 3 cycles of CMT (range: 2-10) between both blood samples. After a median follow-up of 10 mo, baseline levels of vWF >202% showed an associated hazard ratio (HR), for death higher than patients with vWF ≤202%, with tendency to the statistical significance ($P = 0.08$). Meanwhile, post-CMT vWF levels above 189% were related to a fourfold HR for progression with respect to those subjects showing concentrations ≤189% after CMT treatment. These results were adjusted for the rest of the different protein levels measured, age, gender, ECOG performance status, tumor burden, and CMT course and regime.

In conclusion, although vWF and other coagulation/fibrinolysis factors should be seriously considered as potential future prognostic and predictive indicators in colorectal cancer, more dynamic and better designed studies in longer series of patients should be conducted before standardizing their universal use among these patients.

Abstract

Portal hypertension, one of the vascular diseases, not only has lesions in liver, but also changes in vascular structures and functions of extrahepatic portal system, systemic system and pulmonary circulation. The pathological changes of vasculopathy in portal hypertension include remodeling of arterialized visceral veins, intimal injury of visceral veins and destruction of contractile structure in visceral arterial wall. The mechanisms of vasculopathy in portal hypertension may be attributed to the changes of hemodynamics in portal system, immune response, gene modulation, vasoactive substances, and intrahepatic blood flow resistance. Portal hypertension can cause visceral hyperdynamic circulation, and the development and progression of visceral vasculopathy, while visceral vasculopathy can promote the development and progression of portal hypertension and visceral hyperdynamic circulation in turn. The aforementioned three factors interact in the pathogenesis of hepatic cirrhosis-induced portal hypertension and are involved in hemorrhage due to varicose vein rupture.

INTRODUCTION

Portal hypertension is characterized not only by lesions in liver, but also by the changes in vascular structures and functions of extrahepatic portal system, systemic system and pulmonary circulation. During a long-term animal experiment as well as in clinical practice, Yang *et al*.[1], discovered that obvious pathological changes occurred in visceral vessels with the increment of the portal pressure, such as formation of extensive portal-systemic communicating branches, the changes in modeling of visceral veins and arteries, etc., which were named vasculopathy in portal hypertension. Generally, vascular lesions also include microvascular lesions in viscera, especially in stomach and intestine, named as portal hypertensive gastropathy and portal hypertensive intestinal vasculopathy, respectively, which can cause hematochezia, occult blood in stool or hemorrhage of digestive tract. Portal hypertension can also be complicated with pulmonary vascular lesions, leading to pulmonary hypertension and elevation of pulmonary venous pressure, the former might contribute to the inevitable injury of pulmonary arterioles and arteries due to the passage of vasoactive substances into lung through collateral circulation, as well as the synthesis of vasoactive substances produced by lung itself, while the latter can result in varicose vein in lung, trachea and bronchi, and hemorrhage following the disruption of the varicose veins[2,3]. Perforating vein is the special vascular structure of gastric wall in portal hypertension[4], and is considered as a vascular lesion. The connection of varicose vessels outside gastric tunica serosa with the perforating vein leads to the abnormal flow into the submucous layer of the gastric wall to form the varicose vein. In this paper, we have briefly reviewed the research progress in the pathology and pathogenesis of vasculopathy in portal hypertension.

Pathology of vascular lesions in portal hypertension-induced remodeling of arterialized visceral veins

The changes in visceral venous structures, such as collagen, elastic fibers, and smooth muscles, are involved in the vein lesions. Under light microscope, the smooth muscle cells in portal wall display hypertrophy and hyperplasia. Under electron microscope, the traverse areas of the smooth muscle cells have onefold increase as compared with the normal one and that of vascular media is increased subsequently. The rat model of partial portal ligation revealed the changes in vascular structure, contractility, contractile components and structural proteins, and the proportion of desmin and actin was found to be increased. The thickened vascular intima contained hyperplastic collagenous fibers and large numbers of disordered smooth muscles. The interstitial was also obviously thickened with thickened and condensed muscle fibers. In the adventitial layers, there was infiltration of inflammatory cells and onefold increase in the active contractility[5].

The arterialized remodeling exists in both splenic veins and coronary vein of stomach in the patients with portal hypertension[6], which includes: (1) Obviously thickened intima, showing diffuse thickening and locally thickened areas, forming neointima containing hyperplastic collagenous fibers and large numbers of disordered smooth muscle cells.

The hillock-shaped hyperplastic spots extrude towards the vascular cavity, also containing large numbers of collagenous fibers and disordered smooth muscle cells. Platelet aggregation and blood cell attachment to the surface of injured endothelial cells gradually lead to the formation of microthrombi, similar to the plaque of atherosclerosis. The vascular intima is widely injured with infiltration of inflammatory cells; (2) The interstitial layer is significantly thickened, internal circular muscles are arranged lengthwise and breadthwise, and longitudinal muscles undergo up-growth with thickened and condensed muscle fibers; (3) There is infiltration of inflammatory cells in the adventitial layer and few lymphatic nodes are complicated with inflammation. The feeding vessels are squeezed with the formation of thrombi; (4) The phenotypes of part muscle cells convert from contractile type to synthetic type, that is, many rough reticulum and ribosomes and decreased myofilaments exist in the cytoplasm, and migrate from interstitia to intima.

Intimal injury of visceral veins

Vascular endothelial cell, attaching to the surface of vascular intima, is a semi-transparent barrier membrane and possesses complicated metabolic and endocrine functions simultaneously. Researchers are paying attention to the importance of endothelial cells in cardiovascular diseases increasingly, but the correlation between endothelial cells and portal hypertension has not been elucidated clearly. It has been confirmed that the vascular intima in the patients with non-hepatic cirrhosis is intact, there is a thin layer of smooth muscle in subintima, and the feeding vessels are intact and open. While in the patients with hepatic cirrhosis, the vascular intima is severely injured, endothelial cells are detached, the subintima is nude and edematous, and there are large numbers of inflammatory cells and fibroblasts in the vascular cavity, many blood cells adhere to the nude subintima, and mural thrombi form in the vascular cavity. In the vascular adventitia, the feeding vessels become flat by extrusion and thrombi formation also takes place. McCarthy *et al*.[7], found that when the vascular endothelial cells and basement membrane were injured, the sensitivity of vessels to angiotensin-II (AngII) was increased, suggesting that the damage to the intima could influence the contractile function of the vessels.

Destruction of contractile structure in visceral arterial wall

The patients with portal hypertension are in a state of high flow and low resistance in systemic circulation (i.e., the cardiac output and arterial pressure are decreased). Moreover, they are commonly associated with splenomegaly and hypersplenism. The splenic artery has obvious histopathological changes, i.e., destruction of contractile structure in arterial wall[8] as follows: (1) Damage of arterial endothelial cells. Partial endothelial cells detach, platelets attach to intima, which is thickened and the smooth muscles in interstitia migrate to it; (2) Weigert staining certifies that the folded ripples from elastic membrane in arterial wall become flat or completely disappear. The elastic membrane is split into multiple layers. Some parts are ruptured completely. The elastic fibers in arterial wall are also diffusely ruptured and degenerated. Under an electron microscope, split, even partly ruptured elastic membrane, is clearly seen; (3) Under light microscope, the smooth muscles in interstitia can be seen to be migrated to intima. Some medial smooth muscle cells are atrophic and anatrophic, others are hypertrophic and hyperplastic. The smooth muscle cells are separated by collagenous fibers, and arranged disorderly. Under electron microscope, the size and morphology of the smooth muscle cells are uneven, i.e., some are atrophic and anatrophic, vacuoles form in the necrotized local cytoplasm, and even whole muscle cell is lysed, while others are compensatively hypertrophic and hyperplastic. In some muscle cells, cytoplasmic cellular organs are obviously increased, mitochondria are increased and swollen, and their cristae disappear with the formation of vacuoles. In others, there exist many rough reticulum, ribosomes and Golgi bodies in cytoplasm, while the filaments are decreased, indicating that the phenotypes of muscle cells convert from contractile type to synthetic type. The cytoplasm and nuclei in some muscle cells display the characteristics of cell apoptosis; (4) Under light microscope, collagenous fibers and extracellular matrix in whole vascular wall are increased, leading to collagenization of vascular wall, and its thickening and rigidness, and decreased elasticity. Under electron microscope, the extracellular matrix in arterial wall is obviously increased, but the elastic fibers are degenerated and ruptured.

Mechanism of vasculopathy in portal hypertension

The mechanism of vasculopathy in portal hypertension is not clear. The changes in hemodynamics of portal system, immune responses, gene regulation, and vasoactive substances might contribute to the process of vasculopathy in portal hypertension.

Changes in portal hemodynamics

Vascular wall, composed of different biomaterials, possesses multiple layers of compound structure. Within a certain pressure range, vascular tension, transmural blood pressure, and the geometrical parameters follow the Laplace's law of biomechanics: $T = P(R/W)$. The vascular tension (T) has its regulatory limitation. Within an elastic range, when the transmural blood pressure (P) is increased, compensation can be achieved by increasing the vascular width (W) and decreasing vascular radius (R). So, the high pressure of portal vein can thicken the vascular wall.

The increase of vascular resistance in portal system at any part can result in portal hypertension. Neurohumoral factors and vasoactive substances can actively regulate the contractility of vascular smooth muscles. The active changes in vascular resistance can happen in hepatic microcirculation, also in prehepatic portal-systemic communicating vessels, portal vein and their branches. Effect on vascular resistance can be expressed by Poiseuille law: $r = 8\,\mu L/\pi r^4$, in which μ represents the viscosity coefficient of blood, L the length of vessel and r the radius. It can be seen that the changes in vascular radius of extrahepatic portal system are the main factors influencing the resistance of portal resistance. Intimal hyperplasia, spot formation, internal wall roughness, decreased elasticity and contractility in visceral veins can limit the vascular diastolization, promote the mural thrombosis, occlude vessels and narrow vascular cavity, leading to hypostasis, even obstruction, and finally increasing the blood

flow resistance. When visceral veins and portal-systemic communicating vessels are contracted, the portal resistance is obviously increased. The collateral vessels are flexural and tortuous, so their increases in length can also significantly increase the blood flow resistance. The changes of hemoglobin and plasma protein concentration in portal blood, especially the increased blood viscosity following gastrointestinal hemorrhage, can also increase the blood flow resistance in portal veins.

Hypertrophy and hyperplasia of vascular smooth muscle cells are the important features of vasculopathy in portal hypertension. Krieger and Dzau[9] found that the increase in mechanical load of vessels could directly induce the expression of myosin gene, increase the expression of RNA and protein, and finally induce the growth of muscle cells. It is suggested that the hyperplasia and hypertrophy of vascular smooth muscle cells may be one of the adaptive compensatory responses of vessels to increased pressure.

Persistent stimulation of high pressure and blood flow of portal veins may be the main factors responsible for the vascular intimal injury of the patients with portal hypertension. Compression of feeding vessels can decrease the supply of blood to vascular wall and partial pressure of oxygen, causing ischemic damage and nutrient disturbance of vascular intima. In hepatic cirrhosis, dysfunction of liver and kidney, decreased clearance of oxygen-free radical, and increased injurants and oxygen-free radicals in portal blood can directly injure the vascular intima.

Immune response

Researchers pay increasingly more attention to the roles that vascular endothelial cells play in the pathogenesis of cardiovascular diseases. The damages to endothelial cells in portal hypertension can destroy the structure of vascular wall, cause dysfunction, influence substance exchange and result in inflammation and immune response. In the patients with hepatic cirrhosis, the cells are markedly increased in the peripheral tissue around vessels, mainly lymphocytes and inflammatory cells, associated with the proliferation of lymph follicles. Immunohistochemistry reveals that there exists strong expressions of platelet-derived growth factor, basic fibroblastic growth factor, epidermal growth factor, transforming growth factor-α (TGF-α), etc., on the vascular wall of gastric coronary vein in the patients with portal hypertension[10], indicating that the elevated pressure in gastric coronary vein can activate the smooth muscle cells of vascular wall to release many kinds of vasoactive substances. These growth factors can stimulate the proliferation, differentiation, and migration of vascular smooth muscle cells in turn, resulting in abnormal metabolism of collagenous fibers and elastic fibers. The phenotypic shift of smooth muscle cells is a chronic response to mechanical stimulation, which can induce not only cell migration, but also the synthesis of collagen and elastin, leading to the thickening of venous wall, decreased elasticity and compliance, and finally causing the increase in blood flow resistance.

Studies have also confirmed that the levels of inflammatory factors (e.g., C3, C4, IgG, IgE, IgA) in visceral venous wall in portal hypertension are significantly higher than that in the normal controls[11], suggesting that there are obvious immune inflammations in the vessels of portal system in the patients with portal hypertension, and the immune complex deposit and immune response may participate in the process of vasculopathy in portal hypertension.

In some studies, immunohistochemistry and double labeling immunofluorescence combined with laser scanning confocal microscopy are applied to detect the expressions of eNOS, ET-1, PKC, NF-κB in splenic vein of the patients with portal hypertension and portal endothelial cells of mouse portal hypertension model in order to investigate the relationship between the changes in the expression of eNOS and ET-1 in vascular endothelial cells in portal hypertension and signaling molecules PKC and NF-κB. The results showed that in the splenic vein of patients with portal hypertension and portal endothelial cells of mouse portal hypertension model, the expression of PKC was positive or strong positive, while in the controls, the expression of PKC was negative or weak positive[12]. Double labeling immunofluorescence combined with laser scanning confocal microscopy revealed that eNOS, ET-1, and NF-κB were mainly expressed in vascular endothelia and the fluorescent signaling intensity of them in the splenic vein of patients with portal hypertension and portal endothelial cells of mouse portal hypertension model was stronger than controls, suggesting that the increases of ET-1 and NO in venous blood was attributed to the increased synthesis from endothelial cells in portal system. The increased NO production in endothelial cells is related to the upregulation of eNOS expression. In portal hypertension, the mechanical stress signaling pathway in vascular endothelial cells is activated, which is responsible for the upregulation of ET-1 and eNOS expression in endothelial cells.

Recent studies showed that during the development of vasculopathy, endothelial cells and vascular smooth muscle cells are major effector cells. Various traumatic factors, such as shear stress, hydrostatic pressure, endotoxin, cytokines, growth factors, and inflammatory mediators, can result in injury and detachment of endothelial cells, leading to the bareness of collagenous fibers and aggregation of platelets. Endothelial cells express adhesion molecules (e.g., ICAM-1), release chemotactic factors (e.g., MCP-1)[13] and complement fragment C5a after complement activation[14]. As chemotactic factors, they can promote the mononuclear cells to bind to endothelial cells, translocating through endothelial cells to subintima, also enhance the migration of vascular smooth muscle cells to subintima and the phenotypic shift. The migration to subintima and proliferation of vascular smooth muscle cells and synthesized large quantities of extracellular matrix depositing in vascular wall to form neointima can induce remodeling of vessels before vasculopathy occurs. During this process, the interactive regulation between endothelial cells and vascular smooth muscle cells runs through the development of vasculopathy. Endothelial cells are the permissive cells to various stimulators, while vascular smooth muscle cells are the effector cells. This is a repair response of vessels to varied injures, at the same time, a pathological process of vasculopathy.

Gene regulation

c-fos is a message transferring factor. Dzau *et al*.[15], have

found that after vascular smooth muscle cells receive message, nuclear c-fos is expressed, the synthesis of DNA and mRNA is increased and cells proliferate. In the patients with hepatic cirrhosis, the expression of c-fos in splenic vein is increased, indicating that the proliferation, migration, and phenotypic shift of smooth muscle cells are related to the activation of oncogenes. The signaling pathway of c-fos that connects the mechanical signaling with the expression of proliferating gene is the biological basis of vascular remodelization.

Some suppressive oncogenes, such as p53, the effective regulatory factor for apoptosis, can promote the apoptosis of vascular smooth muscle cells, while prokaryotic genes, such as *c-myc* and *bcl-2*, can inhibit the apoptosis of these cells[16,17]. In patients with portal hypertension, the bax gene is strongly expressed and takes part in the regulation of apoptosis of smooth muscle cells in portal hypertension, indicating that the process of vasculopathy in portal hypertension involves gene modulation.

MAPK pathway is one of the important signaling conductive pathways modulating cellular proliferation, differentiation, and apoptosis[18,19]. Many extracellular stimulators, such as ultraviolet radiation[20], oxygen stress[21,22], cytokines[23,24], inflammatory mediators[25-27], can stimulate the cells to upregulate the expression and activation of MAPK. In an experiment using the specific antibody directed against Tyr-phosphorylated site at $ERK_{1/2}$204, the results revealed that in portal hypertension, the expressions of phosphorylated $ERK_{1/2}$ and its downstream factor c-fos were increased in vascular wall of splenic vein, indicating that the activation of $ERK_{1/2}$/c-fos signaling transduction pathway might contribute to the development of vasculopathy in portal hypertension.

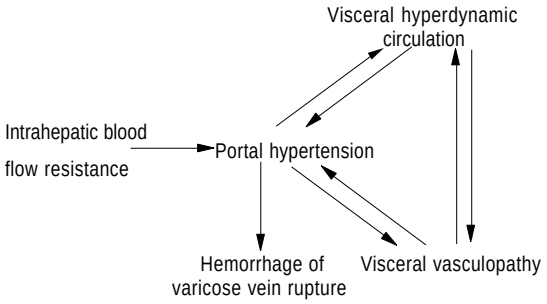
Collagen, an important vascular extracellular matrix protein, can retain the flexibility and intensity of vascular wall. In normal human vascular wall, the predominant collagen subtypes are types I, III, and V[28]. When vascular endothelia are damaged, collagenous fibers, as a strong promoter factor, can promote the aggregation of platelets. During the process of intervention-induced vascular injury and atherogenesis[29,30], the synthesis of vascular wall types I and III collagen and procollagen is increased. Types I and III collagen and procollagen are all the components of extracellular matrix, synthesized and secreted mainly by vascular smooth muscle cells in vasculopathy. A study has shown that a slight change in the constitutional ratio of types I and III collagen can trigger atherogenesis[12]. In the study on vasculopathy in portal hypertension, it was found that in the gastric coronary venous wall, the synthesis of connectin and laminin was increased, suggesting that extracellular matrix might play an important role in the pathogenesis of vasculopathy in portal hypertension. In several studies, RT-PCR was used to detect the expression of types I and III procollagen in portal hypertensive vasculopathy to investigate the mechanism of vasculopathy. The results showed that in portal hypertension, the expression of type III procollagen mRNA in splenic venous wall was 5-6 times higher than that in the patients with non-portal hypertension ($P<0.01$), while there was no significant difference in the expression of type I procollagen mRNA between them. It demonstrated that in the development of vasculopathy in portal hypertension, type III procollagen, depositing in vascular wall when extracellular matrical components are greatly expressed, is one of the important factors promoting the remodelization of splenic veins.

Vasoactive substances

Vasoactive substances act on vascular smooth muscle cells through paracrine and autocrine system. Immunohistochemistry confirmed that in portal hypertension, the activities of iNOS, P substance, and VIP in visceral arterial wall were increased[8]. Among them, the expression of iNOS in vascular smooth muscle cells of splenic vein was increased, indicating that the production of NO was increased correspondingly. NO, a stronger vascular diastolic factor, can attenuate the response of vessels to endogenous systolic active substances, which is contributed to the activation of soluble guanylate cyclase in vascular smooth muscle cells by NO, leading to the increased production of cGMP, and intracellular Ca^{2+}, diastolization of smooth muscles, dilation of vessels, and decreased resistance. However, in hepatic cirrhosis-induced portal hypertension, the expression and activity of eNOS is reduced[31]. Transfection of eNOS[32] or heterogenic nNOS[33] genes by genetic techniques[3] could significantly reduce the animal portal pressure. By using PCR assay, Morales-Ruiz *et al*.[34], confirmed the expression of iNOS mRNA in thoracic aorta, abdominal aorta, and mesenteric arteries. The studies by Suga *et al*.[35], proved that the diastolic effect of mesenteric arteries to vasodilators in response was stronger than that of portal system. It is suggested that the over-release of NO may play an important role in the pathogenesis of visceral vascular low systolization and diastolization in portal hypertension[36].

Endothelin (ET) is the strongest vasoconstrictive polypeptide, crucially regulating the hepatic microcirculation and portal pressure. By using RT-PCR and RIA assays, Tieche *et al*., reported that in the mouse model of hepatic cirrhosis caused by bile duct ligation, the expression of ET gene was increased 6 times at 3 d after ligation and 30 times at 28 d after ligation. Moreover, it was directly correlated with the activation of hepatic stellate cells (HSCs) and the increased portal pressure. The increased expression and activity of ET gene were more obvious in portal vein and hepatic microcirculation than that in visceral arteries, and its systolic effect on veins was significantly stronger than that on arteries[37], suggesting that ET and NO are two important antagonists against portal hypertension.

AngII is an endogenous eight peptide and induces the increase in the targeting cellular Ca^{2+} concentration by binding to the specific receptor on the membrane of targeting cells to form a receptor-ligand compound. The increased Ca^{2+}, as a second messenger, can produce the intensive effects of vasoconstriction and promote smooth muscle cell proliferation by different cascade reactions. In hepatic cirrhosis-induced portal hypertension, the vasodilator substances, such as NO and PGT2, can directly or indirectly reduce the expression of AngII receptors (AT1 and AT2) in vascular endothelial cells and decrease their affinity to AngII on the surface of smooth muscle cells. Both receptors in combination with the phenotypic changes of obviously



hypertrophic or hyperplastic vascular smooth muscle cells can influence the responses of vessels to AngII[38].

TGF-β plays a crucial role in regulating the deposition of external vascular matrix[39], promotes the transcription of types I and III procollagen, and contributes to fibrosis in liver and other organs noticeably. In animal models of hepatic cirrhosis and patients with chronic hepatitis, the increased TGF-β concentration was associated with the deposition of internal vascular matrix in the targeting organs. In HSCs, TGF-β could promote the synthesis of collagen[40]. Administration of TGF-β antibody or antagonists of TGF-β receptors can inhibit the synthesis of collagen. In contrast, the addition of exogenous TGF-β can increase the synthesis of collagen in smooth muscle cells[41,42]. TGF-β has many functions and exerts its biological effects via TGF-β receptors. TGF-β binds with its receptors before phosphorylation of the Smad protein and then enters into nuclei to regulate the transcription of proteins[43]. Also, TGF-β can increase the synthesis of extracellular matrix by activating Ras, Raf-1, and MEK in sequence[44,45].

NF-κB, as an important transcriptional regulatory factor, plays a key role in vasculopathy in portal hypertension[46]. After activation, the inhibition subunit I-κB of NF-κB is released into the nuclei to promote the transcription of fibrosis-associated genes via the JNK, AP-1 pathway. NK-κB is also the transcription of intercellular adhesion molecule-1 and vascular cell adhesion molecule-1[47]. It is known that besides the increased deposition of external vascular collagen for the vascular remodeling, the main factors for angiosclerosis are extracellular matrix and the binding sites of smooth muscle cells. During this process, adhesion molecules take part in regulating the binding of smooth muscles with extracellular matrix, promoting the development of vasculopathy.

Activator protein-1 (AP-1) binds with the AP-1 binding sites at the VEGF gene promoter that can promote transcription of VEGF[48]. VEGF acts through various pathways. Firstly, VEGF, the known strongest factor enhancing the vascular permeability, can increase the permeability of vascular wall[49]. VEGF functions through its receptors FLt-1 and FLk-1. In hepatic fibrosis, visceral vessels mainly express FLt-1, by which VEGF can promote the cell proliferation and collagen synthesis[50]. Secondly, VEGF possesses the chemotaxis to mononuclear macrophages and increases the adhesion of macrophages. The increased vascular permeability and the entry of mononuclear cells and macrophages into vascular intima result in the release of inflammatory factors, which can promote the smooth muscle cells proliferation and increase the synthesis of collagen[51]. VEGF can interact with basic cellular growth factor, TGF-β and hyaluronic acid to coordinately promote the proliferation of smooth muscle cells and collagen synthesis.

To sum up, the pathological changes of vasculopathy in portal hypertension include arterialized remodeling of visceral veins, the intimal injury of visceral veins and the destruction of contractile structure in visceral arterial wall. The mechanism of vasculopathy in portal hypertension may be attributed to the changes of hemodynamics in portal system, immune response, gene modulation, vasoactive substances, and intrahepatic blood flow resistance. On the one hand, portal hypertension can cause visceral hyperdynamic circulation and the development and progression of visceral vasculopathy. The visceral vasculopathy includes the destruction of contractile structure in visceral arterial wall and the remodelization of visceral veins. Vasculopathy results from the increased portal pressure and blood flow. On the other hand, visceral vasculopathy can promote the development and progression of portal hypertension and visceral hyperdynamic circulation in turn. The aforementioned three factors interact in the pathogenesis of hepatic cirrhosis-induced portal hypertension and are involved in hemorrhage of varicose vein rupture. The interaction between them is demonstrated as follows[6]:

Abstract

Patients with chronic hepatitis C virus (HCV) infection have a significantly increased prevalence of type 2 diabetes mellitus compared to controls or HBV-infected patients. Moreover, the incidence rate of post-liver transplantation diabetes mellitus (PTDM) also appears to be higher among patients with HCV infection. PTDM is often associated with direct viral infection, autoimmune disorders, and immunosuppressive regimen. Activation of tumor necrosis factor-α may be the link between HCV infection and diabetes. In this article, we reviewed the epidemiologic association between HCV infection and PTDM, highlighting the most recent pathophysiologic insights into the mechanisms underlying this association.

INTRODUCTION

The last two decades have seen an increase in various types of organ transplantation for the treatment of end stage organ diseases. Prevention of organ rejection requires long-term immunosuppressive therapy, which places recipients at the increasing risk of infection and metabolic disorders, such as recurrent hepatitis C virus (HCV) infection and post-liver transplantation diabetes mellitus (PTDM). Recipients with HCV infection have a higher incidence of PTDM, which depends on the degree and duration of immunosuppressant[1]. On the other hand, the occurrence of PTDM is associated with direct viral infection, autoimmune disorders[3], and immunosuppressive regimen, notably tacrolimus[4]. PTDM characteristically shows insidious onset and aggressive behavior thereafter. PTDM in HCV-infected patients might be partially or completely recovered after reduction or switching of immunosuppressive therapy[5].

PTDM AND HCV ASSOCIATION: RISK FACTORS

The high prevalence of diabetes mellitus, especially type 2 diabetes mellitus (type 2 DM) in HCV-infected patients comes from epidemiologic studies (Table 1), most of which are case control studies,[6,7,9,10-12,14] in addition to two multicenters and cohort[8,13]. Risk factors resulting in the increasing prevalence of type 2 DM in HCV-infected patients include positive family history of diabetes and black ethnicity[15]. Thus, it is conceivable that HCV leads to type 2 DM in susceptible hosts. Immunogenetic studies suggest that an infectious process coexists in patients with type 2 DM and chronic liver disease and HLA-DR2, -DR51, -DQB6 haplotypes provide a two- and three-fold relative risk for the development of diabetes[16].

It is reported that liver transplantation recipients with HCV infection have a four- to eight-fold prevalence of diabetes compared with recipients with other viral or cholestatic liver diseases 1 year after liver transplantation. A recent study of 260 HCV-infected patients has confirmed that insulin resistance is an independent predictor of the degree of fibrosis, and that insulin sensitivity has a significant correlation with serum aspartate aminotransferase, histological activity index and degree of fibrosis[18] in non-diabetic HCV-infected patients. Gray *et al*.[17], observed that abnormal liver function tests are found in 72.3% of HCV-positive diabetic patients and in only 24.7% of HCV-negative diabetic patients ($P<0.001$). In summary, the occurrence of PTDM seems to be associated with HCV infection.

PATHOPHYSIOLOGY

The pathophysiologic mechanism underlying the development of PTDM in patients with HCV infection has not been clearly illustrated. Possible mechanisms are shown in Figure 1.

Tumor necrosis factor-alpha (TNF-α)

A study of liver biopsy specimens from non-diabetic HCV-infected patients has revealed significant impairments in the insulin-signaling pathway[19], which is strikingly similar to the known effect of tumor necrosis factor-α (TNF-α) on insulin resistance[20]. The role of TNF-α in the pathogenesis of this HCV-associated insulin resistance state is strongly

Table 1 Studies of PTDM in patients with chronic HCV infection

PTDM (%)		RR (95%CI)	Study description	Reference

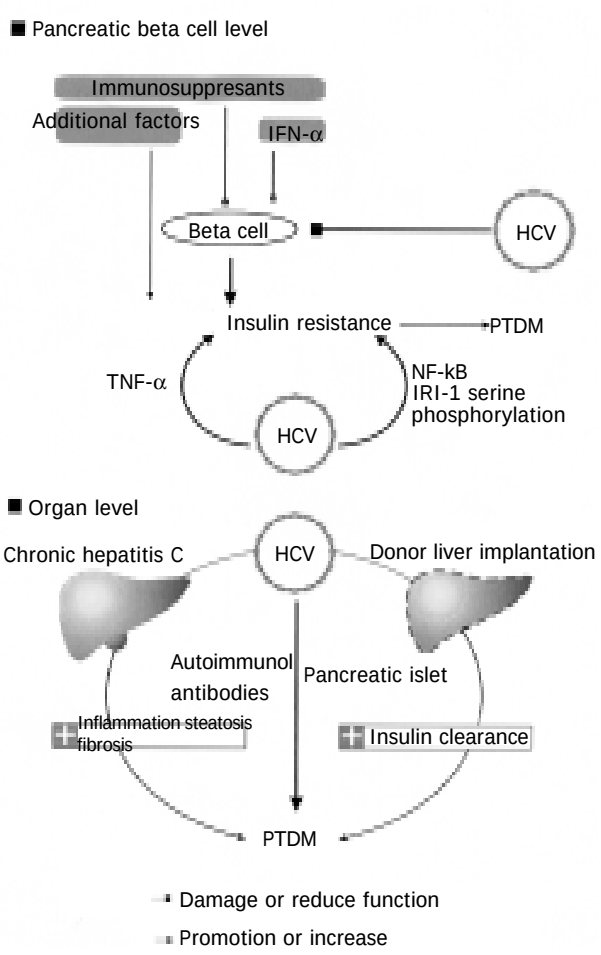

Figure 1 Possible mechanism underlying the development of PTDM in HCV infection (at least four mechanisms contribute to exacerbation of insulin resistance). (1) Chronic activation of TNF-α, which plays a key role not only in the production of and response to HCV itself, but also in the development of insulin resistance. Additional factors for developing PTDM in HCV-infected patients, including obesity, black ethnicity, and aging, are known to be associated with increased TNF-α independent mechanisms; (2) the increased clearance of insulin that occurs in post-transplant recipients thus creates a reactive hyperinsulinemic medium, and that in turn might enhance insulin resistance; (3) a bi-directional relationship between liver disease and diabetes is possible, as both insulin resistance and PTDM can adversely affect HCV liver disease; (4) directly diabetogenic effect of immunosuppressive therapy on pancreatic β cell.

supported by findings of elevated intra-hepatic TNF-α and amelioration of the metabolic abnormalities after TNF-α antibodies are administered[2]. The interrelationship between HCV and other predisposing conditions of PTDM could partly be mediated by TNF-α and most of the established risk factors for PTDM, such as obesity, aging[21], black ethnicity[22], and a family history of type 2 DM[23].

HCV per se

HCV replicates in hepatocytes, but its genome has been identified in a number of other tissues, including pancreatic acinar cells and epithelial cells of the pancreatic duct[24]. The destruction of pancreatic β cells could be mediated either directly by HCV or by HCV-induced immune responses, but evidence is scanty[3]. More recently, a transgenic mouse model that specifically expresses the HCV core protein in hepatocytes has been studied[2]. These animals had insulin resistance at an early age, and when challenged by a high fat diet, they developed glucose intolerance. Further characterization of the metabolic defects in these animals revealed that insulin resistance was caused mainly by failure of insulin to suppress hepatic glucose production. Piquer *et al.*[25], assessed the prevalence of islet cell autoantibodies in 303 non-selected HCV-infected patients (277 non-diabetic and 26 type 2 DM patients) and 273 sex- and age-matched control subjects, and found that patients with HCV have no significantly higher pancreatic autoantibodies compared with controls. However, it was reported that type 1 DM occurs more frequently in HCV patients treated with interferon (IFN) as a result of amplification of previously existing autoimmunity against pancreatic β cells, and that treatment of healthy volunteers with IFN can stimulate counter-regulatory hormone secretion, impair glucose tolerance and insulin sensitivity and induce insulin clearance, suggesting that HCV-induced immune response might be involved in the development of insulin resistance[26].

Immunosuppressive therapy

The overall effects of immunosuppression may potentiate the diabetogenic effects of HCV infection by enhancing the level of viral replication. A study on the effects of corticosteroids on post-transplant levels of viremia and PTDM showed that pulsed intravenous methylprednisolone therapy is associated with transient 4- to 100-fold rise in HCV RNA levels and the reduced translocation of glucose transporter 4 from cytosol into membrane, and that higher HCV RNA level is correlated with increased severity of graft and islet injury[30,45,46]. Immunosuppressive agents, especially steroids and calcineurin

inhibitors, are diabetogenic. The direct and indirect effects of corticosteroids, CyA on pancreatic β cells are well documented. With regard to FK506, the available data are not as extensive as for CyA, and its role in low blood insulin levels *vs* insulin resistance has not been fully evaluated. Human pancreatic allograft biopsies demonstrating both FK506 and CyA can induce structural damage of the graft islets, for example, cytoplasmic swelling, vacuolization, apoptosis, and abnormal immunostaining for insulin and the absent or reduced dense core secretory granules in the β cells. These changes are related to the doses of FK506 and/or CyA used. Although CyA and FK506 bind to different target molecules, both drugs inhibit or perturb the intermediate molecular events of insulin signal transduction (serine phosphorylations/dephosphorylations) in the same fashion. As a result, insulin signal fails to dephosphorylate the cytoplasmic component of the nuclear factor of activated signal transduction and transcription of insulin-sensitive gene, thus incorporating insulin resistance[27,28].

Organ level

Nonalcoholic fatty liver disease is associated with type 2 DM and the metabolic syndrome in patients with HCV[29]. However, the role of HCV as a risk factor for fatty liver has been questioned. It was reported that obesity and hyperlipidemia have a confounding effect on the association between HCV and steatosis[30]. In one study, serum ferritin levels were determined in 123 HCV-infected patients (55 diabetic and 68 non-diabetic patients)[32]. Increased iron store, which occurs in up to 40% of patients with chronic HCV infection[31], has been linked to the pathogenesis of diabetes development in those patients. The hepatic parasympathetic nerves are mediated by the activation of the Ach/NO/cGMP pathway involved in the secretion of a hepatic insulin sensitizing substance to mediate peripheral insulin sensitivity[41,42]. Schneiter *et al.*[33], found that liver transplantation recipients have severe insulinopenia as a result of the increased insulin clearance[33].

CLINICAL FEATURES

PTDM shares many similarities with type 2 DM in that the onset can be insidious, and individuals may experience glucose intolerance and may be asymptomatic for years[5]. The development of PTDM involves two distinct phases: (a) patients are initially at the greatest risk during the first 6 mo post-transplantation, and (b) the number of patients developing diabetes increases progressively thereafter. This has been illustrated by a study of 618 liver allograft recipients in which 7.2% of patients developed diabetes in the first 6 mo after transplantation, but then the percentage of cases increased linearly, leading to cumulative percentages of 7.1%, 10.4%, 13.2%, 20.5%, and 29.8%, respectively after 1, 3, 5, 10, and 15 years[34]. In a recent study, unadjusted cumulative incidences of diabetes 3, 12, and 36 mo after kidney transplantation were 15.6%, 25.6%, and 35.4% compared to 8.8%, 15.4%, and 23.4% in patients who were HCV negative at transplantation ($P<0.0001$)[35]. The potentially asymptomatic and/or transient nature of diabetes after transplantation makes the condition difficult to diagnose, thus underlining the importance of establishing a precise definition. It is recommended that the definition and diagnosis of PTDM should be based on the currently accepted definition of diabetes mellitus by the American Diabetes Association[5]. Diabetes mellitus is diagnosed by three fasting glucose measurements in the plasma above 7.0 mmol/L and/or antidiabetic medication (oral antidiabetic drugs or insulin), excluding periods requiring total parenteral nutrition or high steroid dosages for treatment of acute rejection, which may transiently impair glucose tolerance. After liver transplantation, patients with diabetes mellitus are classified either as non-insulin-requiring PTDM when taking only oral antidiabetic drugs or diet or as insulin-requiring PTDM when they require insulin injections. This classification of the patients should be done more than 1 year after liver transplantation[36]. Some preliminary reports suggest that pre-emptive therapy with IFN or a combination of IFN plus ribavirin may lead to less severe HCV infection recurrence after liver transplantation[43,44]. However, there are no controlled studies evaluating the prophylaxis of IFN in PTDM with HCV infection.

IMPLICATIONS

The HCV-diabetes association represents a major public health problem. Hundreds and thousands of patients in the USA alone are probably affected, and many more may have impaired glucose tolerance. Diabetes-related micro- and macrovascular complications are likely to occur, and the ongoing hepatic inflammatory response may contribute to atherogenesis. Furthermore, a putative bi-directional relationship between HCV-induced liver disease and diabetes may occur. Both insulin resistance and diabetes can adversely affect the course of chronic hepatitis C, and lead to enhanced steatosis, steatohepatitis, and liver fibrosis[37,38]. Moreover, recent evidence strongly suggests that steatosis and diabetes may also significantly enhance the risk of hepatocellular cancer[39,40].

FUTURE DIRECTIONS

There is evidence that HCV infection is related with the presence of PTDM. However, several questions remain to be answered. Firstly, randomized trials aimed to evaluate interactions of immunosuppressive regimens for the prophylaxis and treatment of PTDM are scarce. Secondly, the antiviral therapy for intervention remains to be determined. Finally, information is needed to clarify and diminish the effect of PTDM on quality of life and long-term outcomes. Further studies are necessary to evaluate the prognostic meaning of PTDM and the predictive factors for PTDM and to elucidate the pathophysiologic mechanisms.

Abstract

AIM: To explore the expressions of GST-π and telomerase activity in esophageal carcinoma and premalignant lesions and to investigate the value of endoscopic methylene blue (MB) and Lugol's iodine double staining.

METHODS: Seventy-two patients with esophagopathy were sprayed endoscopically with MB and Lugol's iodine in proper order and the areas stained blue and brown, and the area between the blue and brown stains were obtained. Depending on the pattern of mucosal staining, biopsy specimen was obtained. GST-π and telomerase activity in specimens were examined by immunohistochemistry and PCR-based silver staining telomeric repeat amplification protocol, respectively.

RESULTS: After MB and Lugol's iodine staining, the area between both the colors was obtained in 64 of the 72 patients and the areas were stained blue and brown in all of the 72 patients. Association test of two simultaneous ordinal categorical data showed a correlation between the esophageal mucosal staining and the esophageal histology (P<0.005). The expression of GST-π and telomerase activity in esophageal carcinoma and premalignant lesions increased. The expression of GST-π and telomerase activity in dysplasia and carcinoma was significantly higher than that in normal epithelium (P<0.005). The expression in hyperplasia was slightly higher than that in normal epithelium. With the lesions progressing from low- to moderate- to high-grade dysplasia, the positive rate increased (P<0.025). Expression of GST-π was correlated with that of telomerase activity in dysplasia and carcinoma (φ = 0.4831, P<0.005; φ = 0.3031, P<0.025, respectively); but there was no correlation between them in normal epithelium and hyperplasia.

CONCLUSION: The expression of GST-π and telomerase may be an early event in the carcinogenesis of esophagus. They may play an induced and synergistic role with each other in the carcinogenesis of esophagus. Endoscopic MB and Lugol's iodine double staining and detection of GST-π and telomerase activity may contribute to the early diagnosis of esophageal carcinoma.

INTRODUCTION

The early diagnosis of esophageal carcinoma correlates closely to improvement in prognosis. Much dependent on endoscopy, esophageal carcinoma is clinically diagnosed till now, but the choice of biopsy site, partly, has a limitation. The esophageal mucosal staining technique not only obtains the characteristic of the morphology of the lesions, but also helps to direct its biopsy in esophageal carcinoma. Carcinogen is one of the induced etiological factors. The glutathione *S*-transferases (GSTs) are a family of enzymes, which participate in metabolic detoxication and play important roles in the prevention of carcinogenesis by detoxifying numerous potentially carcinogenic compounds[1]. The present studies showed that telomerase activity had a close correlation with cell immortalization and carcinogenesis. The length of telomerase extends to maintain a proportional balance because telomerase is activated[2,3], therefore, the cells may unlimitedly proliferate to induce carcinogenesis. The aim of this study was to examine the expressions of GST-π and telomerase in esophageal carcinoma and premalignant lesions using immunohistochemistry and telomeric repeat amplification protocol (TRAP)-silver staining assay, respectively, and to investigate the value of endoscopic methylene blue (MB) and Lugol's iodine double

staining and detection of GST-π and telomerase in the early diagnosis of esophageal carcinoma.

MATERIALS AND METHODS

Specimen collection and processing

Tissue specimens were obtained endoscopically from in- and outpatients with abnormal findings, such as mucosal congestion, erosions, swelling or masses in the esophagus in the Affiliated Hospital of Jiangxi Medical College from 2002 to 2003. A total of 72 patients were included in this study, aged between 27 and 78 years, composed of 49 men and 23 women. All 72 patients underwent upper endoscopy and MB and Lugol's iodine staining with biopsy. After the endoscopic examination, the esophageal lumen was washed with 50 mL of distilled water. At first, 5 g/L MB solution was sprayed on the esophageal lesion. After 1 min, approximately 120-200 mL of distilled water was sprayed on the esophageal mucosa to wash off excess dye. Then 30 mL/L Lugol's iodine solution was sprayed on the esophageal lesion. After MB and Lugol's iodine staining, the pattern of mucosal staining was classified as blue, brown and the areas between both the colors. Depending on the color, two to four biopsy specimens of positive staining were obtained using the large cup biopsy forceps. Endoscopic specimens were immediately placed in the Eppendorf tube and a 10% buffered formalin solution, but immediately these specimens in the Eppendorf tube were kept in liquid nitrogen, and after 24 h, were stored at -80 ℃ until extraction for telomerase.

GST-π determination

Expression of GST-π was examined using indirect immunohistochemical staining accompanied by positive and negative controls. The key steps in the staining procedure were as follows: 4-μm-thick sections cut from each formalin-fixed and paraffin-embedded tissue specimen; deparaffinized in xylene, dehydrated through graded alcohol and washed thrice with distilled water; incubated for 5 min with 30 mL/L hydrogen peroxide to block endogenous peroxidase activity; again incubated with citrate buffer (pH 6.0) for 3 min using a household microwave oven at 800 W, followed by incubation for 1 h at 37 ℃ with the primary GST-π antibody at a dilution of 1∶100, and then washed thrice with PBS. After a second incubation with the GST-π anti-rabbit antibody HRP, 3, 3'-diaminobenzidine tetrachloride was used for color development and finally counterstained with hematoxylin. The immunohistochemical expression of GST-π was examined by means of light microscopy. The staining results were assigned to one of the following groups: (-), less than 25% of cells stained or the cells staining intensity being consistent with that of the background; (+), 25-50% of cells stained with light yellow fine granule showing in cells; (++), 50-70% of cells stained with dark brown granule showing in cells; (+++), more than 70% of cells stained with a great amount of dark brown granule showing in cells. Positive staining provided an internal positive control for GST-π staining. The primary antibody was replaced by PBS for the negative control.

Telomerase activity assay

Expression of telomerase activity was measured using TRAP-silver staining assay. Frozen specimens were homogenized and incubated with 20 μL of ice-cold lyses buffer (10 mmol/L Tris-HCl, pH 7.5, 1 mmol/L EGTA, 0.1 mmol/L benzamidine, 5 mmol/L β-mercaptoethanol, 5 g/L CHAPS, 100 mL/L glycerol). After 30 min of incubation on ice, the lysate was centrifuged at 14 500 *g* for 30 min at 2-8 ℃, and the supernatant was frozen and stored at -80 ℃. A total volume of PCR reactions was 25 μL. TRAP reaction was performed using 2 μL extracts, 2.5 μL 10× TRAP buffer (200 mmol/L Tris-HCl, pH 8.3, 15 mmol/L $MgCl_2$, 630 mmol/L KCl, 5 g/L Tween 20, 10 mmol/L EGTA, 1 g/L BSA), 1 μL of 4 mmol/L dNTP, 0.5 μL TS primer, and 18 μL double-distilled water. After 10 min incubation at 23 ℃ for telomerase-mediated extension of the TS primer, the reaction mixture was heated for 5 min at 94 ℃ to inactivate the telomerase, then added 2 U of Taq, 0.5 μL CX primer and finally 30 μL wax barrier. All the above steps were performed on ice. PCR reactions were performed for 27 amplification cycles, each cycle consisting of denaturation at 94 ℃ for 30 s, primers annealing at 50 ℃ for 30 s and extension at 72 ℃ for 90 s, followed by an extra incubation at 72 ℃ for 10 min to ensure full extension of the products. The PCR products were electrophoresed on a 120 g/L gel polyacrylamide for 2-3 h and then gel was stained using $AgNO_3$ and was photographed. The extract, which showed a ladder of products with 6-bp increments after being stained on the gel, was considered telomerase positive. For the negative controls of telomerase, the extract was heat-treated by incubation at 65 ℃ for 10 min prior to TRAP assay to inactivate the telomerase, and no PCR product was observed in the negative controls of telomerase.

Criteria of pathological histology

This was performed by evaluating the H&E-stained tissue sections under a microscope according to the criteria described previously by Qiu and Yang[4]. We classified the tissue sections into eight groups: normal epithelium; pure hyperplasia; low-grade dysplasia; moderate-grade dysplasia; high-grade dysplasia; carcinoma *in situ*; squamous cell carcinoma; and adenocarcinoma.

Statistical analysis

Proportion (relative number, %) was used for result analysis, and statistical significance was tested using χ^2 test, exact method analysis, rank sum test or association test of categorical data. A P value less than 0.05 was considered statistically significant.

RESULTS

Endoscopic methylene blue and Lugol's iodine double staining

After staining with MB and Lugol's iodine, the area between both the colors was obtained in 64 of the 72 patients. We observed areas stained blue and brown in all the 72 patients. Association test of two simultaneous ordinal categorical data showed a significant correlation between the esophageal mucosal staining and the esophageal histology (P<0.005, Table 1, Figure 1).

Table 1 Endoscopic MB and Lugol's iodine double staining (*n*, %)

Histology	*n*	Areas stained blue (%)	Areas between both the colors (%)	Areas stained brown (%)
Normal epithelium	53	49 (92.5)	4 (7.5)	0
Hyperplasia	21	13 (61.9)	6 (28.6)	2 (9.5)
Dysplasia	79	10 (12.6)	45 (57.0)	24 (30.4)
Low-grade	17	7 (41.2)	7 (41.2)	3 (17.6)
Moderate-grade	21	3 (14.3)	13 (61.9)	5 (29.4)
High-grade	41	0	25 (61.0)	16 (39.0)
Carcinoma	55	0	9 (16.4)	46 (83.6)
Carcinoma *in situ*	1	0	1 (100)	0
Squamous cell carcinoma	51	0	8 (15.7)	43 (84.3)
Adenocarcinoma	3	0	0	3 (100)
Total	208	72	64	72

$\chi^2 = 170.58$, $P<0.005$.

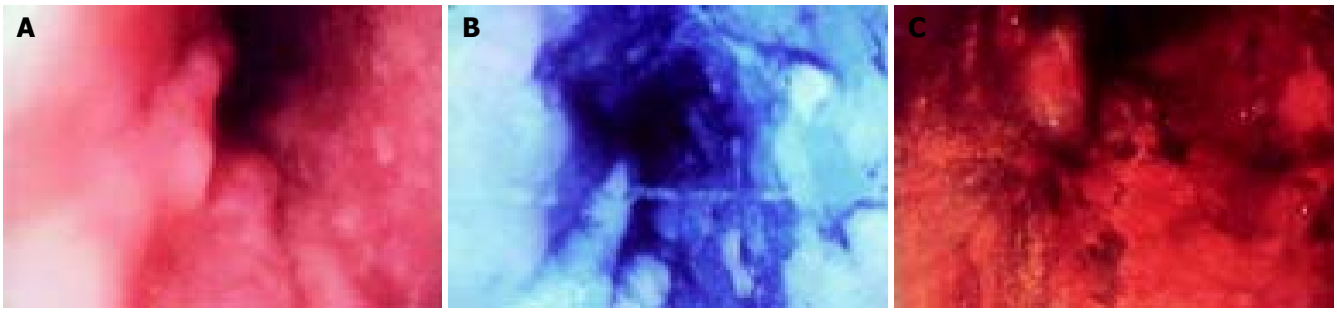

Figure 1 Endoscopic view of esophageal wall after MB and Lugol's iodine double staining. A: Before staining, a large broad-based erosion was observed on esophageal wall and the outlines of erosion were unclearly discernible; B: after MB staining, the same lesion stained more deeper blue than surrounding mucosa; C: after Lugol's iodine double staining, the normal mucosa appeared brown, the same lesion stained more deeper blue than surrounding mucosa and the areas between both the colors were not stained.

Expression of GST-π in esophageal carcinoma and premalignant lesions

GST-π was expressed in 5.7% normal epithelium (3/53), 62.0% dysplasia (49/79) and 83.6% carcinoma (46/55, $P<0.005$); the positive rate of hyperplasia was slightly higher than that of normal epithelium. With the lesions progressing from low- to moderate- to high-grade dysplasia, the positive rate increased ($P<0.025$, Tables 2 and 3, Figure 2).

Table 2 GST-π protein expression in esophageal carcinogenesis (*n*, %)

Histology	*n*	GST-π expression				Positive rate (%)
		–	+	++	++	
Normal epithelium	53	50	3	0	0	5.7
Hyperplasia	21	19	2	0	0	9.5[1]
Dysplasia	79	30	34	12	3	62.0[b]
Carcinoma	55	9	30	13	3	83.6[b]

[1]$P>0.9$, [b]$P<0.001$ *vs* normal epithelium.

Table 3 GST-π protein expression in various histology mucosa of esophagus (*n*, %)

Histology	*n*	GST-π expression				Positive rate (%)
		–	+	++	++	
Low-grade dysplasia	17	11	5	1	0	35.3
Moderate-grade dysplasia	21	9	8	3	1	57.1
High-grade dysplasia	41	10	21	8	2	75.6

$P<0.025$.

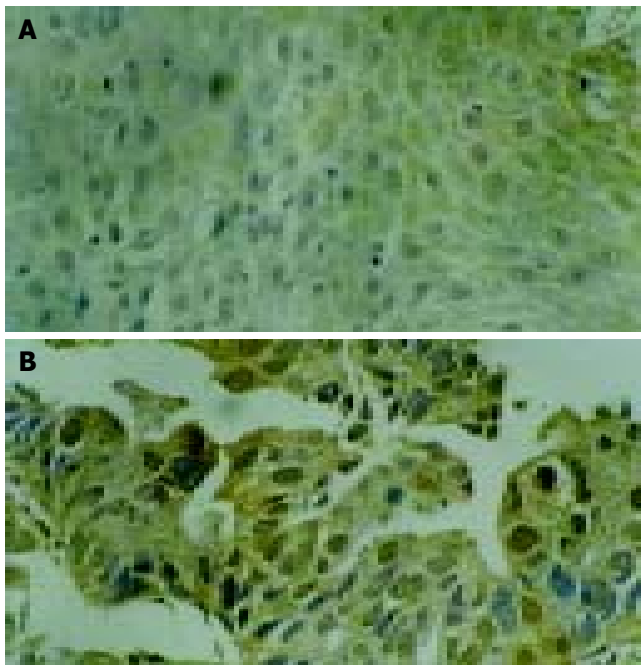

Figure 2 Expression of GST-π in histological esophageal tissues (×400). A: Esophageal dysplasia showing yellow or brown granule in cell substance and nucleus; B: esophageal carcinoma showing yellow or brown granules in cell substance and nucleus.

Expression of telomerase in esophageal carcinoma and premalignant lesions

Telomerase activity was expressed in 3.8% normal epithelium

(2/53), 51.9% dysplasia (41/79), and 89.1% carcinoma (49/55, $P<0.005$); the positive rate of hyperplasia was slightly higher than that of normal epithelium. With the lesions progressing from low-to moderate-to high-grade dysplasia, the positive rate increased ($P<0.005$, Tables 3 and 4, Figure 3).

Table 4 Telomerase activity expression in esophageal carcinogenesis (*n*, %)

Histology	*n*	Telomerase activity expression		Positive number of telomerase (%)
		+	–	
Normal epithelium	53	25	1	2 (3.8)
Hyperplasia	21	1	20	1 (4.8)[1]
Dysplasia	79	41	28	41 (51.9)[a]
Carcinoma	55	49	6	49 (89.1)[c]

[1]$P = 0.998$, hyperplasia *vs* normal epithelium; [a]$P<0.005$, $\chi^2 = 33.45$, dysplasia *vs* normal epithelium; [c]$P<0.005$, $\chi^2 = 78.83$, carcinoma *vs* normal epithelium.

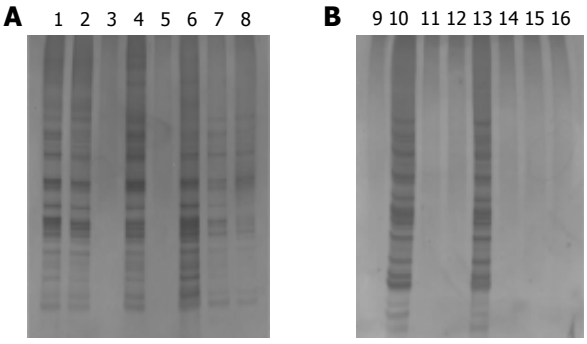

Figure 3 Analysis of telomerase activity of esophageal wall tissues using TRAP-silver staining assay. A: Esophageal carcinoma showing telomerase positivity (lanes 1, 2, 4, 6-8) and telomerase negativity (lanes 3 and 5); B: esophageal dysplasia showing telomerase positivity (lanes 10 and 13), and telomerase negativity (lanes 9, 11, 12, 14, and 15), and negative control (lane 16).

There was a positive correlation between the expression of GST-π and telomerase activity in esophageal carcinoma and premalignant lesions ($r = 0.9687$, $P<0.001$, Table 5). Expression of GST-π correlated to that of telomerase activity in dysplasia and carcinoma ($\varphi = 0.4831$, $P<0.005$; $\varphi = 0.3031$, $P<0.025$, respectively); but there was no correlation between the expression of GST-π and telomerase activity in normal epithelium and hyperplasia. Expression of GST-π was higher than that of telomerase activity in low- and moderate-grade dysplasia (Table 6).

DISCUSSION

In recent years, most scholars have advocated that the esophageal mucosal staining technique can be used for diagnosis of esophageal carcinoma to increase the sensitivity of the detection. Endoscopic MB and Lugol's iodine staining is one of the mucosal staining technique. The basis of the mucosal double staining technique is that MB stains lesion blue and Lugol's iodine reversibly stains glycogen brown. Normal squamous epithelium appears unstained because it does not absorb MB, but in abnormal mucosa, including intestinal metaplasia cells, columnar cells, erosions, ulcers and squamous carcinoma, the superficial epithelium is often stained blue because it absorbs MB. In normal squamous esophageal mucosa, the superficial epithelium contains large glycogen, so the mucosa stains dark brown, but in abnormal mucosa, the superficial epithelium often loses much of its glycogen, and remains partially or totally unstained. Therefore, the area stained blue indicates the existence of carcinoma; the area stained brown belongs to normal squamous esophageal mucosa and the area between both the colors clarifies the invasive lesion of carcinoma. Canto[5] reported that the diagnostic yield in 43 patients with Barrett's esophagus using MB-directed biopsies were compared with surveillance using a random biopsy technique in a controlled trial and the result indicated MB-directed biopsy was a more accurate technique than random biopsy for diagnosing specialized columnar epithelium and dysplasia and cancer. By means of the analysis of comparing the routine endoscopy to the endoscopy with 12 mL/L Lugol's iodine solution, Dawsey *et al*.[6], found that mucosal iodine solution improved endoscopic detection and this simple technique was highly sensitive in identifying these precursors and invasive squamous carcinoma. Our findings showed a correlation between the esophageal mucosal staining and esophageal histology ($P<0.005$), i.e. the areas between both the colors was a majority of dysplasia, especially moderate- and high-grade dysplasia, and the area stained blue was mostly carcinoma, and the area stained brown was mainly normal epithelium and hyperplasia. Overall,

Table 5 Telomerase activity expression in various histological mucosa of esophagus (*n*, %)

Histology	*n*	Telomerase activity expression		Positive number of telomerase (%)
		+	–	
Low-grade dysplasia	17	2	15	2 (11.8)
Moderate-grade dysplasia	21	7	14	7 (33.3)
High-grade dysplasia	41	32	9	32 (78.0)

Comparing among dysplasias $\chi^2 = 25.10$, $P<0.005$; there was significant difference between high- and low- or moderate-grade dysplasia ($\chi^2 = 21.77$, $P<0.005$; $\chi^2 = 11.90$, $P<0.005$, respectively), but no obvious difference between low- and moderate-grade dysplasia ($\chi^2 = 1.37$, $P>0.1$).

Table 6 Expressions of GST-π and telomerase activity in esophageal carcinoma and premalignant lesions

	Normal epithelium		Hyperplasia		Dysplasia		Carcinoma	
	GST-π (+)	GST-π (–)	GST-π (+)	GST- π(–)	GST- π(+)	GST-π (–)	GST-π (+)	GST-π (–)
TA (+)	0	2	0	1	36	5	43	6
TA (–)	3	48	2	18	13	25	3	3

TA: telomerase activity. Expression of GST-π correlated to that of telomerase activity in dysplasia and carcinoma ($\varphi = 0.4831$, $P<0.00$; $\varphi = 0.3031$, $P<0.025$ respectively); but there was no correlation between the expression of GST-π and telomerase activity in normal epithelium and hyperplasia ($P>0.05$).

endoscopic MB and Lugol's iodine double staining improves our ability to see the true size and borders of these esophageal lesions and to take biopsy accurately, which contributes to the early diagnosis of the high risk population and patients with esophageal carcinoma and premalignant lesion, thereby preventing the carcinogenesis of esophagus and reducing the mortality of the esophageal carcinoma.

In 1984, Sato *et al*.[7] firstly reported high level expression of GST-π protein in preneoplastic foci of rat liver, and subsequently the evidence suggested GST-π as an important marker of rat hepatocarcinogenesis. With a close crossing-immunity between GST-π in human tissues and GST-π in rat tissues, GST-π was regarded as a major research focus on the study of human carcinogenesis. A recent study has suggested that GST-π closely correlates with human alimentary carcinoma and is overexpressed in carcinoma and premalignant lesions. Ishioka *et al*.[8], showed that the RNA transcript levels of GST-π in tumor tissues were obviously higher than those in normal tissues in 80% cases (20/25), but no correlation between GST-π mRNA level and clinical stage or histologic characteristics was apparent. Li *et al*.[9], reported that the expression of GST-π increased in esophageal carcinoma and premalignant lesions and was associated with tumor differentiation, but no correlation between GST-π expression and clinical stage or lymphatic metastasis, while found that the mean serum GST-π levels in esophageal squamous cell carcinoma patients were significantly higher than those in normal subjects ($P<0.05$). Our data showed increased expression of GST-π in esophageal carcinoma and premalignant lesions, and with the lesions progressing from low- to moderate- to high-grade dysplasia, the positive rate obviously increased ($P<0.005$). In conclusion, when the cells are in the course of premalignancy, it is possible that some preneoplastic changes in metabolic enzyme have taken place, which are undetectable by using routinely stained sections and it is consistent with the fact of their increased GST-π expression level. Therefore, increased GST-π levels may be recognized as a useful marker of esophageal carcinogenesis.

Telomerase is a ribonuclear protein complex, which contains human telomerase RNA component and binding protein. Telomerase binding protein controls cell senescence, immortalization, and carcinogenesis by means of regulating telomerase activity and changing telomere length[10,11]. Normal somatic cells express undetectable levels of telomerase activity, whereas malignant cells express high levels[12]. Telomerase activity is strongly expressed in most human carcinomas, such as thyroid, breast, esophageal, gastric, lung, pancreatic, hepatocellular, and colorectal carcinoma[13-20]. Lord *et al*.[21], demonstrated that telomerase activation was an important early event in the development of Barrett's esophagus and esophageal adenocarcinoma, suggesting that very high telomerase levels might be a clinically useful biomarker for the detection of occult adenocarcinoma. Using microdissection-TRAP-silver staining assay, Li *et al*.[22], reported telomerase activity was high in both esophageal squamous cell carcinoma and preneoplastic lesions and was related to lymphatic metastasis, but not to cancer differentiation. The data from our studies showed that the positive rates of telomerase activity in low-, moderate-, high-grade dysplasia and carcinoma were 11.8%, 33.3%, 78.0% and 89.1%, respectively, but the positive rates of that in normal epithelium and hyperplasia were 3.8% and 4.8%. These observations reveal a crucial role for telomerase in the esophageal carcinogenesis. High expression levels in dysplasia show that telomerase may be activated in the early stage of esophageal carcinogenesis, indicating that telomerase activation is an early event in the carcinogenesis of the esophagus. It is, therefore, concluded that esophageal premalignant lesion may be effectively prevented from the progression to invasive malignancy in the light of irregularly surveying the variations of expression levels of telomerase activity in esophageal dysplasia patients and the prognosis of early esophageal carcinoma and premalignant lesion will improve significantly.

Our study provided evidence that expression of GST-π was higher than that of telomerase in low-moderate dysplasia. We infer that GST-π may be an early event in the carcinogenesis of esophagus in comparison with telomerase, but the relationship between GST-π and telomerase activity was not statistically significant. With the lesion progressing from dysplasia to carcinoma, expression level of GST-π showed an increased trend in degrees, whereas telomerase activity remained unchanged. We found that expression of GST-π was correlated to that of telomerase activity in dysplasia and carcinoma; but there was no correlation between the expression of GST-π and telomerase activity in normal epithelium and hyperplasia. Consequently, the results suggest that GST-π and telomerase may play an induced and synergistic role with each other in the carcinogenesis of esophageal carcinoma, but we do not know at present the mechanism to correlate GST-π with telomerase.

At present, many methods are widely used for the early diagnosis of esophageal carcinoma, but the sensitivity and specificity of a single method make it difficult to clinically diagnose an esophageal carcinoma. So, several authors have been exploring whether the combined method may improve the early diagnosis of esophageal carcinoma. Koyanagi *et al*.[23], reported that 10 of 18 iodine-nonreactive samples obtained from surgically resected specimens showed telomerase activity and in all 10 telomerase-positive samples, carcinoma *in situ* were observed in iodine-nonreactive mucosa by light microscopy and in 8 telomerase-negative samples, no tumor tissue were observed in iodine-nonreactive lesions. Inai *et al*.[24], also reported similar findings. Our study demonstrated that the expression levels of GST-π and telomerase were high in areas stained blue which was mostly carcinoma and the area between both the colors which was a majority of moderate- and high-grade dysplasia, and with the lesions progressing from low- to moderate- to high-grade dysplasia, the positive rate increased. In summary, the combined method of endoscopic MB and Lugol's iodine double staining and the detection of GST-π and telomerase activity are helpful to the early diagnosis of esophageal carcinoma and provide the chosen method for the physician.

Abstract

AIM: To investigate features of Epstein-Barr virus (EBV)-associated gastric carcinoma (EBVaGC) among a Mexican population.

METHODS: Cases of primary gastric adenocarcinoma were retrieved from the files of the Departments of Pathology at the Instituto Nacional de Cancerología and the Instituto Nacional de la Nutrición in Mexico City. The anatomic site of the gastric neoplasia was identified, and carcinomas were histologically classified as intestinal and diffuse types and subclassified as proposed by the Japanese Research Society for Gastric Cancer. EBV-encoded small non-polyadenylated RNA-1 (EBER-1) *in situ* hybridization was conducted to determine the presence of EBV in neoplastic cells.

RESULTS: We studied 330 consecutive, non-selected, primary gastric carcinomas. Among these, there were 173 male and 157 female patients (male/female ratio 1.1/1). EBER-1 was detected in 24 (7.3%) cases (male/female ratio: 1.2/1). The mean age for the entire group was 58.1 years (range: 20-88 years), whereas the mean age for patients harboring EBER-1-positive gastric carcinomas was 65.3 years (range: 50-84 years). Age and histological type showed statistically significant differences, when EBER-1-positive and -negative gastric carcinomas were compared. EBER-1 was detected in hyperplastic- and dysplastic-gastric mucosa surrounding two EBER-1-negative carcinomas, respectively.

CONCLUSION: Among Latin-American countries, Mexico has the lowest frequency of EBVaGC. Indeed, the Mexican population >50 years of age was selectively affected. Ethnic variations are responsible for the epidemiologic behavior of EBVaGC among the worldwide population.

INTRODUCTION

Gastric cancer (GC) is the second leading cause among cancer deaths in the world[1] and is one of the most frequent malignant neoplasms in Mexico[2]. Although the etiology of gastric carcinoma is now accepted as multifactorial, infectious agents play a central role in the mechanism of neoplastic transformation. The bacterium *Helicobacter pylori* (*H pylori*) has been implicated in a high percentage of gastric adenocarcinomas[3], in intestinal- as well as diffuse-type adenocarcinomas, according to the Lauren histoepidemiologic classification[4]. Another infectious agent, Epstein-Barr virus (EBV) or gamma type 4 herpes virus, has also been proved to be associated with gastric carcinoma in approximately 10% of cases[5]. This association has been reported in intestinal- and diffuse-type adenocarcinomas, as well as in nearly 100% of cases labeled lymphoid stroma-rich, lymphoepithelioma-like (LEL) carcinomas. The etiological role of EBV in GC development has been suspected on the basis of the uniform expression of Epstein-Barr nuclear antigen (EBNA)-1 protein, and EBV-encoded small non-polyadenylated RNA (EBER)-1 in all GC cells, the episomal monoclonality of the EBV genome, the elevated serum antibodies against EBV-related antigens among EBV-GC patients, and the unique 'lace pattern' morphology in some

early-stage EBV-GCs.

EBV-associated gastric carcinoma (EBVaGC) accounts for 1.7-16% of gastric carcinomas throughout the world, excluding LEL carcinomas[6]. The lowest frequency has been recorded in the UK, whereas the highest was in the USA. The definitive explanation for this figure remains unclear, but is probably related with genetic variations among different populations, as well as cultural and environmental influences among different geographic regions. Among Latin Americans, Mexican individuals are less likely to develop GC in association with EBV infection; in a previous study, we reported a prevalence of 8.15%[7]. In these series, diffuse-type EBV-GCs were seen exclusively, and EBER-1 was demonstrated in 100% of LEL carcinomas. In the present study, we expanded the number of cases under scrutiny and provided evidence that the risk for EBVaGC was significantly increased among patients >50 years of age in Mexico.

MATERIALS AND METHODS

Patient population

We retrieved cases of gastric adenocarcinoma from the files of the Departments of Pathology at the Instituto Nacional de Cancerología (1983-2000) and the Instituto Nacional de la Nutrición (1980-1995) in Mexico City. The results of a partial analysis of 135 cases were published previously elsewhere[7]. Eligible cases were included whenever they possessed complete demographic and pathologic information, as well as paraffin blocks with appropriate and well-preserved neoplastic tissue for molecular analysis. The age and gender of patients, and anatomic site, histological type, and depth of invasion of gastric carcinomas were obtained from records at the corresponding Department of Pathology.

Pathologic features

The anatomic site of gastric neoplasia was identified as upper (proximal) third, middle third, or lower (distal) third[8]. On the basis of predominant histological pattern, carcinomas were classified as intestinal- or diffuse-type according to the Lauren criteria[4] and subclassified as proposed by the Japanese Research Society for Gastric Cancer as follows[9]: intestinal types tub1 (well-differentiated adenocarcinoma with distinct glandular pattern and columnar epithelium throughout, moderate or small amount of stroma); tub2 (moderately differentiated adenocarcinoma with small or incomplete tubular structures with cubical or flat epithelium, amount of stroma variable from case to case), and muc (mucinous carcinoma); diffuse types, including por1 (poorly differentiated adenocarcinoma with solid, sheet-like proliferation with an alveolar pattern and indistinct tubular differentiation), por2 (poorly differentiated adenocarcinoma with acinar and trabecular pattern, usually showing diffuse infiltration with abundant fibrous stroma), and sig (signet-ring cell carcinoma). A special category, LEL carcinoma, similar to por1 adenocarcinoma but with dense lymphoid infiltrate exceeding total mass of carcinoma cells, was included. The depth of invasion was specified as mucosa; submucosa; or muscularis propria, subserosa, or serosa.

In situ hybridization

Molecular analysis was conducted as previously described[10]. Briefly, we retrieved one representative formalin-fixed, paraffin-embedded tissue sample from each carcinoma containing the neighboring non-neoplastic gastric mucosa. Two slides with 5 μm sections were prepared from each paraffin block. A set of slides were conventionally stained with hematoxylin and eosin, whereas the remainder were enhanced for EBER-1 *in situ* hybridization. The remaining paraffin-block sections were deparaffinized, rehydrated, predigested with pronase, prehybridized, and hybridized overnight at 37 ℃ with a concentration of 0.5 ng of digoxigenin-labeled probe. After sections were washed with 0.5×saline sodium citrate, hybridization was detected by anti-digoxigenin, antibody-alkaline phosphatase conjugate. Sections from a patient with known EBV-positive gastric carcinoma were used for a positive control, and sense probe to EBER-1 was used for a negative control for each procedure.

EBV genotyping

Preparation of DNA Each formalin-fixed and paraffin-embedded specimen was cut into 10-μm-thick slices, and a DNA sample was prepared following the method reported previously[11]. Each deparaffinized sample was treated with proteinase K (200 μg/mL) at 37 ℃ overnight followed by phenol/chloroform extraction and ethanol precipitation. Finally, the extracted DNA sample was dissolved in 50 μL of TE buffer.

Genotype-specific primer sets and probes Four different regions, the EBNA-3C, *Bam*HI-F, *Bam*HI-I, and *Xho*I sites in LMP-1, were used to determine viral genotypes. Types A and B can be determined by using the EBNA-2, -3A, -3B, or -3C gene[12-14]. In the present study, we chose EBNA-3C for genotyping because we experienced a higher detection rate of the primer set than those of the EBNA-2 region found in previous studies[15,16]. Types A and B, identified by PCR amplification of EBNA-3C region, corresponded to a 153- and a 246-bp band, respectively, and were confirmed by Southern blot hybridization with type-specific internal probes [14]. Wild-type F and f variant were identified by the presence of a 186-bp fragment in amplification of the *Bam*HI F region; after *Bam*HI cleavage, a 186-bp fragment could be identified in the case of wild-type F, and a 127-bp fragment could be identified in the case of the f variant. Wild-type F and f variants were confirmed by Southern blot hybridization with the internal probe as described previously[15].

For the *Bam*HI-I region, a 205-bp fragment was amplified by using primer sets as described previously[17], and types C and D were distinguished after cleavage by *Bam*HI-restriction enzyme. Type C had a 205-bp fragment, and type D had cleaved fragments with 130 and 75 bp. Types C and D were also confirmed by Southern blot hybridization with a cloned *Bam*HI-I DNA fragment probe.

To detect the *Xho*I polymorphism in exon 1 of the LMP-1 gene, we amplified a 497-bp DNA fragment with a primer set as previously described[18]. When two fragments, 340- and 157-bp long, were observed after *Xho*I digestion of the PCR product, the case was considered to contain the *Xho*I cleavage site. The 497-bp fragment of the PCR product of the B95-8 cell line was used as a probe to confirm the *Xho*I

cleavage site of LMP-1 by Southern blot hybridization[19].

PCR and Southern blot hybridization The PCR template contained the appropriate primer pair (1 μmol/L each), deoxyribonucleotide triphosphates (200 μmol/L each), and *Taq* polymerase (Takara Shuzo, Kyoto, Japan) in a total of 100 μL of PCR buffer. PCR products or PCR products digested with *Bam*HI and *Xho*I were confirmed by electrophoresis in 2% agarose gel and by staining with 0.5 μg/mL of ethidium bromide. Then, electrophoretic pattern was photographed under ultraviolet light. Electrophoretic DNA was transferred onto a Hybond N^+ nylon membrane (Amersham Pharmacia Biotech, UK) by capillary blotting using 0.4 N NaOH solution. Membranes were prehybridized with hybridization buffer for 0.5-1 h at 42 ℃. After the probe was added, hybridization was carried out overnight at 42 ℃. Probes of types A and B, and *Bam*HI-F were labeled with Dig oligonucleotide 3'-end labeling kit and detected using a Dig luminescent detection kit (Boehringer Mannheim, Germany). For detecting the *Bam*HI-I fragment and *Xho*I polymorphism in LMP-1, hybridization was carried out using the ECL direct labeling and detection kit (Amersham Pharmacia Biotech, UK) according to the manufacturer's instructions.

Statistical analysis

Odds ratios (ORs) and 95% confidence intervals (95%CIs) were obtained from logistic regression analysis, making comparisons between EBER-1-positive and EBER-1-negative gastric carcinomas with regard to age, gender, decade, anatomic site, histologic type, and depth of invasion.

RESULTS

Patient characteristics

We studied 330 consecutive, non-selected cases of gastrectomies due to primary gastric carcinoma. Among the 330 cases, there were 173 male and 157 female patients. The mean age was 58.1 years (range: 20-88 years) for all the patients, 59.9 years (range: 22-88 years) for male patients, and 56.1 years (range 20-88 years) for female patients. EBER-1 was detected in 24 (7.3%) of the 330 cases, 13 in men (7.5%) and 11 in women (7.0%). The mean age for patients harboring EBER-1-positive gastric carcinomas was 65.3 years: male patients 66.2 years (range: 51-74 years) and female patients 64.4 years (range: 50-84 years). The male/female ratio was 1.1/1 for the entire group and 1.2/1 for those with EBER-1-positive carcinomas.

Pathologic findings

With regard to the anatomic site of the primary neoplasia, 44 (13.3%) carcinomas were localized in the upper-third, 128 (38.8%) were in the middle portion, and 156 (47.3%) were in the lower-third of the stomach. In two cases (one male and one female), the anatomic location could not be determined; the entire stomach showed neoplastic infiltration in the male patient, and information on the original location of primary neoplasia was not available in the female patient. Both cases were EBER-1-negative. The distribution of carcinomas according to anatomic site and histological type, and the anatomic site and histological type of EBER-1-positive carcinomas are shown in Tables 1 and 2, respectively. Fourteen cases corresponded to early carcinomas, and only 4 were confined to mucosa; 10 cases invaded the submucosal layer. The remaining 316 cases were advanced carcinomas affecting muscular, subserosal, and serosal layers, as well as adjacent organs. EBER-1 was positive in all LEL carcinomas, in 4 out of 141 intestinal-type adenocarcinomas and in 11 out of 180 diffuse-type adenocarcinomas. The EBER-1 *in situ* hybridization signal was uniformly distributed in the nuclei of all 24 positive cases (Figures 1-6). A characteristic

Table 1 Distribution of EBER-1-positive gastric carcinomas by anatomic site[1] and gender

	Total (EBER-1+/total) %		Males (EBER-1+/total) %		Females (EBER-1+/total) %	
Total	24/330	7.3	13/173	7.5	11/157	7.0
Upper	3/44	6.8	3/31	9.7	0/13	0

I-type: Intestinal-type adenocarcinoma; *D-type*: Diffuse-type adenocarcinoma.

lace pattern was evident in the intramucosal component of three EBER-1-positive carcinomas, two por1 plus tub2 and one tub2 plus por1 adenocarcinomas. Twenty-two of twenty-four EBER-1-positive cases extended beyond the submucosa, whereas two carcinomas, one from a female and one from a male patient, did not exceed the submucosal layer.

There were two EBER-1-negative carcinomas accompanied by EBER-1-positive gastric lesions. The first case, a 52-year-old male patient (Figures 7 and 8), had EBER-1 expression in regenerative epithelium of gastric mucosa adjacent to an EBER-1-negative primary adenocarcinoma (por1). The second case was a 46-year-old female patient whose EBER-1-negative adenocarcinoma (por1) was in the immediate vicinity of dysplastic gastric glands with EBER-1 expression (Figures 9 and 10).

Among the demographic and pathologic variables analyzed, age and histologic type had statistically significant differences, when EBER-1-positive and EBER-1 negative gastric carcinomas were compared (Table 3). In addition, comparison among patients more or less than 60 years of age showed significant differences ($P = 0.008$).

EBV genotype

We examined the genotype of seven EBV strains detected from

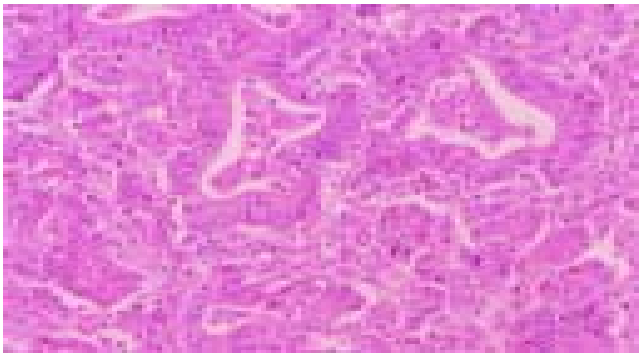

Figure 1 Moderately differentiated, intestinal-type (tub2) adenocarcinoma. Irregular neoplastic tubular structures are seen throughout the field (hematoxylin and eosin stain).

Figure 4 Same case as in Figure 3. A uniform nuclear signal of EBER-1 is seen in neoplastic cells (*in situ* hybridization).

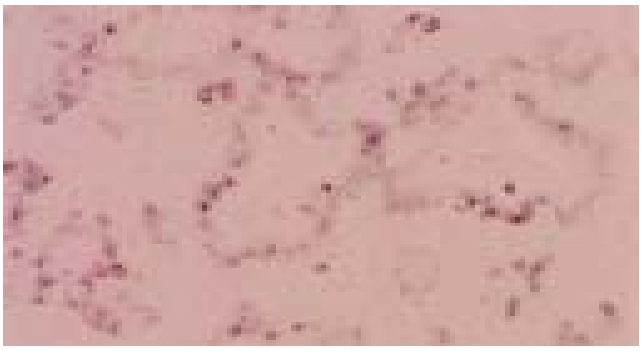

Figure 2 Same case as in Figure 1. EBER-1 nuclear positivity is limited to neoplastic cells lining the tubular structures (*in situ* hybridization).

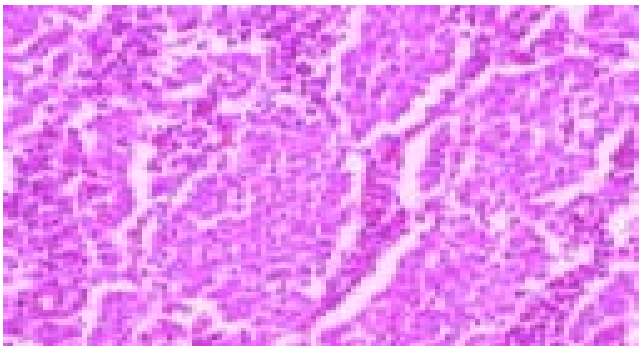

Figure 5 Poorly differentiated, LEL carcinoma. Clusters of neoplastic cells are separated by lymphoplasmacytic infiltrate.

Figure 3 Diffuse-type (por1) adenocarcinoma. Sheets of neoplastic cells are distributed in an indistinct pattern (hematoxylin and eosin stain).

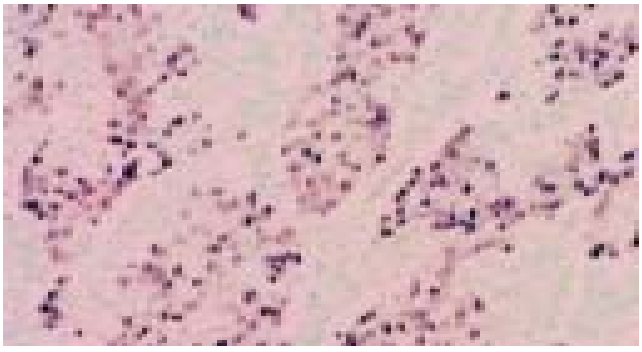

Figure 6 Same case as in Figure 5. An EBER-1-positive signal is detected in the nuclei of neoplastic cells (*in situ* hybridization).

EBER-1-positive cases; genotype could be determined in five of them. All were type A, wild-type F, and type D. In analysis of the *Xba*I cleavage site in LMP-1, we found that the cleavage site was lost in four cases and was maintained in one case.

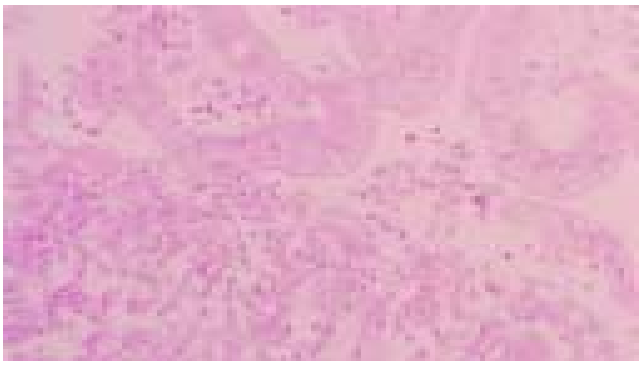

Figure 7 Lining gastric epithelium shows regenerative changes characterized by nuclear growth without atypia. There are few neoplastic cells in the underlying lamina propria (hematoxylin and eosin stain).

Figure 8 Same case as in Figure 7. The EBER-1-positive nuclear signal is restricted to regenerative epithelium. Note the EBER-1 nuclear negativity of neoplastic cells infiltrating the lamina propria (*in situ* hybridization).

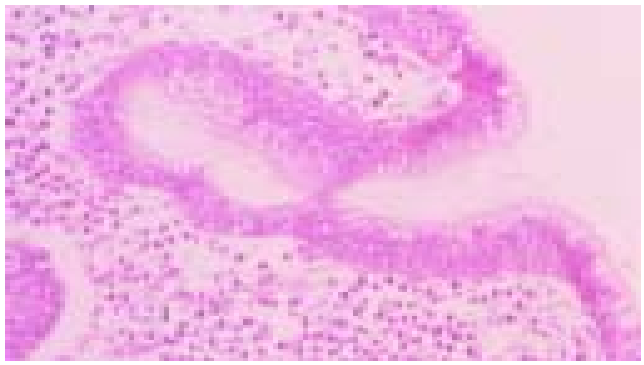

Figure 9 Lining gastric epithelium shows high-grade dysplasia, characterized by cell stratification and crowding, increased nuclear/cytoplasm ratio, nuclear atypia, and prominent eosinophilic nucleoli (hematoxylin and eosin stain).

Figure 10 Same case as in Figure 9. Dysplastic epithelium is intensely positive for the EBER-1 nuclear signal (*in situ* hybridization).

[1]Odds ratios and 95% confidence intervals were obtained from logistic analysis. Age was adjusted in the analysis of variables other than age.

DISCUSSION

In this study, we found a 7.3% prevalence of EBVaGC in Mexico. In Latin America, this frequency is in contrast with that reported by Koriyama *et al*., (11.2%)[20] and Lopes *et al*., (11.3%)[21] in Brazil, Carrascal *et al*., in Colombia (13%)[22], and Corvalan *et al*., in Chile (16.8%)[23]. Excluding LEL carcinomas, the prevalence of EBVaGC in Mexico was 4.7%, whereas in Chile it was 15.8%. In a Brazilian study by Koriyama *et al*.[20], and a Colombian study by Carrascal *et al*.[22], there were no LEL carcinomas. Nonetheless, in the study by Lopes *et al*.[21], a high prevalence of LEL carcinomas (66.7%) among EBVaGC patients was found in a Brazilian population; thus, the prevalence of EBVaGC excluding LEL carcinomas is the lowest (3.8%). Conversely, the prevalence of LEL carcinoma was 7.6% in Brazil, 2.7% in Mexico, and 1.1% in Chile. The male/female ratio (1.2/1) was, as previously noted[7], the lowest among the series reported worldwide. Moreover, after excluding LEL carcinomas, Mexico remains among countries with the low prevalence of EBVaGC worldwide[6].

The frequency of EBVaGC among GC patients of Mexican ancestry in the USA ranged from 10.2%[24] to 12%[25], which is higher than the frequency (7.3%) reported by us. This peculiar migratory phenomenon has also been seen in other countries such as Japan and China. In Japan, the mean frequency of EBVaGC is 6.2%, but among patients of Japanese descent, those who are living in Hawaii, the frequency is 10.2%. In Taiwan, the frequency of EBVaGC among patients of Chinese descent is 11.2%, in comparison to 6.8% in China[26]. This figure probably indicates that besides ethnic and genetic backgrounds, environmental factors are involved in the development of EBVaGC.

A high frequency of EBVaGC at older ages is evident in our Mexican study. Not a single case of EBVaGC was observed among patients aged <50 years. This feature was previously highlighted by Gulley *et al*.[25], who examined American patients of Mexican descent in the USA and found EBVaGC cases only among those aged 56 years or older. Age dependence of EBVaGC frequency was statistically significant in their study ($P = 0.04$). The absence of EBVaGC in a set of patients of Mexican ancestry aged <56 years was also reported by Vo *et al*.[24], although the age difference they reported was not statistically significant. A similar age dependence was reported in China[26], where EBVaGC frequency was higher among those aged 60 years or older than those aged <60 years ($P = 0.03$); interestingly, the frequency of EBVaGC (7.8%) in their study is quite similar to that reported by us (7.3%).

In Brazil, Lopes *et al*.[21], also did not find any patient less than 52 years of age, although other Latin-American studies such as those of Koriyama *et al*.[20], and Corvalan *et al*.[23], did not show any age dependence, reporting EBVaGC cases in patients <50 years. Contrary to the age dependence observed in the present study, a large-scale Japanese study reported a high prevalence of EBVaGC in young men[27]. Furthermore, the same authors showed a significant decreasing trend in EBV prevalence with increasing age for males ($P = 0.04$). Carrascal *et al*.[22], also reported an age-dependent decrease of EBVaGC frequency among Colombian individuals with GC (P for trend = 0.022).

The fact that EBV-associated cancer cannot be detected in other digestive tract organs including the colon and esophagus indicates the importance of epithelial change(s) specific to the stomach[28]. EBV-latent infection products were reported to be expressed in predisposing conditions for gastric carcinoma[29,30]. Our observation showing that EBVaGC could not be found among patients <50 years of age supports the involvement of gastric-mucosal changes occurring late in human life in Mexico, as well as in Brazil and China, and relatively early in Japan and Colombia.

EBVaGC has been related to atrophic gastritis, and EBV DNA has been isolated from epithelial cells in gastric mucosa carrying chronic atrophic gastritis[29-31]. Indeed, intestinal metaplasia may enhance EBV entrance into epithelial cells via adherence of the virus to the secretory component of polymeric immunoglobulin A[32]. Our finding of two cases of EBV non-associated gastric carcinoma, one positive for EBER-1 in adjacent hyperplastic mucosa -a finding not previously described -and the other with an EBER-1-positive signal in dysplastic mucosa -a finding originally reported by Shibata and Weiss[33] -also suggests that the most plausible mechanisms for EBV entry into gastric epithelial cells are those related to previous mucosal damage and cooperation with some unknown promoter factors. In the present study, we did not observe any EBER-1 expression in normal gastric mucosa, even surrounding LEL-EBVaGC or infiltrating lymphocytes. Furthermore, we analyzed endoscopic gastric biopsies from 116 Mexican individuals >40 years of age carrying gastritis with mild atypia, and we did not find any EBER-1-positive case (unpublished data).

In addition to the age dependence of EBVaGC, the present study shows other characteristics of EBVaGC such as distal presentation among female patients and no male preponderance, altogether supporting that ethnicity and genetic backgrounds may address this particular outcome of EBV infection in the Mexican population. Among genetic backgrounds, an immunogenetic constitution may influence the outcome of EBV infection. Human leukocyte antigens (HLA) of the major histocompatibility complex have been implicated in susceptibility to develop EBV-related malignancies[34]. Very recently, we reported an association between the *HLA-DQB1**0501 allele and GC, predominantly in those labeled as diffuse-type carcinomas[35]; unfortunately, EBV status could not be assessed.

In Mexico, EBV antibody prevalence at 4-6 years of age is about 75%[36]. All EBV strains detected in EBVaGC and subjected to EBV genotyping were type A. Previous molecular studies on nasal T-lymphocyte/natural killer-cell lymphomas (nT/NKL) in Mexico[37] documented that EBV type A (EBV-1) is more frequent than EBV type B (EBV-2), as in nT/NKL and sino-nasal-B-cell lymphomas, and as in reactive tonsils from healthy individuals, thus suggesting that viral infection with EBV-1 strain is highly predominant among the Mexican population. In addition, the same authors[37] found a similar incidence of EBV LMP-1 deletions in Mexican individuals harboring nT/NKL as compared with normal subjects. Mori *et al*.[38], found no significant differences in DNA sequences of the LMP-1 region of EBV strains isolated from EBVaGC patients and throat washing samples of healthy individuals. So far no studies

have revealed differences in the genotype of EBV detected in EBVaGC *vs* that found in healthy individuals.

In conclusion, EBVaGC occurs less in Mexico than among other Latin-American populations, but it is as frequent in male as it is in female patients >50 years. In Mexican women, EBVaGC affects the middle and distal portions of the stomach but not the proximal portion. Finally, the participation of sequential steps in the mechanism of neoplastic transformation in EBVaGC, in a similar manner to the cascade of events described by Correa[39] in gastric carcinogenesis, cannot be ruled out.

Abstract

AIM: To assess whether the effectiveness of a combination of transarterial chemoembolization (TACE) and percutaneous ethanol injection (PEI) in the treatment of unresectable hepatocellular carcinoma (HCC) is superior to TACE alone a randomized controlled trial was performed.

METHODS: The effect of combination therapy on long-term survival rates and duration of hospitalization was evaluated in 52 previously untreated HCCs, randomly allocated to TACE-PEI (27 pts) or TACE alone (25 pts).

RESULTS: The cumulative survival rate of the TACE group was 75.8% at 6 mo, 62.9% at 12 mo, and 18.0% at 24 mo and of the TACE-PEI group 76.9%, 61.5%, and 38.7%, respectively. Comparison of overall survival in both groups showed no statistically significant difference. Regarding the patients with HCCs Okuda stage I (n = 26), the median survival of the TACE-PEI group was significantly longer (>24 mo, median not yet reached in the study period) compared to the TACE group (18.4 mo [range 11.6-21.7 mo]; P = 0.04). TACE-PEI reduced the relative risk for mortality to 0.4 (95%CI 0.15-0.96) compared to patients who received TACE alone. Median survival in patients with HCCs Okuda stage II or III was 5.0 mo in the TACE group (1.7 mo-not defined) compared to 10.4 mo in the TACE-PEI group.

CONCLUSION: The combination TACE-PEI improved survival time compared to TACE alone. Our study revealed a statistically significant improved survival in HCCs Okuda stage I. Side effects were minor and the combination therapy did not prolong duration of hospitalization considerably.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the major malignancies worldwide with the highest incidence in Asia and sub-Saharan Africa[1]. Potentially curative therapeutic strategies such as orthotopic liver transplantation and hepatic resection are possible only in a minority of patients[2-7]. Due to tumor size and multicentricity, comorbidity and advanced or decompensated liver cirrhosis 70-80% of HCCs are inoperable at the time of diagnosis[8]. Because HCCs are chemo- and radio-resistant, systemic chemotherapy and radiation therapy are not options for the treatment[9]. Therefore, in most HCC patients, percutaneous ethanol injection (PEI) or thermal ablation, e.g., radiofrequency thermal ablation, and transarterial chemoembolization (TACE) are palliative treatment options[5,10-14].

Ultrasound guided PEI has been shown to be highly effective in the treatment of small HCCs[15-17]. However, PEI treatment was shown to be of limited efficacy in patients with large HCC (>5 cm) because ethanol diffusion within the tumor mass is incomplete and residual viable neoplastic tissue often persists in the periphery of the tumor lesion.

Advanced HCCs have been widely treated with TACE, using various combinations of chemotherapeutic drugs and embolic agents. The standard protocol adopted in many institutions includes repeated intra-arterial injections of a chemotherapeutic agent such as cisplatin, doxorubicin, or mitomycin C mixed with lipiodol. Lipiodol is added because of its relative selective uptake in HCCs and its antitumor effect[18]. The injection of chemotherapeutic oil emulsion is followed by embolization of feeding arteries with small gelatin-sponge particles.

A potential benefit of combining TACE with PEI in the treatment of HCC was first suggested by Tanaka *et al*.[19]. Adding PEI after TACE has been expected to achieve complete necrosis of the main tumors and to alter the texture of the tumor parenchyma, so that a large volume of ethanol can be administered to penetrate entire tumor lesions resulting in a complete necrosis[20]. In a previous study, we prospectively analyzed the clinical factors determining the prognosis of 132 inoperable HCC patients treated at our institution. Multivariate analysis revealed that patients treated with TACE-PEI had a significantly longer survival than patients treated with PEI or TACE alone[15]. These observations

prompted us to do a multicenter randomized controlled trial evaluating the effect of combination therapy with TACE-PEI *vs* TACE on long-term survival rates, duration of hospitalization and quality of life.

MATERIALS AND METHODS

Patient characteristics and study design

The study was performed as a multicenter randomized controlled trial comparing treatment with TACE and TACE-PEI. The mean 3-year-survival rate in patients treated with TACE is about 30%[18,21-24]. To demonstrate an improvement of the 3-year-survival from 30% to 40% with a statistical power of 80%, it was calculated that 308 patients in each group were needed (group 1 = TACE treatment, group 2 = treatment with TACE in combination with PEI). As a period of recruitment, 36 mo were calculated, and 24 mo were planned as follow-up period.

Participants for the trial were recruited from five centers listed in the Appendix. Patients included in the study fulfilled the following criteria: Untreated patients with HCC, confirmed histologically or diagnosed by significantly elevated α-fetoprotein (AFP) levels (>250 ng/mL) and imaging by CT, MRI, ultrasound, or angiography. No indication for surgery or any local treatment, no evidence for extrahepatic metastases, assessed by clinical and chest X-ray examinations. In patients with clinically suspected bone metastases, a bone scan was performed. There was no age limit. Exclusion criteria were: Second malignancy, any local, or systemic pretreatment, extrahepatic metastases, Child-Pugh C score, complete portal vein thrombosis (main trunk or both branches), serum creatinine >1.5 mg/dL, severe- and therapy-resistant hepatic encephalopathy, contraindications for peripheral artery catheterization. The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the ethics committee of the University Hospital Freiburg. All participants provided written informed consent. By external blockwise randomization centrally performed by fax, patients were assigned to treatment with TACE only or treatment with TACE-PEI.

Therapeutic procedures

TACE A diagnostic angiography was performed in all patients. For TACE, the tip of the catheter was placed in the left or right hepatic artery. Under fluoroscopic guidance, 5-10 mL of a solution containing 10 mg mitomycin C (Medac, Hamburg, Germany) in 10 mL iodized oil was injected into the artery feeding the lesion(s). The mitomycin/oil mixture was prepared immediately before injection by vigorous mixing for a few minutes. Embolization was performed with gelatin-sponge particles (Gelfoam; Upjohn, Kalamazoo, MI, USA). In case of unilateral portal vein thrombosis and contralateral localization of the HCC(s), chemoperfusion without embolization (TAC) of the corresponding lobe was performed. At the end of the procedure, the extent of vascular occlusion was demonstrated angiographically. The patients stayed in general, 1 d in the hospital for observation. Two weeks after TACE, a CT scan was performed. The results were interpreted as follows: (1) tumor necrosis: hypo-attenuated and contrast medium-non-enhanced lesion(s) in the early arterial phase; (2) residual tumor: contrast medium-enhanced lesion(s).

The procedure was repeated every 6-10 wk until one of the following end points was reached: (1) no viable tumor cells detectable by CT or biopsy; (2) contraindications for the procedure developed; (3) patient's death. In patients who developed thrombosis of the main portal trunk, TACE was performed only in cases of compensated cirrhosis Child-Pugh A score and adequate collateral circulation around the thrombosis (cavernous transformation with prograde intrahepatic portal perfusion on ultrasound Doppler flow examination). Patients not qualifying for TACE received best supportive care, including treatment of complications of liver cirrhosis and pain relief.

Combination of TACE-PEI Patients assigned to TACE-PEI additionally received PEI treatment for all visible lesions, 10 d after TACE. PEI was performed under real-time ultrasound guidance. A 3-MHz convex probe (Ultramark 4; ATL, Solingen, Germany) with a lateral guide attachment or a 3.5-MHz convex probe (EUB 525; Hitachi, Wiesbaden, Germany) with an incorporated guide was used. Two needle types were used: a 15-cm, 20-gauge spinal needle (Becton Dickinson, Franklin Lakes, NJ, USA) or a 20-cm, 20-gauge needle with a closed conical tip and side holes at the tip over a length of 1 or 2 cm (Pflugbeil, Ottobrunn, Germany). Ethanol (96%, 1-10 mL) was slowly injected. The PEI result was photodocumented. In general, PEI treatment involved 6-12 injections per lesion 1-6 d apart. After PEI treatment, patients regularly stayed in general 1 day in the hospital for observation. The procedure was repeated after every TACE, until one of the end points described above was reached.

Follow up

As primary end point of the study, death of any cause was chosen. Secondary end points were tumor response, quality of life, side effects, and duration of hospitalization because of treatment or side effects.

Follow-up period was 24 mo. Patients were seen on an outpatient basis 1 mo after initiation of the therapy, later on for every 3 mo. Routine follow-up included clinical examination, determination of AFP, and abdominal ultrasound. Abdominal CT or MRI was performed after 1, 3, and 6 mo, and then for every 6 mo. If HCC recurrence was suspected based on ultrasonography or AFP elevation, CT or MRI was performed earlier. Chest X-rays were done after 6, 12, and 24 mo. Quality of life evaluation (EORTC QLQ 30) was performed at inclusion in the study and then after 6, 12, and 24 mo. The therapeutic effect was assessed by CT or MRI every 3 mo according to WHO criteria[25]. A complete response was defined as disappearance of all HCC lesions documented by imaging analyses (ultrasound, CT, or MRI), and confirmation 4 or more weeks later. A partial response was defined as more than 50% reduction of the tumor size based on the measurement of the two longest perpendicular diameters of the tumor.

Statistical analyses

Study design was a multicenter randomized controlled trial to compare therapeutic effect of TACE and TACE-PEI.

Between January 1997 and August 2001, 58 patients

were recruited for the study. Recruitment was stopped after 56 mo. Follow-up period of 24 mo was planned.

Comparison between groups was made on an intention-to-treat basis. Survival time for the TACE- and TACE-PEI group was assessed by the Kaplan-Maier method and log-rank test for univariate analysis. Therapeutic effect was estimated by Cox's proportional hazards regression model for multivariate analysis. All significance tests were two-sided and $P<0.05$ was considered statistically significant. Data processing and analysis were performed using the statistical analysis system (SAS Institute, Cary, NC, USA).

RESULTS

From January 1997 to August 2001, 58 patients were enrolled in the study and were randomly assigned to TACE (n = 29) or to TACE-PEI (n = 29). Five patients were excluded because of complete portal vein thrombosis (1 patient), operability (1 patient), death (1 patient) or retraction of consent (2 patients). The remaining 53 patients (26 TACE and 27 TACE-PEI) received allocated intervention. One patient in the TACE group was lost to follow-up after moving. Thus, the data of 52 patients could be analyzed (Figure 1).

Patient characteristics showed no statistically significant differences between the two treatment groups (Table 1).

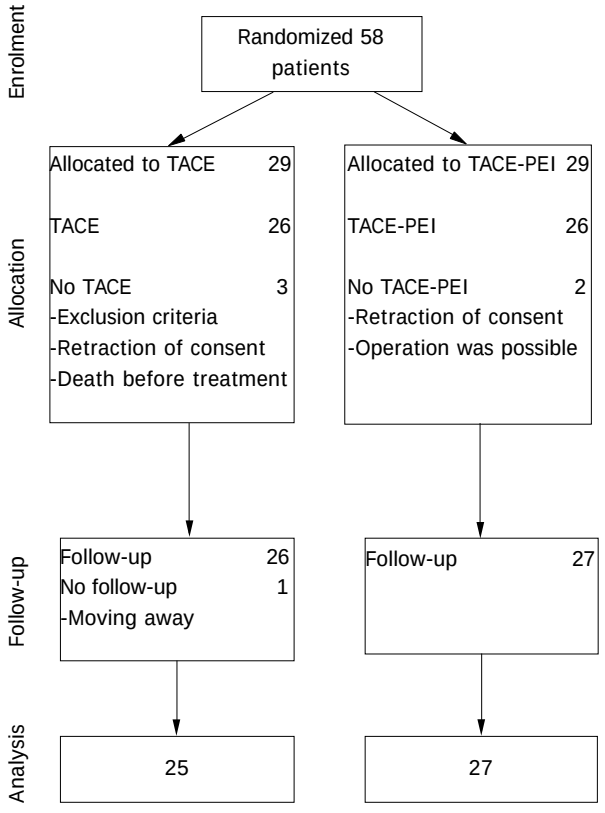

Figure 1 Flowchart of study patients.

Survival

At the time of final analysis (median follow-up time 32 mo [range 5-57 mo]), 18 patients of the TACE group and 17 patients of the TACE-PEI group had died. Median survival time was 18.4 mo (range 5.8-22.0 mo) of the TACE group as compared to 15.3 mo (range 9.2-49.0 mo) of the TACE-PEI group.

The cumulative survival rate of the TACE group was 75.8% at 6 mo, 62.9% at 12 mo and 18.0% at 24 mo and of the TACE-PEI group 76.9%, 61.5%, and 38.7%, respectively (Figure 2A). Comparison of overall survival in both groups showed no statistically significant difference.

Subgroup analysis of patients with HCC Okuda stage I (n = 26) showed a significant longer survival of the TACE-PEI group (>24 mo, median not yet reached in the study period) as compared to the TACE group (18.4 mo [range 11.6-21.7 mo]; P = 0.04; Figure 2B). TACE-PEI treatment reduced the relative risk for mortality to 0.4 (95%CI 0.15-0.96) compared to patients receiving TACE only.

Median survival of patients with HCCs Okuda stage II or III was 5.0 mo in the TACE group (1.7 mo-not defined) compared to 10.4 mo in the TACE-PEI group (Figure 2C). This difference was not statistically significant (P = 0.39).

Table 1 Patients' characteristics according to treatment

Tumor response and side effects

Four patients in the TACE and five patients in the TACE-PEI group showed stable disease, respectively. The remaining 18 patients in the TACE and 20 patients in the combination group had a progressive disease, respectively (Table 2). In both groups, no major treatment-related complication occurred. The most common side effects of TACE were fever, abdominal pain, and elevation of total bilirubin levels. These side effects were transient and disappeared within a week. Side effects of PEI were spontaneously remitting mild local pain in all patients and mild transient fever in most patients.

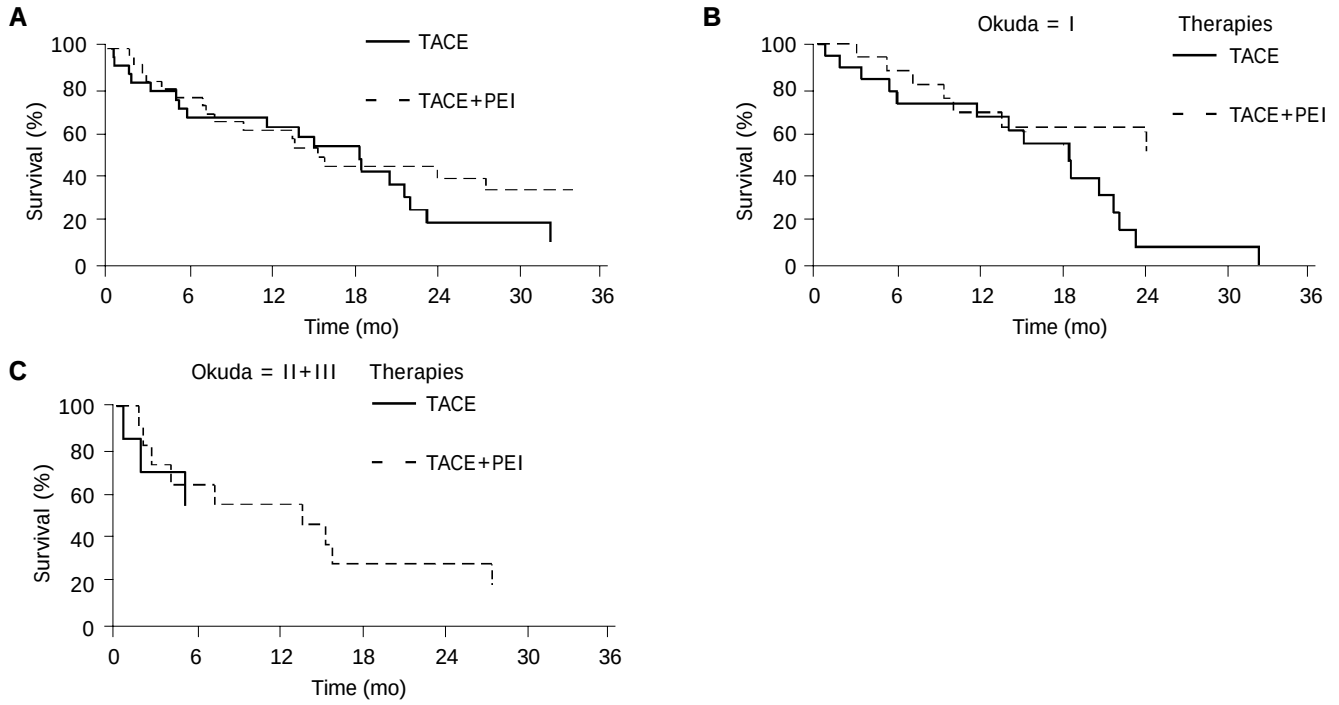

Figure 2 A: Overall survival according to treatment; B: Survival of patients with HCCs Okuda stage I according to treatment; C: Survival of patients with HCCs Okuda stage II or III according to treatment.

Table 2 Tumor response according to treatment

	TACE	TACE+PEI	*P* (χ^2-test)
Patients (*n*)	22	25	
Complete response	-	-	-
Partial response	-	-	-
Stable disease	4	5	NS
Progressive disease	18	20	NS

Duration of hospitalization

For all the 52 study patients, we recorded in-patient stays and out-patient visits during follow-up and discriminated between (1) treatment-related hospital stays/visits including adverse effects or complications and (2) hospital stays/visits because of other reasons (Table 3). As expected, patients treated with TACE-PEI had on average slightly longer hospital stays. Overall, however, there was no statistically significant difference between both treatment groups with respect to in-patient days and out-patient visits, respectively.

Table 3 Hospitalization or out-patient visits according to treatment

	TACE	TACE-PEI	*P* (Wilcoxon rank test)
IST (d)	33	44.67	0.46
OST (d)	2.72	3.07	0.75
ISO (d)	9.16	5.74	0.91

IST = average inpatient hospitalization because of treatment or complications; OST = average outpatient visits because of treatment or complications; ISO = average inpatient hospitalization for other reasons.

Quality of life

To evaluate quality of life, we used a validated self-rating questionnaire (EORTC QLQ 30). According to the design of the study, patients were expected to complete the questionnaire at enrolment into the study and at mo 6, 12, and 24. Unfortunately, only 17 completely filled out questionnaires were obtained. Most patients suffered from poor and worsening physical condition, including hepatic encephalopathy, so that only a minority of patients was able to complete the self-rating questionnaire. Therefore, we could not statistically analyze quality of life.

DISCUSSION

In a previous study, we prospectively analyzed the clinical factors determining the prognosis of 132 patients with inoperable HCCs who were treated with TACE, PEI, the combination of both, or best supportive care[15]. Multivariate analysis revealed that patients treated with a combination of TACE and PEI had a significantly better survival than patients receiving either PEI or TACE only. These observations prompted us to undertake a multicenter randomized controlled trial evaluating the effect of combination therapy with TACE-PEI on long-term survival.

The purpose of the combination is to overcome the shortcomings of both therapies and to get improved therapeutic results by combined effects. TACE is one of the most common therapies in patients with unresectable HCC. This regional therapy combines targeted chemotherapy and arterial embolization in order to induce both selective ischemic and chemotherapeutic effects on HCC. Although survival benefit has been reported after TACE[5], it is difficult to achieve complete necrosis of the target tumor by TACE alone, because HCC often has intercapsular or extracapsular invasion and viable tumor cells remain after TACE[26]. PEI is also widely used and is an effective means of treating

unresectable HCC. The method is effective in cases of capsular invasion. The injection of absolute alcohol causes cellular dehydration, coagulation necrosis, and vascular thrombosis within the treated tumor[27]. But several factors limit the therapeutic effect of PEI, such as tumor consistency, intratumoral septa, tumoral capsule, and tumor vascularization[28]. The rationale for combination of TACE and PEI relies on the fact that after TACE tumor consistency is markedly decreased and intratumoral septa are usually disrupted providing enhanced ethanol diffusion within the tumor. Therefore, combined therapy with TACE-PEI has been expected to improve survival rates of patients with advanced HCC.

In our randomized controlled multicenter trial comparing TACE and TACE-PEI, we observed no difference in overall survival. However, subgroup analysis based on HCC Okuda stage revealed that TACE-PEI results in statistically significant improved survival in patients with HCC Okuda stage I.

Similar to our findings, a recently published retrospective analysis based on medical records showed that patients receiving TACE alone had a median survival rate of 16 mo, whereas the median survival rate in patients receiving TACE followed by PEI was 24 mo[29].

The prospective randomized trials by Kamada *et al.*[30], and by Bartolozzi *et al.*[31], also showed improved survival for patients treated with TACE-PEI compared to TACE alone. Because of the small number of patients included in these studies, the difference did not reach statistical significance. Further, Tanaka *et al.*[32], Koda *et al.*[33], and Yamamoto *et al.*[20], showed a significant improved survival for patients treated with TACE-PEI as compared to TACE alone (Table 4).

Even though these studies included patients with Child-Pugh C score liver cirrhosis[20,32,33], mean survival time in our study, which excluded Child-Pugh C score patients, was shorter. This may be due to the following facts: (1) We only excluded patients with complete portal vein thrombosis (main trunk or both branches) whereas others excluded patients with any evidence of (partial) thrombosis[30-33]; that is predicting poor survival[15,20]. (2) Liver disease in our study was caused in about 50% by alcohol, whereas in all other studies most patients had chronic hepatitis B or C (Table 4). Our findings, therefore, may suggest that combination therapy with TACE-PEI may be less effective in patients with alcohol-induced than in patients with HBV- or HCV-induced cirrhosis. (3) Tanaka *et al.*[32], Koda *et al.*[33], and Yamamoto *et al.*[20], used doxorubicin, whereas in our study mitomycin C was used. Advantages for anthracyclin-based regimes were advocated in one randomized controlled trial[34], but a recently published meta-analysis showed no good evidence for best chemotherapeutic agent[5].

The primary end point of our study was survival time. Secondary end point was the duration of hospitalization and/or the number of out-patient visits. As expected, patients treated with TACE-PEI had on average slightly longer hospital stays than patients with TACE only. There was no statistically significant difference between both treatment groups, however. This aspect is important not only with respect to financial costs, but also with respect to patient's quality of life.

In conclusion, the combination of TACE-PEI compared with TACE alone prolongs survival in patients at Okuda stage I. Side effects were mild and combined therapy with TACE-PEI did not prolong duration of hospitalization or the number of out-patient visits considerably.

Abstract

AIM: To investigate the relation between the expression of cyclooxygenase-2 (COX-2) and liver cancer, to construct the recombinant adenovirus encoding human COX-2 antisense RNA, and to explore its effects on liver cancer cell proliferation.

METHODS: We studied the expression of COX-2 in 34 cases of hepatocellular carcinoma (HCC) and SMMC7402 and SMMC7721 by immunohistochemical technique. Recombinant adenovirus Ad-AShcox-2 was constructed and transfected into human HCC cell lines SMMC7402 and SMMC7721, and its effects on COX-2 expression, cell apoptosis and cell cycle were analyzed by flow cytometry. Cell proliferation was determined by colony-forming efficiency.

RESULTS: We observed COX-2 expression in 82.4% of HCC and SMMC7402 cells, but no COX-2 expression in SMMC7721 cells. In addition, recombinant adenovirus encoding antisense COX-2 fragment Ad-AShcox-2 was obtained with the titer of 1.06×10^{12} PFU/mL. Ad-AShcox-2 could reduce the expression of COX-2 and enhance the percentage of cells in G_1/G_0 phase in SMMC7402 cell line. The difference of apoptotic index between the Ad-AShcox-2 group and control group was statistically significant ($t_{control\ group}$ = 32.62 and $t_{Ad\text{-}LacZ}$ = 10.93, $P<0.001$) in SMMC7402 but not in SMMC7721. Similarly, colony-forming rates of SMMC7402 and SMMC7721 cell lines, after the transfer of Ad-AShcox-2, were (2.7±0.94)% and (33.6±4.24)%, respectively.

CONCLUSION: Reduction in the expression of COX-2 can inhibit COX-2 expressing HCC cells.

INTRODUCTION

Liver cancer is a kind of malignant tumor with a high mortality at present. Its morbidity is rather high in our country. Although a great number of researches on liver cancer as well as many achievements have been made, the exact molecular pathogenesis of liver cancer is not clear. Cyclooxygenase-2 (COX-2) has a high expression in quite a few tumors such as colorectal cancer[1,2], esophageal cancer[3], and other cancers[4]. It is likely to be related to the genesis and development of tumor, but the causing-carcinoma effect can be resisted by COX-2 selective inhibitors[5-7]. Our prophase researches showed that COX-2 antisense RNA obviously inhibits the growth of carcinoma of esophagus with a high expression of COX-2[8,9]. COX-2 is likely to become a new target of treating tumor. The present study aimed to investigate the relationship between the expression of COX-2 and liver cancer, to the construction of the recombinant adenovirus encoding human COX-2 anti-sense RNA, and to treat hepatocellular carcinoma (HCC) with or without the expression of COX-2 and to explore its mechanism.

MATERIALS AND METHODS

Intraremovelase

*Bam*HI, *Xba*I, and T_4 DNA ligase were purchased from Huamei Biological Engineering Company. RPMI 1640 and Lipofectamine were provided by GIBCO/BRL. CsCl was from Sigma Company. COX-2 cDNA and primer of adenovirus PCR were designed and synthesized by Saibaisheng Biology Company.

Plasmid, adenovirus, and cell line

Ad-LacZ was a gift from Dr. Jia-Ning Wang in our Molecular Biological Laboratory. COX-2 plasmid PCR™II vector was supplied by Dr. You-Fei Guan in Vanderbilt University, USA. pHCMVSP1A and pJM17 were donated by academician Wu Zuze in the Second Institute of Academy of Military Medical Sciences. DH_{5a} was donated by Dr. Peng Xu in Cardiology Internal Medicine Department of No. 1 Hospital Peking University. 293 cells and HCC cell lines SMMC7721 and SMMC7402 were purchased from Shanghai Cell Bank

of Chinese Academy of Medical Sciences.

Equipments

High-speed refrigerated centrifuge (Jouan, Italy), carbon dioxide incubator (Sany D, Japan), ultrahigh refrigerated centrifuge (Hitachi, Japan), inversion difference microscope (Olympus IX-To, Japan), PCR amplifier (Amplitron II, USA), flow cytometer (EPICS XL, Beckman Coulter Company, USA), ultraviolet spectrophotometer (752, Shanghai), air bath, and water bath cradle were used in our study.

Expression of COX-2 in HCC tissue

Immunohistochemical transfection was conducted by streptomy-glair-in-biotin-horseradish peroxidase (SP) compound method. The tissue was fixed with paraffin and cut into 5-μm-thick sections. HCC tissue slides were fixed in 4% PFA in PBS for 10 min, washed twice with PBS, and incubated in 3% H_2O_2 to eliminate the endogenous peroxidase activities. The tissues were then incubated either at room temperature for 1 h or at 4 ℃ overnight with 1% goat serum in PBS to block the nonspecific binding of antibodies. The slides were further incubated sequentially with rabbit anti-man COX-2 polyclonal antibody. PBS was used as a control. Color development was performed by incubation with 3,3-diaminobenzidine tetrahydrochloride in 0.03% H_2O_2 and 50 mmol/L Tris-HCl, pH 7.4. The percentage of positive tumor cells was determined semiquantitatively by assessing the whole tumor section, and each sample was assigned to one of the following categories: 0 (0-4%), 1 (5-24%), 2 (25-49%), 3 (50-74%), 4 (75-100%). Transfection strength was indicated with 0 (negative), 1 (weak positive), and 2 (positive). The expression levels were indicated with positive rate of tumor cells of one tumor tissue showing the different transfection strength. Its expression level was the transfection strength fraction by positive rate fraction. For example, if 50 tumor cells of one tumor tissue showed positive staining, we could mark 3 by 2 equaling 6; if 25 showed weak positive staining, we could mark 2 by 1 equaling 2; if 25% showed negative staining, we could mark 2 by 0 equaling 0. Thus the total was 6 plus 2 plus 0 equaling 8. The specific result statistics were carried out as previously described[10].

Construction, identification, amplification, purification, and titer assay

First, we obtained a COX-2 cDNA fragment using *Xba*I and *Bam*HI to bi-mold-cut the plasmid PCR™IICOX-2, and cloned the COX-2 cDNA fragment in the reverse direction onto two spots of *Xba*I and *Bam*HI of the pHCMUSP1A, the connection product was pAd-Ashcox-2. Then the latter was plasmid-amplified by transformed bacillus coli DH_{5a} and identified as positive plasmid by mold-cutting. The shuttle plasmid pAd-Ashcox-2 mediated Lipofectamine and pJM17 were co-transferred into 293 cells. When 293 cells had pathologic lesions and exfoliative cells made up 20%, we collected the upper clear liquid. Then we extracted viral DNA from the upper clear liquid and identified it by PCR. COX-2 primer's upstream sequences are 5'-TTG GCT TCA AGA CTG AGA TA-3' and 5'-AGC CCA AAT TAT TGG TTC-3'. Adenovirus primer's upstream sequence is 5'-TCG TTT CTC AGC AGC TGT TG-3', downstream sequence is 5'-CAT CTG AAC TCA AAG CGT GG-3'. PCR reaction system contained 10 μL viral DNA, 10 μL 20 μmol/L primer respectively (5 μL adenovirus), 5 μL 10× PCR buffer, 2 μL $MgCl_2$, 5 μL 2 mmol/L dNTP and 1 μL Taq enzyme. Water was added until the final volume of PCR reaction was 50 μL. Thirty cycles of PCR were carried out, each consisting of 30 s at 94 ℃, 30 s at 56 ℃, 1 min at 72 ℃, then a final extension at 72 ℃ for 10 min. Electrophoresis in 1.0% agarose gel was performed to amplify cDNA and adenovirus fragments as positive reconstructive cloning. Without adding mould, PCR amplification was used as a negative control. After positive reconstructive adenovirus was identified, we transferred 293 cells again. 293 cells were collected, refrigerated, melted, fragmented and ultracentrifuged twice with CsCl, viruses were collected and purified. At last the virus titer was assayed.

Efficiency of virus transfection

The recombinant adenovirus Ad-LacZ with genes encoding LacZ was used to infect liver cancer cell lines SMMC7721 and SMMC7402 according to multiplicity of infection-MOI 25, 50, 100, and 200. After 48 h, the cells were fixed and stained with X-gal. The number of cells stained blue was recorded under microscope. Then the percentage of cells with blue staining was calculated.

Transfection of recombinant adenovirus and expression of COX-2

Human liver cancer cell lines SMMC7721 and SMMC7402 were incubated in a 50 mL/L CO_2 at 37 ℃. When the density reached 40-50%, the medium was replaced by serum-free RPMI 1640 and incubated for 24 h. The experimental group infected the two cell lines with 100MOI, and was incubated for 2 h with serum. During the process, the culture fluid was shaken every 15 min. Two hours later, the medium was replaced by 10% FCS RPMI 1640. The control groups were Ad-LacZ group and non-virus group. Carcinoma cells were incubated for 24, 48, 72, 96 h respectively, fixed for 10 min in 4 ℃ cold acetone, and dried for 10 min at room temperature. Then the cells were stored at -85 ℃. The experiment was carried out with SP immunohistochemical method.

Flow cytometry

When the density of the two cell lines reached 40-50%, the medium was replaced by RPMI 1640 containing serum and incubated for 24 h. Forty-eight hours after the experimental group and control group finished virus transfection, the cells were collected (using trypsin digestion method) and centrifuged (1 000 r/min, 5 min). The upper clear fluid was discarded, PBS was added to adjust cell density to 10^6/mL. One hundred microliters of cell suspension was put into the tube, 200 μL DNA-PREP™I-PR was added to it and mixed. Two microliters DNA-PREP™ stain reagent (PI stain) was added and mixed after 30 s. After 30 min, the cell cycle and apoptosis was detected with flow cytometry (FCM).

Colony-forming experiment

The two cell lines was digested into single-cell suspension

respectively, and inoculated into a six-well board. Each well was inoculated with 500 cells. Each group had three pang-punches. After being treated with culture fluid Ad-AShcox-2, they were incubated for 10 d and fixed with 1:3 acetic acid:methanol, stained with Rui stain fluid. Then the number of colonies with more than 50 cells was recorded.

Statistical analysis

Expression level of COX-2 in liver cancer tissue was expressed as mean±SD. *t*-Test was used to show the cell apoptosis rate and cell cycle distribution rate.

RESULTS

Expression of COX-2 in liver cancer tissue

COX-2 was positive in 28 of 34 cases of liver cancers and was negative in 6 of 34 cases of liver cancer. Positive rate was 82.4%. The positive staining of COX-2 was mainly in cytoplasm. High expression of COX-2 was correlated with clinical pathological features of liver cancer (Figure 1). COX-2 expression level was high, if the cancer cells were well differentiated. COX-2 expression was not related to AFP levels, source cells and transference in liver (Table 1).

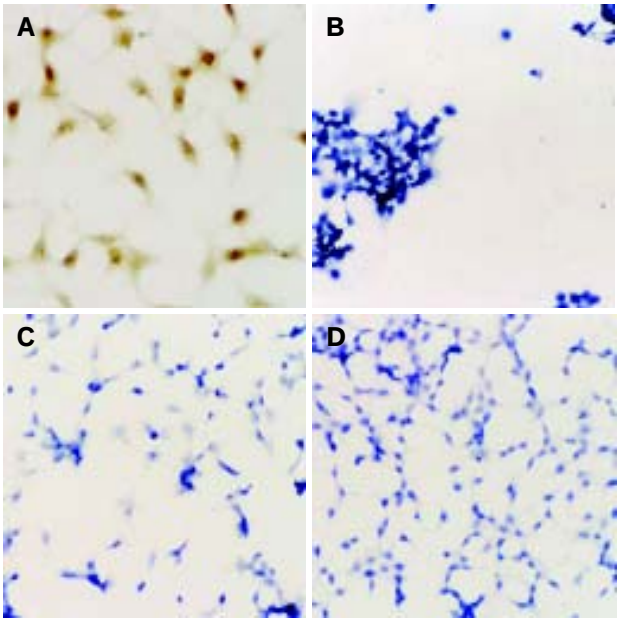

Figure 1 Expression of COX-2 in SMMC7402 and SMMC7721 before (A and B) and after (C and D) the transfer of Ad-AShcox-2.

Identification of recombinant adenovirus by PCR co-amplification method

DNA was extracted and precipitated, then PCR amplification was performed on this DNA model. The product of PCR amplification was evaluated with 0.8% agarose electrophoresis, and 277-bp COX-2 cDNA fragments and 860-bp virus gene frame fragments were obtained. After pAd-AShcox-2 and pJM17 were co-transferred to 293 cells, we produced anti-sense RNA recombinant adenovirus which could express COX-2.

Table 1 Relationship between high expression of COX-2 and clinical pathological features of liver cancer (mean±SD)

Clinical pathological features	*n*	Stain fraction	*t*	*P*
AFP (ng/mL)				
<20	4	6.48±1.46	0.74	>0.05
⩾20	24	6.36±1.15		
Cell category				
Liver cell category	27	6.79±1.60		
Bile duct cell category	1	6.26±1.25		
Transference in liver				
Yes	3	6.43±1.42	1.08	<0.05
No	25	7.15±1.80		
Pathological differentiation				
High	22	8.25±0.86	5.23	<0.05
Middle and low	6	6.11±1.02		

Titer and transfection rate of Ad-AShcox-2

After Ad-AShcox-2 was amplified, extracted, purified, and assayed with ultraviolet spectrophotometer, the virus titer was 1.06×10^{12} PFU/mL. When the MOI was 50 or greater, the transfection rate of SMMC7721 and SMMC7402 reached 100%.

Expression of COX-2 in HCC cell lines

Immunohistochemistry showed that SMMC7402 had a high expression of COX-2. But after Ad-AShcox-2 was transferred, the expression of COX-2 decreased obviously. Before and after Ad-AShcox-2 was transferred, SMMC7721 did not express COX-2 (Figures 1A-D).

Apoptosis of liver cancer cells

Forty-eight hours after SMMC7402 cells were treated with Ad-AShcox-2, FCM showed that apoptotic cells reached apoptosis peak prior to G_0/G_1 peak. The apoptosis rates of Ad-AShcox-2, Ad-LacZ, and the control group were (33.3±3.02)%, (0.42±0.14)%, and (0.25±0.08)%, respectively. The apoptosis rate of the experimental group increased obviously in comparison to the control group. However, after SMMC7721 was treated with Ad-AShcox-2, we could not detect the apoptosis peak with FCM. The apoptosis rates were (0.61±0.25)%, (0.48±0.09)%, and (0.56±0.11)%, respectively. The apoptosis rates of these two liver cancer cell lines, induced by Ad-AShcox-2, differed sharply when compared to each other (t = 32.05, P<0.001).

Effect of Ad-AShcox-2 on cell cycle

Cell cycle from FCM is listed in Table 2. After SMMC7402 cells were treated with Ad-LacZ and non-virus culture fluid, the cell proliferation rate decreased in G_0/G_1 phase, but it was high in S phase indicating that the proliferation of cells was active. After they were treated with Ad-AShcox-2, the number of cells in G_0/G_1 phase increased obviously, while in S phase, the number of cells decreased, suggesting that there was a significant difference compared to control group (P<0.05). The cells were blocked in G_1 phase. But after SMMC7721 was treated with Ad-AShcox-2, the cell proliferation rates in G_1/G_0 phase were low both in experimental group and in control group (Table 3); yet they were high in

Table 2 Cell apoptosis rate and cell cycle after SMMC7402 was treated in experimental group and control group (n = 9, mean±SD)

Groups	Apoptosis rate	Cell cycle (%)		
	(%)	G_0/G_1	S	G_2/M
Control group	0.25	40.39±3.86	49.61±4.27	13.10±1.03
Ad-LacZ	0.42	40.17±4.03	50.18±3.66	12.57±2.85
Ad-ASHcox-2	33.3	66.52±5.48	22.15±3.26	10.33±1.12

Table 3 Cell apoptosis rate and cell cycle after SMMC7721 was treated in experimental group and control group (mean±SD)

Groups	Apoptosis rate	Cell cycle (%)		
	(%)	G_0/G_1	S	G_2/M
Control group	0.56	40.39±3.86	49.61±4.27	13.10±1.03
Ad-LacZ	0.48	42.17±2.63	50.26±2.85	12.27±2.72
Ad-ASHcox-2	0.91	39.92±4.11	49.28±4.13	12.64±1.25

S phase. There was no difference (P>0.05) when compared to each other.

Effect of Ad-AShcox-2 on colony-forming ability of liver cancer cells

After Ad-AShcox-2 infected SMMC7721 and SMMC7402, the colony-forming rates were (2.7±0.94)% and (33.6±4.24)%. There were significant differences between the two groups (P<0.05, n = 6).

DISCUSSION

Cyclooxygenase is a kind of a rate-limiting enzyme, which catalyzes and synthesizes prostaglandin. It has two isomers -COX-1 and COX-2. COX-1 is constitutively expressed in most mammalian tissues and is thought to carry out "housekeeping" functions such as cytoprotection of the gastric mucosa, regulation of renal blood flow, and control of platelet aggregation. In contrast, COX-2 mRNA and protein are normally undetectable in most tissues, but can be rapidly induced by proinflammatory or mitogenic stimuli including cytokines, endotoxins, interleukins, and phorbolester. It has high expression levels in many cancer tissues. Researches showed that COX-2 can promote the formation and opening of tumor vessels[11,12], inhibit tumor immunity[13,14], stimulate transference of tumors and inhibit apoptosis[15-18].

Studies indicate that COX-2 selective inhibitor can inhibit proliferation of colon cancer cells[19,20], and induce their apoptosis[21,22]. In our prophase researches, by using the carrier of COX-2 antisense RNA adenovirus-transferred esophageal carcinoma cells, we successfully inhibited the expression of COX-2 in esophageal carcinoma cells[8,9]. The growth and proliferation of esophageal carcinoma cells were obviously inhibited, showing that reducing the expression of COX-2 or inhibiting the activity of COX-2 is likely to become a new way to treat tumors.

COX-2 is strongly positive in 28 of 34 cases of HCC. The positive rate reached 82.4%, suggesting that the high expression of COX-2 is related to the carcinogenesis and development of HCC. We also found that most HCCs with positive expression of COX-2 were well differentiated, but poorly differentiated HCC had a low expression of COX-2, indicating that COX-2 can promote the proliferation and differentiation of liver cancer cells, which is in line with the report of Koga *et al*.[23]. We can infer that HCC is related to COX-2 inhibiting cell apoptosis and increasing cytoplasmic matrix protein.

We successfully constructed the recombinant adenovirus expressing COX-2 anti-sense RNA. When the two liver cancer cells were treated with it, the expression of COX-2 decreased obviously. Meanwhile, the growth of cells was inhibited and the colony-forming rates of cells decreased apparently as well. But the colony-forming rates of SMMC7721 did not decrease, indicating that inhibiting the expression of COX-2 could inhibit the growth of liver cancer cells with positive expression of COX-2. However, cells with negative expression of COX-2 could not be inhibited. We further confirmed that the feasibility of COX-2 independent way in which NSAIDs could inhibit the colon cancer cells without the expression of COX-2[24].

After SMMC7402 was transferred in Ad-AShcox-2, the rate of cell apoptosis increased notably. There was a significant difference when control group, Ad-LacZ treatment group, and blank group were compared to each other (P<0.001), but the apoptosis rate of SMMC7721 did not increase, showing that by reducing the expression of COX-2, we can increase the apoptosis of cancer cells. This is in line with the result of a previous study[17].

Cell cycle test showed that Ad-AShcox-2 could reduce the expression of COX-2 in SMMC7402, the cell number increased evidently in G_0/G_1 phase. It could prevent cells passing from G_1 to S phase. It is likely to be linked with the expression of raised P_{27} and the inhibition of cyclin/CDK activity[25,26].

In conclusion, the adenovirus carrier with the expression of COX-2 anti-sense RNA is able to inhibit SMMC7402 and induce apoptosis.

Abstract

AIM: To evaluate whether DCP is better than AFP for differentiating HCC from nonmalignant liver disease and further evaluate the usefulness of DCP in early diagnosis of small HCC.

METHODS: Serum DCP and AFP levels were determined in 127 patients. Among these patients, 32 were with non-cirrhotic chronic hepatitis, 34 were with compensated cirrhosis, and 61 were with HCC. The cut-off value for the DCP and AFP were set as 40 mAU/mL and 20 ng/mL, respectively. To compare the diagnostic value of DCP and AFP in distinguishing HCC from nonmalignant chronic liver disease, receiver operating characteristic (ROC) curves were constructed for each assay.

RESULTS: The accuracy, sensitivity, and specificity of DCP were higher than AFP in detecting HCC (81.9%, 77%, and 86.4% *vs* 68.5%, 59%, and 77.3%, respectively). The area under the ROC (AUROC) curves revealed that DCP had a better accuracy than AFP in diagnosis of HCC (0.85 [95%CI, 0.78-0.91] *vs* 0.73 [95%CI, 0.65-0.81], $P = 0.013$). In 39 patients with solitary HCC, the positive rates of DCP were 100% in patients with tumor size larger than 3 cm, 66.7% in patients with tumor size 2-3 cm and 50% in patients with tumor size less than 2 cm. The positive rates of AFP in patients with tumor size larger than 3 cm, 2-3 cm and less than 2 cm were 55.6%, 50%, and 33.3%, respectively. The median level of DCP in HCC patients with tumor size larger than 3 cm was significantly higher than those with tumor size 2-3 cm and those with the size of less than 2 cm.

CONCLUSION: Our study indicates that DCP has a better diagnostic value than AFP in differentiating HCC from nonmalignant chronic liver disease. DCP has not only a stronger correlation with HCC than AFP in tumor size but also more effectiveness than AFP in detecting small size of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers in the world[1]. The major causes of HCC are through chronic infection with HBV or hepatitis C virus (HCV)[2], cirrhosis and finally culminating into HCC[3,4]. HCC tends to occur in a definable population, so-called high risk population. Periodic screening among the high risk population would benefit in detecting HCC in an early curable stage and yield a long-term survival[5,6]. However, the worldwide 5-year survival rate of HCC only slightly increased from 2% to 5% over the past two decades[7]. This is partially due to the poor performance of currently available tumor markers, including α-fetoprotein (AFP), which cause the delay in diagnosis[8]. There is a need to develop an additional sensitive serum marker to improve the early detection of small HCC.

In 1984, Liebman *et al*., firstly reported the increasing levels of DCP in patients with HCC[9]. Since then, numerous studies indicated that DCP would be a useful marker in detecting HCC[10-14]. The conventional enzyme immunoassay (EIA) for DCP can detect advanced HCC with a high specificity. But the conventional EIA was limited in detecting small HCC[14-17]. A new method, revised EIA (Eitest PIVKA-II, Eisai, Tokyo, Japan), had been developed in recent years. The new sensitive DCP kit can measure the low concentration of serum DCP in normal persons. Thereafter, the diagnostic sensitivity of DCP for HCC had been much improved. It had been reported to be more sensitive and specific than AFP for the diagnosis of HCC[18,19]. However, the efficacy of DCP in diagnosis of small HCC still remains unclear.

Thus, we conducted a cross-sectional case control study to evaluate whether DCP is better than AFP for differentiating HCC from nonmalignant liver disease and further evaluate the usefulness of DCP in early diagnosis of small HCC.

MATERIALS AND METHODS

Patients

A total of 127 patients who were regularly followed up at Ren-Ai Branch, Taipei City Hospital were consecutively enrolled. Among the 127 patients, 32 had chronic hepatitis with higher serum alanine aminotransferase (ALT) levels than normal (upper limit of normal: 40 U/L) for at least 6 mo before enrollment, 34 had compensated cirrhosis (Child-Pugh score < 7) (20) and 61 had HCC. Cirrhosis was defined by clinical development of esophageal varices, thrombocytopenia (platelet count less than 100 000/mm^3), splenomegaly or small liver size with irregular liver surface to be noted by imaging studies at enrollment. Among all patients with chronic hepatitis and cirrhosis, HCC must be ruled out on the basis of imaging examinations including sonography and/or computed tomography (CT) performed on a regular examination. Also, cirrhotic patients who developed HCC within 6 mo after getting serum were excluded. The diagnosis of HCC was made on 47 (77%) histologically confirmed patients. The remaining 14 (23%) patients, who had advanced HCC with tumor size larger than 3 cm or patients with portal vein invasion, were confirmed by various combination of imaging studies, such as ultrasonography, enhanced CT, magnetic resonance imaging and/or angiography. Tumor size was estimated by using ultrasonography. Blood samples from HCC patients were drawn before initial treatment. The rest of the data obtained at enrollment included hepatitis B surface antigen (HBsAg), antibody to HCV (anti-HCV), ALT, albumin, total bilirubin, platelet count, prothrombin time, and serum level of tumor markers, AFP and DCP. Patients who had a history of alcohol consumption in excess of 80 g/ethanol per day for more than 5 years, serum total bilirubin level of more than 20 mg/L or under vitamin K medication were excluded. All subjects had given informed consent for the participation in the study. Serum samples were collected and stored at -70 ℃ until examined.

Biochemical and serological testing

The biochemical tests were measured by using routine automated methods. The HBsAg, anti-HCV were assayed by commercial kits (General Biological HBsAg RIA, General Biological Cooperation, Taiwan; HCV EIA II, Abbott Laboratories, North Chicago, IL, USA).

AFP assay

AFP was tested by using commercially available immunometric assay (Architect AFP assay, Abbott Laboratories, North Chicago, IL, USA). The cut-off value of AFP for HCC was set at 20 ng/mL, the most commonly set value[21-24].

DCP assay

DCP level was measured by using an ELISA (Eitest PIVKA-II, Eisai Co., Tokyo, Japan), according to the manufacturer's instructions. The detection limit is 10 mAU/mL. The cut-off value is determined as 40 mAU/mL for differentiation of HCC and nonmalignant liver disease based on previous studies[19].

Histological grading of HCC

Based on the criteria proposed by the Liver Cancer Study Group of Japan[25], each HCC was histologically graded into well differentiated, moderately differentiated, or poorly differentiated. Patients with multiple tumors consisted of more than two grades of histological differentiation; therefore, the most dedifferentiated grade was used.

Statistical analysis

Values were presented as mean ± SD and median:range. Data were analyzed by χ^2 test, Fisher's exact test, Student's *t*-test, Kruskal-Wallis ANOVA median test, and Pearson correlation where appropriate. All of the tests of significance were two-tailed and a *P* value of less than 0.05 was considered statistically significant. To compare the accuracy of DCP and AFP in the diagnosis of HCC, receiver operating characteristic (ROC) curves were constructed by using all possible cut-offs for each assay. The area under the ROC (AUROC) curves were calculated and compared by using a computer program of the MedCalc software version 7.5 (Mariakerke, Belgium).

RESULTS

Patient characteristics

Serum DCP and AFP levels were determined in 32 patients with chronic hepatitis, 34 patients with cirrhosis and 61 patients with HCC (their clinical characteristics were summarized in Table 1). The three groups were comparable in terms of gender, prevalence of HBsAg and anti-HCV. The mean age of HCC patients was significantly higher than those of chronic hepatitis patients and cirrhotic patients (63 ± 13 years *vs* 52 ± 10 years and 57 ± 12 years respectively, $P < 0.001$).

DCP and AFP in patients with chronic hepatitis, cirrhosis, and HCC

Both DCP and AFP levels increased progressively from nonmalignant chronic liver disease to HCC (Table 1). The mean values of DCP in patients with HCC was significantly higher than patients with chronic hepatitis and cirrhosis (2 808 ± 6 216 *vs* 21 ± 9 and 33 ± 14 mAU/mL, respectively, $P < 0.001$). In all, 2 of 32 (6.3%) patients with chronic hepatitis, 7 of 34 (20.6%) patients with cirrhosis, and 47 of 61 (77%) with HCC had DCP levels above the cut-off value of 40 mAU/mL.

The mean values of AFP were comparable among the three groups of patients (54 174 ± 296 329 *vs* 15 ± 24 and 13 ± 14 ng/mL, respectively $P > 0.05$). The AFP level above 20 ng/mL was found in 36 of 61 (59%) HCC, in 9 of 34 (26.5%) cirrhosis and in 6 of 32 (18.8%) chronic hepatitis patients. The overall accuracy, sensitivity, specificity, and positive and negative predictive values for the usefulness in the diagnosis of patients with HCC are shown in Table 2. ROC curves were plotted to compare the accuracy of DCP and AFP in the diagnosis of HCC, AUROC curves indicated

a better accuracy for DCP than AFP in diagnosis of HCC (0.85 [95%CI, 0.78-0.91] *vs* 0.73 [95%CI, 0.65-0.81], $P = 0.013$, Figure 1).

Relation between serum levels of AFP and DCP

Both DCP and AFP levels above cut-off value were found in 32 (52.5%) of 61 patients with HCC. Fifteen (60%) of twenty-five patients with AFP level less than 20 ng/mL had elevated concentrations of DCP. We failed to find any correlation between serum levels of AFP and DCP in 61 HCC patients (Figure 2, $r = 0.12$, $P = 0.36$).

Positive rates of DCP and AFP in patients with HCC

The positive rates of DCP and AFP in patients with HCC were detailed as follows: (1) When the largest size of HCC was more than 3 cm ($n = 22$), between 2 and 3 cm ($n = 16$) and less than 2 cm ($n = 23$), the rates were 100%, 75%, and 56.5% for DCP, 77.3%, 56.3%, and 43.5% for AFP; (2) When HCC was moderately to poorly differentiated ($n = 39$) and well differentiated ($n = 8$), the rates were 76.9% and 37.5% for DCP, 53.8% and 12.5% for AFP; (3) When the number of HCC were more than 2 ($n = 22$) and single ($n = 39$), the rates were 95.5% and 66.7% for DCP, 86.4% and 43.6% for AFP (Table 3).

The relation between the tumor size of HCC and levels of DCP and AFP were further analyzed. In the 39 patients with solitary HCC, 9 more than 3 cm, 12 between 2 and 3 cm, and 18 less than 2 cm, the positive rates were 100%, 66.7%, and 50% for DCP, 55.6%, 50%, and 33.3% for AFP respectively. DCP also had a better correlation with tumor size in comparison with AFP. The median (range) levels of DCP in patients with a size of HCC more than 3 cm was significantly higher than those with 2-3 cm and less than 2 cm [6 729 (40.4-20 000) *vs* 159 (12-655) and 89 (7-348) mAU/mL, respectively, $P = 0.01$] (Figure 3).

Table 1 Clinical characteristics of 127 patients with different stages of liver disease

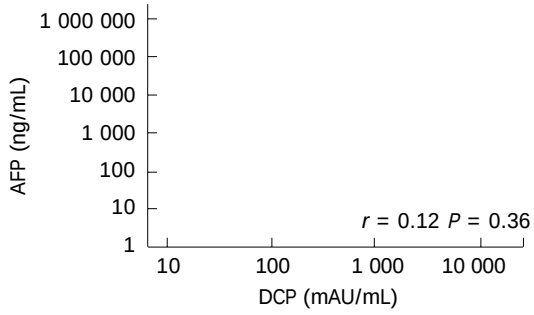

Figure 2 Relationship between DCP and AFP levels in 61 patients with HCC.

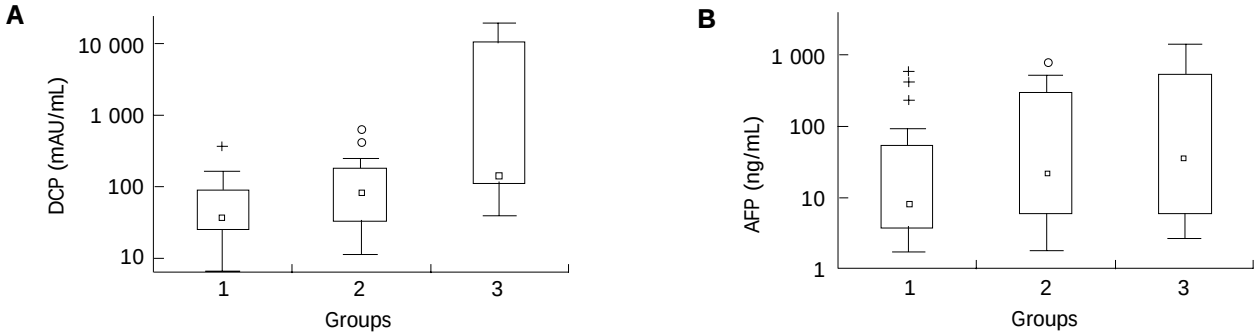

Figure 3 Box plot for DCP and AFP values in relation to size of tumor in 39 patients with solitary HCC (group 1, tumor less than 2 cm; group 2, tumor between 2 and 3 cm; and group 3, tumor more than 3 cm). The data were presented as the median and the range from the 25th-75th percentile(A and B).

DISCUSSION

Almost no symptoms would be noticed in patients with small HCC. The symptomatic HCC was usually incurable and lethal, and most previous studies reported that the median survival was only 3-6 mo after the onset of symptoms[26-28]. Early diagnosis is the most important issue in improving the long-term survival rate of HCC. Up to now, periodic screening among high risk population of HCC is the only way to detect the small HCC[5,6]. AFP is the most commonly used marker in diagnosing HCC. However, in 35-45% of HCC patients, the AFP level may be normal[21-24]; particularly in patients with small HCC[29]. On the other hand, patients with cirrhosis or chronic hepatitis, the elevated AFP level may be observed as well[30]. The dilemma is the reason why some cases of HCC could not be correctly diagnosed by AFP alone.

Based on our results, AUROC curves indicated a better accuracy for DCP than AFP in diagnosis of HCC (0.85 [95%CI, 0.78-0.91] *vs* 0.73 [95%CI, 0.65-0.81], $P = 0.013$). The cut-off value of DCP and AFP for HCC was set at 40 mAU/mL and 20 ng/mL, respectively. These values yielded a sensitivity and specificity for DCP of 77% and 86.4%, and for AFP of 59% and 77.3%, respectively. The sensitivity, specificity, and accuracy of DCP were significantly higher than APP in diagnosis of HCC (Table 2). Meanwhile, 25 of 61 (41%) patients with HCC had AFP level lower than 20 ng/mL. On the other hand, 15 of 66 (22.7%) patients with nonmalignant chronic liver disease had serum AFP level higher than 20 ng/mL. Taken together, DCP would be a better marker than AFP for HCC. Our results are also in accordance with recent studies that showed the unsatisfactory performance of AFP in diagnosis of HCC[8].

We did not find any correlation between the DCP and AFP in HCC patients (Figure 2). AFP secretion in HCC resulted from re-expression in the tumor of fetal origin[31]. DCP was produced by the malignant hepatocyte that resulted from an acquired post-translational defect in the vitamin K-dependent carboxylase system[32]. Because no correlation was observed between DCP and AFP, the simultaneous determination of both markers might be more effective in the diagnosis of HCC[33]. In our data, the increase in sensitivity from 77% to 83.6% (Table 2) in detecting HCC was found by the complementary use of the two markers.

We further analyzed 39 patients with solitary HCC in our study. We found that DCP levels had a better correlation with tumor size when compared with AFP levels (Figure 3). DCP also had a higher diagnostic sensitivity than AFP in patients with tumor size less than 2 cm in diameter. Particularly, for five patients with well-differentiated HCC less than 2 cm, the positive detection rate of DCP was 40%, which was much higher than 0% of AFP. It seems that DCP might be a better marker than AFP in detecting early-stage HCC. Because of the limited number of early-stage HCC in our report, further study is necessary to determine whether DCP plays an important role in early diagnosis of HCC.

In conclusion, our study indicates that DCP has a better diagnostic value than AFP in differentiating HCC from

nonmalignant chronic liver disease. DCP has not only a stronger correlation with HCC than AFP in tumor size but also more effectiveness than AFP in detecting small size of HCC.

Abstract

AIM: To explore the effect and significance of inhibitor of growth 1 (ING1) gene in carcinogenesis and progression of human sporadic colorectal cancer.

METHODS: mRNA expression, mutation, and loss of heterozygosity (LOH) of ING1 gene in 35 specimens of sporadic colorectal cancer tissues and the matched normal mucous membrane tissues were detected by semi-quantitative reverse transcriptase-polymerase chain reaction (RT-PCR), PCR-single strain conformation polymorphism (PCR-SSCP) and PCR-simple sequence length polymorphism (PCR-SSLP) using microsatellite markers, respectively.

RESULTS: The average ratios of light intensities of $p33^{ING1b}$ and $p47^{ING1a}$ mRNA expression in the cancerous tissues were significantly lower than those in normal tissues. The difference between the two mRNA splices was not significant in the matched tissues. In addition, the ratios of light intensities of $p33^{ING1b}$ and $p47^{ING1a}$ mRNA expression in the cancerous tissues of Dukes' stages C and D were significantly lower than those in cancerous tissues of Dukes' stages A and B. However, no mutation of ING1 gene was detected in all 35 cases; only 4 cases of LOH (11.4%) were found.

CONCLUSION: $p33^{ING1b}$ and $p47^{ING1a}$ mRNA expressions are closely related with the carcinogenesis and progression of human sporadic colorectal cancer. No mutation of ING1 gene is found, and there are only few LOH in sporadic colorectal cancers. These might not be the main reasons for the down regulation of ING1 expression. Its low expression may happen in transcription or post-transcription.

INTRODUCTION

A candidate tumor suppressor gene, inhibitor of growth 1 (ING1), has recently been cloned and mapped on human chromosome $13q^{33-34}$[1-3]. It has at least three exons and two introns. Its three alternative spliced transcripts encode $p47^{ING1a}$, $p33^{ING1b}$, and $p24^{ING1c}$ protein, respectively[4]. $p33^{ING1b}$ is a nuclear protein, which physically interacts with p53, and cooperates with it in many ways[2,5]. Overexpression of $p33^{ING1b}$ could efficiently block the growth of cells and induce apoptosis[6-8]. Conversely, inhibition of its expression by antisense constructs could promote cells growth and protect cells from apoptosis[7]. Downregulation of $p33^{ING1b}$ has been reported to be closely related with occurrence of various cancers, such as head and neck[4], esophageal[9], lung[10], gastric[11,12], bladder[13], ovary[14], breast[14,15], liver cell cancer[16,17], and so on. Genetic alterations, such as mutation or allelic imbalance, have been found in some cancers listed above. To the author's knowledge, only a few studies of ING1 gene on colorectal cancer have been reported as yet, and the results are different from each other[18]. Moreover, there is some lack of knowledge about $p47^{ING1a}$ expression in colorectal cancer till now. Accordingly, in order to evaluate the effect and significance of ING1 gene in carcinogenesis and progression of human sporadic colorectal cancer, we examined mRNA expression, mutation, and LOH of ING1 gene by using RT-PCR, PCR-SSCP, and PCR-RFLP.

MATERIALS AND METHODS

Patients and tissues

The tumor and matched normal mucosal tissues (at least 10 cm away from tumor margin) were obtained from 35 patients with sporadic colorectal cancer, who underwent surgical resection in our hospital, from December 2002 to March 2003. The patients consisted of 20 males and 15 females with the mean age of 59 years (range, 25-79 years). All the diagnoses were verified by pathological diagnosis.

Sixteen were colon and 19 were rectal carcinomas with Dukes' stages as follows: stage A (2 cases); stage B (15 cases); stage C (13 cases); and stage D (5 cases). All the specimens were frozen in liquid nitrogen after removal, followed by storage at -80 ℃.

RNA and DNA extraction

Total RNA and genomic DNA were isolated from the specimens using TRIzol reagent (Invitrogen, USA) and spin column genomic DNA isolation kit (BBI, Canada) according to the manufacturer's instructions. The integrity of total RNA and genomic DNA were checked on 10 g/L agarose gel.

RT-PCR

ING1 mRNA expression in tumor and matched normal tissues was examined using RT-PCR. RNase-free DNase I was used to remove DNA contamination at first. Then, cDNA was synthesized using first strand cDNA synthesis kit, following the manufacturer's instructions. At last, PCR was performed in 20 μL reaction mixtures comprising 2 μL of cDNA, 2.5 μL of 10×buffer, 1.5 μL of 2.5 mol/L deoxynucleotide triphosphate mixture (dNTP mixture), 2 U of Taq DNA polymerase (TaKaRa, Dalian, China), 0.5 μL of 10 mol/L each primer of ING1, 0.5 μL of 10 mol/L primer of GAPDH, and 12 μL of sterilized ddH_2O. Intron-spanning primers were: for $p47^{ING1a}$, 5'-CCGCATCTTT-GCTGACCCGA-3' and 5'-GCCTTCTTCTCCTTG-GGTGT-3' (444 bp); and for $p33^{ING1b}$, 5'-CTCCATCGAG-TCCCTGCCTT-3' and 5'-GCCTTCTTCTCCTTGG-GTGT-3' (480 bp). Primers for GAPDH were 5'-CGG-AGTCAACGGATTTGGTGCGTAT-3' and 5'-AGCCTT-CTCCATGGTGGYGAAGAC-3' (306 bp). The samples were amplified through 32 cycles, each amplification consisting of denaturation at 94 ℃ for 1 min, primer annealing at 62 ℃ for 1 min and extension at 72 ℃ for 1 min. Cycles were preceded by incubation at 94 ℃ for 5 min to ensure full denaturation of the target gene, followed by an extra incubation at 72 ℃ for 10 min to ensure full extension of the products. Primers for GAPDH were added to PCR tubes at the end of the 10^{th} cycle. Products of RT-PCR were electrophoresed on 20 g/L agarose gel. The light intensities of DNA bands were scanned by electrophoretic image analysis system (Bio-Rad Gel DOC 2000, USA). Reproducibility was confirmed by processing all samples at least twice.

PCR-SSCP

PCR reactions were carried out in a volume of 20 μL containing 100 ng of genomic DNA, 2.5 μL of 10× buffer, 1.5 μL of 2.5 mol/L dNTP mixture, 2 U of Taq DNA polymerase (TaKaRa, Dalian, China), 0.5 μL of 10 mol/L each primer, and 14 μL of sterilized ddH_2O. The samples were amplified through 32 cycles, each amplification consisting of denaturation at 94 ¡æ for 30 s, primer annealing at 62 ¡æ or 64 ¡æ for 30 s and extension at 72 ¡æ for 1 min. Finally, the samples underwent an extra incubation at 72 ¡æ for 10 min. The sequences of ING1 primers used for PCR-SSCP: exon 1, 5'-TGCAGTGCTATTTTT-TGAGGGG-3' and 5'-CGCCCCCGCCCATCCATCA-3' (248 bp); exon 2a, 5'-ACGCCTGTCCTTCTTGCCCC-3' and 5'-CTTGCCGCTGTTGCCCGCTG-3' (272 bp); exon 2b, 5'-TTCGAGGCGCAGCAGGAGCT-3' and 5'-CTTGGCCTTCTTCTCCTTGGG-3' (210 bp); exon 2c, 5'-TGAGCCCCACGCACGAGAAG-3' and 5'-CAGCA-ACCACGACCACGACG-3' (242 bp); exon 2d, 5'-CCTCC-CCATCGACCCCAACG-3' and 5'-ACATTTTACACT-CCTTGCACCTCA-3' (327 bp). Ten microliters of PCR products was mixed with 10 μL of loading dye (950 mL/L formamide, 20 mol/L EDTA, 0.5 g/L bromophenol blue, and 0.5 g/L xylene cyanol), heat denatured at 98 ¡æ for 10 min, chilled on ice, put onto 120 g/L polyacrylamide gel, and run at a constant rate of 12 V/cm for 10-14 h at variable temperatures. The DNA bands were detected by silver staining as previously described[19]. Reproducibility was confirmed by processing all samples at least twice.

LOH analysis

We examined genomic DNA for LOH by PCR-SSCP using five microsatellite markers (D13S158, D13S278, D13S285, D13S779, and D13S796), which are located in the ING1 locus. The primer pairs were available through the internet genome database (http://www.gdb.org). PCR was performed in 20 μL of reaction mixture comprising 100 ng of genomic DNA, 2.5 μL of 10× buffer, 1.5 μL of 2.5 mol/L dNTP mixture, 2 U of Taq DNA polymerase (TaKaRa, Dalian, China), 0.5 μL of 10 mol/L each primer, and 14 μL of sterilized ddH_2O. The samples were amplified through 32 cycles, each amplification consisting of denaturation at 62 ℃ for 30 s, primer annealing at 52 ℃ or 54 ℃ for 30 s and extension at 72 ℃ for 1 min. Finally, the samples underwent an extra incubation at 72 ℃ for 5 min. Ten microliters of PCR products was mixed with 10 μL of loading dye as described above, heat denatured for 10 min at 98 ℃, chilled on ice, put onto 120 g/L polyacrylamide gel containing 8 mol/L urea, and run at a constant rate of 25 V/cm for 3-4 h at room temperature. The DNA bands were visualized by silver staining. Reproducibility was confirmed by processing all samples at least twice. LOH was scored, if the heterozygous alleles showed at least 50% reduced intensity in tumor DNA bands as compared with the corresponding normal ones.

Statistical analysis

The SPSS 10.0 software package was used for all statistical analyses. Differences in expression of ING1 mRNA between the different groups were compared by using independent *t*-test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

ING1 mRNA expression detected by RT-PCR

All the samples of tumor tissues and normal tissues showed ING1 mRNA expression. Moreover, the average ratios of light intensities of $p33^{ING1b}$ mRNA and $p47^{ING1a}$ mRNA expression in the cancerous tissues were significantly lower than those in normal tissues (0.52 *vs* 1.28, $P<0.01$; 0.51 *vs* 1.21, $P<0.01$, respectively; Figure 1); difference between the two mRNA splices was not significant in the matched tissues.

The average ratios of light intensities of $p33^{ING1b}$ mRNA and $p47^{ING1a}$ mRNA expression in the cancerous tissues of Dukes' stages C and D were significantly lower than those in cancerous tissues of Dukes' stages A and B (0.38 *vs* 0.65, $P<0.01$; 0.40 *vs* 0.63, $P<0.01$, respectively).

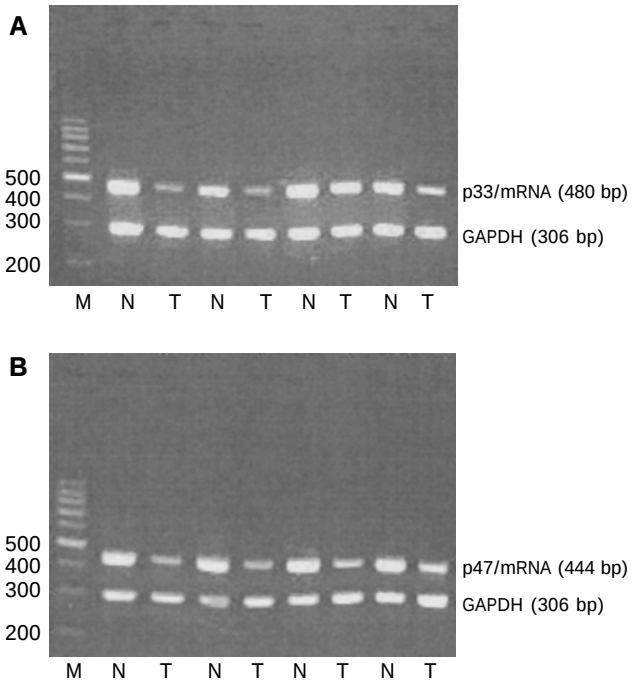

Figure 1 RT-PCR analysis of p33/ING1 and p47/ING1 mRNA expressions. N: normal tissue; T: tumor tissue (A and B).

Detection of ING1 gene mutation

To investigate whether the ING1 gene is the target of functional loss in tumors, we searched for mutation in the encoding regions of the gene in all 35 samples of colorectal cancer by using PCR-SSCP. However, no mutation was found (Figure 2).

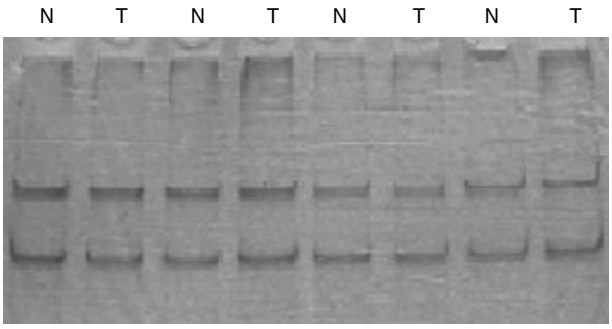

Figure 2 No mutation of ING1 gene was detected by PCR-SSCP (fragment exon 2a).

LOH analysis

To investigate whether allelic imbalance of terminal regions of chromosome 13q is reserved, we examined DNA from 35 pairs of matched tumor tissues and normal tissues for losses at five microsatellite markers (D13S158, D13S278, D13S285, D13S779, and D13S796). But only four cases of LOH (11.4%) were observed, two in D13S158, one in D13S278 and one in D13S285 (Figure 3).

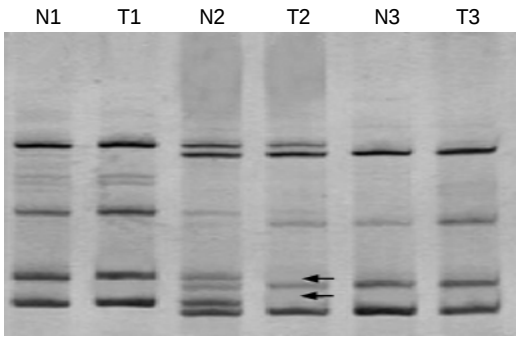

Figure 3 Electrophoretic picture of LOH analysis (LOH is seen in T2).

DISCUSSION

In this study, we found downregulation of $p33^{ING1}$ mRNA, and $p47^{ING1}$ mRNA expressions in the cancerous tissues of sporadic colorectal cancer, and the later Dukes' stage they were in, the less mRNA expression they presented. Our results are consistent with the previous data on head and neck[4], esophageal[9], lung[10], gastric[11,12], breast[14,15], and liver cell[16,17] cancers, neuroblastomas[20], and astrocytoma[21], but not with the other studies on colorectal cancer[18]. The precise mechanisms of tumor suppression by $p33^{ING1}$ and $p47^{ING1}$ remain unclear. Previous several reports thought that $p33^{ING1}$ might inhibit cells growth and promote apoptosis through both p53-dependent[5,8,17,21] and -independent pathways[21-24]. One is: $p33^{ING1}$ could stabilize p53 via disrupting the regulation of p53 by MDM2[23], and promote acetylation of p53 through inhibition of hSIR2[21,24]. Another one is: $p33^{ING1}$ and $p47^{ING1}$ could directly repress transcription promoters, and upregulate $p21^{WAF1}$ promoter activity[21]. Moreover, $p33^{ING1}$ could cooperate with p53. We, therefore, think that reduced expressions of $p33^{ING1}$ and $p47^{ING1}$ may lead to decreased inhibition of cell cycle and apoptosis, and strongly associated with the carcinogenesis and progression of human sporadic colorectal cancer.

Some previous studies have reported about several mis-sense mutations and silent changes in esophageal[9], head and neck[4], esophagogastric junction[25], gastric[11], skin[26], pancreatic[27], and breast[14] cancers. These mutations were all located in PDH finger and/or nuclear localization signal in the COOH-terminal half of ING1, and might lead to loss of the functions of ING1. But the rate of mutations was rare or no mis-sense mutation was found in oral squamous cell carcinoma[28], lymphoid malignancies[29], colorectal carcinoma[18], and hematological malignancies[30]. In our study, we could not detect mis-sense mutation of ING1 gene. Although PCR-SSCP analysis was reported to be less than 100% sensitive for mutation detection, this result suggests that mutation of ING1 occur with a very

low frequency in sporadic colorectal cancer. We, hereby, propose that gene mutation is not the main reason for the downregulation of ING1 expression.

Loss of heterozygosity (LOH), i.e., loss of one allele at a constitutional heterozygous locus, indicates the probability of loss of a tumor suppressor gene, which might promote neoplastic progression and metastasis. LOH is a critical event in the development of human cancers. It is thought to have resulted from either a large deletion or recombination between homologous alleles during repair of DNA double-strand breaks. These types of genetic alterations may produce mutations in some gene mutation assay. Previous studies demonstrated that high rates of LOH were found in human chromosome $13q^{33\text{-}34}$ region[4,9,31], such as the rates in esophageal/head and neck squamous cell cancers were 58.9% (20/34) and 68% (23/34), respectively[4,9]. Because the gene encoding ING1 is located in $13q^{33\text{-}34}$ region, we detected for LOH in this region using five microsatellite markers (D13S158, D13S278, D13S285, D13S779, and D13S796), which are at different locations on chromosome $13q^{33\text{-}34}$. In our study, the rate of LOH was only 11.4% (4/35), which is obviously lower than those in the previous reports. LOH at ING1 locus and the vicinity may affect the function of ING1, but these might not be the main reason for the downregulation of ING1 expression as well.

In conclusion, downregulation of $p33^{ING1}$ and $p47^{ING1}$ mRNA expressions in human sporadic colorectal cancer is substantial, relating with the carcinogenesis and progression, but mutation and LOH of gene might not be the main reason for the downregulation of ING1 expression. The reason for loss of function of ING1 gene is very complex. We speculate that the alterations at transcriptional or post-transcriptional levels, such as acetylation, methylation, ubiquitination, or phosphorylation, might be involved in the downregulation of ING1 gene. Further studies are needed to elucidate the possibility.

Abstract

AIM: To determine the role of Fas/Fas ligand (FasL) in the immune escape of colon cancer cells.

METHODS: Immunohistochemistry was used to observe the expression of Fas and FasL in the tissues of colon cancer patients. *In situ* hybridization was used to detect the localization of FasL mRNA expression in cancer tissues. Terminal deoxynucleotide transferase-mediated dUTP nick end labeling (TUNEL) assay and CD45 staining were performed to detect the apoptosis of tumor-infiltrating lymphocytes (TILs). Co-culture assays of colon cancer cells (SW480) and Jurkat cells (Fas-sensitive cells) were performed to observe the counterattack of colon cancer cells to lymphocytes.

RESULTS: Of 53 cases of colon carcinomas, 23 cases (43.4%) expressed Fas which was significantly lower as compared to the normal colonic mucosa (73.3%, $P<0.01$), and 45 cases (84.9%) of colon carcinomas expressed FasL, whereas only two cases (3.75%) in normal mucosa expressed FasL. FasL expression in the colon cancer cells was found to be associated with increased cell death of TILs. The apoptotic rate of TIL in the FasL-positive staining regions of tumor cells was significantly higher than that in the FasL-negative staining region (54.84±2.79% *vs* 25.73±1.98%, $P<0.01$). The co-culture of SW480 cells and Jurkat cells confirmed the function of FasL on the SW480 cells. The apoptotic rates of Jurkat cells were found to be related with the amount of SW480 cells.

CONCLUSION: Colon cancer cells can escape the immune surveillance and killing via decreasing Fas expression, and can counterattack the immune system via increasing FasL expression. Fas/FasL can serve as potential targets for effective antitumor therapy.

INTRODUCTION

Fas (Apo-1/CD95) is a 45-ku type I membrane protein, and Fas ligand (FasL) is a 37-40-ku type II membrane protein, which belong to the tumor necrosis factor receptor and ligand families. Activation of Fas by certain anti-Fas antibodies or by FasL results in apoptotic cell death in susceptible cells. Fas/FasL interaction constitutes one of the main systems mediating the cytotoxicity of T cells and regulating immune responses, tissue development, and homeostasis[1,2].

Fas system is one of the killing pathways by cytotoxic T lymphocytes (CTL) to tumor cells in human body; however, in recent reports, the most enticing interpretation of FasL expression by tumor cells is that it offers a further novel mechanism of immune evasion. Tumor cells could counterattack the immune system of human body by inducing apoptosis of immune effector cells through Fas/FasL system[3]. We used *in vivo* and *in vitro* methods to determine the role of Fas/FasL in the immune escape of colon cancer cells.

MATERIALS AND METHODS

Immunohistochemical detection of Fas/FasL protein

Fifty-three colon carcinomas were collected after surgical resection performed at Shandong Provincial Hospital. None of the patients had received chemo-, radio- or immuno-therapy before resection. Paraffin wax-embedded surgically resected tumor sections were deparaffinized in xylene and rehydrated before analysis. The primary antibodies were purified rabbit polyclonal anti-human Fas and FasL-specific IgG (Santa Cruz Biotechnology, Santa Cruz, CA, USA) at 0.1 μg/mL in a wash buffer. Antibody binding was localized using a biotinylated secondary antibody, avidin conjugated horseradish peroxidase, and diamiobenzidine substrate, contained within the ABC detection kit. The immunizing peptide (Santa Cruz Biotechnology), to which the antibody was raised, was included at 1 μg/mL during primary antibody incubation as a direct internal competitive control for antibody specificity.

Localization of FasL mRNA expression by in situ hybridization

In situ hybridization was performed on paraffin-embedded human colonic tumor sections (4 μm thick), mounted on aminopropylethoxysilane-treated slides. A digoxigenin-labeled RNA hybridization probe (344 bp) was used, corresponding to codons 96-210 of the human FasL cDNA sequence. The nucleotide sequence of the FasL probe showed insignificant homology to any other sequence in the EMBL DNA sequence database. Prehybridization and hybridization were performed as previously described[3]. In order to confirm the specificity of hybridization, a 10-fold excess of unlabeled riboprobe was added to the digoxigenin-labeled probe prior to hybridization.

In situ apoptosis assessment of tumor-infiltrating lymphocyte

To identify tumor-infiltrating lymphocytes (TILs), CD45 staining was performed on consecutive sections with a mouse anti-human CD45 monoclonal IgG (clone 2B11+PD7/26, Dako Corp., Carpinteria, CA, USA, dilution 1/70) according to the standard immunohistochemical methods as described above. Alkaline phosphatase conjugated anti-alkaline phosphatase complex (DO651, Dako Corp.) was used to display the color of CD45 staining. The membrane of the CD45-positive cells was red. Apoptosis of TILs was detected *in situ* in frozen sections of resected tissues using Terminal deoxynucleotide transferase-mediated dUTP nick end labeling (TUNEL) assay (Boehringer Mannheim GmbH, Mannheim, Germany) applied to the histological sections. Visualization of the final reaction product was achieved by diaminobenzidine. TUNEL-positive TILs (with red membrane and brown nucleus) were counted at high power (×400) from fields of view chosen according to a systematic random sampling method. Approximately 1 000 TILs were counted and a TUNEL index (TI) was expressed as the percentage of TUNEL lymphocytes.

Cell culture and growth assay

Colon cancer SW480 cells were grown in RPMI medium supplemented with penicillin G (100 U/mL), streptomycin (100 μg/mL) and 100 mL/L fetal bovine serum at 37 ℃ in humidified atmosphere containing 50 mL/L CO_2 in air. Cell growth was determined by the 3-(4,5-methylthiazol-2yl)-2, 5-diaphenyl-tertrazolium bromide (MTT) colorimetric assay. The assay was initiated by adding MTT solution to each well at a final concentration of 0.625 μg MTT/mL medium. After 4 h, the optical density was determined with an ELISA plate reader after removal of the medium and dissolving of the dye crystals in acidified isopropylalcohol.

Co-culture assays of colon cancer and Jurkat cells

Different concentrations of SW480 cells (0, 1×10^5/mL, 2×10^5/mL, 4×10^5/mL) were plated in triplicate on 24-multiwell tissue culture dishes. After 24 h, 2×10^4/mL Jurkat cells were seeded onto the plates. The wells with colon cancer cells alone (without overlying Jurkat cells) were maintained as additional controls. After 48 h, the non-adherent phase of the mixed culture was aspirated and assayed for viability using MTT assay. In experiments using recombinant FasFc (ZB4) as a competitor, similar experimental conditions were used with the following exception. MTT assay was used to evaluate the amount of Jurkat cells at the co-culture time of 24, 48, 72, and 96 h.

Detection of apoptosis of Jurkat cells

After being co-cultured with SW480 for 48 h, the Jurkat cells were collected and added with Hoechst 33258 (Sigma) on a slide glass. The specimens were examined under a Nikon fluorescence microscope with B2-type filter (magnification ×200). When apoptotic bodies or chromatin condensations were observed, the observation was defined as apoptosis. Apoptotic cells were assessed morphologically by staining with Hoechst 33258 using cells fixed with Clarke fixative (ethanol:acetic acid = 3:1). Apoptotic index (AI) was defined as follows: AI = 100×apoptotic cells/200 cells.

Statistical analysis

All experiments for cell cultures were performed at least in triplicate. Data were expressed as mean±SD. Statistical analysis was performed by one-way variance (ANOVA), and the comparisons between groups were performed by independent sample *t*-test. The regressive relation between two variables was performed by linear regression. A two-tailed *P* value less than 0.05 was considered statistically significant.

RESULTS

Decrease of Fas expression and increase of FasL expression in colon cancer tissues

Of 53 cases of colon carcinomas, 23 cases (43.4%) expressed Fas which was significantly lower as compared to that in normal colonic mucosa (73.3%) ($P<0.01$), and 45 cases (84.9%) of colon carcinomas expressed FasL, whereas only 2 cases (3.75%) in normal mucosa expressed FasL. Intensity and extent of positive staining varied within individual tumors. Neoplastic areas with positive and negative staining for FasL frequently co-existed within the same tumor. The extent of FasL expression varied significantly between different cancer stages and differentiations (data not shown, Figures 1A and B). FasL expression also existed on TILs in all cases. TILs were smaller in volume than cancer cells, which could distinguish the two kinds of FasL-expressing cells.

In situ hybridization was performed on paraffin-embedded human colonic tumor sections in order to detect the localization of FasL mRNA expression. FasL mRNA was detected in the colon cancer cells and in TILs (Figure 2). The location of FasL mRNA and expression of FasL protein coincided.

To further study the role of FasL expressed in cancer cells in tissues, 23 cases of lymph node metastases from colorectal carcinomas were obtained to detect the expression of FasL immunohistochemically. All cases of lymph node metastases showed FasL immunoreactivity in greater than 60% of the metastatic cells (Figure 1C).

Apoptosis of tumor-infiltrating lymphocytes induced by FasL on colon cancer

To evaluate apoptosis of TILs, we detected the presence of apoptotic cells in tissue sections using CD45 staining

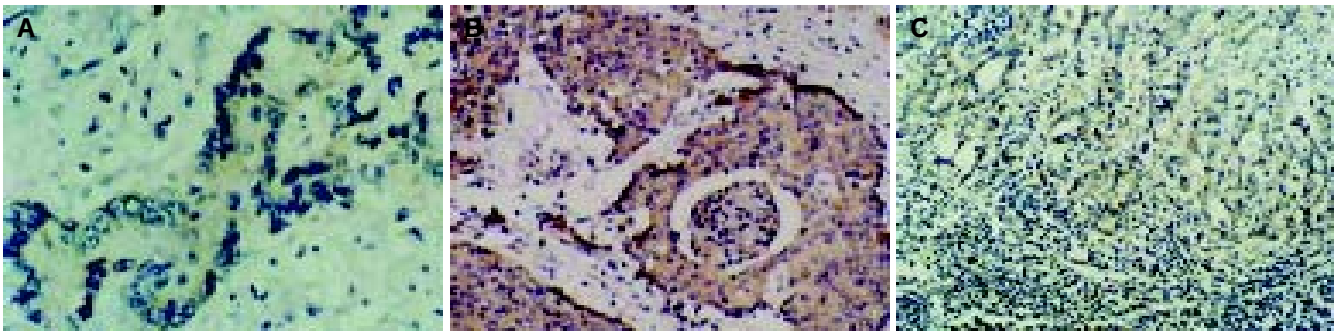

Figure 1 Immunohistochemical staining of Fas and FasL expression in colon cancer cells. A: Low expression of Fas in colon cancer cells; B: high expression of FasL in colon cancer cells; and C: high expression of FasL in lymph node metastases from colon cancer cells.

(WBC common antigen) and TUNEL techniques. Tonsil sections were included as positive controls, stained strongly, and omission of the primary antibody abolished staining. To quantify the extent of apoptosis of TILs, the percentage of TUNEL-positive and CD45-positive cells was calculated. The apoptotic rate of TILs in FasL-positive staining regions of tumor cells was significantly higher than that in FasL-negative region of tumor cells (54.84±2.79% *vs* 25.73±1.98%, $P<0.01$, Figure 3). *In vivo* FasL expression in colon cancer cells was found to be associated with increased cell death of TILs.

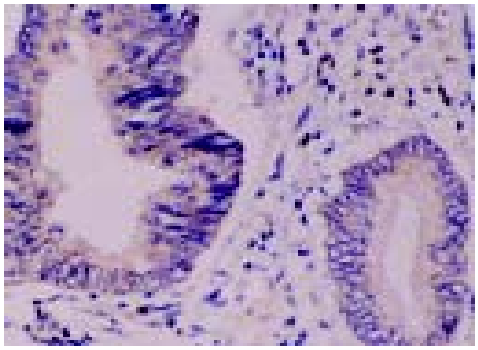

Figure 2 Localization of FasL mRNA by *in situ* hybridization.

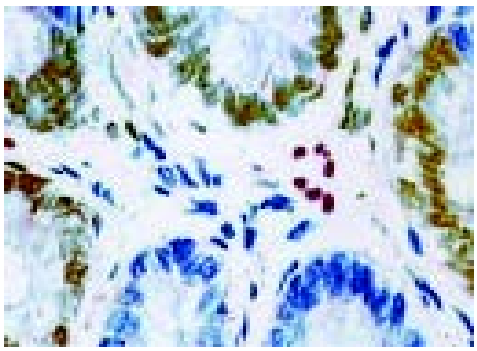

Figure 3 Detection of TILs. They were displayed by double staining (CD45 staining and TUNEL).

Colon cancer cell-mediated killing of Jurkat cells

Jurkat cells grown in the absence of human colon cancer cells showed a marked proliferation after 48 h. However, when co-cultured over a mono-layer of the FasL-expressing colon cancer cell line SW480, we observed a marked decrease in Jurkat cells while using MTT assay (Figure 4). The Jurkat cell killing was largely inhibited by pre-incubating the colon cancer mono-layer with a low concentration of recombinant Fas neutral antibody ZB4, which is capable of binding to FasL and blocking Fas/FasL interaction.

We used fluorescence microscopy to observe the shape of apoptotic Jurkat cells by the untreated SW480 cells. Condensation of chromatin, nuclear fragmentation and typical apoptotic bodies were observed in the tested group (Figure 5). The fluorescence microscopy results revealed that the apoptotic rates of Jurkat cells induced by SW480 cells after being co-cultured had a significant difference with the natural apoptotic rate of Jurkat cells (Table 1).

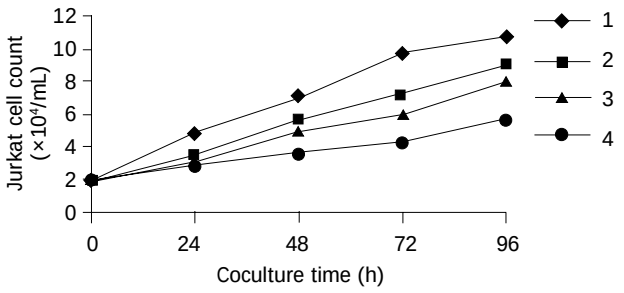

Figure 4 Jurkat cells growth curve after being co-cultured with SW480. 1: Control group; 2: 0.5×10^5/mL SW480 planting group; 3: 1×10^5/mL SW480 planting group; and 4: 2×10^5/mL SW480 planting group.

Table 1 Apoptotic rates of Jurkat cells detected by fluorescence microscopy

Planting concentration of SW480	Apoptotic rate of Jurkat cell (%)
0 (controls)	1.58±0.12
0.5×10^5/mL	5.22±0.13[b]
1×10^5/mL	9.74±0.21[b]
2×10^5/mL	19.33±0.18[b]

[b]$P<0.01$ *vs* controls.

DISCUSSION

Fas molecule was identified for the first time in 1989 by two research groups of Germany and Japanese separately[4,5]. In the beginning days of the twentieth century, researchers worldwide paid attention to the role of Fas system in the process of CTL killing cancer cells. It has been concluded that CTL-induced apoptosis of cancer cells via Fas system is one of the two main ways of CTL killing cancer cells, namely, Fas-based cytotoxicity is one of the two molecular mechanisms of T cell-mediated cytotoxicity, the other is perforin-based[1].

In recent years, some reports found that caner cells could decrease Fas expression which could escape the immune surveillance and killing, but could express FasL which could induce apoptosis of CTL, especially TILs[3,6,7]. In these cases, Fas and FasL may contribute to tumor immune privilege by inducing FasL-mediated apoptosis of host CTL and NK cells. We found that Fas expression on the colon cancer cells decreased significantly compared to the normal colonic epithelial cells ($P<0.05$), which was in agreement with the previous reports by Houston *et al.*[8], and Okada *et al.*[9]. Colon cancer could escape the immune surveillance and killing by decreasing Fas expression.

In addition to decrease in Fas expression, functional FasL expression by certain cancer cell types has been implicated in tumor escape via destruction of infiltrating Fas-bearing lymphocytes. In this study, we also found that FasL expression was absent in normal colonic epithelial cells, whereas markedly increased in colon carcinomas ($P<0.05$), and it was obviously correlated with apoptosis of TILs in colon cancer tissues. To evaluate the functional significance of FasL expression in colon cancer cells, we performed co-culture experiments using the Fas-sensitive Jurkat cell line (of human T-cell origin) as a target cell. These cells have been demonstrated to be capable of apoptosis following exposure to FasL. *In vitro*, colon cancer cells without any treatment could mediate apoptosis of Jurkat cells by Fas and FasL. Expression of FasL potentially enables colon cancer cells to counterattack Fas-sensitive anti-tumor immune effector cells by delivering a Fas-mediated apoptotic death signal. Ohta *et al.*[10], reported that 37 (82%) of the primary pancreatic cancers and both of the hepatic metastases expressed FasL, and the patients with FasL-positive tumor had significantly shorter survival times as compared with the FasL-negative, suggesting FasL as a significant prognostic factor of pancreatic cancer.

FasL expression may have effects on the immune system beyond the tumor site, and soluble FasL has been identified in certain types of FasL-positive leukemias and lymphomas[11]. Circulating forms of FasL (soluble FasL) were also found in blood from cancer patients, this could contribute to the generalized depression of cellular immunity. Thus, FasL expression might facilitate tumor invasion by inducing apoptosis in surrounding Fas-positive tissue, allowing the tumor to grow into the resulting space.

We found that large areas of most colonic tumors co-expressed FasL and Fas, indicating that these cells must have disabled the intracellular Fas apoptotic pathway due to intracellular defects in Fas signal transduction. Strand *et al.*[12], reported that MMP-7 cleavage of Fas resulted in reduced Fas surface expression and decreased Fas-mediated apoptosis sensitivity of tumor cells. Moreover, overexpression of inhibitors of apoptosis or intracellular apoptotic signal transduction may further contribute to the observed resistance to Fas-dependent apoptosis in colon cancer[13]. Several additional mechanisms of the Fas resistance have been described. Expression of soluble Fas by liver cancer cells may be involved in the Fas resistance of liver cancer *in vivo*[14].

A "Fas counterattack" model of colon cancer immune escape can be proposed, in which colon cancer cells, by expressing FasL, may remove Fas-sensitive immune effector cells by apoptosis. Increased expression of FasL is associated with decreased Fas levels in colon cancer cells that can escape immune surveillance and facilitate tumor progression and metastasis. Fas/FasL can serve as potential targets for effective antitumor therapy[15].

Abstract

AIM: To evaluate the activity of apoptosis in liver tissue and explore its possible association with hepatic necroinflammation and fibrosis as well as serum hepatitis C virus (HCV) load.

METHODS: The studied population included 50 chronic hepatitis C patients (20 women and 30 men, aged 18-66 years). HCV-RNA quantification was performed by two-step real-time quantitative RT-PCR method using the TaqMan technology (reagents of Applera Corporation firm, USA). The morphology of liver tissue was assessed descriptively and scored (necroinflammatory activity and fibrosis). The early apoptosis activity in liver tissue was examined by ssDNA apoptosis ELISA kit, (Chemicon, Germany).

RESULTS: The correlation between apoptosis and fibrosis in liver tissue was observed. High intensification of apoptosis was proportional to the increase of fibrosis (ssDNA: 16.65×10^{-5} μg/g; 12.71×10^{-5} μg/g), however, this difference was not statistically significant ($P>0.05$). Activity of apoptosis in the liver tissue, expressed by ssDNA concentration did not depend on hepatic necroinflammatory changes, HCV-RNA viral load, ALT, and AST activity as well as prothrombin time and INR index.

CONCLUSION: Fibrosis in the tissue is closely associated with early apoptosis in HCV-infected patients.

INTRODUCTION

Activity of apoptosis during hepatitis C virus (HCV) infection is a result of inhibitory and stimulatory effects of viral proteins. Apoptosis of HCV-infected hepatocytes influences the elimination of viruses. Insufficient activity of this process can lead to persistent liver inflammation[1]. On the contrary, excessive activity of apoptosis causes uncontrolled damage to liver cells. Moreover, there is evidence that apoptosis influences fibrosis progression.

This study was to evaluate the activity of apoptosis in liver tissue and explore its possible association with hepatic necroinflammation and fibrosis activity as well as serum HCV viral load.

MATERIALS AND METHODS

Patients

The study included 50 chronic hepatitis C patients (20 women and 30 men, aged 18-66 years). Their HCV infection did not exceed 5 years. Inclusion criteria were the following: no focal changes in ultrasonography investigation of liver, absence of drugs or alcohol abuse, autoimmune disease, HIV and hepatitis B co-infection as well as neoplasmatic and other serious diseases, which might alter apoptosis activity. Informed consent was obtained from each patient and the Bioethics Committee at the Medical University of Bialystok approved the study protocol.

The presence of anti-HCV antibodies in serum was detected by MEIA (Abbott, USA). Test was based on recombinant core proteins for HCr43, structural proteins for c200 (NS3 and NS4) and unstructured proteins for c100-3 (NS4) and NS5.

HCV-RNA quantification methods

Blood samples were obtained from 47 patients with known chronic hepatitis C. All blood samples were collected to Vacutainer tubes with no additives and centrifuged within 2 h of collection. The serum was aliquoted and kept at -80 ℃ until further use.

RNA was extracted from 280 μL of each serum sample using Qiagen (Hilden, Germany) QIAamp viral RNA mini kit according to the manufacturer's protocol and dissolved in 50 μL of RNase-free water. This resulted in nearly sixfold concentration of the original output material. RNA was stored at -80 ℃ until further testing. Each isolation was carried out in duplicate.

HCV-RNA quantification was performed by two-step real-time quantitative RT-PCR method using the TaqMan technology[2]. First, 3.5 μL of total RNA was subjected to reverse transcription in 10 μL of reaction mixture using the Applied Biosystems (Applera Corporation, USA) TaqMan

reverse transcription reagents and random hexamers $(dN)_6$. RNA was previously denatured at 70 ℃ for 10 min. The reaction mixture was prepared as follows: 1×reverse transcription buffer, 5.5 mmol/L $MgCl_2$, 0.5 mmol/L of each dNTPs, 2.5 mmol/L of primer $(dN)_6$, 0.4 U of RNase inhibitor per μL and 1.25 U of MultiScribe transcriptase per μL. The reaction was carried out at 48 ℃ for 30 min preceded by the incubation at 25 ℃ for 10 min. Incubation at 95 ℃ for 5 min terminated the reaction. The resulting cDNA was used as a template for PCR amplification.

cDNA amplification was performed by the Applied Biosystem (Applera Corporation, USA) ABI Prism 7 900HT sequence detection system in TaqMan universal PCR master mix, which is optimized for TaqMan reactions and contains Applied Biosystems (Applera Corporation, USA) AmpliTaq gold DNA polymerase, AmpErase UNG, dNTPs with UTP, passive reference ROX and optimized buffer components. For each PCR reaction, 4 μL of cDNA was added to 16 μL of PCR mix containing 450 nmoL each of HCV-specific forward and reverse primers and 300 nmoL of HCV-specific FAM-MGB probe. The primers and probe were designed and manufactured by Applied Biosystems (Applera Corporation, USA) and optimized for HCV genotype RNA detection. Thermal cycling conditions were designed as follows: inactivation of possible contaminating amplicons by AmpErase UNG at 50 ℃ for 2 min, initial cDNA denaturation at 95 ℃ for 10 min, followed by 40 cycles at 95 ℃ for 15 s and at 60 ℃ for 60 s. All amplification reactions were carried out in triplicate.

Fluorescent measurements were recorded during the annealing step of each cycle. At the end of each PCR run, data were automatically analyzed by the system to generate the amplification plots and the threshold cycle (Ct) for each sample was calculated. Sample RNA concentrations were then automatically calculated by interpolation of the experimentally determined standard curve.

An external standard curve was generated with each run by amplification of 10-fold serial dilutions of RNA isolated from the viral quality control serum (PeliSpy, Sanguin), containing 38 000 geq/mL HCV. RNA isolation and cDNA synthesis were carried out as described for unknown samples. All amplification reactions were carried out in duplicate. The standard curve was created automatically by the ABI Prism 7 900HT detection system by plotting the Ct values against each standard dilution of known concentration.

Precautions were undertaken to minimize the risk of PCR contamination during analysis.

Liver morphology

Liver tissue was obtained from the right lobe of the liver (with 1.6-1.8 mm needles from Hypafix packs by Braun, Germany). A part of the liver tissue was subjected to morphologic examination. The morphology of liver tissue was assessed descriptively and scored (necroinflammatory activity and fibrosis) according to Scheuer[3].

Another part of the liver tissue was transferred to 0.9% NaCl buffer and then subjected to apoptosis activity measurement.

Apoptosis in liver tissue

The early apoptosis activity in liver tissue was measured by ssDNA apoptosis ELISA kit, (Chemicon, Germany) based on the mAb to single-stranded DNA (ssDNA). The intensity of the reaction between ssDNA and mAb was evaluated. The amount of ssDNA was calculated with reference to absorbance line of positive and negative control.

The liver tissue was homogenized in 0.9% NaCl buffer. The concentrations of ssDNA and total proteins in the homogenized liver tissue were analyzed in duplicate. The homogenates of liver tissue were transferred to wells 24 h prior to the succeeding steps of the procedure to allow cell attachment. Then formamide was added to denature DNA in apoptotic cells, but not in necrotic cells or in cells with DNA damage in the absence of apoptosis. This process enabled specific receptors of apoptotic ssDNA binding to mAb. Following this reaction, 3-ethylbenziazoline-6-sulfonic acid was added to color the products of this reaction[4].

Absorbance was defined at 405 nm. The concentration of ssDNA was calculated from a prepared standard curve of absorbance (basis of different increasing positive and negative control). The results of ssDNA were referred to 1.0 g of proteins in the liver tissue sample.

Statistical analysis

Statistical analysis was performed by non-parametric Mann-Whitney *U*, Wilcoxon rank, and Pearson tests. $P<0.05$ was considered statistically significant.

RESULTS

Diagnostic biopsy was obtained from 47 patients. In three of the remaining cases, the liver biopsy sample did not contain five portobiliary areas, therefore it was impossible to obtain reliable histology results.

The activity of apoptosis in liver tissue of the studied group was independent of sex and age. ssDNA concentration in liver tissue did not correlate with ALT, AST activity, prothrombin time, and INR index. Moreover, apoptosis was independent of necroinflammatory changes in liver tissue (Table 1).

Table 1 Correlation between ALT, AST activity, prothrombin time, and INR index in chronic hepatitis C patients

	ALT	AST	Prothrombin time	INR index
Pearson test	0.08	0.14	-0.01	0.03

The correlation between fibrosis and apoptosis was observed. Concentration of ssDNA was higher (16.65×10^{-5} μg/g) in patients with more intensified fibrosis of liver tissue than in those with fibrosis (12.71×10^{-5} μg/g). However, this difference was not statistically significant ($P>0.05$). (Figures 1 and 2)

The serum HCV-RNA concentration did not correlate with ALT, AST activity, prothrombin time, and INR index. Moreover, no correlation between serum HCV-RNA and ssDNA concentrations in liver tissue was observed (Table 2).

DISCUSSION

Table 2 Concentration of apoptosis ssDNA in respect to serum HCV-RNA concentration, necroinflammatory changes (G) and fibrosis (S) in liver tissue

n	G1+G2	Concentration of ssDNA (μg/g)	Concentration of HCV-RNA (geq/mL)	Pearson test	*n*	*S*	Concentration of ssDNA (μg/g)	Concentration of HCV-RNA (geq/mL)	Pearson test
16	0-3	13.16×10^{-5} 3.95×10^{-5} SD±	$4.96\text{-}54.2\times10^{3}$	-0.11	39	0-1	12.71×10^{-5} $4.85\text{-}10^{-5}$ SD±	$4.96\text{-}227\times10^{3}$	0.01

Necroinflammatory activity: G1 = 0-4; G2 = 0-4; G1/2 = 0-8; *S* = 0-4.

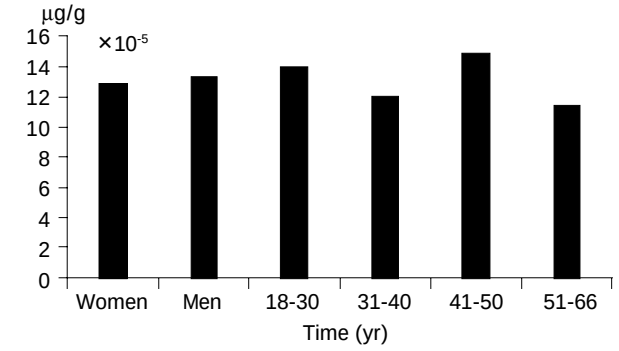

Figure 1 Concentration of ssDNA in HCV-infected patients with respect to age and sex.

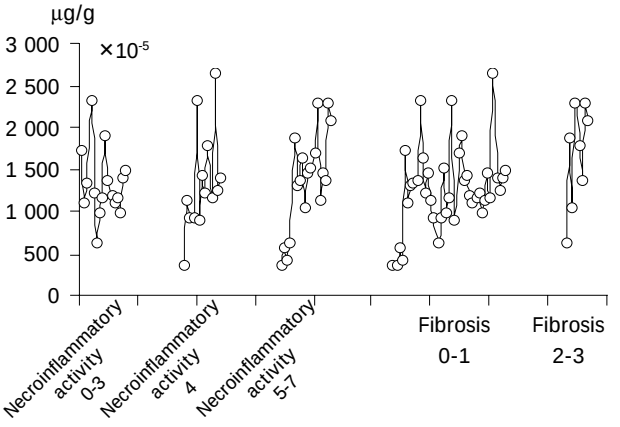

Figure 2 Concentration of ssDNA in liver tissue stratified according to liver morphology changes. Necroinflammatory activity: G1 = 0-4; G2 = 0-4; G1/2 = 0-8; *S* = 0-4.

Apoptosis is one of the factors regulating the course of chronic viral hepatitis. Since this process runs gradually, modification of its course is possible. Different HCV proteins can accelerate or suppress apoptosis.

HCV core proteins overactivate Fas particles expressed on hepatocytes, leading to degradation of cell DNA[5,6]. The Fas particles are "death domains" and indicators of apoptosis. Higher Fas concentration in patients with HCV infection can increase the activity of apoptosis.

HCV non-structural proteins (NS5A) are able to suppress apoptosis by diminishing synthesis of caspase 3, protein kinase A and suppressing TNF-α stimulating polymerase[7,8]. Insufficient activity of apoptosis can influence the persistence of chronic inflammation related to HCV infection[1].

Di Martino *et al*.[9], showed that activity of apoptosis in chronic hepatitis C patients is proportional to HCV-RNA levels. Caronia *et al*.[10], have shown that HCV strongly inhibits apoptosis. In previous investigations, the concentration of ssDNA, as an early indicator of apoptosis was not correlated with HCV viral load, functional state of the liver and necroinflammatory changes in liver tissue samples.

Tsamandas *et al*.[11], evaluated the location and concentration of Bcl-2 and Bax protein, markers of apoptosis activity, in patents with HBV and HCV infection, and found that Bcl-2 and Bax concentrations are enhanced in the regions of intense fibrosis. Takehara *et al*.[12], have shown the linear dependence between the concentration of Bcl-2 family members and activity of fibrosis in the liver. Our results are in accordance with their observations.

Bcl-2 and Bax proteins can mark the late period of apoptosis. Correlation between apoptosis and fibrosis in liver tissue seems unquestionable. However, whether cells with high activity of apoptosis are molecular inductors of fibrosis in HCV-infected patients remains to be solved.

In conclusion, fibrosis of liver tissue is associated with HCV-infection, but apoptosis is not associated with necroinflammatory changes in chronic hepatitis C patients.

Abstract

AIM: To elucidate the sequential gene expression profile in AGS cells co-cultured with wild-type *Helicobacter pylori* (*H pylori*) as a model of *H pylori*-infected gastric epithelium, and to further examine the contribution of *cag*-pathogenicity islands (*cag*PAI)-coding type IV secretion system and the two pathways, nuclear factor kappa B (NF-κB) and extracellular signal-regulated kinases (ERK) on wild-type *H pylori*-induced gene expression.

METHODS: Gene expression profiles induced by *H pylori* were evaluated in AGS gastric epithelial cells using cDNA microarray, which were present in the 4 600 independent clones picked up from the human gastric tissue. We also analyzed the contribution of NF-κB and ERK signaling on *H pylori*-induced gene expression by using inhibitors of specific signal pathways. The isogenic mutant with disrupted *cag*E (△*cag*E) was used to elucidate the role of *cag*PAI-encoding type IV secretion system in the gene expression profile.

RESULTS: According to the expression profile, the genes were classified into four clusters. Among them, the clusters characterized by continuous upregulation were most conspicuous, and it contained many signal transducer activity-associated genes. The role of *cag*PAI on cultured cells was also investigated using isogenic mutant *cag*E, which carries non-functional *cag*PAI. Then the upregulation of more than 80% of the induced genes (476/566) was found to depend on *cag*PAI. Signal transducer pathway through NF-κB or ERK are the major pathways which are known to be activated by *cag*PAI-positive *H pylori*. The role of these pathways in the whole signal activation by *cag*PAI-positive *H pylori* was analyzed. The specific inhibitors against NF-κB or ERK pathway blocked the activation of gene expression in 65% (367/566) or 76% (429/566) of the genes whose activation appealed to depend on *cag*PAI.

CONCLUSION: These results suggest that more than half of the genes induced by *cag*PAI-positive *H pylori* depend on NF-κB and ERK signaling activation, and these pathways may play a role in the gene expression induced by host-bacterial interaction which may associate with *H pylori*-related gastro-duodenal diseases.

INTRODUCTION

Helicobacter pylori (*H pylori*) is the causative agent for various gastro-duodenal diseases[1] and has been classified as a definite carcinogen by the International Agency for Research on Cancer[2]. Previous studies have shown that the eradication of *H pylori* virtually eliminates the recurrence of peptic ulcer diseases, suppresses the recurrence of gastric cancer after mucosal resection, and cures mucosa-associated lymphoid tissue lymphoma[3-10]. The molecular mechanisms underlying these *H pylori*-related diseases have been extensively studied.

The *cag*-pathogenicity island (*cag*PAI), a cluster of about 28 genes, is one of the best known virulence factors; it encodes a type IV secretion system that transports CagA protein, peptidoglycan and possibly other molecules into host epithelial cells[11-16]. Transported CagA binds to molecules such as SH2 domain-containing protein-tyrosine phosphatase-2 (SHP-2), growth factor receptor bound 2 (Grb2), and cortactin[17-19]. Then it induces epithelial disruption as well as cytoskeletal changes[20], which might result in inducing ulcer diseases and gastric cancer[21,22].

The *cag*PAI is also associated with activation of the transcription factors nuclear factor kappa B (NF-κB) and

activator protein-1 (AP-1)[23-26], two key regulators of the expression of various inflammatory genes. NF-κB acts as a transcriptional modulator in the host response to bacterial invasion[27-33]. Its activation may in turn increase inflammation by inducing cytokines similar to the stimulation of interleukin-1 (IL-1) and tumor necrotizing factor-alpha (TNF-α)[34], and induce cell proliferation via activating anti-apoptotic effect[35]. The attachment of *H pylori* to gastric epithelial cells also induces the rapid activation of p38, c-Jun NH2-terminal kinase, and mitogen-activated protein kinase (MAPK)[36]; the downstream effectors of these signals include oncogene c-*fos* and its promoter element serum response element (SRE)[37,38]. These are possibly involved in cellular proliferation and survival[39-41], which might be associated with gastric carcinogenesis.

Some of the host cell responses to infection with *H pylori* induce many gene expressions and appear to function in contradictory directions, such as inflammation and cell proliferation, or apoptosis and anti-apoptosis[35]; the relative importance of each response is thus not immediately obvious. Recently, cDNA microarray analysis has been used to comprehensively characterize the individual responses in host cells[42,43]. The authors and coworkers have previously profiled *H pylori*-induced gene expression *in vitro*[44-51] and *in vivo*[52-54]. However, the contribution of the *cag*PAI-encoding type IV secretion system and the importance of intracellular signaling activation have not been fully elucidated.

In this study, we analyzed sequential gene expression profile in AGS cells co-cultured with wild-type *H pylori* as a model of *H pylori*-infected gastric epithelium. Furthermore, we examined the contribution of *cag*PAI-coding type IV secretion system and the two pathways, NF-κB and extracellular signal-regulated kinases (ERK) on wild-type *H pylori*-induced gene expression.

MATERIALS AND METHODS

Bacterial strains and cell culture

The *H pylori* TN2 strain, which is positive for entire *cag*PAI, and *vacA*, was generously denoted by Dr. M. Nakao (Takeda Chemical Industries, Ltd, Osaka, Japan). The isogenic *cagE* mutant TN2-△*cagE* was prepared by insertion of a kanamycin-resistant gene into the *cagE* gene locus of TN2, as described previously[55]. These strains were cultured on Columbia agar with 50 mL/L horse blood and Dent's selective antibiotic supplement (Oxoid, Basingstoke, UK) at 37 ℃ for 3 d under microaerobic conditions (Campy-Pak Systems; BBL, Cockeysville, MD, USA). The bacterial stocks were stored at -80 ℃ in Brucella broth with 50 mL/L fetal bovine serum (FBS) containing 160 mL/L glycerol. For co-culture experiments, *H pylori* was cultured in Brucella broth containing 7.5% FBS for 24 h, pelleted, resuspended in cell culture medium without FBS, and used to inoculate the host cells at a multiplicity of infection of 50 to 100:1 according to the previous reports[56,57]. At each time point, the AGS cells were collected by scraping, isolated by centrifugation, and stored at -80 ℃ for subsequent isolation of total RNA. Human gastric cancer cells (AGS; ATCC CRL 1739), established from poorly differentiated gastric adenocarcinoma, were maintained in Ham's F12 supplemented with 10% FBS. The medium was replaced with serum-free Ham's F12 at 24 h before the inoculation of the AGS cells with *H pylori*.

Treatment of AGS cells with specific NF-κB and ERK inhibitors

AGS cells were treated with ammonium pyrolidinedithiocarbamate (APDC; 400 μmol/L), which inhibits NF-κB activation, or with the ERK inhibitor PD98059 (25 μmol/L; Calbiochem, San Diego, CA, USA)[58] for 60 min before infection with *H pylori*, as described above. Total RNA was extracted from the AGS cells at 1.5, 3, 6, and 12 h of the co-culture period, as described above.

RNA extraction

Total cellular RNA was extracted using an acid guanidium thiocyanate-phenol-chloroform method, according to the manufacturer's instructions (ISOGEN Reagents; Nippon Gene, Tokyo, Japan), and column chromatography (RNeasy; Qiagen, Tokyo, Japan). The poly(A) mRNA was isolated from the total RNA using the Oligotex-dT30 mRNA purification kit (Takara Shuzo Co., Tokyo, Japan). The integrity of the purified mRNA was confirmed by agarose gel electrophoresis with ethidium bromide staining.

cDNA microarray

A cDNA microarray containing 4 600 cDNAs was made as previously described[44,59-61]. Briefly, human cDNAs were purchased from Research Genetics (Invitrogen Japan K. K., Tokyo, Japan). PCR-amplified cDNA products were mixed with nitrocellulose in dimethyl sulfoxide just before printing and were then spotted onto carbodiimide-coated glass slides using a robotics system (SPBIO-2000, Hitachi Software Engineering, Yokohama, Japan). In this study, we spotted 4 600 sequence-validated cDNAs on the array, including glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and beta-actin to serve as an internal standard and the luciferase gene of *Photinus pyralis* as a negative control.

Sequential changes in gene expression in vitro

For the analysis of the time course of infection-induced gene expression in AGS cells, Cy5-labeled fluorescent cDNAs were prepared from 2 μg mRNA isolated from the infected AGS cells after 1.5, 3, 6, and 12 h of co-culture. The Cy5-labeled sample probes were then applied to the microarray slides for analysis. The Cy3-labeled control probes were similarly prepared from mRNA isolated from uninfected AGS cells. Two independent experiments were performed, and the array data were subject to a simple algorithm (see Data analysis) to set a lower bound threshold and to normalize for unequal incorporation label. Then average ratio was calculated and they were used for the following analysis.

Data analysis

The fluorescence signals from the microarrays were quantified with IMAGENE ver. 4.01 (Biodiscovery, Los Angeles, CA, USA) and analyzed with GENESIGHT LIGHT (Biodiscovery). Briefly, a cDNA spot was included in the analysis only if the raw fluorescence signal intensity was at least 1.5 times that of the local background. The signals were normalized between the arrays using a correction factor calculated from the sum

intensity of all spots. To control the uneven incorporation of the fluorescent dyes, the Cy5 and Cy3 fluorescence intensities for each spot were adjusted so that the mean Cy3:Cy5 ratio was equal to 1.0. We adjusted the raw fluorescence ratios by log transformation, median centering, and normalization to a mean of zero and a variance of one. Changes in expression (Cy3:Cy5 fluorescence ratio) with a factor of 3 or greater in either direction were considered significant, and if the maximum minus minimum values of the log-transformed fluorescence ratios were greater than 1. 0. (Full microarray data are deposited in the Gene Expression Omnibus at NCBI. The platform ID numbers are GPL 1303, and the sample ID numbers are GSM 25915-20). We performed cluster analysis using the average linkage method with uncentered correlation as the distance function by using the Cluster program (ver. 2.11) with TreeView (ver. 1.50) (http://rana.stanford.edu/software)[62]. The Onto-Express program (http://vortex.cs.wayne.edu/Projects.html) was used to perform functional characterization accompanied by the computation of significance values for each functional category, allowing significant biological processes to be distinguished from random events[63-65].

Reverse transcriptase-polymerase chain reaction (RT-PCR)

To validate the results obtained in the microarray experiments, first-strand cDNA was synthesized using 1 μg of total RNA, 1 mmol/L of oligo-dT primer, and reverse transcriptase (Superscript II; Invitrogen, Carlsbad, CA, USA). Each cDNA sample was amplified by PCR using specific primers, as the following, for 10 min at 95 ℃ for initial denaturing, followed by 35-40 cycles of 95 ℃ for 30 s, 52-54 ℃ for 30 s and 72 ℃ for 30 s, yielding products of approximately 300-500 bp. The PCR products were examined, with appropriate molecular size markers, by agarose gel electrophoresis and ethidium bromide staining. The primer pairs used for PCR analysis are listed in Table 1.

RESULTS

Sequential changes in gene expression in AGS cells co-cultured with cagPAI-positive H pylori

We used microarray technology to characterize the time course of changes in gene expression induced by wild-type *H pylori* in AGS cells infected *in vitro* and obtained 3 228 genes that were valid for the analysis. Changes in expression with a factor of 3 or greater in either direction were considered significant. Of the 3 228 genes, about 20% (641 genes) were altered significantly (Figure 1A). The percentage of the significantly altered genes at each time point is shown in Figure 1B. The number of upregulated genes reached their peak at 3 h after infection, while the downregulated genes peaked at 6 h after infection. It implicates that *H pylori*-associated phenomena like inflammatory changes following the induction of IL-8 or *c fos* might occur as the early event *in vitro*. Hierarchical clustering was used to classify the genes into upregulated and downregulated groups (Figure 1C). Each group was further divided into two minor clusters, resulting in a total of four clusters, designated as C-1 to C-4, based on the time course of expression induced by *H pylori*. Genes in both C-1 and C-2 were upregulated during the early phase (1.5-3 h); however, the genes in C-1 were downregulated in the late phase (6-12 h), while those in C-2 remained upregulated. The C-1 cluster contained 764 genes which include *c fos*, DSS1 (DELETED IN SPLIT-HAND/SPLIT-FOOT 1 REGION), NF-κB p65 subunit, Rac1 (Rho family small GTP-binding protein), and MAP2K1 (mitogen-activated protein kinase kinase 1). The C-2 cluster contained 943 genes which include Interleukin-8, NFKBIA (factor of kappa light polypeptide gene enhancer in B-cells inhibitor, alpha), VCL (vincullin), DUSP1 (dual specificity phosphatase 1), and NDRG1 (N-myc downstream regulated gene 1). The sequential changes in the expression of 2 of C-1 genes and 4 of C-2 genes were confirmed by RT-PCR (Figure 1D). In contrast, the expression of the genes in clusters C-3 (950 genes) showed downregulation at early-phase of infection, and C-4 (651 genes) were downregulated at late phase of infection. At late phase of infection, other functional events were modulated by response to these early events. We next performed to characterize the clusters to identify their function.

Gene expression profile and annotated function

The functional profiles of the *H pylori*-induced changes in gene expression *in vitro* are shown in Table 2. The Onto-Express program was used for functional profiling as described in Materials and Methods, using hypergeometric distribution to determine the significance of differences ($n \geqslant 5$, $P<0.05$). This result indicated that the transiently upregulated C-1 cluster included genes that participate in transcription regulator activity, such as Smad4, *c fos*, and RelA, and others involved in chaperon activity, such as DNAJB1 (DnaJ (Hsp40) homolog, subfamily B, member 1) and CD74 antigen (invariant polypeptide of major histocompatibility complex, class II antigen-associated), more frequently than did the other clusters. The C-2 cluster, the members of which were upregulated during both the early and late phases,

contained genes related to signal transduction activity, such as TNF receptor-associated factor 4, and those related to structural molecular activity, such as VCL and ARPS2. The genes in the C-3 and C-4 clusters were downregulated by *H pylori*. The C-3 cluster contained genes related to antioxidant activity, such as TXNRD1 (thioredoxin reductase 1) and GPX (glutathione peroxidase) 1/2, and the C-4 cluster contained genes encoding lyase activity, such as GLO1 and

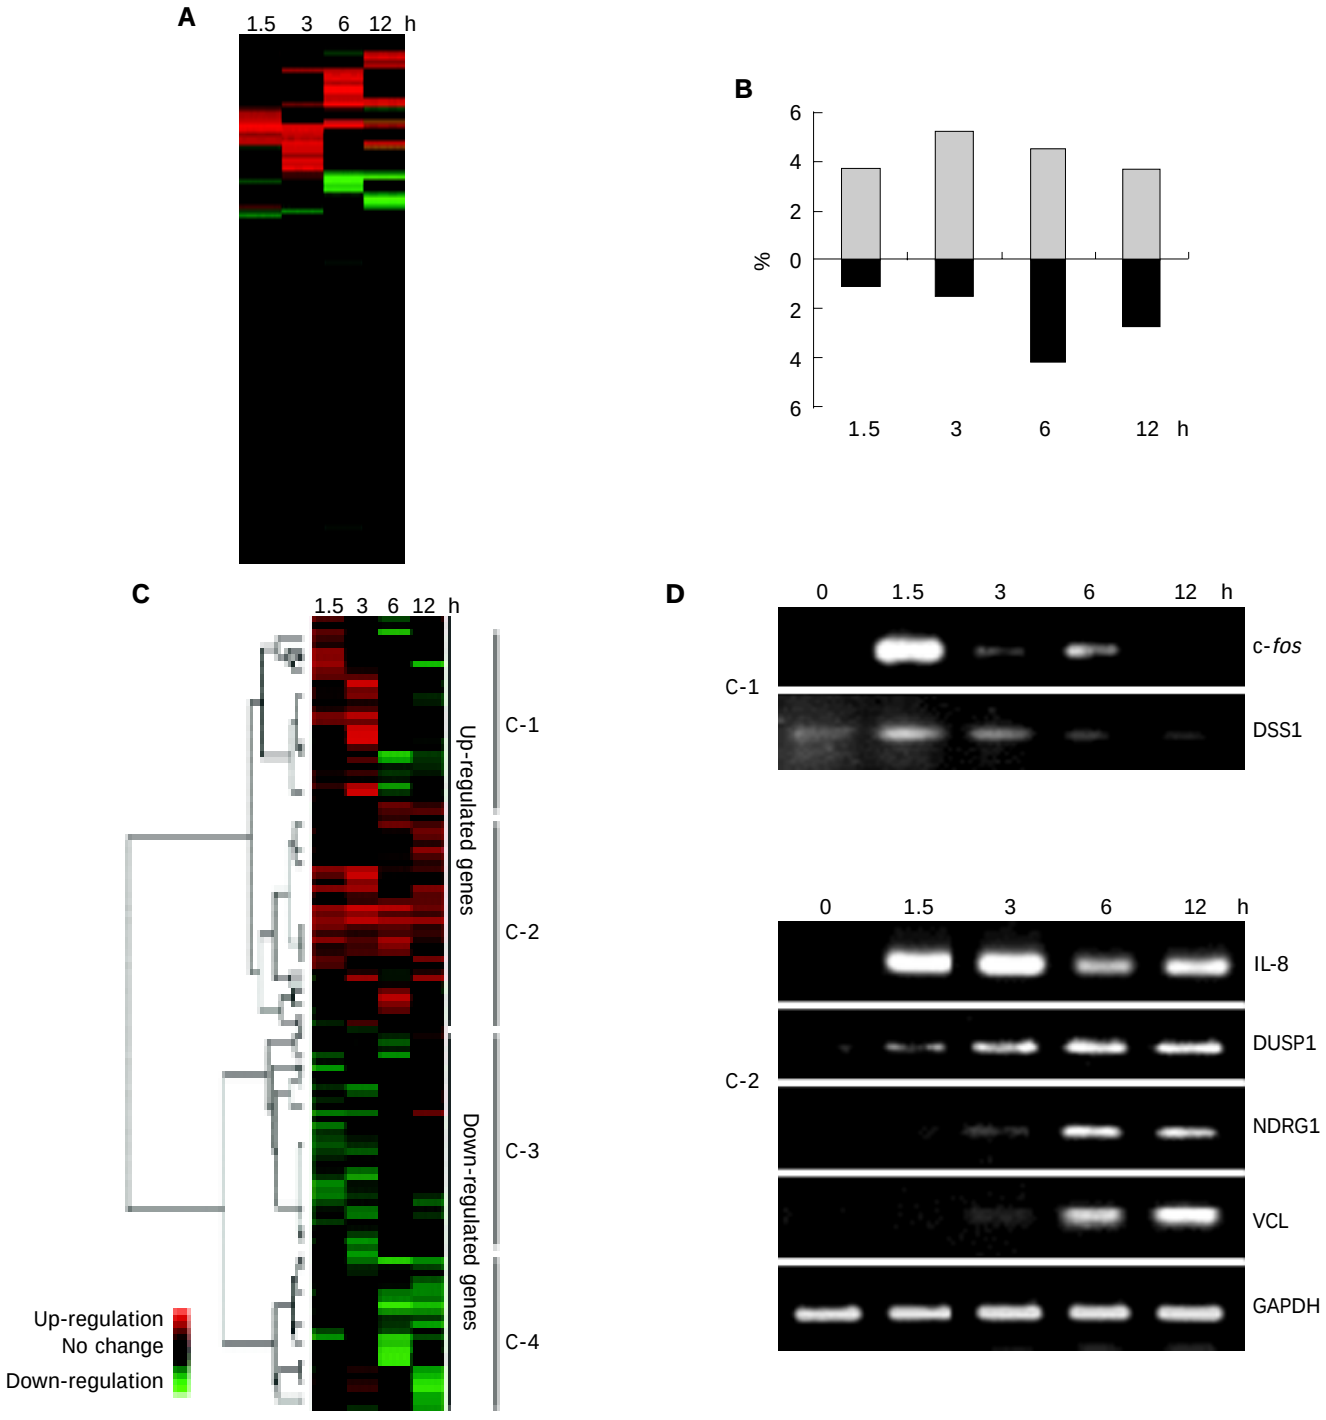

Figure 1 A: Schematic representation of the genes affected by wild-type *H pylori*-infection during 12 h in AGS cells. Red or green indicates up- or downregulation, respectively. About 20% of all the analyzed genes were significantly altered during infection experiments *in vitro*. Changes in expression with a factor of 3 or greater in either direction were considered significant; B: The percentage of the altered genes at each time point. The upregulated genes reached maximum number at 3 h after wild-type *H pylori*-infection, but the downregulated genes peaked at 6 h after infection; C: Cluster diagram of gene expression in AGS cells. The rows correspond to 3 228 genes for which the level of expression in AGS was changed by infection with wild-type *H pylori*, and the columns represent the various time points (1.5, 3, 6, and 12 h after wild-type *H pylori*-infection from left to right, respectively). Red or green indicates up- or downregulation, respectively, compared with the expression level in uninfected AGS cells. The dendrogram on the left and the horizontal distances between the nodes represent the statistical similarities between the neighboring genes and clusters. The genes were divided into two large clusters, comprising upregulated or downregulated genes. Each of the large clusters contained two smaller clusters, resulting in four clusters (C-1 to C-4; see Results for description); D: Validation of the microarray results by RT-PCR. Total RNAs from wild-type *H pylori*-infected AGS cells were isolated at the indicated times and subjected to reverse transcription and PCR with specific primers. The bands of the size corresponding to the expected length of the amplified fragment for each specific transcript were analyzed by agarose gel electrophoresis, along with GAPDH as a loading control.

Table 2 The functional profiles of the *H pylori*-induced changes in gene expression *in vitro*. Cluster represents the assigned cluster numbers in Figure 1C. Functions were defined by using the Onto-Express program, using hypergeometric distribution to determine the significance of differences ($n \geqslant 5$, $P<0.05$, see Materials and methods)

Cluster	Function	No. of the genes (total)	*P*

ENO1, and chaperone proteins. The genes undergoing most striking upregulation during *H pylori* infection *in vitro* are listed in Table 3.

Contribution of cagPAI-coding type IV secretion system in host gene expression

The contribution of *cag*PAI-coding type IV secretion system in host gene expression was examined by comparing the pattern of expression induced by the wild-type *H pylori vs* the isogenic *cag*E mutant strain. We tried to compare the gene expression profile 3 h post-infection when the number of the upregulated genes were most frequent, and when interleukin-8 (IL-8) which is the gene induced by the functional type IV secretion system was upregulated. Five hundred and sixty-six genes on the microarray were upregulated at least threefold by the wild-type *H pylori* infection 3 h post-infection. Four hundred and seventy-six out of five hundred and sixty-six genes (86%) required *cag*PAI-coding type IV secretion system for their upregulation, whereas only 90 out of 566 genes (14%) were upregulated without functional type IV secretion system (Figure 2A). For example, IL-8, RelA, VCL, and Rac1 were upregulated 3- to 15-fold by infection with the wild-type *H pylori*, while the *cagE* mutant induced only one to threefold increases from the control level. On the other hand, some signal transduction-associated genes were significantly upregulated by the *cag*E mutant infection such as STC2, HKR3, and LZTR1. These genes might be induced by the *cag*-independent virulence factor.

Contribution of NF-κB and ERK pathways in H pylori-induced gene expression

It has been reported that wild-type *H pylori* activates NF-κB and ERK pathways; however, the contribution of these signaling pathways on gene expression profiles has not been investigated. Our analysis of the sequential changes in the gene expression profile revealed that signal transducer activity-associated genes show the continuous expression infected with wild-type *H pylori*. We thus analyzed the contribution of NF-κB and ERK signaling on *H pylori*-induced gene expression by using specific inhibitors as previously described[23,36]. As a control sample, we used AGS cells without adding inhibitor reagents because it could avoid the downregulation of the gene expression of nontreated AGS cells by the inhibitors. Among the 566 genes upregulated by wild-type *H pylori*, the expression of 367 genes (65%) was suppressed by pre-incubation with APDC, an inhibitor of NF-κB (Figure 2B).

Table 3 Genes undergoing most striking upregulation during *H pylori*-infection *in vitro*. Values show the mean change in gene expression from two separate microarray experiments *in vitro* (shown at "1.5, 3, 6, and 12 h"). Significantly upregulated values are shown in bold (above threefold)

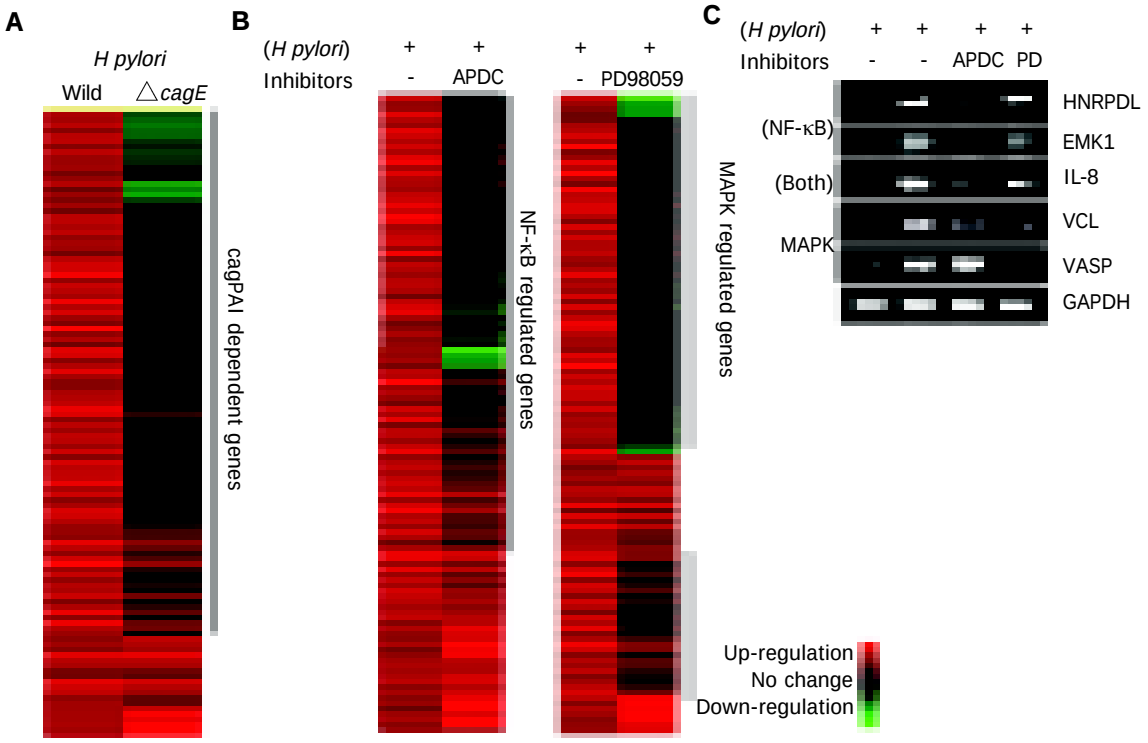

Figure 2 A: The contribution of the *cag*PAI-coded type IV secretion system to the gene expression profile in AGS cells. Hierarchical clustering of genes induced by *H pylori* with or without a functional type IV secretion system (wild type or *cag*E mutant, respectively). Left lane; gene expression profile of AGS cells co-cultured with wild-type *H pylori* relative to control. Right lane; gene expression profile of AGS cells co-cultured with the isogenic mutant *cag*E. Only the 566 significantly upregulated genes at 3 h are shown. About 84% of the genes were induced only by the wild-type *H pylori* infection. These genes were supposed to be induced by the presence of *cag*PAI-coded type IV secretion system. B: The contribution of NF-κB or ERK pathways to the gene expression profile. Inhibitors specific for NF-κB or ERK were added to AGS cells co-cultured with *H pylori*. The gene expression profiles in the presence or absence of the inhibitors were compared. C: The changes in the expression of some representative genes were confirmed by RT-PCR. All genes were induced by wild-type *H pylori* infection, and suppressed by the incubation with inhibitors of specific signal pathways.

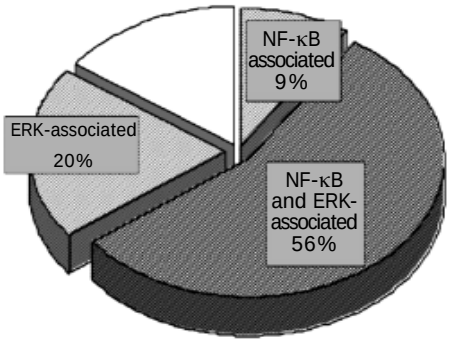

Figure 3 Schematic representation of the distribution of genes affected by wild-type *H pylori* infection. The complete upregulated genes at 3 h after infection is represented by the circle as a whole. The expression of 367 genes (65%) of the 566 genes upregulated by wild type *H pylori* was suppressed by pre-incubation with APDC, an inhibitor of NF-κB. On the other hand, pre-incubation with PD98059, an inhibitor of ERK, suppressed the expression of 429 genes (76%) of the 566 genes upregulated by wild type *H pylori*. Expression of 475 of the 566 genes (84%) was induced under NF-κB and/or ERK signaling activation, whereas changes in the remaining 16% are NF-κB or ERK signaling independent.

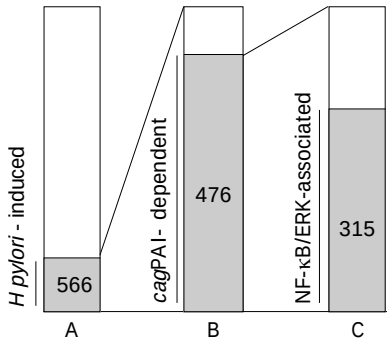

Figure 4 Characterization of the upregulated genes co-cultured with *H pylori* for 3 h (n = 566). A: The bar represents the number of 566 upregulated genes among 3 228 analyzed genes (566 genes). B: The genes induced by *cag*PAI-positive *H pylori* infection among the 566-*H pylori*-induced genes (476 genes). C: The contribution of NF-κB or ERK signaling pathway among the *cag*PAI-dependent gene expression. Among the 476-*cag*PAI-dependent genes, 66% (315 genes) were also involved in the NF-κB- and/or ERK-signaling activation, whereas 34% (161 genes) of 476 genes were dependent on *cag*PAI but not involved in either NF-κB or ERK signaling activation.

The suppressed genes included IL-8, NFKB1A, HNRPDL (heterogeneous nuclear ribonucleoprotein D-like protein) and EMK1 (ELKL motif kinase). On the other hand, pre-incubation with PD98059, an inhibitor of ERK, suppressed the expression of 429 genes (76%). The effects of the inhibitors on several genes were confirmed by RT-PCR (Figure 2C). Among the 566 upregulated genes, 315 genes (56%) were upregulated under NF-κB and ERK signaling activation, and 481 genes (85%) were upregulated under NF-κB and/or ERK signaling activation (Figure 3). HNRPDL was induced at 3.5-fold by wild-type *H pylori* infection, 1.2-fold with APDC, and 2.2-fold with PD98059, and the same

suppression was confirmed by RT-PCR.

It was reported that the activation of NF-κB and ERK by *H pylori* is dependent on the presence of *cag*PAI. Thus, we compared the gene expression profiles under the presence or absence of *cag*PAI-coding type IV secretion system, and we analyzed the contribution of NF-κB or ERK on their gene expression (Figure 4). About 66% (315 genes) of the 476 upregulated genes were induced under NF-κB and/or ERK activation, while 34% (161 genes) of the 476 upregulated genes were dependent on *cag*PAI but not on either NF-κB or ERK.

DISCUSSION

H pylori is now recognized as a definite exogenous carcinogen; hence intensive research effort is currently devoted to investigations of the molecular mechanism of *H pylori*-related gastric pathogenesis. In particular, recent reports have shown the importance of *cag*PAI as a potent bacterial virulence factor and the activation of NF-κB and MAPK signaling as the corresponding host responses[23,36]. However, the relative importance of these factors in gastric pathogenesis among all the events that are raised under *H pylori* infection has not been well established. In the present study, we showed that the genes upregulated by wild-type *H pylori* infection were mostly induced under the presence of *cag*PAI-coding type IV secretion system and that the expression of these genes mostly occurred via NF-κB and/or ERK activation *in vitro*.

Firstly, we analyzed the sequential gene expression changes in cultured cells. The experiments *in vitro* are supposed to simulate the environment in the acute phase of infection and cannot necessarily represent the conditions *in vivo* of chronic infection in which atrophic gastritis and/or gastric cancer actually develops. Therefore we analyzed the sequential changes of gene expression *in vitro* to seek the time-dependent characters of gene function. The genes in the C-1 cluster, which were upregulated during the early phase of infection, included interesting genes which might affect the pathogenesis of *H pylori* infection. *c fos* and DSS1 were included in this cluster. The expression of *c fos* is regulated by ERK (MAPK) signaling and *H pylori* activates the proto-oncogene *c fos* through SRE transactivation[38,66]. DSS1 has not previously been reported to be associated with *H pylori* infection. It has been shown to directly interact with BRCA2 and may play a role in the completion of the cell cycle[67]. The genes in C-2, which were persistently upregulated *in vitro*, contained the genes associated with intracellular signal transduction or cytoskeletal change, including Rho-family GTPases *rac1* and *cdc42*. The activation of them are known to be dependent on *cag*PAI[68]; Rac1 in turn regulates the vacuolation caused by the *vacA* virulence factor of *H pylori*[69]. NDRG1 was upregulated during the late phase of infection as shown in Figure 1D; the protein encoded by this gene is a cytoplasmic protein involved in stress responses, hormone responses, cell growth, and differentiation[70].

We show here that the upregulation of a large part of the genes depends on the presence of functional type IV secretion system. *Cag*PAI codes a type IV secretion system which transports CagA inside the host cells[11-15]; the transported CagA activates SRE[37]. Guilemin *et al*., reported that *cag*A gene, which encodes an effector molecule secreted by the type IV secretion system, induced the expression of many of the cytoskeletal genes. Recently, it has been reported that one of the effectors for NF-κB activation is peptidoglycan[16], and CagA is probably not involved[37,71,72]. In addition, *cag*E, which codes a structural component of the type IV secretion system, is required for the expression of many immune responsive genes. These results suggest that several distinct molecules are involved in *cag*PAI-dependent upregulation. Moreover, the interaction of some molecules of the secretion system with the molecules of the host cell might directly activate some intracellular signaling cascades.

The microarray analysis is useful to identify the downstream genes in the specific intracellular signaling pathway because it could detect a large number of the gene expression at a time. Then we analyzed the alteration of the gene expression by the inhibitor reagents against the signaling molecules to identify the genes which are induced through NF-κB or ERK signaling pathway. In this study, we have shown that the majority of the *H pylori*-induced gene were upregulated under NF-κB and/or ERK activation[23,36] NF-κB activation *in vivo* is associated with gastric inflammation via the production of cytokines, IL-8[24] and is associated with cell survival induced by c-IAP-2 mediated anti-apoptosis[35]. Among the genes affected by NF-κB activation, HNRPDL and EMK1 were identified in the current microarray analysis and were confirmed by RT-PCR to be suppressed by NF-κB inhibition. HNRPDL is reported to be a member of the family of heterogeneous nuclear ribonucleoproteins (hnRNPs) that function in mRNA biogenesis and mRNA metabolism[73]. EMK (ELKL motif kinase) belongs to a small family of serine/threonine protein kinases involved in the control of cell polarity, microtubule stability, and cancer[74].

ERK signaling is activated by *H pylori* infection and leads to the expression of some oncogenes, such as *c fos* and cyclin-D1[75,76]. The upregulated genes under ERK-signaling activation included VCL and VASP, which are involved in integrin-mediated cell adhesion. Jawhari *et al*., reported that E-cadherin contributes to the development and progression of the neoplastic phenotype in gastric carcinoma[77]. Kuroda *et al*., reported that the activation of Rho-Ras signaling induces the dissociation of cell-cell adhesion and it is associated with the cell migration and metastasis of carcinoma cells[78]. Recently, Cottet *et al*., identified that *H pylori*-induced Rho-Ras signaling proteins[79].

In conclusion, we characterized the gene expression induced by *H pylori* using cDNA microarray, and we determined the contribution of *cag*PAI-coding type IV secretion system and NF-κB/ERK signaling pathways on the most part of the gene expression induced by *H pylori*. In the future, we should elucidate how the NF-κB and/or ERK contribute to the development of gastric inflammation *in vivo* and characterize the gastric mucosal gene expression in human beings which may help us to understand the gastric pathogenesis induced by *H pylori* infection.

Abstract

AIM: To examine the ability of ET-1 to affect the cell functions of PSCs and the underlying molecular mechanisms.

METHODS: PSCs were isolated from the pancreas of male Wistar rats after perfusion with collagenase, and cells between passages two and five were used. Expression of ET-1 and ET receptors was assessed by reverse transcription-PCR and immunostaining. Phosphorylation of myosin regulatory light chain (MLC), extracellular-signal regulated kinase (ERK), and Akt was examined by Western blotting. Contraction of PSCs was assessed on hydrated collagen lattices. Cell migration was examined using modified Boyden chambers. Cell proliferation was assessed by measuring the incorporation of 5-bromo-2'-deoxyuridine.

RESULTS: Culture-activated PSCs expressed ET_A and ET_B receptors, and ET-1. ET-1 induced phosphorylation of MLC and ERK, but not Akt. ET-1 induced contraction and migration, but did not alter proliferation of PSCs. ET-1-induced contraction was inhibited by an ET_A receptor antagonist BQ-123 and an ET_B receptor antagonist BQ-788, whereas migration was inhibited by BQ-788 but not by BQ-123. A Rho kinase inhibitor Y-27632 abolished both contraction and migration.

CONCLUSION: ET-1 induced contraction and migration of PSCs through ET receptors and activation of Rho-Rho kinase. ET_A and ET_B receptors play different roles in the regulation of these cellular functions in response to ET-1.

INTRODUCTION

In 1998, star-shaped cells in the pancreas, namely pancreatic stellate cells (PSCs), were identified and characterized[1,2]. In normal pancreas, stellate cells are quiescent and can be identified by the presence of vitamin A-containing lipid droplets in the cytoplasm. In response to pancreatic injury or inflammation, they are transformed ("activated") from their quiescent phenotype into myofibroblast-like cells, which actively proliferate, express the cytoskeletal protein α-smooth muscle actin, and produce extracellular matrix components. Many of the morphological and metabolic changes associated with the activation of PSCs in animal models of fibrosis also occur when these cells are grown in serum-containing medium in culture on plastic. There is accumulating evidence that activated PSCs play a pivotal role in the development of pancreatic fibrosis[1-4]. In addition, PSCs may participate in the pathogenesis of acute pancreatitis[3,5]. The activation of signal transduction pathways such as p38 mitogen-activated protein (MAP) kinase[6], Rho-Rho kinase[7], and c-Jun N-terminal kinase[8] is likely to play a role in PSC activation. But intracellular signal transduction pathways in PSCs remain largely unknown.

Endothelin-1 (ET-1), which acts through G-protein coupled ET_A and ET_B receptors, was initially described as a potent endothelial cell-derived vasoconstrictor isolated from the culture medium of porcine aortic endothelial cells[9]. Subsequent studies have shown that ET-1 is produced by a variety of cells and exhibits several biological activities such as vasoconstriction, regulation of peptide secretion, migration, and positive or negative effects on cell growth[10,11]. ET-1 has been implicated in the pathogenesis of cardiovascular, pulmonary, renal, and developmental disorders[11]. In addition, ET-1 plays a key role in the development of portal hypertension and hepatic fibrosis through its effects on hepatic stellate cells[12,13]. ET-1 has been shown to stimulate contraction via ET_A receptor[14], and inhibit proliferation via ET_B receptor[15] in hepatic stellate cells. But, the roles of ET-1 and ET receptors in the regulation of cell functions of PSCs remain largely unknown. In this study, we examined

the ability of ET-1 to affect the cell functions of PSCs and the underlying molecular mechanisms. We here report that ET-1 stimulated contraction and migration, but not proliferation, of PSCs through ET receptors and Rho-Rho kinase pathway.

MATERIALS AND METHODS

Materials

ET-1 was purchased from Peptide Institute (Osaka, Japan). Collagenase P was obtained from Roche Diagnostics (Mannheim, Germany). Rat recombinant platelet-derived growth factor (PDGF)-BB was purchased from R&D Systems (Minneapolis, MN). Rhodamine-labeled phalloidin was purchased from Molecular Probes (Eugene, OR). BQ-123, BQ-788, and U0126 were purchased from Calbiochem (La Jolla, CA). Y-27632 was a generous gift from Mitsubishi Pharma Co. (Osaka, Japan). Rabbit antibodies against extracellular-signal regulated kinase (ERK; phosphorylated and total), Akt (phosphorylated at Ser^{473} and total), and myosin regulatory light chain II (MLC; phosphorylated at Ser^{19} and total) were purchased from Cell Technologies, Inc. (Beverly, MA). Rabbit antibody against glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was obtained from Trevigen (Gaithersburg, MD). All other reagents were purchased from Sigma-Aldrich (St. Louis, MO) unless specifically described.

Cell culture

All animal procedures were performed in accordance with the National Institutes of Health Animal Care and Use Guidelines. Rat PSCs were prepared from the pancreas tissues of male Wistar rats (Japan SLC Inc., Hamamatsu, Japan) weighing 200-250 g using the Nycodenz solution (Nycomed Pharma, Oslo, Norway) after perfusion with 0.3 g/L collagenase P as previously described[16]. The cells were resuspended in Ham's F-12 medium containing 100 mL/L heat-inactivated fetal bovine serum (MP Biomedicals, Irvine, CA), penicillin sodium, and streptomycin sulfate. Cell purity was always more than 90% as assessed by a typical star-like configuration and by detecting vitamin A autofluorescence. All experiments were performed using cells between passages two and five. We incubated PSCs in serum-free medium for 24 h before the addition of experimental reagents. For some experiments, BQ-123, BQ-788, U0126, or Y-27632 were added 30 min prior to the ET-1 treatment.

Reverse transcription-PCR

Total RNA was isolated using RNeasy total RNA preparation kit (Qiagen, Chatsworth, CA). Total RNA was reverse-transcribed, and the resultant cDNA was subjected to PCR as previously reported[17]. Specific primer sets were as follows (listed 5'-3'; forward and reverse, respectively). ET-1 precursor (preproET-1): TTGCTCCTGCTCCTC-CTTGAG and GGTCTTGATGCTGTTGCTGATG; ET_A: CGTCTTCTGCTTGGTTGTCA and TGGTTCT-GCTCCTGGTTCTT; ET_B CAAGACAGTATTCTGC CTGG and CAAGCAGGATTGCTTCTCCT. They were amplified using 30 cycles at 94 ℃ (for 1 min), at 50 ℃ (for 1 min), and at 72 ℃ (for 1 min). The products of PCR were separated by 15 g/L agarose gel electrophoresis and visualized under ultraviolet light after staining with ethidium bromide. The expected sizes of the PCR products were 382 bp for preproET-1, 321 bp for ET_A receptor, and 297 bp for ET_B receptor.

Immunostaining

PSCs were grown directly on slides, serum-starved for 24 h, and immunostaining for ET-1 was performed using a streptavidin-biotin peroxidase complex detection kit (Histofine Kit; Nichirei, Tokyo, Japan) as previously described[18]. Briefly, cells were fixed with 1 000 mL/L methanol at -20 ℃, and then endogenous peroxidase activity was blocked by incubation with hydrogen peroxide in methanol. After immersion in normal rabbit serum, the slides were incubated with mouse anti-ET-1 antibody (at 1:200 dilution) at 4 ℃ overnight. The slides were incubated with biotinylated anti-mouse immunoglobulin antibody, followed by peroxidase-conjugated streptavidin. Finally, color was developed by incubating the slides for several minutes with diaminobenzidine (Dojindo, Kumamoto, Japan). The expression of ET_A and ET_B was examined in a similar manner.

Western blotting

The level of activated, phosphorylated ERK was determined by Western blotting as previously described[19]. Cells were lysed in sodium dodecyl sulfate buffer. Cellular proteins (approximately 100 μg) were fractionated on a 100 g/L sodium dodecyl sulfate-polyacrylamide gel. They were transferred to a nitrocellulose membrane (Bio-Rad, Hercules, CA), and the membrane was incubated overnight at 4 ℃ with rabbit anti-phosphospecific ERK antibody. After incubation with peroxidase-conjugated goat anti-rabbit immunoglobulin G antibody for 1 h, proteins were visualized using an ECL kit (Amersham Biosciences, UK). The levels of total ERK, Akt (phosphorylated and total), and MLC (phosphorylated and total) were determined in a similar manner.

Fluorescence microscopy

Stress fibers were stained with rhodamine-labeled phalloidin as previously described[20]. After fixation with 40 g/L paraformaldehyde for 5 min, PSCs were permeablized with 1.5 mL/L Triton X-100 in PBS for 5 min. Cells were then incubated for 2 h at room temperature in a dark place with rhodamine-labeled phalloidin in blocking buffer (10 g/L bovine serum albumin in PBS). Cells were then washed thrice with PBS for 10 min each, and coverslipped with Fluoromount (Vector Laboratories, Burlingame, CA). Cells were observed with a Leica fluorescence microscope. Images were captured with a Leica QFISH system (Wetzlar, Germany).

Collagen gel contraction assay

Contraction of PSCs on collagen lattices was examined in six-well flat-bottom tissue culture plates (Becton Dickinson, Bedford, MA) as previously described[21]. Culture vessels were preincubated with PBS containing 10 g/L bovine serum albumin for 2 h at 37 ℃, washed, and air-dried. The gel mixture consisted of eight parts Vitrogen-100 (Collagen Corp., Palo Alto, CA), one part 10×minimal essential medium,

and one part 0.2 mol/L HEPES, pH 9.0, which resulted in a final collagen concentration of 2.4 g/L. It was prepared at 4 ℃, added to the culture vessel, and incubated at 37 ℃ for 2 h to allow gelation. PSCs were trypsinized, resuspended in serum-free medium (at 1×10^9 cells/L), plated on top of the gels (1 mL/well), and allowed to attach for 2 h. The collagen lattices were detached from the plate by gentle circumferential dislodgement using a fine needle, and ET-1 (at 100 nmol/L) was added to elicit contraction. After 24-h incubation, we measured the diameter of the collagen lattices, and calculated the "% of the original diameter (= 35 mm)". In addition, cell-free collagen lattices were incubated with 100 nmol/L ET-1 or serum-free medium alone.

Cell migration assay

Cell migration was assessed as previously described[16]. Serum-starved PSCs were trypsinized, and resuspended at the concentration of 3×10^8 cells/L in serum-free medium containing 10 g/L bovine serum albumin. For the assay, we used modified Boyden chambers with 8-μm pore filters (Iwaki Glass Co. Ltd., Funabashi, Japan) coated with rat-tail type I collagen. ET-1 was added to the lower chamber, and 250 μL of cell suspension was added to the upper chamber. The chambers were then incubated at 37 ℃ for 24 h. At the end of the incubation, the cell suspension in the upper chamber was aspirated, and the upper part of the filter was cleaned with cotton plugs. The cells migrated to the underside of the filter were stained with Difquick (Sysmex, Kobe, Japan), viewed, and counted at 200× magnification.

Cell proliferation assay

Serum-starved PSCs (approximately 80% density) were treated with ET-1 in the presence or absence of 100 mL/L fetal bovine serum or PDGF-BB (at 25 μg/L). Cell proliferation was assessed using a commercial kit (Cell proliferation ELISA, BrdU; Roche Diagnostics) according to the manufacturer's instruction. This is a colorimetric immunoassay based on the measurement of 5-bromo-2'-deoxyuridine (BrdU) incorporation during DNA synthesis. After 24-h incubation with experimental reagents, cells were labeled with BrdU for 3 h at 37 ℃. Cells were fixed, and incubated with peroxidase-conjugated anti-BrdU antibody. Then the peroxidase substrate 3,3',5,5'-tetramethylbenzidine was added, and BrdU incorporation was quantitated by $A_{370\text{-}492}$.

Statistical analysis

The results were expressed as mean±SD. Luminograms and autoradiograms are representative of at least three experiments. Differences between the groups were evaluated by ANOVA, followed by Fisher's test for post hoc analysis. A P value less than 0.05 was considered statistically significant.

RESULTS

Activated PSCs expressed ET-1 and ET receptors

We first examined whether culture-activated PSCs expressed ET-1 and ET receptors. ET-1 is a product of the gene coding for a large precursor protein (i.e. preproET-1)[9]. Culture-activated PSCs expressed ET_A and ET_B receptors, and ET-1, as assessed by reverse transcription-PCR and immunostaining (Figure 1).

ET-1 induced phosphorylation of ERK and MLC, but not Akt

In an attempt to elucidate the effect of ET-1 on cell functions of PSCs, we examined whether ET-1 activated intracellular signaling pathways. We examined the activation of ERK, Akt, and MLC, all of which are implicated in ET-1-induced cellular contraction and/or migration[22-24]. PSCs were treated with ET-1 at 100 nmol/L, and the activation of the signaling pathways by Western blotting using anti-phosphospecific antibodies. We chose this ET-1 concentration because previous studies have shown that ET-1 acts on ET receptors in a dose-dependent manner and ET-1 at this concentration effectively elicited effects in a variety of cell types[14,15,25,26]. PDGF-BB induced phosphorylation of ERK, Akt, and MLC whereas ET-1 induced phosphorylation of ERK and MLC but not Akt (Figure 2).

Y-27632 decreased stress fiber formation and MLC phosphorylation

It has been shown that RhoA, acting through its downstream effector Rho kinase, stimulates MLC phosphorylation, stress fiber formation, and contractile force generation[27,28]. The fact that ET-1 induced phosphorylation of MLC prompted us to examine the effect of Y-27632, a specific Rho kinase inhibitor[29], on the phosphorylation of MLC and stress fiber formation. Y-27632 decreased phosphorylation of MLC in a dose-dependent manner (Figure 3A). When cells were treated with Y-27632 at 25 μmol/L for 24 h, disassembly of stress fibers was observed (Figures 3B and 3C). In these experiments, Y-27632 up to 25 μmol/L did not affect the cell viability during the incubation as assessed by trypan blue exclusion test (data not shown). In addition, the effects of Y-27632 were reversible within 48 h after the removal of Y-27632 (Figures 3A and 3D). However, when PSCs were treated with Y-27632 at 50 μmol/L, cytotoxic effects were observed during the incubation (data not shown).

ET-1 induced contraction of PSCs

We examined whether ET-1 induced contraction of PSCs using collagen lattices. With no stellate cells, the size of the collagen lattices did not change in response to ET-1 (data not shown). When PSCs were plated on the lattices, and incubated with serum-free medium alone for 24 h, there was a slight reduction in the diameter of the lattices to 89±3% of their original size (Figure 4A). By incubation with 100 nmol/L ET-1, the diameter of the lattices decreased to 54±8% (Figure 4B). ET-1-induced contraction of PSCs was inhibited by an ET_A receptor antagonist BQ-123[30], an ET_B receptor antagonist BQ-788[31]. Y-27632 abolished ET-1-induced contraction, whereas a MAP kinase inhibitor U0126[32] was ineffective.

ET-1 induced migration, but did not alter proliferation of PSCs

ET-1 induced migration of PSCs, which was inhibited by BQ-788, Y-27632, and U0126, but not BQ-123 (Figure 5).

Previous studies have shown that ET-1 showed positive or negative effects on cell growth[15,25,26]. In agreement with the previous study[16], PDGF-BB and 100 mL/L fetal bovine serum increased proliferation of PSCs (Figure 6). ET-1 did not affect basal proliferation or proliferation in response to PDGF or serum.

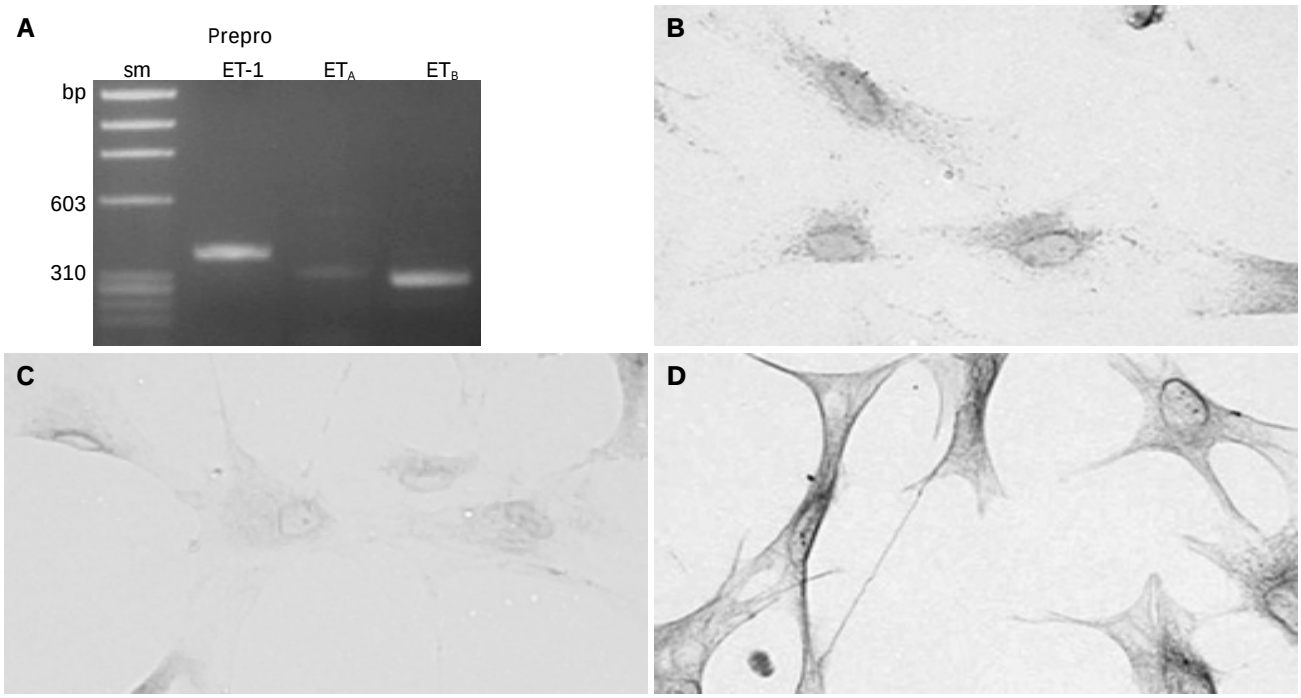

Figure 1 Culture-activated PSCs expressed ET and ET receptors. A: Total RNA was prepared from culture-activated, serum-starved PSCs. The expression of preproET-1, ET_A receptor and ET_B receptor was examined by reverse transcription-PCR. The expected sizes of the PCR products were 382 bp for preproET-1, 321 bp for ET_A receptor, and 297 bp for ET_B receptor. sm: size marker (ϕX174 *Hae*III digest). bp: bp; B-D: Serum-starved PSCs were grown directly on slides. Immunostaining for ET-1 (panel B), ET_A receptor (panel C), and ET_B receptor (panel D) was performed using a streptavidin-biotin peroxidase complex detection kit. Original magnification: ×20 objective.

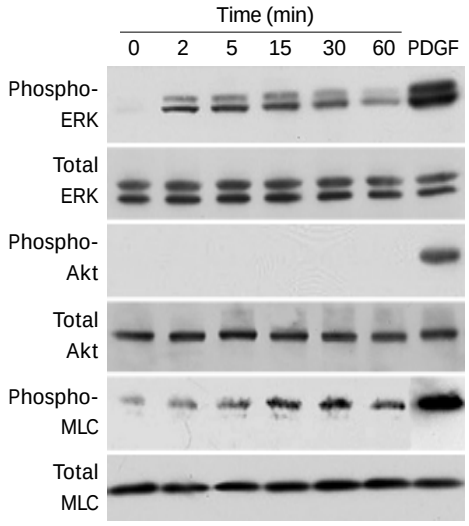

Figure 2 ET-1 induced phosphorylation of ERK and MLC, but not Akt. PSCs were treated with ET-1 (at 100 nmol/L) for the indicated time. Total cell lysates (approximately 100 μg) were prepared, and the levels of phosphorylated ERK, Akt, and MLC were determined by Western blotting. As positive controls, total cell lysates were prepared from PSCs treated with PDGF-BB (at 25 μg/L) for 5 min, and Western blotting was performed in a similar manner. Levels of total ERK, Akt, and MLC were also determined.

DISCUSSION

There is accumulating evidence that activated PSCs play a pivotal role in the pathogenesis of pancreatic fibrosis and inflammation[1-5]. We here showed that culture-activated PSCs expressed ET_A and ET_B receptors, and ET-1. ET-1 stimulated contraction and migration of PSCs, suggesting autocrine and paracrine mechanisms of ET-1-regulated cellular functions of PSCs. ET-1-induced contraction was inhibited by ET_A and ET_B receptor antagonists whereas ET-1-induced migration was inhibited by ET_B receptor antagonist but not by ET_A receptor antagonist. Thus, ET_A and ET_B receptors play different roles in the regulation of these cellular functions in response to ET-1.

Cellular migration and contraction are complex processes involving dynamic changes in the actin-myosin cytoskeleton, including generation of contractile forces[33]. It has been shown that contractile force is powered by myosin, which is activated by phosphorylation of MLC[33]. Phosphorylation of MLC is regulated by the balance of two enzymatic activities, i.e., MLC kinase(s) and myosin phosphatase. For example, MLC is phosphorylated by MLC kinase in a Ca^{2+}/calmodulin-dependent manner in smooth muscle cells[34]. RhoA, acting through its downstream effector Rho kinase, stimulates MLC phosphorylation and consequently contractile force generation through the inhibition of myosin phosphatase[27,28]. Activated Rho kinase promotes the contraction of isolated stress fibers and generates a long-lasting tensile activity by the maintained inhibition of myosin phosphatase[35]. On the other hand, contractile force generation by certain non-muscle cell types including fibroblasts may occur independently of myosin phosphorylation[36,37]. To clarify the role of myosin in ET-1-induced contraction and migration of PSCs, we examined the effect of ET-1 on the phosphorylation of MLC. We here showed that ET-1 induced the phosphorylation of MLC, supporting a role of myosin in contractile force generation in PSCs. In addition, an inhibitor of Rho kinase

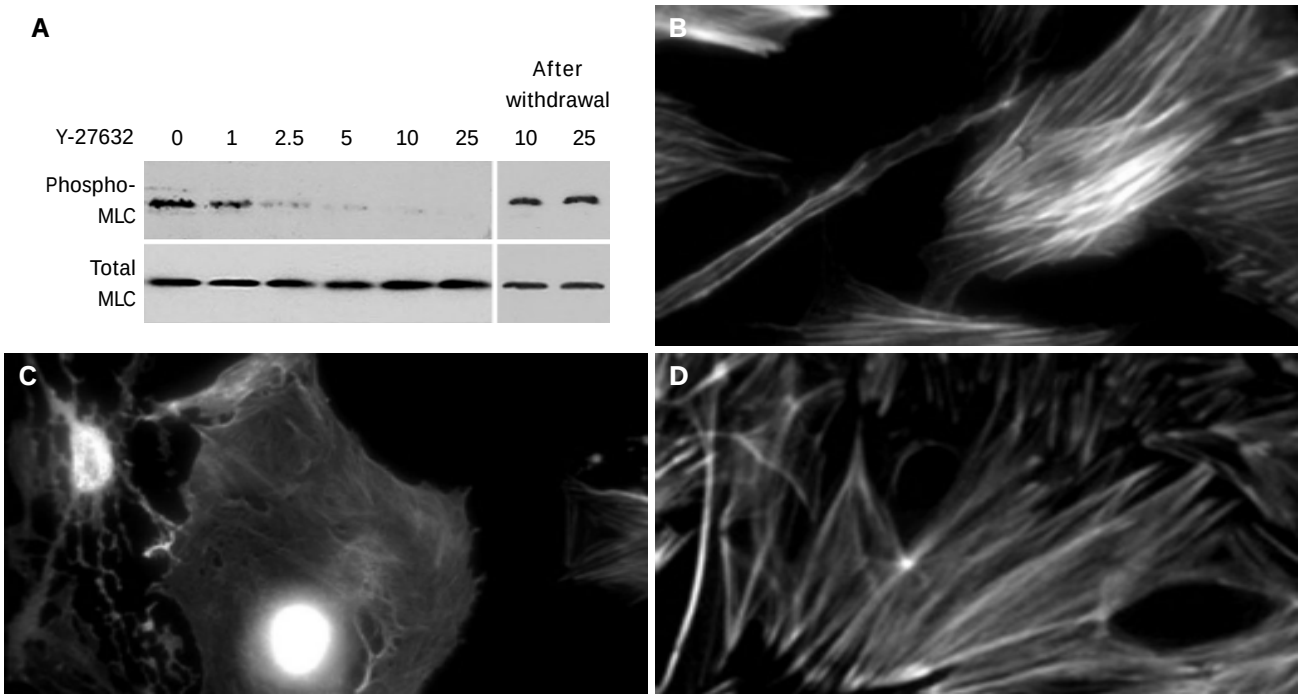

Figure 3 Y-27632 decreased stress fiber formation. A: PSCs were treated with ET-1 (at 100 nmol/L) in the presence of Y-27632 at the indicated concentrations (at μmol/L) for 30 min. Total cell lysates (approximately 100 μg) were prepared, and the levels of phosphorylated and total MLC were determined by Western blotting. In parallel experiments, Y-27632 was withdrawn after 30-min incubation, and replaced with 10% FBS. After 48-h incubation with 10% FBS, total cell lysates were prepared, and the levels of phosphorylated and total MLC were determined by Western blotting; B-D: PSCs were incubated with ET-1 (at 100 nmol/L) in the absence (B) or presence (C) of Y-27632 (at 25 μmol/L) for 24 h, and stained with rhodamine-labeled phalloidin. In parallel experiments, Y-27632 was withdrawn and replaced with 10% FBS. After 48-h incubation with 10% FBS, PSCs were stained with rhodamine-labeled phalloidin (D). Original magnification: ×60 objective.

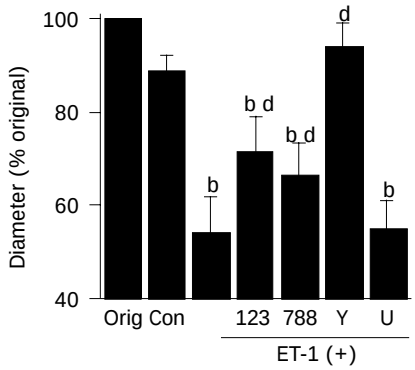

Figure 4 ET-1 induced contraction of PSCs. PSCs were plated on the surface of collagen lattices prepared in each well of a six-well plate and incubated for 2 h to allow adherence. The collagen lattices were then detached from the plate by gentle circumferential dislodgment. Serum-starved PSCs were left untreated ("Con") or were treated with ET-1 (at 100 nmol/L) in the absence or presence of BQ-123 ("123" at 10 μmol/L), BQ-788 ("788" at 10 μmol/L), Y-27632 ("Y" at 25 μmol/L), or U0126 ("U" at 5 μmol/L). Lattices were then detached from the plate, and incubated in serum-free medium (control, "Con") with or without 100 nmol/L ET-1. After 24-h incubation, we measured the diameter of the collagen lattices, and calculated the "% of the original diameter ("Orig" = 35 mm)". Data are shown as mean±SD (% of the original diameter, n = 8). ^{b}P<0.01 *vs* control (serum-free medium only), ^{d}P<0.01 *vs* ET-1 treatment only.

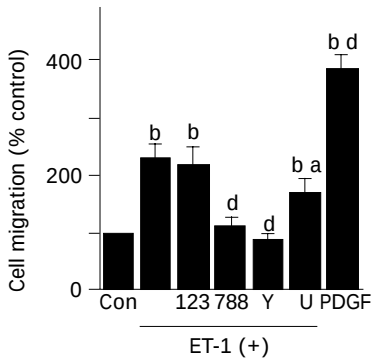

Figure 5 ET-1 induced migration of PSCs. Cell migration was assessed using modified Boyden chambers with 8-μm pore filters. Serum-starved PSCs were left untreated ("Con") or were treated with ET-1 (at 100 nmol/L) in the lower chamber in the absence or presence of BQ-123 ("123" at 10 μmol/L), BQ-788 ("788" at 10 μmol/L), Y-27632 ("Y" at 25 μmol/L), or U0126 ("U" at 5 μmol/L). After 24-h incubation, the cells migrated to the underside of the filter were stained, and counted under a light microscopy. As positive controls, cells were treated with PDGF-BB (at 25 μg/L) in the lower chamber, and cell migration was assessed in a similar manner. Data are shown as mean±SD (% of the control, n = 6). ^{b}P<0.01 *vs* control (serum-free medium only), ^{a}P<0.05, ^{d}P<0.01 *vs* ET-1 treatment only.

Y-27632 abolished the phosphorylation of MLC, stress fiber formation, contraction, and migration. These results agree with the idea that force generation by the myofibroblasts depends on the isometric contraction of stress fibers containing α-smooth muscle actin, and is mediated through Rho-Rho kinase[38]. Indeed, myosin mediates contractile force generation by hepatic stellate cells in response to ET-1[24]. We have previously shown that PDGF-BB induced migration of PSCs through the activation of phosphatidylinositol 3-kinase/Akt pathway[16]. Unlike PDGF-BB, ET-1 did not activate Akt but did induce migration of PSCs, excluding a role of phosphatidylinositol 3-kinase/Akt pathway in ET-

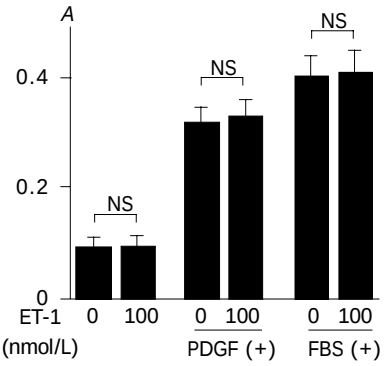

Figure 6 ET-1 did not alter basal or inducible proliferation of PSCs. Serum-starved PSCs were treated with ET-1 at 0 or 100 nmol/L in the absence or presence of PDGF-BB (at 25 μg/L) or 100 mL/L fetal bovine serum ("FBS"). After 24-h incubation, DNA synthesis was assessed by BrdU incorporation enzyme-linked immunosorbent assay. Data are shown as mean±SD (n = 6). NS: not significant, *A*: optical density.

1-mediated migration.

In this study, ET-1 induced contraction of PSCs through both ET_A and ET_B receptors as assessed by the contraction of collagen lattices. This is in agreement with the previous study showing that both ET_A and ET_B receptors play an important role in contraction of colonic myofibroblast cells[26], but disagrees with hepatic stellate cells where ET-1 induced contraction is through ET_A receptor[14]. Investigation of cellular contraction using collagen lattices (gels) was introduced by Bell *et al*.[39], and has been validated as a model of study of cellular contraction in a variety of cell types. Fibroblasts seeded on top of type I collagen gels bind and organize underlying collagen fibrils, both in close proximity and at a distance from cells[40]. After such reorganization, lattices are converted into a dense mass with the morphological appearance of dermal scar. Kawada *et al*.[41], reported a morphological study of ET-1-induced contraction of hepatic stellate cells on hydrated collagen gels. They demonstrated that contracted form of the stellate cells was morphologically characterized by the retraction of dendritic processes and the bending of the extended cell bodies that enfold the underlying collagen matrix. Because the cell body and processes are both closely attached to the collagen fibers, their contraction generates effective forces for the contraction of collagen gels.

ET-1 did not alter the proliferation of PSCs. The effect of ET-1 on growth and the underlying mechanisms depend on cell type. For example, ET-1 promotes the proliferation of human pulmonary artery smooth muscle cells through ET_A and ET_B receptors[25]. ET-1 did not affect the proliferation of human colonic myofibroblast cells[26]. In human hepatic stellate cells, ET-1 has been shown to inhibit the serum-induced proliferation through ET_B receptor, whereas ET-1 did not induce proliferation by itself[15]. Of note, Pinzani *et al*.[14], reported that ET-1 induced proliferation of early-passaged human hepatic stellate cells (passages 1 and 2), but the effect was less evident at a later stage of culture. This phenomenon is attributable at least in part to the progressive shift from a relative predominance of ET_A receptor to ET_B receptor during culture[14]. Because the effects of ET-1 on cell growth might be mediated by distinct ET receptors, the ratio between ET_A and ET_B receptors in the cells might constitute an additional factor that could affect the sensitivity of cells to the growth regulatory effects of ET-1. We and others have shown that ERK is a key mediator of PDGF-BB-induced mitogenic signals in PSCs[16,42]. In spite of the ability to activate ERK, ET-1 failed to alter the proliferation, suggesting that activation of ERK is required but not sufficient for the proliferation of PSCs. This is also in the case of stimulation by ethanol, acetaldehyde, and 4-hydroxy-2,3-nonenal in PSCs[43], and in agreement with the concept that activation of ERK, although necessary, may not be sufficient to justify the mitogenic properties of an agonist[44].

Klonowski-Stumpe *et al*.[45], reported that activated PSCs expressed ET_A receptor and ET-1, and that ET-1 increased cytosolic Ca^{2+} concentration[45]. Exogenous ET-1 did not induce contraction, and, even in the absence of exogenous addition of ET-1, PSCs reduced the area of hydrated collagen lattices to 75% of the original value within 6 h, which was significantly attenuated by BQ-123, but not by another ET_B receptor antagonist IRL-1 038. The reason for discrepancy of the results between our study and theirs remain unknown, but the different experimental systems (e.g., different cell passages, different ET-1 concentrations, different ET_B receptor antagonist, and different serum-starvation condition) employed may be one explanation. As the ET_A receptor antagonist inhibited basal contraction of PSCs in their study, the endogenous ET-1 from PSCs or ET-1 that remained in the culture supernatant appeared to be responsible for the basal contraction of PSCs. In addition to ET_A receptor, we here have shown for the first time that activated PSCs express ET_B receptor, and that exogenously added ET-1 induces migration of PSCs.

It has been accepted that hepatic stellate cell contraction in response to ET-1 plays an important role in the regulation of sinusoidal blood flow, and in the development of portal hypertension and hepatic fibrosis[12,13]. ET-1 is markedly overexpressed in different cellular elements in cirrhotic liver tissue, particularly in sinusoidal endothelial cells and activated hepatic stellate cells located in the sinusoids of the regenerating nodules at the edge of fibrous septa[16]. On the other hand, the pathophysiological implication of ET-1-induced contraction of PSCs remains obscure. Although PSCs are located predominantly in the periacinar regions in normal pancreas[1,2], perivascular and periductal localization has been also reported[46]. Ikejiri[46] showed that vitamin A-storing cells (now recognized as PSCs) were perivascularly localized in the pancreas of rats fed with vitamin A. Perivascular PSCs might participate in the regulation of blood flow and the development of microvascular ischemia during pancreatitis through ET-1 production[47]. Izumi *et al*.[48], reported that PSCs were found in the pancreatic duct wall of normal pancreas, and that the amount of such cells was excessively increased in patients with focal pancreatitis. They assumed that circular contraction of the ductal wall by proliferating PSCs might induce the stenosis of the main pancreatic duct and block the efflux of pancreatic juice from branch pancreatic ducts at the stenotic portion, leading to localized acinar atrophy and fibrosis[48]. In addition, PSCs might participate in control of the intraductal pressure, epithelial

cell reconstitution, and duct remodeling during the healing of ductal injury. Along this line, it is now well accepted that the contractile activity of myofibroblasts is responsible for connective tissue remodeling during wound healing[38]. Obviously, further studies are necessary to clarify the pathop-hysiological relevances of ET-1-mediated cell functions of PSCs.

Abstract

AIM: To identify the gene (s) related to the antagonistic activity of *Enterobacter cloacae* B8 and to elucidate its antagonistic mechanism.

METHODS: Transposon-mediated mutagenesis and tagging method and cassette PCR-based chromosomal walking method were adopted to isolate the mutant strain (s) of B8 that lost the antagonistic activity and to clone DNA fragments around Tn5 insertion site. Sequence compiling and open reading frame (ORF) finding were done with DNAStar program and homologous sequence and conserved domain searches were performed with BlastN or BlastP programs at www.ncbi.nlm.nih.gov. To verify the gene involved in the antagonistic activity, complementation of a full-length clone of the *anrF* gene to the mutant B8F strain was used.

RESULTS: A 3 321 bp contig around the Tn5 insertion site was obtained and an ORF of 2 634 bp in length designated as *anrF* gene encoding for a 877 aa polyketide synthase-like protein was identified. It had a homology of 83% at the nucleotide level and 79% ID/87% SIM at the protein level, to the *admM* gene of *Pantoea agglomerans* andrimid biosynthetic gene cluster (AY192157). The Tn5 was inserted at 2 420 bp of the gene corresponding to the COG3319 (the thioesterase domain of type I polyketide synthase) coding region on B8F. The antagonistic activity against *Xanthomonas oryzae pv. oryzae* was resumed with complementation of the full-length *anrF* gene to the mutant B8F.

CONCLUSION: The *anrF* gene obtained is related to the antagonistic activity of B8, and the antagonistic substances produced by B8 are andrimid and/or its analogs.

INTRODUCTION

Enterobacter cloacae strain B8 isolated from rice leaves was first recognized as an antagonistic bacterium of *Xanthomonas oryzae pv. oryzae*[1]. Its biological characteristics, antagonistic activity, and substances have been reported[2,3]. Satisfactory results have been obtained on anti-rice bacterial leaf brilliant in net house and in field[4]. Additionally, *E. cloacae* B8 is also antagonistic to many other plant bacterial pathogens such as *Pseudomonas*, *Agrobacterium*[3]. It has been reported that substances purified from *E. cloacae* B8 inhibit human (animal) bacterial pathogens such as MRSA[5,6].

Few but an *E. cloacae* strain EcCT-501R3 was reported to have antagonistic activity, which inhibits *Pythium ultimum* sporangium germination[7,8]. A competitive exclusion mechanism, competitive utilization of long-chain fatty acids of seed exudates, has been discovered and verified with transposon-mediated mutagenesis and tagging[9]. Previous researches on *E. cloacae* B8, however, showed that it produces antagonistic substances and differs from EcCT-501R3[1,3].

To elucidate the antagonistic mechanism of *E. cloacae* B8, transposon tagging[9-12] strategy was employed to clone DNA fragment related to its antagonistic activity. After a DNA fragment was cloned, cassette PCR-based chromosomal

walking[13-15] was used to get the flanked unknown DNA. We have previously reported the cloning and analysis of an antagonistic-related DNA fragment[16,17] and the verification of loss of antagonistic activity of mutant strains, by Southern blotting analysis, as a result of the insertion of a single copy of Tn5[18]. Here, we report the cloning and identification of the full-length *anrF* gene and the verification of its participation in the antagonism of B8.

MATERIALS AND METHODS

Bacterial strains, plasmids and chemicals

E. cloacae B8 (rif^r) is the antagonistic bacterium isolated from rice leaves in our laboratory[3,19]. *X. oryzae pv. oryzae* strain Xcom3104 (rif^r kan^r) was used as an indicator bacterium of antagonistic activity. The suicide plasmid pZJ25 (cm^r kan^r mob::Tn5) and its host *E.coli* S17-1 (thi pro $hsdR^-$ $hsdM^+$ recA RP4)[20] were gifts from Professor Jin-Sheng Wang of Nanjing Agricultural University, China. The cloning vector pBluescript SK+ (pBS) and its host *E. coli* DH5a were purchased from Stratagene. pFastBac^{TM}HTA was purchased from Invitrogen. pMD18-T vector was a product of Takara. Restriction enzymes, T4 DNA ligase, CIAP, *Taq* DNA polymerase, dNTPs, DNA marker DL2000, marker 3 kb, PCR product purification kit, etc., were supplied by Promega, Takara, Sangon and/or Zeheng. Oligonucleotides and primers used in this research were synthesized in Bioasia Biotech.

Transposon-mediated mutagenesis

The transfer of suicide plasmid pZJ25 from *E. coli* host S17-1 (donor) to *E. cloacae* B8 (receptor, rif^r) was mediated with conjugation[21]. Tranposonated B8 clones (rif^r kan^r cm^s) were selected on plates with rifampicin and kanamycin. The antagonistic characteristics were then checked using Xcom 3104 (rif^r kan^r) as an indicator[19].

Cloning of F fragment from B8F with tagging method

Genomic DNA of B8F, an antagonistic mutant strain of B8, was isolated, cut with *Bam*HI and ligated to *Bam*HI cut and dephosphorylated pBS. Recombinant clones were selected on plates with both kanamycin and ampicillin. Only one DNA fragment on the left of the insertion site was obtained with this step, as *Bam*HI cut Tn5 into two fragments and the intact Kan^r gene was in the 2.7 kb left fragment. The F fragment was a DNA fragment on the left of inserted Tn5 on B8F genome (Figure 1).

Cloning of DNA on the right of insertion site with chromosomal walking

Two sets of cassettes and primers were adopted in our chromosomal walking experiments. The *Pst*I cassette and its related CP primer were synthesized as previously described[12]. The *Sau*3AI cassette and its related CS primer and FS2, F1815 and F2000, the specific primers corresponding to known sequences, were newly designed and synthesized. They were as follows:

*Pst*I cassette:
5' HO-AGATTCGGTGCGTGCTTGACTGCA-OH 3'
3' HO-TCTAAGCCACGCACGAACTG-OH 5'
*Sau*3AI cassette:
5' HO-CTGTGGTGGTTCCGATGTATG-OH 3'
3' HO-ACCACCAAGGCTACATACCTAG-OH 5'
Cassette primers:
CP primer: AGATTCGGTGCGTGCTTGAC
CS primer: CTGTGGTGGTTCCGATGTAT
Specific primers:
FS2: GTTTACTGGCCAGTTATTGTTG
F1815: CCACAGAACGTCTTGTCAT
F2000: CGGAATGAAGAGGGTAAGG

Genomic DNA was extracted from B8 and partially digested with *Sau*3AI or completely digested with *Pst*I. DNA of 2-10 kb in length was recovered from gel and ligated to *Sau*3AI or *Pst*I cassette to construct cassette genomic libraries. Related cassette primer (CS or CP) and specific primer were used to amplify target DNA of unknown region from the libraries. The PCR conditions were as follows: pre-denaturation for 5 min at 94 ℃, and denaturation at 94 ℃ for 30 s, annealing at 52 ℃ for 60 s and extension at 72 ℃ for 5 min for 30 cycles, and a final extension at 72 ℃ for 10 min. Three rounds of PCR-based chromosomal walking, using *Pst*I and *Sau*3AI cassettes and related primers by turns, were performed to cover the full length of *anrF* gene (Figure 1).The full-length *anrF* gene was shown on the top (gray single line). The direction of the gene (narrow horizontal arrow, at right) and the Tn5 insertion site (thick vertical arrow) were marked. The long double line underneath stood for the F contig obtained in this research. The dark part on

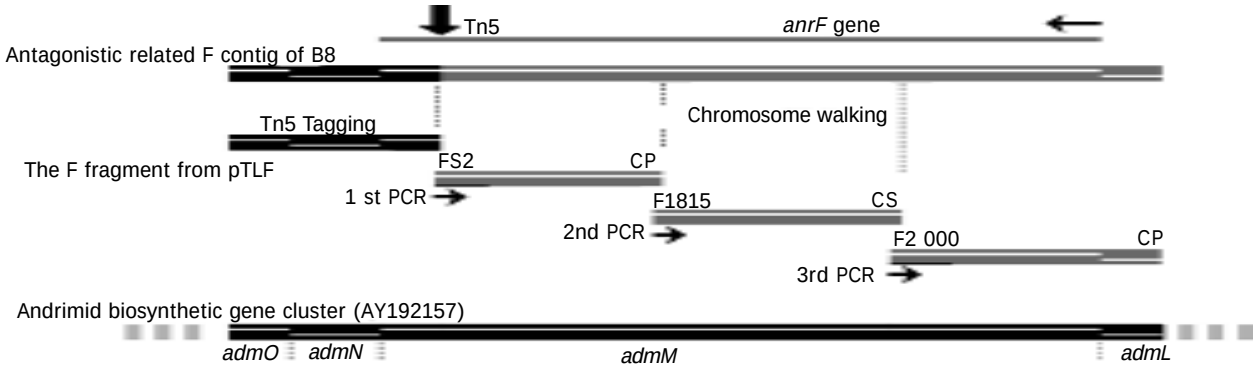

Figure 1 Framework of the cloning of full-length *anrF* gene with transposon tagging and chromosome walking.

the left of Tn5 insertion site (the F fragment) was obtained with transposon tagging. The gray part on the right was obtained with chromosomal walking. The four separate lines below were four steps (one tagging and three rounds of PCR) to get the contig. Primers were marked on top of the three gray lines. The black double line at the bottom showed the corresponding genes of *P. agglomerans* andrimid biosynthetic gene cluster (AY192157).

DNA sequencing and data analysis

The F fragment was sequenced, after subcloning of pTLF from M13 universal primer and P1 primer (CATGGAAG-TCAGATCCTGGA), a primer designed according to the sequence of the left edge of Tn5. PCR products of chromosomal walking were cloned into T-vector and sequenced using M13 universal primer. The DNA sequencing was done in Bioasia Biotech, Shanghai. DNA sequences obtained were edited, compiled, translated, and compared using DNAStar program. Homologous sequence and putative-conserved domain searches were done with BlastN and/or tBlastX and/or BlastP program at www.ncbi.nlm.nih.gov.

Continuity analysis of anrF gene in original B8 and its mutant B8F strain

Two primers were designed to amplify the full-length *anrF* gene. The upstream primer F21 (TTTTGTTGATGGAA-AGTCGCA) was located 144-126 bp up of the start codon. The downstream primer F2600 (CACCCAGCTGA-TGAAGTAAT) was located on opposite strand 73-56 bp down of the stop codon. The DNA fragments between the primers in the genomes of B8 and B8F were about 2 851 bp and 8.3 kb respectively. Genomic DNA of B8 or B8F was used as template. After 30 cycles of amplification, 6 μL of PCR products were applied to agarose gel electrophoresis to check the amplification. The amplified products were cloned and sequenced.

Verification of anrF gene participation in antagonism of B8

The full-length *anrF* gene amplified from B8 was cloned into pMD18-T vector and the resulting recombinant plasmid was designated as pMD-F. Gentamicin-resistance gene (*Gen*^{r}) was amplified with two primers (acc1-up: CGTGGAAACG-GATGAAG, acc1-down: ACCTGGCGGCGTTGTGACA) from pFastBac^{TM}HTA and cloned into pMD18-T too. The resulting recombinant plasmid was designated as pMD-G. The *Gen*^{r} gene was recovered from pMD-G with *Hin*dIII and *Bam*HI double cut and filled with klenow and inserted into *Xba*I cut and klenow filled pMD-F. The target plasmid with *Gen*^{r} and the full-length *anrF* gene was designated as pMD-FG.

Mutant *E. cloacae* B8F was cultured to an A_{600} about 0.6 in LB medium, and washed thrice in cold glycerol buffer. Plasmid pMD-FG was transformed into B8F with electroporation. The transformed bacteria were screened on plates with both ampicillin and gentamicin and verified by PCR amplification of *anrF* and *Gen*^{r} genes. The pMD-FG transformed strains were then inoculated on Wakimoto agar and cultured at 30 ℃ for 48 h, the resume of antagonistic characteristics was checked with the indication of *X. oryzae pv. oryzae* strain Xcom3104.

RESULTS

Transposon-mediated mutagenesis

The suicide plasmid pZJ25 was transferred into *E. cloacae* B8 by conjugation with the help of donor *E. coli* S17-1. The conjugation and transposition ratio was about 5×10^{-6}. A total of 1 500 transposed colonies (Rif^r Kan^r Cm^s) were obtained and two antagonistic mutant strains, one of which was designated as B8F, were selected.

Cloning of F fragment from B8F with tagging method

A recombinant plasmid designated as pTLF, a plasmid with intact *Kan*^{r} gene of Tn5 and a DNA fragment on the left of the insertion site (designated as F fragment), was isolated. The pTLF had two foreign *Bam*HI fragments, one of which was about 3.5 kb in length and contained the target F fragment and a fragment of Tn5 (with the *Kan*^{r} gene, about 2.7 kb in length). After subcloning, the 735 bp sequence of the F fragment was obtained with M13 universal sequencing primer and P1 primer.

Cloning of DNA fragments on the right of Tn5 insertion site with chromosomal walking

Only one DNA fragment on the left of insertion site was obtained with transposon tagging method. In order to know the full-length gene interrupted by Tn5 insertion, cassette PCR-based chromosomal walking method was adopted to clone DNA fragments on the right of insertion site. The framework of the cloning of the full-length *anrF* gene with transposon tagging and chromosomal walking was shown (Figure 1). With the use of specific primers (FS2, F1815, or F2000) and cassette primers (CP or CS) by turns, DNA fragments of unknown region were amplified from related cassette (*Pst*I or *Sau*3AI) libraries. The PCR products from three different rounds of chromosomal walking were obtained (Figure 2). They were about 1.2 kb in *Pst*I library (1st walking), about 950 bp in *Sau*3AI library (2nd walking), and about 900 bp in *Pst*I library (3rd walking), respectively. The total sequence obtained with chromosomal walking was 2 586 bp.

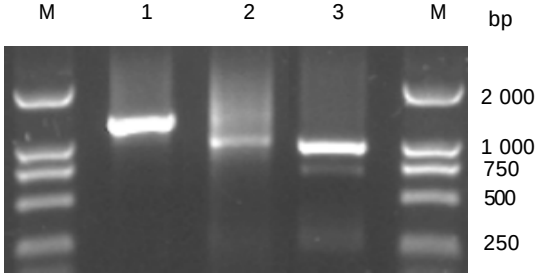

Figure 2 PCR products from three rounds of chromosomal walking. 1: PCR products, 1 209 bp in size, amplified from B8/*Pst*I-cassette library with FS2 and CP primers; 2: PCR products, 962 bp in size, amplified from B8/*Sau*3AI cassette library with F1815 and CS; 3: PCR products, mainly 900 bp in size, amplified from B8/*Pst*I cassette library with F2000 and CP; M: marker DL2000.

Sequence analysis of full-length anrF gene

A contig of 3 321 bp in length was obtained by transposon tagging and three rounds of chromosomal walking. Four ORFs, two complete and two partial were identified. One ORF, 2 634 bp in length, disrupted by the insertion of Tn5

in B8F was designated as *anrF* gene (accession no. AY633625) encoding for a 877 aa polyketide synthase-like protein. The Tn5 insertion site was at 2 420 bp of the *anrF* gene, and was at 214 bp before the stop codon.

BlastN search showed that the nucleotide sequence of *anrF* gene had a homology of 83% to that of *admM* gene of *P. agglomerans* andrimid biosynthetic gene cluster (AY192157). The alignment of *anrF* and *admM* genes is shown in Figure 3.

BlastP search showed that the deduced amino acid sequence encoded by the *anrF* gene was homologous to AdmM (79%

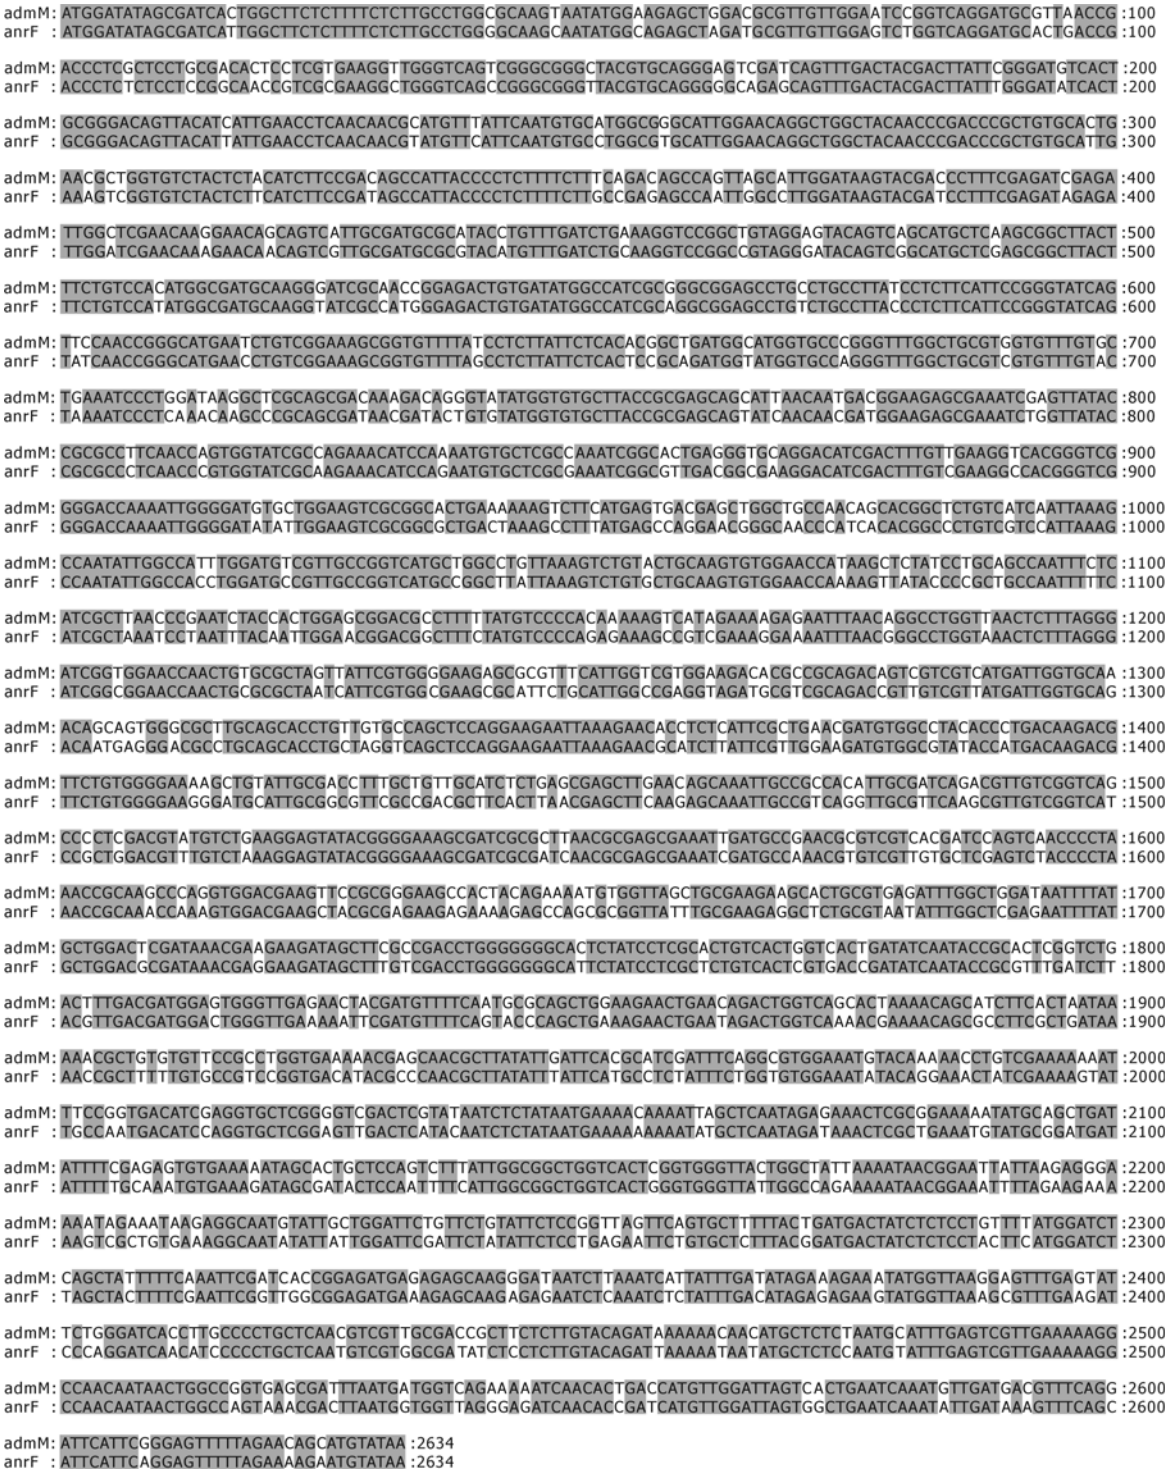

Figure 3 Alignment of nucleotide sequences of *anrF* gene and *admM* gene of *P. agglomerans* andrimid biosynthetic gene cluster (AY192157). The names of the genes are typed at the left and the number of nucleotides is at the right. The identical nucleotides between two genes are marked with gray background.

ID/87% SIM) and many other proteins of polyketide/non-ribosomal peptide synthetase or polyketide synthase (type I) modules (about 28-38% ID/45-58% SIM). Conserved domain search showed that the N-terminal of the protein (about 1-410 aa) encoded for a polyketide synthase module (COG3321) or animal-type fatty-acid synthase (KOG1202) or ketoacyl synthase (pfam00109 and pfam02801) or 3-oxoacyl-(acyl-carrier-protein) synthase (FabB or COG0304, and KOG1394)-like domain. The middle sequence (about 550-610 aa) encoded for a phosphopantetheine attachment site (pfam00550)-like domain. The C terminal (about 640-877 aa) encoded for a thioesterase of type I polyketide synthase (COG3319, pfam00975, and COG3208)-like domain, which was disrupted by the insertion of Tn5 in B8F.

Continuity analysis of anrF gene in original B8 and its mutant B8F strain

With F21 and F2600 as primers, no band was amplified in the reaction mixture using B8F genomic DNA as template, while a PCR product 2.8 kb in length, as expected, was observed in that of B8 (Figure 4). The 2.8 kb PCR product of B8 was further cloned and sequenced. The sequence result conformed the continuity of the *anrF* gene in B8.

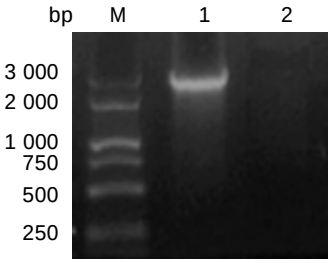

Figure 4 PCR amplification of full-length *anrF* gene. 1: PCR products amplified from B8; 2: PCR products amplified from B8F; M: marker 3 kb.

Verification of anrF gene participation in antagonism of B8

The pMD-FG, a plasmid with the full-length *anrF* and *Gen*^{r} genes, was constructed and transformed into the mutant *E. cloacae* B8F. The antagonistic activity of pMD-FG transformed B8F against *X. oryzae pv. oryzae* was then resumed, though the antagonistic ring was a little bit small and ambiguous (Figure 5).

DISCUSSION

E. cloacae B8 is an antagonistic bacterium isolated from rice leaves, using *X. oryzae pv. oryzae* Xcom3104 as an indicator[1]. It has a strong antagonistic activity against *X. oryzae pv. oryzae* and satisfactory results have been obtained on anti-rice bacterial leaf brilliant in net house and in field[4]. Further researches showed that *E. cloacae* B8 and its antagonistic substances are also antagonistic to many other plant bacterial pathogens such as *Pseudomonas*, *Agrobacterium*[3], and human (animal) bacterial pathogens such as MRSA[5,6]. *E. cloacae* B8 and its antagonistic substances can be potentially used for the control of the rice bacterial leaf brilliant and many other bacterial diseases of plants, animals and humans.

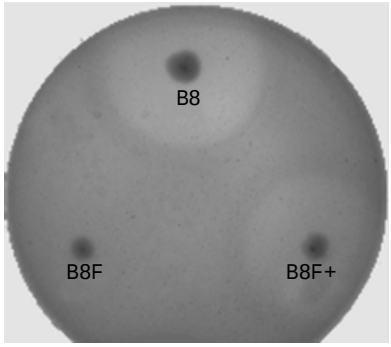

Figure 5 Antagonistic activity of B8, B8F and B8F/pMD-FG. B8F+: pMD-FG transformed B8F.

It was reported that *E. cloacae* EcCT-501R3 has an antagonistic activity[7,8]. Two antagonistic-related genes for linoleic acid utilization, *fadB* and *fadL*, have been cloned using transposon-mediated mutagenesis and tagging. Further researches have verified that *E. cloacae* EcCT-501R3 inhibits *Pythium ultimum* sporangium germination by a competitive exclusion mechanism, the competitive utilization of long-chain fatty acids of seed exudates[9].

Our previous work, however, showed that B8 has an antagonistic mechanism different from what has been reported[1,3]. To elucidate the antagonistic mechanism and to clarify the antagonistic substances of *E. cloacae* B8, transposon tagging strategy[9-12] was employed to clone genes related to its antagonistic activity. With suicide plasmid pZJ25 carrying Tn5, two antagonistic mutant strains, one of which was named B8F, were selected. Tagging with *Kan*^{r} gene of Tn5, the F fragment on the left of Tn5 insertion site was cloned in pTLF. Then, cassette PCR[13-15]-based chromosomal walking was applied to the amplification of unknown DNA fragments on the right of Tn5 insertion site. A contig of 3 321 bp in length was obtained after three rounds of chromosomal walking together with the F fragment from transposon tagging. One complete ORF of 2 634 bp in length, disrupted by the Tn5 insertion in B8F, was identified in the contig. It encoded for a 877 aa polyketide synthase-like protein and was designated as *anrF* gene. The Tn5 insertion site was at 2 420 bp of the *anrF* gene, and was at 214 bp before the stop codon, suggesting that the loss of antagonistic activity of mutant strain B8F was a result of the knock-out of *anrF* gene by Tn5.

To confirm this theory, the continuity of the *anrF* gene in the original B8 and its mutant B8F strains was checked. The complete *anrF* gene 2.8 kb in length was amplified from the B8 genome. The sequence result further confirmed the continuity of *anrF* gene in the original B8. The length of the DNA fragment between the primers in the genome of B8F was about 8.3 kb. However, no band was amplified from B8F. As the parameters set for amplification were suitable for amplification fragments 2.8 kb or less in length but not for fragments up to 8.3 kb.

In addition, plasmid pMD-FG with full-length *anrF* and *Gen*^{r} genes was constructed. After pMD-FG was transformed into B8F, a mutant strain of B8 knocked out by Tn5-mediated mutagenesis, the antagonistic

characteristics were resumed, indicating that the *anrF* gene participated in the production of the antagonistic activity of B8.

BlastN search showed that the nucleotide sequence of the *anrF* gene had a homology of 83% to that of the *admM* gene of *P. agglomerans* andrimid biosynthetic gene cluster (AY192157). BlastP search showed the deduced amino acid sequence encoded by the *anrF* gene was homologous to the AdmM (79% ID/87% SIM) and many other proteins of polyketide synthase/non-ribosomal peptide synthetase (about 28-38% ID/45-58% SIM). Domain search showed that the N-terminal of the protein encoded for a polyketide synthase module (COG3321) or animal-type fatty-acid synthase (KOG1202)-like domain. The middle sequence encoded for a phosphopantetheine attachment site (pfam00550)-like domain. And the C terminal encoded for a thioesterase of type I polyketide synthase (COG3319)-like domain, which was disrupted by the insertion of Tn5. It was this insertion that led to the loss of antagonistic activity of B8F, suggesting that the protein encoded by *anrF* gene is a polyketide synthase similar to AdmM of *P. agglomerans*, and that the antagonistic substances produced by B8 are andrimid and/or analogs of andrimid. This result is consistent with our early observations[1,3].

Andrimid and its analogs are antibiotic substances of the polyketide (pyrrolidinedione) family[22]. Only three different strains of bacteria, other than B8, have been reported to produce these substances so far. Frenenhagen *et al.*[23], first reported the identification of andrimid, a new peptide antibiotic produced by an intracellular bacterial symbiont isolated from a brown planthopper. It has been reported that andrimid exhibits a moderate activity against *Bacillus sp.* and a very good activity against *X. campestris*, an early name of the pathogen of bacterial blight in rice plants[23]. Needham *et al.*[24], reported that andrimid and Moiramides A-C are produced in culture by a marine isolate of *Pseudomonas fluorescens*. Singh *et al.*[25], further showed that andrimid secreted from this strain exhibits antibacterial activity against both Gram-positive and Gram-negative bacteria. Oclarit *et al.*[26], found that anti-*Bacillus* peptide antibiotic, an andrimid in the marine sponge, *Hyatella* species, is produced by an associated *Vibrio* species bacterium. Freiberg *et al.*[22], reported that andrimid and its analogs act as selective inhibitors of bacterial acetyl-CoA carboxylase.

However, no genes related to the production of andrimid are published so far, except for the andrimid biosynthetic gene cluster of *P. agglomerans* (AY192157). The complete genome of AY192157 is 28 485 bp in length and encodes for 21 genes, from *admA*, *admB* to *admU*. The *anrF* gene cloned in this research has a homology of 83% to *admM*. Furthermore, the arrangement and the sequences of other ORFs or non-coding regions around the *anrF* gene have shown that the F contig obtained in this research is an equivalent of a part of AY192157 (data not shown). *P. agglomerans* (formerly *Erwinia herbicola*) is a closely related but nonpathogenic bacterium of *E. amylovora*[27]. It usually accompanies *E. amylovora* in the wild and produces a family of antibiotics[28-30] to inhibit fire blight, a devastating disease of rosaceous plants such as apple and pear caused by the latter bacterium. *E. cloacae* B8 has been isolated from rice leaves as an antagonistic bacterium of *X. oryzae pv. oryzae*. However, both *E. cloacae* and *P. agglomerans* are members of the *Enterobacteriacea* family. Whether this is the reason why the *anrF* and *admM* genes have a high similarity, or whether the equivalents of andrimid biosynthetic genes are similar or identical in bacteria other than *Enterobacteriacea* family, including *Pseudomonas* and *Vibrio* remains to be studied.

Abstract

AIM: To find a soluble and functional recombinant receptor-binding domain of severe acute respiratory syndrome-associated coronavirus (SARS-Cov), and to analyze its receptor binding ability.

METHODS: Three fusion tags (glutathione *S*-transferase, GST; thioredoxin, Trx; maltose-binding protein, MBP), which preferably contributes to increasing solubility and to facilitating the proper folding of heteroprotein, were used to acquire the soluble and functional expression of RBD protein in *Escherichia coli* (BL21(DE3) and Rosetta-gamiB (DE3) strains). The receptor binding ability of the purified soluble RBD protein was then detected by ELISA and flow cytometry assay.

RESULTS: RBD of SARS-Cov spike protein was expressed as inclusion body when fused as TrxA tag form in both BL21 (DE3) and Rosetta-gamiB (DE3) under many different cultures and induction conditions. And there was no visible expression band on SDS-PAGE when RBD was expressed as MBP tagged form. Only GST tagged RBD was soluble expressed in BL21(DE3), and the protein was purified by ÄKTA Prime Chromatography system. The ELISA data showed that GST•RBD antigen had positive reaction with anti-RBD mouse monoclonal antibody 1A5. Further flow cytometry assay demonstrated the high efficiency of RBD's binding ability to ACE2 (angiotensin-converting enzyme 2) positive Vero E6 cell. And ACE2 was proved as a cellular receptor that meditated an initial-affinity interaction with SARS-Cov spike protein. The geometrical mean of GST and GST•RBD binding to Vero E6 cells were 77.08 and 352.73 respectively.

CONCLUSION: In this paper, we get sufficient soluble N terminal GST tagged RBD protein expressed in *E.coli* BL21 (DE3); data from ELISA and flow cytometry assay demonstrate that the recombinant protein is functional and binding to ACE2 positive Vero E6 cell efficiently. And the recombinant RBD derived from *E.coli* can be used to developing subunit vaccine to block S protein binding with receptor and to neutralizing SARS-Cov infection.

INTRODUCTION

Severe acute respiratory syndrome (SARS), a newly emerging infectious disease, is caused by a SARS-associated coronavirus (SARS-Cov)[1,2]. SARS-Cov can infect African green monkey kidney cells (Vero E6) and cause a similar disease in *Cynomolgus macaques* (*Macaca fascicularis*)[3,4]. The SARS viral genome comprises approximately 30 000 nucleotides, which are organized into approximately 13-15 open reading frames (ORFs), taking into consideration only those exceeding 50 amino acids in translational capacity[5,6]. Sequence comparison with corresponding ORFs of other known coronaviruses reveals a similar pattern of gene organization typical of coronaviruses[7]. SARS-Cov contains a single-strand plus-sense RNA genome about 30 kb in length and has a 5'-cap structure and a 3'-polyadenylation tract. And the genomic organization is typical of coronaviruses, having five major ORFs that encode the replicase polyproteins: the spike (S), envelope (E), and membrane (M) glycoproteins. The full-length genome sequence of SARS-Cov has been elucidated within few weeks after the identification of this novel pathogen[8-10].

When coronavirus enters the cells, the 50-region of viral genome is translated into a large poly-peptide that is cleaved by viral-encoded proteases to release RNA-dependent RNA polymerase and adenosine triphosphatase/helicase. These proteins, in turn, are responsible for replicating the viral genome as well as generating nested transcripts that are used in the synthesis of viral proteins. Viral membrane proteins, including S and M, are inserted into the endoplasmic reticulum (ER), while RNA genome assembles with the N

protein. This RNA-protein complex then associates with M proteins and buds into the lumen of the ER. The virus particles then migrate through the Golgi complex and exist in the cells by exocytosis[6,11]. The first step *in viral* infection is the binding of viral proteins to certain cellular receptors. So far, the S protein of coronavirus is considered as the site of viral attachment to the host cells. It has been shown that a cellular metallopeptidase, angiotensin-converting enzyme 2 (ACE2), could bind to S1 domain of SARS-Cov' S protein and support viral replication[12]. And a 193-amino-acid fragment of the S protein (residues 318-510) is a receptor binding domain (RBD) of SARS-Cov S protein[13]. Here we reported the soluble expression, purification, and functional characterization of RBD expressed in *Escherichia coli*.

MATERIALS AND METHODS

Materials

E.coli DH5α competent cells, *E.coli* BL21(DE3) competent cells, *E.coli* Rosetta-gamiB (DE3) competent cells, pET22b, TrxATag (Thioredoxin) expression vector pET32a were products of Novagen Inc. The genotype of Rosetta-gamiB (DE3): △*ara-leu 7697* △*lacX74* △*phoAPvuII pho*R *araD139 ahpC gale galK rspL* F'[*lac*+(*lacIq*)*pro*] *gor522*::Tn*10* (TcR) *trxB*:: kan (DE3) pRARE (CmR). GSTag (glutathione *S*-transferase) expression vector pGEX-4t-2 was purchased from Invitrogen Inc. Chromatography media Q Sepharose Fast Flow, Q Sepharose High Performance, Butyl Sepharose Fast Flow, Superdex 75, goat anti-GST polyclone antibody were purchased from Amersham Inc. FITC-labeled rabbit anti-goat IgG, goat anti-mouse IgG conjugated with HRP were products of Beijing Xin Jing Ke Biotechnology Co., Ltd. The primers with restriction enzyme sites *Bam*HI and *Xho*I to amplify RBD gene were synthesized by Beijing Bioasia Inc. pET-S plasmid containing the full length gene of S protein of SRAS-Cov (isolate BJ01, GenBank accession number AY278488) was kindly provided by Beijing Hua Da Gene Research Center. Anti-RBD of S protein mouse monoclonal antibody 1A5 was provided by the Institute of Microbiology and Epidemiology, Academy of Military Medical Sciences. pET-MBP was constructed by inserting maltose-binding protein (MBP) gene derived from *E.coli* JM109 strain into pET22b between *nde*I and *Bam*HI restriction enzyme sites, conserved by the Institute of Biotechnology, Academy of Military Medical Sciences.

Plasmids construction and engineering bacteria

A pair of primers was used in PCR reaction to amplify RBD gene (N terminal 318-510 amino acid fragments) of S protein from pET-S plasmid (EC1: 5'-CGGGATCCGACG-ATGACGATAAGAATATTACAAACTTGTGTCCT-3', EC2: 5'-CCG CTCGAGTTAAACCGTGGCCGGT-GGATTTAA-3'). The amplified RBD gene fragment was purified on a 10 g/L low-melting agarose gel, utilizing the PCR purification system (Q Biogene Inc.) The purified PCR products were directly ligated into expression vector pET32a, pETGEX-4t-2, and pET-MBP respectively. The progress of vector construction follows the example of pET32-RBD according to the clone strategy from TaKaRa Biotechnology Co., Ltd. (Figure 1). After transformation of the *E.coli* strain DH5α competent cells, the clone was selected on ampicillin containing (100 mg/L) plates for mini-preparation and insert evaluation was by enzyme digestion and DNA sequencing. Bacterial transformation for expressing RBD was carried out by incubating bacterial strain BL21(DE3) (Novagen) with pET32-RBD, pGEX-RBD, and pET-MBP-RBD plasmid DNAs on ice for 30 min and heat-shock treatment for 90 s as per the manufacturer's instruction, so did transforming pET32-RBD into bacterial strain Rosetta-gamiB(DE3) (Novagen) but ampicillin (100 mg/L), chloramphenicol (34 mg/L), kanamycin (12 mg/L), tetracycline (12.5 mg/L) selection. Hence expression of four engineering bacteria was performed (Table 1).

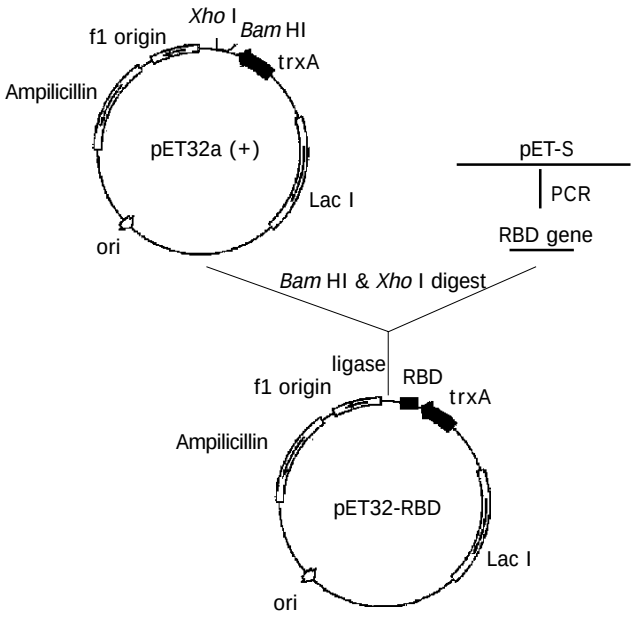

Figure 1 Schematic illustration of the constructs of expression vector pET32-RBD.

Optimization of protein expression and solubility analysis in E.coli

Each single colony on the LB plate was inoculated into

Table 1 Construction of recombinant plasmid and expression of engineering bacterium

Engineering bacterium	Recombinant plasmid	Expression host (*E.coli* strain)	Expression vector used	Fusion tag
E.coli BL-TB	pET32-RBD	BL21(DE3)	pET32a	TrxA·tag S·tag
E.coli R-TB	pET32-RBD	Rosetta-gamiB(DE3)	pET32a	TrxA·tag S·tag
E.coli BL-GB	pGEX-RBD	BL21(DE3)	pGEX-4t-2	GST·tag
E.coli BL-MB	pET-MBP-RBD	BL21(DE3)	pET-MBP	MBP·tag

5 mL of LB broth containing 100 μg/mL ampicillin (chloramphenicol (34 mg/L), kanamycin (12 mg/L), tetracycline (12.5 mg/L) additional for *E.coli* R-TB) and incubated overnight at 37 ℃ in a bacterial shaker. One hundred microliters of fresh engineering bacterium preparation was added to 20 mL of antibiotic containing LB broth. The bacteria were induced with 0.25-5 mmol/L IPTG when the optical density of the bacteria reached between 0.5 and 0.6 $A_{600\ nm}$, then shaked for an additional 1-8 h in a bacterial shaker at 20 or 37 ℃. One milliliter of the bacteria was taken out at 2, 4, 6, and 8 h, centrifuged, and lysed. Four microliters of cell lysate, after centrifuging the soluble and insoluble fragments, was electrophoresed on a 150 g/L SDS-PAGE for evaluation of protein expression. The expression of engineering bacteria derived from BL21(DE3) also performed by FML medium which is enriched in LB broth (7 g/L K_2HPO_4, 3 g/L NaH_2PO_4, 0.5 g/L $MgSO_4$, 2 g/L glucose, 2 mmol/L lactose) and target protein was induced by lactose. The protein expression has been evaluated after being cultured 9 h later as the same way.

Purification of the recombinant RBD protein

The *E.coli* BL-GB pellet from the 1 L culture was washed with 20 mmol/L Tris-HCl, pH 7.4, 5 mmol/L sodium EDTA, and 200 g/L sucrose. The pellet was resuspended with sonication buffer (20 mmol/L Tris-HCl, pH 8.0, 5 mmol/L EDTA) at the ratio of 1:40. The suspension was sonicated for lysing cells cooled in ice between sonication pulses. The lysate was centrifuged at 12 000 *g* for 30 min at 4 ℃ to separate out the debris. Then supernatant containing the recombinant RBD protein was purified by ÄKTA Prime Chromatography system using Q Sepharose FastFlow, Q Sepharose High Performance, Butyl Sepharose FastFlow, Superdex 75 gel exclusion Columns (Amersham-Pharmacia) respectively. The purified protein which conserved in 1×PBS was electrophoresed on a 150 g/L SDS-PAGE gel and stained with Coomassie blue. The gel was destained with 70 mL/L acetic acid and 50 mL/L methanol. The protein appeared to be induced quite well and purified to single band entities, demonstrating high purity of the protein products. The protein migrated at approximately 48 ku as expected.

ELISA

Purified GST·RBD protein was blocked to Maxisorp ELISA plate in 1×PBS at 1 μg/well. Anti-RBD of SARS-Cov spike protein mouse monoclonal antibody 1A5, then goat anti-mouse IgG conjugated with HRP was incubated with different ratios of dilution in each well at 37 ℃ for 2 h. Wells were washed with buffer then $A_{450\ nm}$ was measured.

Flow cytometry assay

A Becton Dickinson FACSCalibur cytofluorometer, which was in the Institute of Biotechnology, Academy of Military Medical Sciences, was used for flow cytometry. SARS-Cov susceptible Vero E6 cell was cultured in 12-well plate (5×10^6 cells/well). Cells were incubated at 37 ℃ for 3 h with 0.4 mg/mL purified GST protein and GST·RBD protein respectively, then washed thrice with fluorescence-activated cell sorting (FACS) buffer (PBS containing 20 g/L bovine serum)[14-16]. After being trypsinized, the cells were washed thrice with FACS buffer and then centrifuged at 2 000 r/min for 4 min in a 1.5 mL eppendorf tube for collecting cells. The prime antibody goat anti-GST polyclone antibody diluted in PBS containing 50 g/L bovine serum albumin at the ratio 1:2 000 were adsorbed to 5×10^6 cells in suspension for 1 h at room temperature. Then the secondary antibody was also adsorbed. Control, which was negative, was Vero E6 cells alone.

RESULTS

Soluble expression of recombinant RBD protein

TrxA tagged RBD protein expressed in two engineering bacteria (*E.coli* BL-TB and R-TB) were inclusion bodies. Under various cultures and induction conditions, *E.coli* BL-TB expressed RBD protein as inclusion body, including reduced IPTG induction concentration, shortened induction time and lowered induction temperature (data not shown). *E.coli* R-TB yielded high target protein expression, with level approaching approximately 40% of the total cellular protein but inclusion body. Especially, bacterial strain Rosetta-gamiB carries the thioredoxin reductase (*TrxB*) and glutathione reductase (*gor*) mutations which have the potential to enhance disulfide bond formation and ultimately solubility and activity, meanwhile it carries pRare plasmid which directs the rare tRNA genes synthesis that can enhance the expression of target protein. But the predominance of Rosetta-gamiB (DE3) for protein soluble expression was not clear. Maybe the overexpression of heteroprotein greatly counteract the helpfulness of host's *TrxB* and *gor* double mutations to the proper folding of the protein . Or the nature RBD folding form does not depend upon the disulfide bond formed by two cysteines (Figure 2A).

There was no visible expression in *E.coli* BL-MB in which RBD was MBP fused according to SDS-PAGE analysis. Some secondary structure might emerge at the upstream of ribosome binding domain of cloned gene in the pET-MBP-RBD. Or there was very little protein expressed and needed detection by Western blot. Among all four engineering bacteria, only *E.coli* BL-GB expressed soluble RBD protein GST tagged, and its expressional capacity was greater in FML medium than in LB broth. The protein migrated on SDS-GAGE at approximately 48 ku as expected (Figure 2B). So engineering bacterium BL-GB was selected to generate recombinant GST·RBD for further research (Figure 2C).

ELISA

Data from ELISA showed that the purified GST·RBD antigen had positive reaction with anti RBD mouse monoclonal antibody 1A5. Test result primarily indicated that the recombinant protein was by nature a three-dimensional structure (Figure 3).

Flow cytometry assay

To better detect the receptor binding ability of GST·RBD and then prove it was of dimensional structure and functional, flow cytometric analysis was performed (Figure 4). Because Vero E6 cell is SARS-Cov susceptible, the functional recombinant RBD should bind to ACE2 existing at the cell membrane of Vero E6 cell, after prime antibody and fluorescence-

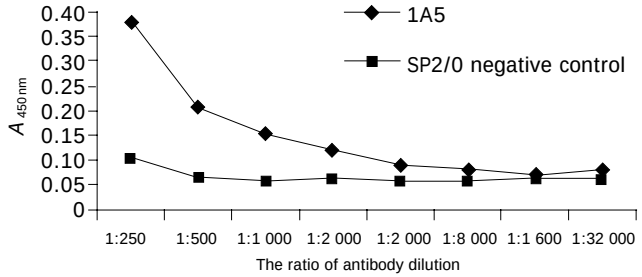

Figure 3 ELISA of GST·RBD antigen.

labeled secondary antibody was absorbed, it can be subjected to flow cytometry assay. Another negative control was set (Vero E6 cells with purified GST protein) to exclude the interference of GST tag and antibodies binding to cells. It has been seen that GST·RBD bound Vero E6 cells effectively. It also proved that the binding progress was decided by three-dimensional structure attachment because no side chain glycosylation was formed when heteroprotein expressed in *E.coli*.

DISCUSSION

During the pandemic outbreak of SARS in 2002/2003, despite the lack of effective and specific therapy, most SARS patients survived after the acute illness, and neutralizing antibodies were detectable in the sera of convalescent SARS patients[17,18]. Many researchers devoted themselves into developing anti SARS-Cov drugs. Currently, one candidate vaccine using inactivated SARS-Cov is in a phase I clinical trial in China. Although the inactivated SARS-Cov may be effective in protecting animals from challenge by the virus, its efficacy in human is unclear. There has been a serious safety concern since some antigens in the virions may elicit antibodies that did not neutralize, but rather infected. Some viral proteins may induce harmful immune and inflammatory response, a potential cause of SARS pathogenesis[19]. Now a number of vaccine candidates are of preclinical study, including inactivated vaccines, DNA vaccines, and attenuated viruses encoding SARS-Cov S protein[20-23]. Especially, vaccine blocking SARS-Cov entry into susceptible cell is a good way to fight against the virus[24].

The S proteins of coronaviruses are large type I membrane glycoprotein projections from viral envelope[25]. S proteins are responsible for both binding to receptors on host cells and for membrane fusion[11,12]. S proteins also contain important virus-neutralizing epitopes that elicit neutralizing

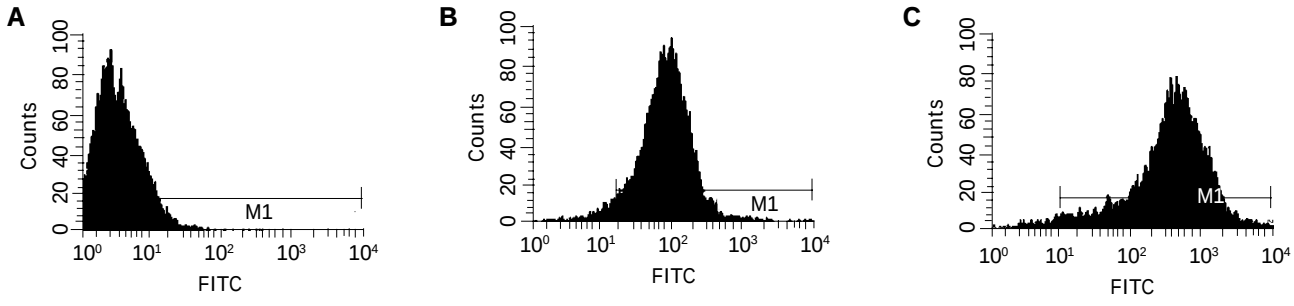

Figure 4 Cell binding test preformed by flow cytometry assay. A: Vero E6 cells alone, geometrical mean 3.3; B: Vero E6 cells+GST protein+two antibodies, geometrical mean 77.08; C: Vero E6 cells+GST·RBD+two antibodies, geometrical mean 352.73.

antibody in the host species. Furthermore, mutations in this gene dramatically affect the virulence, pathogenesis, and host cell tropism. The S1 domain of all characterized coronaviruses, including that of SARS-Cov, meditated an initial-affinity interaction with a cellular receptor[26-28]. In respect of that mutations in S protein' gene dramatically affect the virulence, pathogenesis, and host cell tropism, at the same time S proteins also contain important virus-neutralizing epitopes that elicit neutralizing antibody in the host species, so much work about antigenicity and receptor-binding ability of full length or fragments were done to discover the potent neutralization of SARS-Cov infection[29-32]. It has been proved that a cellular metallopeptidase, ACE2, could bind to S1 domain of SARS-Cov S protein and support viral replication[20]. Recent reports showed that a 193-amino-acid fragment of the S protein (residues 318-510) bound ACE2 more efficiently than did the full S1 domain and should be RBD of S protein of SARS-Cov, and rabbit antisera directed against RBD (cell expressed) were effective in binding to RBD on the S1 domain of SARS-Cov S protein and blocking RBD binding to soluble and cell-expressed ACE2. These data confirmed that the RBD of S protein has the potential to be developed as a subunit vaccine since it induces highly potent antibodies to block S protein binding to ACE2 and to neutralize SARS-Cov infection and has lower level of risk comparing with inactivated viruses. In these researches, the RBD protein was all expressed in mammalian cells and still in research pipeline.

These results suggested that RBD of S protein is a good candidate for vaccine because neutralizing antibodies are directed against S protein. Moreover, RBD of S protein is also a good target for antiviral therapies because blockade of binding of S protein to cellular receptor can prevent virus entry.

To research the receptor-binding ability of RBD, we chose *E.coli* as an expression host to get recombinant protein. According to the database from Internet there is 88.2% possibility of the recombinant RBD expressed in *E.coli* as inclusion body (www.biotech.ou.edu), at the same time, the gene of RBD contains lots of codon rarely used in *E.coli*, the expressional capacity should be little. In order to acquire soluble and functional recombinant protein, different fusion vectors, *E.coli* strain, culture, and induction conditions were considered. In this paper we adopted three fusion tags (GST, TrxA, MBP) which preferably contributes to increasing solubility and to the proper folding of heteroprotein when expressed in *E.coli*. At the same time we chose two *E.coli* strains: BL21 (DE3) and Rosetta-gamiB(DE3). Unexpectedly, TrxA tagged RBD protein expressed in Rosetta-gamiB(DE3) was inclusion body still, nature RBD folding form might not depend upon the disulfide bond formed by two cysteines. At last we got soluble expressed recombinant RBD protein as GST fusion form.

The recombinant GST·RBD protein was purified, and then proved positive reaction with anti RBD of S protein monoclonal antibody by ELISA and to have effective binding ability to ACE2 positive Vero E6 cell by flow cytometry assay. After removing the fusion tag, the recombinant protein can be directly used to develop subunit vaccine for blocking S protein binding with receptor and to neutralize SARS-Cov infection.

Abstract

AIM: To assess the effects of *Sb* on fecal flora and short-chain fatty acids (SCFA) in patients on long-term TEN.

METHODS: Ten patients (3 females, 7 males, 59±5.5 years), on TEN for a median of 13 mo (1-125), and 15 healthy volunteers (4 females, 11 males, 32±2.0 years) received *Sb* (0.5 g bid PO) for 6 d. Two stool samples were taken before, on the last 2 d and 9-10 d after treatment, for SCFA measurement and for culture and bacterial identification. Values (mean±SE) were compared using sign tests and ANOVA.

RESULTS: Fecal butyrate levels were lower in patients (10.1±2.9 mmol/kg) than in controls (19.2±3.9, $P = 0.02$). Treatment with *Sb* increased total fecal SCFA levels in patients (150.2±27.2 *vs* 107.5±18.2 mmol/kg, $P = 0.02$) but not in controls (129.0±28.6 *vs* 113.0±15.2 mmol/kg, NS). At the end of treatment with *Sb*, patients had higher fecal butyrate (16.0±4.4 *vs* 10.1 [2.9] mmol/kg, $P = 0.004$). Total SCFAs remained high 9 d after treatment was discontinued. Before the treatment, the anaerobe to aerobe ratio was lower in patients compared to controls (2.4±2.3 *vs* 69.8±1.8, $P = 0.003$). There were no significant changes in the fecal flora of TEN patients.

CONCLUSION: *Sb*-induced increase of fecal SCFA concentrations (especially butyrate) may explain the preventive effects of this yeast on TEN-induced diarrhea.

INTRODUCTION

Diarrhea is the most frequent complication of enteral tube feeding, with an incidence as high as 63%[1]. Its consequences range from discomfort to life-threatening acidosis, increased morbidity and mortality, and higher financial costs for health providers[2]. One of the causes of diarrhea in tube-fed patients may be the consequences on colonic trophicity of a deficiency in luminal short-chain fatty acids (SCFAs). We have reported a major imbalance (namely a drop in the number of fecal anaerobic bacteria and an increase in the number of aerobic bacteria) in patients on long-term total enteral nutrition (TEN)[3]. The modifications of the intestinal microflora induced by a fiber-free polymeric enteral diet can be compared to those induced by broad-spectrum antibiotics such as ceftriaxone[4,5]. These effects may be synergic[6] and explain why antibiotics are a risk factor for enteral nutrition-induced diarrhea[7,8] and why enteral nutrition is a risk factor for antibiotic-induced diarrhea[9] and *Clostridium difficile* infection[10]. SCFAs, one of the most important by-products of anaerobes in the colon, are the main fuel for the colonocyte and they are involved in water and electrolyte absorption by the colonic mucosa. They have been shown to reverse fluid secretion in the ascending colon during enteral feeding[11], and may represent the link between diarrhea and the intestinal microflora during enteral nutrition.

Saccharomyces boulardii (*Sb*) is a probiotic yeast that has been successfully used for years in the prevention of antibiotic-associated diarrhea[12]. *Sb* has been proven to prevent the relapse of *Clostridium difficile* infection[13], and seems effective in preventing relapses in patients with Crohn's disease[14]. Three randomized controlled studies have reported its efficacy in the prevention of diarrhea in TEN patients from intensive care units, with a reduction in the number of patient-days with diarrhea by 25-83%[15-17]. However, these studies did not address the mechanisms of action of the probiotic. We therefore designed a prospective study to assess the effects of *Sb* on fecal SCFAs and intestinal microflora in TEN patients. Healthy volunteers (HVO) were

used as controls.

MATERIALS AND METHODS

Subjects

The TEN group consisted of 10 patients (3 females and 7 males), mean age 59±5.5 years (mean±SE), who had been on TEN for a median of 13 mo (range: 1-125 mo). The indication for TEN was dysphagia in six patients (three head and neck tumors, two strokes, and one resected neurinoma); three patients had upper gastro-intestinal surgery, and one patient had low oral intake due to severe depression. Two patients were receiving proton pump inhibitors. A commercially available polymeric diet, fiber-, lactose-, and gluten-free, with a concentration of 1.33 kcal/mL (Sondalis HP®, Nestlé Clinical Nutrition, Noisiel, France) was used to provide 20% protein (50% from casein and 50% from soy protein), 45% carbohydrate (maltodextrin), and 31% fat (24% from corn oil, 22% from colza oil, and 47% as medium-chain triglycerides). Nutrition was given through gastrostomy ($n = 7$), jejunostomy ($n = 2$), or naso-gastric ($n = 1$) tubes. Enteral nutrition was total, but patients who could drink water or tea were allowed to do so. Fifteen HVO (4 females and 11 males), mean age 32±2.0 years ($P<0.05$ *vs* TEN patients) were also studied. All HVO consumed a regular Western diet, and none of them had a history of gastrointestinal disease. At the time of the study, all experimental and normal subjects were in a stable condition, and none had diarrhea. Energy provided by the diet was covering their maintenance needs as calculated using the Harris and Benedict formulas, and the enteral feeds were stable throughout the study. No subject had undergone colectomy, and none had taken antibiotics or laxatives for at least 2 wk prior to the study. All subjects gave their written informed consent and the study was performed according to the Declaration of Helsinki and approved by the regional Ethics Committee.

Study design

Five hundred milligrams b.i.d. of *Sb* as lyophilized powder, provided by Laboratoires Biocodex (Montrouge, France), were administered orally (HVO) or via the feeding tube (TEN patients) for six consecutive days. Two fecal samples were collected at 1-d intervals from all subjects on the 2 d before treatment, on the last 2 d of treatment, and 9 and 10 d after treatment was discontinued. Antibiotic or laxative use during the study was an exclusion criterion.

Stool analysis

Stool samples were taken immediately after production, and analyzed within 2 h. SCFAs were studied as follows[18]: an aliquot of 200 mg of feces was weighed. This was suspended in sterile distilled water (1.6 mL) and hexanoic acid (0.2 mL) was added. 50% aqueous H_2SO_4 (0.4 mL) and diethyl ether (2 mL) were then added. The sample was mixed for 45 min with an orbital shaker, and centrifuged for 5 min at 3 000 r/min at room temperature. Anhydrous $CaCl_2$ was then added in order to remove residual water, and 2 μL of the extract was injected in the gas-liquid chromatograph (Hewlett-Packard 5890 Series II with a flame ionization detector). The standard solution was as follows: acetic, propionic, isobutyric, butyric, isovaleric, valeric, isocaproic, caproic, and hexanoic acids (10 meq/L each); it was assayed before each stool sample was analyzed. Sensitivity was 1 mmol. 500 mg of feces was taken from the center of the stool, weighed and submitted to serial dilutions up to 10^{-8} in BHI broth. Then, 0.1 mL of each dilution was spread on a range of selective and non-selective media. Whenever necessary, the media were pre-reduced to allow anaerobic growth. Media inoculated and incubated at 37 ℃ in aerobiosis were as follows: trypticase agar, Columbia agar supplemented with sheep blood, Columbia agar supplemented with nalidixic acid and colistin, and Drigalski medium (equivalent to Mac Conkey medium) at dilutions 10^{-2}, 10^{-4}, and 10^{-6}[19]. For anaerobic bacteria, media inoculated were as follows: Columbia agar supplemented with sheep blood spread with the dilutions 10^{-2}, 10^{-4}, and 10^{-8}, Columbia blood agar supplemented with kanamycin and vancomycin, *Bifidobacterium* agar, and *Bacteroides* agar (dilutions 10^{-2}, 10^{-4}, and 10^{-7}), rifampicin agar (10^{-1} and 10^{-7}), and CCFA (for isolation of *Clostridium difficile*), MRS agar (for isolation of lactobacilli), *Veillonella* agar, and crystal violet agar, all spread with dilutions 10^{-1} and 10^{-5}[19]. The differences between dilutions for each medium were based on the differences between the concentrations of concerned bacteria[20]. After 24-48 h of incubation in an anaerobic cabinet, the number of colonies of each colony type growing on each of the media used were counted. The absence of growth under 50 mL/L carbon dioxide was verified for anaerobic strains. Routine identification was performed with standard methods, then with microstrips (API 20 Enterobacteries or ID 32 Anaerobies, BioMerieux, Marcy L'Etoile, France). The ratio between anaerobes and aerobes was calculated as a marker of microbial imbalance[3,21].

Statistical analysis

Results are expressed as mean±SE. All fecal bacterial counts (colony-forming units [CFU] per gram of wet feces) were transformed to logarithms ($\log_{10}$ CFU) for statistical analysis. Values were compared at baseline using a non-parametric method. Comparisons within groups used a sign test; differences *vs* baseline are presented with distribution-free confidence intervals.

A two-way ANOVA was performed for quantitative parameters for exploratory purposes. The model included group (TEN or HVO), period of time (before, during or after treatment) and interaction group*period of time; all two by two differences between adjusted means were calculated and tested using *t*-tests. No adjustment was performed in this exploratory context. For SFCA assessments, two values were considered in the model at each time. Statistics were performed on SAS software from SAS Institute (Cary, NC, USA). Differences were considered as statistically significant for P lower than 0.05. A pilot study that reported a 40% increase of total SCFA concentration after treatment with *Sb* allowed us to calculate a number needed to treat ten subjects per group.

RESULTS

Fecal short-chain fatty acids

Acetate, propionate, and butyrate values are represented in Table 1. For all three main SCFAs, no significant change,

either during or after treatment, was observed in HVO. In TEN patients, butyrate concentrations were increased significantly (about 60%) during treatment. SCFA values 9 d after discontinuing *Sb* were not significantly different from baseline. The sum of all SCFAs was increased significantly in TEN patients under treatment, with an average increase of 42.8 mmol/kg (95%CI: 0.0-55.2, $P = 0.02$) during treatment and an average increase of 51.8 mmol/kg (95%CI: 14.4-110.6, $P = 0.02$) after treatment (Figure 1). There were no changes in HVO. Minor SCFAs did not change in either group.

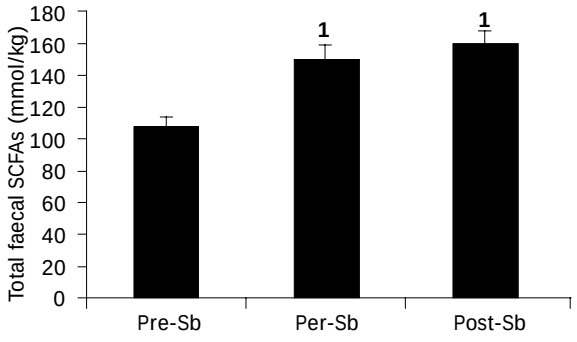

Figure 1 Fecal SCFAs in TEN patients. SCFA: short-chain fatty acids; *Sb*: *Saccharomyces boulardii*; [1]$P = 0.02$ *vs* pre-treatment values.

ANOVA showed an overall increase for acetate and SCFA sum after treatment on change from baseline values; significant interactions were noticed for propionate due to the increase in the TEN group opposed to a decrease in the HVO group, and for butyrate corresponding to differences in after-treatment concentrations higher in the HVO group in spite of higher baseline values in this group.

Fecal flora

Before treatment, there were significant differences in the fecal flora between HVO and TEN patients, as the latter had higher counts of aerobic bacteria and a lower anaerobes/aerobes ratio (Table 2). Among aerobes, the number of enterococci was higher in TEN patients (7.42±0.64 log CFU/g) than in HVO (6.1±0.46 log CFU/g, $P = 0.02$). Among anaerobes, peptostreptococci and *Bifidobacterium* spp., present in HVO, were absent in TEN patients. *Clostridium difficile* was not identified in any subject. There were no significant changes in the numbers of colony forming units of individual species or groups of bacteria in TEN patients during treatment with *Sb*, or after treatment. The only change observed in HVO was a decrease of Gram-positive anaerobes from 8.6±0.3 log CFU/g to 6.8±0.8 during treatment ($P = 0.035$).

Table 2 Fecal bacterial populations in TEN patients and HVO

		Before treatment concentration	During treatment concentration	After treatment concentration
Total bacteria	TEN	9.64 (0.31)	9.31 (0.41)	9.54 (0.36)
(log CFU/g)	HVO	9.53 (0.16)	9.56 (0.21)	9.20 (0.19)
Anaerobes	TEN	8.25 (1.01)	7.72 (0.76)	8.63 (0.62)
(log CFU/g)	HVO	9.47 (0.16)	8.73 (0.45)	8.97 (0.25)
Aerobes	TEN	8.84 (0.26)	8.83 (0.34)	8.71 (0.32)
(log CFU/g)	HVO	7.63 (0.22)	7.63 (0.24)	7.61 (0.26)
Anaerobes/				
aerobes ratio	TEN	2.42 (2.28)	0.51 (2.23)	2.89 (2.43)
	HVO	69.81 (1.81)	60.13 (2.47)	23.02 (2.01)

Mean (SE). TEN, total enteral nutrition; HVO, healthy volunteers. No significant difference.

Tolerance

There were no significant changes in the number of bowel movements and the consistency of stools during or after treatment in either HVO or TEN patients (data not shown). No fever or fungemia was reported. The only adverse effect attributed to *Sb* was a case of mild diarrhea in one patient which resolved without discontinuation of treatment.

Table 1 Fecal SCFAs in TEN patients and HVO

		Before treatment concentration (SEM)	During treatment			After treatment		
			Concentration (SEM)	Difference with pre-treatment value (95%CI)	P^1	Concentration (SEM)	Difference with pre-treatment value (95%CI)	P^1
Acetate	TEN	69.9 (12.3)	97.9 (25.2)	28.0 -6.1; 36.2	0.18	110.3 (24.1)	40.4 14.4; 71.4	0.02
	HVO	71.3 (10.3)	98.4 (29.8)	27.1 -13.1; 35.6	0.79	111.5 (17.5)	40.2 -7.0; 116.0	0.42
Propionate	TEN	20.9 (3.7)	26.2 (3.8)	5.3 -0.2; 12.6	0.18	26.0 (3.4)	5.1 -3.3; 14.3	0.18
	HVO	22.9 (3.0)	18.4 (2.4)	-4.5 -11.8; 4.5	0.30	23.0 (2.7)	0.1 -3.1; 6.9	0.12

Values in mmol/kg of wet feces: mean (SE); TEN: total enteral nutrition, HVO: healthy volunteers. [1]Probability of sign test.

DISCUSSION

This study shows that both the fecal concentration of butyric acid and the anaerobe/aerobe ratio were lower in patients at high risk for diarrhea due to TEN than in HVO. Despite great inter-individual variations, treatment with *Sb* increased total SCFAs and butyrate fecal concentrations in TEN patients with a long-lasting increase of total SCFA concentrations when treatment was discontinued. Treatment with *Sb* did not affect the fecal flora in TEN patients, while it decreased Gram-positive anaerobes in HVO.

Sb is known to interact with the intestinal flora. Yeast proteins have been shown to neutralize cholera toxin[22] and to repress *Clostridium difficile* toxins A and B[23]; *Sb* also has an antagonistic effect on the growth of pathogenic micro-organisms in the intestine[24]. In our study, increased SCFA concentrations might explain the reported prevention by *Sb* of TEN-induced diarrhea by an increased water and electrolyte absorption and by a reduction in colonic pH, even though it was not measured in the stool samples from our subjects. A lower pH inhibits the growth of *Clostridium difficile*[25,26], a bacteria that can be acquired in up to 15% of hospitalized EN patients[10]. A viable mixed culture of *Lactobacillus acidophilus* and *Lactobacillus bulgaricus* (1 g t.i.d.) failed to prevent diarrhea in hospital inpatients receiving EN in a randomized controlled study[27]. Unlike *Sb*, lactobacilli taken orally do not increase SCFA fecal levels[28,29], which might explain these negative results. Prebiotics can also increase SCFAs in the colon; in a recently published study, administration for 2 wk of a soluble dietary fiber (galactomannans) in 20 elderly inpatients receiving EN was shown to decrease the water content of the feces and the frequency of daily bowel movements[30]. These results were associated with an increase of fecal SCFA levels, significant for total SCFAs, acetic and propionic acids. Although we confirmed the 40% increase in total SCFAs in the pilot phase of the study that was used to determine the number of subjects, a high variability prevented some important differences from reaching statistical significance. This variability did not seem to be time- or diet-dependent, as it was comparable in volunteers on a free diet and in patients who were on a stable controlled diet. *Sb* recovery in the stools after chronic administration is known to reach a plateau by the 3rd d and to disappear 5 d after treatment is discontinued[31]. The persistence of the effects on total SCFA concentrations 9-10 d after *Sb* discontinuation is suggestive of a prolonged action of the yeast and may indicate that daily treatment may not be necessary to sustain its effects on fecal SCFA concentrations.

known to be associated with a decrease of fecal anaerobes[35]; however, age does not influence fecal SCFA levels[36]; (2) Bacterial concentrations are known to differ depending on the intestinal segment in which samples are taken; nevertheless, analysis of feces is the most feasible technique and provides an accurate information on the intestinal microflora[37]; (3) Analysis of samples rather than 24 h-stools certainly deprives us of some information as TEN is known to modify the volume of daily stools. However, stool collection is often difficult in bed-ridden patients, especially those with neurological disorders. This is the main reason why we chose to perform this study in patients without diarrhea; (4) The correlation between SCFAs and bacterial counts in feces is reportedly poor[38]; (5) Lastly a standard bacterial count, however thorough, may miss some information. Molecular techniques[39] may help progressing in this field.

There is growing evidence regarding the health benefits of probiotics. In EN patients; besides prevention of diarrhea, a recent study reports less post-operative infections in patients receiving EN supplemented with fiber and *Lactobacillus plantarum* 299 than in those receiving parenteral nutrition of fiber-free TEN[40].

In conclusion, this study suggests one possible mechanism of action of the probiotic yeast *Sb*, especially for its preventive effects in enteral nutrition-induced diarrhea. It also supports its use, especially in patients who have other risk factors, such as antibiotic intake.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Christine Alquier and Dr. Marie-Emmanuelle Le Guern for their invaluable help with study design and data handling, and Dr. Philippe Marteau and Dr. Ian Janssen for their advice.

Abstract

AIM: To investigate the effect of chronic inflammatory bowel disease (CIBD) specific risk factors for cholecystolithiasis, as duration and involvement pattern of the disease and prior surgery in patients with Crohn's disease (CD) and ulcerative colitis (UC).

METHODS: A total of 222 patients with CD (135 females, 87 males; average age, 35.8±11.8 years; range 17-81 years) and 88 patients with UC (39 females, 49 males; average age, 37.2±13.6 years; range 16-81 years) underwent clinical and ultrasound examinations. Besides age, sex and degree of obesity, patients' CIBD specific parameters, including duration and extent of disease and prior operations were documented and evaluated statistically using logistic regression.

RESULTS: The overall prevalence of gallbladder stone disease in patients with CD was 13% (n = 30). Only age could be shown to be an independent risk factor (P = 0.014). Compared to a collective representative for the general population in the same geographic region, the prevalence of cholecystolithiasis was higher in all corresponding age groups. Patients with UC showed an overall prevalence of gallbladder stone disease of only 4.6%.

CONCLUSION: Only age but not disease-specific factors such as duration and extent of disease, and prior surgery are independent risk factors for the development of cholecystolithiasis in patients with CIBD.

INTRODUCTION

Besides the other extraintestinal complications[1], there is an increased rate of cholecystolithiasis in patients suffering from chronic inflammatory bowel disease (CIBD)[2-5]. The findings reported for ulcerative colitis (UC) are contradictory[6,7]. In the case of Crohn's disease (CD), the reports published to date are also inconsistent with regard to disease-specific factors, such as the duration of the disease[3,5,7,8], prior surgery (bowel resection)[2-4,7,8] and the pattern of disease involvement[2-6]. However, the incidence rate of gallbladder stone disease in patients with CIBD is often twice as high as in the general population, though the reason for this difference has yet to be satisfactorily explained[2-4].

In the majority of European and North American studies of the prevalence of cholecystolithiasis, there is a preponderance of cholesterol gallstones in the general population. The main identifiable risk factors for developing gallbladder stones include female sex, obesity and increasing age. In Asians, who show a high proportion of pigment gallstones, this predominance of females over males is not seen[9,10].

The pathophysiological explanation for the increased prevalence of gallbladder stones in patients with CD refers to the reduced absorption of bile acids in individuals with extensive involvement of the terminal ileum or following ileal resection[6,8]. The absolute number of bowel resections, the length of resected bowel and postoperative hypomotility of the gallbladder with subsequent formation of sludge and later, stones are currently under discussion as major risk factors for the higher prevalence of cholecystolithiasis in patients with CIBD[2-5].

The present study was to evaluate the importance of both the classical cholecystolithiasis risk factors, such as age, female sex and obesity and the effect of disease-specific parameters such as duration of the disease, pattern of involvement and prior surgery on the prevalence of gallbladder stones in patients with CD and UC.

MATERIALS AND METHODS

Patients

A total of 310 patients with CIBD presenting consecutive to our departmental section on Crohn's disease and ulcerative colitis over a period of approximately one year were screened for inclusion in the present study. The present study was conducted prospectively in accordance with the

principles of the Helsinki Declaration and approved by the Ethics Commission of the Medical Faculty.

Inclusion criteria included histologically confirmed CIBD and no history of cholecystolithiasis prior to first diagnosis of CIBD. Included in the study population were 222 patients with CD (135 females, 87 males; average age, 35.8±11.8 years; range 17-81 years) and 88 patients with UC (39 females, 49 males; average age, 37.2±13.6 years; range 16-81 years). The average period since the first diagnosis was 8.9±7.5 years (range: 0-34 years) in the group with CD and 6.8±5.8 years (range: 0-29 years) in the UC collective.

Risk factors

Besides the classical risk factors (age, female sex, obesity), disease-specific parameters such as time elapsed since the first diagnosis, pattern of disease involvement and prior surgical bowel resection in patients with CIBD were studied. Patients were subdivided into four age groups: ⩽30 years, 31-40 years, 41-50 years and 51 years and above.

For evaluation of obesity, patients were divided into three groups on the basis of their body-mass index (BMI):

Females:		Males:	
Ideal weight:	BMI < 21 kg/m²	Ideal weight:	BMI < 22 kg/m²
Normal weight:	BMI 21 -25 kg/m²	Normal weight:	BMI 22 -26 kg/m²
Overweight:	BMI > 25 kg/m²	Overweight:	BMI > 26 kg/m²

In order to study the effects of the duration of the disease (expressed as time elapsed since the first diagnosis with histological confirmation to the time of examination in the present study), patients were divided into four groups: up to 5 years, 6-10 years, 11-15 years and greater than 15 years. With regard to the parameter extent/pattern of disease, we differentiated in the CD group between patients who underwent or did not undergo surgical bowel resection. The group of patients who underwent resection was further subdivided into those who underwent ileocaecal resection and those who had undergone colectomy we did not further differentiate between partial and total colectomy (Figure 1). Type and number of bowel resections were obtained from the patient's chart. Patients with UC were divided into three subgroups: patients with no active disease, patients with disease involvement up to the left colic flexure, and patients with disease extending beyond the left colic flexure (Figure 2). Because only a few patients in the UC collective underwent either partial or total colectomy, a further differentiation between subcollectives with or without history of prior surgery was not done.

Examination

Patients presented in the morning for ultrasound examination in a fasting state.

The criteria for the diagnosis of cholecystolithiasis were defined as follows: one or more echogenic structures in the gallbladder with dorsal shadow; one or more echogenic structures in the gallbladder without dorsal shadow, which by means of multiplanar visualization or attempted mobilization could be differentiated with certainty from a gallbladder septum, Heister's valve or gallbladder polyps; a structure with significant echogenicity and dorsal shadow in the area of the gallbladder,

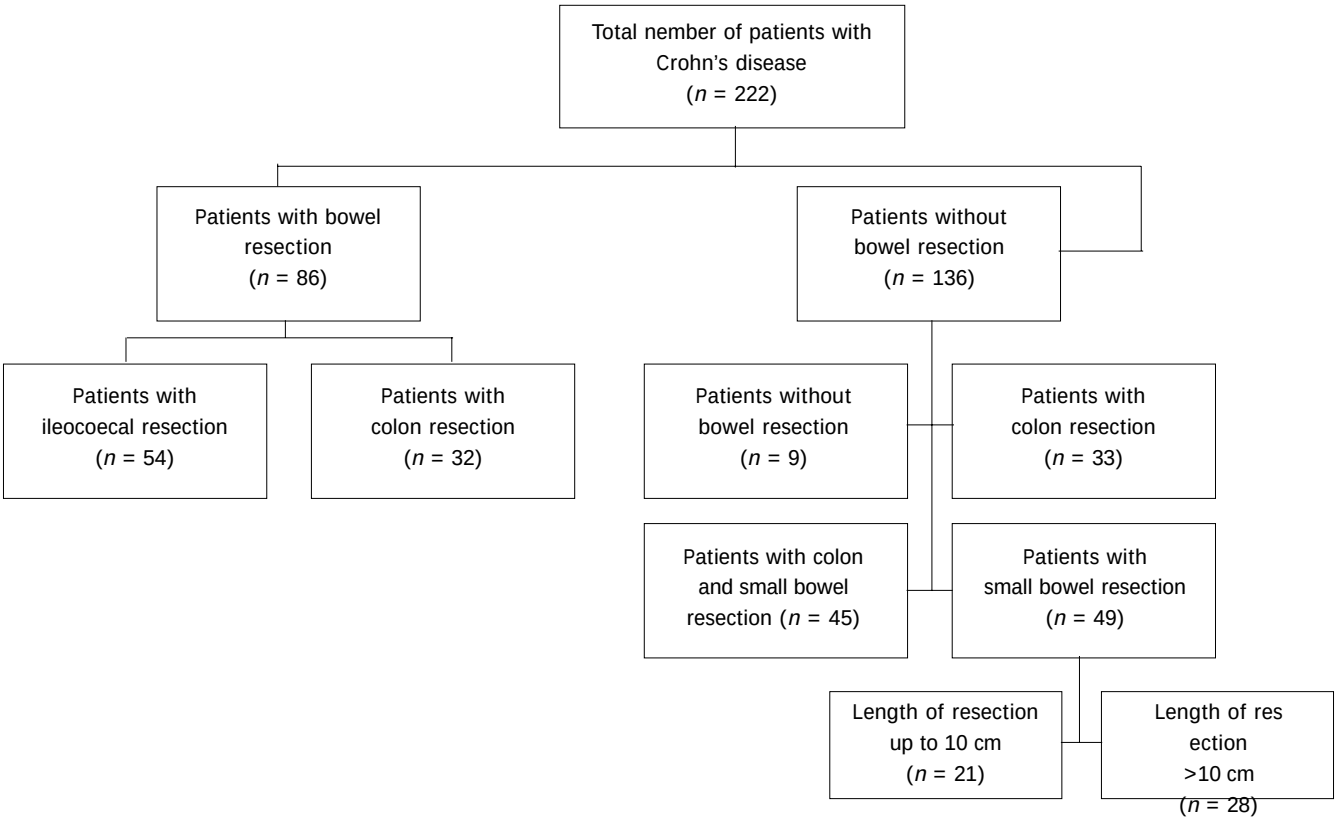

Figure 1 Pattern of involvement and bowel resections in patients with Crohn's disease.

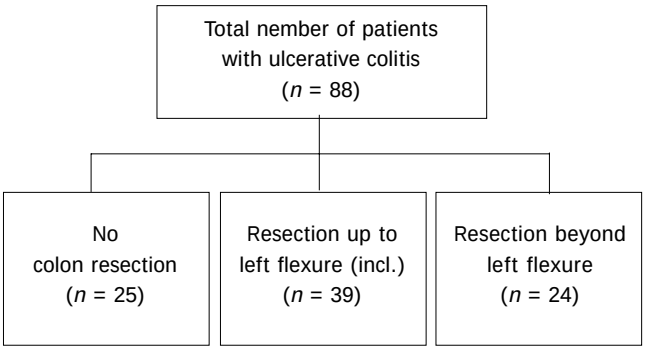

Figure 2 Pattern of involvement and bowel resections in patients with ulcerative colitis.

whose lumen was not definitely visualized; one or more echogenic structures in the gallbladder with or without dorsal shadow in the biliary tract; and no visualized gallbladder lumen in patients with history of prior cholecystectomy and corresponding incision(s) in the right upper abdominal quadrant.

Ultrasound examinations were performed using either the Ultramark 4 Plus or Ultramark 9 HDI with the 3.5- and 5.0-MHz transducer heads (ATL, Bothell, Washington, USA). Examination of the upper abdomen was conducted using the 3.5-MHz transducer head, while examination of the bowel was performed using the 5.0-MHz head. Ultrasound examinations were performed exclusively by two physicians experienced in diagnostic ultrasound of the abdomen. One-time visualization of concrements in the gallbladder based on the above criteria led to the patient's classification as suffering from cholecystolithiasis.

Evaluation of the pattern of disease involvement in the bowel was performed on the basis of sonographic criteria considering thickening of the intestinal wall. Wall thickness greater than 3 mm was considered pathologic. Bowel resection and time elapsed since the first diagnosis were established from the patient's history and chart.

Statistical treatment of the data

All data were first evaluated descriptively. For quantitative parameters, either mean with standard deviation or median with minimum and maximum was documented. While for qualitative parameters, relative and absolute frequencies were calculated.

The evaluation for prevalence in the subgroups and their confidence intervals was performed using a logistic regression model[11]. This model reproduces the influence of potential risk factors (independent variables) for the occurrence of a disease (dichotomous target parameter: here, cholecystolithiasis: yes/no). The importance of the potential risk factor was determined by the likelihood ratio test. By multiple application, several influence parameters could be simultaneously tested in one model and their respective influences were adjusted with regard to the other variables. The respective odds ratios, 95% confidence intervals and *P*-values served to quantify the change in risk of developing cholecystolithiasis due to the given factor. *P*-values between 0.05 and 0.1 were considered to represent trends or tendencies, while $P<0.05$ was considered statistically significant and the factor was classified as a "risk". The classical risk factors such as age, sex and BMI were included in the evaluation. Statistical calculation was performed using the SAS statistics software program (Institute Inc., Cary, NC).

RESULTS

Crohn's Disease

Patients with existing cholecystolithiasis and those with prior cholecystectomy were treated as a single group. Examination revealed gallbladder stones in 18 of the 222 patients with CD, while the other 12 underwent prior cholecystectomy, yielding a gallbladder stone prevalence of 13.5% ($n = 30$). The group of patients ⩽30 years of age numbered 101 subjects, representing nearly half of the collective. In these patients, gallbladder stone prevalence stood at 8% ($n = 8$). Prevalence of gallbladder stone disease increased with advancing age. The highest prevalence was found in the group of patients aged ⩾51 years, and stood at 37% in 10 of 27 subjects. No sex-specific differences were observed (Table 1).

Due to disease-specific implications, overweight patients with CD were rare. Thus, 45% of patients belonged to class I ($n = 100$), 37% to class II ($n = 83$) and only 18% to class III ($n = 39$). Assignment of patients to the various weight classes yielded a gallbladder stone prevalence of 14% ($n = 14$) for class I, 11% ($n = 9$) for class II and 13% ($n = 7$) for class III (Table 2).

Another parameter studied was the duration of CIBD. In the group of patients in whom elapsed time since the first diagnosis was 1-5 years, prevalence was the lowest. While in the other groups, the prevalence stood at 12%, 9%, and 28%, respectively (Table 2).

Isolated disease involvement affecting only the small bowel was observed in 49 patients. Isolated disease involvement affecting only the colon was seen in 33 patients, while the remaining 45 patients suffered from disease involving both the small bowel and colon. Patients who underwent surgical treatment were counted as a separate subgroup. The subgroup of patients with isolated disease affecting either the small intestine or colon only showed prevalence of 6%, each.

Table 1 Prevalence of cholecystolithiasis in relation to age and sex in Crohn's disease patients

Age(yr)	Males		Females		Total	
	n	prevalence (%)	*n*	prevalence (%)	*n*	prevalence (%)
⩽30	39	3	62	11	101	8

Isolated to colon	33	6
Both small bowel and colon involved	45	13
Ileocaecal-/ileal resection	54	22
Partial or total colectomy	32	16
Total	222	13.5

Patients with disease affecting both the small and large bowel, gallbladder stone prevalence stood at 13% (Table 2).

Evaluating for length of affected bowel segments, prevalence of gallbladder stones in a group of 21 patients with segment length up to 10 cm stood at 5% (n = 1) and at 7% in 28 patients with segment length exceeding of 10 cm (n = 2).

Eighty-six of all the patients in the CD group, underwent surgical bowel resection. Fifty-four patients underwent ileocaecal and/or ileum resection, while four other patients underwent ileotransversostomy or ileoascendostomy in addition to ileocaecal resection. Seventeen patients had a history of right hemicolectomy, while the other 10 underwent segmental colectomy. Only one patient underwent total colectomy. The groups with ileocaecal resection and ileum resection were combined in the univariate statistical analysis and compared to the group with colon resections.

In the group of patients who underwent partial resection of the small bowel, prevalence of gallbladder stone disease stood at 22% (12 of 54) and at 16% (5 of 32) in the colectomized group.

A logistic regression model considering patients' age, sex and BMI identified only age as a risk factor for developing gallbladder stone disease. No correlation with the prevalence of gallbladder stones was observed for the parameters such as sex, BMI, disease pattern, duration of the disease and prior intestinal resections (Table 3).

Ulcerative Colitis

Criteria used in the evaluation of the collective of patients with UC corresponded to those applied to CD patients. The overall prevalence of gallbladder stones in the UC group was lower than the comparable prevalence in the CD group. In the smaller subcollective of the UC group, gallbladder stones were observed only in female subjects. Using the same BMI-based weight classes applied to the CD collective, the following distribution according to weight was found in the UC group: 42% (n = 37), ideal weight; 34% (n = 30), normal weight; and 24% (n = 21), overweight. In the group of UC patients at ideal body weight, 5% (n = 2) had gallbladder stones, compared to 7% (n = 2) in those at normal weight and in none of the 21 overweight patients

Table 3 Risk factors for gallbladder stone disease at multiple logistic regression in patients with Crohn's disease

Risk factors	Odds ratio (OR)	95% CI	*P*
Age (yr)	1.048	1.010-1.089	[1]0.0143
Female Sex	1.732	0.704-4.263	0.2321
BMI (kg/m²)	0.937	0.822-1.069	0.3357
Duration of disease	1.045	0.983-1.111	0.1627
Pattern of involvement / bowel resections	0.236	0.025-4.611	0.4970

[1]statistically significant.

Univariate analysis yielded a gallbladder stone prevalence of 2% in patients who had elapsed 1-5 years since the first diagnosis of UC, 10% in the 6-10 year group and 6% in the 11-15 year group. In the group of patients who had passed 16-34 years since the first diagnosis, no disease was complicated by the development of cholecystolithiasis.

In 39 patients, disease did not extend the left colic flexure, while areas of bowel involvement beyond the left colic flexure were observed in 24 patients. Failure to visualize thickening of the intestinal at the time of examination was documented in 25 patients. Prevalence of gallbladder stone disease stood at 3% (n = 1) in patients with disease not extending the left colic flexure, but in 12.5% (n = 3) in those with disease involvement beyond the left colic flexure. We did not find evidence of gallbladder stone disease in any of the patients without documented bowel wall thickening at the time of examination. Unlike the group of patients with CD, the number of patients in the UC group with a history of prior bowel resections was too small for meaningful statistical analysis.

Because of the small number of gallstones (n = 4) identified in the UC group, no subgroup analyses were conducted.

DISCUSSION

The prevalence of gallbladder stones in patients with Crohn's disease in our collective was 13.5%, which is almost twice as high as that (7-8%) for age-matched groups of the general population in the same geographic area[12]. Comparable findings have also been reported from Italy and Sweden[2-4]. On the other hand, patients with ulcerative colitis have a prevalence of 4.6% and are not more frequently affected by cholecystolithiasis. Only Lorusso *et al.*[6], and Jones *et al.*[13], have reported that the prevalence of cholecystolithiasis is higher in UC patients than in the general population. Recent prospective sonographic surveys of larger CD and UC populations have studied the prevalence of cholecystolithiasis in these groups in comparison to a general population and used a multivariate logistic regression model to estimate the relative risk associated with the respective parameters[2-6].

Many, mostly earlier studies are unsuitable for comparison because of selection bias in the reference group, non-correspondence of the survey period or survey in another geographic region[14-17]. Other researchers have not drawn a comparison[7,18].

In the group of patients with CD, the prevalence increased with age from 8% in the group of subjects under 30 years of age to 37% in the 51-and-over age group. The multivariate analysis identified only age as an independent risk factor (OR: 1.048; CI: 1.010-1.089; $P = 0.0143$). It was reported that the prevalence of gallbladder stone increases in higher age groups[5,6] . In our own collective of patients with UC, we were not able to identify any correlation between advancing age and increased prevalence of cholecystolithiasis.

In our initial evaluation, sex was also identified as a univariate risk factor in CD and UC patients, though this did not hold true when the multiple logistic regression model was applied. The actual influence of female sex as a risk factor in the etiology of gallbladder stones is controversial[2,3,6,7,14]. Because of the small number of subjects in most studies, the results should be interpreted with caution.

Multiple analysis failed to demonstrate an increased prevalence of cholecystolithiasis in relation to the degree of obesity in either the CD ($P = 0.3357$) or UC ($P = 0.8397$) groups in our population. Most studies, especially the newer ones, have not included BMI as a risk factor in studies of UC patients[14-16,19]. Lorusso *et al*.[6], and Schölmerich *et al*.[7], have also failed to identify evidence supporting patients' degree of obesity as an independent risk factor contributing to the development of cholecystolithiasis.

Univariate analysis of disease duration suggested a correlation between the increasing length of time elapsed since the first diagnosis of CIBD and the prevalence of gallbladder stone disease. This was not confirmed by multiple logistic regression analysis ($P = 0.1627$) as it has been previously[2,3]. Findings in the literature are contradictory[17,20,21]. Reasons for the divergent findings are to be sought in the characteristics of the disease and in individual disease history of patients. In order to arrive at a relevant and objective evaluation of disease duration as an independent risk factor contributing to increased prevalence of cholecystolithiasis, analysis must include other factors, such as inflammatory activity, pattern of disease involvement, number and type of bowel resections, number and duration of remission phases, as well as type and success of other therapeutic measures. Because of the small number of cases in this subgroup, further statistical evaluation of these influence parameters was not meaningful. Gallstone prevalence was at 22% in patients with partial resection of the small bowel ($n = 12$) and 16% in the group that underwent resection of the colon ($n = 12$). Partial resection of the small bowel could not be identified as an independent risk factor in the multivariate analysis ($P = 0.4970$). Our data contradict those of previous[2,3]. A possible reason for the failure to identify the extent and number of bowel resections as independent risk factors at multivariate analysis may be the smaller number of patients in our collective who underwent ileocecal resection.

Because a separate evaluation of pattern of disease involvement and bowel resection is difficult, we defined these as a single parameter in our multiple logistic regression. The retrospective evaluation of surgical findings further limits the strength of our results. Multiple analysis failed to reveal any correlation between cholecystolithiasis, pattern of disease involvement and prior surgical bowel resection in CD patients ($P = 0.4970$). Earlier radiologic studies have shown an increase in gallbladder stone prevalence in relation to the length of resected bowel segments[4,8,9,16,18]. The disadvantages of these studies, however, refer primarily to the absence of multivariate analysis and a small number of subjects.

Studies showed that the bile acid pool reduces in patients with Crohn's disease[22]. Lapidus *et al*.[23,24], showed that the risk for pigment gallstones increases in patients with ileocoecal resections accompanied with manifestly elevated bilirubin and deoxycholic acid fractions in the bile suggesting that an increased risk for cholesterol gallstones in these patients does not exist.

Recently published data show that patients with Crohn's disease after colectomy or patients with small bowel Crohn's disease have an increased risk for cholesterol stones, and that patients with ileitis are prone to develop mixed, pigment-rich gallstones[25]. These changes after colectomy have not been detected in patients with ulcerative colitis[26].

In conclusion, the findings of the present study have identified only "age" as an independent risk factor for increased prevalence of gallbladder stones. Neither disease duration, pattern of disease involvement nor number or total length of resected bowel segments appear to be risk factors contributing to the development of gallbladder stones in these patients. Prospective multicenter studies should be conducted to assess all potential risk factors including therapy intervals between disease flares, phases of parenteral nutrition and prospective documentation of surgical data.

Abstract

AIM: The treatment of liver disease is severely limited by a shortage of donor livers. In trying to address this growing problem, hepatocellular transplantation (HTx) has received much attention as an alternative to whole organ transplant. However, the expansion of transplanted cells is at low level, and the reconstitution of functional liver tissue is limited by this cellular property. We set up an animal model to better understand cell dose effect and the kinetics of liver repopulation following HTx.

METHODS: Dipeptidyl peptidase IV (DPPIV)-deficient rats treated with retrorsine and subjected to partial hepatectomy were infused with DPPIV-positive hepatocytes. Rats were injected with varying numbers of donor hepatocytes down to 100 cells low, and liver repopulation was examined at different time points up to 20 mo long. Repopulation was assessed by computer-aided quantitative detection.

RESULTS: Transplanted hepatocytes underwent multiple rounds of proliferation and stably repopulated the injured livers after 20 mo and at all cell doses. Transplanted cells divided 14 times within the 3-mo time period following infusion, and the liver repopulation reached a plateau between 3 and 20 mo. Approximately 90% replacement occurred. Donor-derived cells also reconstituted the bile ductules of the recipients.

CONCLUSION: The ability of transplanted hepatocytes to fully reconstitute injured livers strongly supports further investigation into the clinical potential of HTx. Additionally, the observation that transplanted hepatocytes also form components of the biliary system suggests that these cells may have bi-potential property of the stem cells.

INTRODUCTION

In patients with end-stage liver disease, liver transplantation is the only effective treatment, but this is limited by the shortage of potential organs. Cell transplantation (Tx) has the potential to overcome this shortage as well as the high cost and morbidity associated with the whole organ transplant. Isolated hepatocellular transplantation (HTx) was investigated several decades ago as one of the earliest forms of cell transplantation[1] and has come to the stage of clinical therapies in recent years[2,3]. However, transplanted hepatocytes do not seem to proliferate well and reconstitution of liver function is not sufficient in the models used thus far[3,4]. Endogenous hepatocytes greatly outnumbered the transplanted cells and it is conceivable that, if both populations respond equally well to proliferative stimuli, donor cells would never achieve sufficient numbers[5]. Some models allowing for the selective proliferation of transplanted cells have made progress in addressing this problem[6-9]. Disruption of the proliferative capacity of endogenous hepatocytes followed by transplantation is an alternative strategy to achieve these goals. Retrorsine[7,10] or irradiation[9] has been used to inhibit the proliferation of endogenous hepatocytes and allow transplanted hepatocytes to fully repopulate the liver, making the clinical application of HTx more feasible. Application of the prospective therapy may become a reality if answers to the following questions are obtained. How long can donor-derived hepatocytes continue to repopulate the damaged recipient liver? What is the relationship between repopulation efficiency and cell dose of HTx? Will transplanted hepatocytes be able to repopulate other tissues in addition to the liver parenchyma? Moreover, the capability of long-term tissue repopulation[5] should also be addressed in the animal model, with a longer post-transplant period than the life span of liver cells.

We used dipeptidyl peptidase IV (DPPIV) as a genetic marker of transplanted cells in rats treated with retrorsine and subjected to partial hepatectomy (PH). Retrorsine, a DNA-alkylating agent that disrupts cell-cycle progression in hepatocytes, prevented the recipient hepatocytes from proliferating, and, following PH, only transplanted cells proliferated and repopulated the liver[7]. Using this model, we addressed the above questions and discussed the prospects of HTx in clinical application, and also the heterogeneity and the stem cell property of hepatocytes.

MATERIALS AND METHODS

Animals

Male Fischer 344 DPPIV wild-type ($DPPIV^+$) rats used as hepatocyte donors for Tx were purchased from SLC of Japan and female Fischer 344/DuCrj DPPIV-deficient ($DPPIV^-$) recipient rats were purchased from Charles River of Japan. Animals were maintained in daily 12-h cycles of alternating light and darkness. All studies were conducted under protocols approved by the Laboratory Animal Resource Center of University of Tsukuba, Japan.

Retrorsine treatment and partial hepatectomy

Recipients, 4-wk-old Fischer 344 rats, were treated with retrorsine similar to previous descriptions with some modifications[7,11]. Briefly, a retrorsine (Sigma) working solution was prepared in acidified saline with 1 mol/L HCl; this was neutralized with 1 N NaOH and adjusted to a final concentration of 6 mg/mL. The animals received two intraperitoneal injections with 30 mg/kg body weight 2 wk apart. Donor cells were infused either 1 mo or 2 wk following retrorsine treatment. All recipients were subjected to two-thirds surgical PH.

Cell isolation and transplantation

Parenchymal hepatocytes were isolated from normal adult rats (8-10-wk old) using a standard two-step collagenase perfusion method described by Seglen[12]. After perfusion, the cells were centrifuged at 50 g for 1 min and filtered with a nylon mesh to remove aggregated cells and residual tissue. Cell viability was between 80% and 90% as determined by trypan blue dye exclusion. Limiting dilution of the freshly isolated cells was performed from 2×10^6, 1×10^6, 1×10^5, 1×10^4, and 1×10^3 to 1×10^2. Hepatocytes in 0.2 mL Dulbecco's modified Eagle's medium were infused through the portal vein. Two to three animals were used for each time point, and experiments were repeated at least twice. After 1-3 mo, and up to 20 mo following Tx, animals were killed and the livers were sampled.

Histochemical staining

DPPIV histochemical staining was performed as described[7,13]. Sampled rat livers were embedded in optimum cutting temperature compound, frozen in liquid nitrogen and stored at -80 ℃. DPPIV activity was visualized in tissues fixed with chloroform–acetone (1:1, v/v) for 10 min, followed by incubation with glycyl-L-proline-4-methoxy-2-naphthyl-amide (Sigma) substrate for 30 min at room temperature. The counterstaining was performed with hematoxylin.

Quantitative detection

DPPIV-positive areas were captured by Photograb-2500, v1.0 (Fujifilm) through a Nikon Eclipse E800 microscope and analyzed by computer program, WinROOF v3.2 (Mitani Corp.).

To determine the number of hepatocytes per repopulated colony, we considered a colony as a large sphere and a single hepatocyte as a small sphere. If the average radius of one colony in cross-sectional analysis on slide is expressed as R, the overall volume of the colony is $2\pi R^3\sqrt{1.5}$. The number of hepatocytes estimated per colony sphere was calculated by $\text{volume}_{\text{colony-sphere}}/\text{volume}_{\text{hepatocyte}}$. Cell division during Tx for a colony sphere was calculated by $\log_{10}(1.5(R/r)^3\sqrt{1.5})/\log_{10}2$ ($r\approx10$ μm, radius of one hepatocyte).

RESULTS

Kinetics of liver repopulation

The canaliculi enzyme DPPIV is highly expressed in epithelial cells (including hepatocytes) of many organs in rats except in one substrain of inbred Fischer rats. It is a stable and easily distinguishable marker for use in enzyme histochemistry in models of HTx[7,14]. After transplantation, DPPIV-positive cells constituted 14.8±4.2%, 50.7±13.9% and 70.4±9.0% of the total hepatocyte number at 1, 2, and, 3 mo of follow-up, respectively (Figures 1A-C). Twenty months after transplantation, a repopulation rate as high as 95% was observed, with an average rate of 89.8±4.7% (Figure 1D). Histochemical analysis also clearly showed that donor cells proliferated and expanded through recipient liver tissue (Figure 2A and Table 1), and, at the latest time point, occupied nearly the full volume of the recipient liver (Figure

Table 1 Effect of transplant cell dose and time on the efficiency of liver repopulation *in vivo* after HTx

Donor cells were derived from $DPPIV^+$ rats. Recipients were DPPIV-deficient rats treated with retrorsine and two-thirds PH; $DPPIV^+$ cells were visualized by their enzymatic activity after histochemical staining of cryostat sections. The characteristics of repopulation, colony number and colony diameter were analyzed based on $DPPIV^+$ cells. Computer-aided area analysis was used for quantitative detection of repopulation. All of the data presented as mean±SD from three to six individuals in two or three independent experiments. HTx: hepatocellular transplantation; Tx: transplantation; NA: not applicable.

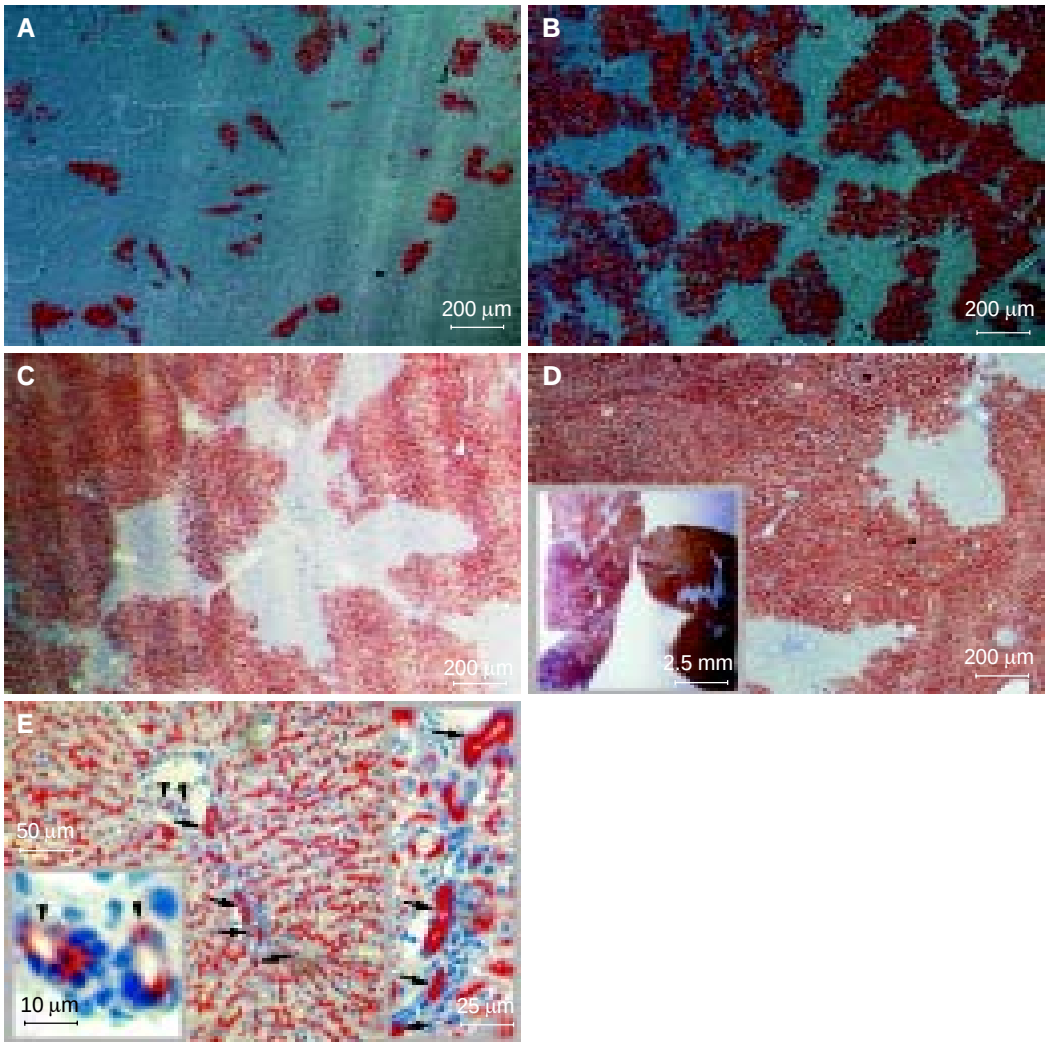

Figure 1 Long-term liver repopulation 1-20 mo after hepatocellular Tx and hepatic epithelial reconstitution from donor hepatocytes. Recipient DPPIV-deficient Fischer rats were treated with retrorsine and subjected to two-thirds PH. DPPIV-positive donor hepatocytes were infused through the portal vein. 2×10^6 donor cells per recipient in A-C and 1×10^6 in D and E. Cryostat sections show DPPIV-positive cells as red-brown after histochemical staining. Data presented as mean±SD from three to six individuals in two or three independent experiments. Tx: transplantation; DPPIV: dipeptidyl peptidase IV. A: 1-mo repopulation: 14.8±4.2%; polarization contrast image; B: 2-mo repopulation: 50.7±13.9%; polarization contrast image; C: 3-mo repopulation: 70.4±9.0% with hematoxylin counterstaining; D: 20-mo repopulation: 89.8±4.7% with hematoxylin counterstaining. The inset box displays the cross-sections of hepatic lobes under stereomicroscopy and E: DPPIV-positive cells not only were expressed in parenchyma but also were found in Hering's canal-like structures (arrow) and interlobular bile duct-like structure (arrowhead) in recipient liver; hematoxylin counterstaining.

1D, inset). Between 3 and 20 mo, the repopulation rate increased by only 20%, suggesting that the phenomena had reached a plateau. Using a similar model, Laconi *et al.*[15], observed a repopulation rate of 81% at 8 mo in female recipients; this is consistent with our results.

The lobular architecture and overall histological appearance of the livers were normal following HTx, and hepatocyte morphology, hepatic plate structure, and the appearance of cells lining the sinuses were normal compared to untreated livers (data not shown). Despite extensive hepatocyte proliferation and the appearance of "nodules" of transplanted cells, no tumors were observed in the liver up to 20 mo after Tx. Additionally, the survival of all four recipients up to 20 mo indicates that no abnormalities incompatible with life develop following transplant.

Colony size and cell replication

Colony size analyses more clearly defined the magnitude of transplanted cell proliferation in recipient animals. Table 1 presents the characteristics and distribution of donor cells following transplantation with varied cell numbers and at different time points after Tx. $DPPIV^+$ colonies expanded linearly between 1 and 3 mo after Tx from 150 to 425 μm in diameter (Figure 2B). The area of recipient livers occupied by donor cells similarly increased over 3 mo.

Hepatocytes are thought to be symmetric, 8 or 12-sided cells[16], but, in order to simplify calculations, we considered a hepatocyte as a sphere and assumed that one colony arose from one hepatocyte. Additionally, we made the assumption that repopulated colonies assumed a grossly spherical shape, and the number of cells occupying these colonies could be calculated by comparing the volume of one cell with the volume of a colony. Based on these assumptions and analyses, transplanted hepatocytes underwent about nine rounds of cell replication after the 1st mo and another three and two rounds in 2nd and 3rd mo, respectively. Donor cell

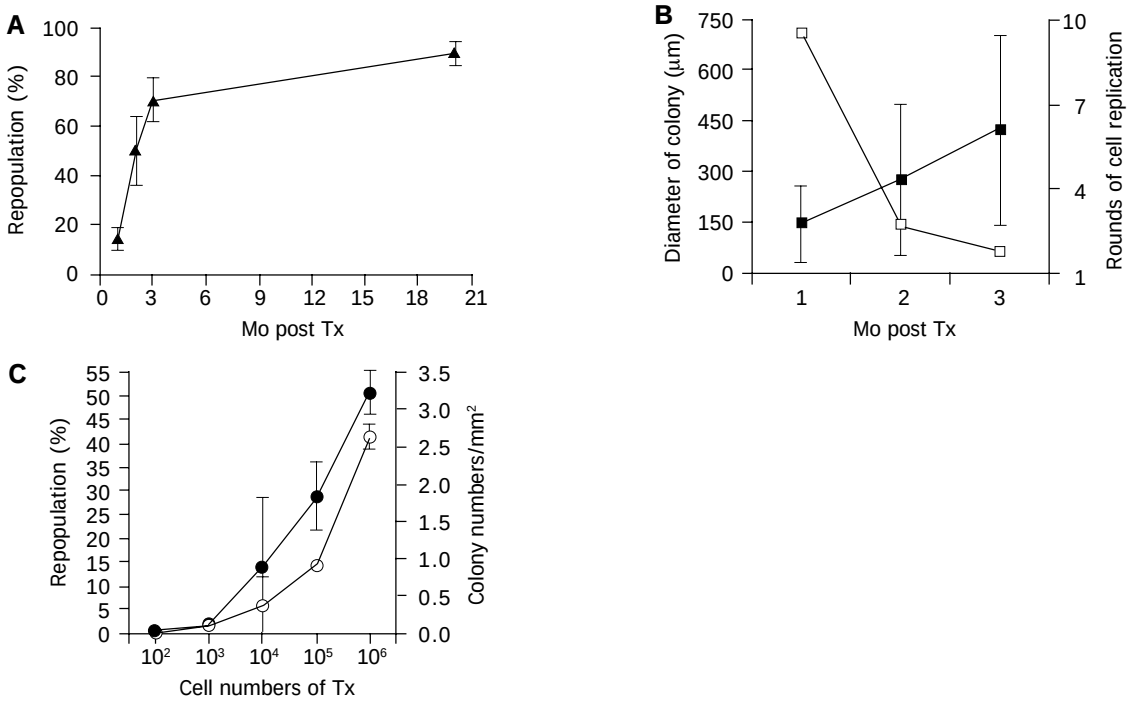

Figure 2 Repopulation kinetics of hepatocellular Tx. DPPIV$^+$ donor hepatocytes were isolated and infused into DPPIV-deficient rats through the portal vein. The visualized DPPIV$^+$ cells in recipient were processed by a computer-aided analysis. Data are presented as mean±SD from three to six individuals in two or three independent experiments. Tx: transplantation; DPPIV: dipeptidyl peptidase IV. A: Kinetics of liver repopulation. Transplanted cell numbers into 1-3 mo and 20 mo were 2×10^6 and 1×10^6, respectively. The repopulation rate increased dramatically over 3 mo and reached a plateau at 20 mo; B: Kinetics of colony size and cell replication. Transplanted cell numbers into 1-2 mo and 3 mo were 2×10^6 and 1×10^6, respectively. The estimation technique of cell replication rounds is explained in Results. The average colony size from donor hepatocytes in the 3 mo after Tx are filled squares and the estimated number of rounds of cell replication are open squares and C: Cell-dose effect on liver repopulation and colony numbers. All samples collected at 3 mo after Tx and the repopulation rate (filled circles) and colony numbers (open circles) showed a similar trend.

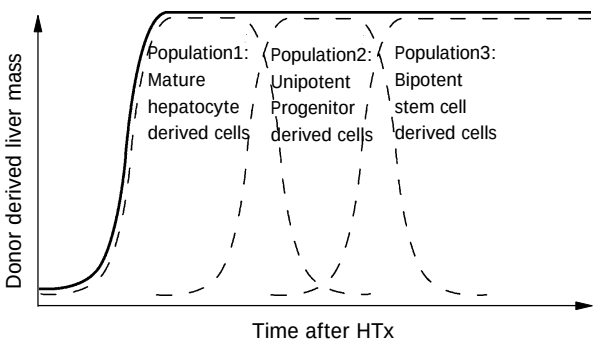

Figure 3 Schematic diagram of long-term repopulation after HTx. Different cell populations may be required for different phases of liver regeneration/repopulation. The solid lines express the repopulation of donor-derived cells in the liver and the broken lines are the repopulation from the possible contributors. This assumes a heterogeneous population of transplanted hepatocytes. HTx: hepatocellular transplantation.

division was high only in the 1st mo, and it dramatically decreased over the following period (Figure 2B), but replication never stopped although it slowed down to very low level.

Effect of cell dose on liver repopulation

The ability of different numbers of transplanted cells to repopulate the liver is unknown, despite the importance of this information for stem cell biology and the clinical application of HTx. As seen in Table 1 and Figure 2C, transplantation of 10^2-10^6 led to liver repopulation rates from 0.6% up to 51% 3 mo after transplant, and the repopulated colonies reached 0.01-2.64/mm^2 in recipient livers. Effective repopulation occurred even in the 100-cell group. Therefore, liver repopulation for no more than 3 mo does not seem to depend on an infrequent cell fraction, but hepatocytes in general are able to form colonies following transplantation.

DPPIV-positive cholangiocytes in recipient livers

DPPIV is expressed in both hepatocytes and bile duct epithelial cells, in a characteristic bile canalicular distribution and a diffuse cytoplasmic pattern, respectively[7,17,18]. Twenty months after transplant with one million hepatocytes, interlobular bile duct-like cells and Hering's canal-like cells also expressed the donor-derived genetic marker, DPPIV (Figure 1E). To our knowledge, this is the first report of bile duct differentiation of transplanted hepatocytes. This finding contrasts with the widely accepted view that hepatocytes are uni-potential following transplant[19].

DISCUSSION

In contrast to fully differentiated cells in adult mammalian tissues, hepatocytes possess an enormous proliferative capacity and are capable of replacing the entire liver mass under some circumstances. In the normal resting liver, the hepatocyte turnover rate at any given time is about 1 in 20 000-40 000 cells, and normal liver tissue is replaced over the course of 1 year[20]. If transplanted hepatocytes did not undergo cell

division or the division did not last for a sufficient duration of time, few donor cells would have remained at the 20-mo time point. However, recipient livers were almost exclusively comprised of donor cells at 20 mo after transplant (Figure 1D, inset). The tissue renewal by donor-derived hepatocytes occurs multiple times in the recipient liver in more than 1-year long-term repopulation. The present findings demonstrate that the 'long-term tissue repopulation' characteristics defined for stem cells[5] are expressed by adult hepatocytes as well. The present study markedly differs from previous reports[7,14,15] in having the post-transplantation period longer than the life span of liver cells, and it also takes into account the cell-dose effect. The extremely long period of observation was necessary because it facilitated analysis of cell kinetics of long-lived cells to trace the transplanted cells and to show whether they possess the stem cell properties or not.

To differentiate and colonize, a wide range of tissues to reconstitute them *in vivo* is another important property of stem cells. In the present study, bi-potential capability of donor-derived cells displayed an interesting aspect of tissue reconstitution. Hepatocytes are thought to be "functional" or "committed" progenitors[19], but 20 mo after transplant, cholangiocytes (interlobular bile duct-like cells and Hering's canal-like cells) expressed the donor cell marker (Figure 1E). It indicates that the bi-potential stem cells, however, existed in donor-derived cells. We had not previously observed donor-derived cholangiocytes in other no longer than 6-mo old Tx groups. Why is the regeneration of biliary system so rare to be observed? One possible answer is that a minor proportion of donor-derived bi-potential cells spend a long time to differentiate and competitively reconstitute the system in the recipient. The low frequent appearance may predict and represent an important inherent nature of hepatic stem cells.

Hepatocytes may be capable of only one or two rounds of cell division when responding to cell loss under normal physiological conditions[21,22], but we observed at least 14 rounds of replication in the 3-mo time period following transplantation. Various physiological needs may stimulate a variety of responses from different populations of hepatocytes. It is possible that the transplanted cells were not a homogenous population of hepatocytes. This could explain the ability of the donor cells to proliferate to a greater extent than previously thought as well as the generation of cholangiocytes. Indeed, adult hepatocytes exhibit heterogeneous proliferative potential *in vitro*[23]. The potential complexity of the liver cells populations is outlined in Figure 3. Liver tissue may be comprised of a large number of mature hepatocytes that rapidly respond to physiological cell loss and tissue injury (population 1) for a short time, a small number of uni-potential progenitors that rapidly replicate in response to liver injury for a limited time period (population 2), and rare bi-potential stem cells capable of self-renewal that slowly respond to severe liver injury for a long time (population 3). Further studies with some other approaches, such as, flow-cytometric cell sorting and *in vitro* colony assay[24,25] are clearly needed to investigate this hypothesis.

While the biological phenomena underlying our observations are not very clear, the therapeutic potential of hepatocyte transplant is very clear. A small number of transplanted cells efficiently and stably repopulated injured rat livers. With the expansion of waiting lists for orthotopic liver transplant growing, the availability of donor cells makes HTx even more attractive. Among the potential applications of HTx, supply metabolic support in acute or chronic liver failure and definitive treatment of inherited metabolic disorders are included. At the very least, HTx could be used as a bridge therapy to prolong the lives and function of patients awaiting transplants. It is reasonable to assume that mechanism that controls regeneration may be fairly similar among various species, and the knowledge obtained from researches of liver regeneration in the animal model is applicable to the human liver. Our study may be a guide for initial investigations of HTx in human. For example, in our animal model, the cell infusion ratio of donor cells to recipient liver cells was about 1/200 ($2\times10^6/4\times10^8$), and we achieved 50% and 70% repopulation rates 2 and 3 mo after Tx. Human liver tissue is thought to weigh 1 500 *g* with 2.5×10^{11} parenchymal cells. Extrapolating from our data, approximately 1.25×10^9 cells would be used for human HTx, and if 10% of isolated hepatocytes could be collected from a liver (2.5×10^{10}cells), a single liver could be used for 20 HTx. The low cost, high preservability and availability of sources could make HTx an extremely promising treatment for end-stage liver disease.

Taken together, the long-term repopulation potential, high replacement rate and full tissue reconstitution following HTx in our model further strengthens the therapeutic potential of this technique. Additionally, our observations raise interesting possibilities as to the composition and proliferation of hepatocyte populations as well as the hepatic stem cell nature.

Abstract

AIM: To establish an association between the serum leptin levels and the development of gallstone disease (GD).

METHODS: We carried out a non-matched case-controlled study in a university hospital in Mexico City. Two hundred and eighty-seven subjects were included: 97 cases with gallstones and 190 controls. Body mass index (BMI), fasting plasma leptin, insulin, serum lipid, and lipoprotein levels were measured. Insulin resistance was calculated by homeostasis model assessment (HOMA-IR). Unconditional logistic regression analysis (univariate and multivariate) stratified by BMI was used to calculate the risk of GD.

RESULTS: The multivariate conditional regression analysis revealed a model for those patients with BMI <30. The selected variables in the model were HOMA-IR index with OR = 1.31, P = 0.02 and leptin higher than median with OR = 2.11, P = 0.05. In the stratum of BMI ⩾30, we did not find a useful model.

CONCLUSION: We concluded that insulin resistance and the development of GD appears to be associated with serum leptin levels in subjects with overweight, but not in obese subjects with similar metabolic profiles.

INTRODUCTION

The prevalence of obesity has been increasing progressively worldwide, and is closely associated with the increased morbidity caused by several of the most common diseases in the Western world, including diabetes, hypertension, cardiovascular disease, cancer, and gallstone disease (GD)[1]. Obesity is one of the main risk factors for cholesterol gallstone formation and has been associated with the supersaturation of bile with cholesterol as a result of the increased hepatic secretion of this sterol[2-5].

On the other hand, leptin, the product of the *ob* gene, is an adipose-tissue-derived hormone considered to regulate the limitation of food intake and increased energy expenditure, and thus adiposity[6]. These findings are similar in human beings mainly failure to produce adequate amounts of leptin, or resistance to its central action, which may result in the development of obesity[7].

To identify a link between leptin and the effects of obesity on gallstone formation, Duggirala *et al*.[8], in a previous study explored the role of leptin as an indicator of adiposity and its relation to GD in a Mexican-American population. They reported that leptin levels correlated significantly with the incidence of GD in both sexes, especially in women. Ruhl and Everhart[9] evaluated the possibility that serum leptin levels are better predictors of GD than the body mass index (BMI). They found that leptin concentrations were associated with GD in both sexes (P<0.001), but this association disappeared after controlling BMI and waist-to-hip circumference in both women (P = 0.29) and men (P = 0.65). They concluded that serum leptin concentrations are not better predictors of GD than anthropometry.

Mendez-Sanchez *et al*.[10], demonstrated a significant and positive correlation between plasma leptin levels and biliary cholesterol saturation in a group of obese subjects. This correlation emerged following a modest degree of weight loss. We believe that one additional mechanism with obesity and high risk for GD is serum leptin level and insulin resistance. The aim of the present study was to find whether there is an association between serum leptin levels and the development of GD.

MATERIALS AND METHODS

Populations and sample

This study was carried out at the check-up unit of the Diagnostic Clinic at the Medica Sur Clinic and Foundation. This hospital provides care mainly for middle- and high-income individuals from Mexico City and other metropolitan Mexican areas. The study was approved by the Human Subjects Committee at The Medica Sur Clinic and Foundation as conforming to the ethical guidelines of the 1975 Declaration of Helsinki, and written informed consent was obtained from all participants before entry. A total of 287 subjects were included in this study: 97 cases with gallstones (42 women and 55 men) and 190 controls (79 women and 111 men). Ages were similar in both groups (52.9±11.8 and 52.7±11.7 years). GD cases and controls were a series of consecutive asymptomatic subjects who were referred to the unit by their companies as an annual requirement, but not for symptomatic disease. Abdominal ultrasound was performed on all subjects using a Sonoline Elegra instrument (Siemens Medical System, Germany) with a 3.5 MHz transducer. Ultrasound diagnosis of GD was assessed by the presence of strong intraluminal echoes that were gravity-dependent or attenuated ultrasound transmission (acoustic shadowing). At the completion of each patient's participation in the study, all ultrasonographic studies were evaluated by the same radiologist. No discrepancies were found between the results of the first and second evaluations ($\kappa = 0.93$).

Physical examination

Body weight was measured, in light clothing and without shoes, to the nearest 0.10 kg. Height was measured to the nearest 0.5 cm. BMI was calculated as weight in kilograms divided by height in square meters.

Analytical techniques

Plasma leptin levels were determined by radioimmunoassay using a human leptin RIA kit (Linco Research, St. Charles, MO, USA). Both the intra- and inter-assay coefficients of variation were less than 5%. Insulin levels were measured using an immunoenzymometric assay (MEIA; Abbott Diagnostics), with inter- and intra-assay coefficients of variation less than 3%. Plasma glucose in the fasting state was measured in duplicate with an automated analyzer. The coefficient of variation for a single determination was 1.5%. Cholesterol, HDL-cholesterol, and triglycerides were measured by enzymatic colorimetric methods, using CHOL, HDL-C plus (second generation) and TG assays (Roche Diagnostics Co., Indianapolis, IN, USA). Low-density lipoprotein (LDL) cholesterol concentrations were calculated using the Friedewald formula[11]. Non-HDL cholesterol was calculated as total cholesterol minus HDL cholesterol, as surrogate in cases where LDL cholesterol was inaccurate[12]. Insulin resistance was calculated by means of the homeostasis model assessment (HOMA-IR). HOMA-IR = [fasting insulin (μU/mL) ·fasting glucose (mmol/L)]/22.5, high index of insulin resistance a value >2.5[13].

Statistical analysis

We examined the relationship between anthropometric measures and serum leptin and concentrations by first comparing means of these variables in persons with and without GD. To further study these relations while controlling the effects of covariates related to GD, we used logistic regression for the univariated and multivariated analysis stratifying by BMI (EGRET: Epidemiological Graphics, Estimation, and Testing Package v 1.02.10. Cytel Software Corporation, USA, 1997). Multivariate analyses excluded persons with missing values for any factor were included in the model. The comparison of single frequencies and crossing variables, χ^2 test, *F* exact test, and Mann-Whitney U, and clustering by using SPSS/PC 10.0 program (Chicago, IL, USA, 1999). $P<0.05$ was considered to indicate statistical significance.

RESULTS

We collected information from 97 cases and 190 matched controls (control/patient ratio of 1.96). Cases and their respective controls did not differ in age or lipid values (Table 1). Patients and controls tended to differ in BMI values (28.2 *vs* 27, $P = 0.12$). The index for resistance to insulin (HOMA-IR) was higher among patients than controls (2.9 *vs* 2.4, $P = 0.04$, Table 1).

We stratified subjects according to overweight or obesity, with a BMI value of 30 as the cut-off point, according to World Health Organization[14]. We observed a statistically

Table 1 Comparison of variables between cases and controls

Variable	Cases *n* = 97					Controls *n* = 190					*P*[1]

significant difference in rate between cases and controls according to the tercile distribution in those patients who were not obese (34.7% *vs* 22.9%, $P = 0.04$, Table 2). In the same stratum (BMI<30), cases had a higher prevalence of insulin resistance, according to HOMA-IR, than controls, with borderline statistical significance (40.3% *vs* 27.5%, $P = 0.07$, Table 2). In a multivariate model, adjusted for BMI and insulin levels did not change the association related with leptin levels (data not shown). In the stratum of obese patients (BMI≥30), we observed no statistical differences between control and patient variables, except for hypertriglyceridemia, which had a higher incidence among cases than among controls.

Because of the matched design of the investigation, we analyzed the data under conditional logistic regression analyses. With univariate conditional logistic regression, we observed a higher probability of GD in those patients with BMI <30 according to HOMA-IR index value (OR = 1.33; 95%CI 1.06-1.68, $P = 0.02$) and to both leptin levels (by median or tercile distribution with an OR=2.25; 95%CI 1.08-4.69, $P = 0.03$ and OR = 1.67; 95%CI 1.03-2.69, $P = 0.04$, respectively; Table 3). In the stratum of obese patients, we identified a lower probability of GD associated with high levels of leptin, with both median and tercile distributions (OR = 0.12; 95%CI 0.01-1.0, $P = 0.05$ and OR = 0.14; 95%CI 0.02-0.98, $P = 0.05$, respectively; Table 3). Other variables were not significantly associated.

Multivariate conditional regression analysis (92 cases and 188 controls) identified a correlation for those patients with BMI <30. The selected variables in the model were HOMA-IR with OR = 1.31; 95%CI 1.04-1.66, $P = 0.02$ and

DISCUSSION

This study was designed to examine the role of serum leptin levels as a risk factor for developing GD. We observed that plasma leptin levels and the HOMA-IR are highly associated in the group of subjects with BMI <30, because they increase the probability of GD, but that the same plasma leptin levels are associated with a lower probability of GD in the group of subjects with BMI >30.

How can we explain these findings? Bile is the route by which cholesterol is eliminated from the body, and reverse cholesterol transport is the metabolic pathway by which cholesterol is moved from peripheral tissues to the liver for biliary secretion[15,16]. Van Patten *et al.*[17], reported that obesity in leptin-receptor-defective Zucker (*fa/fa*) rats is associated with decreased biliary cholesterol secretion due to the uncoupling of cholesterol and phospholipid from bile-salt secretion. High-dose leptin partially normalized cholesterol secretion in these obese rats without altering lipid composition, implying that both the chronic effects of obesity and a relative resistance to leptin contributed to the impaired biliary cholesterol elimination. From these data, it is clear that leptin plays a role in the elimination of cholesterol from the body.

In the present study, the question arises: Why is BMI important in the association between serum leptin levels and GD, especially in subjects with BMI <30. It has been suggested that in human obesity, leptin levels adapt to changes in energy balance. During fasting[17] or weight loss[18], leptin concentrations decrease, whereas they increase during overfeeding or weight gain. Obese human beings have high leptin concentrations[18]. Leptin mRNA expression in fat cells correlates significantly with body fat mass[18]. Hyperleptinemia is thought to be indicative of "leptin resistance", and may play a role in the pathogenesis of obesity[18,19]. We believe that leptin levels are important risk factors for GD, before "leptin resistance" is apparent, i.e., when the leptin levels are not as high as those observed in obese subjects. In accordance with this hypothesis, Hyogo *et al.*[20], showed that weight loss in chow-fed C57BL/6J *ob/ob* mice induced by chronic intraperitoneal administration of high-dose leptin (10 μg/g per d) is associated with cholesterol gallstone formation.

A 25% reduction in body weight over a 28-d period was sufficient to produce cholesterol crystals and gallstones in the gallbladder bile of all lithogenic-diet-fed mice treated with low-dose leptin. Nevertheless, neither cholesterol crystals nor stones were observed in any chow-fed mouse. These findings indicate that, whereas leptin replacement is required for cholesterol cholelithiasis in *ob/ob* mice, a lithogenic diet accelerates this process[21].

The other variable associated with GD in the present study was the HOMA-IR. Recently, we have found a strong relationship between GD and metabolic syndrome, of which the cardinal feature is hyperinsulinemia[22]. In fact, hyperinsulinemia has been proposed as a risk factor for GD, and some studies support this hypothesis. For example, Scragg *et al.*[23], found that mean fasting insulin levels to be higher in patients of both sexes with GD, independent of age and triglyceride levels. Laakso *et al.*[24], also found that subjects with GD had significantly higher levels of insulin than controls. Haffner *et al.*[25], in the San Antonio Heart Study, observed increasing hyperinsulinemia and a high incidence of GD in both Mexican-Americans and non-Hispanic whites. In Mexico, Gonzalez Villalpando *et al.*[26], found higher fasting insulin levels in women with GD than in controls, but no such relationship was observed in men. Ruhl and Everhart[27], in an well-presented study, have confirmed this association of GD with higher fasting serum insulin and C-peptide levels in women. The association was independent of fasting glucose levels and other covariates related to GD.

Increasing cholesterol saturation of the bile and decreasing gallbladder motility are two possible mechanisms by which insulin plays a role in gallstone formation. At present, these are considered very important in the pathogenesis of gallstones. It has also been suggested that high concentrations of insulin increase the activity of 3-hydroxy-3-methylglutaryl coenzyme A reductase[28,29], the rate-limiting enzyme in hepatic synthesis of new cholesterol, or by activating LDL receptors, resulting in greater hepatic uptake of LDL cholesterol[30]. By inhibiting basal and cholecystokinin-stimulated gallbladder motility, insulin might also increase the risk of developing gallstones through an effect on motility[31].

There are several unresolved issues concerning the biological effects of leptin and its relationship to GD about the importance of motility[32], secretion or both. Tran *et al.*[33,34], included other factors in the link between obesity and gallstone formation, particularly an impaired response to neurotransmitters (mainly neuropeptide Y). The present work shows that there is probably a threshold to the biological activity of leptin, and the differences between our experimental groups indicate that leptin has a "lithogenic effect" in selected overweight subjects. Wauters *et al.*[35], analyzed how polymorphisms in the leptin-receptor gene influence fat topography and levels of abdominal fat in human beings, providing further evidence for the wide response spectrum to several grades of obesity and several grades of leptin-resistance. Similar data on the effects of leptin on lipid metabolism demonstrate differences between sexes and grades of obesity[36], including evidence for the independent effects of leptin on lipid metabolism[37]. These complex data were observed in both healthy subjects and disease models[38,39]. Recently, it was observed that besides fat mass and gender, which are the main determinants of leptin levels in type 2 diabetic and healthy subjects, insulin

secretion and the degree of insulin resistance also contribute significantly to leptin levels[40]. In the present study, there were more insulin-resistant subjects in the BMI >30 group, and these data indicate a correspondence between greater obesity, higher resistance, and a lack of biological effects (in this case GD). This study contribute to show one side of a wide clinical response of a metabolic disturbance, in subjects with similar grade of insulin resistance, but different phenotype (BMI) we observe an unexpected response of leptin effect. However, this is only a hypothesis drawn from the data on the relationship between leptin and insulin resistance[41].

Due to the sample analyzed (mainly employees) we loose randomization effect, and could not reflect general population behavior. By otherwise a lack of metabolic difference between cases and controls (HOMA-IR), could explain contradictory data in obese group; however, this unexpected finding could represent similar leptin response even do differences in body composition.

In conclusion, the results of the present study show that, as with insulin resistance, the development of GD appears to be associated with serum leptin levels in overweight subjects.

ACKOWLEDGEMENTS

The authors thank to Dr. Antonio R. Villa for his kind assistance in the statistical analysis.

Abstract

AIM: Before pegylated interferon alpha (IFN) was introduced for the therapy of chronic hepatitis C virus (HCV)-induced hepatitis, conventional thrice weekly IFN therapy was supplemented by ribavirin. Also, at that time, higher and more frequent doses of IFN were expected to be more effective than the standard regimen of 3 MU thrice weekly. As ribavirin significantly increases side effects and negatively influences the quality of life particularly in young patients, we started a prospective non-randomized study with a daily IFN-2a monotherapy as an initial treatment for chronic hepatitis C.

METHODS: Forty-six consecutive chronic HCV-infected patients received 3 MU IFN-2a per day as an initial treatment. Patients with genotype 2 or 3 (n = 12) were treated for 24 wk, and patients with genotypes other than 2 or 3 (n = 34) for 48 wk. Treatment outcome was followed up for 48 wk after the end of treatment (EOT). Virological response was defined as the absence of detectable serum HCV-RNA. Patients without virological response at 12 wk after the start of treatment received low-dose ribavirin (10 mg(kg • d)) additionally.

RESULTS: During treatment, three genotype 3 patients were excluded from the study due to incompliance. The remaining patients (n = 9) infected with genotype 2 or 3 showed an initial virological response rate of 100%. Six patients (66.7%) were still found to be virus-free at the end of follow-up period. In these patients, initial virological response was evident already after 2 wk of treatment. In contrast, initial virological response occurred first after 4 wk of treatment in the three patients who relapsed (33.3%). In comparison, patients infected with genotypes other than 2 or 3 (n = 34) showed an initial virological response rate of only 23.5% (n = 8), and even in combination with ribavirin a sustained virological response (SVR) rate of only 11.8% (n = 4) could be achieved.

CONCLUSION: In chronic HCV-infected patients with genotype 2 or 3, a SVR can be expected after 24 wk of daily dose IFN-2a treatment without ribavirin, if initial virological response develops early. This finding is worth to be confirmed in a prospective randomized study with pegylated IFN.

INTRODUCTION

The hepatitis C virus (HCV) is the most common infectious agent associated with post-transfusion and community-acquired non-A-non-B hepatitis as well as cryptogenic cirrhosis[1,2]. Most of the patients with acute HCV infection will develop chronic liver disease[2]. In studies with 10-20 years of follow-up, cirrhosis secondary to chronic HCV infection develops in 20-30%[2,3] and is the most common indication for liver transplantation worldwide[4]. Also, patients with HCV-associated cirrhosis have an increased risk for the development of hepatocellular carcinoma, which is estimated to be between 1% and 4% per year [5].

Even before the discovery of HCV, introduction of interferon alpha (IFN) for the treatment of non-A-non-B hepatitis was an outstanding revolution in antiviral therapy in 1986[6]. Initial therapeutic regimen consisted of 3 MU IFN thrice weekly (TIW) for 6 mo. The response rate at the end of treatment (EOT) resulted in 29-32%[7,8], but the sustained virological response (SVR) rate was only about 6-18%[7-10]. Apart from extending the duration of IFN monotherapy to 12 or 18 mo, higher doses of IFN TIW failed to significantly increase virologic response rates at EOT and SVR rates (range 13-20%) in most studies[7,11,12]. Combination of IFN 3 MU TIW and ribavirin 1 000-1 200 mg/d for 6 mo was shown to increase the response rate at EOT up to 53-57% and SVR rates up to 31-35%[7,12]. With the combination of IFN 3 MU TIW and ribavirin 1 000-1 200 mg/d for 12 mo, the response rates at EOT of 50-54% and SVR rates of 38-47% could be obtained[7,12-14]. However, ribavirin can increase side effects (e.g., hemolysis and renal dysfunction) and has been shown to have teratogenic

and/or embryocidal effects[15]. Many HCV-infected patients are either women at child bearing age or fertile men. Thus, addition of ribavirin to IFN should be avoided when possible. One of the reasons for marginal response to IFN is its short half-life of approximately 8 h[16], which leads to wide fluctuations in IFN plasma concentrations during treatment. Among patients treated with IFN TIW, an intermittent increase in viral load can be observed on treatment-free days[17]. Daily dose IFN therapy might sustain more stable IFN plasma concentrations, thus maintaining a better antiviral effect on HCV. Viral kinetic studies suggest that higher and more frequent doses of IFN may improve the initial response rate and may be more effective in HCV clearance[18,19]. Therefore, we evaluated the efficacy, safety, and tolerability of initial daily IFN monotherapy in naive patients with chronic HCV-infection. This monocentric non-randomized study was started before pegylated IFN was introduced into the market.

MATERIALS AND METHODS

Selection of patients

Patients who were 18 years or older, with compensated chronic HCV infection, not previously treated with IFN or ribavirin were eligible for the study. Eligible patients had persistent elevations of serum alanine aminotransferase (ALT) and/or aspartate aminotransferase (AST) activities for at least 6 mo before the start of treatment, a positive third-generation anti-HCV test using an immunoblot procedure (CHIRON RIBA HCV 3.0 SIA, Ortho Diagnostic Systems Inc., Raritan, USA), and positive serum HCV RNA by reverse transcriptase-polymerase chain reaction (RT-PCR). Patients with decompensated liver disease, serum elevated alpha-fetoprotein concentration, previous organ transplantation, severe cardiac or chronic pulmonary disease, neoplastic disease, seizure disease, hemoglobinopathies, poorly controlled diabetes, severe retinopathy, autoimmune disorders, thyroid gland alterations, active alcohol or injection drug abuse, history of major psychiatric disease, pregnancy, unwillingness to practice contraception, significant anemia (hemoglobin <120 g/L), leukocytopenia (<3 000/μL) or thrombocytopenia (<50 000/μL) were not included. Active hepatitis A virus, human immunodeficiency virus, hepatitis B virus, cytomegalovirus or Ebstein-Barr virus infections were excluded by conventional laboratory tests. Findings consistent with a diagnosis of chronic hepatitis C were shown on liver biopsy during the preceding year, as determined by a single pathologist. The study was approved by the local ethics committee and conformed to the ethical guidelines of the 1975 Declaration of Helsinki. Informed consent was obtained from all treated patients.

Detection of serum HCV-specific RNA by RT-PCR

RNA was extracted from serum samples (140 μL) using the QIAamp Viral RNA Kit (Qiagen, Hilden, Germany) according to the manufacturer's protocol. One-fifth of the extracted material from serum was subjected to a nested RT-PCR procedure essentially as described[20].

Quantification of serum HCV-specific RNA

The amount of serum HCV-RNA was determined by using the AmpliSensor System according to the instruction of the manufacturer (AmpliSensor System, BAG, Lich, Germany).

Determination of HCV genotypes

HCV genotyping was performed using the Innolipa HCV II line probe assay (Innogenetics, Ghent, Belgium).

Treatment

Patients received subcutaneously 3 MU IFN-2a (Roferon-A, F.Hoffmann-La Roche, Basel, Switzerland) daily. Patients with genotype 2 or 3 were treated for 24 wk, and patients with genotypes other than 2 or 3 for 48 wk. Follow-up period was 48 wk after EOT. Virological response was defined as non-detectability of serum HCV-RNA. Patients who had no virological response after 12 wk of treatment received ribavirin (10 mg/kg BW/day) additionally as described previously[21].

Monitoring

All patients were assessed in an outpatient setting for safety, tolerance, and efficacy at the end of weeks 2, 4, 6, 8, and every further 4th wk during treatment. When treatment was completed, patients were assessed at wk 4, 12, and 24, 36 and 48. Clinical examination, total blood cell counts and routine biochemical tests were conducted at that time. Serum was analyzed for the presence of HCV-RNA by RT-PCR before treatment, and at wk 2, 4, 12, 24, 36, and 48 during treatment for patients treated for 48 weeks and at wk 2, 4, 12, and 24 for patients treated 24 wk. During follow-up period, serum was tested for the presence of HCV-RNA at wk 4, 12, 24, 36 and 48.

RESULTS

Characteristics of the patients

Forty-six consecutive chronic HCV-infected patients (16 female, 30 male, mean age 42 years, ranging from 21 to 67 years) were enrolled. The cause for HCV transmission could be identified as blood transfusions in 17.4% (n = 8) and injection drug use in 39.1% (n = 18). Twenty patients (43.5%) had other or unknown transmission of HCV infection. Before treatment, AST levels were elevated with a mean of 27.9 U/L ranging from 12 to 67 U/L, ALT levels with a mean of 51.5 U/L ranging from 16 to 142 U/L, and gamma glutamyl transpeptidase (gamma-GT) levels with a mean of 34.5 U/L ranging from 5 to 288 U/L. HCV genotypes were classified in 12 patients (26%) as 1a, in 20 (43.5%) as 1b, in 1 (2.2%) as 1a and 1b, in 1 (2.2%) as 2a and 2c, in 4 (8.7%) as 3a, in one (2.2%) as 3a and 3c, in 6 (13%) as 3c, and in 1 (2.2%) as 5a. Before treatment, the mean serum HCV-RNA level was 4.87×10^5 copies/mL ranging from 1×10^3 to 6.5×10^6 (SD 1.02×10^6). Patients showed histological diagnosis of mild chronic hepatitis (39.1%, n = 18), moderate chronic hepatitis (37%, n = 17), severe chronic hepatitis (8.7%, n = 4), cirrhosis (8.7%, n = 4), or unknown histology in 6.5% (n = 3). All patients received daily dose IFN-2a therapy as initial treatment.

Outcome of patients with genotype 2 or 3

Patients with genotype 2 or 3 (n = 12) showed an initial

virological response rate of 100% under daily dose IFN-2a treatment. During treatment, however, three genotype 3 patients were excluded from the study due to incompliance. Thus, at that time (two patients after 4 wk and one patient after 12 wk of treatment) the drop outs were virological responders. All patients who completed therapy (n = 9) had a complete biochemical and virological response at the end of 24-wk treatment. During follow-up, after EOT three of nine patients (33.3%) developed a relapse. In these patients, initial virological response first occurred after 4 wk of treatment. The remaining six patients (66.7%) sustainingly eradicated the virus, i.e. serum viral RNA was non-detectable for at least a 48-wk period after EOT. Data of treatment response and follow-up are shown in Figure 1.

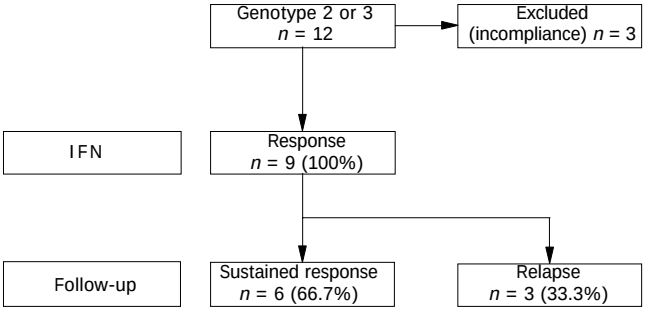

Figure 1 Outcome of 12 HCV-infected patients with genotype 2 or 3 after *the* end of treatment and follow-up. Abbreviations: EOT (end of treatment), IFN (interferon al*pha*).

Outcome of patients with genotypes other than 2 or 3

Patients with genotypes other than 2 or 3 (n = 34) showed an initial virological response rate of 23.5% (8/34) under daily dose IFN-2a treatment. These 8/34 patients (23.5%) were still virological responders at the end of 48 wk daily dose IFN-2a treatment. Two of thirty-four patients (5.9%) stopped IFN therapy due to alopecia (n = 1) and loss of weight (n = 1). During follow-up, five patients (14.7%) who had eliminated the virus at EOT relapsed, and three (8.8%) had a SVR, 48 weeks after EOT.

Twenty-four of thirty-four patients (70.6%) failed to develop an initial virological response under IFN-2a monotherapy and were treated with ribavirin (10 mg/kg BW/day) in combination as described previously[22]. Ten patients (29.4%) showed a response and 13 (38.2%) a non-response at the end of 48-wk treatment. One patient (2.9%) stopped combination therapy due to hemolysis. During follow-up, 9 (26.5%) patients with a response at EOT relapsed and only one (2.9%) patient showed a SVR, 48 weeks after EOT.

Overall outcome

During treatment, three patients with genotype 3 had to be excluded from the study due to incompliance. At the completion of 24- and 48-wk treatment, 27 of 43 patients (62.8%) showed a virological response and 13 of 43 patients (30.2%) showed a virological non-response. In 3 of 43 patients (7%), treatment was discontinued due to alopecia (n = 1) and loss of weight (n = 1) under IFN-2a monotherapy, and due to hemolysis (n = 1) under combination therapy. Forty-eight weeks after the end of 24- and 48-wk treatment, 17 of 27 patients with a response at the end of 24- and 48-wk treatment relapsed (63%). In summary, the overall SVR rate was 23.3% (10 of 43 patients) 48 wk after EOT.

Side effects

Beside the 3/43 (7%) drop outs, daily dose IFN-2a therapy (3 MU) was well tolerated. Monitoring of side effects by questioning and clinical examination revealed flu-like symptoms (e.g. pyrexia, myalgia and rigors) in one quart of cases. Mild leukocytopenia (minimum 1 800/μL) and thrombocytopenia (minimum 70 000/μL in a patient without cirrhosis and 59 000/μL in a patient with cirrhosis) was generally seen.

Side effects of additional ribavirin therapy were thyroid gland alterations (two patients with hypothyroidism and one with hyperthyroidism) and loss of weight (n = 1). Beside the one drop out due to hemolysis (minimum hemoglobin 86 g/L), decrease in hemoglobin was generally seen to a minimum of 98 g/L. There was no need of transfusion or drug dose reduction. All side effects were completely reversible within 1 mo after EOT.

DISCUSSION

In chronic HCV-infected patients, SVR rates range from 6-15% after a 6-mo course of IFN TIW to 13-25% after 12 mo of therapy[11]. One of the reasons for marginal response to IFN is its short half-life of approximately 8 h[16], which leads to wide fluctuations in the plasma concentrations of the drug during treatment period. Among patients treated with IFN TIW, an intermittent increase in viral load can be observed on treatment-free days[17]. In this prospective monocentric non-randomized study, we report our experience on 46 consecutive chronic HCV-infected patients who received 3 MU IFN-2a daily as initial regimen. Patients with genotype 2 or 3 were treated for 24 wk, and patients with genotypes other than 2 and 3 for 48 wk. Three patients with genotype 3 were excluded from the study due to incompliance. At the end of 24-wk treatment, 17/43 (39.5%) of our patients including 9/9 (100%) with genotype 2 or 3 and 8/34 (23.5%) with genotypes other than 2 or 3 eliminated the virus below the limit of detectability. In comparison, IFN 3 MU TIW for 24 wk resulted in virological response rates of 29-32% at EOT[7,8]. The rate of complete responders (23.5%) was unchanged after 48 wk of treatment in our patients with genotypes other than 2 or 3. IFN 3 MU TIW for 48 wk can induce virological response at EOT in 24-33%[7,12] of patients including different genotypes. Also, a dose of IFN 6 MIU TIW for 12 wk followed by IFN 3 MIU TIW for the remaining 36 wk resulted in a complete response rate of 25% at EOT in patients including different genotypes[22].

SVR, 48 wk after EOT resulted in 6/9 (66.7%) of our patients with genotype 2 or 3 after 24 wk 3 MU IFN daily therapy and 3/34 (8.8%) with genotypes other than 2 or 3

after 48 wk 3 MU IFN daily therapy. Compared to our results, IFN 3 MU TIW for 24 wk resulted in SVR in 2% of patients with genotype 1 and in 16% with other genotypes[7]. IFN 3 MU TIW for 48 wk resulted in SVR in 7% of patients with genotype 1 and in 29% with other genotypes[7]. In the trial of Poynard *et al.*[12], a SVR after IFN 3 MU TIW for 48 wk was observed in 33% of patients with genotype 2 and 3 and in 11% with genotype 1, 4, 5, and 6.

Combination of IFN 3 MU TIW with ribavirin at a dosage of 1 000-1 200 mg/d for 24 wk is able to induce response rates at EOT in 53-57%[7,12]. SVR was observed in 18% of patients with genotype 1, 4, 5, or 6[12] and in 16% of patients with genotype 1[7]. Our results are difficult to compare with these results, because we added ribavirin in a lower dose (10 mg/kg BW/day) after 12 wk of daily dose IFN-2a therapy in patients with genotype other than 2 or 3 who were virological non-responders at that time. However, addition of low-dose ribavirin (10 mg/kg BW/day) is able to induce a response at 48-wk EOT in 10/24 (41.7%) initial virological non-responders to a daily dose IFN-2a monotherapy. But SVR 48 wk after EOT is low (1/10 patients), because relapse occurred in the other 9 patients. Therefore, for patients with genotypes other than 2 or 3, this regimen appears not to be sufficient. They need a combination therapy from the beginning on for a longer time or in higher dose.

Nowadays, data on pegylated IFN for treatment of HCV-infected patients are available in the literature[13,14,22]. Interestingly, pegylated IFN-2a monotherapy at a dosage of 180 μg once a week for 48 wk can induce SVR rates of 45% in patients with genotype 2 and 3[22]. Compared to these results, daily dose IFN 3 MU for 24 wk is able to induce 66.7% SVR rates in patients with genotype 2 and 3. These patients with a SVR 48 wk after EOT showed an initial virological response already after 2 wk daily dose IFN-2a monotherapy, whereas patients who relapsed after EOT showed the initial virological response first after 4 wk daily dose IFN-2a treatment. Thus, avoidance of ribavirin in a subgroup of patients with genotype 2 and 3 who showed an initial virological response early after 2 wk of IFN treatment might prevent drug associated adverse events and potential teratogenic effect in patients at child bearing age[15]. This is of particular interest, because the majority of treated patients in our study had a mean age of 42 years and 41-44 years in studies using IFN TIW monotherapy, pegylated IFN monotherapy, and combination with ribavirin[7,12-14,22]. During and 6 mo after the administration of ribavirin, at least two forms of effective contraception are advised[15]. An additional economic fact is the increased cost of ribavirin treatment in HCV patients.

Side effects are comparable with those reported for 3-6 MU TIW IFN therapy[7,12,22]. None of our patients needed dose modification due to adverse event or laboratory abnormality, but in 7% of our patients IFN therapy was discontinued due to alopecia (n = 1) and loss of weight (n = 1), and ribavirin associated hemolysis (n = 1). For comparison of our results, meta-analysis of individual patient data from European centers revealed approximately 10% withdrawal of patients during treatment[23]. In studies with 3-6 MU IFN TIW, discontinuation from therapy ranges from 10% to 14% of patients[7,12,22]. Daily dose IFN therapy does not increase the discontinuation rate in comparison to TIW IFN therapy.

In conclusion, the use of daily dose IFN-2a 3 MU for HCV-infected patients is safe and well tolerated, but is able to induce only similar SVR rates 48 wk after EOT compared to IFN TIW for patients with genotypes other than 2 or 3. Addition of low-dose ribavirin after 12 wk daily dose IFN-2a monotherapy in virological non-responders at that time can increase the initial response at EOT, but relapse rate is high during follow-up. However, in patients with genotype 2 or 3, SVR rates of 66.7% can be achieved (48 wk after EOT with 3 MU IFN-2a monotherapy daily for 24 wk). Thus, our regimen appears to be at least as effective as pegylated IFN-2a for 48 wk[22]. Noteworthy is the finding that the development of a SVR seems to be related to the time of the initial virological response. In all cases, an early initial virological response after 2 wk of IFN treatment was followed by a SVR after 24 wk daily IFN monotherapy without ribavirin. A later initial virological response after 4 wk was associated with a relapse after EOT. In accordance with our results, Bekkering *et al.*[24], retreated 11 non-responders to previous TIW IFN therapy with daily dose IFN and found that all three sustained responders (genotype 3 in two cases and genotype 1a in one case) had undetectable plasma HCV RNA at d 14.

Recently, promising results in patients with genotype 2 and 3 treated with pegylated IFN and ribavirin combination therapy have been published[25,26]. Cornberg *et al.*[25], reduced the duration of combination therapy with standard weight-based dose of ribavirin (1 000-1 200 mg/d) from 48- to 24-wk treatment in patients with genotype 2 and 3. This regimen resulted in a SVR of approximately 85%[25]. In March 2004, Hadziyannis *et al.*[26], published the results of 1 311 patients treated with different regimens of short- and long-term pegylated IFN-2a (24 or 48 wk) in combination with low-dose ribavirin (800 mg/d) or standard weight-based dose of ribavirin (1 000 or 1 200 mg/d). Patients with genotype 2 or 3 were shown to be adequately treated with low-dose ribavirin in combination with pegylated IFN-2a for 24 wk[26]. Furthermore, our data suggest that there is a subgroup of patients with genotype 2 or 3 that can clear the virus with IFN-2a alone. As a result of the introduction of pegylated IFN, daily dosing of IFN has become outdated and in patients with genotype 2 or 3 HCV-infection pegylated IFN should be used as primary treatment for 24 wk with secondary addition of low-dose ribavirin (after 2 wk) only in case of failure of initial virological response 2 wk after initiation of therapy.

Abstract

AIM: To assesse changes in plasma HBV DNA after TAE in HBV-related HCC and correlate the levels with the pattern of lipiodol accumulation on CT.

METHODS: Between April and June 2001, 14 patients with HBV-associated HCC who underwent TAE for inoperable or recurrent tumor were studied. Levels of plasma HBV DNA were measured by real-time quantitative PCR daily for five consecutive days after TAE. More than twofold elevation of circulating HBV DNA was considered as a definite elevation. Abdominal CT was performed 1-2 mo after TAE for the measurement of lipiodol retention.

RESULTS: Circulating HBV DNA in 10 out of 13 patients was elevated after TAE, except for one patient whose plasma HBV DNA was undetectable before and after TAE. In group I patients (n = 6), the HBV DNA elevation persisted for more than 2 d, while in group II (n = 7), the HBV DNA elevation only appeared for 1 d or did not reach a definite elevation. There were no significant differences in age or tumor size between the two groups. Patients in group I had significantly better lipiodol retention (79.31±28.79%) on subsequent abdominal CT than group II (18.43±10.61%) (P = 0.02).

CONCLUSION: Patients with durable HBV DNA elevation for more than 2 d correlated with good lipiodol retention measured 1 mo later, while others associated with poor lipiodol retention. Thus, circulating HBV DNA may be an early indicator of the success or failure of TAE.

INTRODUCTION

In patients with advanced hepatocellular carcinoma (HCC), transcatheter arterial embolization (TAE) has been widely used in Asian countries[1,2]. After TAE, tumor necrosis appears to be complete by 2 d[3]. Circulating plasma DNA is increased after traumatic injury and has been postulated as a prognostic marker for such condition[4]. We wondered if there were other circulating markers that would allow an earlier assessment of response to treatment. Although HCC lacks universal oncogene, HBV is closely linked to HCC. Integrated HBV fragments are frequently detected in the tumors of patients with positive hepatitis B surface antigen (HBsAg)[5]. We therefore studied patients with HBV-related HCC to determine how their circulating plasma and HBV DNA changed after TAE and how those measurements correlated with lipiodol retention on computed tomography (CT).

MATERIALS AND METHODS

Patients

HBsAg-positive patients with advanced HCC between April and June 2001 at the Mackay Memorial Hospital, Taipei, Taiwan were considered for enrollment. Only those who had inoperable tumors that were also not suitable for percutaneous ethanol injection were included. Diagnosis of HCC was made by cytology or by elevated α-fetoprotein (AFP) and typical imaging results (CT and celiac angiography). Patients with contraindications for TAE (such as uncorrectable bleeding disorder, severe thrombocytopenia [platelet count <50 000], a history of radiocontrast allergy, Child's grade C liver cirrhosis, elevated serum creatinine [>2.0 mg/dL], or tumor thrombus in the main portal trunk) were excluded. All patients studied gave informed consent. Patients who could not complete five consecutive days of study were excluded from the final analysis.

TAE through selective hepatic arterial catheterization

was performed via a femoral artery by radiologists at Mackay Memorial Hospital. Under fluoroscopic guidance, 3-10 mL of iodized oil (Laboratoire Guerbet, France) was injected slowly followed by gelatin-sponge pieces (Gelfoam, Johnson and Johnson Med Ltd) and 1 g of cephazolin. Gelfoam was used to activate intravascular thrombosis and cephazolin was used to prevent bacterial infection. After embolization, angiography was performed to determine the extent of vascular occlusion and to assess blood flow in other arteries. After the procedure, patients received intravenous hydration, antiemetic medication, and acetaminophen for pain control. They were discharged from the hospital when oral intake was adequate.

Blood tests and follow-up studies

Blood samples for HBV DNA were taken before TAE and after the procedure every 18-24 h for five consecutive days. Liver function was evaluated before and at 1 wk and 1 mo after TAE to assess the degree of toxicity. Enhanced CT scans of the abdomen using a 10-mm thick slice were performed on a GE HiSpeed scanner (GE Medical Systems) 1-2 mo after TAE. The tumor volume and volume of tumor retaining lipiodol were calculated with GE HiSpeed CT/i system software by reconstructing and viewing the data on a GE Advantage Windows Workstation. The morphologic therapeutic response was assessed by calculation of lipiodol-retaining tumor volume as a percentage whole tumor volume: Percentage of lipiodol retention = (lipiodol-retained lesion volume)/(whole tumor volume)×100%.

Real-time quantitative PCR for HBV DNA

Real-time quantitative PCR analysis was performed on an ABI Prism 7700 Sequence detection system (PE Applied Biosystems) by using SYBR green I as a double-strand DNA-specific binding dye. Briefly, DNA was extracted from a 400 μL plasma sample by using a QIAamp Blood kit (Qiagen Ltd) according to the manufacturer's instruction. The primers for HBV DNA were 184F 5'-GGA CCC CTG CTC GTG TTA CA-3' and 273R 5'-GAG AGA AGT CCA CCM CGA GTC TAG A-3' according to Pas *et al*.[6]. A product of 89 bp from a region of the HBV pre-S gene was amplified. The region was chosen because the pre-S to S open reading frame is generally conserved whereas the core gene is frequently deleted and the X ORF is often truncated[7]. Each reaction mixture contained 5 μL of 10× SYBR Green PCR buffer, 25 mmol/L $MgCl_2$, 200 nmol/L of each deoxynucleoside triphosphate (dATP, dCTP, dTTP, and dGTP), Taq Gold DNA polymerase 0.25 μL, AmpErase uracil *N*-glycosylase (UNG) 0.5 μL, 100 nmol/L of forward and reverse primers and 5 μL of the DNA extract from the plasma sample. The final volume of each PCR reaction mixture was 50 μL. Each sample was assayed in triplicate. Multiple negative water blanks were included in each run as a negative control. Thermal cycling was performed under the following conditions: stage I: at 50 ℃ 2 min, during which UNG could inactivate possible contaminating amplicons, and at 95 ℃ for 10 min, to allow Taq Gold polymerase to activate and inactivate the UNG; stage II: 40 cycles at 95 ℃ for 15 s and 60 ℃ for 1 min, and then stage III: 95 ℃ for 15 s, followed by 60 ℃ for 2 min. After real-time PCR, the amplified products were gradually heated to 95 ℃ for about 20 min. The instrument automatically measured the changing level of fluorescence continuously. This analysis gave the melting temperature. HBV standards were prepared from the serum of two patients with recently reactivated hepatitis B. Amplified PCR products were cloned into pGEM®-T easy vector (Promega Co.) and transformed into JM 109 competent cells. Plasmid DNA was isolated using a plasmid DNA miniprep system (Viogene, USA). Plasmid preparations were quantified spectrophotometrically and standards were prepared by serial dilution from 4×10^1 to 4×10^8 copies/mL.

Data analysis

After amplification, data were captured onto a Macintosh computer, analysis was done with Sequence Detection software (PE Applied Biosystems). Data were collected at the annealing step (60 ℃) of every cycle, and the threshold cycle (Ct) for each sample was calculated by determining the point at which the fluorescence exceeded the threshold limit. A standard curve was calculated automatically by plotting the Ct values against standards of known concentration and calculation of the linear regression line of this curve. Calculation of the correlation coefficient (r^2) was done for each run, using a minimal value of 0.95. Sample copy numbers were calculated by interpolation of the experimentally determined standard curve. In this study, the percent coefficient of variation (%CV) of threshold cycle was 1.25% (range: 0-4.73%) for HBV DNA, similar to that of a previous report 19.

Changes in plasma HBV DNA and statistical analysis

Patient's plasma HBV DNA with twofold elevation was considered as a definite elevation. We classified the changes in plasma HBV DNA into two groups. Group I patients had an elevated HBV DNA level post-TAE for more than 2 d. In group II patients, the HBV DNA elevation only appeared for 1 d or did not reach the definite elevation before d 5. Data were reported as the mean±SD. Clinical characteristics and lipiodol retention of the two groups were compared by using Student *t* test and Fisher test. A P value <0.05 was considered statistically significant.

RESULTS

Fourteen HBsAg seropositive patients with HCC (12 men and 2 women) were studied. The average age was 62 years, ranging between 39 and 81 years. Thirteen had Child Class A and one had Child Class B cirrhosis. Five patients received TAE for the first time and the others were being treated again for recurrent disease. The post-embolization symptoms (fever, abdominal pain, and vomiting) in all patients were mild and subsided within one week. Liver function recovered completely in all patients within one week, and no subsequent liver dysfunction was noted over the course of the study.

Plasma HBV DNA changes after TAE

Except for one patient with undetectable plasma HBV DNA before and after TAE, 10 out of 13 patients had increased plasma HBV DNA after embolization. Six patients had HBV DNA rising for more than 2 d (group I). Among seven

patients in group II, three patients did not reach definite HBV elevation and the other four had temporal HBV DNA elevation within 3 d after TAE. The mean diameter of the embolized tumor in group I was 5.92±3.98 and 5.00±2.20 cm in group II, a non-significant difference (P = 0.61). The lipiodol retention in the embolized tumors in group I was 79.31±28.79% and in group II, 18.43±10.61%, a statistically significant difference (P = 0.02). No significant differences were observed between the two groups regarding age or tumor size (Table 1).

Table 1 Basic characteristics before TAE and lipiodol retention percentage after TAE of group I and group II patients

	Group I (n = 6)	Group II (n = 7)	P
Age, yr (range)	57.6 (39-79)	65.6 (38-81)	0.34
Gender (male/female)	6/0	5/2	-
Pretreatment AFP (ng/mL)	707±1 536	3 024±5 307	0.32
Tumor size (cm)	5.92±3.98	5.00±2.20	0.61
Disease status at entry			-
For the first time TAE (n)	3	2	
For recurrence (n)	3	5	
Lipiodol retention (%)	79.31±28.79	18.43±10.61	0.02[a]

n: patient number. Statistical data are expressed as mean±SD. [a]P<0.05, with statistical significance.

DISCUSSION

Our study showed a significant correlation between durable elevation of plasma HBV DNA concentration after TAE and lipiodol retention one month later. Group I patients with an persistently elevated HBV DNA level apparently sustained more tumor damage after TAE as evidenced by good lipiodol retention, while group II patients with temporary or no elevation in HBV DNA probably had unsuccessful TAE, as indicated by poor lipiodol retention.

The anticancer effects caused by TAE are due to selective blockade of the tumor blood supply. Integrated HBV DNA can be detected in both tumor and nontumor liver tissues of HBV carriers[8]; so the immediate elevation of plasma HBV DNA after TAE might come from damages to the two parts of the same arterial territory. Both integrated HBV DNA and non-integrated episomal HBV DNA are included. Although it has been recently published that HBV may be reactivated by transarterial chemoembolization (TACE), the reported time to reactivation after the last TACE was more than 25 d[9]. In our study, none of our patients had persistently abnormal or deteriorating liver dysfunction after TAE, suggesting that HBV reactivation was not likely to occur within the short period.

With gelfoam embolization, it can produce temporary or permanent occlusion of the targeted artery[10]. From our results, plasma HBV DNA elevated within short-term follow-ups in 10 out of 13 patients. They can be considered as consequences of ischemic injury to liver although the effects may be temporary or persistent. Persistence of HBV DNA in our patients indicates that the occlusion of tumor feeding artery by TAE was complete. It correlated with good lipiodol retention, a factor known to predict a good response. Among patients without persistent elevation of circulating DNA (group II), they tend to have less successful TAE, which may be due to technical or tumor factors (such as incomplete arterial occlusion, presence of collateral blood supply, or tumors with resistance to reperfusion injury)[11-15]. In such patients, other treatment modalities should be considered early to achieve better tumor control.

Monitoring the outcome of TAE is important because it is an important prognostic factor influencing management decisions, such as retreating, incorporation of various non-surgical procedures (e.g., percutaneous ethanol injection, intra-arterial chemotherapy, or local ablation techniques), or deciding to withhold further anti-tumor therapy[16]. In order to evaluate response to TAE, clinicians commonly use tumor regression, AFP levels, and the degree of lipiodol accumulation on CT. All these methods have limitations. Tumor regression is seldom recognized before 4 wks after TAE, and some tumors fail to shrink despite complete necrosis found on pathology of resected lesions[17,18]. Although a good correlation has been found between histologically proven tumor necrosis and reduction in AFP, this correlation has only been demonstrated in patients with a pre-TAE AFP level $\geqslant$200 ng/mL[19]. This marker is therefore of little use in patients who do not have markedly elevated AFP before TAE. The degree of lipiodol retention also correlates well with the degree of necrosis[18]. Compact lipiodol uptake has also been correlated with a better chance of survival than less compact uptake, indicating its usefulness as a post treatment prognostic marker. However, the need to wait 4 wk after treatment for the agent to be cleared from the uninvolved hepatic parenchyma[20] limits its usefulness. In some cases, hepatic washout is particularly slow, making interpretation of the CT image difficult[21].

Recent data indicate that human plasma DNA possesses a short half-life in the circulation[22]. The rapid kinetics suggests that circulating DNA analysis may be useful in monitoring clinical progress. One potential limitation of its clinical application is that serial blood sampling after TAE may be inconvenient for patients. If, as implied by this preliminary study, circulating plasma DNA persistently correlates with lipiodol retention, it may prove to be a useful tool for early evaluation of the response to TAE. If further studies support our findings, circulating levels of HBV DNA after TAE may be an early indicator for which patients require additional treatment.

Abstract

AIM: To evaluate whether the effect of Gln dipeptide-enriched total parenteral nutrition (TPN) on postoperative cytokine alteration depended on the disease severity of surgical patients.

METHODS: Forty-eight patients with major abdominal surgery were allocated to two groups to receive isonitrogenous (0.228 g nitrogen/kg per d) and isocaloric (30 kcal/kg per d) TPN for 6 d. Control group (Conv) using conventional TPN solution received 1.5 g amino acids/kg per day, whereas the test group received 0.972 g amino acids/kg per day and 0.417 g L-alanyl-L-glutamine (Ala-Gln)/kg per day. Blood samples were collected on d 1 and d 6 postoperatively for plasma interleukin (IL)-2, IL-6, IL-8, and interferon (IFN)-γ analysis.

RESULTS: Plasma IL-2 and IFN-γ were not detectable. IL-6 concentrations were significantly lower on the 6th postoperative day in the Ala-Gln group than those in the Conv group in patients with APACHE II≤6, whereas no difference was noted in patients with APACHE II>6. There was no difference in IL-8 levels between the two groups. No difference in cumulative nitrogen balance was observed on d 2-5 after the operation between the two groups (Ala-Gln -3.2±1.6 g *vs* Conv -6.5±2.7 g). A significant inverse correlation was noted between plasma IL-6 levels and cumulative nitrogen balance postoperatively in the Ala-Gln group, whereas no such correlation was observed in the Conv group.

CONCLUSION: TPN supplemented with Gln dipeptide had no effect on plasma IL-8 levels after surgery. However, Gln supplementation had a beneficial effect on decreasing systemic IL-6 production after surgery in patients with low admission illness severity, and lower plasma IL-6 may improve nitrogen balance in patients with abdominal surgery when Gln was administered.

INTRODUCTION

Glutamine (Gln) is the most abundant amino acid in plasma and in the intracellular free amino acid pool[1]. It is essential for a wide variety of physiologic process, in particular, the growth and function of immune cells including lymphocytes and macrophages[2]. Gln has traditionally been thought as a nonessential amino acid; however, previous reports have shown that Gln depletion occurs in critically injured patients. The extent and duration of Gln depletion are proportional to the severity of illness[3,4]. Laboratory and clinical data suggest that Gln is essential during certain catabolic conditions, such as burns, major surgery, and infection[5-8]. Total parenteral nutrition (TPN) is widely used in the treatment of critically ill patients. Conventional TPN solution does not contain Gln, because Gln is relatively unstable in solution during heat sterilization and long-term storage. Exogenous Gln may be required to satisfy the body's Gln requirement under stressed conditions. Previous studies have shown that TPN supplemented with Gln improved nitrogen balance, enhanced immune response and shortened hospital stay in surgical patients[9-12].

Surgery is known to impair the immune response, and may consequently increase risk of postoperative infection and sepsis[13]. The decrease in the plasma Gln

level following major surgery may contribute to the state of immunosuppression[12,14]. Studies have shown that depressed Gln concentrations were associated with reduced proliferation of lymphocyte in healthy volunteers[14], and Gln depletion may be partly responsible for T cell suppression seen in severely stressed patients[15,16]. In addition to its role in lymphocyte function, Gln may have an indirect effect to mediate a reduction in proinflammatory cytokine release. Parry-Billings *et al*.[3], demonstrated that plasma Gln level was negatively correlated with the production of interleukin (IL)-6 under major surgery. De Beaux *et al*.[17], showed that Gln-supplemented TPN significantly reduced blood mononuclear cell IL-8 release in severe acute pancreatitis patients. A previous report by our laboratory have shown that the effect of Gln administration on improving nitrogen economy was only observed in patients with low, but not high Chronic Health Evaluation (APACHE II) scores[11]. This result indicates that the effect of Gln on attenuating catabolic response may depend on the characteristics and severity of the diseases. We hypothesized that the effect of synthetic Gln supplementation on proinflammatory cytokine release was also associated with the severity of diseases. In this study, we administered a Gln-dipeptide containing TPN to patients postoperatively to investigate the effect of synthetic Gln-dipeptide on cytokine production after surgery. Also, the Gln effect on the severity of stress and cytokine production was evaluated.

MATERIALS AND METHODS

Patients

This was a randomized, double-blind, parallel multicenter clinical trial carried out in National Taiwan University Hospital and Veterans General Hospital, Taipei, Taiwan. This study was performed from August 1999 to May 2000, and was approved by the ethical committee of the two centers. Patients with major metabolic, circulatory, and renal diseases were excluded, and no emergency cases were included. Only major gastrointestinal surgery patients who needed TPN for nutritional support were enrolled. APACHE II score and Therapeutic Intervention Scoring system (TISS) were evaluated after admission[18]. Patients with APACHE II between 2-10 and TISS>10 were included. The informed consent was obtained from each patient before the experiment was performed. A total of 48 patients (28 males and 20 females, age range 40-82 years, mean 66 years) were included. These patients were randomly allocated to either a test group or a control group. The separation of patients into low and high APACHE II groups was post hoc. Since patients with APACHE II score between 2 and 10 were enrolled, we chose the midpoint 6 as the cut-off point to differentiate low- and high-disease severity in this study. Demographic for all patients is summarized in Table 1.

Feeding regimen

The two groups were isonitrogenous and isocaloric. Nitrogen intake was 0.228 g/kg body weight per ds. Caloric intake was 30 kcal/kg per ds. The nonprotein calories were given as dextrose and fat in a ratio of 70:30. Patients of the control group (Conv group, n = 23) were administered a commercially available amino acid solution (Moriamin-SN 10%, Chinese Pharmaceuticals, Taipei, Taiwan). The Conv group received 1.5 g amino acid/kg per day. Patients of the test group (L-alanyl-L-glutamine (Ala-Gln) group, n = 25) received 0.972 g amino acid/kg per day supplemented with 0.417 g/kg per ds Ala-Gln, which provide 0.28 g Gln/kg per day (Dipeptiven, Fresenius Kabi, Bad Homburg, Germany). The Gln containing solutions were prepared by the clinical pharmacist under aseptic condition and adjusted to the weight of each individual patient. The amino acids and dextrose mixture with electrolytes, vitamins, and trace elements were administered through a central venous catheter. Fat emulsion (Lipovenos 20%, Fresenius AG, Germany) was given through a separate canal in the central venous line. Half strength was administered on the 1st d, and full strength was given thereafter for the remaining days. During the experimental period, no enteral nutrition was administered. Neither the patients nor the investigator knew that the applied TPN regimens were with or without Ala-Gln.

Measurements of the plasma parameters and cumulative nitrogen balance

Routine clinical chemistry was measured before and after the surgery. The blood samples were also obtained on postoperative d 1 and on d 6 after TPN administration for analysis of plasma cytokine concentrations. Cytokines including IL-2, IL-6, IL-8, and interferon (IFN)-γ were measured using a commercially available ELISA in microtiter

Table 1 Demographic data of the patients

	Ala-Gln group			Conv group		
	All patients	APACHE ≤6	APACHE >6	All patients	APACHE ≤6	APACHE >6
Age (yr)	66.7±9.0	61.7±11.2	70.1±6.0	67.6±8.4	64.5±7.6	70.6±8.7
Weight (kg)	56.9±9.1	57.7±8.6	56.3±10.1	57.6±10.3	55.3±8.6	59.8±12.0
Height (cm)	157.8±6.4	160.4±6.7	156.0±6.1	160.1±8.3	158.8±8.0	161.3±9.0
Male/female	14/11	4/6	10/5	14/9	6/5	8/4
Diagnosis:						
Gastric Ca	18	6	12	14	6	8
Pancreas Ca	4	3	1	4	2	2
Colon Ca	1	0	1	3	2	1

Duodenal Ca	0	0	0	1	0	1
Rectal Ca	1	0	1	0	0	0

plates (BioSource International, Camarillo, CA, USA). Antibody specific for human IL-2, IL-6, IL-8, and IFN-γ were coated onto the wells of microtiter stripes provided. Urine and drainage was collected throughout the study, and cumulative nitrogen balance was calculated from postoperative d 2-5 as previously described[11].

Statistics

The data are expressed as mean±SD, repeated measure analysis of variance were used to compare the treatment differences at each day, and *t*-test was used for the difference between the two groups. Pearson's correlation coefficients were used to calculate the linear relationship between plasma IL-6 and cumulative nitrogen balance of the patients. A *P* value <0.05 was considered significant.

RESULTS

Most of the patients had laboratory values within normal range at baseline and on d 6 after the operation despite the patients being administered with Conv or Ala-Gln solution (data not shown). No adverse reactions were found after the Gln-dipeptide containing solution was administered.

Plasma IL-2 and IFN-γ levels were not detectable. Plasma IL-6 concentrations were significantly lower after TPN administration for 6 d, regardless whether the patients were in Conv group or Ala-Gln group. In patients with APACHE II≤6, plasma IL-6 concentrations on the postoperative d 6 in the Ala-Gln group were significantly lower than those in the Conv group. However, there were no differences in IL-6 concentrations between the two groups after infusing TPN for 6 d in patients with APACHE II>6 (Table 2). No significant difference in plasma IL-8 concentrations were observed between the postoperative d 6 and d 1, regardless whether the patients were infused with Ala-Gln or Conv solution. Also, there were no differences in IL-8 levels between the two groups on d 6 and 1 postoperatively (Table 3).

There was no difference in cumulative nitrogen balance on days 2-5 after the operation between the two groups (Ala-Gln -3.2±1.6 g *vs* Conv -6.5±2.7 g). A significant inverse correlation was observed between plasma IL-6 levels on d 6 and cumulative nitrogen balance postoperatively in the Ala-Gln group ($P = 0.027$), whereas no such correlation was noted in the Conv group ($P = 0.919$) (Table 4).

DISCUSSION

In this study, we analyzed plasma IL-2, IL-6, IL-8, and IFN-γ concentrations on postoperative days, because these cytokines are involved in the response to tissue injury[19,20]. IL-2 is produced by mitogen-stimulated T lymphocyte, and was originally isolated as a T-cell growth factor. IFN-γ promotes production of proinflammatory mediator such as IL-1 and TNF-α[19,20]. IL-1β, TNF-α, and IL-6 are major mediators of inflammation and acute phase response. We only measured IL-6 levels, because TNF-α and IL-1 have rarely been detected in the plasma of injured patients[20,21]. In this study, plasma IL-2 and IFN-γ were not detectable either. It is possible that the cytokines are bioactive in biologic fluid at levels well below the range of detectability by current immunoassays[20]. The effect of Gln supplementation on plasma IL-2 and IFN-γ cannot be found in this study.

IL-8 is a chemotactic and activating factor for immune response. Previous reports had shown that plasma IL-8 concentration were much higher in patients with sepsis compared with noninfectious shock, and associated with a fatal outcome[19]. Study by De Beaux *et al*.[17], showed that Gln-supplemented TPN reduces *in vitro* blood mononuclear cell IL-8 release in acute pancreatitis. In this study, no significant differences in plasma IL-8 concentrations were observed between the postoperative d 1 and 6. Also, there were no differences in IL-8 levels between the two groups on postoperative days. This result indicated that Gln administration did not influence the changes of IL-8 in surgical patients. Since IL-8 is associated with clinical,

biochemical, and inflammatory markers of sepsis[22,23], it is compatible to the fact that patients in this study were not complicated with infection, as shown in our previous report[11].

IL-6 is a multifunctional cytokine expressed by a variety of cells. Cruickshank *et al.*[21], reported that systemic response of IL-6 to surgical trauma increased with the severity of surgical insult. Elevation of IL-6 after trauma and elective surgery has been associated with infectious morbidity as well as mortality[24]. Foex and Shelly[25] suggest that IL-6 is a sensitive marker of tissue damage after surgery. In this study, we observed that plasma IL-6 concentrations significantly reduced after TPN administration for 6 d, regardless whether the patients were in Conv group or Ala-Gln group. This result might mean that TPN formula administration attenuated the inflammatory response of the surgical insult. The result also showed that plasma IL-6 levels on postoperative d 6 in the Ala-Gln group were significantly lower than the Conv group in patients with APACHE II$\leqslant$6, but not in patients with higher APACHE II scores. This finding suggests that in patients with lower disease severity, TPN supplemented with Gln had a significant favorable effect on reducing inflammatory response postoperatively. Studies have shown that after operation and trauma, Gln deprivation is observed and the severity of Gln deprivation is proportional to the severity of diseases[3,4]. It is possible that in patients with lower APACHE II score, the demand of Gln is much less than the patients with higher score, and Gln supplementation provides adequate substrate for the function of immune system, and thus reduced the inflammatory response of the surgical insult. Palmer *et al.*[4], showed that TPN supplemented with Gln had no effect on muscle and plasma biochemical changes in critically ill patients. Since this study was a post hoc investigation, whether higher dose of Gln may have beneficial effect on reducing IL-6 concentrations in patients with higher disease severity needs to be clarified.

In this study, we observed a negative correlation between plasma IL-6 and cumulative nitrogen balance postoperatively in the Ala-Gln group, whereas such correlation was not found when data of all patients were pooled and in the Conv group. This finding may indicate that the severity of protein catabolism cannot be predicted by plasma IL-6 level, possibly because the variation of nitrogen loss and plasma IL-6 levels was wide among individual surgical patient. However, Gln administration may consistently improve nitrogen balance and reduced plasma IL-6, and thereby a negative correlation between cumulative nitrogen balance and plasma IL-6 was found. Since nitrogen balance represents a complicated net result of protein catabolism and synthesis in the body, whether Gln play roles in modulating the relationship between IL-6 and protein metabolism required further investigation.

In summary, this study showed that TPN supplemented with Gln dipeptide had no significant influence on plasma IL-8 levels after surgery. However, Gln supplementation had a beneficial effect on decreasing systemic IL-6 production after surgery in patients with low admission illness severity, and lower plasma IL-6 may improve nitrogen balance in patients with abdominal surgery when Gln was administered.

Abstract

AIM: To provide the expression profile of serine protease SNC19/matriptase and its inhibitor hepatocyte growth factor activator inhibitor type 1 (HAI-1) in normal and malignant tissues of gastrointestinal tract at mRNA level for further study on their correlations with tumor progression and metastasis.

METHODS: Total RNAs were prepared from 37 samples of colorectal cancer tissues, 40 samples of gastric cancer tissues, and their adjacent normal tissues. The expression of SNC19/matriptase and HAI-1 in these samples was detected by real-time fluorescent quantitative PCR using glyceraldehyde-3-phosphate dehydrogenase as internal standard, and the clinical significance for the correlation with clinicopathological parameters was evaluated.

RESULTS: In gastric cancer tissues the expression of HAI-1 and SNC19/matriptase was significantly lower than that in the corresponding adjacent normal tissues (Z = -3.280, P = 0.006; Z = -4.651, P = 0.000). HAI-1:SNC19/matriptase ratio showed no difference between normal and malignant tissues (P>0.05). Analysis of clinicopathological parameters showed decreased expression of HAI-1 and HAI-1:SNC19/matriptase ratio associated with stage III/IV gastric tumors as compared to stage I/II ones (Z = -2.140, P = 0.031; Z = -2.155, P = 0.031), and with lymph node-positive gastric cancer tissues as compared to lymph node-negative ones (Z = -2.081, P = 0.036; Z = -2.686, P = 0.006). The expression of SNC19/matriptase had no relationship with stages and lymph node metastasis (P>0.05). The expression of HAI-1 and HAI-1:SNC19/matriptase ratio increased in well-differentiated gastric cancer tissues, but there was no statistical significance (P>0.05). The difference of SNC19/matriptase expression was not significant in gastric cancer tissues of different histological differentiation status (P>0.05). In colorectal cancer tissues, the expression of HAI-1 and SNC19/matriptase was also markedly lower than that in their adjacent normal tissues (Z = -3.100, P = 0.002; Z = -2.731, P = 0.006), whereas HAI-1:SNC19/matriptase ratio showed no difference. Decreased expression of HAI-1 was associated with increased invasive depth and lymph node metastasis, but there was no statistical significance (P>0.05). The difference of SNC19/matriptase expression and HAI-1:SNC19/matriptase ratio was not significant in different stages and different lymph node metastasis status (P>0.05). The expression of SNC19/matriptase, HAI-1 or HAI-1:SNC19/matriptase ratio showed no difference in colorectal cancer tissues of different histological differentiation status (P>0.05).

CONCLUSION: The expressions of SNC19/matriptase and its inhibitor HAI-1 are decreased in gastrointestinal cancer tissues compared to their normal counterparts, and the decreased expression of HAI-1 may correlate with invasion and lymph node metastasis. The possible mechanisms involved need to be further investigated.

INTRODUCTION

Hepatocyte growth factor (HGF), also known as scatter factor (SF)[1], is a pleiotropic factor which functions as a mitogen, a morphogen, and a motogen for a variety of cells bearing Met receptor tyrosine kinase, particularly for epithelial cells and vascular endothelial cells[2-4]. To date, a significant body of evidence is accumulating in favor of the notion that HGF/SF and Met play an important role in tumorigenesis, invasiveness, differentiation and angiogenesis of tumor cells[5,6]. HGF/SF is secreted by mesenchymal cells as an inactive precursor form, which lacks biological activity. The proteolytic activation of a single-chain precursor

form to a two-chain heterodimeric active form is a critical limiting step in the HGF/SF-induced Met signaling pathway[7]. Five proteases have been supposed to be responsible for the activation of HGF/SF: hepatocyte growth factor activator (HGFA), which exhibits the most potent activity, urokinase-type plasminogen activator (uPA), tissue-type plasminogen activator, blood coagulation factor XIIa[8,9], and SNC19/matriptase[10,11]. SNC19 initially identified from subtractive hybridization screening[12], has been confirmed to be indistinguishable from serine protease matriptase, which was first found in T47-D human breast cancer cells[13]. In addition to activation of HGF/SF, SNC19/matriptase can also degrade extracellular matrix (ECM), and activate another ECM-degrading protease uPA which is involved in tumor invasion[13-15]. SNC19/matriptase contributes to ECM degradation, cellular motility, epithelial migration and turnover, tissue remodeling, and it is supposed to be involved in tumor cell invasion and metastasis[14,16].

Hepatocyte growth factor activator inhibitor type 1 (HAI-1) is a Kunitz-type serine protease inhibitor which was initially purified from the conditioned medium of a human MKN45 stomach carcinoma cell line in 1997[17]. HAI-1 can specifically inhibit serine proteases HGFA and SNC19/matriptase, and they both are activators of HGF/SF[17-19]. Although it is supposed that HAI-1 and SNC19/matriptase may be involved in tumorigenesis, progression, and metastasis[16,20-22], more evidence is needed to draw a definite conclusion. This paper presents new evidence for the expression of HAI-1 and SNC19/matriptase in normal and malignant tissues of gastrointestinal tract at mRNA level, and their correlations with tumor progression and metastasis.

MATERIALS AND METHODS

Patients and tissues

A total of 40 samples from gastric cancer patients (median age, 58.95±12.43 years; range, 29-82 years; 28 men and 12 women) and 37 samples from colorectal cancer patients (median age, 61.64±13.54 years; range, 32-89 years; 13 men and 24 women), after surgical treatment in Second Affiliated Hospital, Zhejiang University College of Medicine, were studied retrospectively. The stage of gastric cancer was classified according to UICC guidelines (1985). Dukes' stage of colorectal cancer was classified according to the diagnosis and treatment criteria for common malignancy in China (1990). Tumor location, tumor histology, and histological grade were determined by pathological examination.

Specimens and RNA preparation

Cancer tissues and their adjacent normal tissues at least 15 cm away from cancer were collected immediately after excision, snap-frozen in liquid nitrogen, and stored at -80 ℃ for RNA extraction. Total RNAs were extracted from the tissue samples by TRIzol reagent (Gibco BRL Co., USA) according to the manufacturer's instructions in 0.1% RNase-free DEPC H_2O. RNA samples were quantified by ultraviolet spectrophotometry (Hewlett-Packard Co., USA).

Primers and probes

Primers and probes used for real-time fluorescent quantitative PCR were designed with the software PrimerExpress (Applied Biosystems Inc., USA). To avoid possible amplification of contaminating genomic DNA, primers were designed, so that each PCR product covered at least one intron. The sequences of primers and probes are listed in Table 1.

Table 1 Sequences of primers and probes

Target gene (amplicon size)		Sequence (5′–3′)

PCR standards

Plasmids containing HAI-1, SNC19/matriptase or glyceraldehyde-3-phosphate dehydrogenase (GAPDH) cDNAs were constructed and maintained in our laboratory. Purified plasmid DNAs were quantified by absorbance at 260 nm and serially diluted as PCR standards.

Real-time RT-PCR

Two micrograms of total RNA was used in a 25 μL reverse transcription reaction system containing oligo $(dT)_{15}$ and M-MLV reverse transcriptase (Promega Co., USA). For real-time PCR, the cDNA samples were brought to a final concentration of 50 mmol/L KCl, 10 mmol/L Tris-HCl (pH 9.0), 1.5 mmol/L $MgCl_2$, 0.1% Triton-X 100, 200 μmol/L dNTPs, 0.2 μmol/L each primer, 0.1 μmol/L probe, and 5 U/μL Taq DNA polymerase (Promega Co., USA). The reactions were carried out under pre-optimized conditions. Samples were amplified with a hold at 95 ℃ for 5 min, followed by 40 cycles of denaturation at 95 ℃ for 20 s, annealing at 60 ℃ for 20 s and extension at 72 ℃ for 20 s in the ABI Prism 7700 sequence detector (Perkin Elmer Co., USA). Serially diluted standard specimens with the concentration of 10^6-10^{10} copies/mL were used to plot the standard curve. No template control and no reverse transcription control were included; 2% agarose gel electrophoresis was used in optimizing procedure.

Statistical analysis

All statistical analyses were done by the SPSS 11.0 software package. Non-parametric data were analyzed with Wilcoxon, Mann-Whitney, and Kruskal-Wallis rank sum tests to evaluate the association between SNC19/matriptase and HAI-1 mRNA expression and clinicopathological parameters. $M(Q_R)$ was computed as summary statistics.

RESULTS

Real-time RT-PCR of SNC19/matriptase and HAI-1

Real-time fluorescent quantitative RT-PCR was performed to determine the expression of SNC19/matriptase and HAI-1 at mRNA level using GAPDH as internal control. Figure 1 shows the detection and plotting of the GAPDH standard curve. The PCR products were subjected to 2% agarose gel electrophoresis in optimized procedure, as shown in Figure 2. The products were specific, with anticipated sizes confirmed by DNA sequencing.

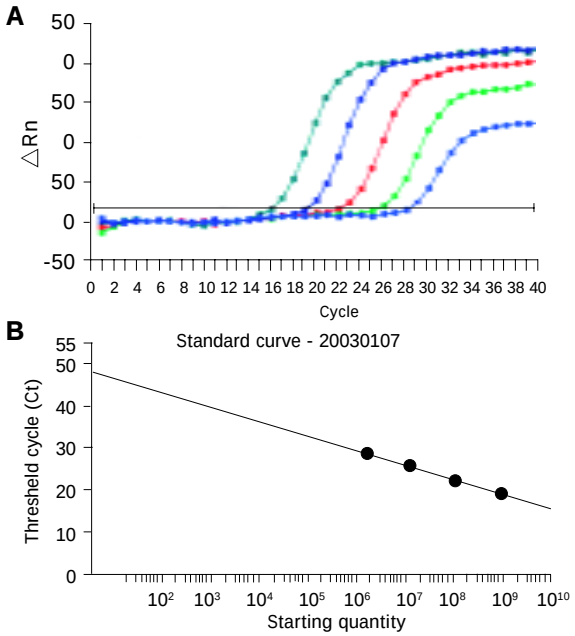

Figure 1 Representative real-time RT-PCR analysis for GAPDH mRNA copy levels. A: Amplification plots of pGEM-T Easy/GAPDH cDNA; B: standard curve plotted against pGEM-T Easy/GAPDH cDNA copy number.

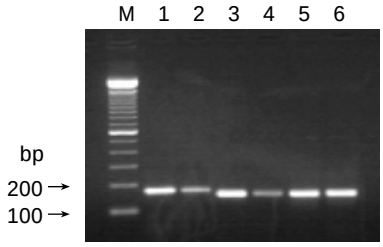

Figure 2 Expression of SNC19/matriptase and HAI-1 in gastric cancer tissue and its corresponding normal tissue (real-time RT-PCR products assay). M: Marker (100-bp DNA ladder); lanes 1 and 2: SNC19/matriptase (168 bp); lanes 3 and 4: HAI-1 (151 bp); lanes 5 and 6: GAPDH (151 bp); lanes 1, 3 and 5: gastric normal tissues; lanes 2, 4, and 6: gastric cancer tissues. Figures in brackets indicate the sizes of real-time RT-PCR products.

Expression of HAI-1 and SNC19/matriptase in normal and malignant tissues of gastrointestinal tract and correlation with clinicopathological parameters

The mRNA copy numbers of HAI-1, SNC19/matriptase and internal control GAPDH in each of normal and malignant tissues of gastrointestinal tract were detected by real-time fluorescent quantitative RT-PCR technique. The ratios of HAI-1:GAPDH and SNC19/matriptase: GAPDH were used as the relative expression level of HAI-1 and SNC19/matriptase, respectively. As shown in Table 2, the expression of HAI-1 and SNC19/matriptase in both gastric and colorectal cancer tissues was markedly lower than that in their adjacent normal tissues ($P<0.01$), while HAI-1:SNC19/matriptase ratio showed no significant difference between normal and malignant tissues of gastrointestinal tract ($P>0.05$).

The correlations between the expression of HAI-1 and SNC19/matriptase and clinicopathological parameters were evaluated (Tables 3 and 4). In gastric cancer tissues (Table 3), decreased expression of HAI-1 and HAI-1: SNC19/matriptase ratio were associated with stage III/IV cancer tissues compared to stage I/II ones ($Z = -2.140$, $P = 0.031$; $Z = -2.155$, $P = 0.031$). The expression of SNC19/matriptase had no relationship with clinical stages ($P>0.05$). The expression of HAI-1 and HAI-1:SNC19/matriptase ratio in lymph node-positive cancer tissues were lower than those in lymph node-negative ones ($Z = -2.081$, $P = 0.036$; $Z = -2.686$, $P = 0.006$). The expression of HAI-1 and HAI-1:SNC19/matriptase ratio increased in well-differentiated gastric cancer tissues, but there was no statistical significance ($P>0.05$). The differences of SNC19/matriptase were not significant in gastric cancer tissues with different histological differentiation status ($P>0.05$). In colorectal cancer tissues, the expression of HAI-1 was lower in Dukes' C/D cancer tissues than in Dukes' B ones. HAI-1 expression in lymph node-positive cancer tissues was lower than that in lymph node-negative ones. Decreased expression of HAI-1 was associated with increased invasive depth and lymph node metastasis, although there was no statistical significance ($P>0.05$). However, the differences of SNC19/matriptase expression and HAI-1:SNC19/matriptase ratio were not significant in different stages and different lymph node metastasis status ($P>0.05$). All the expression of HAI-1 and SNC19/matriptase and their ratio showed no statistical significance in different histological differentiation status ($P>0.05$). In gastrointestinal cancers, the expression of HAI-1 and SNC19/matriptase and HAI-1:SNC19/matriptase ratio showed no difference in patients of different ages, genders, location of tumors, and histological types ($P>0.05$).

DISCUSSION

The inhibitors of serine proteases are important regulators of enzyme activities. They are classified into at least 10 families[23]. Among them, serpins (serine protease inhibitor) such as Kunitz-type inhibitors are correlated with suppression of tumor invasion[24].

Serine protease SNC19/matriptase is a newly characterized ECM-degrading protease, which may also function as an activator for HGF/SF and other proteases. HAI-1, the cognate Kunitz type inhibitor of SNC19/matriptase, was first found in the stomach carcinoma cell line. Although the expression of HAI-1 has been studied in some types of cancer, the expression profile in normal and malignant gastric tissues is still absent.

As was found in epithelial ovarian cancers that all HAI-1-positive tumors are also SNC19/matriptase positive[16], the imbalance between the protease and the inhibitor may play an important role in the development of tumors. In this study, HAI-1 and SNC19/matriptase showed a remarkable decrease in cancer tissues compared to their adjacent normal tissues in gastrointestinal tract, but the ratio of HAI-1: SNC19/matriptase showed no significant difference between normal and malignant gastrointestinal tissues. Whether the ratio is critical to tumor development or progression needs to be further investigated. Since a novel function of the integral membrane Kunitz-type inhibitor in the regulation of pericellular protease activity has been suggested, HAI-1 may act not only as an inhibitor but also as a reservoir of this enzyme on cell surface[25,26]. With this possibility and other lines of evidence, the situation in cancer may be more complicated. HAI-1 has a strong affinity for both HGFA and SNC19/matriptase to form a protease/inhibitor complex and its specific Kunitz domains are responsible for the inhibitory activity[27]. It was reported that HAI-1 may participate in the activation of SNC19/matriptase through their low-density lipoprotein receptor class A domains interacting with each other, and HAI-1-mediated activation and inhibition of SNC19/ matriptase occur in human mammary epithelial cells[28]. At the same time, HAI-1 not only inhibits the activity of SNC19/matriptase but also prevents it from being hydrolyzed by other proteases[29]. It was reported that decreased immunoreactivity of membrane-form HAI-1 and enhanced ectodomain shedding of HAI-1 are found in colorectal adenocarcinoma cells[30]. There might be a more complicated interaction between HAI-1 and SNC19/matriptase rather than simple activity inhibition. In breast cancer cells, SNC19/matriptase is detected mainly as an uncomplexed form, whereas in human milk a complex containing matriptase and HAI-1 is detectable[18]. The active form of SNC19/matriptase may release from HAI-1 fragment into extracellular milieu, thus playing a role in tumor cells as ectodomain shedding of HAI-1 enhances, which may provide SNC19/matriptase opportunities to actively down-stream biological factors.

HAI-1 expression and HAI-1: SNC19/matriptase ratio decrease in gastric cancer tissues where invasion and lymph node metastasis occur. HAI-1 may play a role in progression and metastasis of gastric cancer by inhibiting HGF. SNC19/ matriptase showed no significant difference in invasive tumors in this study. Lower ratio of HAI-1:SNC19/

matriptase in stage III/IV cancers compared to stage I/II ones may be due to the down-regulated expression of HAI-1. The expression of HAI-1 tends to increase in well-differentiated gastric cancer tissues. It was reported that the expression of HAI-1 increases as the histological grade decreases in hepatocellular carcinoma [31], and decreases in poorly differentiated breast tumors [32]. HAI-1 displays different patterns of expression in different tissues[33].

In colorectal cancer tissues, HAI-1 expression is inverse correlated tumor invasion and lymph node metastasis. In our study, the expression of HAI-1, SNC19/matriptase and their ratio did not show differences in colorectal cancer tissues with different differentiation status, but the expression of HAI-1 seemed to be related to histological grades. Further analysis regarding the patients' age, gender, location, and histological type of tumor showed no correlation with HAI-1 expression.

In conclusion, both SNC19/matriptase and HAI-1 are downregulated in gastrointestinal cancer tissues, and the underlying mechanisms need to be extensively investigated. A larger scale study both in case number and disease spectrum needs to be carried out to elucidate the exact role of SNC19/matriptase and HAI-1 in tumor development and progression.

Abstract

AIM: To study the effects of microcirculation disturbance (MD) on rats with acute severe pancreatitis (ASP).

METHODS: We developed ASP rat models, and anatomized separately after 1, 3, 5, 7, and 9 h. We took out blood and did hemorrheologic examination and erythrocyte osmotic fragility test, checked up the water content, capillary permeability, and genetic expression of intercellular adhesion molecule-1 (ICAM-1) in lung tissues, examined the apoptosis degree of blood vessel endothelium while we tested related gene expression of Bax and Bcl-2 in lung tissues. We did the same examination in control group.

RESULTS: The viscosity of total blood and plasma, the hematocrit, and the erythrocyte osmotic fragility were all increased. Fibrinogen was decreased. The water content in lung tissues and capillary permeability were increased. Apoptosis degree of blood vessel endothelium was increased too. ICAM-1 genetic expression moved up after 1 h and reached its peak value after 9 h.

CONCLUSION: MD plays an important role in ASP following acute lung injury (ALI). The functional damage of blood vessel endothelium, the apoptosis of capillary vessel endothelium, WBC edging-concentration and the increasing of erythrocyte fragility are the main reasons of ALI.

INTRODUCTION

Microcirculation change has a great effect on causing diseases and acute severe pancreatitis (ASP) process. The lung can be damaged easily[1]. About 70% of deaths are due to acute respiratory distress syndrome[2,3]. In this study, we observed the microcirculation in rats and the changes in lung. The relationship between acute lung injury (ALI) and microcirculation change in rats with ASP was studied.

MATERIALS AND METHODS

Experimental animals and grouping

Rats were provided by the Experimental Animal Center of Medical School of Xi'an Jiaotong University. Experiment group (40 rats) was injected with 4% sodium taurocholate 1 mL/kg by puncturing pancreatic duct to make ASP models. Control group (eight rats) was only turned over duodenum. Experiment group was divided into five subgroups, eight rats in each group. They were anatomized after 1, 3, 5, 7, and 9 h, respectively.

Hemorrheologic examination and erythrocyte osmotic fragility test

Blood sedimentation (BS) was done with 0.2 mL venous blood. After centrifugation, hematocrit was read. The content of fibrinogens (CB) was recorded after water bath and centrifugation. The viscosity of total blood (VTB) and plasma (VP) was checked up in another 1-2 mL venous blood. The resistance of RBC to different concentrations of hypo-osmotic saline was examined. The permeability fragility of RBC was detected.

TUNEL examination

Lung tissues were fixed and sliced. Apoptosis staining experiment was done. We observed the change of lung capillary vessel endothelium apoptosis under a light microscope. The cells with brown-blue nuclei were considered as apoptosis cells.

Lung Bcl-2 and Bax protein examination with immunohistochemical method

The cells stained brown or brown-yellow were positively stained cells. To account the positive staining, we counted four high-power fields according to the formula: positive rate = the number of positive cells/total number of cells×100%. It was determined as negative staining (-) when the positive rate was <15%, and as positive staining when the positive rate was 15-50% (+), 50-75% (++), and >75% (+++), respectively.

Lung capillary permeability

The change of lung capillary permeability was detected by injecting Evan's blue into veins. Using a 625-nm spectrophotometer, the concentration of Evan's blue represented the milligrams of the dyes per gram of wet weight lung.

Water content in lung tissue

First, we weighed the wet weight of lung tissues, and after being parched for 72 h at 70 ℃, we weighed the dry weight. The water content (%) = (wet weight-dry weight)/wet weight.

RT-PCR examination of ICAM-1

We took β-actin as an inner contrast gene. Lung RNA was isolated by TRIzol. Oligo(dT)$_{15}$ was used as a primer. The reaction conditions were at 42 ℃ for 15 min, at 99 ℃ for 5 min, at 4 ℃ for 4 min, and then we got the first chain of cDNA. PCR was done for 1 min at 94 ℃, for 1 min at 55 ℃, for 2 min at 72 ℃, 35 circles in all. Finally, it was expanded for 10 min at 72 ℃. After electrophoresis, we confirmed the quantity with a white/ultraviolet transilluminator. The expanding quantity of targeted genes/the expanding quantity of inner contrast genes expressed the quantity of detected genes.

Statistical analysis

The data were expressed as mean±SD. Kruskal-Wallis method and Mann-Whitney method were adopted to compare the two indexes.

RESULTS

Pathological observation of lung tissues

We observed the pathological change of lung tissues and found that interstitial pulmonary edema, focal and congestive pulmonary atelectasis were present at the forepart of ASP. PMNs were present in capillaries, and thrombosis was visible in capillaries (Figure 1). The changes aggravated gradually.

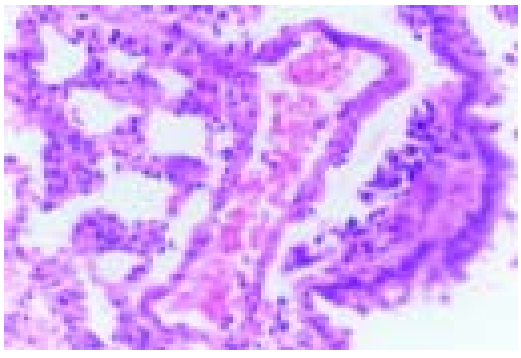

Figure 1 Interstitial pulmonary edema, infiltration of PMNs, and thrombosis in capillaries in lung, HE staining, ×20.

Apoptosis of capillary endothelium in lung

Apoptosis endothelium could be examined in lungs of control group. After the models were made, the number of apoptosis endothelial cells was increased. When we compared the number of apoptosis cells at 3 h with that at 9 h, we found that the number of apoptosis endothelial cells at 9 h was greater than that at 3 h. This trend was related to the grade of ALI.

Lung Bcl-2 and Bax protein expression

Bcl-2 and Bax protein were less expressed in normal lung tissues. After ASP models were made, we found that Bcl-2 and Bax protein expression was obvious. Bax protein expression accorded with the changes of cell apoptosis, and reached its peak in 7-9 h. Bcl-2 expression was inversely correlated with the changes of cell apoptosis, and declined gradually after 3 h (Table 1).

Table 1 Positive staining rate of Bcl-2 and Bax in each period of time (%, mean±SD, n = 8)

	1 h	3 h	5 h	7 h	9 h
Bcl-2[a]	37.3±4.3	84.6±4.3	67.4±2.1	70.3±4.2	52.3±5.3
Bax[a]	42.3±4.4	62.6±4.8	68.2±3.3	77.6±4.2	79.3±5.7

[a]P<0.05 *vs* each period of time.

ICMA-1 and RT-PCR examination

The genetic expression of intercellular adhesion molecule-1 (ICAM-1) in lung tissues was increased after 1 h and reached its peak after 9 h. The gene expressions of ICAM-1 were significantly different in each period of time (P<0.05, Figure 2).

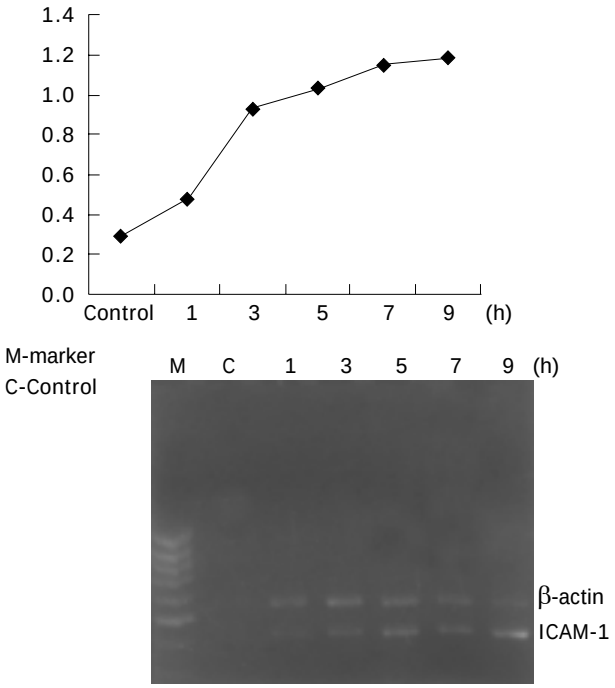

Figure 2 ICAM-1 genetic expression in different periods of time. The genetic expression of ICAM-1 in lung tissues was increased after 1 h and reached its peak after 9 h (n = 8).

Water content and capillary permeability in lung

Compared with control group, the water content and capillary permeability in lung tissues in ASP group were both increased

obviously in each period of time (Table 2).

Hemorrheologic examination

Compared with control group, each items of hemorrheology were diverse in each period of time (Table 3).

DISCUSSION

The main characteristic of acute pancreatitis is the change in blood circulation of pancreas and the whole body[4-6]. Blood volume declined obviously in early period of ASP. Hemoperfusion could exacerbate ASP. In this experiment, sodium taurocholate was injected through the pancreatic duct to make ASP models. We observed various indexes of ASP at different time points. Significant hemorrheology changes could be observed in rats with ASP. The blood viscosity and the erythrocyte osmotic fragility were increased. The capillary permeability in lung tissues was also increased. Interstitial pulmonary and microthrombosis were found. Obvious microcirculation disturbance (MD) could be observed in lung tissues and the whole body of rats with ASP. After the models were made, the number of apoptosis endothelial cells and the genetic expression of ICAM-1 in lung tissues were significantly increased, suggesting that ASP can cause MD in many ways and plays an important role in causing and exacerbating ALI.

WBCs adhered to the blood vessel endothelium could cause inflammation[7-9]. Adhesion molecule could play an important role in adhesion process, and its expression could reflect the change of blood vessel endothelium[10-17]. After ASP models were made, ICAM-1 gene expression was increased and became easier for WBCs to adhere to blood vessel endothelium. Therefore, it made WBCs to invade the lung tissues more easily.

For vein wall permeability, blood vessel endothelium is the main barrier. In this study, the number of apoptosis cells increased and apoptosis was accorded with the increasing of lung tissues, vessel permeability and water content. We think that the increasing of apoptosis cells in lung tissues could alter the structure integrality of capillary endothelium. Because the endothelial cells could not renew rapidly by themselves, apoptosis could lead to decrease of blood vessel endothelial cell storage. This kind of change results in the increase of blood vessel endothelium gap and its permeability[18,19].

Our study found that hemorrheology changed obviously in blood of ASP rats, thus leading to more serious MD of pancreas and other organs. This is the main reason for pancreas necrosis and ARDS representation[20,21]. The primary presentations are the decline of RBC aggregation capacity, increase of VTB and VP as well as WBC edging-concentration. The later is the primal step of WBCs swimming outside of blood vessel, leading to grievous inflammation and ALI[22]. WBC edging-concentration in rats with ASP was affected not only by inflammation medium and chemotatic factor but also by other factors, such as tiny vein, blood viscosity, and RBC aggregation[23].

The erythrocyte fragility was increased after ASP presentation, and became more serious following the progress of the disease. The increase of erythrocyte fragility could reflect the defective capacity of RBC distortion. RBCs break up easily, and release adenosine diphosphate, thus causing the activation of coagulation system and disseminated intravascular coagulation, leading to the decrease of fibrinogen.

In conclusion, MD plays an important role in the process of ASP with lung injury. Ameliorating MD could not only reduce local damages in pancreas, but also protect the lung and other organs in the body. Therefore, ameliorating MD is an effective therapy in treating ASP.

Abstract

AIM: To investigate the contribution of HBV in the development of hepatocarcinoma by examining the effects of HBV on p53 function in SMMU-7721 cell line.

METHODS: Plasmid pCMVp53 was transfected or cotransfected with pCMVHBVa (wild-type HBV) or PCMVHBVb (mutation type HBV) into the hepatoma cell line SMMU-7721 by lipofectamine. Apoptosis cells were labeled with annexin V-FITC and confirmed by flow cytometry. Reporter plasmid PG13-CAT or p21-luc was cotransfected, respectively, into each group to determine the transactivation activity of p53 and its effect on p21 promoter. Western blot was performed to observe p53 expression in hepatoma cell line of each group.

RESULTS: The group transfected with pCMVp53 alone exhibited higher luciferase activity and higher apoptosis rate, otherwise, the p53 expression and reporter activity of PG13-CAT or P21-luc as well as cell apoptosis rate were obviously higher in the group cotransfected of pCMVp53 with pCMVHBVa, but not in the other cotransfected group.

CONCLUSION: Transient transfection of HBV into the SMMU-7721 cell line can enhance p53 expression and its effects on development of hepatocarcinoma.

INTRODUCTION

HBV is a major etiological factor associated with hepatocarcinogenesis, but its role in the transformation process remains unknown. p53 is an important tumor suppressor and its mutation or inactivation is thought to be involved in the development of various types of cancers, including primary hepatocellular carcinoma (PHC)[1]. It has been reported that the p53 protein could bind with HBx antigen to form the complexes, which led to p53 inactivation[2,3]. Genetic alterations in the cellular genome in HBV-transfected HepG2 cells were also detected, which could indicate HBV replication[4]. In view of the intimate relationship between HBV infection and hepatoma, relationship between HBV and p53 is always a research spot. In this experiment, we observed the effect of HBV on p53 expression and activity in SMMU-7721 cell line.

MATERIALS AND METHODS

Materials

Plasmids and cell Human hepatoma cell line, SMMU-7721, was constructed in our laboratory, which can express wild type p53, but without HBV replication. The plasmids of pCMVHBVa (wild type HBV), pCMVHBVb (mutant type HBV, C-T substitution at 1 653 bp) and pCMVp53 (containing wild type p53 1.8 kb cDNA) were supplied by the Center for Human Virology of Thomas Jefferson University. PG13-CAT was kindly provided by Dr. Vogelstein, which contains 13 consecutive p53 recognition sites, making the expression of chloramphenicol acetyltransferase (CAT) regulated by p53 protein in the cells, and its inner control plasmid was pSVβ-gal (Promega, USA). p21-luc (kindly provided by Dr. Vogelstein) contains p53 binding site with p21 promoter and luciferase reporter gene. The inner control plasmid PRL-SV40 (Promega) was cotransfected into cells to eliminate the difference caused by transfection efficiency or cell counts.

Chemicals and reagents Lipofectamine™ transfection reagent was purchased from Gibco BRL (Gaithersburg, MD, USA). Dual Luciferase Assay System was purchased from Promega (USA). Annexin-V-FITC reagent was from Bender MedSystems (Vienna, Austria), CAT-ELISA kit was purchased from Roche (Mannheim, Germany). BCA protein detection kit was from Tian-Cheng Company (Shanghai, China). Protein prestained marker was provided by BioLabs (Australasia). Western blotting luminal reagent was from Santa Cruz (USA). Mouse mAb P53-DO7 was from Antibody Diagnostica Incorporation (USA). Internal control β-actin antibody was from Sigma (USA). Goat-anti-mouse horseradish peroxidase antibody and PVDF were from Hua-Mei Biological Company (Shanghai, China).

Methods

Cell culture and transient transfection with plasmid DNA SMMU-7721 cells were cultured in DMEM media supplemented with 100 mL/L fetal calf serum (FCS) and antibiotics, and incubated at 37 ℃ in a humidified atmosphere containing 50 mL/L CO_2. The experiment was divided into four groups: pCMVp53 was transfected alone or cotransfected with pCMVHBVa or pCMVHBVb into the SMMU-7721 cell; and the control group was transfected by sperm DNA. The total of 2 μg DNA was transfected into the cells in each group. DNA amount was held constant in all experiments by adjusting with sperm DNA. Plasmid DNAs were introduced into SMMU-7721 by lipofectamine™ following the manufacturer's instructions. Briefly, cells were seeded into 35-mm culture dishes for 24 h and the medium was refreshed 4 h before transfection. The DNA mixed with 12 μL of lipofectamine™ was added to each plate and incubated in serum-free medium at 37 ℃ for 6.5 h, and then the medium was replaced with RPMI containing 100 mL/L FCS. Sixty hours after transfection, cells were observed under microscope. Cells were harvested to detect the apoptotic rate by flow cytometry or p53 expression by Western blot.

CAT ELISA Cells were prepared and transfected as aforementioned. Total amount (2.0 μg) of DNAs were kept constant by adding PG13-CAT. SV40-driven β-gal internal control plasmid and the respective test plasmids were as follows: pCMVHBVa, pCMVHBVb, pCMVp53, or the control sperm DNA. Before harvesting, the cells were washed thrice with PBS and extracted following the manufacturer's instructions. β-Galactosidase activity was determined in 96-well plates. A total of 200 μL aliquot of the clear lysates was tested for CAT concentration in the CAT ELISA according to the manufacturer's instructions (Roche Molecular Biochemicals). The CAT concentration of each sample was normalized with respect to β-gal activity.

Luciferase assays Transfections were carried in triplicate. Exponentially growing cells were plated at a density of 5×10^4/well in 0.5 mL medium into 24-well plates. Cells were cultured overnight before transfection. Then 300 ng of luciferase reporter constructs were cotransfected with 300 ng of constructs expressing wild-type p53 proteins or pCMVHBVa or pCMVHBVb. Renilla luciferase expression vector (3 ng) was regarded as an internal control. DNA amount was held constant in all experiments by adjusting with sperm DNA. The cells were harvested 60 h after transfection by lysis with passive lysis buffer (Promega). Firefly and Renilla luciferase activities were assayed using Dual Luciferase Assay System (Promega) according to the manufacturer's instructions. The firefly luciferase activity was normalized to Renilla luciferase activity to compensate for variability in transfection efficiencies.

Flow cytometric analysis of apoptotic cells The cells were stained with FITC-labeled annexin V (Bender MedSystems) and propidium. FITC-labeled annexin V has been used to detect apoptotic cells because annexin binds PS exposed to the outer membrane in apoptotic cells[5-7]. Flow cytometric analysis was performed with a Becton Dickinson flow cytometer (FACScan), and the results were analyzed with the CELLQUEST program (Becton Dickinson).

Western blot analysis Cell pellets were lysed in lysis buffer containing protease inhibitors. The protein concentration of each cell lysate was determined with the BCA assay kit. Eighty micrograms of total protein was separated in a 100 g/L SDS-polyacrylamide gel and transferred to a polyvinylidene difluoride transfer membrane according to standard procedures. Western blotting using anti-p53 mouse mAb DO-7 (1:1 000 dilution) was performed. ECL internal control protein β-actin detection was performed simultaneously.

Statistical analysis

The results were expressed as mean±SD. Differences between experimental groups were evaluated by Student's *t*-test. *P* value <0.05 was considered statistically significant.

RESULTS

The promoter activity of p21 in each transient transfection group

Expression of p53 has an influence on the p21 promoter. As a control, we first tested whether wild-type p53 protein could activate transcription from a p21 promoter. Wild-type p53 triggered an increase in transcription from the p21 promoter and the luciferase values increased significantly when pCMVHBVa was cotransfected, but not in the pCMVHBVb-cotransfected group (Table 1).

Table 1 Luciferase activity in each group (mean±SD)

Groups	p21-luc
pCMVp53	1.218±0.041[a]
pCMVp53+pCMVHBVa	2.197±0.522[a,c]
pCMVp53+pCMVHBVb	0.937±0.210[e]
Control	0.764±0.274

[a]*P*<0.05 *vs* control group; [c]*P*<0.05 *vs* pCMVp53 group; [e]*P*<0.05 *vs* pCMVp53+pCMVHBVa group.

Effect of HBV on transcription activity of p53

To determine the effect of HBV on the transcriptional activities of p53, p53 plasmid was transfected transiently alone or cotransfected with HBVa or HBVb, along with the PG13-CAT reporter construct (the CAT reporter gene under the control of a p53-responsive element). Even in the group transfected with PG13-CAT plasmid alone, a weak expression of CAT enzyme (1.272±0.253) was observed, which suggested that there was an underlying transcription effect of p53 in SMMU-7721. However, in the group with pCMVp53 transfection-induced overexpression of p53, CAT activity was found to be greatly increased (3.585±0.869). Moreover, the group cotransfecting HBVa with PG13-CAT also had a significantly increased CAT activity than that of the group transfected with PG13-CAT alone (2.559±0.231), while cotransfection of HBVb had no marked influence on CAT activity of PG13-CAT (Table 2).

Western blot for p53 expression

It was found that an increase in p53 transcription activity was associated with HBV replication, then it was interesting to examine whether it was caused by the upregulation of p53 protein expression. Our results showed that p53 had a weak expression in the normal SMMU-7721 cells. However,

Table 2 CAT activity in each group

Groups	CAT activity
PG13-CAT	1.272±0.253
HBVa+PG13-CAT	2.559±0.231[a]
HBVb+PG13-CAT	1.585±0.347
pCMVp53+PG13-CAT	3.585±0.869[a]

[a]$P<0.05$ *vs* PG13-CAT group.

p53 expression was markedly increased after transfection with the pCMVp53 plasmid. Furthermore, cotransfection of pCMVp53 with pCMVHBVa showed an even higher p53 expression, while the change was not remarkable when pCMVHBVb was cotransfected with p53 (Figure 1).

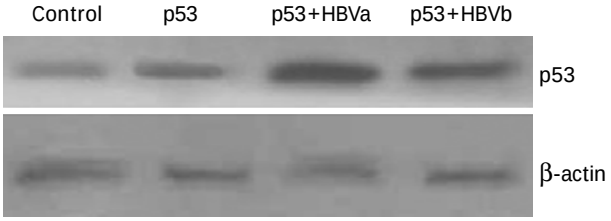

Figure 1 Western blot analysis of p53 expression in each group. Cell lysates (80 μg) were electrophoresed on SDS-PAGE gels and proteins were transferred to PVDF membranes.

Detection of apoptosis by FITC-annexin V/PI double staining

One of the important effects of p53 was its apoptosis-promoting effect. Thus, we observed the apoptosis rate which, in some sense, could indicate p53 activity. We observed that pCMVp53-transfected group had a significantly higher apoptosis rate than the control group (12.32% *vs* 6.91%). There was a much higher apoptosis rate in the pCMVp53 and pCMVHBVa cotransfected group (23.08%), but not in the pCMVp53 and pCMVHBVb cotransfected group (12.20%, Figure 2).

DISCUSSION

Although several data have suggested that the transformation process and tumorigenesis result from activation of oncogenes and inactivation of tumor suppressor genes of the DNA repair system, the question remains of what applies to PHC development. Despite the long-standing association between HBV and PHC development, the role of HBV in the transformation process is still unknown.

The long list of loci with frequent mutations associated with PHC suggests that the mechanism generating these genetic changes might be important in PHC development and needs to be identified. Mutation or inactivation of tumor suppressor gene p53 and its downstream gene p21WAF1 may have an implication in the PHC development [8]. Under normal conditions, p53 is most probably latent. Exposure of cells to p53-activating signals can lead, within a relatively short time, to a marked elevation of p53 protein.

In this experiment, HBV and p53 were transiently transfected into SMMU-7721 cell in order to investigate the apoptosis of the cells, p53 expression, and activity of p53 downstream gene-p21WAF1 promoter and the replication of HBV. Our results showed that the transfection of p53

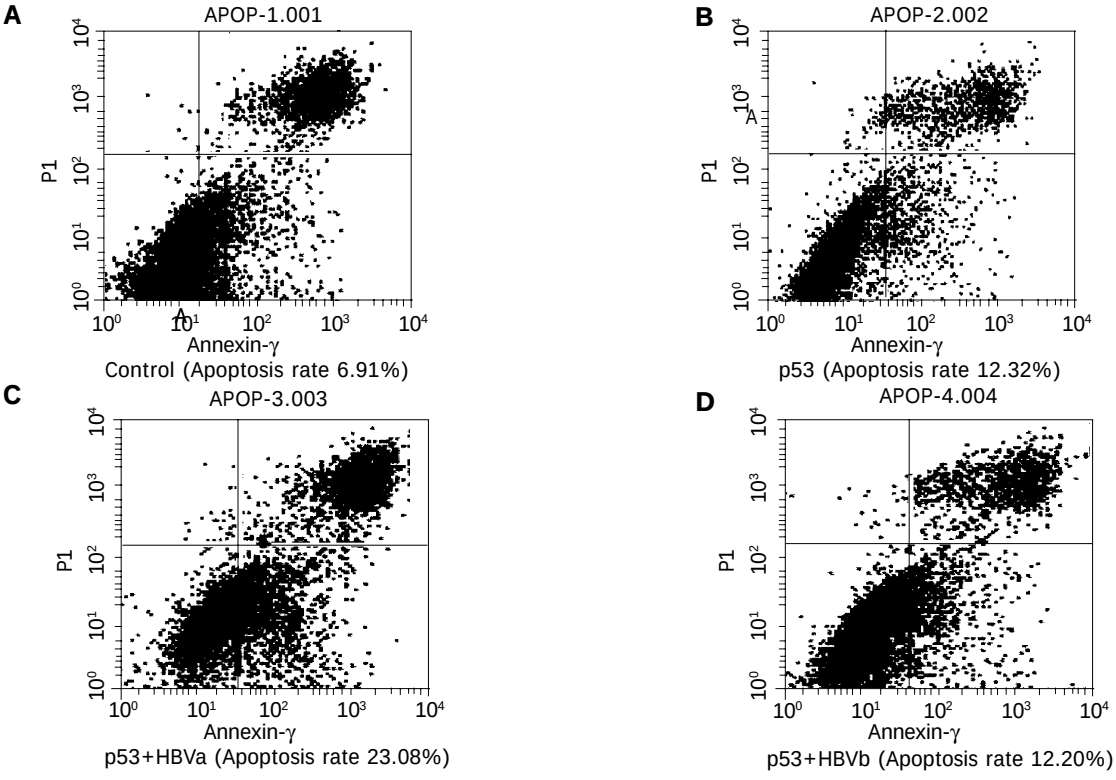

Figure 2 Flow cytometric analysis of cell apoptosis. SMMU-7721 cells were transfected with p53, p53+HBVa, p53+HBVb. The cells were stained by FITC-labeled annexin V and propidium (A-D).

alone in SMMU-7721 cells could increase p21-promoter activity and the apoptosis rate of the cells, suggesting that p53 could promote p21 transcription and contribute to the apoptosis process of the cells. While cotransfection of wild-type HBV markedly increased both p53 protein expression and its transcription activity, and simultaneously, the cell apoptosis rate was significantly increased. In contrast, cotransfection of mutant HBV did not show any effect.

As we know, wild-type p53 is usually a very labile protein, turning over with a half-life sometimes as short as few minutes[9]. On contrary, mutant p53 has a longer half-life, which makes its accumulation in cells. It is generally accepted that the accumulation of active p53 in response to stress occurs mainly through post-translational mechanism, which stabilizes the p53 and increases the ability of nucleolus location[10]. The current results showed that HBV may contribute to promote the stability and activity of p53.

Shi *et al*.[11], showed that p21 (WAF1/CIP1) expression was inversely correlated with p53 expression in hepatitis C virus (HCV)-related hepatocellular carcinomas (HCCs), but not with HBV-related HCCs and HCCs without viral infection, suggesting that different modes of p21 (WAF1/CIP1) regulation are involved in HCCs, differing from their hepatitis viral infection status, and p21 (WAF1/CIP1) expression appears to be predominantly related to altered p53 in HCV-related HCCs. Livezey *et al*.[12], analyzed the p21/Waf1 protein expression in several different kinds of cells by Western blot and indicated that p21/Waf1 protein was upregulated in cells that replicate HBV, but there was still no reasonable interpretation about this phenomenon. Since p21WAF1/CIP1 (p21) is a universal inhibitor of cyclin-dependent kinases and is regulated transcriptionally by p53, which is activated by DNA stress, its expression reflects DNA stress in chronic hepatitis. We observed the correlationship of HBV with p53 and p21, raising the possibility that HBV may have an effect on p21 expression through p53 upregulation, thereby leading to the cell apoptosis.

It has been reported that expression of p21WAF1 in the hepatic disease may be correlated with the disease progression. p21 expression has been reported to be upregulated by the stress of inflammation and fibrosis, and might be influenced by viral proteins in human chronic liver disease. Once the liver develops HCC, the p21 mRNA expression decreases to prominently low levels[13]. In hepatocarcinogenesis induced by HBV and aflatoxin B in tree shrews, the immunopositivity for p21 was found before HCC development, which suggested that p21 protein might be an early marker in the development of HCC[14]. The upregulated p21 expression may play a role as a guard to prevent hepatocytes from tumorgenicity in hepatitis.

Most of the previous reports deemed that apoptosis could not happen to the carcinogenesis cells and/or such cells had no response to the death signal, which lead to unlimited cell growth. But recent research indicates that tumor cells not only exhibited excessive proliferation, but also underwent apoptosis at rates that far exceed those in normal tissue. Proliferation and apoptosis of the tumor cells coexist at all stages and the rates of cell replication are higher than that of apoptosis, allowing a preferential net gain of pre-neoplastic cells[15]. Though HBV chronic infection is an important risk factor of HCC development, HBV-related hepatocarcinoma often happens after dozens of years of infection. In this study, we found that transient transfection of HBV induced apoptosis of SMMU-7721 cells and inactively proliferation. Thus, it is considered that there may be a balance between proliferation and apoptosis in HBV-infected hepatic cells. Hence, disruption of this balance, that is, predominance of proliferation over apoptosis, leads to tumorigenesis.

Abstract

AIM: To discuss the changes of intestinal mucosal immune function in rats with experimental severe acute pancreatitis (SAP) and the regulatory effect of L-arginine.

METHODS: Male adult Wistar rats were randomly divided into pancreatitis group, sham-operation group, and L-arginine treatment group. Animals were killed at 24, 48, and 72 h after SAP models were developed and specimens were harvested. Endotoxin concentration in portal vein was determined by limulus endotoxin analysis kit. CD3+, CD4+, CD8+ T lymphocytes in intestinal mucosal lamina propria were examined by immunohistochemistry. Secretory immunoglobulin A (SIgA) in cecum feces was examined by radioimmunoassay.

RESULTS: Compared to the control group, plasma endotoxin concentration in the portal vein increased, percentage of CD3+ and CD4+ T lymphocyte subsets in the end of intestinal mucosal lamina propria reduced significantly, CD4+/CD8+ ratio decreased, and SIgA concentrations in cecum feces reduced at 24, 48, and 72 h after SAP developed. Compared to SAP group, the L-arginine treatment group had a lower level of plasma endotoxin concentration in the portal vein, a higher CD3+ and CD4+ T lymphocyte percentage in the end of intestinal mucosal lamina propria, an increased ratio of CD4+/CD8+ and a higher SIgA concentration in cecum feces.

CONCLUSION: Intestinal immune suppression occurs in the early stage of SAP rats, which may be the main reason for bacterial and endotoxin translocation. L-arginine can improve the intestinal immunity and reduce bacterial and endotoxin translocation in SAP rats.

Qiao SF, Lü TJ, Sun JB, Li F. Alterations of intestinal immune function and regulatory effects of L-arginine in experimental severe acute pancreatitis rats. *World J Gastroenterol* 2005; 11(39): 6216-6218
http://www.wjgnet.com/1007-9327/11/6216.asp

INTRODUCTION

Infection is a common and usually lethal complication during severe acute pancreatitis (SAP). In previous studies, the prevalence of infection in SAP varies between 40% and 70%, and most of the deaths of patients are related with infection. The gastrointestinal tract may be the origin of bacterial translocation during SAP, and SAP may influence the gut barrier function, leading to the occurrence of gut origin sepsis. In this study, we discussed the changes of intestinal immunity in SAP rats.

MATERIALS AND METHODS

Animals and materials

Male Wistar rats weighing 250-300 g; L-arginine (Sigma Chemical Co.); sodium taurocholate (Sigma Chemical Co.); mouse anti-rat anti-CD3, CD4, CD8 mAb (Santa Cruz Co.); SIgA radioimmunoassay kit (Institute of Atomic Energy Physics Chinese Academy of Sciences, Beijing); limulus endotoxin analysis kit (Shanghai Medical Laboratory) were used in the study.

SAP model and experimental groups

Rats were fasted for 14 h before the experiment. Animals were anesthetized by intraperitoneal injection of 10% chloral (3 mL/kg) and then SAP models were developed as previously described[1]. Under sterile conditions, a middle laparotomy was performed. The SAP rat model was developed by pumping 3% sodium taurocholate (TCA) into the pancreatic tract at a rate of 18 mL/h (1 mL/kg). Fifty-four rats were randomly divided into SAP group (n = 18), sham group (n = 18), and L-arginine treatment group (n = 18). The rats were allowed to drink 1% L-arginine water for 5 d before SAP model was developed. At 24, 48, and 72 h after the model was developed, animals from each experimental group were killed and specimens were harvested.

Analysis of serum endotoxin in portal vein by limulus methods

The serum endotoxin concentration in portal vein was assayed by chromogenic limulus analysis kit according to the manufacturer's protocol.

Immunohistochemistry

Intestinal tissue fragment (3 cm from cecum) was cut and fixed by immersing in 4% paraformaldehyde immediately. The specimens were embedded in regular paraffin wax and cut into 4-μm-thick sections. Tissue sections were deparaffinized and rehydrated in PBS. Endogenous peroxidase activity was blocked by incubation with 3% H_2O_2/PBS for 10 min. After being immersed in 1% BSA/PBS at 37 ℃ for 1 h, the sections were incubated with mouse anti-rat anti-CD3, CD4, CD8 mAb at 4 ℃ overnight. The specimens were incubated with peroxidase-conjugated goat anti-rat secondary antibody for 2 h at room temperature. Finally, the specimens were immersed in DAB for 10 min. Brown staining cells were defined as positive cells and counted in four high microscope view, the percentage of positive cells and CD4+/CD8+ ratio were calculated.

Analysis of SIgA content by radioimmunoassay methods

Cecum feces were diluted with water to double volumes. Samples were shaken at 4 ℃ overnight and then examined by SIgA radioimmunoassay test kit.

Statistical analysis

Data were analyzed by *t* test and expressed as mean±SD. $P<0.05$ was considered statistically significant.

RESULTS

Changes of serum endotoxin in portal vein of rats

Compared to the control group, plasma endotoxin concentration in the portal vein increased significantly 24, 48, and 72 h after SAP model was developed ($P<0.01$). The L-arginine treatment group had a lower level of endotoxin concentration than SAP group ($P<0.01$, Table 1).

DISCUSSION

SAP is a very common disease in clinical surgery. Though the diagnosis and therapy have been improved, its mortality is 10-20%. Secondary pancreatic infection and multiple organ dysfunction syndrome (MODS) are major causes of death in patients with SAP. Infection is the most common clinical syndrome at present and the morbidity in SAP patients is about 40-70%[2]. Infection is also an important factor for SAP followed by MODS[3]. Bacterial infection is devastative for the pancreas and other tissues, and increases the mortality of acute pancreatitis patients. Clinical data and animal experimental studies have shown that most bacteria-associated pancreatic and peripancreatic infection are of enteric origin[4], and the gut seems to be the principal source of the infection[5]. The gastrointestinal tract is regarded as the largest immune organ in the body containing diverse immunocytes to prevent bacterial and endotoxin translocation from indigenous gut flora. Viable enteric bacteria must pass through the intestinal mucosal barrier to extraintestinal sites, leading to gut-associated infection. During the course of SAP, gastrointestinal tract may be attacked and gut-barrier function is damaged, allowing a large amount of bacteria and endotoxin to enter into the systemic circulation, leading to bacteremia and endotoxemia that may cause more severe complications. Prevention of gut bacterial translocation is most important in avoiding extraintestinal infection and improving the prognosis of SAP patients.

SIgA plays an important role in intestinal mucosal defense and is the first line of defense on intestinal and extra-intestinal mucosal surfaces. SIgA can prevent bacterial adherence and subsequent invasion of the mucosal surface, which is considered crucial in initiating mucosal invasion and infection. SIgA deficiency results in bacterial overgrowth, adherence and translocation[6]. Our results showed that SIgA concentration in cecum feces of the SAP group reduced significantly, indicating that SIgA secretion from intestinal mucosa to the intestinal tract was decreased in SAP rats. SIgA deficiency may increase dissociative bacteria and

endotoxin concentration in the intestinal tract, and their migration through the intestinal mucosa and entry into the portal vein blood[7].

CD3 molecules are expressed on the surface of all mature T lymphocytes and can be used to measure the total number of mature T lymphocytes. In our study, the number of CD3+, CD4+ T lymphocytes in intestinal mucosal lamina propria reduced significantly in SAP rats and remained at the lower level at 72 h. The ratio of CD4+/CD8+ T lymphocytes markedly decreased, indicating that mature T lymphocytes are decreased in intestinal mucosa and immune function is suppressed in SAP rats, while CD8+ T lymphocytes do not change significantly. Because the majority of T lymphocytes in intestinal mucosal lamina propria are CD4+ T lymphocytes, change of CD8+ T lymphocytes is not the main trend[8]. Further experiments are needed to validate the results. Since the number of CD4+ T lymphocytes reduces, cytokines including IL-2, IL-4, IL-6, IL-7, IL-12, IFN-γ are secreted by CD4+ T helper (T_H) lymphocytes and the number of active effector Tc cells reduces accordingly. Thus, the intestinal immune function decreases significantly in SAP rats.

L-arginine is important for the proliferation and maturation of CD3+ T lymphocytes. Dietary arginine may increase the number of CD4+ and CD8+ T lymphocytes as well as the IgG and IgA content[9-11]. Our results have confirmed that oral supplement of L-arginine increases the number of CD3+ and CD4+ T lymphocytes as well as the ratio of CD4+/CD8+ T lymphocytes in intestinal mucosal lamina propria and SIgA concentration in cecum feces in SAP rats, suggesting that L-arginine can improve the immune responsibility of intestinal mucosa and decrease the bacterial and endotoxin translocation in SAP rats.

Abstract

Primary biliary cirrhosis (PBC) is an autoimmune disease characterized by anti-mitochondrial antibodies and destruction of intra-hepatic bile ducts. Though little is known about the etiology of PBC, some reports suggest that xenobiotics and viral infections may induce PBC. We describe a case of PBC after the aortoiliac reconstruction surgery using a Y-graft.

INTRODUCTION

Primary biliary cirrhosis (PBC) is a chronic inflammatory process primarily affecting the medium-sized intra-hepatic bile ducts, leading to chronic cholestasis and often progressing to cirrhosis and liver failure, which requires liver transplantation. PBC is thought of as an autoimmune disease because it is closely associated with various immunological abnormalities, the hallmark being the presence of anti-mitochondrial antibodies in over 95% of patients.

CASE REPORT

A 61-year-old male was admitted to our hospital in September 1995 with biochemical cholestasis and abnormal liver function tests. He had taken anti-hypertensive agents (amlodipine and betaxolol) since February 1995. His blood examination sometimes presented very mild biochemical cholestasis without any symptoms. Viral hepatitis was denied, but autoantibody was not checked at that time. Earlier in March 1995, he had an abdominal aortic aneurysm and underwent aortoiliac reconstruction using a Y-graft. Ten days after the surgery, his chemistry showed marked cholestasis, including alkaline phosphatase levels 5-10 times the upper limit of normal and gamma glutamyltransferase levels 5-15 times higher than the upper limit of normal. At first, drug-induced cholestasis was suspected and he started other anti-hypertensive medications (nifedipine and imidapril). Cholestasis improved after changing these medications for a while, but it worsened in August 1995. On admission to our hospital in September 1995, he denied any preceding or on-going fever, flu-like illness, pruritus, abdominal pain, anorexia, vomiting, joint pain, dry eyes, or skin rashes. He denied previous blood transfusion, iv drug abuse, or alcohol abuse. There was no family history of liver disease or malignancy.

Physical examination revealed mild hepatomegaly, but no ascites or mass. The laboratory data showed an alkaline phosphatase level of 572 IU/L, a gamma glutamyltransferase level of 726 IU/L, an AST of 43 IU/L, an ALT of 30 IU/L, a total bilirubin of 0.5 g/dL, a direct bilirubin of 0.2 g/dL, an IgG level of 2 180, an IgM level of 384, and a total cholesterol level of 204 mg/dL. Antinuclear antibody titer was 1 280-fold beyond the upper normal limit, anti-smooth muscle antibody was 80-fold, and anti-mitochondrial antibody was 80-fold higher. A hepatitis profile for hepatitis B and C was negative. An abdominal ultrasound revealed a slightly atrophic liver with dull edge, dilated common bile duct (12 mm), and a gallbladder stone. His liver biopsy showed inflammatory destruction of the intrahepatic septal and interlobular bile ducts within the portal space, and expanded portal tracts by lymphocytes with sparse neutrophils or eosinophils, suggesting PBC (stage I by Scheuer staging) (Figure 1).

A diagnosis of asymptomatic PBC was established on the basis of cholestasis, a positive AMA, and the histological findings. The patient was started on ursodeoxycholic acid 600 mg thrice a day, with a positive response to the cholestasis.

DISCUSSION

PBC is a chronic cholestatic liver disease of unknown cause. Progressive bile duct injury from portal and periportal inflammation could result in progressive fibrosis and eventually cirrhosis. Evidence to date suggests that

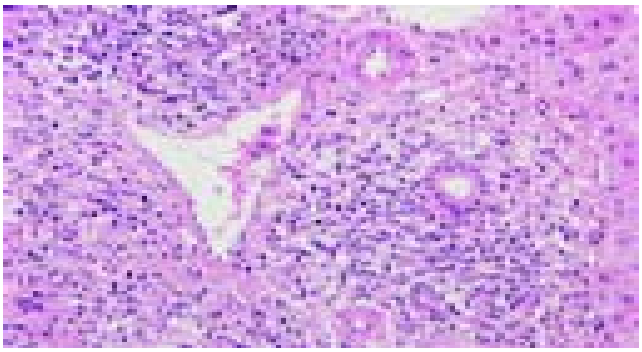

Figure 1 The liver biopsy showed inflammatory destruction of the intrahepatic septal and interlobular bile ducts within the portal space, and expanded portal tracts by lymphocytes with sparse neutrophils or eosinophils.

immunological and genetic factors might cause the disease. Evidence for an immunologic cause of PBC includes immunohistochemical data showing the presence of activated T cells in areas of bile duct destruction and the presence of highly specific autoantibodies reactive with antigens on the surface of biliary epithelial cells. Environmental factors[1] and infectious agents[2-4] also may trigger an autoimmune attack. Other reports suggest that the disease may be induced by xenobiotics and that halogenated compounds will bind to the PDC-E2 autoantigen, breaking tolerance and leading to an intense mucosal response[5]

Our patient had mild cholestasis before the operation and developed marked biochemical cholestasis after the aortoiliac reconstruction using a Y-graft. This suggests that he may have been in the very early stages of PBC before the surgery and the graft implantation might have exacerbated the autoimmune response, leading to further bile duct injury. The trigger might be the graft itself or the drugs used in the perioperative period. There is only one case report of PBC after graft replacement for abdominal aortic aneurysm[6], in which the graft itself was considered to induce the autoimmune response, resulting in liver injury. Some reports suggest that xenobiotics are metabolized in the liver, thereby increasing the potential for liver-specific alteration of proteins, and that a liver-specific autoimmune disease can be observed in some patients exposed to anesthetics[5]

We report a rare case of PBC after aortoiliac reconstruction using a Y-graft, suggesting that the graft itself or medications in the perioperative period might induce or exacerbate an autoimmune response, leading to bile duct injury. In the view of the risk to trigger onset of PBC, it becomes worthwhile to carefully evaluate past surgeries and medications carefully.

Abstract

We present the fourth case of a primary pancreatic anaplastic large cell lymphoma (ALCL), ALK-. An 80-year-old man was admitted to our clinic for further investigation of a fever of unknown origin. He noted anorexia, weight loss and fatigue. His laboratory tests showed anemia and a great elevation of ESR, LDH, and β_2 microglobulin. In CT and MRI scan, a soft tissue mass in the pancreas was observed. A repeated endoscopy after his admission revealed an ulcerated mass-like deformity of the duodenal bulb. Explorative laparotomy confirmed a diffuse spread of an unresectable malignant pancreatic mass extending to the adjacent organs. Duodenal and surgical biopsies identified an ALCL of T-cell lineage, ALK-. The patient died in the Intensive Care Unit due to hemodynamic instability. Our case is the first one indicating that primary pancreatic lymphoma should be suspected in a patient with pancreatic mass and elevated serum LDH and β_2 microglobulin.

INTRODUCTION

Malignant tumors of the pancreas constitute about 15% of cancer patients and the most frequent of them is the adenocarcinoma of the pancreas[1]. Primary pancreatic lymphoma (PPL) is a very rare disease constituting less than 0.5% of all pancreatic malignancies and less than 2% of extranodal lymphomas[2]. Primary pancreatic anaplastic large cell lymphomas (PPALCL) are extremely rare. Only three cases of PPALCL have been reported in the literature[1,3,4]. Herein we report the fourth case of PPALCL which was diagnosed by duodenal and surgical biopsies.

CASE REPORT

An 80-year-old man, who was under evaluation of a fever of unknown origin in a Private Health Center, was admitted to our clinic for further investigation. He was complaining of an intermittent fever of 2 mo duration which stabilized during the last 3 wk. Anorexia, weight loss of about 10 kg in the last 6 mo and fatigue were also reported. Physical examination was unremarkable except for a leg edema. His hematological profile was as follows: Hct: 31%, Hb: 9.9 g/L, MCV: 92 fl, MCH: 30 pg/cell, reticulocytes: 1.6%, WBC: 10.6×10^9 cells/L (neutrophils 80% -lymphocytes 11% -monocytes 6% -eosinophils 2.5% -basophils 0.5%), PLT: 389×10^9/L, ESR: 110 mm, CRP: 13 mg/dL (normal range: 0-0.8 mg/dL). Serum biochemistry showed a great elevation of LDH: 1 880 U/L (normal range: 313-618 U/L) and hypoalbuminemia: 2.1 g/L (normal range: 3.4-4.8 g/L), with normal total proteins: 7.1 g/L (normal range: 6.6-8.7 g/L) though. Elevated b_2 microglobulin: 4.19 mg/L (normal range: 1.42-3.21 mg/L) was also found. Other biochemical, serologic and immunologic investigations were normal. Laboratory studies performed after the onset of the symptoms, with values similar to our findings, were available from the patient's file. A chest and abdominal CT scan, also available to us, had demonstrated that the uncinate process and partially the head of the pancreas were blurred (Figure 1A); enlarged peripancreatic, mesenteric, para-aortic and inferior vena cava lymph nodes were found. At that time, he had undergone a gastrointesinal endoscopy without pathologic findings. In further imaging study with MRI scan, a soft tissue mass located in the head of the pancreas and especially the uncinate process had appeared (Figure 1B). A slow flow signal of inferior vena cava had been observed due to the mass compression. After his admission in our clinic, a new endoscopy of the upper gastrointestinal tract revealed an ulcerated mass-like deformity of the duodenal bulb with a friable surface (Figure 2). Gastric and duodenal mucosal biopsy specimens were taken. Bone marrow biopsy was also performed. Glucocorticoids were administrated

as a second choice therapy after antibiotics treatment, based on FUO treatment's protocol and on the high indication of a lympho-proliferative disorder. Temporary clinical and laboratory improvement was noticed (ESR declination: 55 mm). Explorative laparotomy confirmed a diffuse spread of a malignant mass of the pancreas extending to the adjacent organs. Because of the brittle consistency and necrotic surface of the pancreatic mass, the biopsy specimen was taken from the adhesion of pancreatic surface with gastric serosa. Hematoxylin-and-eosin-stained sections of the duodenal biopsy revealed a diffuse dense infiltration of duodenal mucosa by large pleomorphic cells with abundant eosinophilic cytoplasm, ovoidal or irregular nuclei with one or prominent nucleoli (Figure 3A). Rare cells with embryo-like, horseshoe-shaped nuclei or cells with multiple nuclei resembling Reed-Sternberg cells were found. The mitotic activity was intermediate and several atypical mitoses were observed. Scanty neoplastic cells infiltrated the epithelium of intestinal glands as well as the surface epithelium. Histologic sections from the second biopsy material showed loose connective tissue with numerous dilated vessels and lymphatics, most of them having tumor cell emboli with morphology similar to the neoplastic population of the duodenal mucosa (Figure 3B). The intravascular presence of neoplastic cells was confirmed by immunohistochemistry using the endothelial cell marker CD34 (Novocastra, Newcastle, UK). Immunohistochemical stains of both biopsies showed the following tumor-cell immunophenotype: CD45+, CD45RO+, EMA+, CD43+ (DakoCytomation, Glostrup, Denmark), CD30+ (Figure 4), Muc1+, Fascin+ (Novocastra, Newcastle, UK), CD20-, CD45RA-, CAM 5.2-, Anaplastic Lymphoma Kinase (ALK)1-(DakoCytomation, Glostrup, Denmark) and CD3- (Novocastra, Newcastle, UK). Cellular phenotype and immunophenotype support

the diagnosis of anaplastic large cell lymphoma (ALCL), of T-cell lineage, ALK negative. Fluorescent *in situ* hybridization (FISH) using LSI ALK dual color, break apart rearrangement probe (Abbott GmbH and Company, KG, Wiesbaden-Delkenheim, Germany) was performed in paraffin-embedded tissue sections from both specimens. Presence of two fused yellow signals or two adjacent (one orange and one green signals) in 200 non-overlapping tumor-cell nuclei showed lack of ALK gene rearrangement at 2p23 region. Bone marrow biopsy showed no evidence of lymphoma involvement. The patient died in the Intensive Care Unit 2 d later due to hemodynamic instability.

DISCUSSION

PPL is an extremely rare neoplasm that may be confused with the most common pancreatic adenocarcinoma. The majority of PPL reported to date in literature have been classified as B-cell type, but several cases of T-cell pancreatic lymphomas have also been described[2]. Most cases are intermediate or high grade NHL with diffuse large B-cell lymphoma being the predominant type. Presenting symptoms are nonspecific, including abdominal pain, weight loss, nausea, vomiting. Systemic-B symptoms such as fever, chills and night sweats are uncommon. Imagining techniques such as CT, percutaneous U/S and recently endoscopic U/S are the most useful procedures to evaluate the staging of pancreatic masses, although they cannot identify their neoplastic nature. A cytohistological diagnosis can be performed by U/S and CT guided techniques, endoscopy and explorative laparotomy[2]. Chemotherapy treatment with CHOP (cyclophosphamide, adriamycin, vincristine, and prednisolone) is usually administrated in patients with lymphomas[1,2]. The accurate distinction of ALCL from non-lymphoid malignancies is critical from the standpoint of patient's management because primary ALCL responds to radically different chemotherapy than adenocarcinoma[5,6].

ALCL is an uncommon type of NHL, first described by Stein *et al.*, in 1985 as a pleomorphic large cell lymphoma with strong membrane and Golgi associated CD30/Ki-1 antigen expression in a very high percentage of neoplastic lymphoid cells, with the involvement of paracortical region and sinuses of lymph nodes[7]. In the latest World Health's Organization (WHO) classification of NHLs, ALCL is a distinctive nature T-cell lymphoma subtype[5]. Clinical presentations of ALCL include a systemic form with nodal and/or extranodal involvement, primary cutaneous ALCL, HIV-related ALCL and ALCL occurring as a secondary event in patients with lymphomatoid papulosis, mycosis fungoides and rarely Hodgkin disease. The main histologic patterns accepted by WHO are the common variant, the lymphohistiocytic and the small cell variant[5]. In these lymphomas, the most frequent genetic alteration is the translocation t (2; 5) (p23; q35) between the ALK gene on chromosome 2 and the nucleophosmin (NPM) gene on chromosome 5. As a result of this translocation, the hybrid (NPM-ALK) gene promotes the production of chimeric NPM-ALK protein. The NPM-ALK fusion chimeric protein can be detected immunohistochemically using monoclonal or polyclonal antibodies, by RT-PCR and FISH[5,8]. ALK immunohistochemical expression is detected in 60-85% of ALCL cases[5]. ALK+ ALCL is most frequent in the first decades of life, shows a male predominance and often has advanced stage disease with frequent B-symptoms and extranodal involvement. It also tends to respond better to chemotherapy than ALK-systemic ALCL[5,8].

Our patient was considered to be affected by PPL according to Dawson *et al.*, clinical criteria which include: (1) the absence of superficial lymphadenopathy or enlargement of mediastinal lymph nodes on chest radiography, (2) a normal leukocyte count in peripheral blood, (3) main mass in the pancreas with lymph-nodal involvement confined to the peripancreatic region, and (4) the absence of hepatic or splenic involvement[9]. The elevated values of LDH and β_2 microglobulin in addition to the clinical characteristics of our patient, such as intermittent fever, anorexia, weight loss and fatigue, also suggested the lymphoproliferative nature of the mass. Moreover, the presence of the mass in the pancreas at imaging techniques while the duodenum was normal in the first endoscopy, proved that it originated in the pancreas and not in the duodenum which is an extremely rare location also.

Only three patients with primary pancreatic ALCL are reported in the literature. The first case described in 1997 in Japan by Maruyama *et al.*, was diagnosed by both duodenal and surgical pancreatic biopsies[3]. The second case was published in 2003 in Israel by Cohen *et al.*, and was diagnosed by operative pancreatic biopsy[1]. Chim *et al.*, recently reported the third case and they supported the diagnosis on operative mesenteric lymph node material biopsy because the tumor resection was not possible[4]. In our case a pancreaticoduodenectomy, the "Whipple procedure" was not performed, as in the case of Chim *et al.*, because of a friable tissue consistency and patient's hemodynamic instability during surgery. Therefore, the diagnosis of our PPALCL was based on the biopsy material taken from duodenal mucosa (three small pieces) and the adhesion of pancreatic surface with gastric serosa.

LDH and β_2 microglobulin are considered to be tumor markers in lymphoproliferative disorders and have an important prognostic value[10,11]. According to the textbook of Sleisenger and Fordtran's, whenever a large mass is identified in the pancreas without biliary obstruction or pain the diagnosis of pancreatic lymphoma should be contemplated, particularly in the presence of an elevated serum LDH level[12]. A high LDH level was found in our patient in contrast to the three previously reported cases of PPALCL. The LDH values were normal in the cases of Chim *et al.*, and Cohen *et al.*, and non-recorded in the case of Maruyama *et al.* In addition, an elevated β_2 microglobulin level was noticed in our case such as reported in ALCL either ALK+ or ALK-in the study of Rassidakis *et al.*[11].

After chemotherapy administration, a remission of disease for 30 mo in the case reported by Cohen *et al.*, and for 18 mo in the case reported by Maruyama *et al.*, were achieved respectively, whereas in the recently reported case by Chim *et al.*, a partial remission of 6 mo duration was noticed because the patient died of disease progression. Our patient did not receive a postoperative chemotherapy because unfortunately he died 2 d after the explorative

Table 1 Clinical and pathologic data of primary pancreatic ALCL reported cases in chronological order

	Maruyama *et al*.[3]	Cohen *et al*.[1]	Chim *et al*.[4]	Present study
A/G	46/F	22/M	27/F	80/M

Treatment	MACOP-P	CHOP	CHOP	Glucocorticoids (symptomatic)
Follow up	NED at 18 mo	NED at 30 mo	6 mo, died of disease progression	Died due to hemodynamic instability 2 d after explorative laparotomy

A/G: age/gender, ALK: anaplastic lymphoma kinase, ALP: alkaline phosphatase, ALT: alanine aminotransferase, AST: aspartate aminotransferase, CHOP: chemotherapy regimen consisting of cyclophosphamide, adriamycin, vincristine and prednisolone, EMA: epithelial membrane antigen, ERP: endoscopic retrograde pancreatography, F: female, FUO: fever of unknown origin, GI: gastrointestinal, IHC: immunohistochemistry, IVC: inferior vena cava, LDH: lactate dehydrogenase, M: male, MACOP-P: chemotherapy regimen consisting of methotrexate, adriamycin, cyclophosphamide, vincristine, prednisolone and peplomycin, MPD: main pancreatic duct, ND: no data available, NED: no evidence of disease.

laparotomy.

The clinical information, laboratory and pathologic findings of the present case and the previously reported ones, are summarized in Table 1.

In conclusion, our case - added to the three published cases - is the fourth one of primary pancreatic ALCL, ALK-. From the clinical point of view, since most clinicians do not consider PPL in the differential diagnosis of a pancreatic mass, our case indicates that PPL should be suspected in a patient with pancreatic mass and elevated serum markers, particularly LDH and β_2 microglobulin. Biopsy specimens' results from either the mass or the adjacent infiltrated organs, such as the duodenum in our case, confirm the diagnosis and identify the lymphoma. Thus, an earlier diagnosis leads to an appropriate and timeable treatment and finally, a better prognosis.

Abstract

Retrorectal, developmental tail gut cysts, include dermoid cysts, rectal duplication cysts and retrorectal cyst-hamartomas. Retrorectal cyst-hamartomas (RCH) are derived from remnants of the tail gut, the most caudal part of the embryonic hind gut, which normally involutes by the 8th wk of embryonic development (3-8 mm stage). They have specific radiological and histopathological features that distinguish them from other similar formations (dermoid cysts, enteric duplication cysts and teratomas). We report a patient with adenosquamous carcinoma arising within RCH, who underwent complete resection of the cyst through anterior laparotomy, and reached complete (recurrence-free for 14 mo, so far) functional recovery. The cyst was incidentally discovered during hysterectomy 12 years ago. Diagnostic, therapeutic and histopathological aspects of this rare case are discussed. The mentioned period between diagnosis and surgical treatment suggests that RCH, given enough time, can develop malignant degeneration, and should be resected at the time of diagnosis.

CASE REPORT

The report was about a 47-year-old woman with a family history, where both her mother and daughter underwent surgery for presacral cysts in other institutions. Both of these cysts were benign in nature. The patient also had a positive history of obstructional bronchitis. The presacral cyst was discovered 11 years ago during hysterectomy because of myomatous uterus. Physical examination showed a fistulous opening on the perianal skin near posterior commissure with no apparent communication with the cyst. Proctoscopic examination showed posterior extrinsic compression of the rectum. Aside from these findings, there were no other abnormalities. Laboratory studies showed anemia and hypoproteinemia (RBC 2, 40×10E12/L; HGB 79 g/L; total proteins 45 g/L). Abdominal ultrasound showed no abnormalities. Transrectal ultrasound showed the tailgut cyst posterior to and causing deformity of rectal wall. The scan identifies five layers of the rectal wall of which the outer hypoechoic layer represents the muscularis propria (Figure 1). There was no radiological evidence of extrapelvic disease. After preoperative immunological testing, because of hypersensitivity to a number of drugs, she underwent complete resection of the mass through anterior laparotomy. The cystic mass was loosely connected to the lower sacrum through fibrous attachments. Communication with the opening was not established. After removal of the intact cyst, the opening on perianal skin was sutured. The patient soon reached a complete functional recovery.

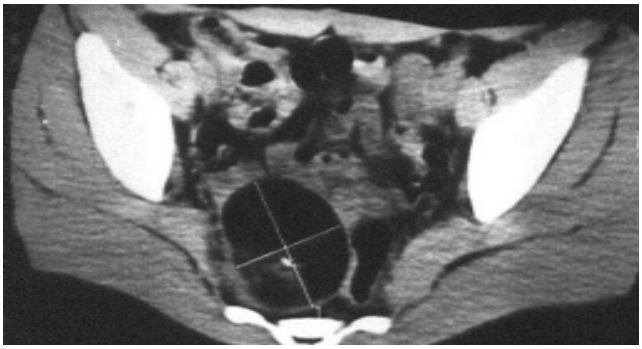

Figure 1 CT scan of the pelvis showing solitary cystic, retrorectal tumor.

PATHOLOGIC FINDINGS

Gross examination revealed irregularly shaped ovoid multiloculated cystic formation measuring 85 mm in greatest diameter (Figure 2). On cut surface, there was a large dominant cyst surrounded by number of small irregular cysts with diameter up to 15 mm, all of them showing mucopurulent content. Microscopically, a wide range of epithelial covering were represented, commonly found in gastrointestinal tract, focally eroded or displaced by respiratory-type epithelium in some areas. Ulcerated areas were surrounded with strong histiocyte infiltrate.

Figure 2 Showing irregularly shaped ovoid formation measuring 85 mm in greatest diameter.

Malignant alteration of the cyst was presented as ill-defined nodular thickening (7 mm), histologically presenting adenosquamous carcinoma, mostly well-differentiated adenocarcinoma admixed with foci of squamous differentiation or poorly differentiated areas and clear resection margins (Figures 3A and B).

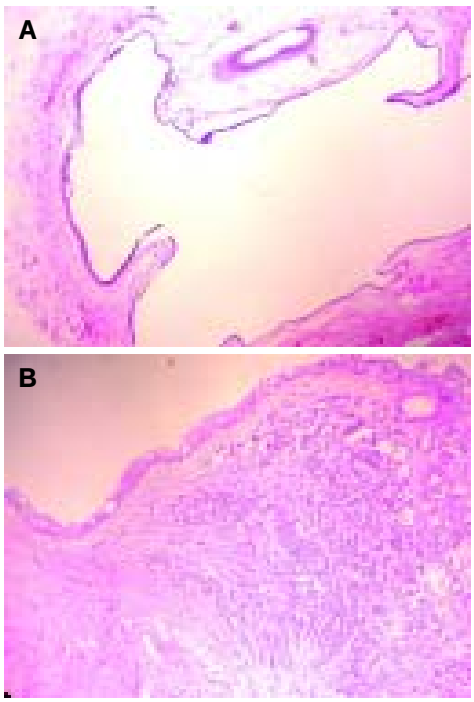

Figure 3 A and B Showing malignant alteration of the cyst histologically presenting adenosquamous carcinoma, mostly well differentiated adenocarcinoma admixed with foci of squamous differentiation or poorly differentiated areas and clear resection margins.

DISCUSSION

Retrorectal cyst-hamartomas (RCH) are reasonably rare, and they are always localized within the retrorectal space, which is bordered by rectum anteriorly, posteriorly by the sacrum, superiorly by the peritoneal reflection, inferiorly by the levator ani and coccygeus muscle, and laterally by the ureters and iliac vessels[1].

They can be found in all age groups including infancy, but they are more commonly reported in middle-aged females, and as mentioned, they are thought to arise from postnatal primitive gut remnants[2,3].

The clinical presentation of the cyst is non-specific, and it is most frequently related to a compressive effect of a growing mass within the pelvis (e.g. rectal fullness, urinary frequency, change in stool caliber, rectal bleeding)[4].

Around 50% of the cysts are discovered incidentally on routine physical examination[1]. Symptoms due to infection are also possible, and fistulous communication with the rectum or with the perianal skin can develop, often after inappropriate surgery. Recurring retrorectal abscess or recidivant perianal fistula can in fact be the infected tail gut cyst[1].

Plain radiography may show a soft tissue mass without destruction of the bone. Irigography can only confirm extramural compression of the rectum[1]. Computed tomography (CT) shows a well marginated retrorectal mass with CT numbers varying from water to soft tissue density.

Transrectal ultrasound is used to asses rectal and perirectal masses[1]. Its good sides are that it is simple, accurate and inexpensive. A diagnostic biopsy for cystic masses is not advised[4]. It may fail to confirm potential malignant diagnosis, and it carries a significant hazard of spillage of malignant cells, or may lead to the infection of the cyst.

Malignant transformation of RCH is very rare. Prasad *et al*.[5], identified 10 cases of malignancy in the literature. The outcome of the treatment of these malignancies varies from case to case. The most important factors for the prognosis are the time of the diagnosis, radicality of surgical resection and histopathological diagnosis; much better prognosis is with neuroendocrine cases, than with adenocarcinomas.

Complete excision of the cyst along with the margin of normal tissue followed by careful examination of the specimen is recommended. Anterior approach, as mentioned, was used in this case. Posterior approach is used for resection of the cyst localized below the level of S4, higher lesions are addressed through anterior approach, and smaller lesions can be reached through transvaginal approach. Combined anterior and posterior pelvic approach is advised by some authors[4] in cases of malignant transformation of the cyst.

Although this case demonstrates how malignant cyst can be successfully removed, with complete functional and oncological recovery, other experiences[4] show rapid and diffuse systemic failure and it is strongly recommended to aggressively address all RCHs as early as identifiable. For the same reason, adjuvant chemotherapy should be considered in some cases at least. Other interesting aspect of this case is the possible hereditary component, which certainly needs additional investigation.

Abstract

Isolated agenesis of the gallbladder is a rare anomaly, often asymptomatic. However, one patient out of four presented with right upper abdominal pain, nausea, and fatty food intolerance. The condition is frequently mistaken with an excluded or sclero-atrophic gallbladder, regardless of the imaging modality used. Consequently, AG often leads to unnecessary and potentially dangerous laparoscopic surgery as described in a few case reports over the last 10 years. The aim of this study is to clarify the diagnostic and therapeutic approach of this unusual pathology. Two cases seen in our institutions were retrospectively reviewed, together with a review of the American and European literature. During laparoscopy, the absence of normal anatomical structures and the impossibility of pulling on the gallbladder to expose and dissect the triangle of Callot increases the risk of iatrogenic injury to biliary or portal structures. Depending on the experiment of the surgeon in laparoscopic procedure, this has to be taken into account to decide a conversion to laparotomy. A high index of suspicion is necessary when interpreting the radiological images. In case of doubt, a MRI-cholangiography is mandatory. Because of possible inherited transmission, relatives with a history of biliary symptoms should be investigated.

INTRODUCTION

In animals, the absence of a gallbladder has been a subject of research since the Aristotelian era[1]. Present in 1/6 of cases of biliary atresia[2], the isolated absence of the gallbladder and cystic duct is rare. Patients become symptomatic in 23% of cases[3,4], and agenesis of the gallbladder (AG) will almost always be misinterpreted as cholecystitis with cystic duct obstruction or as a sclero-atrophic gallbladder, therefore leading to unnecessary surgery. Reported for the first time in human beings by Bergman in 1702[5], it has since been described several times in case reports. During laparoscopic surgery, it represents a pitfall for the surgeon[6,7]: the biliary or portal structures can easily be injured during dissection as one searches for a gallbladder that does not exist. The absence of normal anatomical structures and the inability to pull on the gallbladder to dissect the triangle of Callot represent a risk of iatrogenic injury.

This review is based on a Medline and PubMed search from 1960 to 2003. Keywords used were agenesis of the gallbladder, absence of gallbladder, congenital syndromes, ultrasound, cholangiography, hepatobiliary scintigraphy, endoscopic retrograde cholangiopancreatography, magnetic resonance cholangiography, biliary dyskinesia, postcholecystectomy syndrome, laparoscopic surgery. Relevant literature was selected from the abstracts and cross-references of the retrieved literature were used to complete the search.

Between 1992 and 1999, two cases of AG were reported in our two institutions (Centre Hospitalier Universitaire Vaudois and Centre Hospitalier Cantonal de Fribourg), which are briefly described.

CASE REPORT

Case one

A 34-year-old man was admitted for right upper abdominal pain and bloating after meals for the last 9 years. The ultrasonography showed a scleroatrophic gallbladder and the intravenous cholangiogram revealed a very narrow biliary tree without opacification of the gallbladder. Total bilirubin was slightly elevated, and the direct fraction was twice the normal value. Other laboratory results were within normal limits. During the laparoscopic procedure, no gallbladder could be identified. A branch of the right hepatic duct was injured. Laparoscopy was converted to a median laparotomy. Initial dissection was carried out on the vena portis thought to be an ectopic gallbladder. Neither the intraoperative cholangiogram performed through the accidentally divided segmental duct nor the surgical exploration could demonstrate a gallbladder. The segmental biliary duct was ligated and the area drained.

Case two

A 76-year-old asymptomatic man went to his physician for

a check-up. Ultrasonography revealed a tumor of the right kidney, which was confirmed by a CT scan. Both failed to identify the gallbladder, but showed an increased size of the common bile duct. A median laparotomy was decided in order to deal with both pathologies. In place of the gallbladder, a small fibrous structure (1.5 cm×1 cm) was found and excised. The intraoperative cholangiogram did not show an ectopic gallbladder. A choledocotomy with the extraction of two gallstones was realized and an abdominal right nephrectomy performed. The histopathological analysis did not demonstrate any gallbladder tissue.

DISCUSSION

AG can be observed in both children and adults, with a median age of 46 at the time of diagnosis[8]. It is almost always a fortuitous finding during abdominal surgery or at autopsy. The prevalence range is 0.007-0.13%. The incidence of this malformation is slightly lower in surgical cholecystectomy series (0.007-0.027%)[9,10] than that in autopsy reports (0.04-0.13%)[5,11-13]. The male to female ratio is equal in autopsy reports[11,14] but seems to reach the same ratio (2-3 women for 1 man) in the clinical group as other biliary tract diseases[15,16]. AG occurs in association with other malformations in 40-65% of cases[8,11,17]. It is then found above all in children[8,11,13], leading in most cases to death in the first year of life[8,13,18,19]. Two congenital syndromes with multiple anomalies including gallbladder agenesis have been described: cerebrotendinous xanthomatosis[20] and the G syndrome[18]. AG has been occasionally mentioned with trisomy 18 and the Klippel-Feil syndrome[8,21,22]. Some authors[23-25] reported this anomaly in children with congenital malformations caused by thalidomide (up to 10% in Männl's series)[24].

This anomaly is explained by an embryological disturbance occurring during the 3rd wk of gestation and concerning the caudal portion of the anterior diverticulum of the primitive gut. It is an anomaly of the development of vessels located on each side of the gallbladder bud (sinus venosus cordis, omphaloenteric, and umbilical veins)[26]. This may explain the association of this anomaly with cardiac, vascular, gastro-intestinal, and abdominal wall malformations observed in the multiple fetal anomaly group[18]. AG may be inherited, with several familial cases observed, including across two generations[4,15,19,27-29]. These series suggest a non-sex-linked heredity with variable penetration.

Patients with AG will become symptomatic in about 23% of cases[4,19,30,31]. In 1988, Bennion *et al*.[8], found 208 symptomatic cases of AG in the literature. 90.1% presented with right upper abdominal pain, 66.3% with nausea or vomiting and 37.5% with fatty food intolerance. Thirty-two percent of these patients presented with a common bile duct dilatation whereas only 27% had gallstones. In the literature, AG is associated with a dilatation of the common duct or gallstones in 25-50% of cases[15,31,32]. The symptomatology and the increased frequency of gallstones has been attributed, by some authors, to biliary dyskinesia[16,30-34] and compared by others to a postcholecystectomy syndrome[8]. According to Toouli *et al*.[35], and Meshkinpour *et al*.[36], the biliary dyskinesia may be due to a hypertonic muscular retrograde contraction of the Oddi sphincter leading to a common duct dilatation, biliary stasis and gallstone formation[35,37]. Tanaka *et al*.[38], showed in 1983 that induction of a spasm of the Oddi sphincter reproduced the same painful symptomatology as biliary dyskinesia, and was associated with increased pressure in the common bile duct. However, it does not explain why the majority of patients become asymptomatic postoperatively (94% of cases in Bennion's series)[8]. Furthermore, the presence and development of a sphincter regulating the bile flow seems to be related to the presence or absence of the gallbladder. Indeed in animals without a gallbladder, the sphincter is poorly developed[39]. According to Lindskog[40], common bile duct dilatation without stones may simply indicate that the calculi have passed. Nevertheless, when we compare the frequency of common duct stones after cholecystectomy (5%) with the frequency of stones in AG (23%), we must recognize that this condition predisposes to calculus formation. Ahlberg *et al*.[9], did not show any changes in the bile lipid composition of patients with AG. However, the small number of patients in this study does not allow any conclusions to be drawn. Similar studies were realized in postcholecystectomy patients with conflicting results due to differences in methodology and patient selection[9,41-44].

When reviewing the literature, with the exception of two cases of AG[27,33], the preoperative investigations carried out on symptomatic patients failed to demonstrate the diagnosis. Whatever the method was used, cholangiography, hepatobiliary scintigraphy, ultrasound (US) or even endoscopic retrograde cholangiopancreatography (ERCP), the diagnosis proposed was almost always cystic duct obstruction or a small contracted gallbladder[3,6,7,45-47].

Ultrasonography is actually the investigation method of choice for the diagnosis of common bile duct stones, with a sensitivity of 95-98%. Crade *et al*.[48], defined three categories of abnormal ultrasounds of the gallbladder. The only case of AG in this study came from the second category (as also seen in other numerous cases described in the literature[7,30,46,47,49]): (1) shadowy gravity-dependent opacities within the gallbladder, (2) nonvisualization of the gallbladder lumen, and (3) nonshadowy opacities within the gallbladder lumen. The accuracy of US in these three different categories is 100%, 96%, and 61%, respectively[48]. The great difficulty in visualizing a contracted gallbladder on stones is well known[48,50]. According to Hammond[51], there is always either a recognizable segment of wall or a thin rim of bile identifying the gallbladder. He bases his assertion on MacDonald's *et al*.[52], and Raptopoulos's *et al*.[53], reports, which described the WES triad (demonstration of the gallbladder wall, the echo of the stone, and the acoustic shadow) or the double arc shadow (two parallel arcuate echogenic lines separated by a thin anechoic space with distal acoustic shadowing). However, the examination conditions as well as the examiner's experience does not always permit such accurate appreciation. Shadowy opacities misdiagnosed as stones can be due to intestinal gas artefacts or to other structures in close proximity, such as a calcified hepatic lesion or a surgical clip[46,51].

The hepatobiliary scintigraphy with new ^{99m}Tc-IDA agents and quantification of function is increasingly giving results,

especially in the detection of gallbladder anomalies[54]. Nevertheless, the nonvisualization of the gallbladder remains typical of cystic duct obstruction, as well as AG[54].

ERCP has been used in addition to other diagnostic methods[6,27,33,55,56]. Again, the nonvisualization of the gallbladder was interpreted as an occlusion of the cystic duct.

Magnetic resonance cholangiography is a noninvasive and well demonstrated imaging method in the evaluation of the biliary tract[57–59]. As it does not require contrast administration to visualize the bile, it is not compromised by biliary stasis. It can then demonstrate an excluded and/or ectopic gallbladder. However, this technique is not readily available. It may not yet replace ultrasound as the gold standard of acute gallbladder imaging but it is an ideal complementary study to inconclusive sonographic studies[60].

Selective arteriography of the hepatic artery has been proposed to prove gallbladder agenesis[6,61], but remains a very invasive procedure.

Reviewing the recent literature[62-65] concerning the AG, we noticed that symptomatic patients are still unnecessarily operated. In only two cases, AG was demonstrated by nonoperative means[27,33]. It was the evocation of this disorder in the initial assessment (US and cholangiography), which led to diagnosis. An ERCP increased the suspicion and AG was confirmed in each case by repeated US and cholangioscintigraphy during follow-up in asymptomatic patients.

In conclusion, AG is an unusual anomaly, mimicking a biliary stone disease in 23% of cases. This condition must be kept in mind in the differential diagnosis of ultrasonographically undetected or scleroatrophic gallbladder. When the WES triad or double arc shadow are not present, this congenital malformation should be suspected. An ectopic location of the gallbladder should be excluded. In case of doubt a conservative approach involving repeat investigations, in asymptomatic patients or after the acute phase, will avoid unnecessary surgery.

When AG is a laparoscopical discovery, the possibility of iatrogenic injury, by dissecting the portal structures without normal anatomical landmarks, has to be taken into account to decide a conversion to laparotomy. An intraoperative cholangiography should be realized through the common duct. Intraoperative ultrasound can demonstrate an ectopic gallbladder but is not always available. The lesser omentum, the falciform ligament, and the liver must be palpated. The exploration will also include a Kocher maneuver to explore the posterior wall of the duodenum as well as the head of the pancreas. The scar tissue in the gallbladder bed and the portal area must be carefully explored.

Associated malformations need not be systematically sought in adults, but family heredity has to be taken into account. Relatives with past or repetitive biliary symptomatology should have at least an ultrasonography when asymptomatic.

Abstract

Perforation is one of the most serious complications of endoscopic sphincterotomy (ES) necessitating immediate surgical intervention. We present a case of successful management of such a complication with endoclipping. A 85-year-old woman developed duodenal perforation after ES. The perforation was identified early and its closure was achieved using three metallic clips in a single session. There was no procedure-related morbidity or complications and our patient was discharged from hospital 10 d later. Endoclipping of duodenal perforation induced by ES is a safe, effective and alternative to surgery treatment.

INTRODUCTION

The most serious complications of endoscopic sphincterotomy (ES) are pancreatitis, hemorrhage and perforation[1]. Although perforation is uncommon, occurring in less than 1% of patients undergoing ES, it is associated with high morbidity and mortality[2].

Applications of endoscopic metallic clips other than the treatment of bleeding lesions have been reported, such as sealing of iatrogenic endoscopic perforations[3].

We describe a 85-year-old woman who developed symptomatic post-ES perforation and was successfully treated by endoscopic clip placement. To our knowledge, this is the second reported case of post-ES perforation that was treated endoscopically with clip placement.

CASE REPORT

A 85-year-old woman was admitted because of recurrent episodes of abdominal pain, fever, and jaundice over a period of 1 mo. Her past medical history revealed a cholecystectomy 10 years ago, mild heart failure and hypertension. Laboratory tests showed cholestasis. US demonstrated intra- and extra-hepatic biliary dilatation. Magnetic resonance imaging cholangiography showed a large stone (diameter 18 mm) in the lower part of the common bile duct.

Endoscopic biliary sphincterotomy was performed using an electrosurgical unit with standard pull sphincterotome without the use of guidewire. The length of sphincterotomy was large, according to the size of the common bile duct stone. The extraction of the stone was impossible. We performed a successful mechanical lithotripsy and the fragments were extracted with a basket.

Twelve hours later, the patient complained of moderate pain in the upper abdomen, which diminished after analgesics administration. Physical examination disclosed fever of 37.8 ℃ but no signs of peritoneal irritation. A chest X-ray was normal. Laboratory studies revealed an elevated ESR (75 mm/h) and C-reactive protein concentration (3.62 mg/dL, normal <0.5 mg/dL). The WBC count was 11 888/μL (normal 4 000-8 000/μL) and the percentage of neutrophils was high (86%).

An abdominal CT demonstrated free retroperitoneal air and a small amount of dirty fluid around the duodenum as well as enhancement of choledochal duct with gastrografin (Figure 1).

We decided to try endoscopic repair of the duodenal perforation, after an extensive discussion about the type of therapy with her relatives, and an informed consent was signed. With a rotating colon clipping device (HX-6UR-1, Olympus), five clips were carefully placed in the upper part of sphincterotomy. Although two were misclipped, the other three were well fitted (Figure 2). A standard 0.035-inch biliary super-stiff guidewire (Jagwire, Microvasive) was then passed endoscopically and fluoroscopically into the jejunum and a nasogastric tube with the tip removed was passed into the duodenum and centered over the perforation site.

Intravenous hyperalimentation and treatment with antibiotics (ciprofloxacin 1 g/d and metronidazole 1.5 g/d)

were administered. Clinically, the patient did well and the abdominal pain that was initially present decreased, no signs of peritonitis developed and the fever subsided. Three days later, a water-soluble contrast was instilled via the nasogastric tube and on radiography no leakage of contrast was found. She began to eat 7 d after the clipping procedure and was discharged on d 10. A second abdominal CT performed 20 d later demonstrated resolution of the retroperitoneal air and inflammation.

No further problems occurred after 5 mo of follow-up.

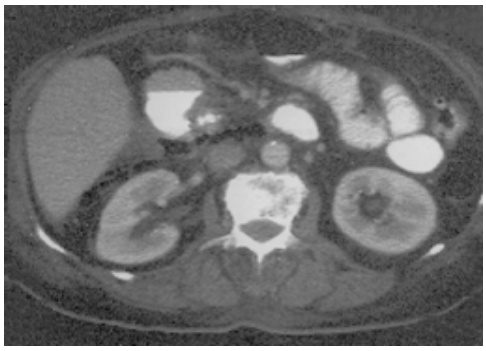

Figure 1 Free retroperitoneal air and a small amount of dirty fluid around the duodenum.

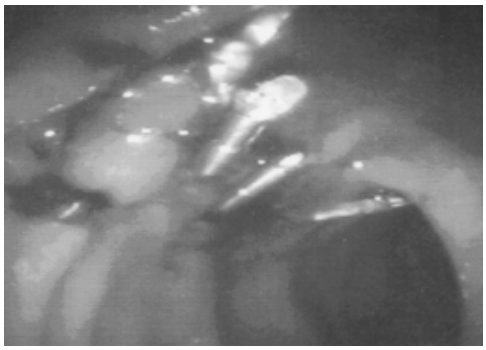

Figure 2 Three clips placed on the upper part of sphincterotomy.

DISCUSSION

The approach to management of duodenal perforation after ES is controversial. Some investigators advocate conservative management based on clinical course, while others advocate surgical repair in all cases because of the complications associated with delayed operative intervention[4-6].

Dunham *et al*.[4], have reported about the outcome after conservative treatment in seven patients when free air was recognized immediately. Two of these patients died after the development of toxic shock despite delayed surgery. In a recent prospective study by Freeman *et al*.[1], five of the eight ES perforations were severe and one resulted in death.

In recent years, endoscopic clip placement, developed as a hemostatic procedure, has been used for closure of iatrogenic perforations[3]. Binmoeller *et al*.[7], described the first successful endoscopic closure of an iatrogenic perforation by using a clip-application device in 1993. Subsequently, the use of this method in the esophagus[8,9], duodenum[10], and colon[11,12] has been described. Baron *et al*.[13], described the first case of a 39-year-old man with familial adenomatous polyposis who presented duodenal perforation after a papillectomy and ES. They identified immediately free air in the retroperitoneum and the perforation was closed by the use of a clipping device and the placement of five clips.

The decision about the treatment after an iatrogenic perforation must be made very carefully, because conservative treatment may surely be used when perforation is small and retroperitoneal, non-operative management failed but with delayed laparotomy results in greater contamination necessitating major surgery. In our patient, the perforation was small, well defined, and detected without delay, thus meeting all the criteria for a conservative approach. Therefore, we decided to try to close the perforation immediately with metallic clips. After successful endoscopic clipping, our patient recovered quickly without any complication and was discharged early from hospital. The immediate closure of the perforation prevented any further abdominal contamination and contributed to the good outcome of the patient. Although this complication could be resolved with the conservative management strategy of nasogastric suction and antibiotics, we believe that our patient with the size of the duodenal wall defect may require prolonged hospitalization and/or surgical management.

It must be emphasized that the endoclipping device has been designed for use through the end-viewing endoscope. Therefore, the deployment of clips is more difficult when a side-viewing endoscope is used and damage to the endoclipping device may occur. The deployment of the clips requires significant experience from the endoscopist when a duodenoscope is used, especially in a limited space as is the major papilla area. The placement of the clips should be made carefully on the upper part of the sphincterotomy to avoid closure of pancreatic or common bile duct orifice.

In cases of iatrogenic perforation, if the defect is closed early with metallic clips, contamination of the peritoneal cavity or retroperitoneal space can be minimized. Although the difference in outcome between conservative management and clipping is unknown, clipping therapy is more certain to prevent contamination.

In conclusion, when perforation is caused by ES, endoscopic closure using metallic clips without laparotomy might be the first choice of treatment, although it is essential to monitor the patient closely, with particular attention to signs of transition from localized to generalized peritonitis.

Abstract

Hepatoblastoma is the most common primary hepatic tumor of children. However, only a very few cases have been reported in adults. Most studies support treatment with chemotherapy followed by surgical resection. We present the first reported case of adult hepatoblastoma in Taiwan. A 52-year-old female suffered from sudden onset of abdominal pain and general weakness for days. Internal bleeding with hemorrhagic shock was suspected and two massive lesions in both lobes of the liver with hemoperitoneum were noted from imaging studies. Surgical resection of the larger left lobe tumor and radio-frequency ablation of the right smaller one were performed. The histopathology diagnosis was of a hepatoblastoma.

INTRODUCTION

Hepatoblastoma is the most common tumor of the liver for children under the age of 2 years[1]. Reports of adult cases are extremely rare. Most of these tumors arise in the embryo during the development of the liver and contain embryonic features such as numerous mitoses. They sometimes show ribbon-like, rosette-like, or papillary formations[2]. We present the first case of adult hepatoblastoma that was reported in Taiwan.

CASE REPORT

The patient was a 52-year-old female, who suffered from abdominal discomfort and called into a regional hospital for help. Abdominal computed tomography (CT) revealed two large hepatic masses with intra-abdominal fluid accumulation. Hepatic tumor with rupture was suspected, and she was referred to our hospital for further evaluation. She had been relatively healthy in the past. There was no significant past history or family history. Laboratory studies showed the following values: AST 58 U/L; ALT 44 U/L; hemoglobin 74 g/L; platelet count 101 000/UL; hepatitis B antigen negative; anti-hepatitis B antibody positive; anti-hepatitis C antibody positive. CT scans of the abdomen (Figure 1) showed massive accumulation of intra-abdominal fluid and one large heterogeneous mass (c. 11.4 cm×18.8 cm×22 cm) with cystic and solid components in the left lobe of the liver. Another homogeneous well-enhanced lesion about 3 cm wide in segment 8 of the liver was also noted. Catheter angiography (Figure 2) showed a huge hepatic tumor with faint tumor blush in the left lobe and a 2.5 cm large hypervascular tumor in the right lobe. These were presumed to be hepatocellular carcinomas. Further intra-arterial embolization was not performed because of technical problems and lack of cooperation by the patient. We diagnosed a ruptured and bleeding hepatocellular carcinoma. Exploratory laparotomy with a left lateral hepatectomy was performed to resect the tumor. Intraoperative radio-frequency ablation (RFA) was also applied to the smaller tumor in the right lobe of the liver.

The specimen recovered consisted of an encapsulated mass measuring 22 cm×16 cm×15 cm in size with extensive necrosis and hemorrhage. Grossly, it was friable and soft in consistency (Figure 3). Microscopically, histopathology sections showed pictures of immature hepatocytic epithelial elements intermixed with prominent vessels and extramedullary hematopoiesis including all three lineages (Figure 4A). There was extensive tumor necrosis and hemorrhage. Immunohistochemical stains showed the following: vimentin positive (Figure 4B); myeloperoxidase (MPO) positive for the extramedullary hematopoietic myeloid series (Figure 4C); factor 8 positive for extramedullary hematopoietic megakaryocytes (Figure 4D); CD34 positive for vascular endothelium and hematoprogenitor cells; alpha fetoprotein negative; S100 positive. These pathology results were consistent with the diagnosis of a hepatoblastoma. The patient was discharged 10 d after the operation.

Figure 1 CT scans of the abdomen showed massive accumulation of intra-abdominal fluid and one large heterogeneous mass (c 11.4 cm×18.8 cm×22 cm) with cystic and solid components in the left lobe of the liver.

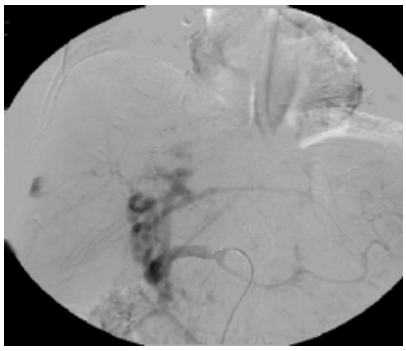

Figure 2 Catheter angiography showed a huge hepatic tumor with faint tumor blush in the left lobe and a 2.5 cm large hypervascular tumor in the right lobe. These were presumed to be hepatocellular carcinomas.

Figure 3 The specimen recovered consisted of an encapsulated mass measuring 22 cm×16 cm×15 cm in size with extensive necrosis and hemorrhage. Grossly, it was friable and soft in consistency.

DISCUSSION

Hepatoblastoma is a highly malignant tumor occurring in infants, and reports of adult cases are extremely rare. A review search in the literature revealed only 23 adult cases of hepatoblastoma including the present one. This case is also the first adult hepatoblastoma that was reported in Taiwan.

Ishank and Glunz classified hepatoblastomas into two groups in 1967: epithelial type and mixed epithelial and mesenchymal type[3]. The tumor type from this patient was distinguished from a hepatocellular carcinoma by the presence of angiodysplasia and also by the peculiar arrangement of bright and dark epithelial cells in sheets or ribbons[3-5]. This patient, therefore, had a tumor of the mixed epithelial and mesenchymal type according to this

Table 1 Summary of reported hepatoblastoma in adults

Case	Reporter	Sex/Age (yr)	Pathology type	Diagnosis	Survival time
1	Barnett[6] (1958)	M/35	Mixed	Embryonic tumor	Died 1 mo after surgery
2	Alexander[7] (1961)	F/68	Mixed	Primary mixed tumor	Postmortem
3	Ojima[8] (1964)	M/48	Mixed	Malignant mixed tumor	Postmortem
4	Kerr[5] (1966)	M/56	Mixed	Hepatic embryonic mixed tumor	Sudden death

classification. Most cases in the literature are of the mixed type.

The precise mechanism to cause the tumor has been elusive; present investigations of the cytogenetic and molecular genetic aberrations in hepatoblastomas revealed involvement of chromosomal loci on 1q, 2 (or 2q), 4q, 8 (or 8q), and 20[21]. Loss of heterozygosity imprinting at locus 11p 15.5 also suggest a common genetic basis for hepatoblastoma[21]. Shin-ichi *et al*., found that abnormalities in Wnt signaling pathway seen in frequent mutation of the β-catenin gene may play a role in the genesis of hepatoblastoma[22]. They also found that the patients with hepatoblastoma with high expression of polo-like kinase 1 (PLK1) represented significantly poorer outcome[22]. Therefore, PLK1 may become a useful tool to develop new diagnostic as well as therapeutic strategies of hepatoblastoma.

Otherwise, only one of the previously reported cases was a 12-year-old boy who presented with a ruptured tumor with massive bleeding as we saw in this patient[23]. We successfully resected the larger hepatic tumor and treated the smaller one with RFA, although most adult cases of hepatoblastoma have been unresectable[4]. The clinical and pathological findings of previously reported cases and the present one are summarized in Table 1. The mean age of the 23 patients was 48.5 years and there were more males (13) than females (10). Eleven patients received surgery. Twenty one of these tumors were of the mixed type. Survival time ranged from 1 to 38 mo after surgery with a mean survival time of 9.7 mo. The prognosis for patients with this disease is very poor. Current treatments for the tumor include surgery and chemotherapy. Combination chemotherapy with adriamycin and cisplatin has been considered effective for hepatoblastoma[2]. Our patient has just been discharged and will be followed up.

Abstract

AIM: To study adhesion capacity and CD44 expression of human gastric adenocarcinoma MKN45 cells at different stages of a first cell cycle.

METHODS: MKN45 cells were synchronized by aphidicolin and assayed for adhesion to an endothelial cell (HUVEC) monolayer. Surface expression of CD44 and CD44 splice variants on MKN45 cells was evaluated by flow cytometry. Functional relevance of CD44 adhesion receptors was investigated by blocking studies using anti CD44 monoclonal antibodies or by hyaluronan digestion.

RESULTS: Adhesion of MKN45 to HUVEC was increased during G2/M transit, after which adhesion returned to baseline levels with cell cycle completion. In parallel, CD44 splice variants CD44v4, CD44v5, and CD44v7 were all up-regulated on MKN45 during cell cycle progression with a maximum effect in G2/M. The function of CD44 surface receptors was assessed with specific receptor blocking monoclonal antibodies or removal of hyaluronan by digestion with hyaluronidase. Both strategies inhibited tumor cell adhesion to HUVEC by nearly 50%, which indicates that MKN45-HUVEC-interaction is CD44 dependent.

CONCLUSION: CD44 expression level is linked to the cell cycle in gastrointestinal tumor cells, which in turn leads to cell cycle dependent alterations of their adhesion behaviour to endothelium.

INTRODUCTION

Enhanced invasive capacity and proliferative activity are among the array of functions a tumor cell must fulfil to settle as a metastasis in a distant organ. The dynamic process of tumor dissemination requires cooperative activities between the tumor cell itself and the surrounding tissue and involves several molecule classes. The CD44 transmembrane glycoproteins belong to the families of adhesion molecules and were originally thought to mediate lymphocyte homing to peripheral lymphoid tissues. It has now been recognized that CD44 molecules may also initiate metastatic spread of the tumor cells[1]. Still, the precise role of CD44 as a regulatory element of tumor growth and invasion is not clearly understood.

Several clinical studies have been carried out on patients suffering from colorectal neoplasms, but no consistent statement can be drawn about the relevance of CD44 receptors in tumor cell malignancy. Some authors hypothesize that CD44 contributes to both tumor cell proliferation and motility, whilst others do not see any logical link between CD44 expression, proliferative activity and migratory behaviour: Sumiyoshi *et al*., (28 cases) and Yue *et al*., (31 cases) reported a positive relationship between the expression of the proliferating nuclear antigen PCNA, CD44, and metastasis formation in colorectal cancer[2,3]. In contrast, no statistical correlation was found between CD44 positivity and disease free intervals in studies including a total of 113 colorectal tumor patients[4,5]. Additionally, evaluation of the characteristics of colorectal carcinoma during the metastatic process did not favour an association between CD44 expression, proliferative activity and metastatic ability of tumor cells.

Analyses of surgical specimens of 22 colorectal carcinomas revealed CD44 expression in tumors associated with proliferative areas. However, there was no apparent association between CD44 positivity and tumor stage, differentiation and progression[6]. In a further study, CD44 expression in a series of 110 colorectal carcinomas correlated well with tumor size, although extensive CD44 expression was also found in the majority of adenomas that were investigated[7]. Based on a

topographical investigation, the cellular localization of CD44 and PCNA was found to be different in colorectal tumor cells, and PCNA was present most frequently in cells lacking CD44. The authors concluded that tumors, negative for CD44, have a higher probability of replicating[8].

The conflicting results are partially caused by the retrospective nature of immunohistochemical studies. Furthermore, examination of tissue specimen does not allow unequivocable evaluation of the time-dependent dynamics of tumor-host interactions. There is no doubt that tumor dissemination and malignancy is characterized by a fine-tuned interplay between CD44 expression level, cell cycle activation and migratory capacity. However, there is still little knowledge about how these processes are linked together. To clearly assess if CD44 triggered tumor cell invasion is cell-cycle dependent, we established a cell culture system consisting of aphidicolin-synchronized human gastric adenocarcinoma MKN45 cells. CD44 surface expression was quantified, when MKN45 cells were released into S-phase, G2/M-phase and G0/G1-phase, as well as when adhering to human umbilical vein endothelial cells (HUVEC).

MATERIALS AND METHODS

Cell cultures

Endothelial cells (HUVEC) were isolated from human umbilical veins and harvested by enzymatic treatment with chymotrypsin. HUVEC were grown in Medium 199 (Biozol, Munich, Germany), 10% fetal calf serum (FCS; Gibco, Karlsruhe, Germany), 10% pooled human serum (Blood Bank of The German Red Cross, Frankfurt am Main, Germany), 20 μg/mL endothelial cell growth factor (Boehringer, Mannheim, Germany), 0.1% heparin (Roche, Basel, Switzerland), 100 ng/mL gentamicin (Gibco) and 2% 1 mol/L HEPES-buffer (Seromed, Berlin, Germany). To control the purity of HUVEC cultures, cells were stained with fluorescein isothiocyanate (FITC)- labelled monoclonal antibody against Factor VIII-associated antigen (Von Willebrand factor; clone F8/86; Dako, Hamburg, Germany) and analyzed microsc-opically, or by FACscan (Becton Dickinson, Heidelberg, Germany; FL-1H (log) channel histogram analysis; 1×10^4 cells/scan). Cell cultures with a purity >95% were serially passaged. Subcultures from passages 2-4 were selected for experimental use.

Human gastric adenocarcinoma MKN45 cells were obtained from the tumor cell bank of the Johannes Gutenberg University, Mainz, Germany, and grown in RPMI medium supplemented with 10% FCS, 100 ng/mL gentamicin and 2% 1 mol/L HEPES-buffer. To prepare the tumor cells for the invasion assays, cells were detached from the culture flasks by Accutase (PAA Laboratories).

Cell synchronization

MKN45 cells were reversibly blocked at the G1/S transition by a 24 h treatment with 5 μg/mL aphidicolin (Sigma, München, Germany). To allow S-phase progression, cells were washed extensively and replated in tumor cell culture medium in the absence of aphidicolin. Cells were sampled at successive time points to assess their position in the cell cycle, their adhesion capacity and their CD44 expression level. Non-synchronized control cell cultures were incubated in aphidicolin free culture medium. Viability of tumor cells was assessed by propidium iodide dsDNA-intercalation (facs-analysis) or by the evaluation of lactate dehydrogenase (LDH) release (Cytotoxicity Detection Kit; Roche) at 490 nm using an automatic microtiter plate reader.

Flow cytometric analysis of cell cycle status

MKN45 cells were reversibly blocked with aphidicolin and subsequently washed and replated in tumor cell culture medium in the absence of aphidicolin. Cells were sampled at successive time points and incubated with propidium iodide and RNAse (Cycle Test Plus; Becton Dickinson). DNA content and cell cycle distribution were analyzed using a Becton Dickinson FACScan flow cytometer. Cytofluorometric analysis was performed using CellQuest software (Becton Dickinson), on 10 000 cells per sample. The percentage of cells in S-phase, G2/M-phase and G0/G1-phase was determined using Modfit 2.0 software (Becton Dickinson).

Flow cytometric analysis of CD44 expression

CD44 standard and splice variant (v) expression were determined with anti human CD44 monoclonal antibodies: CD44standard, clone SFF-2; CD44v3, clone VFF-327v3; CD44v4, clone VFF-11; CD44v5, clone VFF-8; CD44v6, clone VFF-7; CD44v7, clone VFF-9; CD44v7+8, clone VFF-17; CD44v10, clone VFF-14 (all: Bender MedSystems, Eching, Germany). Primary antibodies were conjugated with fluorescein isothiocyanate (FITC). CD44 surface expression of MKN45 cells was then measured using a FACscan (Becton Dickinson; FL-1H (log) channel histogram analysis; 1×10^4 cells/scan) and expressed as mean fluorescence units (MFU). Mouse IgG1-FITC (Dianova-CBL, Hamburg, Germany) was used as an isotype control.

Adhesion of MKN45 to HUVEC monolayer

HUVEC were transferred to six-well multiplates (Falcon Primaria; Becton Dickinson). When confluency was reached, MKN45 cells (synchronized *versus* non-synchronized) were detached from the culture flasks and 0.5×10^6 cells were then added to the HUVEC monolayer for 60 min. Subsequently, non-adherent tumor cells were washed off using 37 ℃ Medium 199. The remaining cells were fixed with 1% glutaraldehyde. Adherent tumor cells were counted in five different fields of a defined size (5 mm×0.25 mm) using a phase contrast microscope (20×objective) and the mean cellular adhesion rate was calculated. Proliferative activity of tumor cells was estimated by the PicoGreen assay[9]. Cells were washed and dried at several time points (0-24 h). Cells were then digested with papain (0.125 mg protein/mL) for 20 h at 60 ℃. Thereafter, the fluorescent dye PicoGreen (MoBiTec, Goettingen, Germany), which shows high specificity for dsDNA, was added (1:200 dilution) for 10 min at 20 ℃. Fluorescence intensity was determined using a computer-controlled fluorescence reader (Cytofluor 2300 plate scanner; Millipore, Eschborn, Germany) at λ_{ex} = 485 nm and λ_{em} = 530 nm.

CD44 blocking experiments

MKN45 cells were preincubated for 60 min with anti CD44v4,

anti CD44v5 or anti CD44v7 monoclonal antibodies at 1:80 dilution. MKN45 cells were then added to HUVEC monolayer to evaluate the adhesion capacity as described above. In a second set of experiments, HUVEC were treated with hyaluronidase (Worthington, Lakewood, USA) for 60 min (1 000 U/mL, 2 500 U/mL, or 5 000 U/mL), before MKN45 cells were added. Non treated HUVEC served as the controls. Adhesion capacity of tumor cells was then analyzed as described above.

Statistical analysis

All studies were performed 3-6 times. Statistical significance was investigated by the Wilcoxon-Mann-Whitney-*U*-test. Differences were considered statistically significant at a *P* value less than 0.05.

RESULTS

Synchronization of MKN45 cells

MKN45 tumor cells were synchronized to monitor the changes in adhesion behaviour at various stages during cell cycle transit. The procedure based on treatment with aphidicolin effectively allowed us to follow cells in distinct phases of a single cell cycle prior to any cell division: in G0/G1, at the G2/M transition and in S phase.

Non-synchronized MKN45 reside in the S phase of the cell cycle (Figure 1). However, they were reversibly blocked at the G1/S transition by a 24 h treatment with 5 μg/mL aphidicolin. After extensive washing and replacement in fresh medium to allow cell cycle progression, MKN45 quickly entered S phase after 4 h and reached G2/M after 8 h. MKN accumulated in G0/G1 after 16 h (Figure 1).

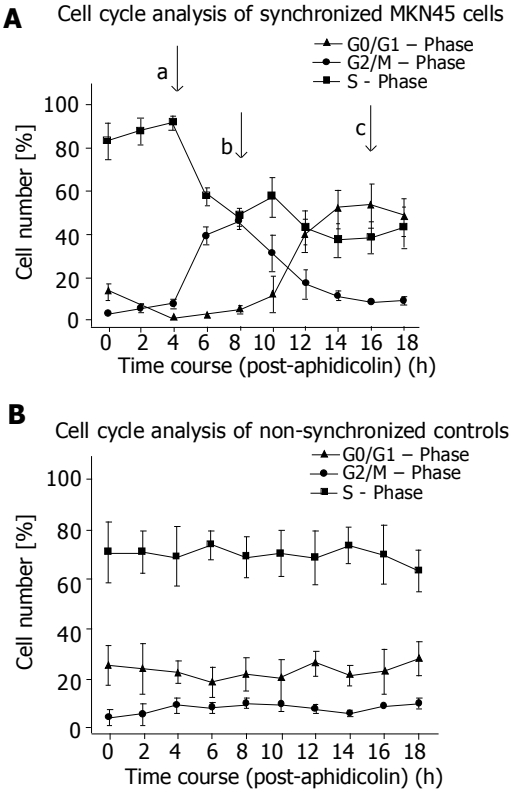

Figure 1 Facs analysis of synchronized MKN45 cells. Cell number is given in %. Non-synchronized control cells reside in the S-phase of the cell cycle. When MKN45 cells were blocked with aphidicolin and then replated in fresh medium to allow cell cycle progression, MKN45 entered S phase after 4 h (arrow a), G2/M after 8 h (arrow b) and G0/G1 after 16 h (arrow c). Mean±SD of *n* = 3 experiments (**A**,**B**).

Aphidicolin synchronization had no toxic effects on MKN45 because cell viability and adhesion events of synchronized cells to HUVEC were not diminished, compared to untreated controls.

Adhesion of synchronized MKN45 to HUVEC

Adhesion of MKN45 to HUVEC was determined at 0 h (immediately after washing out aphidicolin), 4, 8, and 16 h after the end of aphidicolin treatment. This was in accordance to the maximum accumulation of synchronized MKN45 in the S phase, G2/M phase or in G0/G1. Typically, adhesion capacity increased when cells progressed to G2/M (Figure 2; $P<0.05$). The increased number of adherent MKN45 seen after 8 h was not due to an increase in the total cell number. The PicoGreen assay, which had been carried out as well, revealed no proliferative activity of MKN45 during the experimental procedure. Furthermore, non-synchronous control cultures adhered to HUVEC uniformly at all time points.

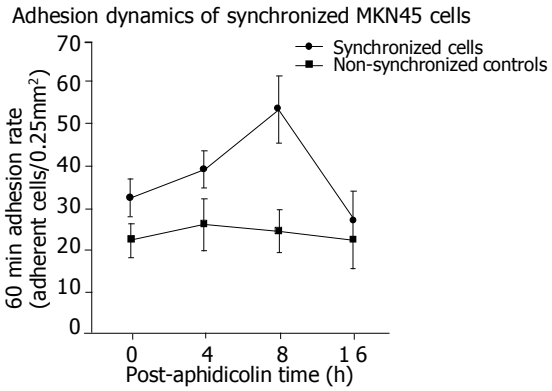

Figure 2 Adhesion capacity of synchronized MKN45 cells to HUVEC. MKN45 cells were treated for 24 h with aphidicolin. Cells were then washed and replated in fresh medium to allow cell cycle progression. Cells were sampled after 0, 4, 8 and 16 h following aphidicolin treatment (*n* = 6). A 60-min adhesion to HUVEC was determined at each time point and compared with non-synchronous cells. Mean±SD of *n* = 6 experiments.

Expression of CD44 variants on synchronized MKN45 cells

Analysis of CD44 expression in asynchronous control cultures revealed significant expression of CD44 splice variants CD44v4, CD44v5, and CD44v7. CD44 variants CD44v3, CD44v6, CD44v8, and CD44v10 were not detected (Figure 3). Therefore, subsequent studies concentrated on CD44v4, CD44v5, and CD44v7 adhesion receptors. To correlate the differences in CD44 expression level during cell cycle transit with parallel changes of MKN45 adhesion behavio, CD44 splice variants were evaluated 0, 4, 8, 12, and 16 h after the end of aphidicolin treatment. Figure 4 shows that CD44v4, CD44v5 and CD44v7 expression in synchronized cell cultures were all up-regulated during cell cycle progression with a maximum effect 8 h after the experimental onset, i. e. in G2/M ($P<0.05$). In contrast, non-synchronized MKN45

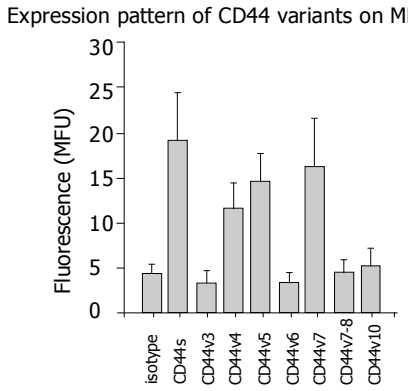

Figure 3 Facs analysis of CD44 and CD44 splice variant expression of MKN45 cells. Primary antibodies, indicated in methods, were conjugated with fluorescein isothiocyanate (FITC). CD44 surface expression of MKN45 cells was then measured using a FACscan (FL-1H (log) channel histogram analysis; 1 x10^4 cells/scan) and expressed as mean fluorescence units (MFU). Mouse IgG1-FITC was used as an isotype control. Mean±SD of n = 3 experiments.

expressed CD44 variants equally well at all time points.

Relevance of CD44 for MKN45 adhesion

To evaluate whether CD44v4, v5 and v7 receptors facilitate adhesion of MKN45 to HUVEC, tumor cells were treated with their respective monoclonal antibodies, or the CD44 ligand hyaluronan on HUVEC was removed by digestion with hyaluronidase. Pretreatment of MKN45 cells with anti CD44 monoclonal antibodies decreased adhesion to HUVEC by nearly 50%, irrespective of the CD44 splice variant used (P<0.05). In good accordance, digestion of hyaluronan on HUVEC blocked MKN45 cell attachment to HUVEC with a maximum effect at a hyaluronidase concentration of 2 500 U/mL (P<0.05; Figure 5).

DISCUSSION

CD44, an integral membrane glycoprotein expressed by many cell types, serves as the principal receptor which binds hyaluronan and might be a determinant of metastatic and invasive behaviour in carcinomas[10]. One of the basic features of carcinoma cells is their ability to generate a large number of alternatively spliced isoforms of CD44[11,12]. Although the structural characteristics of these isoforms are documented, the functional consequences of CD44 isoform expression on the biology of colon cancer cells still remains unclear.

CD44 surface analysis demonstrated that MKN45 tumor cells strongly express the CD44 splice variants CD44v4, CD44v5 and CD44v7. This is in good accordance with studies on tissue specimens revealing elevated expression of CD44v5 in human colon carcinoma cells which was associated with tumor progression and growth[13]. Mulder and coworkers observed high expression of CD44v5 in most colorectal neoplasms (83%-96%), independent of stage, which indicates that CD44v5 might be an earlier marker of colonic epithelium transformation[14,15]. Using immunohistochemical staining and Northern blotting, Harn HJ *et al.* showed that the expression of CD44 variant encoding exon v5 was up-regulated in human gastric carcinomas[16]. Most notably, CD44v5 was expressed preferentially in poorly differentiated human gastric carcinomas and metastatic lymph nodes[17].

Overexpression of CD44 variants v4 and v7 contributes to the genesis of gastric cancer as well[18,19], although limited data are available and the biological significance of the receptor modulation is not clear[20].

Based on our adhesion-blocking study using specific anti-CD44 monoclonal antibodies, we hypothesize that CD44v4, CD44v5, as well as CD44v7 receptors are important elements which regulate adhesive interactions between gastric tumor cells and the vessel wall. Results of additional experiments, in which endothelial cells were treated with hyaluronidase, further demonstrate that the interaction of CD44 molecules on MKN45 cells with hyaluronan on HUVEC is a critical factor in the adhesion process.

To address the question of whether CD44 expression is linked to the cell cycle, the CD44 splicing isoforms CD44v4, CD44v5 and CD44v7 were evaluated on synchronized MKN45 tumor cells. Intriguingly, CD44 variants increased after cells were released from arrest, showing maximal expression 8 h after the experimental onset. At the same time point, cells passed through G2/M. Therefore, these experiments clearly indicate that CD44 receptor expression "follows" the proliferative

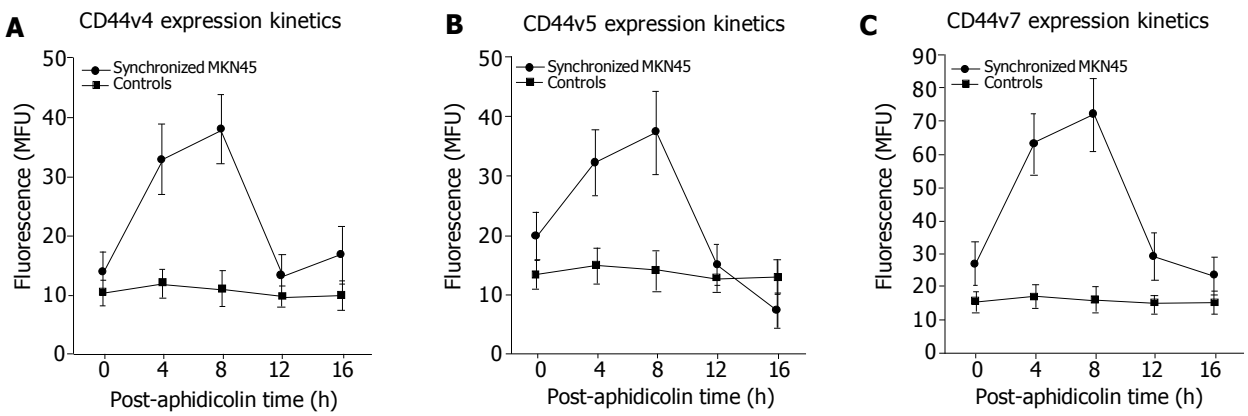

Figure 4 Expression of CD44v4(**A**), CD44v5(**B**) and CD44v7(**C**) on MKN45 cells during cell cycle transit. Synchronized MKN45 cells were labeled with anti-CD44v4, anti-CD44v5 or anti-CD44v7 at indicated time points. Non-synchronized cells served as controls. Fluorescence intensity was measured using a FACscan (FL-1H (log) channel histogram analysis; 1 x10^4 cells/scan) and expressed as mean fluorescence units (MFU). Mean±SD of n = 6 experiments.

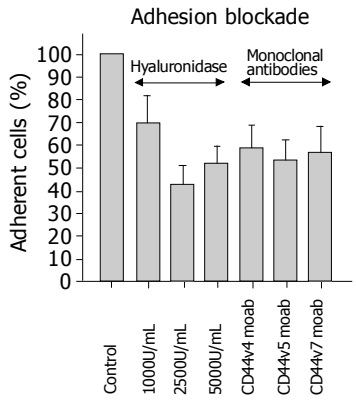

Figure 5 MKN45 cells were preincubated for 60 min with anti CD44v4, anti CD44v5 or anti CD44v7 monoclonal antibodies at 1:80 dilution. MKN45 cells were then added to HUVEC monolayer to evaluate the adhesion capacity (right part of Figure 5). In a second set of experiments, HUVEC were treated with hyaluronidase for 60 min (1 000, 2 500, or 5 000 U/mL), before MKN45 cells were added (left part of Figure 5). Non treated HUVEC served as the 100% control. Mean±SD of n = 6 experiments.

activity of tumor cells with an enhanced expression level in G2/M, and subsequent repression in G0/G1 and S.

This is the first report demonstrating a link between cell cycle and CD44 expression in gastric carcinoma cells. However, data derived from other tumor entities support our findings. CD44 ligation with an anti-CD44 monoclonal antibody inhibited the proliferation of human acute myeloid leukemia cells. The effects of anti-CD44 on myeloid cells were associated with specific disruption of cell cycle events and induction of G0/G1 arrest[21]. Experimentally induced proliferation blockade of malignant rhabdoid tumors led to an accumulation in G0/G1, which was accompanied by CD44 down-regulation[22]. In a similar way, CD44 was down-modulated, when human breast cancer cells were blocked in the G1 phase[23]. Interestingly, analysis of 131 patients who underwent surgery for papillary thyroid carcinoma revealed a close relation between extrathyroidal invasion, G2M-phase fraction and CD44 expression[24].

The molecular background of the cell cycle-CD44 axis has not been evaluated in detail. Experiments on myeloid leukemia cells demonstrated that ligation of CD44 with monoclonal antibodies causes growth arrest through the down-regulation of c-Jun expression via AP-1 sites. Decreased JNK expression and a consequent decrease in c-Jun phosphorylation was also assumed to be involved in the down-regulation of the c-Jun promoter activity[21]. Nevertheless, although this is an attractive hypothesis, these events might not necessarily occur in our culture system. Several authors describe progressive changes of the p53 protein and the anti-apoptotic protein bcl-2 in carcinomas, with an inverse relationship between p53, bcl-2 and CD44 expression[7,25]. Both p53 and bcl-2, as well as their downstream targets p21, p27, and/or p130, play key roles in cell proliferation and cell cycle progression[26,27], and therefore might also contribute to CD44 modulation.

The finding that CD44 surface expression was altered during mitosis, together with the fact that CD44 receptors regulate tumor cell endothelial cell interactions, prompted us to speculate that tumor cells change their adhesive behaviour in a cell-cycle dependent manner. Indeed, the number of synchronized MKN45 binding to HUVEC drastically increased in G2/M, and dropped down to basal values in G0/G1 and S. The adhesion dynamics exactly match the cell-cycle dependent expression course of CD44 variants v4, v5, and v7. Based on this, we conclude that CD44 expression level, cell cycle activation and migratory capacity of gastric tumor cells are linked together, with the most aggressive behaviour of tumors in the G2/M phase.

From a clinical viewpoint, therapeutic modulation of the tumor cell cycle might alter the sensitivity of these cells to anti-tumoral compounds and, consequently, might enhance the efficacy of the current treatment protocols.

Abstract

AIM: To explore the preliminary identification of serum protein pattern models that may be novel potential biomarkers in the detection of gastric cancer.

METHODS: A total of 130 serum samples, including 70 from patients with gastric cancer and 60 from healthy adults, were detected by surface-enhanced laser desorption and ionization time-of-flight mass spectrometry (SELDI-TOF-MS). The data of spectra were analyzed by Biomarker Patterns Software (BPS). Thirty serum samples of gastric cancer patients and 30 serum samples of healthy adults were grouped into the training group to build models, and the other 70 samples were used to test and evaluate the models. The samples of the test group were judged only with their peaks' height and were separated into cancer group or healthy control group by BPS automatically and the judgments were checked with the histopathologic diagnosis of the samples.

RESULTS: Sixteen mass peaks were found to be potential biomarkers with a significant level of $P<0.01$. Among them, nine mass peaks showed increased expression in patients with gastric cancer. Analyzed by BPS, two peaks were chosen to build the model for gastric cancer detection. The sensitivity, specificity, and accuracy of the model were 90%, 36/40, 86.7%, 26/30, and 88.6%, 62/70, respectively, which were greatly higher than those of clinically used serum biomarkers CEA (carcinoembryonic antigen), CA19-9 and CA72-4. Stage I/II gastric cancer samples of the test group were all judged correctly.

CONCLUSION: The novel biomarkers in serum and the established model could be potentially used in the detection of gastric cancer. However, large-scale studies should be carried on to further explore the clinical impact on the model.

INTRODUCTION

Gastric cancer is the second leading cause of cancer death in the world and is predicted still to be one of the leading causes of all deaths in the near future[1,2]. Almost 40% of gastric cancer cases occur in China, where it is the most common cancer. According to WHO IARC (International Agency for Research on Cancer) database and Globocan 2002 database, about 393 000 cases are diagnosed with gastric cancer in China, and of these about 308 000 have died. However, few specific tumor markers with high sensitivity could be useful in the diagnosis of gastric cancer. The sensitivity of existing serum biomarkers carcinoembryonic antigen (CEA), CA19-9 or CA72-4 is only about 40%[3-6].

Proteomic technologies, especially the surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF-MS) technology, are providing the tools needed to discover and identify the disease-associating biomarkers[7-10]. Ciphergen Biosystems has developed the ProteinChip technology coupled with SELDI-TOF-MS to facilitate protein profiling of complex biological mixtures[11-14]. In SELDI-TOF-MS analysis, a nitrogen laser desorbs the protein/energy-absorbing molecule mixture from the array surface, enabling the detection of the proteins captured by the array[15,16]. It has been reported recently that the promising SELDI-TOF-MS technology could be used for the diagnosis of cancer by analyzing the protein markers in serum[17,18]. Moreover, the SELDI-TOF-MS technology could be used to analyze other kinds of sample, such as nipple aspirate fluid, urine,

serum-free conditioned medium of cell culture, *etc*.[19-21].

In this study, not only 16 peaks were identified as the potential biomarkers with a significant level of $P<0.01$, but also a model of two markers combination was established, which can be used in the detection of gastric cancer. In the double-blind test, this model was evaluated. The sensitivity, specificity, and accuracy are much better than those of any other biomarker used clinically.

MATERIALS AND METHODS

Serum samples

A total of 130 serum specimens from 60 healthy adults and 70 patients with gastric cancer were obtained from Tissue Bank of Beijing Cancer Hospital and Beijing Chaoyang Hospital in 2002-2003. All patients of gastric cancer were confirmed histopathologically. Serum samples of gastric cancer had been collected from patients preoperatively and without chemotherapy. The median age of the patients with gastric cancer was 64 years (range, 32-81 years), and the median age of the control group was 52 years (range, 15-84 years). The TNM staging of 70 patients with gastric cancer are shown in Table 1. All samples were obtained with the consent of the patient and Institutional Review Board approval.

Table 1 Samples of control and gastric cancer staged by TNM classification

	Training group	Test group	Total
Gastric cancer	30	40	70
Stage I	6	6	
Stage II	4	5	
Stage III	12	16	
Stage IV	8	13	
Control	30	30	60
Total	60	70	130

Preparation of serum samples for SELDI analysis

All samples were stored at -80 °C until use. WCX2 (Weak Cation Exchange) chips and software were provided by Ciphergen Biosystems (Fremont, CA, USA). The array spots of WCX2 chips were preactivated with binding buffer (100 mmol/L sodium acetate, pH 4.5) at room temperature for 5 min in a humidifying chamber with gently shaking, and repeated once. Each serum sample was first diluted 1:2 with 1% DTT U9 (DTT: dithiothreitol; U9: 9 mol/L urea, 2% Chaps, 50 mmol/L Tris-HCl, pH 9.0), and then diluted 1:12 in binding buffer. One hundred microliters of each diluted sample was spotted onto preactivated WCX2 protein array chips and incubated in a humidfiying chamber for 1 h at room temperature. The chips were washed twice with binding buffer and once with HPLC H_2O, air-dried, then sequentially treated by 0.5 μL 100% saturated sinapinic acid (3,5-dimethoxy-4-hydroxycinnamic acid) solution twice. The sinapinic acid solution was 50% acetonitrile and 0.5% trifluoroacetic acid. The chips were analyzed by the Ciphergen ProteinChip Reader (model PBSII). All reagents were provided by Sigma Co.

Ciphergen ProteinChip SELDI-TOF-MS analysis

The mass spectra of proteins were generated by using 112 laser shots at a laser intensity of 175-180.The optimized detection size range was between 3 000 and 10 000 u, with a high mass to 100 000 u. The laser was focused at by optimization center. The starting detector sensitivity was set at 9, and the mass deflector was set to 800 u.

Statistical analysis

The data were analyzed with Ciphergen ProteinChip Software version 3.1.1 (Ciphergen Biosystems). For comparison, the mass peaks of test group (n=70) were normalized to that of all 60 training samples using one peak as common calibrate before analysis. The Biomarker Wizard application (Ciphergen Biosystems) was used to automatically detect mass peaks to cluster. Peak labeling was completed by using first-pass 7 S/N, minimum peak threshold 30% of all, second-pass 3 S/N, with 0.3% of the cluster mass window, and estimated peaks were added. The cluster data was analyzed by using Biomarker Patterns™ Software (BPS) 4.0.1 (Ciphergen Biosystems).

RESULTS

By using Biomarker Wizard application, more than 100 mass peaks were identified in the samples of the training group, and 16 qualified mass peaks were identified with a significant level of $P<0.01$ (Table 2). Nine mass peaks, 7 567, 15 117, 15 326, 15 847, 7 934, 4 524, 8 052, 6 982, 4 714 u, showed increased expression in patients with gastric cancer. The other seven mass peaks, 5 252, 2 675, 5 546, 5 340, 4 177, 3 995, 3 245 u, showed decreased expression in patients with gastric cancer. A representative pseudogel view of specific candidate gastric cancer tumor markers and a stacked trace view of candidate markers from diseased *vs* control individuals are shown in Figure 1.

All clusters were exported to BPS 4.0.1 and analyzed.

Table 2 Mass peaks found in the model group

M/Z	*P*	Mean-cancer	Mean-control
7 567	0.0000000037	9.92	2.14
15 117	0.0000001024	10.14	1.69
15 326	0.0000002675	2.57	0.60
15 847	0.0000286434	7.08	2.32
5 252	0.0000742542	1.59	4.24
2 675	0.0006036111	1.16	2.29
5 546	0.0008794540	2.09	3.97
7 934	0.0012685350	8.04	3.25
4 524	0.0013355919	2.63	1.66
5 340	0.0013355919	14.90	27.46

4 177	0.0022105930	2.80	6.73
3 995	0.0052019227	1.35	1.97
6 982	0.0074510883	2.78	1.78
4 714	0.0088747087	3.10	2.08
3 245	0.0096738522	1.49	2.26

The model was generated by using Gini method with favor-even-splits 0. The v-fold cross-validation was set to 11, while the other options remained as defaults. The relative cost of the model tree is 0.200, shown in Figure 2. Two peaks, 7 567 and 5 252 u, were chosen to make the model tree. And the judgment of cancer or healthy control was made according to the rules of the model tree (data not shown). The double-blind test group samples were normalized to the training group using the same procedure and the same parameters. Seventy test samples were judged only with their peaks' height of the two mass ranges and were separated into cancer group or healthy control group by BPS automatically. The judgments were checked with the histopathologic diagnosis of the test samples. The results demonstrated that the sensitivity, specificity, and accuracy were 90% (95% confidence interval 76.9-96.0%), 86.7% (70.3-94.7%), and 88.6% (79.0-94.1%), respectively, shown in Table 3.

Table 3 Statistical summary of the model (by BPS)

Group	Sensitivity (%)	Specificity (%)	Accuracy (%)
Training	96.7	96.7	96.7
Test	90.0	86.7	88.6

DISCUSSION

Recent advances in genomics and proteomics hold great potential for diagnostic, prognostic, and therapeutic applications[22-24]. They help to discover new therapeutic target, design rational individual drug and obtain early-detection biomarkers[25-28]. Proteomic analysis to identify biomarkers has been reported for the detections of several kinds of cancer, such as pancreatic cancer, ovarian cancer, renal cancer, *etc.*[29-32]. However, to our best knowledge gastric cancer has not found potential biomarkers, which can be used for detection as yet. Although the serum tumor-related antigen, such as CEA, CA72-4 and CA19-9 have been examined as routine in some clinics, their sensitivity and specificity for gastric cancer were too low to be used alone for diagnosis, which limited their diagnostic value. SELDI-TOF-MS technology provides a better and easier tool to identify cancers with barely 3 μL serum.

In this study, we found a novel panel of biomarkers and a model built with them. The sensitivity, specificity, and accuracy of the model in test group were 90%, 86.7%, and 88.6%, respectively, which are greatly higher than those of CEA , CA72-4 and CA19-9 whose molecular weight are more than 100 000 u. This made it possible that the model can be used as biomarkers in the detection for gastric cancer.

The four miss-judged (false negative) test samples of the gastric cancer group were obtained from patients with poorly differentiated tumor, and in stage III or IV, are shown in Table 4. Stage I/II gastric cancer samples of the test group were all judged correctly. It suggested that the model can also be used for early detection, not only for advanced gastric cancer. In the test group, 14 gastric cancer samples obtained from patients were with poorly differentiated tumor. The miss-judged samples may reflect the biological heterogeneity of tumor, which leads the change in serum proteins and influences the judgment. In the test group, 3 of 17 female patients of gastric cancer

Tree Sequence

Tree number	Terminal nodes	Resubstitution relative cost	Cross-Validated relative cost	Complexity
1	5	0.300 ± 0.091	0.000	0.000
2	3	0.200 ± 0.077	0.067	0.017
3	2	0.200 ± 0.077	0.167	0.050
4	1	1.000 ± 0.000	1.000	0.417

Figure 2 Model tree established by BPS using the training group and relative cost. **A:** Two peaks, 7 567 and 5 252 u, were chosen to make the model tree. n represents the number of the samples that belong to the node; **B:** The relative cost of the model tree is 0.200.

Table 4 Status of the miss-judged test samples

Sex	Age (yr)	Differentiation of tumorgy	TNM	Stage
1 Female	32	Poor	T4N1M1	IV
2 Male	58	Poor, partially with signet ring cell	T3N2M0	III
3 Female	63	Poor	T4N2M1	IV
4 Female	50	Poor, partially with signet ring cell	T4N1M0	III

and 2 of 10 female healthy adults were miss-judged. Therefore, the sensitivities of the female group and the male group are 82.4% and 95.7%, and the specificities are 80% and 90%, respectively. However, the sensitivities had no statistical difference between sexes (P=0.394), neither did the specificities (P=0.407). Large-scale studies should be carried on to further explore the clinical impact on the model.

Although the model was composed of two peaks, 7 567 u had the highest importance score (data not shown), and can contribute to the model independently with cross-validated relative cost 0.200, as shown in Figure 2B. The peak was significantly higher in the gastric cancer group than in the control group. Therefore, it is more important. We now have focused on the purification and identification of it by using tandem mass spectrometry. If antibodies against the specific proteins are available, we will perform ELISA or immunohistochemistry to further verify the biomarker and make the cancer detection cheaper and easier. Besides, more samples are needed to confirmthat this peak is a specific biomarker of gastric cancer, not of other types of cancer.

Abstract

AIM: Capsaicin, a pungent ingredient found in red pepper, has long been used in spices, food additives, and drugs. Cell death induced by the binding of capsaicin was examined in a human gastric adenocarcinoma cell line (AGS cells).

METHODS: By using XTT-based cytotoxicity assay, flow cytometry using the TUNEL method, and quantitation of DNA fragmentation, both cell death and DNA fragmentation were detected in AGS cells treated with capsaicin. By using Western blotting methods, capsaicin reduced the expression of Bcl-2, the antiapoptotic protein, in AGS cells in a concentration-dependent manner.

RESULTS: After incubation of AGS cells with capsaicin for 24 h, cell viability decreased significantly in a dose-dependent manner. After incubation of AGS cells with capsaicin for 24 h, apoptotic bodies also significantly increased, and were again correlated with the dose of capsaicin. When the concentration of capsaicin was 1 mmol/L, the amount of DNA fragments also increased. Similar results were also in the lower traces.

CONCLUSION: These results suggest that capsaicin-induced cell death might be via a Bcl-2 sensitive apoptotic pathway. Therefore, capsaicin might induce protection from gastric cancer.

INTRODUCTION

Carcinoma of the stomach is currently the leading cause of cancer-related death among the Chinese. The two most likely factors for such a high incidence of stomach cancer has been thought to be either *Helicobacter pylori*[1] or diet. Capsaicin (8-methyl-N-vanillyl-6-nonenamide), the main ingredient of hot chili peppers, has long been used in spices, food additives, and drugs[2]. Capsaicin has been shown to protect the gastric mucosa of animals and humans against various kinds of damage[3-6]. It is generally considered that capsaicin's effect results from the activation of sensory afferent neurons in the stomach, and is mediated by various physiological functions, such as mucosal blood flow[7-10], mucus secretion[11], and bicarbonate secretions[12]. Vanilloid receptor subtype 1 (VR1), a receptor responsible for capsaicin action, has been cloned[13] and demonstrated to be located in both neural and non-neural cells[14]. VR1 has also been found to be expressed peripherally in gastric mucosal epithelial cells, playing a role in cell protection[15]. Recently, a series of studies have demonstrated that capsaicin inhibits mutagenicity and DNA binding of some chemical carcinogens, possibly by suppressing their metabolic activation[16-18]. With cells in culture, capsaicin-inhibited proliferation of HeLa, ovarian carcinoma, and mammary adenocarcinoma by decreasing NADH oxidase activity[19]. Capsaicin can also alter the expression of tumor forming-related genes by mediating the overexpression of *p53* and/or *c-myc* genes in a Korean stomach cancer cell line[20]. Capsaicin was found to induce apoptosis in T cells by increasing the reactive oxygen species and by a subsequent mitochondrial transmembrane potential[21]. In this report, we have examined the underlying mechanism by which capsaicin induces apoptotic cell death in a human gastric adenocarcinoma cell line (AGS).

MATERIALS AND METHODS

Cell line

A human gastric adenocarcinoma cell line (AGS) was

obtained from American Type Culture Collection. The cells were maintained in RPMI 1640 medium (Life Technologies, Inc., Melbourne, Australia) supplemented with 10% heat-inactivated fetal bovine serum with penicillin (100 U/mL) and streptomycin (100 μg/mL). Cultures in 75- or 25-mL culture flasks were incubated at 37 ℃ in a humidified gas mixture containing 50 mL/L CO_2 balanced with air.

XTT-based cytotoxicity assay

Unlabeled AGS cells (1×10^4/well) were distributed on to a 96-well flat-bottomed plate. Appropriate numbers of cells were added, resulting in triplicate wells, and a final volume of 100 μL of RPMI medium with 10% bovine serum was obtained. After incubation of AGS cells for 24 h, the medium was then replaced with serum-free RPMI medium containing capsaicin (0.05 μmol/L-10 mmol/L) at 37 ℃ for 24 h. The quantity of viable cell was determined using a cell proliferation ELISA kit from Boehringer Mannheim (No. 1465015), according to the recommendations of the supplier. Each sample was tested in triplicate.

Detection of apoptotic cells by flow cytometry using TUNEL method

For demonstration of apoptosis, TUNEL assay was performed with an *in situ* cell death detection kit (POD, Boehringer Mannheim) according to the manufacturer's recommendations. After incubation of AGS cells for 24 h, cells were analyzed by Epics Elite ESP flow cytometer. Apoptosis was analyzed using the Wincycle Software (Coulter). Adherent cells were harvested and stained in hypotonic fluorochrome solution (propidium iodide 50 μg/mL in sodium citrate plus 0.1% Triton X-100, Sigma). Apoptotic nuclei were identified as a subgenomic DNA peak and were distinguished from cell debris on the basis of both forward light scatter and fluorescence of propidium iodide.

Quantitation of DNA fragmentation

Apoptosis was also evaluated with a cell death ELISA kit (Boehringer Mannheim, Indianapolis, IN, USA) which utilizes a monoclonal antibody against histone to detect DNA fragments in the cytosolic fraction of lysed cells. Cells treated with or without capsaicin were harvested and lysed according to the manufacturer's instructions. The samples were transferred into 96-well dishes coated with a mouse monoclonal antibody against histone. After incubation and washing, anti-DNA-peroxidase was added to the wells. The reaction was developed with the substrate supplied by the manufacturer and the absorbance of the wells was read at 410 nm. The ratio of the absorbance of the treated cells to the untreated cells was calculated as an enrichment factor, which provides a qualitative assessment of apoptosis. Each sample was tested in triplicate.

Western blotting

After incubation of AGS cells for 24 h, about 10^7 cells were washed in PBS and solubilized buffer (50 mmol/L Tris-HCl pH 7.4, 125 mmol/L NaCl, 0.1% NP-40, 5 mmol/L NaF, 1 mmol/L PMSF, 1 ng/mL leupeptin, 10 ng/mL soybean trypsin inhibitor, 1 ng/mL aprotinin, 10 ng/mL N-tosyl-L-phenylalanyl chloromethyl ketone) for 60 min on ice. Lysates were centrifuged at 2 500 *g* for 5 min. Protein concentration was determined by means of the Bradford protein assay (BioRad Lab., Richmond, CA, USA) using bovine serum albumin as the standard. Thirty micrograms of protein was resolved by electrophoresis on 10% polyacrylamide gels, electrotransferred to a polyvinylidene difluoride filter (Millipore, Bedford, MA, USA), and then blotted with mouse monoclonal antibody for Bcl-2 (1∶500 dilution). Blots were developed with peroxidase-labeled anti-mouse IgG (1∶400 dilution) using a Lumi-Light Plus Western Blotting Kit (Boehringer Mannheim).

Statistical analysis

All values in the text and figures are expressed as mean±SE. Statistical differences were evaluated by Student's *t*-test in unpaired samples, by paired *t*-test in paired samples, or by Wilcoxon's sum of ranks test. When evaluating multiple values, the Bonferroni correction was used. Probability values less than 0.05 were considered to be significant in all experiments. Analysis of the data and plotting of the figures were done with the aid of software (SigmaStat and SigmaPlot, Version 5.0, Jandel, USA; PHARM/PCS, Version 4.2, MCS, USA) run on an IBM PC-AT computer. Protein blot images were captured by an Imaging Densitometer with the aid of software (Bio-ID, V.97 software for Windows 95, Vilber Laurmat, France). Comparisons were made only between averaged values of bands within the same gel.

RESULTS

Based on the XTT assay, DNA fragmentation and flow cytometric analysis, induction of apoptosis by capsaicin was reconfirmed in stomach tumor cell line AGS. In this study, after incubation of AGS cells with capsaicin for 24 h, cell viability decreased significantly in a dose-dependent manner (Figure 1A). This reduction in cell viability induced by treatment with capsaicin was ascribed to apoptotic DNA fragmentation, and the amounts of fragmented DNA were also dependent on the dose of capsaicin (Figure 1B). After incubation of AGS cells with capsaicin for 24 h, apoptotic bodies also significantly increased, and were again correlated with the dose of capsaicin. The upper traces of Figure 2 show capsaicin-induced, concentration-dependent positive TUNEL staining. When the concentration of capsaicin was 1 mmol/L, the amount of DNA fragments also increased. Similar results were also in the lower traces of Figure 2, where apoptotic bodies increased due to the application of capsaicin. Figure 3 shows that the expression of Bcl-2, the antiapoptotic protein, was significantly reduced in AGS cells by capsaicin in a concentration-dependent manner.

DISCUSSION

Apoptosis, or programmed cell death, is a natural form of cell death controlled by a constitutively expressed machinery that induces condensation of the nucleoplasm and cytoplasm, blebbing of cytoplasmic membranes, and fragmentation of the cell into apoptotic bodies that are rapidly recognized and eliminated by adjacent cells[22-24]. Induction of apoptosis by the vanilloid compound capsaicin has been reported in several studies. Vanilloid compounds

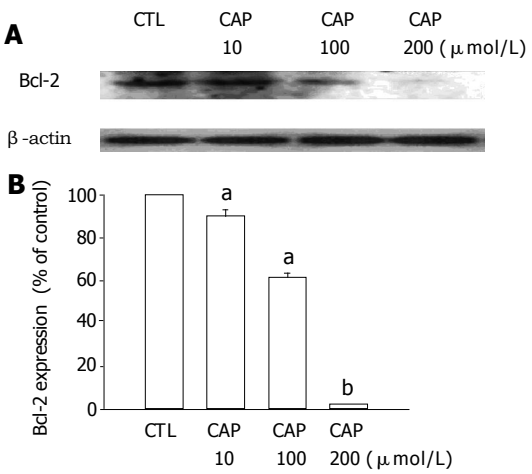

Figure 3 Effect of capsaicin (CAP) on the expression of Bcl-2 in AGS cells. Each bar represents means±SE of three experiments(**A**,**B**). $^{a}P<0.05$, $^{b}P<0.01$ *vs* solvent control (CTL).

are quinone analogs that inhibit the NADH-plasma membrane electron transport system and induce apoptosis in transformed cells[21]. Capsaicin (3.5-10 μmol/L) induces apoptotic cell death in an *in vitro* Korean stomach tumor cell (SNU-1), which may possibly be mediated by overexpression of *p53* and/or *c-myc* genes, but not by overexpression of those of *c-erb*B-2, *c-jun* and *bcl*-2 genes[20], based on XTT assay, DNA fragmentation and flow cytometric analysis. In our study, induction of apoptosis by capsaicin was reconfirmed in another stomach tumor cell line, AGS. In this study, cell viability significantly decreased in a dose-dependent manner after incubation of AGS cells with capsaicin for 24 h. This reduction in cell viability induced by treatment with capsaicin was ascribed to apoptotic DNA fragmentation, and the amounts of fragmented DNA were also dependent on the dose of capsaicin. After incubation of AGS cells with capsaicin for 24 h, apoptotic bodies increased significantly in a dose-dependent manner.

We examined the role of Bcl-2 in capsaicin-induced cell death. In this study, the expression of Bcl-2, the antiapoptotic protein, was significantly reduced by capsaicin. Savill J *et al*.[25] were the first to report that *bcl*-2 can prolong cell survival. Recently, the *bcl-2* gene has emerged as a critical regulator of programmed cell death in a variety of physiological and pathological contexts[26]. Bcl-2 has also been reported to regulate transmembrane calcium fluxes[27,28]. It is of interest to note that when AGS cells were exposed to higher doses (10-200 μmol/L) of capsaicin, the expression of Bcl-2 protein was reduced, which differs from findings reported by Kim *et al*.[20], and suggests that vanilloid compound-induced cell death might be via a Bcl-2 sensitive apoptotic pathway in the AGS cells.

In conclusion, capsaicin reduced the expression of Bcl-2 in a concentration-dependent manner in AGS cells, which suggests that Bcl-2 may play an important role in capsaicin-induced apoptosis.

Abstract

AIM: To investigate the reduction of cell viability in human hepatocellular carcinoma (HCC) cell lines induced by inhibition of nuclear factor κB (NFκB).

METHODS: HLE, SKHep1, and HepG2 were incubated and E3330 was used to compare the stimulation of some chemotherapeutic drugs with that of TNF family, Fas ligand, TNFα and TNF-related apoptosis-inducing ligand (TRAIL) at the point of the reduction of cell viability by inhibiting NFκB.

RESULTS: E3330 decreased NFκB levels in HLE cells stimulated by TNF and TRAIL. The cytotoxicity of the combination of TRAIL, TNFα, Fas ligand, and E3330 increased synergistically in a dose-dependent manner compared to either E3330 alone in all HCC cell lines by MTT assay. However, the combination of some chemotherapeutic drugs and E3330 did not decrease the cell viability.

CONCLUSION: Inhibition of NFκB sensitizes human HCC cell lines to TNF-mediated apoptosis including TRAIL, and TRAIL-based tumor therapy might be a powerful potential therapeutic tool in the treatment of human HCC.

INTRODUCTION

The process of apoptosis is fundamental in the developmental and homeostatic maintenance of complex biological systems[1,2]. Dysregulation or failure of normal apoptotic mechanisms contributes to the transformation of cells and provides a growth advantage to cancer cells[3]. TNF family members, such as TNFα and Fas ligand, play an important role in determining cell death or survival in a variety of human cells and transformed cells[2,4]. However, the potential use of systemically administered TNFα and Fas ligand is limited by their acute cytotoxic effects on normal tissues *in vivo*, thereby limiting their widespread use in the treatment of cancer[5,6]. In contrast, TNF-related apoptosis-inducing ligand (TRAIL) is able to kill a wide spectrum of tumor cells, and appears to be nontoxic to most normal cells[7].

Nuclear factor κB (NFκB) is an essential survival factor in many physiological conditions, such as embryonic liver development and liver regeneration[8]. In liver neoplasm, NFκB plays an important role in the resistance to TNF cytotoxicity and functional pathways including TNF receptor-associated factor 2[9].

Compound E3330 has a therapeutic effect in murine models of endotoxin-mediated hepatitis and in rats with galactosamine-induced hepatitis, presumably as a result of E3330 inhibition of TNFα generation[10,11]. E3330 inhibits NFκB DNA binding, most probably via an interaction with a nuclear factor that activates NFκB activity[12].

Previously we have demonstrated that incubation with TRAIL induces NFκB activation in hepatocellular carcinoma (HCC) cell lines, and the cells show strong resistance to TRAIL-induced apoptosis[13-17]. Therefore, we have investigated the reduction of cell viability induced by inhibition of NFκB using E3330 and some chemo-therapeutic drugs or TNF family members, especially TRAIL.

MATERIALS AND METHODS

Reagents

E3330, a quinone derivative ((2E)-3-[5-(2,3-dimethoxy-6-methyl-1,4-benzoquinoyl)]-2-propenoic acid), was a gift from

Eisai Co., Ltd. E3330 could inhibit LPS-induced TNFα generation in human monocytes[18]. TNF-family members, TRAIL, TNFα, Fas ligand were obtained from MBL, Nagoya, Japan. Chemotherapeutic agents doxorubicin and camptotecin were obtained from Sigma.

HCC cell lines

The HLE cell line was purchased from the Health Science Research Resources Bank (Osaka, Japan). HepG2 and SKHep1 cells were purchased from American Type Culture Collection (Rockville, MD, USA). Cells were cultured in Dulbecco's modified Eagle's medium (Dainippon Pharmaceutical Co., Ltd., Osaka, Japan) at 37 ℃. All media were supplemented with 1% penicillin/streptomycin (GIBCO BRL) and 10% heat-inactivated fetal calf serum (GIBCO BRL).

NFκB luciferase reporter gene assay

The pNFκB-Luc vector (Mercury Pathway Profiling System) and the pCMV-IkBa vector were obtained from Clontech (San Diego, CA, USA). Human HCC cells (2×10^5) were grown in six-well plates in triplicate the day before transfection. Cells were transfected using FuGENE 6 (Boehringer Mannheim) and incubated for 18 h at 37 ℃. The medium was removed and cells were incubated in complete media for 24 h. Cells were stimulated with 20 ng/mL TRAIL (R&D Systems, Nagoya, Japan), 100 U/mL TNFα (Genzyme-Techne, Cambridge, MA, USA) for 24 h. Luciferase activity was determined from cell extracts using a luciferase assay system (Promega) and a luminometer (Berthold Analytical Instruments, Nashua, NH, USA). The results were presented as the fold induction above the luciferase activity found in cells without stimulation.

Detection of apoptosis

To assess the viability of human HCC cell lines, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay was performed. The cells ware plated at a density of 5×10^3 cells/well in 96-well microtiter plates and each plate was incubated for 24 h at 37 ℃ in 50 mL/L CO_2. HCC cell lines were treated with E3330 for 12 h and then with TRAIL (20 ng/mL), TNFα (100 U/mL), Fas ligand (500 ng/mL), doxorubicin (0.1 μg/mL) and/or camptotecin (0.1 μg/mL) for another 12 h. The live-cell count was assayed using a cell titer 96 assay kit (Promega, Madison, WI, USA) according to the manufacturer's instructions. The absorbance of each sample was measured at 570 nm with a microtiter plate reader (Bio-Rad Laboratories, Hercules, CA, USA).

RESULTS

NFκB activation was induced by TNFα, TRAIL and E3330 in HLE cells. Because all human HCC cell lines showed strong resistance to TNFα- and TRAIL-mediated apoptosis, we investigated NFκB levels by NFκB luciferase reporter gene assay 12 h after NFκB inhibitor (E3330) application in HLE cell line. E3330 decreased NFκB levels in a dose-dependent manner in HLE cells stimulated by TNFα and TRAIL (Figure 1).

The cell viability was decreased by the combination of TRAIL, TNFα, Fas ligand, and E3330 in HCC cell lines. The effect of E3330 on apoptosis induced by TRAIL, TNFα and Fas ligand was examined because E3330 was shown to inhibit the activity of NFκB. We incubated human HCC cell lines with E3330 for 12 h, then combined E3330 with TNFα (100 U/mL), Fas ligand (500 ng/mL), or TRAIL (20 ng/mL), and examined the cell viability after 12 h by MTT assay. The cytotoxicity of the combination of TRAIL, TNFα, Fas ligand and E3330 increased synergistically in a dose-dependent manner compared to E3330 alone in all HCC cell lines (Figure 2).

Next, we investigated the cell viability of HCC cell lines inhibited by both chemotherapeutic agents and E3330. We incubated human HCC cell lines with E3330 for 12 h, then combined E3330 with doxorubicin (0.1 mg/mL) or camptotecin (0.1 mg/mL) for an additional 12 h and examined the cell viability after 12 h by MTT assay. Interestingly, doxorubicin and camptotecin had little effect on the reduction of cell viability in all HCC cell lines though they were used in combination with E3330 (Figure 2).

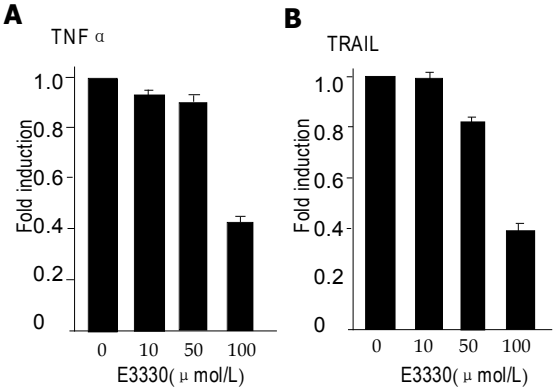

Figure 1 TRAIL-induced NFκB activation in HLE cells (**A**,**B**).

DISCUSSION

TRAIL can induce apoptosis by interaction with two receptors, TRAIL-R1 (DR4) and TRAIL-R2 (DR5)[19-24]. These receptors have a death domain that mediates cellular apoptosis. Two other receptors, known as TRAIL-R3 and TRAIL-R4, inhibit apoptosis by acting as decoy receptors because they do not contain the cytoplasmic death domain. These decoy receptors are highly expressed in normal tissues, but have a substantially lower expression in malignant cells[21-26].

However, it is of interest to determine at which level HCC cells inhibit TRAIL-induced death signaling in HCC cells. NFκB is a key mediator in the inhibition of apoptotic responses and NFκB activation has been shown to increase the antiapoptotic threshold of cells and tissues exposed to cytotoxic cytokines such as TNF by suppressing the initiation of caspase-8 activation[27]. On the other hand, NFκB has many wide-ranging effects that are controlled by a complex regulatory network of inhibitors and coactivators[28-30]. Given the intimate connection between host defense reactions and NFκB, this transcription factor and its associated regulators

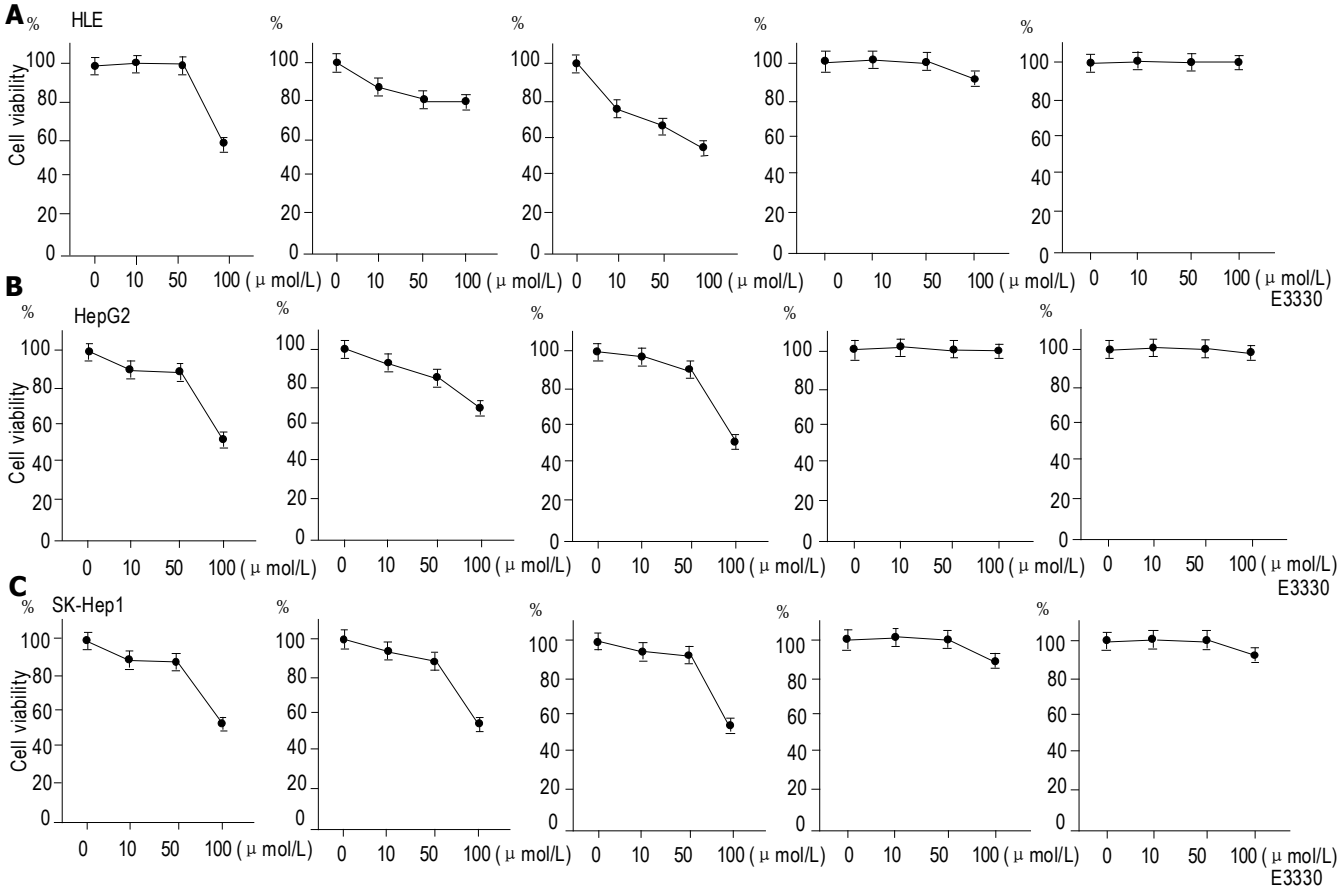

Figure 2 Proliferation of HLE (**A**), HepG2 (**B**), SK-Hep1 (**C**) cells induced by TNFα (1), Fas ligand (2), TRAIL (3), doxorubicin (4), and camptotecin (5).

could provide attractive targets for therapeutic intervention in a number of diseases or pathologic conditions. In this line, a number of anti-NFκB drugs have already been developed[12].

In the current report, E3330 inhibits NFκB DNA binding, most probably via an interaction with a nuclear factor that activates NFκB activity[12]. We studied E3330-inhibited NFκB activity in HCC cell line and found that E3330 decreased NFκB levels in a dose-dependent manner at HLE cells stimulated by TNFα and TRAIL.

NFκB may inhibit the apoptosis induced by TNF family members such as TRAIL, TNFα, Fas ligand. Our results indicate that the inhibition of NFκB could increase cytotoxicity in combination with TNF family members such as TRAIL, TNFα and Fas ligand in HCC cell lines, while E3330 could inhibit NFκB in a dose-dependent manner. Thus, we believe that inhibition of NFκB could augment the cellular apoptosis induced by TNF family members.

Within the TNF family members, the receptor/ligand pair Fas/Fas ligand has been noted to play an important role in the apoptosis of hepatocytes. In contrast to Fas/Fas ligand, TRAIL is able to kill a broad spectrum of tumor cells, but appears to be nontoxic to most normal cells[7]. We demonstrated that inhibition of NFκB sensitized human HCC cell lines to TNF-mediated apoptosis, suggesting that TRAIL-based tumor therapy in combination with anti-NFκB agents might be a powerful potential therapeutic tool in the treatment of human HCC.

Abstract

AIM: To design a classification tool for the histological assessment of hepatocellular carcinoma (HCC), dysplastic nodules (DN), and macroregenerative nodules (MRN) in cirrhotic liver.

METHODS: Two hundred and twelve hepatocellular nodules (106 HCC; 74 MRN; 32 DN) were assessed systematically, quantitatively, and semiquantitatively as appropriate for 10 histological features that have been described as helpful in distinguishing small HCC, DN, and MRN in cirrhotic livers. The data were analyzed by multiple correspondence analysis (MCA).

RESULTS: MCA distributed HCC, DN, and MRN as defined by traditional histological evaluation as well as the individual histological variables, in a "malignancy scale". Based on the MCA data representation, we created a classification tool, which categorizes an individual nodular lesion as MRN, DN, or HCC based on the balance of all histological features (i.e., vascular invasion, capsular invasion, tumor necrosis, tumor heterogeneity, reticulin loss, capillarization of sinusoids, trabecular thickness, nuclear atypia, and mitotic activity). The classification tool classified most (83%) of a validation set of 47 nodules in the same way as the routine histological assessment. No discrepancies were present for DN and MRN between the routine histological assignment and the classification tool. Of 25 HCC assigned by routine assessment in the validation set, 8 were assigned to the DN category by the classification tool.

CONCLUSION: We have designed a classification tool for the histological assessment of HCC and its putative precursors in cirrhotic liver. Application of this tool systematically records histological features of diagnostic importance in the evaluation of small HCC.

INTRODUCTION

The current histological classification of hepatocellular carcinoma (HCC) and its putative precursor nodular lesions is controversial and unsatisfactory, particularly with small lesions of 1-2 cm in diameter. Most of the histological criteria for the evaluation of early HCC and its putative precursors have not been validated properly, and the diagnosis of these lesions still depends largely on subjective interpretation of histological features, which are rarely recorded either in routine diagnostic practice or in the published literature.

The aim of this study was to derive a classification tool based on individual histological features that enable the distinction between HCC, dysplastic nodules (DN), and macroregenerative nodules (MRN) in cirrhotic liver. The design of this classification tool was based on the correspondence between the routine histological classification of liver cell nodules and the classification of the same liver cell nodules by a systematic analysis of the individual histological features that may contribute towards the subjective diagnostic assignment. Lesion size was considered specifically in addition because this aspect is currently the most important item that determines the management of HCC in cirrhotic patients according to the recent Barcelona guidelines[1].

MATERIALS AND METHODS

Dataset for construction of the classification tool

Two hundred and twelve liver hepatocellular nodules were retrieved from the files of the Department of Histopathology of the Royal Free Hospital using the Liver Tumor Database of the Royal Free Liver Pathology Unit. These nodules had been isolated during the routine diagnostic pathological examination of the cirrhotic livers, which were removed from 321 consecutive liver transplant patients who received liver transplantation at the Royal Free Hospital between 1996 and 2001 for various etiologies. Sixty-eight of these patients (59 males, 26 HCV, 19 HBV, 10 cryptogenic cirrhosis, 6 alcoholic liver disease, 3 alcoholic liver disease and HCV, 2 HCV and HBV, 1 Wilson's disease, 1 primary biliary cirrhosis) were found to have HCC in the explanted liver, and/or DN and/or MRN, and livers of these patients constitute our study group. For each nodule, a hematoxylin and eosin (H&E)-stained section was performed as part of the routine histological assessment, as well as a silver impregnation for reticulin fibers using the Gordon and Sweets' method and an immunohistochemical staining for CD34 and smooth muscle actin (SMA).

Histological assessment

The overall assessment was performed assigning each liver cell nodule to one of the three groups: HCC; DN; or MRN by "traditional" subjective diagnostic assessment (APD), using the histological criteria defined by Ferrell *et al*[2], and the International Working Party[3]. The systematic scoring procedure (AQ) was conducted separately from the overall assignment, in order to eliminate bias.

Histological features used to construct the classification tool

The following histological features were chosen for the systematic histological assessment of each lesion: nodule size, nodule heterogeneity, reticulin loss, trabecular thickness, capillarization, number of solitary arterioles, cellular atypia and mitotic activity, necrosis, vascular invasion, and capsular invasion.

These features were chosen because they are currently considered by many liver pathologists as the most useful histological criteria in the histological assessment of hepatocellular lesions, as it appears from published work on this subject[4-8]. Each lesion was reviewed with systematic documentation of these individual features, and a semiquantitative score was given to reticulin loss, capillarization, and cellular atypia (Table 1), as described below.

Size The evolution from cirrhotic liver to MRN, DN, and HCC is usually accompanied by an increase in nodule size. In other words, the greater the size of the lesion, the greater the likelihood that it is a dysplastic nodule or HCC[2-4,7,9,10]. Size was determined macroscopically as maximum diameter of the lesion and expressed in millimeters.

Reticulin loss This has been traditionally considered to be a diagnostic feature of HCC. The following scale was used: grade 0 was given when the reticulin stroma was preserved; grade 1-5 was defined by the number of liver cells included between residual strands of silver-staining reticulin, with grade 1 when liver plates were 3-cell thick; and subsequent 1-cell increments up to grade 5 when liver plates were 7-cell thick or more.

Trabecular thickness This means, the number of liver cells composing a hepatocyte plate and may be considered as a corollary of reticulin loss (see above). In overt HCC, hepatocyte plates tend to be thicker than normal[3,11]. Trabecular thickness was assessed using H&E staining and graded as number of liver cells composing a trabecular plate.

Arterialization and capillarization Number of solitary arterioles[12-14] and capillarization[15] are related to the changes of vascular supply in the evolution of HCC from precursor nodular lesions including acquisition of a predominantly arterial vascular supply and of a diffuse pattern of expression of CD34 by sinusoidal endothelium.

Capillarization was graded as 0 when marginal (i.e., staining only septal endothelium and endothelium of limiting plate of the nodule); Patchy (grades 1-2) when non-confluent patches (grade 1 = in one-third of the nodule; grade 2 in at least two-thirds of the nodule) showing diffuse CD34 immunostaining were seen; incomplete (grade 3) when confluent areas showing diffuse CD34 immunostaining were seen, occupying approximately two-thirds of the nodule; diffuse incomplete (grade 4)

Table 1 Scheme for the systematic assessment of histological features in liver cell nodules in cirrhotic livers

Feature	Modality of assessment					
Nodule maximum diameter	Measurement in millimeter					
Solitary arterioles	Average of individual arteries ×100 (medium power field, MPF) fields					
Mitotic activity	Number of mitoses per 10 ×400 (10 high power fields, 10 HPF) fields					
Trabecular thickness	Number of liver cells forming trabecular (LCT) width					
Vascular invasion	Present/absent					
Capsular invasion	Present/absent					
Necrosis[2]	Present/absent					
Nodule heterogeneity[1]	Present/absent					
Reticulin loss[3]	None	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
Capillarization (CD34)[3]	None	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
Cellular atypia[3]	None	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5

[1]Phenotypically recognizable "clonal" changes e.g. clear cell change, fatty change, microacinar structures; [2]excluding post-treatment necrosis; [3]see text pages 5-6.

when diffuse CD34 staining was seen in the whole nodule apart from scattered CD34-ve patches; diffuse (grade 5) when the entire nodule stained for CD34.

Solitary arterioles: these were counted as average of unpaired arteries detected in 10 medium (100×) power fields, on H&E sections[14].

Cellular atypia and mitotic activity The International Working Party included both cellular atypia and mitotic activity in morphological diagnostic criteria of HCC[3]. Cellular atypia was graded as mild (grades 1-2), moderate or severe (grades 4-5) depending on the similarity in terms of features, such as nuclear contour, hyperchromatism, and nuclear cytoplasmic ratio, when compared to background cirrhotic liver[8] with mild atypia described as minimal difference (and grade 1 or 2 depending on the extent of the changes within the nodule, grade 1 in 1/3 of the surface examined; grade 2 in 2-3/3 of the surface examined), severe atypia as prominent nuclear changes with marked pleomorphism and severe hyperchromatism (and grade 4 or 5 depending on the extent of the changes within the nodule, grade 1 in 1/3 of the surface examined; grade 2 in 2-3/3 of the surface examined), and moderate atypia as intermediate changes.

Mitotic activity was graded as shown in Table 1, counting the number of mitoses in 10 high (400×) power fields[3].

Heterogeneity This term describes the morphological changes seen in a hepatocellular lesion and presumably related to the clonal evolution seen in the development of HCC. This is evident morphologically, for example, as a "nodule in nodule pattern" and consists of areas with one or more morphological changes distinct from the parent nodule and often with compression of the parent nodule suggesting an increased growth rate. These morphological changes include small cell change, microacinar change, clear cell change, fatty change, groups of Mallory body or fibrinogen containing cells, and loss or accumulation of iron or bile compared to the background liver[3,4].

Tumor necrosis usually occurs when cell growth exceeds the vascular supply and is usually seen in tumors at a relatively advanced biological stage. Necrosis was considered to be diagnostically relevant only when it was "spontaneous" in the absence of previous history of pre-transplantation local treatment (e.g., trans-arterial chemoembolization, percutaneous ethanol injection, *etc.*).

Invasion Vascular invasion was considered as invasion of vascular structures identified histologically. Capsular invasion was recorded when there was invasion of perinodular dense fibrous tissue[5,8,16].

For each nodule, H&E-stained section was performed as part of the routine histological assessment, as well as a silver impregnation for reticulin fibers using the Gordon and Sweets' method and an immunohistochemical staining for CD34 and SMA.

Dataset for validation of the classification tool

The classification tool (Table 3) was tested prospectively on a subsequent separate set of hepatocellular nodules identified in 11 consecutive liver explants with 47 distinct nodular liver cell lesions removed at transplantation in the year 2002. The test set of nodules consisted of 25 HCC (mean size, 19.4 mm; SD, 14 mm), 9 DN (mean size, 10.7 mm; SD, 3 mm), and 13 MRN (mean size, 7.7 mm; SD, 2.2 mm).

Statistical analysis

The individual histological features described above were analyzed by multiple correspondence analysis (MCA). MCA is an exploratory technique[17] allowing the synthesis, description, and graphic analysis of large contingency tables. The results provide information that is similar in nature to those produced by factor analysis techniques, and they allow one to explore the structure of categorical variables included in the table. No tests of statistical significance are applied to the results and the main goal is to produce a "simplified" representation of the data.

In the present work, MCA was used in two ways: (1) To see whether this method could reliably categorize HCC, DN, and MRN using the individual histological features described above, and how this analysis compared to the overall (routine) histological assessment. MCA produces a graphic representation of the data in the form of a horizontal line, which represents a "malignancy" scale and shows how each nodule is placed in a "malignancy" scale. In theory, malignant nodules are placed at one end of the scale and benign nodules are placed at the opposite end of the scale, with equivocal nodules in between. Each variable has a certain value in an axis, and the « position » in the chart represents the composite point of different planes (features) for a given nodule; (2) To see if this method could rank the individual histological features in order to assess the relative contribution of each individual histological observation in the assignment of a liver cell nodule to one of the three categories (HCC, DN, and MRN), so that the histological features could be incorporated into a classification tool to distinguish HCC from DN from MRN.

RESULTS

Multiple correspondence analysis

An exploratory set of 212 hepatocellular nodules (106 HCC mean size 18.8 mm, SD 13 mm; 74 MRN mean size 10 mm, SD 3.2 mm; 32 DN mean size 12.4 mm, SD 5.5 mm, as per routine histological assessment) were analyzed histologically. Figure 2 shows how MCA redistributes these nodules. The horizontal line represents a "malignancy" scale. In other words, the projection of every dot towards the horizontal line (e.g., three dotted lines in chart) shows how each nodule is placed in a "malignancy" scale. HCC are placed in the left-hand side of the chart, whereas MRN are placed towards the other end. Each variable has a certain value in an axis, and the « position » in the chart represents the resulting point of different planes for a given nodule. Size (Figure 1) does not allow a reliable classification of nodules. In other words, HCC can be of all sizes, and although large nodules are usually HCC, small nodules may also be HCC. Conversely, MRN and DN can be of considerable size (up to 21 and 24 mm, respectively, in our series).

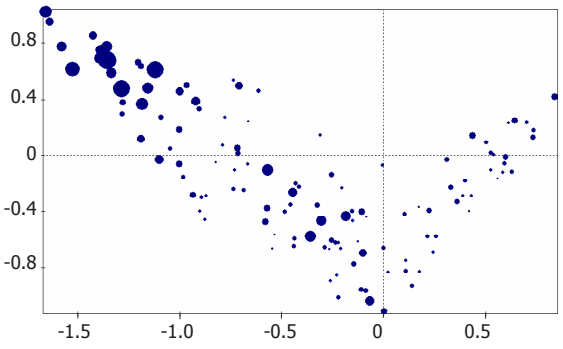

Figure 1 MCA of exploratory set of 212 hepatocellular nodules in cirrhotic livers. The relative lesion size of the hepatocellular nodules is depicted as blue dots. The diameter of the dots varies according to the size of the nodule observed. Size does not seem to allow a classification of nodules, in other words, HCC can be of all sizes, and large nodules are usually HCC. However, small nodules are not necessarily MRN or DN.

Figure 2B shows how the individual variables (e.g., capsular invasion, vascular invasion, etc.) relate to each other, and how they are distributed along the "malignancy scale". As in Figure 2A, the horizontal line represents a "scale of malignancy". The projection of each group of values in the horizontal axis shows that the variables form a continuum, with capsular invasion being the "most" malignant feature, and absence of heterogeneity the "least" malignant feature. Table 2 shows how the groups of values depicted in Figure 2B are distributed in the three types of nodular lesions.

These data were used to create a classification tool for the assessment of these nodular lesions.

Construction of the classification tool

The values shown in Figure 2 and Table 2 can be distributed into six main groups, depending on their proportional representation in the three categories HCC, DN, and MRN, as follows:

Group 1 (capsular invasion, vascular invasion). Features present exclusively in HCC 44 (41.5%) and 27 (25.5%), respectively, by definition.

Group 2 (necrosis present, mitosis present, capillarization = 5, cellular atypia = 3-5, reticulin loss = 4-5, trabecular thickness>4). Features present, in 16-52.8% (mean 36%) of HCC but not present in MRN or DN.

Group 3 (solitary arterioles ⩾1, heterogeneity present, capillarization = 4, reticulin loss = 1-3, trabecular thickness = 4). Features present in 21.7-94.3 (mean = 47%) HCC, 3-72% (mean = 37%) DN and 0-14% (mean = 20%) MRN.

Group 4 (capsular invasion not present, vascular invasion not present, necrosis not present, mitosis not

Table 2 MCA of the values of the histological variables in the three categories (HCC, MRN, and DN) in the exploratory set of 212 hepatocellular nodules in cirrhotic livers

Position	Feature	Grade	HCC number (total 106)	%	DN number (total 32)	%	MRN number (total 74)	%

22	Capsular invasion	Not present	62	58.5	32	100	74	100
23	Mitosis	Not present	56	52.8	32	100	74	100
24	Solitary arterioles	<1	13	12.3	19	59	62	84
25	Capillarization	0–2	4	3.8	23	72	72	97
26	Cellular atypia	0	1	0.9	20	63	58	78
27	Heterogeneity	Not present	6	5.7	9	28	69	93
28	Reticulin loss	0	3	2.8	23	72	72	97

Position = This means the position of each variable in "malignancy scale" as shown in Figure 2, i.e. position number 1 = left side of the chart (higher "degree of malignancy") and position 28 = right side of the chart (lower degree of malignancy).

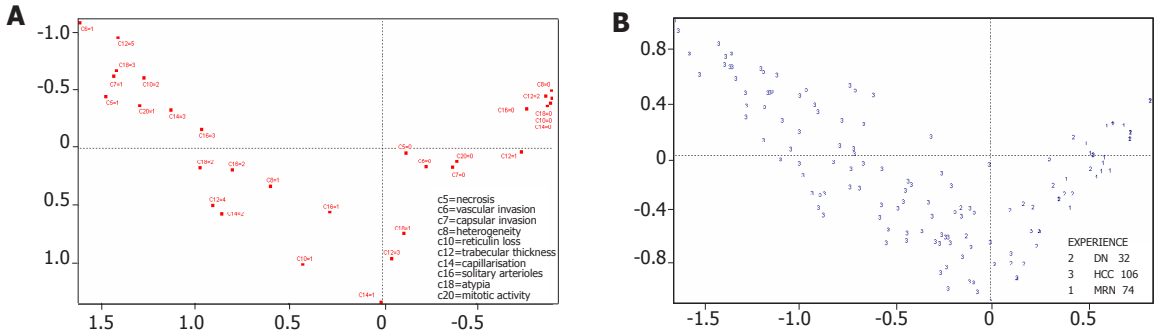

Figure 2 **A**: MCA of exploratory set of 212 hepatocellular nodules in cirrhotic livers; **B**: Distribution of histological variables in the exploratory set of 212 hepatocellular nodules. This chart shows how MCA redistributes the different types of nodules (i.e. HCC, DN, and MRN as assigned by routine histological evaluation), taking into consideration all variables of the scoring system except size. Each variable has a certain value in an axis, and the « position » in the chart represents the resulting point of different planes for a given nodule. Please note that the total number of « nodules » shown does not equal 212 because there is a certain degree of overlapping among observations and there is a lack of resolution in the chart.

present). Features present in 100% MRN and DN, and in 53-84% (mean 67%) of HCC.

Group 5 (capillarization = 3, cellular atypia = 1-2). Features present in 25-38% (mean = 31%) DN, 17.9-34.9% (mean = 26%) HCC and 3-22% (mean = 12%) MRN.

Group 6 (solitary arterioles<1, heterogeneity not present, capillarization = 0-2, reticulin loss = 0, trabecular thickness<4). Features present in 78-97% (mean = 91%) MRN, 59-72% (mean = 63%) DN and 0.9-41.5 (mean = 11%) HCC.

These six groups can be organized into a three column table as shown in Table 3. This table constitutes the classification tool.

The histological features of a given nodule are assessed individually and then allocated to the classification tool.

Table 3 Classification tool for hepatocellular lesions in cirrhotic liver. Assess each individual histological feature (as per Table 1) and go to Table 4a

3a HCC *vs* DN/MRN

Column 1	Column 2
HCC	DN or MRN
	Vascular invasion not present
	Capsular invasion not present
Necrosis present	Necrosis not present
Mitosis present	Mitosis not present
Capillarization score 4 or 5	Capillarization Score 0, 1, 2 or 3
Cellular atypia score 3, 4, or 5	Cellular atypia score 0, 1, or 2
Reticulin loss score 1, 2, 3, 4, or 5	Reticulin loss score 0
Trabecular thickness>3	Trabecular thickness<4
Solitary arterioles ⩾1	Solitary arterioles<1
Heterogeneity present	Heterogeneity absent

If the given lesion is not HCC according to this table, Table 3b provides guidance regarding the assignment of DN *vs* MRN.

3b DN *vs* MRN. The nodule is DN, if the number of features in the "DN, column 3" is higher than the number of the features in the "MRN, column 4" and vice versa. In case of an even balance, the nodule is regarded as DN

Column 3	Column 4

Trabecular thickness >3	Trabecular thickness <4
Solitary arterioles ⩾1	Solitary arterioles <1
Heterogeneity present	Heterogeneity absent
Necrosis present	
Mitosis present	

HCC, hepatocellular carcinoma; DN, dysplastic nodule; MRN, macroregenerative nodule.

Validation of the classification tool

This classification tool, when tested prospectively on the separate set of liver cell nodules described above gave the following results: out of 47 nodules, 39 (83%) were classified in the same way as the routine histological assessment. All 13 MRN and all 9 DN, as defined by routine histological assessment were considered as such by the classification tool. Of the 25 HCC, as defined by routine histological assessment, 8 were considered as DN by the classification tool (Table 4).

Table 4 Performance of the classification tool on a second validation set of liver cell nodules in cirrhotic livers

			Histological assessment using the classification tool

Routine Histologica Diagnosis	HCC 25	17	8	0	25
	lDN 9	0	9	0	9
	MRN 13	0	0	13	13
	Total	17	17	13	*Total*

DISCUSSION

Despite the consensus document published by the International Working Party[3], the terminology used in the literature is still confusing, particularly due to the use of different classifications and different histological criteria by different centers[6]. In fact, the bulk of the relevant literature offers few clues about which precise observations allocated any particular lesion (however, named) into the given categorical assignment. In this work, we have investigated how those individual histological features considered in the literature will be helpful in the histological assessment of small hepatocellular

nodular lesions in cirrhosis that can be used to create a classification tool for the evaluation of these nodules. Application of the classification tool documents systematically the individual histological features that contribute to the categorical assignment of MRN, DN, and HCC.

MCA is a descriptive technique, which identifies the best factor representing a set of data. In the present analysis, the horizontal factor, which could be called "malignancy" is the most important one in representing the dataset. The nodular lesions of the present study can be imagined as a "cluster" of dots in space, and the distance between two points depends on the plane (axis of assessment, or histological features) used to look at them. For example, if the horizontal axis is used to look at two lesions, and the projections of these lesions are close together on that axis, these lesions may be considered to be at a similar degree of malignancy. The same lesions on another plane may be very far apart from each other.

MCA distributes the 212 lesions assessed by the components of the histological assessment placing HCC at the left and MRN at the right of the "malignancy" scale, and DN in the middle, although some "misclassifications" are present, with overlap between different categories (Figure 2A), i.e. between HCC and DN and DN and MRN. This is not unexpected, as this analysis represents the nodular lesions as a continuum in a "malignancy" scale. Moreover (Figure 2A), one could also imagine different degrees of malignancy within the HCC subgroup.

When tested on a second set of nodules, the classification tool classified the large majority of all nodules (83%) in the same way as the routine histological assessment. No discrepancies were noted for DN and MRN between the routine diagnosis and the assignment by the classification tool. Eight of twenty-five HCC (32% of HCC, 17% of all nodules, as defined by routine histological assessment) were assigned to the DN category by the classification tool, which is not surprising given the well-recognized difficulties in separating these two categories[3]. The reason for this discrepancy is obscure, and underlines the need for correlation with other modalities of investigation, such as molecular data and clinical follow-up, which may be informative to validate the histological criteria[3] (and this will be the subject of further work). Overall, the classification tool seems to correspond reasonably well to the routine histological assessment.

The classification tool has several advantages. Firstly, the idea of including all important histological features in the evaluation, systematically ensures that the final assignment does not rest on a single feature subjectively or selected group of features, but on the balance of all components. This classification tool is based on a systematic collection of histological data and can be integrated in a database. Once all the fields required for the completion of the classification tool have been entered, a computer can easily run the classification tool and return the result. As more data become available[18], and as additional informative histological features of HCC (such as stromal invasion) are characterized[16,19,20], the accumulated information can be used to improve and refine the classification tool.

In conclusion, we have designed a classification tool for the histological assessment of HCC and its putative precursor nodular lesions in cirrhotic liver. The classification tool is based on a systematic and balanced assessment of 10 histological features.

Abstract

AIM: To investigate the precise role of membrane type 1-matrix metalloproteinase (MT1-MMP) in hepatocellular carcinoma (HCC) metastasis.

METHODS: Human HCC cells Hep3B with overexpression of MT1-MMP were established by stable transfection, and compared with control cells carrying the empty vector. Cells were examined *in vivo* for their differences in the metastatic ability of athymic nude mice, and analyzed *in vitro* for their differences in invasion ability by invasion chamber coated with Matrigel, adhesion towards collagen I and migration through culture chamber. Cell proliferation and apoptosis in adherent and suspension status were evaluated by MTT and flow cytometry analysis.

RESULTS: We found that overexpression of MT1-MMP could increase intrahepatic metastasis in nude mice with orthotopic implantation of HCC cells (incidence of 100% [MT1-MMP transfectants] *vs* 40% [vector control transfectants], $P<0.05$). MT1-MMP could also enhance cell invasion through Matrigel (107.7 *vs* 39.3 cells/field, $P<0.001$), adhesion towards matrix (0.30 *vs* 0.12 absorbance unit at 540 nm, $P<0.001$), cell migration (89.3 *vs* 39.0 cells/field, $P<0.001$), and cell proliferation (24.3 *vs* 40.5 h/doubling, $P<0.001$). We also observed that MT1-MMP supported cell survival (71.4% *vs* 23.9%, $P<0.001$) with reduced apoptosis (43.7% *vs* 51.0%, $P<0.05$) in an attachment-free environment.

CONCLUSION: MT1-MMP overexpression could enhance metastasis. In addition to its active role in matrix degradation during tumor invasion, MT1-MMP enhances tumor cell survival upon challenge of detachment, which is important during metastasis when cells enter the circulation.

INTRODUCTION

Membrane type 1-matrix metalloproteinase (MT1-MMP or MMP14) is the well-characterized transmembrane MMP. It triggers the activation cascade of other pro-MMPs via the activation of pro-MMP2[1] and pro-MMP13[2] resulting in the cleavage of a complex array of extracellular matrix proteins. MT1-MMP itself also aids in maintaining the homeostasis of extracellular matrix by regulating the turnover of types I-III collagens, fibronectin, vitronectin, laminin, fibrin, and proteoglycan[3,4] for tissue remodeling and development. MT1-MMP knock-out mice show inadequate collagen turnover resulting in dwarfism, osteopenia, arthritis, connective tissue abnormalities, and early postnatal death[5]. In addition, MT1-MMP deficiency causes impaired endochondral ossification and angiogenesis[6].

MT1-MMP is involved in the progression of different malignancies[7], and localizes in invadopodia of invading tumor cells tethering extracellular matrix breakdown at invasive front[8,9]. Numerous studies support its role in cancer dissemination by demonstrating that MT1-MMP alters cell behaviors through proteolysis[10-13]. All these point out that MT1-MMP is a versatile enzyme that contributes to invasion and metastasis through numerous mechanisms[14].

Our recent study has revealed upregulation of MT1-MMP specifically in hepatocellular carcinoma (HCC) tissues with venous invasion ($P<0.001$)[15]. HCC is a hypervascular tumor, in which venous invasion is common and an important risk factor for tumor metastasis. Earlier studies of MT1-MMP focused on its increased expression in invasive HCC[16-20], association with extracellular matrix remodeling[21], poor prognosis[19], and induction of its expression by HBV X protein[22]. In this study, we demonstrated a novel role of MT1-MMP in metastasis, where cell survival in an attachment-deprived condition was maintained with reduced apoptosis. The current data indicate that MT1-MMP plays an important role in supporting cell survival when cells enter the circulation during metastasis, in addition to its prominent role in matrix degradation during tumor invasion.

MATERIALS AND METHODS

Construction of plasmid

Full-length human MT1-MMP cDNA was PCR-amplified

using the first-stranded cDNA reverse-transcribed from total RNA of normal liver according to the published sequence (GenBank accession number NM 004995) using specific primers (forward primer: 5'-GAGAT ATCAT GTCTC CCGCC CCAAG A-3'; reverse primer: 5'-CCTCT AGACA CCTGC TGCCA CTG-3') under the conditions: at 94 ℃ for 10 min; at 94 ℃ for 1 min, at 60 ℃ for 1 min, at 68 ℃ for 1 min for 30 cycles by Platinum® *Taq* DNA polymerase high fidelity (Invitrogen, Carlsbad, CA, USA). Expression construct was made by cloning the PCR product into a mammalian expression vector, pcDNA3.0 (Invitrogen).

Cell culture and transfections

Human HCC cell line Hep3B purchased from the American Type Culture Collection (ATCC, Rockville, MD, USA) was cultured in DMEM supplemented with 100 mL/L fetal bovine serum (FBS), 2 mmol/L L-glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin. Constructs were transfected using the LipofectAMINE reagent (Invitrogen) according to the protocol suggested by the manufacturer. Stable transfectants were selected in DMEM complete medium with 400 μg/mL Geneticin (USB, Cleveland, OH, USA) for 3 wk. Hep3B cells stably transfected with empty pcDNA3.0 vector were used as control for all the experiments, in comparison with the MT1-MMP transfectants. Expression levels of MT1-MMP in transfectants were compared by semi-quantitative RT-PCR and Western blotting.

Intrahepatic tumor model

Male BALB/c *nu/nu* (nude) mice were obtained from the Charles River Laboratories (Wilmington, MA, USA) and the study protocol was approved by the Committee on the Use of Live Animals in Teaching and Research of the University of Hong Kong. Hepatic tumor was generated by slow intrahepatic injection of 2×10^6 cells into the left liver lobe of a 7-wk-old mouse during laparotomy. Ten mice were injected for each transfectant and were killed 60 d after the operation. After macroscopic examination and measurement, livers, hearts, spleens, lungs, kidneys, and pancreas were harvested. Intrahepatic metastasis was defined macroscopically as nodules that were clearly distinguishable from primary tumors by naked eyes or microscopically as clusters of tumor cells with α-fetoprotein (AFP) expression confirmed by immunohistochemistry and hematoxylin and eosin staining on paralleled sections.

MT1-MMP RNA expression quantitation

MT1-MMP RNA expression level was assessed by semi-quantitative RT-PCR using MT1-MMP specific primers (forward primer as described above; reverse primer: 5'-AATGC TCGAG CCCCA GGGCA-3') and control 18S rRNA (forward primer: 5'-CTCTT AGCTG AGTGT CCCGC-3' and reverse primer: 5'-CTGAT CGTCT TCGAA CCTCC-3'). PCR for MT1-MMP and 18S rRNA was first performed for 20-32 and 10-32 cycles, respectively. The PCR product was electrophoresed in agarose gel and the intensity was quantified by densitometric scanning using a gel-imaging system and UVP GelWorks ID Intermediate version 3.01 (Ultra Violet Products Ltd, Cambridge, UK). The number of cycles at linear increase of PCR product was chosen for comparison. The relative MT1-MMP RNA level was determined as the MT1-MMP intensity normalized by the 18S rRNA intensity of respective samples.

Immunohistochemistry

For immunohistochemical staining, AFP polyclonal antibody (DAKO, Carpinteria, CA, USA) and Ki67 mAb (BD PharMingen, San Diego, CA, USA) were used at 1:3 000 and 1:100, respectively. Paraffin-embedded tissues were cut into 4-μm-thick sections, dewaxed, rehydrated in graded ethanol and antigen retrieved by boiling for 10 min in a citrate buffer, pH 6.0. Endogenous peroxidase activity was quenched by DAKO peroxidase block, followed by 30-min incubation with primary antibody. After being washed with PBS, localization of protein was detected using the DAKO Envision™+System. The tissue sections were counterstained with hematoxylin.

Protein extraction and Western blotting

Total protein was extracted with urea buffer (9 mol/L urea, 50 mmol/L Tris-Cl, pH 7.5) in the presence of Complete™ protease inhibitor cocktail (Roche, Mannheim, Germany). Twenty micrograms of total protein was analyzed with 2 μg/mL MT1-MMP polyclonal antibody (AGI, Sunnyvale, CA, USA).

Immunoreactive bands were visualized with the Enhanced Chemiluminescence Western Blotting Detection Kit (Amersham Biosciences, Buckinghamshire, UK). β-actin antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA) served as loading control. The reactive bands in the exposed films were quantified by densitometric scanning as described above. The relative amount of MT1-MMP level for the active form (62 ku) and the total MT1-MMP (summation of pro-form, 64 ku; active form, 62 ku; and cleaved forms, 20-43 ku) were calculated, respectively, after normalization by the actin reactive band.

Cell proliferation

Three thousand cells per well were seeded at the start of the experiment. Cell proliferation was assessed using conversion of 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT, Sigma-Aldrich, St. Louis, MO, USA) to formazan product at 24-h intervals. Briefly, 0.5 mg/mL MTT was added to the well for 4 h and terminated by adding 100 μL of 0.1 mol/L HCl/isopropanol. Absorbance was measured at 540 nm. Cell proliferation was also assessed by counting the total cell number. Briefly, 30 000 cells/well were seeded at the start of the experiment. The cells were trypsinized and counted at 24-h intervals for 5 d by the trypan blue exclusion method. The doubling time of the cells was assessed at the linear phase of the growth curve.

In vitro invasion assay

Fifty thousand cells were seeded in 500 μL DMEM in the upper compartment of the BD BioCoat™ Matrigel™ Invasion Chamber (Becton Dickinson, Bedford, MA, USA). The lower compartment was filled with 500 μL of DMEM/10% FBS. After 24 h, cells on the undersurface of the filters were fixed, stained with hematoxylin and eosin, and counted under a microscope at a magnification of ×200

for 10 random fields.

Cell attachment assay

Fifty thousand cells were seeded in 100 μL DMEM/10% FBS in collagen I-coated plates for 1 h. After extensive washes, adherent cells were fixed and stained with crystal violet in 10% ethanol. Following washing with PBS, the incorporated dye was extracted with a 1:1 mixture of 100 mmol/L sodium phosphate, pH 4.5 and 50% ethanol. Absorbance was read at 540 nm.

Cell migration assay

Fifty thousand cells were re-suspended in 0.5 mL DMEM and loaded into cell culture insert. The lower chamber was filled with 0.5 mL DMEM/10% FBS. After 24 h, cells at the membrane's undersurface were fixed, stained, and counted at a magnification of ×200 for four microscopic fields.

Anoikis assay

Three million cells were held in suspension in poly-HEMA (Sigma-Aldrich)-coated petri dishes. At indicated time points, the cells were collected, centrifuged, and washed once in PBS. Cell clumps were dispersed by a 5-min treatment of 500 μL 0.5 mmol/L EDTA, followed by an addition of 9.5 mL DMEM/10% FBS. Then, 100 μL cells was seeded and the ability to convert MTT to formazan product was examined as described above for 3 h. The percentage of absorbance value divided by the absorbance value at 0 h after background correction was presented. Cells at indicated time points were also stained with propidium iodide for 15 min followed by an analysis using the flow cytometer (Becton Dickinson).

Statistical analysis

Each data point represented results from at least three independent experiments performed in duplicate and was presented as mean±SD. Comparison between groups was made with the Student's *t*-test and considered statistically significant if the *P* value was less than 0.05. Statistical analysis was carried out using the statistical software (SPSS version 9.0 for Windows; SPSS, Chicago, IL, USA).

RESULTS

Establishment of stable MT1-MMP overexpression transfectant

To examine the biological function of MT1-MMP, we first established a stable Hep3B transfectant that overexpressed MT1-MMP. Semi-quantitative RT-PCR (Figure 1A) confirmed that the MT1-MMP RNA transcript level in overexpressing transfectants increased by 2.9-fold compared to vector control transfectants, whereas the Western blot analysis (Figure 1B) showed that in MT1-MMP transfectants there was an 1.5-fold increase of active MT1-MMP and 2.0-fold increase of total reactive forms of MT1-MMP protein compared to the vector control. The higher levels of the 43 and 20 ku MT1-MMP, which are cleavage products generated by active MMP2, indirectly evidenced the increased active MMP2 generated by MT1-MMP in overexpression transfectants compared to the vector control[23,24].

MT1-MMP increased metastasis and tumorigenicity

The stable transfectants were inoculated into the left liver lobe of the athymic nude mice to study the effect on metastasis (Figure 2). The intrahepatic tumors grew within the liver and the tumor nodules were physically close to each other. Physical separation of tumor and non-tumor liver tissues by detailed dissection for weight and volume measurement became infeasible, because this would ruin the subsequent histological analysis for tumor margin assessment of these nodules. Hence, the size was presented as the greatest dimension measured reflecting the weight and volume of the tumor mass. In 60 d, MT1-MMP overexpression resulted in a higher incidence of xenograft formation and a larger primary tumor (incidence of 80% and size of 2.0±1.3 cm), as compared to the control group (incidence of 50% and size of 0.8±0.5 cm; Table 1), supporting its role in enhancing tumorigenicity and

Table 1 Summary of *in vivo* tumorigenicity assay

	Primary tumor		Metastasis
	Incidence	Size (cm)	tumor
MT1-MMP	8/10	2.0±1.3	8/8
Vector control	5/10	0.8±0.5	2/5

MT1-MMP overexpression resulted in significantly larger primary tumor and frequent metastasis.

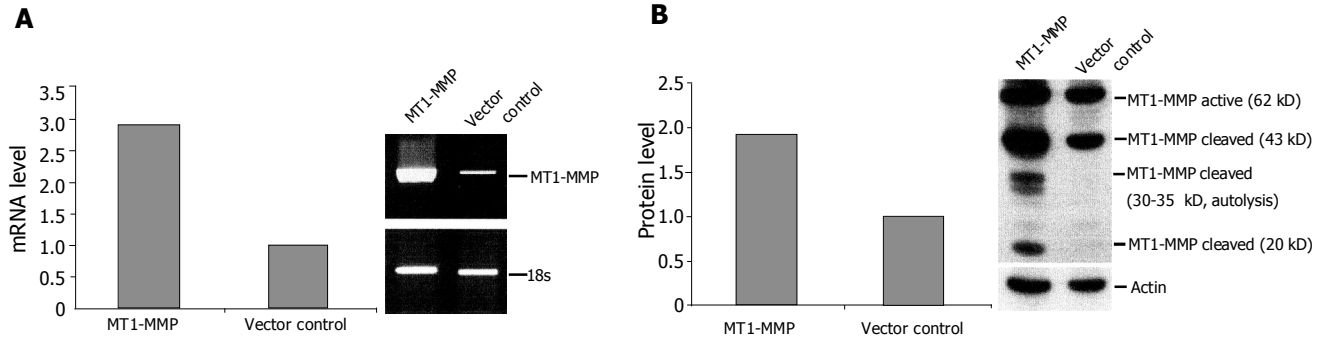

Figure 1 Establishment of stable MT1-MMP transfectants. **A**: RNA transcript levels were compared in linear phases by semi-quantitative RT-PCR after normalization with 18S level; **B**: protein expression levels were compared by Western blotting analysis after normalization with actin level.

growth. The possibility of tumor implantation into the portal vein during the experiment was excluded, because portal vein injection resulted in multiple liver tumors (data not shown).

In the non-injection liver lobes, a higher incidence of variably sized tumor nodules was found in the MT1-MMP transfected group (Figure 2). Microscopic metastasis was further confirmed by AFP staining, as Hep3B cells expressed AFP but not the normal mouse hepatocytes. The microscopic metastases were counted by the presence of clusters of AFP-positive cells, as the clinical significance of single solitary AFP-positive tumor cells was unknown. In general, more intrahepatic metastases were found in the MT1-MMP transfected group than in the vector control group (100% and 40%, respectively; Table 1). No AFP-producing cell was found in kidneys, lungs, spleens, hearts, and pancreas.

MT1-MMP enhanced tumor dissemination and growth

Enhanced metastasis *in vivo* further prompted us to look

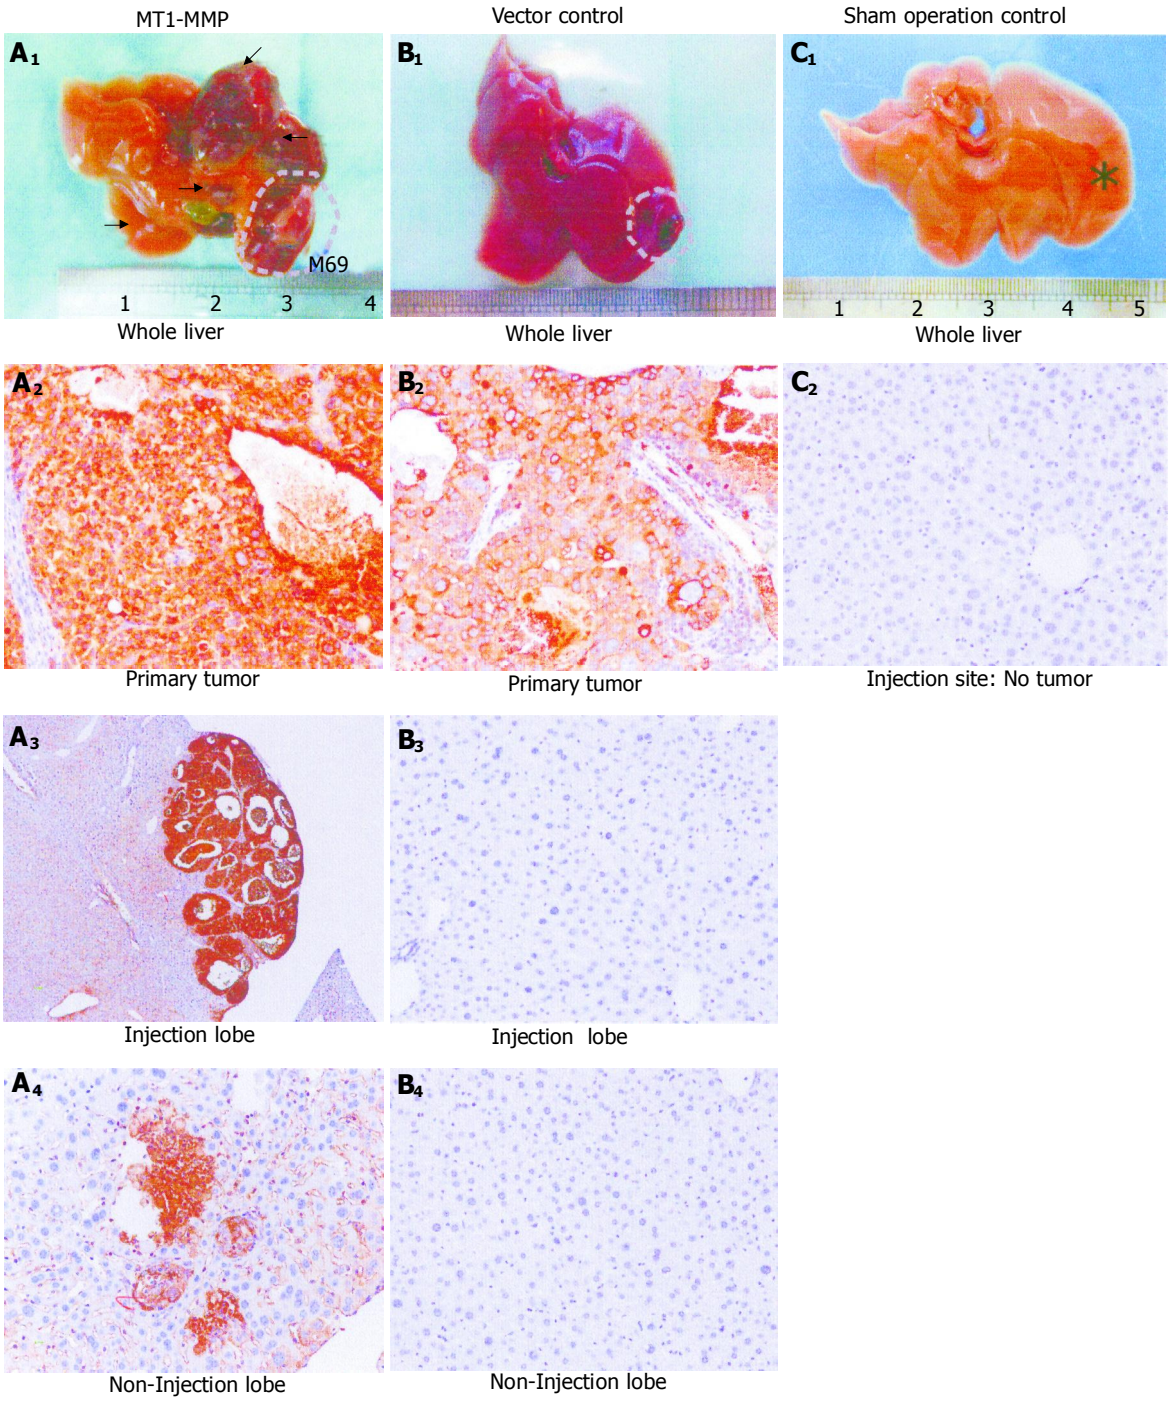

Figure 2 Tumorigenicity and metastasis *in vivo* enhanced by MT1-MMP. A_{1-4}: Large primary tumor nodule with prominent metastases produced by MT1-MMP overexpression; B_{1-4}: Small primary tumor nodule and rare metastasis produced by vector control transfectants; C_{1-2}: Tumor-free control liver injected with saline. Primary tumors, metastases, and injection site were indicated by dotted lines, arrows, and an asterisk, respectively. Sections from all tissues collected were then subjected to AFP staining.

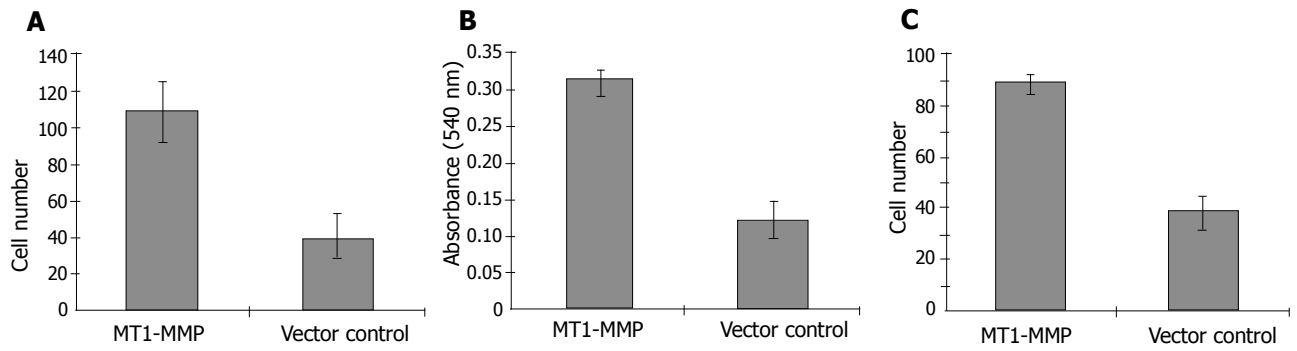

Figure 3 Cell invasion, adhesion efficiency, and cell motility *in vitro* enhanced by MT1-MMP. **A**: Cell invasive ability in standard Boyden chamber; **B**: Adhesion efficiency on collagen I; **C**: Directional migration ability by cell motility assay.

into the sequential steps of metastasis by *in vitro* assays. In a standard Boyden chamber assay, MT1-MMP transfectants significantly increased the number of cells that invaded through Matrigel-coated filters by 174.0% (107.7±15.5 and 39.3±12.1 cells/field, respectively; $P<0.001$; Figure 3A). Furthermore, 150% more MT1-MMP transfectants adhered onto collagen I compared to the control within a fixed time (0.3±0.02 and 0.12±0.03 absorbance unit at 540 nm, respectively; $P<0.001$; Figure 3B). When the transfectants were plated into plain transwells without a Matrigel layer, increased MT1-MMP enhanced cell migration by 129.0% (89.3±6.7 and 39.0±2.3 cells/field, respectively; $P<0.001$; Figure 3C). Collectively, increased MT1-MMP facilitated cells in suspension to arrest onto collagen I (cell attachment to matrix during metastasis at the secondary site), enhanced their directional cell motility and thereby promoted invasion through matrix. This was particularly important during extravasation.

Increase in tumor size *in vivo* led us to examine the cell proliferation rate. Intense Ki67 staining was observed in MT1-MMP xenografts (Figure 4A) indicating MT1-MMP enhanced growth *in vivo*. Cell proliferation of transfectants in culture was monitored by the assessment of mitochondrial activity in MTT assay (Figure 4B) and counting the total cell number (Figure 4C) at 24-h intervals over 5 d, and both assay methods demonstrated that MT1-MMP promoted cell proliferation *in vitro*. The doubling time of MT1-MMP overexpressing transfectants and control transfectants was 24.3 and 40.5 h, respectively. Taken together, MT1-MMP increased cell proliferation *in vivo* and *in vitro*.

MT1-MMP reduced anoikis

Adherent cells undergo apoptosis shortly after loss of cell-substratum adhesion, a phenomenon known as

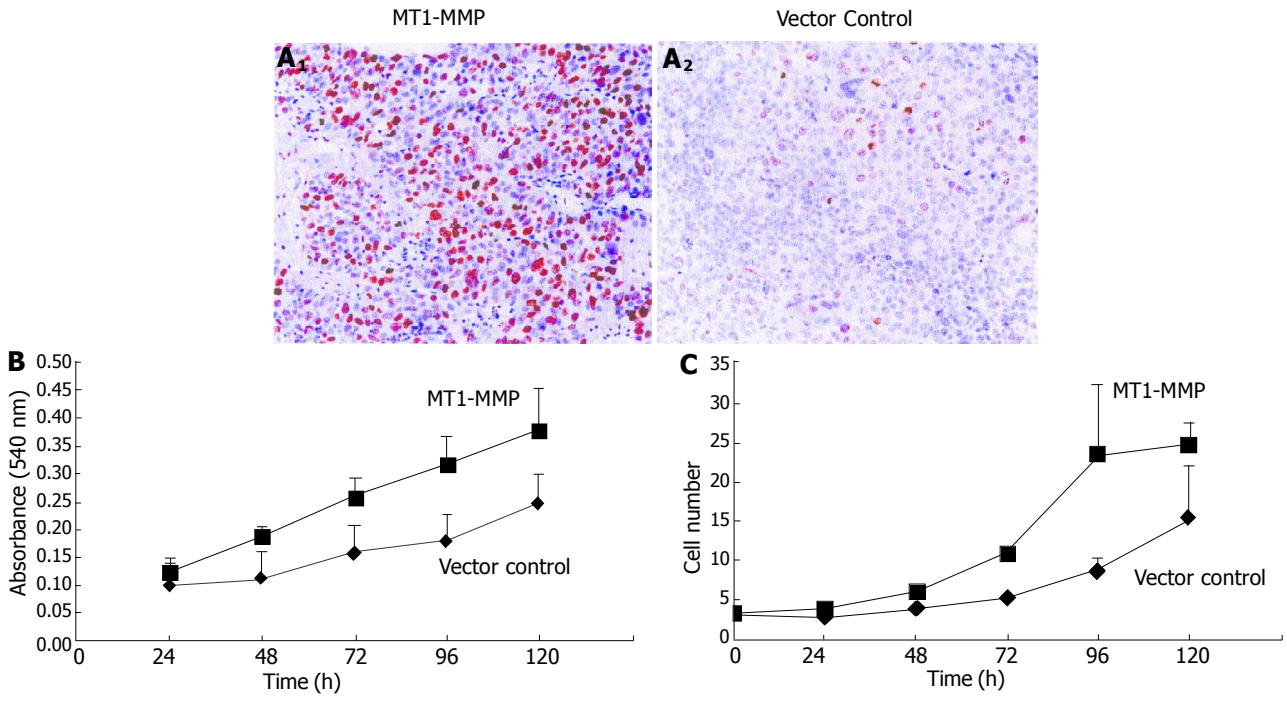

Figure 4 Cell proliferation *in vivo* and *in vitro* enhanced by MT1-MMP. A_{1-2}: Primary tumors in athymic nude mice examined by Ki67 staining; **B**: Cells examined by MTT assay; **C**: Cell number counted at regular time intervals.

"anoikis". Cell viability under attachment-deprived conditions is critical after the cells enter the circulation during the process of metastasis. To examine the cell viability under attachment-deprived conditions, the transfectants were prepared as single cell suspension, challenged by anoikis by plating out in attachment-deprived dishes and examined by MTT assay (Figure 5). As reflected by the conversion of MTT to its substrate, MT1-MMP transfectants maintained a higher metabolism than the vector control during the 24 h detachment. By 24 h in an attachment-free environment, MT1-MMP transfectants maintained 71.4% metabolic activity, whereas the metabolic activity of control transfectants declined to only 23.9%.

To evaluate if the MT1-MMP level plays a role in anoikis, the two transfectants at 0 and 24 h after detachment were subjected to propidium iodide staining and then analyzed by the flow cytometer. Difference in detachment-induced death was observed between the MT1-MMP and vector control transfectants at 24 h (43.7±2.0% *vs* 51.0±4.1%, respectively; $P<0.05$). In summary, MT1-MMP enhanced cell survival with reduced apoptosis upon detachment challenge.

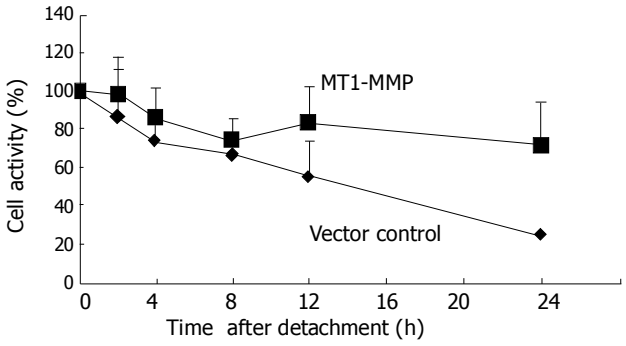

Figure 5 MT1-MMP delayed anoikis. The cell metabolic activity of two transfectants after detachment was compared.

DISCUSSION

MT1-MMP is crucial in HCC progression[15,17,20-22]. Here, we have demonstrated that MT1-MMP protected tumor cells from anoikis, in addition to its classical roles in tumor invasion to pave way for tumor cells to migrate in circulation for distal metastasis after crossing the extracellular matrix and basement membrane. Such a finding is important because even when large number of tumor cells enter the circulation successfully, only a small percentage of tumor cells can actually metastasize due to "metastastic inefficiency"[25-28], the failure to establish metastasis. Only if tumor cells have sustained survival in circulation, the attachment-deprived environment, there would be successful metastasis. Thus, the protection from anoikis contributed by MT1-MMP in the first 24 h upon detachment is of paramount importance during HCC invasion and metastasis.

Increased intrahepatic metastasis by MT1-MMP was observed in the spontaneous metastasis assay performed *in vivo*. *In vitro,* MT1-MMP was also shown to enhance invasion through matrix, adhesion to collagen I and in directional cell migration. Collagen I is the most abundant extracellular matrix component in liver, especially in cirrhotic liver. Enhanced cell attachment to collagen I was observed in the MT1-MMP transfectants in suspension status. Thus, MT1-MMP could also facilitate cell attachment at a new site for metastasis, aside from its leading role in matrix degradation and enhanced cell migration ability for cell invasion to take place to leave the primary site.

Apoptosis is the "rate-determining" step subsequent to the cells entering the circulation. Others have reported that inhibition of apoptosis in the first 24 h could already enhance lung metastasis[25,29,30]. In the current study, MT1-MMP expression conferred a survival advantage in the attachment-deprived environment. Notably, MT1-MMP expression also contributed to evasion of apoptosis in suspension status, although the percentage difference was not enormous but statistically significant. The significant gain in survival advantage but marginal improvement in evasion of apoptosis by MT1-MMP overexpression during suspension status could be due to a number of reasons. The remaining viable control cells became dormant (or less active in converting MTT to a formazan product) in adverse conditions, whereas the viable MT1-MMP transfectant was able to withstand the stress and maintained the cell metabolism. Therefore, even when a similar proportion of cells died, a considerable difference in cell metabolism between two transfectants was observed. The higher cell metabolism of MT1-MMP transfectants in suspension culture also suggests that MT1-MMP may still underpin proliferation and, therefore, promotes the selection for a population of cells that are more tumorigenic and resistant to anoikis. Although other factors like immune attack and mechanical shear force from circulation were not taken into account in our experimental settings, cell survival upon detachment could definitely enhance metastatic potential. Further, experiments on proliferation and apoptosis are needed to confirm if proliferation occurs during suspension.

Potential mechanisms exist for the contribution of MT1-MMP to survival advantage during cell suspension status. Indirect links might be mediated through its enzymatic activity. MT1-MMP may alter processing of proteins and thus overrides the apoptotic stimuli during the challenge of detachment. For instance, MT1-MMP modulation of integrin processing and downstream regulation of FAK signaling pathways[31] are related to apoptotic pathways. During osteoblast transdifferentiation, MT1-MMP activates latent transforming growth factor-β and maintains osteoblast survival[32,33]. In support of this view, MMP1 degradation of type I collagen has been shown to expose new cryptic domains that bind to the αvβ3 integrin and trigger survival signals in melanoma cells[34]. On the other hand, MT1-MMP might directly link to various pathways[12,31,35,36] leading to distinct biological outcome in a number of recent studies[36-38]. The localization of MT1-MMP in clathrin-coated pits[39,40] and caveolae[41-44], which are rich in signaling molecules[45], also raises the possibility of direct activation of signal transduction pathways by MT1-MMP. Therefore, it is conceivable that MT1-MMP can contribute to the activation

of intracellular pathways.

From therapeutic perspectives, total elimination of MMP protease function by inhibitors is impossible and would cause a number of side effects. Nevertheless, the MMP-related subject is promising in the field of tumor detection, prognosis, prevention, and therapeutic purposes in defined situations[46,47]. Our findings have a direct impact on cancer therapy because molecular understanding of the biological activities mediated by proteases provides exciting opportunities for specific interventions in pathways critical for tumor progression.

In conclusion, MT1-MMP promotes HCC tumorigenicity and intrahepatic metastasis with increased tumor growth and invasion ability. More importantly, increased MT1-MMP expression reveals survival advantage and protects HCC cells from apoptosis in the first 24 h in the attachment-free condition. These results strengthen the emerging opinion that the role of MT1-MMP does not only confine to matrix degradation, but also extends to alteration of cell behaviors including survival advantage in the attachment-deprived environment.

Abstract

AIM: To evaluate the therapeutic effect and the indication of percutaneous ethanol injection (PEI), radiofrequency ablation (RFA) and their combination in treatment of hepatocellular carcinoma (HCC).

METHODS: Two hundred and fifty-five patients with HCC received treatment of PEI, RFA or their combination. Group1 (< 3 cm in diameter, *n*=85) was treated with PEI, group2 (< 3 cm in diameter, *n*=153) with RFA. Group3 (>3 cm in diameter, *n*=86) was divided into two groups. Group 3a (*n*=34) was treated with RFA, while group 3b (*n*=52) was treated with RFA for 2 wk after transcatheter arterial chemoembolization or PEI. Contrast-enhanced sonography was performed for 61 patients before and after RFA. Liver function and serum alpha-fetoprotein (AFP) were measured for all patients. Changes of the lesions on ultrasound and contrast-enhanced CT/MRI were evaluated for assessing the therapeutic responses. The 1-, 2-, 3- and 5-year survival rates were recorded after treatment.

RESULTS: In group 1, the complete necrosis rate of lesions after 1 mo was 77.6% (66/85). The level of AFP declined conspicuously after 1 mo. The 1-, 2-, 3- and 5-year survival rate after treatment was 80.0% (52/65), 60.4% (32/53), 52.5% (21/40) and 33.3% (7/21), respectively. In group 2, the complete necrosis rate of lesions after 1 moh was 92.2% (141/153). The level of AFP decreased conspicuously after 1 mo. The 1-, 2-, 3- and 5-year survival rate after treatment was 94.6% (88/93), 73.2% (52/71), 63.5% (33/52) and 46.4% (13/28), respectively. In group 3a, the complete necrosis rate of lesions after 1 mo was 23.5% (8/34). AFP dropped down to the normal level in only one patient after 1 mo. The 1-, 2- and 3-year survival rate after treatment was 47.6% (10/21), 42.9% (6/14) and 27.3% (3/11), respectively. Only one patient was still alive after 5 years. In group 3b, the complete necrosis rate of lesions after 1 mo was 57.7% (30/52). The level of AFP decreased after 1 mo. The 1-, 2-, 3- and 5-year survival rate after treatment was 68.6% (24/35), 46.2% (12/26), 36.8% (7/19) and 27.3% (3/11), respectively.

CONCLUSION: The therapeutic effect of RFA on small HCC is better than that of PEI. Small HCC is the optimal indication of RFA. For recurrent HCC (diameter>3 cm), the combined treatment of RFA and PEI/ACE should be used.

INTRODUCTION

With the advance in surgical techniques, surgical resection in combination with intervention therapy for hepatocellular carcinoma (HCC) has been developed. This combined treatment has improved the survival rate of HCC patients. However, most HCC patients lose the chance of resection because they are in advanced stage of the disease when they see a doctor. Furthermore, some HCCs are multicenter in origin. All these factors lead to a high recurrence after resection[1-4]. Though patients with recurrent tumor can undergo re-resection, most of them do not endure it because of poor liver function[5] or poor quality of life after surgery. Therefore, non-surgical partial ablative treatments, such as transcatheter arterial chemoembolization (TACE), PEI, RFA and microwave ablation, are commonly used for HCC. These methods have their own advantages and limitations. It is worth discussing how to choose a suitable method according to the different situation of patients to achieve the best therapeutic effect. This study aimed to compare the therapeutic effects of different treatments.

MATERIALS AND METHODS

Materials

From August 1999 to May 2005, 255 patients with HCC received the treatment of PEI, RFA or their combination. There were 187 men and 68 women. Their age ranged from 31 to 72 years, Two hundred and eleven of the 255 patients had liver cirrhosis due to hepatitis B (n=206) or alcoholic hepatitis (n=5). Their liver function was Child A in 36, Child B in 208 and Child C in 11.

In group 1, 71 patients were treated with PEI. The diameter of the lesions ranged 1.32~2.91 cm (2.21±1.48 cm). In group 2, 118 patients were treated with RFA. The diameter of the lesions ranged 1.07~2.96 cm (2.39±1.57 cm). In group 3, 24 patients were treated with RFA (group 3a). The diameter of the lesions ranged 3.09~6.18 cm (4.86±2.24 cm). The remaining 42 patients underwent RFA after TACE or PEI. The diameter of the lesions ranged 3.56~7.21 cm (5.44±2.87 cm). The level of alanine aminotransferase in each patient before and two weeks after treatment was measured. AFP level and imaging changes on B-mode sonography, color Doppler flow imaging (CDFI) and contrast-enhanced CT/MR were also evaluated. Contrast-enhanced ultrasound (CEUS) was performed in 61 patients before and after RFA. The 1-, 2-, 3- and 5-year survival rates were recorded. If hypervascularity was observed in the lesions by imaging techniques, TACE or PEI was given followed by FRA within one week. On the contrary, if the lesions were hypovascular, RFA was performed. In the patients with partial necrosis of the lesions, RFA or PEI was done again in the remaining part.

Criteria

The criteria for the therapeutic effect were based on the imagings. Complete necrosis: no enhancement of the lesion on contrast-enhanced CT/MR 1 mo after treatment and no blood flow on CDFI or CEUS with enhanced echo of the whole lesions; partial necrosis: partial enhancement of the lesion on contrast-enhanced CT/MR 1 month after treatment and blood flow signals of the lesion on CDFI or CEUS with partial or no enhancement of the echo in the whole lesion. The 1-, 2-, 3- and 5-year survival rates after treatments were recorded.

Machines

A cool tip RF system (Radionics, UAS) was used in the study. The cooling liquid used was 0 °C pure water. The puncture was guided by Esaote Technos MPX (Esaote SpA, Italy) or ALOKA SSD-2000 (Aloka Co., Japan) sonographic unit.

Statistical analysis

Statistical analysis was done using the SPSS 11.0. Homogeneity test of variance was performed before statistical analysis. Medians were used to describe the data in non-normal distribution. The data in normal distribution were expressed as mean±SD. T-test was used to analyze the difference between the two groups. Paired t-test was used to detect the difference before and after treatment. Analysis of variance and paired Snk-q test were used to detect the differences among the groups. P<0.05 was considered statistically significant.

RESULTS

In group 1, a total of 268 times of PEI were performed with guidance of ultrasound in 71 patients with HCC (mean, 3.2 times/lesion). Eleven lesions received PEI once, 15 lesions PEI twice, 19 lesions PEI thrice, 30 lesions PEI 4 times and 10 lesions PEI 5 times. The complete necrosis rate 1 mo after the treatment was 77.6% (66/85). The AFP level before treatment ranged 11.8 - 4102 μg/mL (median, 192.6 μg/mL) and was higher than 25μg/mL in 48 of the patients and dropped below 25 μg/mL 1 mo after the treatment in 31 of them. But the AFP level was even higher than before in 4 patients. The AFP level after treatment ranged 2.8~2313 μg/mL (median, 17.7 μg/mL). The 1-, 2-, 3- and 5-year survival rate after treatment was 80.0% (52/65), 60.4% (32/53), 52.5% (21/40) and 33.3% (7/21), respectively (Figure 1).

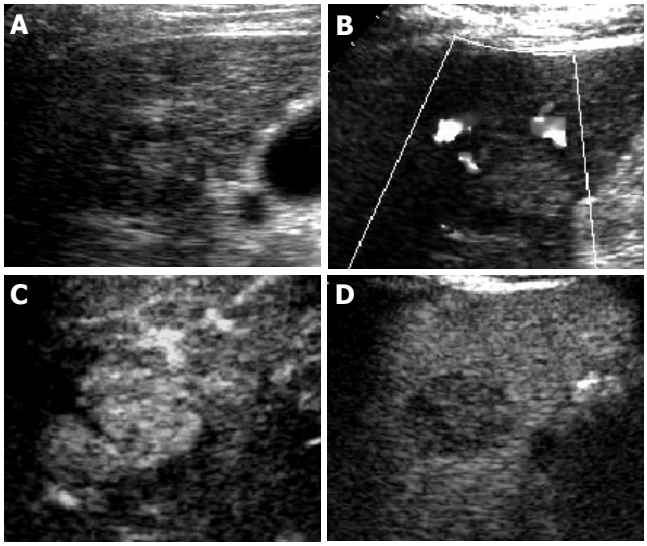

Figure 1 Typical HCC in contrast-enhanced sonography of hypervascular HCC before RFA. **A:** Hypoechoic lesion in the right lobe of the liver on B-mode sonography; **B:** Blood signals of the lesion on CDFI; **C:** Intratumoral enhancement in the early arterial phase of contrast-enhanced sonography; **D:** Hypoechoic lesion compared to the peripheral liver tissue in the late phase.

In group 2, 118 patients received RFA 199 times (mean, 1.3 times/lesion). Ninety-five lesions received RFA once, 35 lesions RFA twice and 13 lesions RFA thrice. The complete necrosis rate 1 mo after treatment was 92.2% (141/153). The level of AFP (2.8~31.3 μg/mL, median 18.5 μg/mL) decreased 1 mo after treatment in 74 patients. The 1-, 2-, 3- and 5-year survival rate was 94.6% (88/93), 73.2% (52/71), 63.5% (33/52) and 46.4% (13/28), respectively (Figure 2).

In group 3a, 24 patients received RFA 91 times (mean,

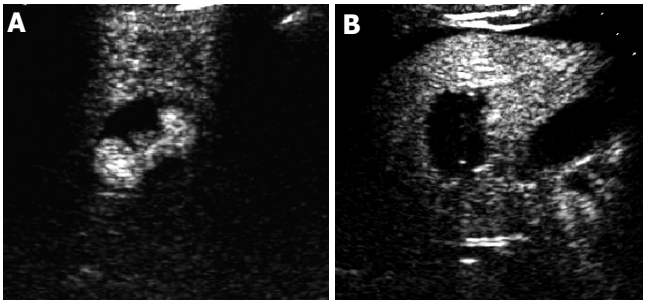

Figure 2 HCC after RFA. **A:** Incomplete necrosis of the lesion in the early arterial phase of contrast-enhanced sonography; **B:** Complete necrosis of the lesion after further RFA.

2.7 times/lesion). Four lesions received RFA once, 10 lesions RFA twice, 13 lesions RFA thrice, 7 lesions RFA 4 times. The complete necrosis rate 1 mo after treatment was 23.5% (8/34). Before treatment, the level of AFP ranged 5.8 - 11 246 μg/mL (median, 417.3 μg/mL). One month after treatment, the level of AFP ranged 12.8~13 513 μg/mL (median, 412.2 μg/mL). The level of AFP dropped below 25 μg/mL in only 1 patient. The 1-, 2-, 3-year survival rate was 47.6% (10/21), 42.9% (6/14) and 27.3% (3/11), respectively. Only one patient was alive after 5 years (Figure 3).

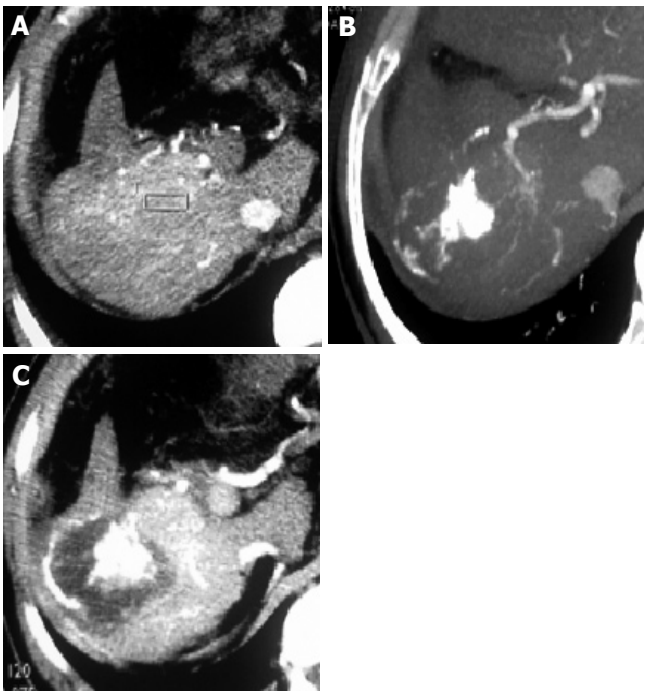

Figure 3 HCC treated with TACE and RFA. **A:** Enhancement of the recurrent HCC after resection in the early arterial phase; **B:** After TACE, lesion restrained with iodine (red arrow) and an un-embolized feeding artery (yellow arrow) in the arterial phase; **C:** After RFA, no enhancement in the lesion in the early arterial phase (red arrow) and enhancement in the inner part of the lesion (yellow arrows) indicating incomplete necrosis.

In group 3b, 42 patients received RFA 110 times (mean, 2.1 times/lesion) after TACE or PEI. Fourteen lesions received RFA once, 23 lesions RFA twice, 10 lesions RFA thrice, 5 lesions RFA 4 times. The complete necrosis rate 1 mo after treatment was 57.7% (30/52). Before treatment, the level of AFP ranged 4.7 - 10 247 μg/mL (median, 423.9 μg/mL). One month after treatment, the level of AFP ranged 5.7~8912 μg/mL (median, 17.7 μg/mL). The 1-, 2-, 3- and 5-year survival rate was 68.6% (24/35), 46.2% (12/26), 36.8% (7/19) and 27.3% (3/11), respectively (Figure 4).

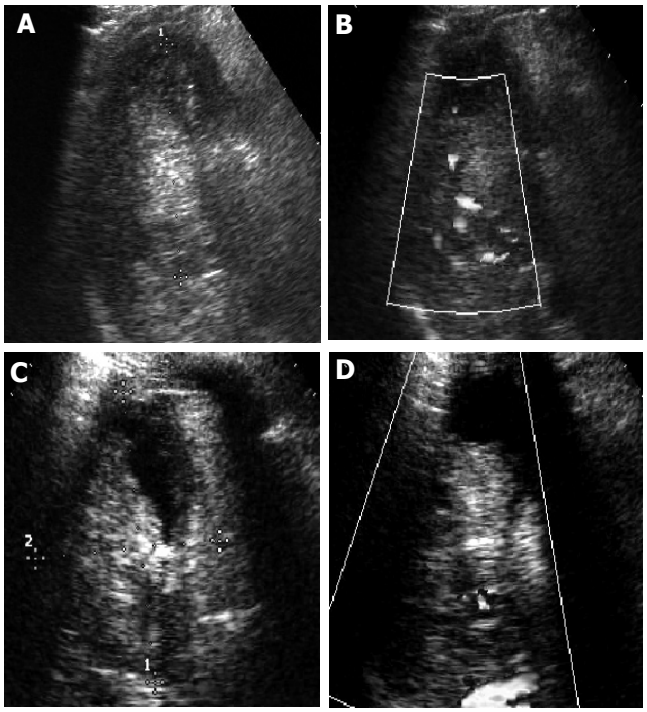

Figure 4 Recurrent HCC treated with TACE and RFA. **A:** hyperechoic lesion on B-mode image; **B:** Color blood signals on CDFI; **C:** Irregular echo-free area in the lesion on B-mode image after combined treatment, indicating partial colliquation of the necrotic tumor; **D:** Color blood signals inside the tumor on CDFI, suggesting incomplete treatment.

There was no significant difference in the levels of ALT before and after RFA. Two weeks after treatment, the level of ALT (73±38 IU) in group 1 was higher than that (32±23 IU) before treatment ($P<0.05$). There was no significant difference in the level of ALT (36±25 IU) 4 wk after treatment compared to that before treatment ($P>0.05$).

DISCUSSION

PEI has become a new interventional method for HCC, and better therapeutic effect has been achieved[6, 7]. However, because of the repetitive injection and the inhomogeneous diffusion of ethanol within the tumor, it is difficult to achieve complete necrosis of some large inhomogeneous

tumors. In addition, the treatment is often suspended because of unendurable pain. Furthermore, PEI decreases the immune function of patients and leads to severe impairment of liver function because of the damage to peripheral liver tissue caused by diffusion of ethanol. In patients with liver cirrhosis before treatment, the curative dose of ethanol may elicit severe complications such as hemorrhage of the congestive ducts or liver failure [8]. RFA is a local chemotherapy and kills tumor cells more completely with less influence on the peripheral liver tissue. This study showed that the complete necrosis rate of lesions and the 1-, 2-, 3- and 5-year survival rates of patients receiving PEI were significantly lower than those of patients receiving RFA. The lower therapeutic effect, worse complications and severer pain of PEI compared to RFA suggest that it is better to choose RFA for treatment of small HCC.

Furthermore, the complete necrosis rate of lesions in group 2 one month after the treatment was 92.2% (141/153). The level of AFP in this group decreased conspicuously. The 1-, 2-, 3- and 5-year survival rates after treatment (94.6%, 73.2%, 63.5%, and 46.4%, respectively) were significantly higher than those of in groups 3a and 3b, suggesting that the therapeutic effect of RFA is good, which is comparable to that of surgical resection.

However, even RFA has better therapeutic effect of HCC with fewer side effects[9-12], it is difficult to obtain complete coagulation in large HCC. One of the limitations of RFA is the small volume of treatment because of the heat from the pole is quickly decreased when it is transmitted in tumor tissue. When the electrode is used, the largest-treated area is about 3 cm in diameter, resulting in more times of RFA and worse therapeutic effect[13] in large tumors. In this study, even more times of ablation were performed in group 3a, the complete necrosis rate was lower than that in group 2. The residual tumor in the treated area maybe one of the most important reasons.

Many different methods have been used to obtain a larger treated area of RFA. TACE is one of the most commonly used non-surgical methods for HCC. It can acquire good therapeutic effect in enveloped small HCC[14]. But for HCCs without envelope or the envelope has been invaded, even small HCC can not be completely necrotized by TACE[15]. However, TACE can reduce the blood supply for the tumor[16]. In group 3b, TACE was performed before RFA in 23 patients (27 lesions), while PEI was performed before RFA in 19 patients (25 lesions). The complete necrosis rate after 1 mo was 57.7% (30/52) in group 3b, significantly higher than that in group 3a (23.5%, 8/34) ($P<0.05$). Therefore, when the tumor is larger than 3 cm in diameter, combined treatment of RFA with TACE or PEI is suggested in order to improve the therapeutic effect.

In conclusion, RFA is one of the optimal choices of treatment for small HCC and combined treatment is suggested for larger HCC.

Abstract

AIM: To investigate the cyclooxygenase-2 (COX-2) expression level in human HepG2, Bel-7402 and SMMC-7721 hepatoma cell lines and the molecular mechanism of COX-2 selective inhibitor celecoxib-induced cell growth inhibition and cell apoptosis.

METHODS: Hepatoma cells were cultured and treated with celecoxib. Cell *in situ* hybridization (ISH) and immunocytochemistry were used to detect COX-2 mRNA and protein expression. Proliferating cell nuclear antigen and phosphorylated Akt were also detected by immunocytochemistry assay. Cell growth rates were assessed by 3-(4, 5-dimethylthiazol-2-yl-2, 5-diphenyltetrazolium (MTT) bromide colorimetric assay. Celecoxib-induced cell apoptosis was measured by terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) and flow cytometry (FCM). The phosphorylated Akt and activated fragments of caspase-9, caspase-3 were examined by Western blotting analysis.

RESULTS: Increased COX-2 mRNA and protein expression were detected in all three hepatoma cell lines. Celecoxib could significantly inhibit cell growth and the inhibitory effect was in a dose- and time-dependent manner evidenced by MTT assays and morphological changes. The apoptotic index measured by TUNEL increased correspondingly with the increased concentration of celecoxib and the reaction time. With 50 μmol/L celecoxib treatment for 24 h, the apoptotic index of HepG2, BEL-7402 and SMMC-7721 cells was 25.01±3.08%, 26.40±3.05%, and 30.60±2.89%, respectively. Western blotting analysis showed remarkable activation of caspase-9, caspase-3 and dephosphorylation of Akt (Thr^{308}). Immunocytochemistry also showed the reduction of PCNA expression and phosphorylation Akt (Thr^{308}) after treatment with celecoxib.

CONCLUSION: COX-2 mRNA and protein overexpression in HepG2, Bel-7402 and SMMC-7721 cell lines correlate with the increased cell growth rate. Celecoxib can inhibit proliferation and induce apoptosis of hepatoma cell strains in a dose- and time-dependent manner.

INTRODUCTION

Cyclooxygenase (COX), known as a PGs synthase, catalyzes the metabolism of arachidonic acid to PGs and thromboxanes, and has three isoforms: COX-1, COX-2 and COX-3[1]. COX-1 is a constitutively expressed enzyme found in most tissues and remains unaltered in cancer. COX-2 is expressed at sites of inflammation, which has led to the speculation that its inhibition could provide all the benefits of current non-steroidal anti-inflammatory drugs (NSAIDs) but without their major side effects on the gastrointestinal system[2,3] (which are due to the inhibition of COX-1). New NSAIDs, which are selective inhibitors of COX-2, can exert therapeutic efficacy without toxic effects due to the inhibition of COX-1. Celecoxib, a selective COX-2 inhibitor approved by US FDA, has been shown preclinically and clinically to have efficacy comparable to that of NSAIDs on relief of pain and inflammation in osteoarthritis.

Recently, COX-2 has been suggested to be associated with carcinogenesis and high expression of COX-2 has been

found in many cancers[4-6] such as colorectal cancer, prostatic cancer, breast cancer and gastric cancer. Although selective COX-2 inhibitors could reduce the growth of various cancer cell lines[7-9] and display anti-tumor effect by sensitizing cancer cells to apoptosis[10-12], it is unknown whether COX-2 contributes to the malignant growth and whether inhibition of COX-2 function modifies the malignant potential of tumors.

In hepatocarcinoma (HCC), the expression pattern of COX-2 protein is well correlated with the differentiation grade, suggesting that abnormal COX-2 expression plays an important role in hepatocarcinogenesis[13]. However, the exact anti-tumor mechanisms are not well known. Leng *et al*.[8] have proved that COX-2 could promote HCC cell growth and selective COX-2 inhibitor celecoxib could mediate cell apoptosis in HepG2 and Hep3B cell lines. In this article, we investigate the expression pattern of COX-2 on HepG2 and two other human HCC cell lines, BEL-7402 and SMMC-7721 and evaluate the efficacy of selective COX-2 inhibitor celecoxib in order to understand the potential role of COX-2 in promoting HCC cell growth and to provide theoretical evidence for searching a new agent for the treatment of HCC.

MATERIALS AND METHODS

Materials

Human HepG2, BEL-7402 and SMMC-7721 hepatoma cell lines were obtained from The Committee of Type Culture Collection of Chinese Academy of Sciences (Shanghai, China). RMPI1640, DMEM and MEM culture medium were purchased from Gibco BRL. Fetal bovine serum (FBS) was provided by Sijiqing Biological Engineering Material (Hangzhou, China). Rabbit anti-COX-2 was from Cayman. Mouse anti-caspase3 was from Boster Biological Technology (Wuhan, China). Rabbit anti-caspase9, anti-actin, rabbit anti-phospho-Akt/PKB (Thr^{308}), sheep anti-rabbit, sheep anti-mouse secondary antibody, Western blotting luminol reagent were purchased from Santa Cruz. *In situ* cell death detection kit (TUNEL) and sensitive *in situ* hybridization detection kit were purchased from Roche. Rainbow molecular weight markers were from Amersham. 3-(4, 5-Dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) was provided by Amersco. Celecoxib was provided by Scenry Chemical (Hefei, China).

Cell lines and culture conditions

SMMC-7721 cell line was cultured in DMEM supplemented with 100 mL/L heat-inactivated FBS and 100 U/mL penicillin/streptomycin. Bel-7402 cell line was cultured in RPMI 1640 supplemented with 100 mL/L heat-inactivated FBS and 100 U/mL penicillin/streptomycin. HepG2 cell line was cultured in MEM supplemented with 100 mL/L heat-inactivated FBS, 100 U/mL penicillin/streptomycin and 1% nonessential amino acid. All cells were grown in 50 mL/ L CO_2 humidified atmosphere at 37 ℃.

Morphological changes

Celecoxib-treated cells and control were digested by trypsin, washed with phosphate-buffered saline (PBS) and centrifuged at 1 500 r/min for 5 min. After the cells were mixed with glycerine and egg white, the mixtures were fixed in alcohol for 30 min. Then the mass was embedded and fabricated to paraffin section with H&E staining. Morphological changes were observed under light and inverted microscopes.

In situ hybridization (ISH) assays

The digoxigenin-labeled COX-2 oligonucleotide probe for ISH was prepared with the sequence 5'-TGATATCA-TCTAGTCCGGAGCGGGAAG-3'(TaKaRa Bio). ISH was performed according to the instructions of the enhanced sensitive ISH detection kit. Briefly, the sections were deparaffinized with xylene, dehydrated with graded ethanol and embryos were incubated in 1 mL of 20 μg/mL proteinase K for 20 min. Re-fix embryos were incubated for 10 min in 4% formaldehyde. Then all were removed and 20 μL pre-hybridization solution was added for 2 h. Solution was removed and replaced with 20 μL hybridization solution to hybridize overnight at 37 ℃. After these, embryos were washed twice in 2× SSC and 0.01× at 37 ℃ SSC for 5 min each, replaced with anti-digoxygenin-alkaline phosphatase antibody and 40 μL AP-coupled antibodies at 37 ℃ for 1 h. The last wash was replaced with AP reaction buffer and the reaction was terminated when it became dark.

Westen blotting

Celecoxib-treated three cell lines and control were lysed by 4 g/L trypsin containing 0.2 g/L EDTA, then collected after being washed twice with cold PBS. Total protein extract from cells was prepared using cell lysis buffer [50 mmol/L Tris-HCL (pH 8.0), 150 mmol/L NaCl, 1%Triton X-100, 100 μg/mL PMSF, 1 μg/mL aprotinin]. The extract (40 ug) was electrotransferred to nitrocellulose membrane. The membranes were blocked with 5% nonfat dry milk in TBST (10 mmol/L Tris-HCL, pH 8.0, 100 mmol/L NaCl, and 0.05% Tween-20) for 1 h at room temperature and then incubated with appropriate primary antibody overnight at 4 ℃, followed by incubation with horseradish peroxidase-conjugated secondary antibody at 1∶2 000 dilution for 1 h at room temperature. The polyclonal anti-COX-2 and anti-actin were used at 1∶1 000 dilution. The polyclonal anti-caspase-3, anti-caspase-9, anti-phospho-Akt/PKB were used at 1∶400 dilution. The immunoblots were visualized by enhanced chemiluminescence.

Immunocytochemical assays

Briefly, the sections were subjected to immunostaining using an ultrasensitive streptavidin–peroxidase technique (DAKO). Endogenous peroxidases were blocked by incubating with 5 mL/L H_2O_2 for 30 min at room temperature. The sections were subsequently treated for 10 min with Triton X-100, and incubated for 30 min at 37 ℃ with normal non-immune serum before overnight incubation at 4 ℃ with specific antibody at a dilution of 1∶200. The sections were then treated with biotin-conjugated second antibody before streptavidin-peroxidase was added. For color reaction, diaminobenzidine (DAB) was used. If the positive signals were present, the cytoplasm or the nuclei were stained brown. For negative control, the antibody was replaced by PBS.

Cell growth assays (MTT assays)

The number of viable cells was determined by MTT assays. Each cell sample was plated at a density of 10 000 cells/well in 96-well cluster dishes before treatment. On the same day, the medium was changed and celecoxib was added in concentrations and analyzed at indicated time points. After addition of MTT solution (10/100 μL medium) in each well, the cells were incubated at 37 ℃ for 4 h, and then 100 μL DMSO was added to dissolve the dark blue crystals. The absorbance was measured in an ELISA plate reader with a test wavelength of 570 nm.

Cell cycle analysis by FCM

Celecoxib-treated cells were fixed with 700 mL/L alcohol for 15 min at 4 ℃, and then stained with propidium iodide (PI, Sigma, USA). The red fluorescence of DNA-bound PI in individual cells was measured at 488 nm with a FACSCalibur (Becton Dickinson, USA) and the results were analyzed using CELL QuestV1.22 software.

Apoptosis detection (TUNEL assay)

The apoptotic cells were identified by the terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) assay according to the manufacturer's instructions. The cells were counterstained with royal blue. In each experiment, 400 cells were examined using four high-power fields each (magnification×400). The experiments were performed at least twice independently.

Image analysis

The results of TUNEL and immunocytochemistry were analyzed in a blinded fashion by image analysis system (RXA_2, Leica) using *Qwin* software. The apoptosis index (AI) was determined by observing more than 400 nuclei for each sample.

Statistical analysis

Statistical significance was assessed by the nonparametric ANOVA test with SPSS 10.0 software and $P<0.05$ was considered statistically significant.

RESULTS

COX-2 expression in hepatoma cell lines

ISH, Western blotting and immunocytochemical staining were performed on HepG2, Bel-7402 and SMMC-7721 cell lines. Significant mRNA and protein of COX-2 were detected in all test cell lines. A representative Western blotting showed that the COX-2 expression level of the HCC cell lines in sequence was SMC-7721>BEL-7402>HepG2 (Figure 1). COX-2 protein was located in the cytoplasm of the cells shown by immunocytochemical staining. No staining was observed in the negative control slide.

Growth inhibitory effect of celecoxib

The effects of celecoxib on the cell viability were determined by MTT assay. Cells became sparse, round and detached from the dishes when treated with 6.25, 12.50, 25.00, 50.00, and 100.00 μmol/L concentrations of celecoxib for 24 h (Figure 2), and resulted in 11.9%, 23.9%, 43.8%, 62.4% and 72.7% cell growth reduction, respectively, in HepG2 cells (Figure 3).

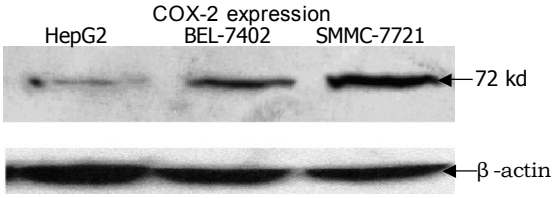

Figure 1 Expression of COX-2 in HepG2, BEL-7402 and SMMC-7721 HCC cell lines shown by Western blotting.

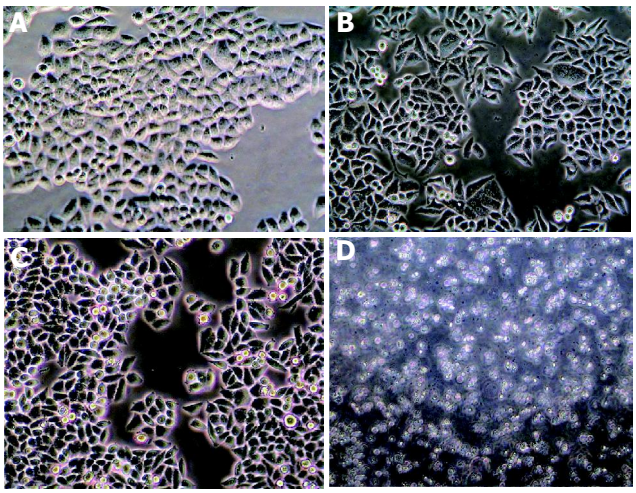

Figure 2 Growth inhibitory effect of celecoxib on SMMC-7721 cell lines. **A**: Normal control; **B**: 25.00 μmol/L celecoxib for 6 h; **C**: 25.00 μmol/L celecoxib for 24 h; **D**: 50.00 μmol/L celecoxib for 48 h. (Original magnification, ×200).

Down-regulation of PCNA expression in celecoxib-treated hepatoma cells

The effects of celecoxib on PCNA expression in cultured HCC cells were assessed by immunocytochemical staining. PCNA-positive cells were more abundant in control cells than in celecoxib-treated cells (Figure 4).

Human HCC cell apoptosis induced by celecoxib

Morphologic changes were evident in the three cell lines after treatment with celecoxib for 24 h. Progressive cytoplasmic shrinkage and nuclear condensation (the typical morphologic signs of apoptosis under light microscope) could be observed. To further make sure of these apoptotic morphologic changes, TUNEL staining was performed. As shown in Figure 5, celecoxib induced HepG2 cell apoptosis in a dose-dependent manner, the percentage of TUNEL-positive cells increased from 2.80±0.84% to 25.01±3.08% after treatment with 6.25 or 50 μmol/L celecoxib for 24 h, respectively. Celecoxib-treated BEL-7402 and SMMC-7721 cell lines showed the same results.

Results of FCM also showed apoptosis induced by celecoxib in SMMC-7721 cell lines. A subdiploid (subG1) peak was observed after being treated with 6.25, 12.

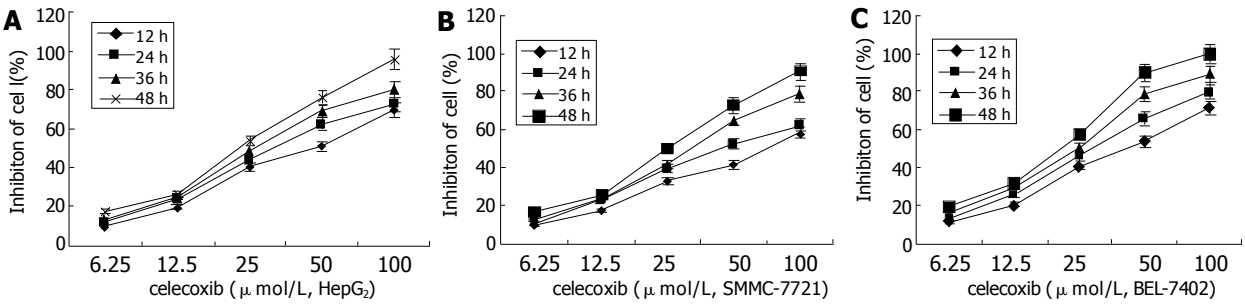

Figure 3 Growth inhibitory effects of celecoxib on HepG2 (**A**), SMMC-7721 (**B**) and BEL-7402 (**C**) HCC cells.

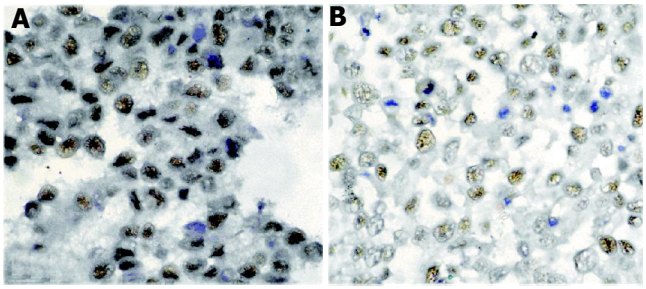

Figure 4 Immunocytochemical staining of PCNA in HepG2 cells in the presence or absence of celecoxib. **A**: normal control; **B**: 25.00 μmol/L celecoxib for 24 h.

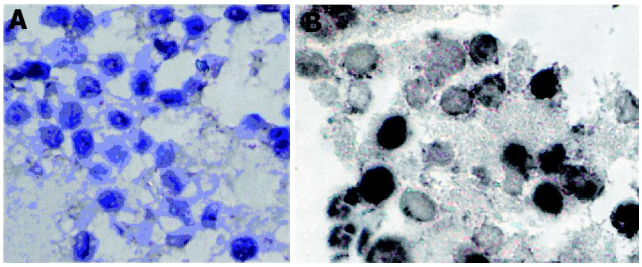

Figure 5 Cell apoptosis induced by celecoxib. **A**: Normal control; **B**: Apoptosis of BEL-7402 cell assessed by TUNEL.

50, 25.00 and 50.00 μmol/L celecoxib for 24 h, and the apoptosis rate was 4.84%, 16.10%, 22.80% and 33.80%, respectively, compared to 0.81% in normal control (Table 1).

Caspase-9 and caspase-3 activated by celecoxib

Western blotting analysis revealed that celecoxib induced activation of caspase-9 and caspase-3 (Figure 9). Activation of caspase-3 was reflected by a decrease in the 32-kd precursor and a concomitant increase in the 20-kd cleaved band. Activation of caspase-9 was reflected by conversion of the 47-kd precursor to the active 35- and 37-ku proteolytic cleavage products. The activation level of caspase-9 and caspase-3 was in a dose- and time-dependent manner to the celecoxib treatment (Figure 6).

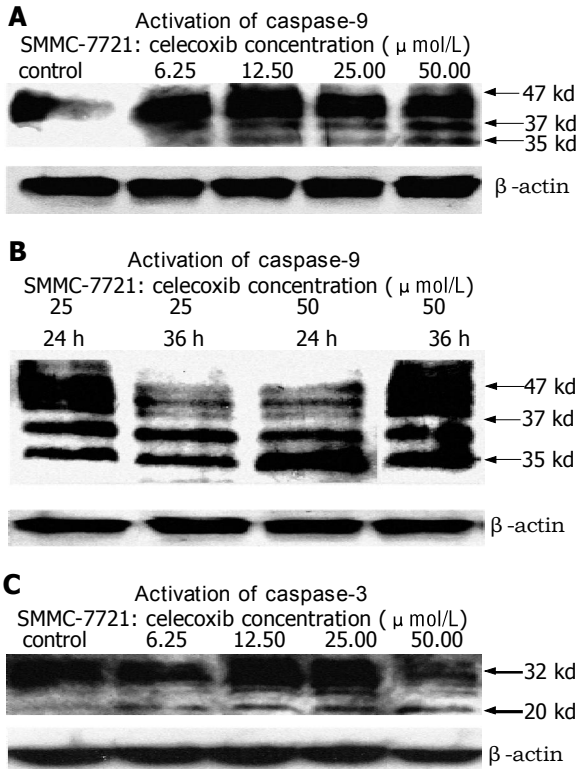

Figure 6 Activation of caspase-9 and caspase-3 after treatment with celecoxib. **A:** Activation of caspase-9 after being treated with celecoxib for 12 h; **B:** Activation of caspase-9 after being treated with different concentrations of celecoxib for different time; **C:** Activation of caspase-3 after being treated with celecoxib for 12 h.

Phosphorylation of Akt reduced by celecoxib

[a]$P<0.05$ *vs* control

To evaluate the effect of celecoxib on Akt/PKB activity, HepG2, BEL-7402 and SMMC-7721 cells were treated with celecoxib for 4, 12 or 24 h, and phosphorylation at Thr^{308} was examined by specific phospho-Akt antibody. Western blotting analysis showed that celecoxib significantly reduced Akt/PKB phosphorylation (Figure 7). Immunocy-tochemistry assay also displayed dephosphorylation of Akt Thr^{308} (Figure 8) in a dose- and time-dependent manner when analyzed with Leica-*Qwin* computer image analysis system. The results are shown in Figure 9.

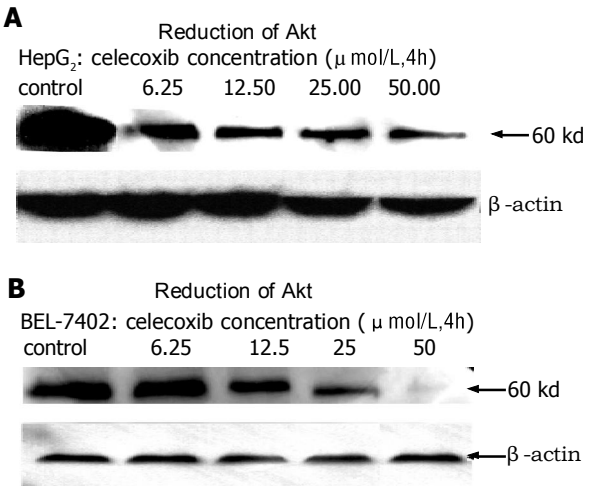

Figure 7 Dephosphorylation of Akt/PKB after treatment with celecoxib for 4 h. **A**: HepG2 cell line; **B**: BEL-7402 cell line.

DISCUSSION

COX-2, an isoform of cyclooxygenase, is inducible by a variety of factors including cytokines, growth factors, and tumor promoters[2,3]. It was reported that COX-2 expression increases in many human cancers including HCC[13]. The mechanism leading to COX-2 overexpression in HCC is still unknown. It was demonstrated that overexpression of COX-2 increases cell survival by inhibiting cell apoptosis and stimulating angiogenesis, and enhancing cellular adhesion to the matrix proteins[14,15]. In this article, we have observed a high expression of COX-2 mRNA and protein in human HepG2, Bel-7402 and SMMC-7721 hepatoma cell lines. These results suggest that studies are warranted to determine the role of COX-2 in hepatocarcinogenesis. Furthermore, we have shown that celecoxib, a selective COX-2 inhibitor, could strongly suppress cell proliferation.

Morphologic changes and results obtained by MTT assay support the suggestion that celecoxib down-regulates cell growth activity. It was reported that COX-2 inhibitors may have antineoplastic effects during the early stages of hepatocarcinogenesis[16].

PCNA is an essential protein found in proliferating eukaryotic cells, and plays a crucial role in DNA replication, repair, and control of cell proliferation[17,18]. This protein is involved in the synthesis of both leading and lagging DNA strands, providing an anchorage site and increasing the processivity of DNA polδ and DNA polε, which is the basis of PCNA serving as a DNA synthesis marker for evaluating cell proliferation[19,20]. Therefore, overexpression of COX-2 may be mitogenic in HCC cells through up-regulation of PCNA expression. Selective COX-2 inhibitor celecoxib can block the activity of COX-2 and down-regulate PCNA expression, thus causing cell growth inhibition.

Apoptosis plays a central role in tumor development and lack or failure of apoptosis leads to the development of many tumors including hepatocarcinoma[21,22]. Thus, induction of apoptosis of tumor cells is an effective approach to delay the tumor progress. In this study, we found that celecoxib could induce the characteristic features of apoptosis including morphological changes, TUNEL-positivity, FCM and caspase-9/3 activation of the three tested HCC cell lines.

There are at least two extrinsic and intrinsic broad pathways that lead to apoptosis[23-25]. The "extrinsic" pathway begins with the binding of Fas ligand (FasL or CD95L) to the Fas receptor (CD95) and results in recruiting FADD and pro-caspase-8 to the complex. Concentration of pro-caspase-8 results in its autocatalysis and activation. Activated caspase-8 cleaves pro-caspase-3, which then undergoes autocatalysis to form active caspase-3, a principle effector caspase of apoptosis. The "intrinsic" apoptosis pathway always begins with mitochondrial damage and results in release of cytochrome C from damaged mitochondria. In cytosol or on the surface of mitochondria, cytochrome C is bound to the protein Apaf-1 (apoptotic protease activating factor) which then activates an initiator caspase, caspase-9, then activates caspase-3[26,27]. Caspase families play an important role in apoptosis signaling pathway. They are present in the cytoplasm in normal condition as inactive pro-enzymes, most of which are activated by proteolytic cleavage when undergoing apoptosis[28,29]. Both caspase-8 and caspase-9 can activate the effector caspase, caspase-3, by proteolytic cleavage and subsequent processes result in the nuclear DNA fragmentation and formation of apoptotic bodies, indicating that activation of caspase-3 is a central event in the process of apoptosis.

In this article, Western blotting analysis revealed that celecoxib induced the activation of caspase-9 and caspase-3. Activation of caspase-9 is reflected by conversion of the 47-kd inactive precursor to the active 35-kd and 37-kd proteolytic cleavage products. Activation of caspase-3 is indicated by a decrease of the 32-kd precursor accompanied with a concomitant increase in the 20-kd cleaved band. Leng *et al*.[8], reported that celecoxib-treated HepG2 cells significantly release cytochrome C in the cytosol. Thus we propose the hypothesis that celecoxib allows the release of cytochrome C from mitochondria and activates caspase-9 and caspase-3 in sequence and finally induces apoptosis of HCC cells.

Our works have also shown that celecoxib down-regulates the phosphorylation of Akt/PKB at Thr^{308} in a dose- and time-dependent manner. Akt/PKB[30,31], the major downstream effector of PI3-kinase, is a Ser/Thr

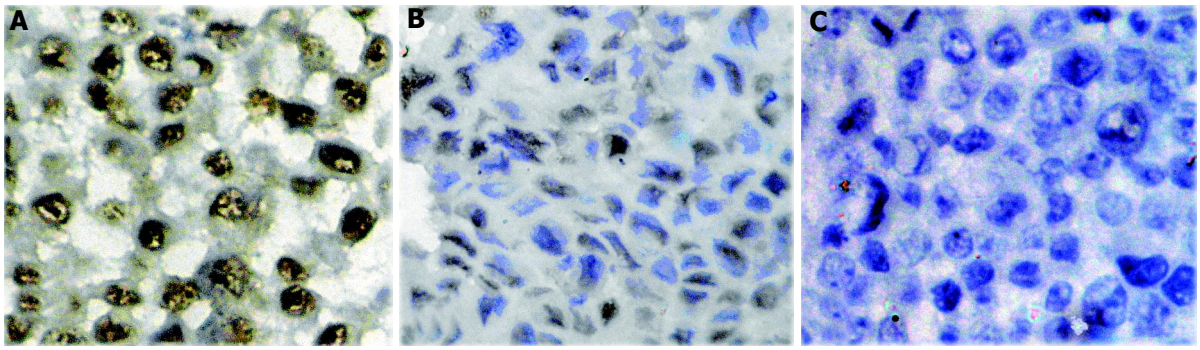

Figure 8 Down-regulation of phosphorylation of Akt Thr308 after treated with celecoxib. **A:** Normal control; **B:** SMMC-7721 cell line; (**C**): Negative control.

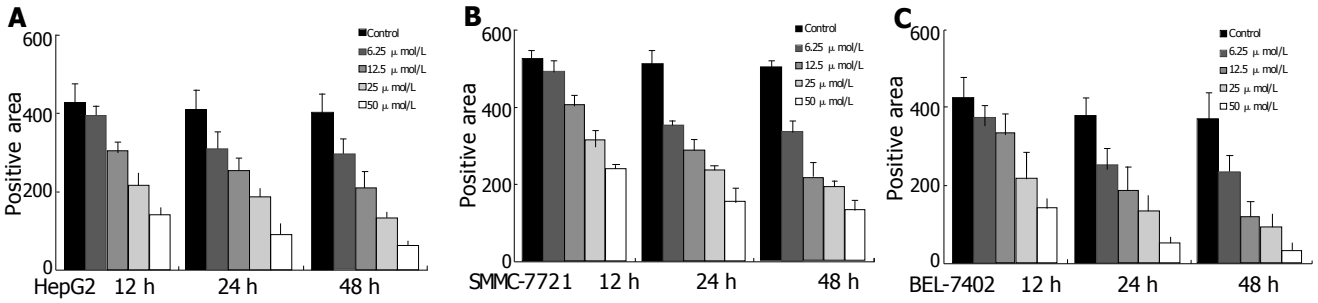

Figure 9 Dose- and time-dependent effects of reduced phosphorylation of Akt (Thr^{308}) on HepG2 cell (**A**), SMMC-7721 cell (**B**), BEL-7402 cell (**C**).

protein kinase that exerts a crucial role in the regulation of several cellular signaling pathways. Akt/PKB is a regulator of cell survival and apoptosis, and its activation can protect a variety of cells against apoptosis. Akt/PKB is phosphorylated at two regulatory sites, Thr^{308} and Ser^{473}, essential for its activation. Activated Akt/PKB can phosphorylate BAD, IκB kinase, glycogen synthase kinase-3β, and forkhead transcription factors[32,33], leading to their inactivation and cell survival. Interestingly, it was reported that caspase-9 activity is regulated by phosphorylation[34]. Akt phosphorylates pro-caspase-9 at Ser^{196} and inhibits proteolytic processing of pro-caspase-9.

Celecoxib blocks the activation of Akt, thereby attenuating the activity of a major anti-apoptotic pathway and inducing cell apoptosis. It remains unclear how celecoxib affects Akt phosphorylation because it does not affect PI3-kinase activity directly[35]. Other potential consequences of COX-2 inhibition, such as modulation of the RAS-signaling pathway, p53 expression, and other members of the BCL-2 family, such as MCL-1[36,37], activation of the sphingomyelin-ceramide pathway, and interference with the NF-κB[38] need to be investigated in future.

In conclusion, COX-2 is overexpressed in human HepG2, BEL-7402 and SMMC-7721 hepatoma cells and may play a key role in tumor cell proliferation and carcinogenesis. Selective COX-2 inhibitor celecoxib can suppress the growth of HCC cells by inhibiting cell growth and inducing cell apoptosis. The mechanism of apoptosis induced by celecoxib is due to activation of the caspase cascade, which is correlated with phosphorylation of Akt/PKB. These results suggest that selective COX-2 inhibitor offers potential as an effective chemotherapeutic and chemopreventive strategy against human liver cancer.

Abstract

AIM: To evaluate the multi-step pretargeting radioimmunoimaging (RII) and radioimmunotherapy (RIT) in nude mice bearing human colon carcinoma with avidin-biotin system labeled with ^{153}Sm.

METHODS: Two- and three-step strategies for avidin-biotin system pretargeting techniques were established. In a three-step procedure, human colon carcinoma bearing nude mice were first injected with biotinylated monoclonal antibody (McAb-Bt) followed by cold avidin (Av) 48 h later and then ^{153}Sm-DB_2 24 h thereafter; whereas the two-step procedure consisted of injection of ^{153}Sm-SA 48 h after pretargeting with biotinylated anti-CEA monoclonal antibody (CEA McAb-Bt). SPECT imaging and biodistribution were performed at 4, 24, 48, or 72 h after injection of ^{153}Sm-labeled compounds. Five groups of nude mice subcutaneously grafted with human colon carcinoma were treated 3 d after grafting. One group received the injection with 100 μg CEA McAb-Bt followed by cold avidin (80 μg) after 2 d and 11.1 MBq ^{153}Sm-DB_2 after 1 d. Four control groups were treated respectively with 11.1 MBq ^{153}Sm-CEA McAb, 11.1 MBq ^{153}Sm-nmIgG, 11.1 MBq ^{153}Sm-DB_2, 100 μL normal saline. Toxicity was evaluated by changes of leukocyte count, and the efficacy by variation in tumor volume. Histological analyses of tumors were performed.

RESULTS: The three-step procedure allowed faster blood clearance and yielded higher tumor blood ratios (5.76 at 4 h and 12.94 at 24 h) of the ^{153}Sm-DB_2. The tumor was clearly visualized at 4 h in γ-imaging after the injection of ^{153}Sm-DB_2, while a significant accumulation of ^{153}Sm-SA in the tumor was observed only 24 h after the injection and tumor blood ratios at 4 and 24 h were 1.00 and 2.03, respectively, in the two-step procedure. Pretargeting RIT and ^{153}Sm-CEA McAb had a strong tumor-inhibiting effect. The tumor inhibitory rate was 80.67% and 78.44%, respectively, five weeks after therapy. Histopathological evidence also indicated radioactive damage in tumor tissues as necrosis of tumor cells, while in the other organs such as liver and kidney no radioactive damage was observed. Leukocyte counts showed significant decrease after treatment in groups of ^{153}Sm-CEA McAb and ^{153}Sm-nmIgG.

CONCLUSION: The two kinds of pretargeting strategies can elevate the target-to-nontarget ratio, decrease the blood background and shorten the imaging time compared to ^{153}Sm-CEA McAb. Three-step pretargeting RIT is as efficient as ^{153}Sm-CEA McAb, but markedly less toxic. This study provides experimental evidence for the clinical application of pretargeting RII and RIT.

INTRODUCTION

Radioimmunoimaging (RII) and radioimmunotherapy (RIT) are nowadays popular research realms in tumor nuclear medicine[1,2]. Various groups have investigated the concept of tumor pretargeting based on the avidin-biotin system[3-6], exploiting the high specificity and strong affinity (Ka = 10^{-15} mol/L) of avidin (or streptavidin, SA) for biotin, so as to accelerate the elimination of tumor-unbound labeled antibodies from blood and enhance the tumor-to-nontumor (T/NT) ratio. Two-step procedures were thus designed[7]. Paganelli *et al*.[8], have further explored the potential of the avidin-biotin system by devising a three-step procedure, based on the administration of a cold biotinylated antibody, followed by an excess of cold avidin and finally by a radiolabeled biotin derivative. Currently, the pretargeting technique based on avidin-biotin system is widely applied to RII and radioimmunoguided surgery (RIGS) for tumor[9-11]. Avidin-biotin pretargeting RIT is also utilized to treat various tumors and has achieved promising clinical results[12-15].

Samarium-153 (^{153}Sm) is a nuclide that can be produced in high yield and has a high specific activity. It is a β-emitter [E_{max} = 640 (30%), 710 (50%), and 810 (20%) keV] with a half-life ($T_{1/2}$) of 1.95 d and 2.5-mm peak path length in tissue and also emits a 103 keV γ-ray that is suitable for γ-camera detection. It possesses excellent property in nuclear physics and chemistry for diagnosis and therapy. Dosimetry estimates can therefore be made by quantification of γ-camera data. Compared to ^{131}I, ^{153}Sm can result in minimal cross irradiation of normal organs and minimal radiation exposure to medical personnel and is a very attractive radioisotope for RII and RIT[16].

We, in this investigation, established the labeling method of SA and biotin with ^{153}Sm, and then the two- and three-step pretargeting RII and three-step RIT were adopted in nude mice bearing human colon carcinoma. The biodistribution and the SPECT imaging were observed and the feasibility of this three-step pretargeting RIT in tumor treatment was also explored.

MATERIALS AND METHODS

Biotinylation of anti-CEA McAb

mAb against carcinoembryonic antigen (anti-CEA McAb) and normal mouse IgG (nmIgG) were prepared by Shanghai Institute of Immunology. BNSH/dimethyl sulfoxide (DMSO) solution was added into bicarbonate buffer solution containing CEA McAb (1 g/L) at a ratio of 15-50∶1. The mixture was gently stirred at room temperature for 2 h and finally purified by Sephadex G50 chromatography. Indirect ELISA was performed to assess the activity of biotin, and the purity of biotinylated antibody was determined by SDS-PAGE.

Conjugation of anti-CEA McAb or nmIgG with DTPA

Coupling of cyclic anhydride DTPA (cDTPAa) to anti-CEA McAb or nmIgG was carried out as previously described[19]. Briefly, cDTPAa was suspended in chloroform (1 g/L). An aliquot containing cDTPAa at a molar ratio of 20∶1 DTPA: IgG was added to an acid-washed vial and evaporated to dryness under a stream of high-purity dry nitrogen. Anti-CEA McAb or nmIgG (200 μg) was added, the vial was vortexed for 1 min, and then allowed to stand at room temperature for 15-20 min. Acetic acid was added to the mixture to stop the reaction. Separation of the DTPA-CEA McAb or nmIgG conjugate from free DTPA was achieved by Sephadex G50 chromatography. Immunoreactivity of the DTPA-CEA McAb conjugate was assessed using indirect ELISA.

Radiolabeling of anti-CEA McAb, nmIgG, or SA

$^{153}SmCl_3$ was supplied by Isotopes Center of China Atomic Energy Institute. SA was purchased from Sigma Chemical Co. (St. Louis, MO, USA). $^{153}SmCl_3$ at a dose of approximately 40 MBq (with specific activity of 22.2 GBq/mL) was mixed with purified CEA McAb, nmIgG, or SA-DTPA conjugate (0.1 mL) and incubated at room temperature for 20 min. Paper chromatography was carried out, using Xinhua No.1 filter paper (30% ammonium nitrate-treated) as the supporter and the mixture of tributyl phosphate, butanone, and acetic ether (at a proportion of 4∶10∶3) as the developing agent, to determine the labeling efficiency and radiochemical purity. Immunoreactivity of the labeled McAb was tested using indirect ELISA.

Radiolabeling of DB_2

Diethylenetriaminepentaacetic acid *d,ω-bis*(biocytinamide) (DB_2; Sigma Chemical Co., St. Louis, MO, USA) was labeled with ^{153}Sm as follows. $^{153}SmCl_3$ (37 MBq) was added into 10 μL DB_2 solution (2 g/L) for reaction at room temperature for 20 min. Thin-layer chromatography was employed to determine the labeling efficiency and radiochemical purity, using 85% methanol as the developing agent. ^{153}Sm-DB_2 had a specific activity of 37 MBq/mL, with a binding capacity to 80% biotin agarose beads.

Nude mouse models bearing human colon carcinoma

Balb/c nu/nu mice (female, 20 g) were xenografted subcutaneously in the thigh with 5×10^6 LoVo cells. Tumor growing to approximately 1 cm in diameter was cut into tiny pieces, which were suspended in normal saline, aspirated and injected (approximately 0.2 mL) subcutaneously into the forelimb of nude mice (4- to 5-wk old). The wounds healed in 12 h. When the tumor grew to a volume of 0.5-1.0 cm^3, the mice were used for the subsequent study of pretargeting RII and biodistribution. Therapeutic study was initiated on the 3rd d following tumor inoculation.

Pretargeting radioimmunoimaging and biodistribution studies

Fifty nude mice bearing human colon carcinoma were randomly divided into five groups (three-step group, two-step group, directly labeling group, ^{153}Sm-DB_2 group, and ^{153}Sm-SA group), with 10 in each group. In three-step group, the mice were subjected to injections via the tail vein with 100 μg McAb-Bt, then with 30 μg avidin 48 h later, followed by intra-peritoneal (ip) injection of 3.7 MBq (20 μg) ^{153}Sm-DB_2. In two-step group, the mice were injected with 100 μg McAb-Bt followed by ip injection of 3.7 MBq (15 μg) ^{153}Sm-SA 48 h later. In directly labeling group, only ^{153}Sm-DTPA-CEA McAb (3.7 MBq, 20 μg) was administrated via ip injection 72 h after the initiation of the experiment. In ^{153}Sm-DB_2 group, the mice received only ip injection of ^{153}Sm-DB_2 (3.7 MBq, 20 μg). In ^{153}Sm-SA group, the mice received only ip injection of ^{153}Sm-SA (3.7 MBq, 15 μg). Static plane imaging with Siemens ZLC3700 SPECT was performed on the mice of each group at 4, 24, 48, and 72 h, respectively, after the injections. The mice were killed at each time point following the imaging, their organs were isolated and weighed, and the radioactivity counts were determined. The percentage of injected dose per gram of tissue (% ID/g) and T/NT ratio were calculated.

Pretargeting radioimmunotherapy studies

Grouping of the mice Twenty-five tumor-bearing mice were randomly divided into A-E groups (five in each group). The mice in group A received three-step treatment, consisting of injections via the tail vein with 100 μg McAb-Bt, 80 μg Av 48 h later and 11.1 MBq (100 μL) ^{153}Sm-DB_2 ip injection after another 24 h. Groups B-D were therapeutic control groups, which were given ^{153}Sm-CEA McAb, ^{153}Sm-nmIgG, and ^{153}Sm-DB_2, respectively, at a dose of 11.1 MBq (100 μL). As nontherapeutic control, mice in group E were only given

100 μL of normal saline by ip injection.

Observation of tumor inhibiting effect The length (*a*) and width (*b*) of tumor mass were measured double-blindly with a sliding caliper once a week for 5 wk. Tumor volume (*V*) was calculated according to the formula: $V = (1/6)\pi ab^2$. The inhibition rate (IR) of tumor growth was calculated according to the formula: IR = [(mean tumor volume of nontherapeutic control-mean tumor volume of therapeutic group)/(mean tumor volume of nontherapeutic control)]×100%.

Histological examination Pathological examination was also performed on these mice at the end of the treatment. The mice were killed. Their organs were isolated, weighed, and fixed in a 40 g/L formaldehyde solution, embedded in paraffin, cut into 4-μm-thick sections and then stained with hematoxylin and eosin (HE) for microscopic observation.

Observation of radiation toxicity Toxicity was evaluated by the change of the peripheral WBC counts. The number of WBC of all animals was determined on the day of injection and then once a week for 5 wk consecutively.

Statistical analysis

Data were expressed as mean±SD and analyzed by Student's *t*-test. $P<0.05$ was considered statistically significant.

RESULTS

Quality control of labeled compounds

In the preparation of McAb-Bt, it was found that one molecule of antibody could conjugate with three molecules of biotin on average at the biotin/McAb molar ratio of 20∶1. The resultant McAb-Bt possessed better capability of SA-binding and immunoreactivity. The optimal coupling condition of the McAb and DTPA was as follows: McAb to cDTPAa molar rate of 1∶20, pH value of 7-8, and an antibody concentration at 20 mg/mL. The labeling efficiency of ^{153}Sm-CEA McAb was 56-60%, radiochemical purity was over 95% and immunoreactivity was about 50%. The labeling efficiency of ^{153}Sm-DB_2 exceeded 80%, and radiochemical purity was over 95% after binding to SA. The labeling efficiency of ^{153}Sm-SA was over 95% and radiochemical purity was over 98%.

Biodistribution in tumor-bearing nude mice during multi-step pretargeting

The percent of ID/g and T/NT ratio in various organs at different time points during three- and two-step pretargeting are listed in Tables 1 and 2, respectively.

As shown in Tables 1 and 2, tumor uptake (% ID/g) was 1.78% and 1.36% in three-step pretargeting group, 4 and 24 h after the injection, and 1.35% and 2.10% in two-step pretargeting group. The tumor/blood ratio at the same time point was 5.76 and 12.94 in three-step pretargeting group, and only 1.00 and 2.03 in two-step pretargeting group. In directly labeling group, the tumor uptake (% ID/g) reached as high as 1.42% 48 h after the injection, but the level of blood background activity was also high (1.01%ID/g). The tumor uptake (% ID/g) and the ratios of tumor to other organs were all lower in ^{153}Sm-DB_2 and ^{153}Sm-SA groups.

Pretargeting radioimmunoimaging

In the three-step procedure, higher radioactive uptake in the implanted tumor was observed 4 h after the injection, and better tumor display and higher T/NT ratio were also obtained at 24 h because the level of blood background activity was markedly reduced. In the two-step procedure, radioactivity accumulation in the tumor could be visualized at 24 and 48 h. However, higher radioactive uptake was observed in the liver, spleen, and kidney. In the group of directly labeled McAb with ^{153}Sm, radioactive uptake at the site of tumor implantation occurred 72 h after the injection; while in ^{153}Sm-DB_2 and ^{153}Sm-SA groups, no significant radioactivity uptake in tumor was observed.

Observation of tumor inhibiting effect

In the 1st wk of treatment, the tumor volume showed little difference among the groups; while in the 2nd wk slower tumor growth rate in groups A and B was observed, indicating tumor inhibition. Till the 5th wk, the tumor volume was obviously smaller in groups A and B than in nontherapeutic control group (Figure 1), and the difference was statistically

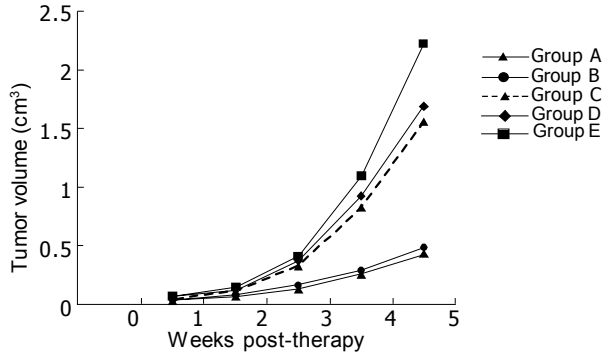

Figure 1 Transplant tumor growth curves.

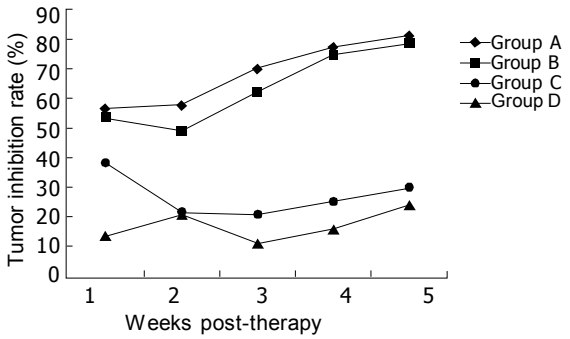

Figure 2 Curves of growth inhibition rate of transplant tumors.

significant (P<0.01). It was also noted that the tumor volume was smaller in groups C and D than in group E, and the difference was also statistically significant (P<0.01). If the tumor inhibition rate in nontherapeutic control group was considered as zero, the tumor inhibition rate 5 wk post-therapy was as high as 80.67% and 78.44% in groups A and B, much higher than that in groups C and D (Figure 2). In the latter two groups, the tumor inhibition rate was only 29.78% and 23.99%, and no significant difference existed between them. However, significant difference existed between the former two and the latter two groups (P<0.01).

Histopathological evidence also showed that the tumor cell nuclei were pyknotic, karyoclastic, and autolytic in three-step pretargeting RIT and ^{153}Sm-CEA McAb groups, which were not seen in the other controls (Figure 3). In the non-treated group, tumor tissue was characterized by the absence of necrosis, and took on typical forms of carcinoma cells (Figure 3).

Observation of side effects

Compared to non-treatment group, the number of peripheral blood WBC in treatment groups decreased after injection of 11.1 MBq of ^{153}Sm to some degree (Figure 4). However, WBC counts showed significant decrease after treatment in ^{153}Sm-CEA McAb and ^{153}Sm-nmIgG groups, and WBC recovery was also slower in both groups. Microscopic observation revealed no obvious tissue radiation damage in organs such as heart, liver, spleen, lungs, and brain in all nude mice at the end of the treatment.

DISCUSSION

Radiolabeled McAb specific for tumor-associated antigens is used for diagnosis and therapy of malignant tumors[1,2]. However, the blood clearance of antibodies is slow and T/NT ratio of radioactivity in the current system is not high. In order to increase the amount of radioactivity bound to cancer cells, a new approach in cancer therapy called pretargeting has been used. The pretargeting approach can be carried out as a two-step or as a three-step procedure. The two-step procedure is based on the administration of SA-antibody conjugate followed by radioactive biotin or biotinylated antibody is injected followed by radioactive SA[4,18]. In the three-step procedure, biotinylated antibody is injected followed by an excess of avidin/SA and then radioactive biotin is injected[4,19]. In both the methods, the radioactivity of tumor cells is increased[14,20]. Using pretargeting technique of avidin-biotin system, high T/NT ratios have been reported, not only in animal experiments, but also in clinical trials. The avidin-biotin system is also used to reduce the background radioactivity of directly labeled antibody as well as RIGS[9,21]. The success of the approach is due, in part, to the extremely high binding affinity of

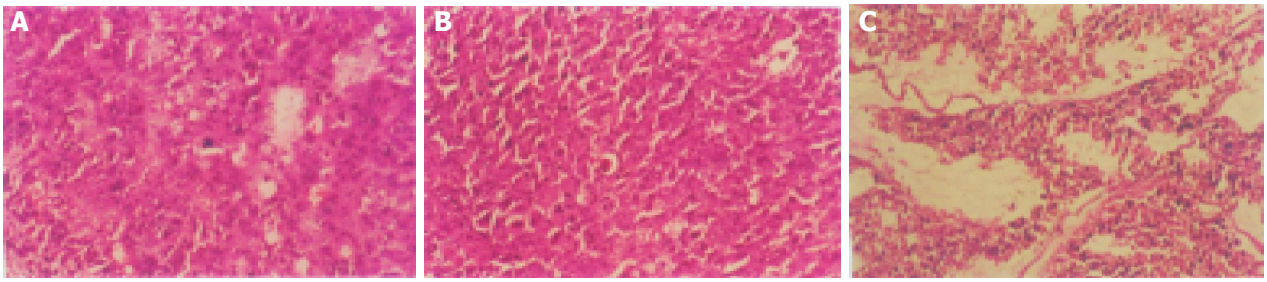

Figure 3 HE staining of tumor tissues in nude mice bearing human colon carcinoma after receiving three-step pretargeting RIT (**A**), ^{153}Sm-CEA McAb RIT (**B**) and normal saline (**C**).

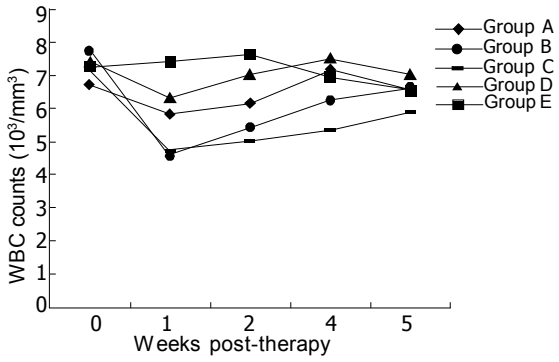

Figure 4 WBC counts after injection of drugs.

biotin to avidin/SA, which provides a high tumor targeting efficiency and a long retention at the tumor site. Further, the small size of biotin and its derivatives provides rapid renal clearance of radiolabeled biotin, eliminating much of the irradiation of nontarget tissues. In the present study, the two-step procedure applied consists of injection of radiolabeled SA after pretargeting with biotinylated antibody. The three-step procedure described in our study is as follows. First, tumor pretargeting was done by biotinylated anti-tumor McAbs. Second, when the uptake of McAbs in tumor cells reached its maximum within 24-48 h postinjection, circulating biotinylated McAbs were quickly (5-10 min) removed from the blood by the liver following the administration of avidin as a clearing agent. Finally, postlabeling of the tumor was done by a fast-clearing radioactive biotin and its derivatives. Since one molecule of McAb is capable of binding multiple molecules of biotin, the reaction of avidin with biotin and its derivatives is amplified. One molecule of avidin can bind to four molecules of biotin, and then further amplification of the reaction takes place. In other words, three-step pretargeting technique, like an amplifier, may result in an amplification of signals at the tumor target sites. Meanwhile, transchelating time of radioactive metal *in vivo* is shortened, and consequently normal tissue uptake of the antibody is reduced and antibody immunoreactivity is preserved unlike directly radiolabeled antibodies, which result in the loss of antibody immunoreactivity due to autoradiolysis and enzyme treatment.

Studies using ^{90}Y-biotin have been successful[14,22]. Biotin has also been labeled with several chelated radionuclides for cancer therapy such as ^{99m}Tc, ^{188}Re, ^{166}Ho, and ^{211}At[23-26]. ^{153}Sm is a radiolanthanide, which has not yet been widely used, but possesses nuclear characteristics suitable for RIT. It can be produced in reactors by enriched samarium (^{152}Sm) through the (n, γ) reaction. This enables the production of ^{153}Sm at low cost. As far as we know, studies of labeling antibodies and biotin with ^{153}Sm are very few[27]. It has been recognized that the cation $^{153}Sm^{3+}$ has good chelating capabilities with polyaminopolycarboxylic acids, such as EDTA or DTPA. In our study, we chose DTPA as the intermediate chelating agent, which can be linked to the antibodies or SA via bicyclic anhydride (cDTPAa). The main purpose of our investigation was to establish the labeling method of McAb and SA as well as biotin with ^{153}Sm and to evaluate the pretargeting RII and RIT in nude mice bearing human colon carcinoma with SA-biotin system labeled with ^{153}Sm. In the three-step procedure, the tumor was clearly visualized at 4 h in γ-imaging and at the same time point tumor blood pool ratio was 5.76, which was significantly higher than that of control groups. In the two-step procedure, a significant accumulation of ^{153}Sm-SA in the tumor was observed only 24 h after injection. The tumor blood ratios at 4 and 24 h were 1.00 and 2.03, respectively. However, the higher radioactive accumulation was also observed in the liver, spleen, and kidney. This deposition may result from complex formation of biotinylated antibodies with radiolabeled SA in circulation. In addition, in molecule of SA there exists three-peptide amino acid sequences (Arg-Thy-Asp), which may bind to the surface of many types of cells[28]. The advantages of pretargeting technique lie in that it is safe and simple, biotinylation of antibody and other reagents are easily prepared. Since the clearance of radiolabeled biotin or SA from normal tissue is much more rapid than that of directly radiolabeled antibody because of its small molecular weight, background radioactivity levels are drastically reduced, and the high T/NT ratio can be reached shortly after injection of the radiolabel[3,15,29]. Our preliminary studies also showed that compared to directly labeled McAb with ^{153}Sm, multi-step pretargeting could efficiently decrease the blood background levels, elevate the T/NT ratio, shorten the imaging time and improve the quality of imaging. Earlier and better images of tumor can be obtained using these methods, especially the three-step procedure.

RIT has shown disappointing results in bulky, solid tumors, probably due to the low specific accretion of radiolabeled antibody in the tumor target as compared to normal tissues[30]. Tumors have intrinsic characteristics

that unfavorably affect localization and intratumoral distribution of McAbs: heterogeneous expression of the antigen, relatively poor tumor vasculature, elevated interstitial pressure and tumor necrosis. Previous investigations have shown that tumor uptake and radiation doses are inversely correlated with tumor size [31,32]. Therefore, RIT may be a viable option, especially for small-volume and minimal residual tumors. ^{153}Sm emits β-rays with intermediate or low energy, which can effectively kill microtumors. In view of these considerations, our RIT experiment was devised to initiate on the 3rd d following tumor inoculation. The results showed that pretargeting RIT and ^{153}Sm-CEA McAb had a strong tumor inhibition effect. The tumor inhibitory rate was 80.67% and 78.44%, 5 wk after therapy. Histopathological evidence also indicated radioactive damage as necrosis of the tumor, which was not seen in the other controls. RIT and pretargeting RIT may be more effective for early stage carcinoma. The reason may be related to lower quantity of tumor cells in early stage, less heterogeneity in tumor antigen expression and greater sensitivity to radiation. In addition, there was, to certain degrees, tumor inhibitory effect in groups of ^{153}Sm-nmIgG and ^{153}Sm-DB_2 with a tumor inhibitory rate of 29.78% and 23.99%, respectively, 5 wk after therapy. This may result from unspecific radiation effect. Because ^{153}Sm-nmIgG and ^{153}Sm-DB_2 cannot bind specifically with anti-CEA McAb, effective localization in tumor cells *in vivo* would not take place, thus this unspecific radiation effect is limited.

In three-step pretargeting RIT, ^{153}Sm-DB_2 at a single dose of 11.1 MBq/100 μL produced potent tumor-inhibiting effect, and no significant bone marrow toxicity was observed as evidenced by milder decrease of WBC counts. However, in ^{153}Sm-CEA McAb and ^{153}Sm-nmIgG groups, WBC counts significantly decreased, and WBC recovery was also slower than that in three-step pretargeting RIT, indicating that the hemopoietic function of bone marrow might be affected. When ^{153}Sm-CEA McAb and ^{153}Sm-nmIgG enter into blood circulation, its slower blood clearance may result in high background radioactivity levels and cause more radiation-related damage to normal tissues or organs. The rapid clearance of ^{153}Sm-DB_2 from blood may drastically reduce background radioactivity levels. Consequently, radiation exposure to normal tissues especially bone marrow is decreased.

In conclusion, pretargeted RIT with ^{153}Sm-DB_2 has higher anti-tumor efficacy but lower toxicity than ^{153}Sm-CEA McAb. It may serve as an adjuvant therapy for tumor, particularly for small tumor or micrometastatic disease and residual cancer cells in surgical tumor resection areas. Therefore, it is of good prospect in clinical application.

Abstract

AIM: To explore the propriety of providing hepatitis B virus (HBV) genotypes F and H with two distinct genotypes.

METHODS: Eleven HBV isolates of genotype F (HBV/F) were recovered from patients living in San Francisco, Japan, Panama, and Venezuela, and their full-length sequences were determined. Phylogenetic analysis was carried out among them along with HBV isolates previously reported.

RESULTS: Seven of them clustered with reported HBV/F isolates in the phylogenetic tree constructed on the entire genomic sequence. The remaining four flocked on another branch along with three HBV isolates formerly reported as genotype H. These seven HBV isolates, including the four in this study and the three reported, had a sequence divergence of 7.3-9.5% from the other HBV/F isolates, and differed by >13.7% from HBV isolates of the other six genotypes (A-E and G). Based on a marked genomic divergence, falling just short of >8% separating the seven genotypes, these seven HBV/F isolates were classified into F2 subtype and the former seven into F1 subtype provisionally. In a pairwise comparison of the S-gene sequences among the 7 HBV/F2 isolates and against 47 HBV/F1 isolates as well as 136 representing the other six genotypes (A-E and G), two clusters separated by distinct genetic distances emerged.

CONCLUSION: Based on these analyses, classifying HBV/F isolates into two subtypes (F1 and F2) would be more appropriate than providing them with two distinct genotypes (F and H).

INTRODUCTION

Seven genotypes of hepatitis B virus (HBV) have been differentiated by a sequence divergence in the entire genome >8%, and they are named by capital alphabet letters from A to G[1-3]. Among the seven genotypes of HBV, F is the most divergent from the other six and separated from them by >14% in the full-length sequence. Recently, an eighth genotype was proposed for HBV isolates from Central America based on a sequence divergence from those of the seven genotypes (A-G) barely exceeding 8%[4].

An attempt was made in the present study to evaluate the independence of genotype H from the others by systematic phylogenetic analysis on the entire nucleotide sequences and their open reading frames of 25 HBV isolates of genotype F (HBV/F) or H, including the 11 from patients with acute or chronic hepatitis B from San Francisco, Japan, Panama, and Venezuela that were determined anew.

Because of a mediocre sequence divergence, a little short of clearing the >8% difference separating the seven HBV genotypes (A-G), taken along with their relationship in phylogenetical analysis, the two clades of HBV/F isolates would better be classified into two subtypes of genotype F, and they were provisionally assigned the designations F1 and F2. A possibility is proposed for distinguishing F1 and F2 subtypes by combining serotypes of the preS2-region product[5-7], for the determination of HBV genotypes, and subtypes of hepatitis B surface antigen (HBsAg).

taken care of in Gastroenterology Division of California Medical Center in San Francisco, Ryukyu University Hospital in Okinawa, Japan and National Hospitals in Panama and Venezuela, 11 were found to be infected with HBV/F. Demographic characteristics and liver diseases of the 11 patients are shown in Table 1. Their sera were tested for HBV markers, and HBV/F isolates in them were sequenced over the entire genome. The study design was approved by Ethics Committees of the institutions, and an informed consent was obtained from each patient.

Determination of the seven HBV genotypes (A-G) by preS2 serotypes

The seven major genotypes of HBV, i.e., A, B, C, D, E, F and G, were determined by ELISA with commercial kits (HBV Genotype EIA, Institute of Immunology, Tokyo, Japan) which distinguishes serotypes of the product of the preS2 region that are specific for each genotype[5-7]. It involves monoclonal antibodies directed to five preS2 epitopes designated *b*, *k*, *m*, *s* and *u*, respectively. Since the expression of preS2 epitopes are influenced by HBV genotypes, the combination thereof can define genotypes serologically; the epitope *b* is expressed regardless of HBV genotypes and guarantees the presence of preS2 product in the test serum. Thus, a serotype *bsu* is specific for genotype A, *bm* for B, *bks* for C and *bk* for F. Although genotypes D and E have the same serotype (*bksu*), they are differentiated by distinct behavior in the binding with another monoclonal antibody against the epitope *g* immobilized on a solid support. HBsAg of genotype E binds with immobilized anti-*g*, so that it is sandwiched between antibody to the common determinant *a* of HBsAg labeled with horseradish peroxidase, while HBsAg of genotype D is not. Although HBsAg of genotype G has a preS2 serotype for D, *bksu(g)*, it has HBsAg subtype of *adw* unlike *ayw* in almost all HBsAg samples of genotype D. Thus, genotype G can be detected serologically by the combination of preS2 serotype *bksu(g)* and HBsAg subtype *adw*.

Determination of the full-length sequences of six HBV/F isolates

Nine sets of primers used in this study are shown in

[1]The first three pairs of primers (HBV/Ff1 to HBV/Fr3) were used for PCR and sequencing, while the remaining six pairs (HBV/Ff4 to HBV/Fr9) for sequencing only.

Table 2. The genomes of 11 HBV/F isolates were sequenced through 3 overlapping fragments; they were amplified by PCR with 3 sets of primers (HBV/Ff1-HBV/Fr1, HBV/Ff2-HBV/Fr2 and HBV/Ff3-HBV/Fr3). AmpliTaq Gold was activated at 96 ℃ for 9 min, and PCR was performed for 40 cycles (96 ℃ for 1 min; 55 ℃ for 1 min; 72 ℃ for 1.5 min [5 min in the last cycle]). The three nucleotide fragments were sequenced directly by the dideoxy method with use of the BigDye Terminator cycle sequencing kit in a fluorescent 3100 DNA sequencer (Applied Biosystems, Foster City, CA, USA) using the remaining six sets of primers along with the three primer sets used for PCR (Table 2).

Molecular evolutionary analyses

The number of nucleotide substitutions per site was estimated by the 6-parameter method[8], and phylogenetic trees were constructed by the neighbor-joining method[9] based on the numbers of substitutions. To confirm the credibility of phylogenetic analyses, bootstrap resampling tests were carried out 1 000 times[10]. Evolutionary distances between nucleotide sequences of the S gene were calculated in accordance with the HCV Database. These analyses were conducted with use of the ODEN program of the National Institute of Genetics (Mishima, Japan)[11]. Frequency distribution analysis was performed with the StatView J-4.5 program.

RESULTS

Eleven HBV/F isolates

Eleven patients with HBV-associated liver disease were found to be infected with HBV/F by ELISA with monoclonal antibodies against preS2 epitopes[5-7]. Table 1 shows demographics and liver disease of the 11 patients from whom HBV/F strains were recovered. Four of them had liver cirrhosis, three had acute hepatitis and one presented with chronic hepatitis; diagnosis of liver disease was not available for the remaining three. They included six Hispanics, two Asians and one Caucasian.

The entire nucleotide sequences of the 11 HBV/F isolates designated USF2573 (accession no. AB064316), USF10 (AB059659), USF1122 (AB064315), USF1778 (AB058660), USF2065 (AB059661), JPF1130 (AB086397), JPNTAKA (AB116654), PAMAN5 (AB116549), PANAM6 (AB116550), VENEZ2 (AB116551) and VENEZ4 (AB116552) have been deposited in the international DDBJ/GenBank/EMBL database. They were subjected to phylogenetic analyses over the entire genome and within the open reading frames among themselves and against 59 HBV isolates of the 7 genotypes (A-G) for which the full-length sequences are known (Figure 1).

Eleven HBV/F and three HBV/H isolates with known entire genomic sequences were recruited from the literature[2,12,13]. One (USF2573) of the five San Franciscan HBV/F isolates, two from Japan (JPF1130 and JPNTAKA), two from Panama (PANAM5 and PANAM6) and two from Venezuela (VENEZ2 and VENEZ4) clustered with the 11 reported HBV/F isolates in phylogenetic trees (Figures 1A-D). The remaining four (USF10, USF1122, USF1778 and USF2065) flocked on a separate branch along with two isolates from Nicaragua and one from Los Angeles, that have been classified into genotype H[4].

Classifying genotype F of HBV into F1 and F2 subtypes

The four strains (USF10, USF1122, USF1778 and USF2065) as well as three reported (LAS2523 [accession no. AY090460], 1853Nic [AY090454], 2928Nic [AY090457]) were compared among one another and against the seven isolates each representative of genotype F (AB064316 [USF2573 isolate]) and the other six genotypes (AB064314 for genotype A, D23678 for B, S75184 for C, D23681 for D, X75657 for E and AF160501 for G) over the full-length sequence and regions thereof (Table 3). In the comparison of the full-length sequence, the seven isolates were similar among themselves in $\geqslant$96.3%, and to the representative HBV/F isolate in $\geqslant$91.0%. They were, however, similar to any representatives of the other six genotypes in only $\leqslant$86.5%.

Table 4 compares homology in the entire nucleotide sequence among the 11 HBV/F isolates examined in this

Table 3 Sequence homology of seven HBV/F2 isolates among themselves and to seven HBV isolates representative of HBV/F1 as well as the other genotypes (A, B, C, D, E, and G)

[1]The seven representatives of each genotype were: F1 (AB064316 [USF2573 isolate]), A (AB064314), B (D23678), C (S75184), D (D23681), E (X75657) and G (AF160501).

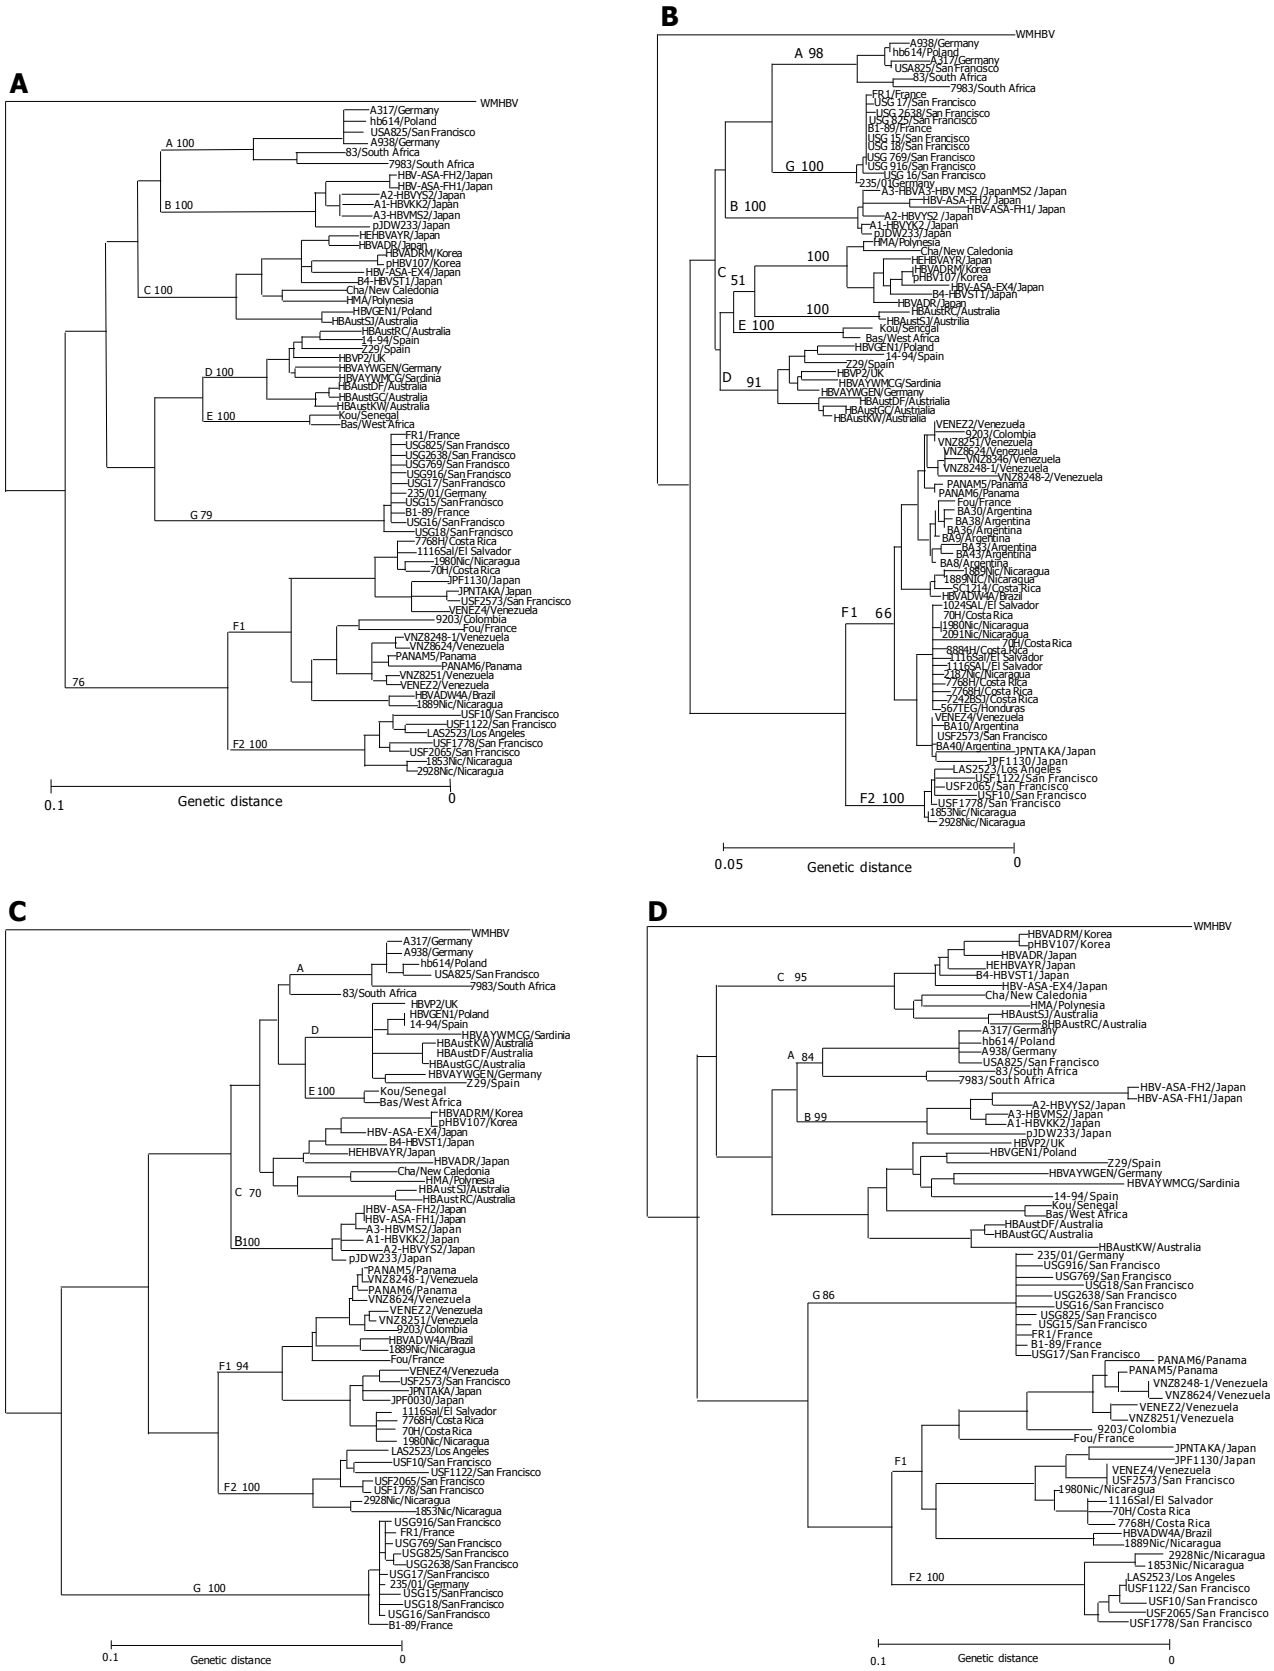

Figure 1 Phylogenetic trees constructed by HBV isolates of the major seven genotypes (A-G) on the full-genome (**A**), S gene (**B**), X gene (**C**) and core gene (**D**). Each tree includes 11 HBV/F isolates identified in this study as well as 59 HBV isolates retrieved from Database, and an additional 22 HBV/F isolates (shown as boldface) joined in the phylogenetic tree of the S region. Confidence values calculated by bootstrap analysis are indicated as a suffix to each genotype.

study and the 13 reported. The sequence divergence among the 7 isolates (USF10, USF1122, USF1778, USF2065, LAS2523, 1853Nic and 2928Nic) and the 10 reported[2,4,12,13] as well as the 7 (USF2573, JPF1130, JPNTAKA, PANAM5, PANAM6, VENEZ2 and VENEZ4) in this study exceeded 7.3%, which fell a little short of clearing a sequence divergence >8% distinguishing the 7 genotypes of HBV[1-3]. It would be appropriate, therefore, to classify the seven isolates into subtypes of genotype F. Thus, F1 subtype (HBV/F1) was assigned to the 11 reported HBV/F isolates and the 7 in this study (USF2573, JPF1130, JPNTAKA, PANAM5, PANAM6, VENEZ2 and VENEZ4) (Figure 1), while F2 subtype (HBV/F2) was consigned to the 7 isolates, 4 from San Francisco (USF10, USF1122, USF1778 and USF2065), 1 from Los Angeles (LAS2523) and 2 from Nicaragua (1853Nic and 2928Nic), all of which were examined in the present study.

Three HBV/F2 isolates examined in this study (USF10, USF1778 and USF2065) had the identical genomic length of 3 215 bp as the original three HBV/F isolates including X69798[12], X75658[2] and AB036905 [13]. The remaining one HBV/F2 isolate (USF1122) had a shorter length of 3 206 bp due to a deletion of 9 bp in the preS2 region. They all possessed 226 amino acids (aa) coded for by the S gene, 29 aa by the preC region, 183 aa by the C gene, 843 aa by the polymerase (P) gene (840 aa for USF1122) and 154 aa by the X gene. The subtype of HBsAg was deduced to be *adw4* in all HBV/F isolates by the expression of Lys^{122}, Leu^{127}, and Lys^{160} [14]. The YMDD motif that is prone to mutation during the lamivudine therapy was identified over aa 549-552 (aa 546-549 in USF1122) with methionine at position 550 (547 in USF1122).

Distribution of genetic distance within the S-gene sequence

Figure 2 illustrates genetic distance in the S-gene sequences of 47 HBV/F1 isolates, 7 HBV/F2 isolates and 136 HBV isolates of the other 6 genotypes (A-E and G). When all of them were compared two-by-two, they clustered into two heaps that were not separated clearly (Figure 2A). The heap with the mean genetic distance of 0.017 represented divergence of HBV isolates among the same genotype (intra-genotype), and that with the mean distance of 0.073 represented divergence between any two HBV isolates of distinct genotypes (inter-genotype). In Figure 2B, the 7 HBV/F2 and 47 HBV/F1 were compared among themselves (F1 *vs* F1 or F2 *vs* F2), each other (F1 *vs* F2) and against the other genotypes. In this two-by-two comparison, the genetic distance was distributed in two clusters of different orders. The genetic distance among 47 HBV/F1 isolates as well as the 7 HBV/F2 isolates stayed within the intra-genotype heap, and that of HBV/F1 as well as HBV/F2 against other genotypes stood within the inter-genotype heap. Notably, the genetic distance between HBV/F1 and HBV/F2 isolates clustered within the heap of intra-genotype. These distinct hierarchical orders of sequence divergence indicated that HBV/F2 would be closer to HBV/F1 than to any HBV isolates of the other six genotypes (A-E and G). Genetic distance in the S-gene sequences of 22 HBV/E isolates, 16 HBV/D isolates and 158 isolates of the other HBV genotypes is shown in the right half of Figure 2B. The genetic distance within HBV/D and HBV/E stayed within the intra-genotype heap, and that of those against the other genotypes as well as that between HBV/D and HBV/E isolates were kept within the inter-genotype heap.

Genotype- or subtype-specific nucleotide substitutions

When all the nucleotide sequences of 68 HBV isolates including 7 HBV/F2 isolates were compared, nucleotide substitutions specific for HBV/F2 were identified at 8 positions (A^{22}, T^{1467}, C^{1552}, G^{1754}, T^{2495}, C^{2628}, C^{3121}, and A^{3129}) (Table 5). Genotype- or subtype-specific nucleotide substitutions clustered within the P gene, and they were unique to each genotype except for genotype A as well as two subtypes of genotype F. Thus, C^{2606} was specific for genotype B, A^{2596} for C, C^{2579}/C^{2634} for D, T^{2603}/C^{2636} for E, C^{2558}/C^{2660} for G, T^{2622} for F1, and C^{2628} for F2.

Genotype- or subtype-specific amino acid substitutions

Substitutions specific for HBV/F2 were identified at the amino acid level within each open reading frame except for the preS2 region. Eight unique amino acid residues were identified within the polymerase (Gln^{92}, Ser^{267}, Thr^{272}, Thr^{275}, Glu^{282}, Thr^{308}, Thr^{313}, and Pro^{823}), four in X (Trp^{32}, Ala^{60}, Pro^{102} and Leu^{127}), two in preS1 (Ala^{8} and Pro^{90}), two in HBsAg (Val^{44} and Pro^{45}) and one in core region (Ala^{157}). Six of the eight (75%) unique amino acid residues identified in the polymerase region were found within the spacer region.

Serotypes of the preS2-region product determined by ELISA

Figure 3 illustrates amino acid sequences of the preS2-region product with reference to the expression of preS2 epitopes detected by four monoclonal antibodies named *b*, *f*, *k*, and *s*[5]. The preS2 epitope *b*, which is common to HBV isolates of any genotypes and borne by a tetramer with the sequence of LYFP[5], was not fully conserved in two of the seven HBV/F2 isolates despite the detection of epitope *b* in their preS2-region products; it was present in all 13 HBV/F1 isolates. The seven HBV/F1 isolates (USF2573, JPF1130, JPNTAKA, PANAM5, PANAM6, VENEZ2, and VENEZ4) had the *bkf* serotype that was compatible with the preS2 serotype assigned to genotype F[5]. Although serotypes of the six reported HBV/F1 isolates were unknown, they all shared the amino acid sequence for the expression of *k* and *f* epitopes; their combination is characteristic of the preS2 serotype (*bkf*) for genotype F[5].

Unlike the 13 HBV/F1 isolates, all the 7 HBV/F2 isolates possessed G as amino acid 19, and therefore, would bind to the monoclonal antibody against *s*[5], for the expression of *bksf* serotype. Thus, the expression of preS2 epitope *s* would be able to differentiate between F2 and F1 subtypes. Taking the other genotypes into consideration, the combination of preS2 serotype of *bksf* with HBsAg serotype *adw* would be specific for HBV/F2, since that with HBsAg serotype *adr* occurs in HBV isolates of genotype C[5,6]. Hence, HBV/F2 can be serologically differentiated

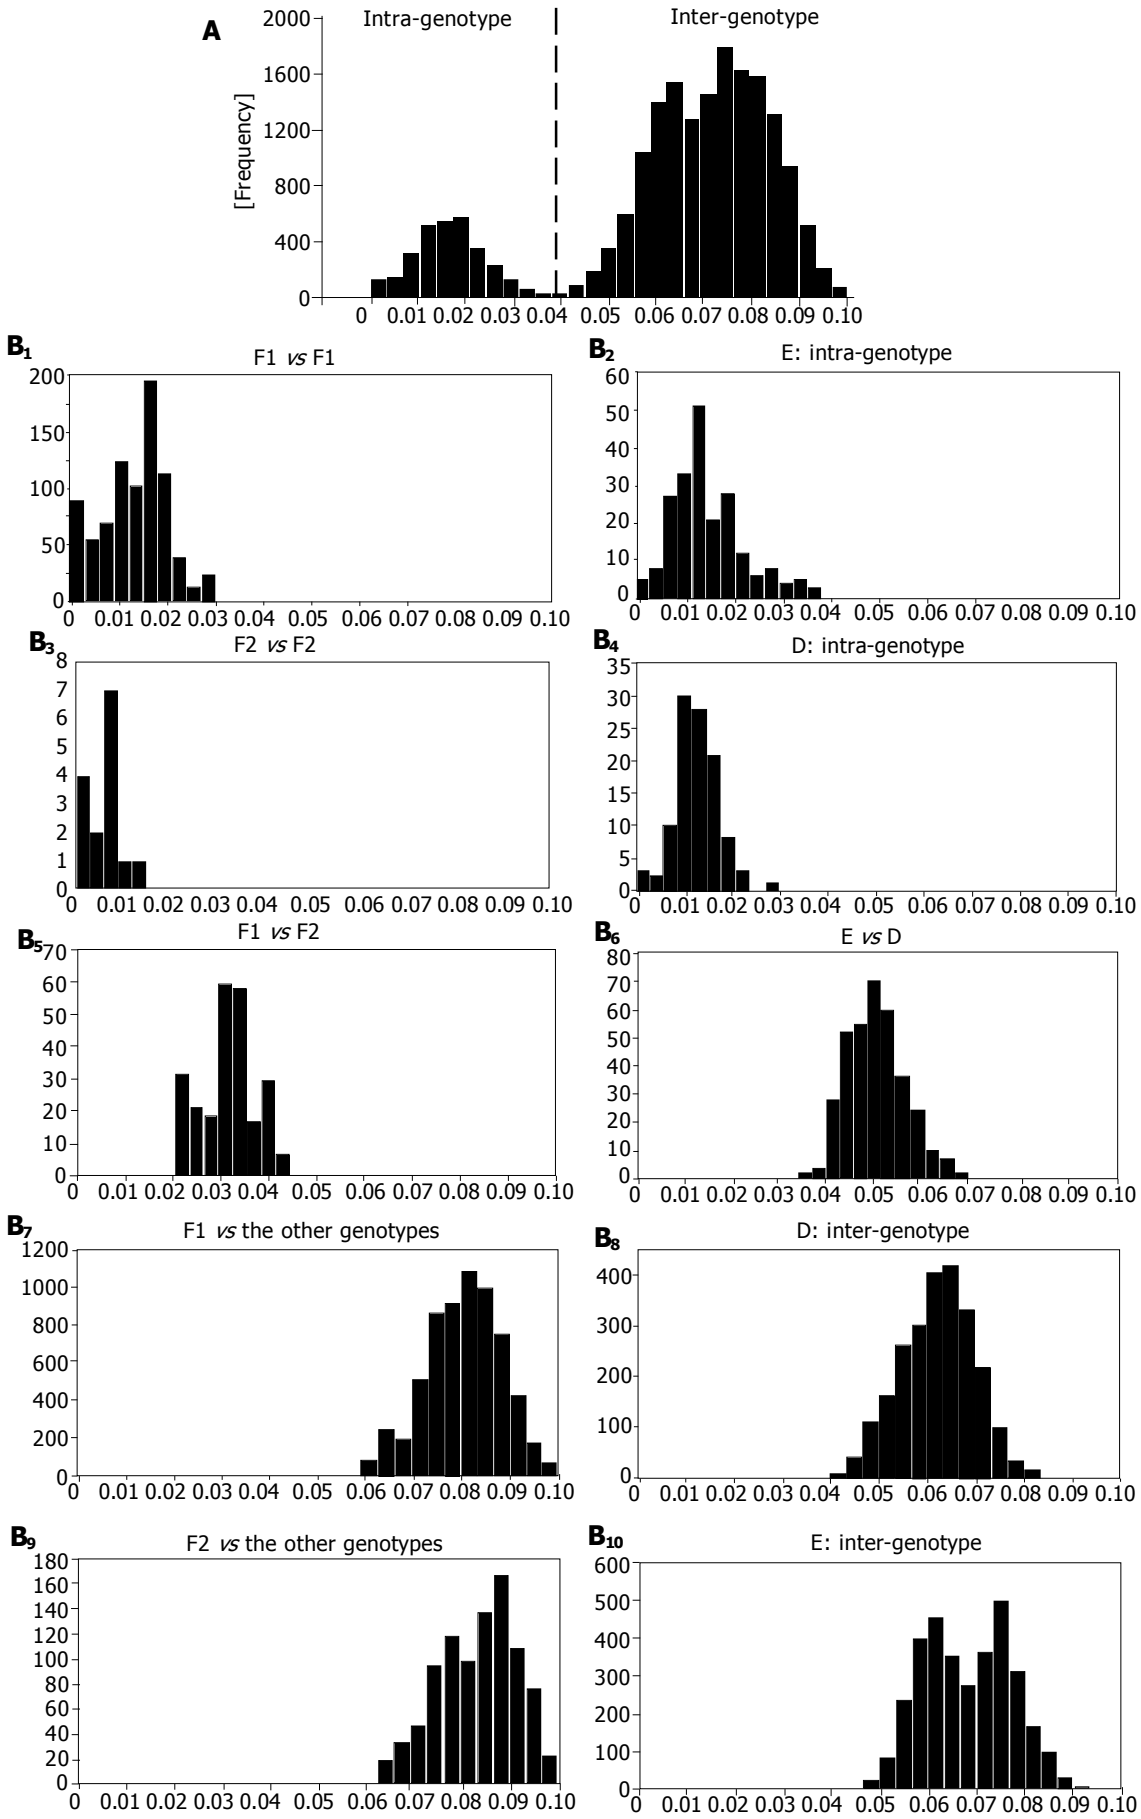

Figure 2 Pair-wise comparison of S-gene sequences. Distribution of genetic distance among HBV isolates of all genotypes (**A**) and that of HBV/F1, HBV/F2, HBV/D, HBV/E, each other and among themselves ($\mathbf{B}_{1\text{-}10}$). Joined in comparison were seven HBV/F2 isolates, 47 HBV/F1 isolates and 136 HBV isolates of the other genotypes. X-axis and y-axis indicate genetic distance and frequency, respectively.

from HBV/F1 as well as the other six genotypes (A-E and G).

DISCUSSION

Of the seven HBV genotypes (A-G), which are defined by a sequence divergence >8% in the entire genomic sequence, F is unique in that it is the remotest (>15%) from the other six genotypes (A-E and G)[2,12,13]. The origin of HBV/F is proposed in the New World, because it is frequent in Central and South America; F is the major HBV genotype in Venezuela and Argentina[15-19]. A remote genetic distance of genotype F from the other six genotypes mirrors the relationship between HBV of woolly monkeys in the New World and HBV species of major apes (orangutans, gibbons, gorillas, and chimpanzees) in the Old World (reviewed in Ref.[20]). Furthermore, human HBV of genotype F is closer to HBV of woolly monkeys than those of the other six genotypes (A-E and G). Combined, these lines of evidence would point to the co-evolution of human HBV of genotype F and HBV of woolly monkeys in the New World since the distant past, as well as their distinction, respectively, from those of the other six HBV genotypes and HBV species of great apes in the Old World.

Originally, four HBV genotypes (A-D) were proposed by sequence divergence in the entire genome >8%[1]. The four genotypes were followed by three others (E-G) defined by the same criterion[2,3]. In the present study, 11 HBV/F isolates were recovered from patients in San Francisco, Japan, Panama and Venezuela, and they were found to cluster into two groups of four (USF10, USF1122, USF1778 and USF2065) and 7 isolates (USF2573, JPF1130, JPNTAKA, PANAM5, PANAM6, VENEZ2, and VENEZ4) in the phylogenetical analysis on the full-length sequence. The 7 HBV/F isolates in 1 group nested on the same branch as reported 11 HBV/F isolates[2,4,12,13], and the remaining 4 flocked on the same branch as 3 isolates reported under the classification of genotype H [4]. The two groups of HBV isolates differed in the full-length sequence by only >7.3% (range: 9.5-7.3; mean: 8.4±0.6%) (IV).

The observed sequence difference of the seven HBV/F isolates, four in this study (USF10, USF1122, USF1778, and USF2065) and three reported (LAS2523, 1853Nic, and 2928Nic), from the others fell in short of clearing >8% separating the seven HBV genotypes, although two of them (USF10 and USF1122) cleared this margin. It has to be pointed out that the >8% distance was set arbitrarily in

Genotype- or subtype-specific nucleotides are shown in boldface, and a dash (–) indicates the nucleotide identical to that of X70185.

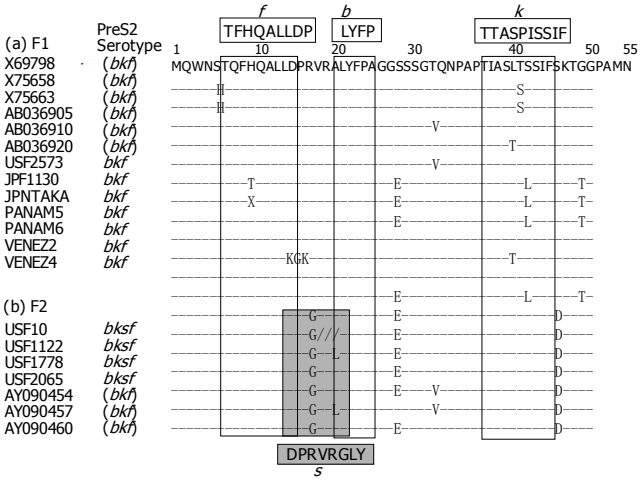

Figure 3 Amino acid sequences of the product of preS2 region of HBV/F isolates. Sequences are shown for the 13 HBV/F isolates of F1 subtype and the 7 of F2 subtype. Epitopes recognized by monoclonal antibodies, used for ELISA for the determination of serotypes[5,6], are shown above and below the nucleotide sequences in columns.

1988 when only a score of HBV isolates with the entire sequence known were available, and before genotype F came along[1]. Although the criterion has helped distinguishing the seven HBV genotypes, it may not be "the gold standard" in genotyping and would need to be modified as new developments arise.

In 1993, Simmonds and his colleagues performed an elegant analysis of HCV isolates by two-by-two comparison of a partial sequence of 222 bp[21]. They found them distribute in three clusters, thereby attesting to the three distinct orders of sequence divergence. They considered a cluster with the shortest evolutionary distance would represent isolate variation, another with a middle distance intra-subtypic variation and the other with the longest distance intra-typic variation. Based on their analysis, they constructed a hierarchical system to classify HCV into six types named by Arabic numbers, each of which breaks down into respective subtypes designated by lower-case alphabet letters. Their classification straightened out a big turmoil created by various nomenclature systems, and has become the standard of HCV genotypes.

The entire sequences of the seven HBV isolates including four in this study (USF10, USF1122, USF1778, and USF2065) and three reported (LAS2523, 1853Nic, and 2928Nic), differing by >7.3% from the other HBV/F isolates[2,12,13], were subjected to the classification method of Simmonds *et al.*[21], within the S-gene sequence (Figure 3). Just like HCV isolates, two clusters with different degrees of genetic distance (intra- and inter-genotypic heap) emerged in the comparison of S-gene sequences of the seven HBV isolates among themselves and against representatives of the seven HBV genotypes (A-G) (Figure 2B). Although the seven HBV isolates were separated from the other HBV/F isolates, they were closer to them than to any HBV isolates of the other six genotypes (A-E and G) in the S-gene sequence.

Bowyer and Sim[22] found ranges of genetic distance among isolates, subtypes and genotypes overlap in the S-gene sequence, thereby preventing distinction between them. In support of their findings, no clear differentiation between isolates and subtypes was observed in pairwise comparison of the S-gene sequence, while genotypes were clearly distinguished from isolates and subtypes (Figure 2A). When looking from HBV/F1 isolates, the genetic distance to HBV/F2 distributed within the intra-genotype range. Hence, it would be justified to classify the four isolates from San Francisco (USF10, USF1122, USF1778, and USF2065) and three reported (LAS2523, 1853Nic, and 2928Nic) into distinct subtypes rather than different genotypes.

On the basis of these analyses, and in hope of avoiding future confusion created by logging into an ever expanding alphabet list of HBV genotypes, four HBV isolates from San Francisco (USF10, USF1122, USF1778, and USF2065) and three reported (LAS2523, 1853Nic, and 2928Nic) would better be classified into subtypes of genotype F, rather than given an independent genotype. Accordingly, the seven variants of HBV/F (USF10, USF1122, USF1778, USF2065, LAS2523, 1853Nic, and 2928Nic) were classified into F2 subtype, while the former HBV/F isolates and the one from San Francisco (USF2573), two from Japan (JPF1130 and JPNTAKA), two from Panama (PANAM5 and PANAM6) and two from Venezuela (VENEZ2 and VENEZ4) into F1 subtype, provisionally. Mbayed *et al.*, have reported four clusters of HBV/F isolates by comparison of S-gene sequences[18,19]. F1 subtype covers Clusters I, II and IV, while F2 subtype corresponds to Cluster III in their classification. As the entire genomic sequences of HBV isolates accumulate, there may be HBV/F isolates that are closer to F1 and F2 than to any of the other six genotypes (A-E and G). They will be assigned F3 and F4 subtypes in the chronological order of sequence determination.

There is a possibility for distinguishing between F1 and F2 subtypes by serological means[5,6]. HBV/F2 isolates expressed a preS2 serotype of *bksf*, in contrast to that of *bkf* in HBV/F1 isolates. The combination of preS2 serotype of *bksf* with HBsAg serotype *adw* appears specific for HBV/F2, distinguishing it from HBV/F1 and the other six genotypes (A-E and G). Serological differentiation of HBV/F2 from HBV/F1 would facilitate their detection in epidemiological and clinical settings. It will allow easy evaluation of F1 and F2 subtypes for different virological virulence and disease-inducing capacity which have been reported for HBV genotypes[23-25].

In classifying microbes, one is tempted to be either a *lumper* who wants to put groups together in a simplified system or a *splitter* who likes to break down a clade into many. In classifying HBV genotypes, one may need to lump or split them as required, taking into considerations virological phylogeny and clinical relevance of each genotype or subtype[26,27]. For instance, there are two subtypes of genotype B, one of which has the recombination with genotype C in the precore region and core gene, while the other does not have it[28]. Because these two subtypes of genotype B influence the response to lamivudine in patients with chronic hepatitis B, they are clinically useful[29]. Our proposal for two subtypes of HBV genotype F based on phylogenetic analysis would be preferred to classifying them into genotypes F and H[4]. The method for serologically distinguishing between subtypes F1 and F2 would facilitate the evaluation of their differences, some of which may turn out to be clinically relevant.

Abstract

AIM: To determine the role of interleukin (IL)-17 in gastric ulcerogenesis.

METHODS: Thirty-six gastric ulcer (GU) patients and 29 non-ulcer (NU) patients were enrolled in this study. Mucosal biopsy samples were obtained from the gastric antrum and GU site during endoscopy. Samples were used in *in situ* stimulation for 48 h in the presence of 10 μg/mL phytohemagglutinin-P (PHA), histological examination, and *Helicobacter pylori* (*H pylori*) culture. IL-17 and IL-8 protein levels in culture supernatants were assayed by ELISA. IL-17 mRNA expression was analyzed by reverse transcriptase-polymerase chain reaction (RT-PCR). *H pylori cagA* and *vacA* status was assessed by reverse hybridization using a line probe assay (LiPA). IL-8 levels in culture supernatants were assayed after AGS cells were co-cultured with *H pylori* strain 26 695 or recombinant human (rh) IL-17.

RESULTS: All 36 GU patients and 15 of 29 NU patients were found to be *H pylori*-positive, while 14 NU patients were *H pylori*-negative. All 51 *H pylori* strains from both GU and NU patients were *cagA*- and *vacA*s1/m1-positive. Antral mucosal tissues from *H pylori*-positive patients contained significantly (*H pylori*-positive NU patients: median 467 pg/mg/protein, range 53-2 499; *H pylori*-negative NU patients: median 104 pg/mg/protein, range 16-312, $P<0.0005$) higher levels of IL-17 than those from uninfected patients. IL-17 levels at the ulcer site were significantly (ulcer site: median 1 356 pg/mg/protein, range 121-1 3730; antrum: median 761 pg/mg/protein, range 24-7 620, $P<0.005$) higher than those at distant sites in the antrum. Biopsies from *H pylori*-positive GU and NU patients showed IL-17 mRNA expression in all samples whereas those from the antrum of the *H pylori*-negative controls showed no detectable expression. A significant correlation was seen between IL-17 and IL-8 levels at each biopsy site (ulcer: $r = 0.62$, $P<0.0001$; antrum: $r = 0.61$, $P<0.0001$) in GU patients. RhIL-17 and *H pylori* strain 26 695 each stimulated IL-8 production from AGS cells.

CONCLUSION: IL-17 may play an important role in the inflammatory response to *H pylori* colonization, and may ultimately influence the outcome of *H pylori*-associated diseases that arise within the context of gastritis.

INTRODUCTION

Helicobacter pylori (*H pylori*), a microaerophilic, Gram-negative bacterium that selectively colonizes the human stomach, is the major cause of chronic active gastritis and peptic ulcer disease[1-3]. In *H pylori* infection, neutrophils are present within epithelial glands and the underlying lamina propria, and an increase in chronic inflammatory cells such as lymphocytes, macrophages, eosinophils, and plasma cells is also found in the lamina propria[4-8]. Recent studies have shown that *H pylori* produces various cytokines that are related to neutrophil or mononuclear cell accumulation, such as interleukin-β (IL-1β), interferon (IFN)-γ, IL-6, IL-8, tumor necrosis factor (TNF)-α and MIP-1α[7-10]. Among these cytokines, IL-8, the major human PMN chemoattractant, plays an important role in *H pylori*-associated acute inflammatory responses[7,8,11]. IL-8 mRNA has been detected in the vast majority of antral biopsy tissues from *H pylori*-positive patients[8], indicating that *H pylori*-infected gastric mucosa is an active site of IL-8 synthesis. It was reported that IL-8 activity increases at ulcer sites[12], a finding which may be important to gastric ulcerogenesis.

IL-17, originally identified as cytotoxic T lymphocyte-associated antigen 8 (CTLA-8)[13], is a proinflammatory cytokine derived mainly from activated T cells[14-16]. A number of recently discovered related molecules form a family of

cytokines, the IL-17 family, and have been designated as IL-17A-F, with the prototype member being IL-17A[13,17-22]. IL-17A is produced exclusively by $CD4^+$ activated T cells[13,23], and more specifically by $CD4^+CD45RO^+$ memory T cells[18,24]. The human IL-17A gene product is a protein of 155 amino acids with a molecular weight of 20-30 ku which is secreted as a disulfide-linked homodimer of a 30-35-ku glycoprotein[25,26]. IL-17 stimulates IL-8 release by gastric epithelial cells and facilitates the chemotaxis of neutrophils through an IL-8-dependent mechanism, and contributes to the enhancement of IL-8 levels in *H pylori*-colonized gastric mucosa[27].

Recently, several *H pylori* genes related to an increased risk of disease have been identified[28]. The cytotoxin-associated gene (*cagA*) is a marker for the *cag* island, the presence of which is associated with a more severe clinical outcome[29-32]. *vacA* encodes a protein that induces vacuoles in epithelial cells[33]. *vacA* is present in all *H pylori* strains and contains at least two variable regions[34]. The s-region (encoding the signal peptide) exists as a s1 (including s1a, s1b, and s1c) or a s2 allelic type[35], while the m-region (middle) occurs as a m1 or a m2 allelic type. It was reported that *vacA*s1/m1 *H pylori* strains are more strongly associated with disease than *cagA*-negative *vacA*s2/m2 strains[36,37]. The evaluation of these genes is therefore an essential part of any investigation into the association between *H pylori* infection and pathogenesis.

In view of evidence that the eradication of *H pylori* reduces the risk of peptic ulcer recurrence[38] and ameliorates associated gastric inflammatory changes and chemokine production in the background gastric mucosa[7,8], clarification of the pathogenesis of *H pylori*-positive peptic ulcer disease requires an understanding of the host inflammatory response to this pathogen. We hypothesized that IL-17 secreted at the ulcer site might play a role in ulcerogenesis through the mucosal damage caused by the emigration and activation of various inflammatory effector cells together with IL-8. In the present study, we examined the secretion of IL-17 and expression of IL-17 mRNA using biopsy specimens from the ulcer site in 36 gastric ulcer (GU) patients with *H pylori* infection, and compared results to the severity of gastritis and IL-8 levels.

MATERIALS AND METHODS

Study groups and mucosal biopsy samples

Mucosal biopsy samples were obtained from the gastric antrum and ulcer site in 36 patients with GU, 15 with *H pylori* infection but without ulcers and 14 without either *H pylori* infection or ulcers whose conditions were diagnosed during upper gastroduodenal endoscopic examination in Nagoya University Hospital from October 2001 to January 2002 (Table 1). Thirteen patients had an active open ulcer and 23 had ulcer scaring. None of the patients took non-steroidal anti-inflammatory drugs, antibiotics or bismuth compounds during the preceding 3 mo. Six antral specimens were taken from adjacent areas of endoscopically intact mucosa in the GU and control patients, with one for bacterial culture, and rapid urease test (CLO test; Delta West, Bentley, Australia) and histological examination, and three for *in vitro* organ cultures for IL-17 and IL-8 measurement. Four additional specimens were taken from the margin of the open ulcer or the center of the ulcer scar in GU patients, one for histological examination and three for IL-17 and IL-8 measurement. All samples were obtained under informed consent in accordance with the Helsinki Declaration. *H pylori* infection was confirmed by positive results in at least two of four diagnostic methods, namely bacterial culture, rapid urease test, [^{13}C]-urea breath test and identification of the organism on tissue sections (Giemsa stain). The absence of infection was defined by a negative result in all the four tests.

Table 1 Characteristics of study groups (mean±SD)

	Patients (*n*)	Sex (male/female)	Age (yr)
GU	36	27/9	57.8±8.4
H pylori-positive			
Open ulcer	13	12/1	56.5±9.5

Organ culture

Mucosal biopsy tissues were weighed and cultured in a 50 mL/L CO_2 incubator for 48 h on a culture insert (Falcon, Oxnard, CA, USA) placed over polystyrene plates (Falcon) containing RPMI 1640 (Life Technologies, Inc., Rockville, MD, USA) medium with 5% heat-inactivated fetal calf serum, 15 mmol/L HEPES buffer, 100 U/mL of penicillin-G, and 100 μg/mL of streptomycin (culture medium) under the conditions of 10 μg/mL of phytohemagglutinin-P (PHA; Sigma Chemical Co., St. Louis, MO, USA). At the end of the culture period the supernatants were collected and kept at -70 ℃ until assayed for IL-17 and IL-8 levels. Total protein in biopsy homogenates was assayed by a modification of the Lowry method.

Histology

In accordance with the updated Sydney system[6], activity (neutrophil infiltration), inflammation (mononuclear cell infiltration), glandular atrophy and intestinal metaplasia and *H pylori* density were assessed on a four-grade scale of 0, 1, 2, and 3 (corresponding to none, mild, moderate, and severe in the Sydney system) using tissue sections stained with hematoxylin-eosin and those stained with Giemsa. In addition, the numbers of neutrophils and mononuclear cells infiltrating the lamina propria were counted in five high-power fields (×200 magnification). Respective numbers were classified into four grades of 0, 1, 2, and 3. All histologic evaluations were conducted without the knowledge of *H pylori* status or experimental results.

Cell cultures

AGS human gastric epithelial cells (American Type Culture Collection CRL 1739) were grown in RPMI 1640 supplemented with 10% fetal bovine serum (FBS) and

gentamicin 20 μg/mL in an atmosphere of 50 mL/L CO_2 at 37 ℃. For coculture experiments, *H pylori* was grown in brucella broth with 5% FBS for 48 h. Cells were harvested by centrifugation (2 000 r/min) and resuspended in antibiotic-free RPMI 1640 with 10% FBS to yield a final concentration of 10^9 CFU/mL. *H pylori* was added to AGS cells at a bacteria/cell ratio of 1 000:1 for the IL-8 assay. Experiments were performed in antibiotic-free medium with 10% FBS using T-150 flasks (Corning Costar, Cambridge, MS, USA) or 6-well polypropylene tissue culture plates (Becton Dickinson, Franklin Lakes, NJ, USA).

IL-17 and IL-8 assay

IL-17 and IL-8 protein levels in culture supernatants were assayed in duplicate using ELISA kits specific for IL-17 (R&D Systems, Minneapolis, MN, USA) and IL-8 (Biosource International, Camarillo, CA, USA) according to the manufacturer's instructions. In these assays, the lower limits of detection were 15 pg/mL for IL-17 and <5.0 pg/mL for IL-8. The amount of IL-17 and IL-8 in the organ cultures was expressed relative to protein content in the homogenate of biopsy tissues (IL-17, pg/mg protein; IL-8, ng/mg protein).

Extraction of RNA and RT-PCR amplification for human IL-17 mRNA

RNA was extracted from freshly obtained biopsy tissue by the acid guanidinium thiocyanate-phenol-chloroform method[41]. As a positive control, RNA was also extracted from peripheral blood mononuclear cells (PBMC) stimulated with PHA for 3 h. Two micrograms of extracted RNA was reverse-transcribed into first-stand complementary DNA (cDNA) at 42 ℃ for 1 h using 0.5 μL of Rous-associated virus 2 reverse-transcriptase (Takara Biomedicals, Ohtsu, Japan) and 0.1 μmol/L of oligo d(T) (Amersham Pharmacia Biotech, UK) in a 50-μL reaction mixture. Twenty-five microliters of cDNA from samples was amplified with 0.2 μmol/L of the sense and anti-sense primers for β-actin or IL-17 in a 100 μL reaction mixture containing 0.5 μL of Taq polymerase (Promega Corporation, Madison, WI, USA) for 35 cycles of denaturation at 94 ℃ for 1 min, annealing at 55 ℃ for 1 min, and extension at 72 ℃ for 2 min in a DNA thermal cycler (Perkin Elmer Cetus, Norwalk, CO, USA). PCR primers were as follows: β-actin, 5'-GTG GGG CGC CCC AGG CAC CA-3' and 5'-CTC CTT AAT GTC ACG CAG GAT TTC-3'[42], and IL-17, 5'-AGA GAT ATC CCT CTG TG ATC-3' and 5'-TAC CCC AAA GTT ATC TCA -3'[43]. Negative controls for PCR amplification were prepared by omitting the cDNA sample from the reaction mixture. The amplified products were subjected to electrophoresis in an 1.5% agarose gel containing ethidium bromide and visualized by UV transillumination.

Assessment of H pylori cagA and vacA status

A chloroform-phenol extraction method was used to obtain DNA from the *H pylori* isolates as previously described[44]. *cagA* and *vacA* status was assessed by reverse hybridization using a line probe assay (LiPA)[45].

Statistical analysis

Statistical analysis was performed using the Mann-Whitney *U* and paired tests and linear regression analysis. The results were expressed as mean±SD. $P<0.05$ was considered statistically significant.

RESULTS

Mucosal IL-17 and IL-8 levels

Mucosal IL-17 (Figure 1A) and IL-8 (Figure 1B) levels were determined using *in vitro* organ cultures of mucosal tissues taken from the gastric antrum and ulcer site of 36 patients with GU and from the gastric antrum of 29 patients with non-ulcer (NU) under PHA stimulation. Among the 36 GU patients, the ulcer was located in the corpus in 27 and in the antrum in 9. Culture supernatants contained measurable levels of IL-17 and IL-8 in both *H pylori*-positive and -negative subjects. IL-17 levels were significantly higher in antral mucosal tissues from GU (median 761 pg/mg protein, range 24-7 620: $P<0.0001$) and *H pylori*-positive NU patients (median 467 pg/mg protein, range 53-2 499: $P<0.0005$) than in those from *H pylori*-negative NU patients (median 104 pg/mg protein, range 16-312). There was no significant difference in IL-17 levels in the supernatants of antral gastric tissue between GU and *H pylori*-positive NU patients. Levels were significantly higher in mucosal tissues from the ulcer site of GU patients (median 1 356, range 121-13 730) than in those from the antrum of any patient group, including GU patients themselves (median 466, range 24-7620: $P<0.05$, Figure 1A). IL-8 levels were significantly higher in mucosal tissues of the antrum from GU (median 30 ng/mg protein, range 3-261: $P<0.0001$) and *H pylori*-positive NU patients (median 38 ng/mg protein, range 7-107: $P<0.0005$)

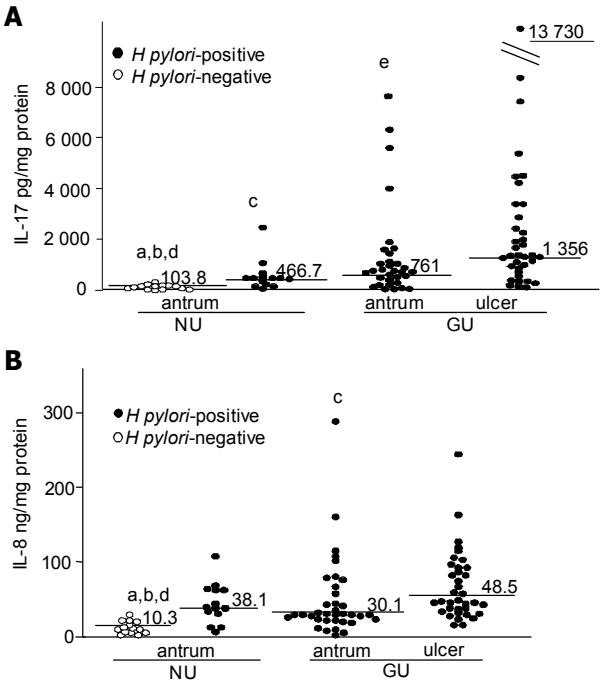

Figure 1 Levels of IL-17 (**A**) and IL-8 (**B**) secreted in organ cultures of biopsies from *H pylori*-positive (closed circle) and -negative (open circle) patients. The bar indicates the median value for each group. **A**: [a]$P<0.0005$ a *vs* b, [b]$P<0.0001$ a *vs* c, [c]$P<0.0005$ b *vs* c, [d]$P<0.0001$ a *vs* d, [e]$P<0.0005$ c *vs* d; **B**: [a]$P<0.0005$ a *vs* b, [b]$P<0.0001$ a *vs* c, [c]$P<0.0005$ a *vs* d, [d]$P<0.0001$ a *vs* d (NS:not significant).

than in those from *H pylori*-negative NU patients (median 10 ng/mg protein, range 1-22). There was no significant difference in IL-8 levels in the supernatant of gastric tissue from the antrum between GU and *H pylori*-positive NU patients. Levels were also significantly higher in mucosal tissues of the ulcer site of GU patients (median 49, range 15-164) than in those from the antrum of any patient group, including GU patients themselves (median 30, range 1-161: $P<0.05$, Figure 1B). There was a significant relationship between IL-17 and IL-8 levels in both antrum ($r = 0.61$, $P<0.0001$, Figure 2A) and ulcer site ($r = 0.62$, $P<0.001$, Figure 2B). With regard to ulcer stage in GU patients, there was no significant difference in IL-17 and IL-8 levels between samples from open ulcers (Figure 3A) and ulcer scars (Figure 3B).

Cytokine levels and histological findings

The association between cytokine levels and histological findings was investigated by comparing levels of IL-17 and IL-8 secretion *in vitro* with the severity of gastritis (activity, inflammation, atrophy, and metaplasia). A significant association was identified between IL-17 and IL-8 levels and the histological degree of activity and inflammation, but IL-17 and IL-8 levels were not associated with the degree of glandular atrophy or intestinal metaplasia (data not shown). The association was further investigated by quantifying the number of infiltrating neutrophils and mononuclear cells. In the antrum, IL-17 showed a stronger association ($r = 0.55$, $P<0.0001$) with the number of infiltrating mononuclear cells than IL-8 ($r = 0.45$, $P<0.0005$), whereas IL-17 ($r = 0.51$, $P<0.0001$) and IL-8 ($r = 0.54$, $P<0.0001$) showed a similarly strong association with the number of neutrophils. At the ulcer site, IL-17 had a stronger correlation with mononuclear cells (IL-17: $r = 0.64$, $P<0.0001$; IL-8: $r = 0.38$, $P = 0.012$, Figures 4A and B) and neutrophils (IL-17: $r = 0.74$, $P<0.0001$; IL-8: $r = 0.44$, $P = 0.078$) than IL-8 (Figures 4C and D).

IL-17 mRNA expression

The potential of gastric mucosa to synthesize IL-17 was studied by RT-PCR analysis using biopsy specimens from the ulcer sites and antrum of 5 *H pylori*-positive GU patients, and from the antrum of 5 *H pylori*-positive and 5 *H pylori*-negative NU patients. Consistent with the enhanced activity of IL-17 identified in organ cultures, all fresh biopsy specimens from the ulcer sites and antrum of *H pylori*-positive GU or NU patients had detectable IL-17 mRNA expression (IL-17: GU patients; ulcer sites 5/5, antrum 5/5, NU patients; antrum 5/5) (Figure 5). In contrast, IL-17 transcripts were not detected in any of the 5 *H pylori*-negative NU patients.

Effect of IL-17 on IL-8 production in AGS cells

To further investigate the role of IL-17 in the induction of IL-8 in gastric mucosa, we tested the effect of recombinant human (rh) IL-17 on the secretion of IL-8 by AGS cells (Figure 6). Stimulation of AGS cells cultured with graded doses of rhIL-17 at 1, 10 or 100 ng/mL for 24 h was followed by a dose-dependent increase in IL-8 secretion as measured by ELISA compared to unstimulated cell culture

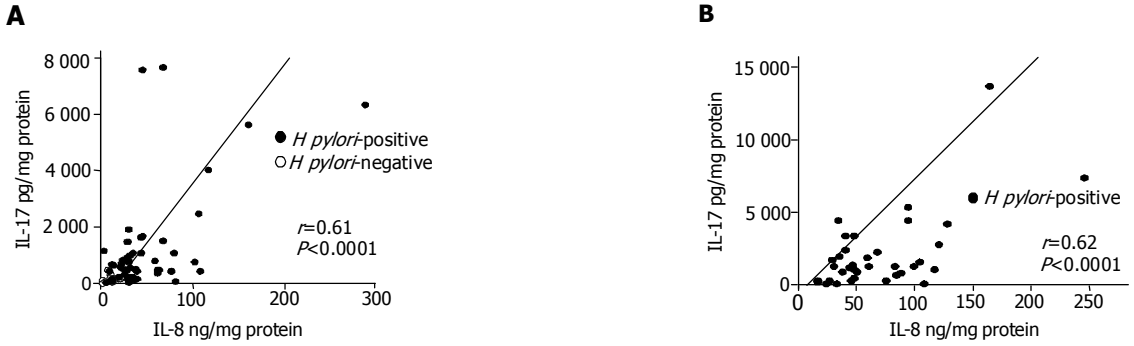

Figure 2 Relationship between IL-17 and IL-8 levels in biopsy culture supernatants from antrum (**A**) and ulcer site (**B**). The bar indicates the median value for each group.

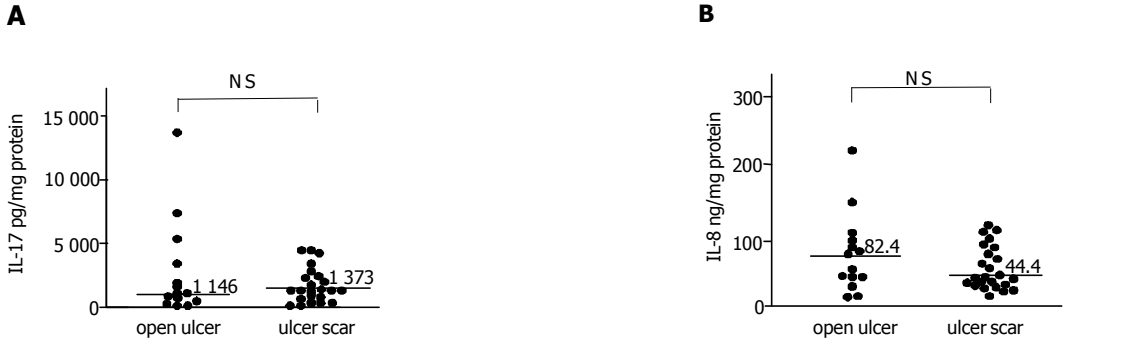

Figure 3 IL-17 (**A**) and IL-8 (**B**) levels in biopsy culture supernatants of GU patients according to ulcer stage.

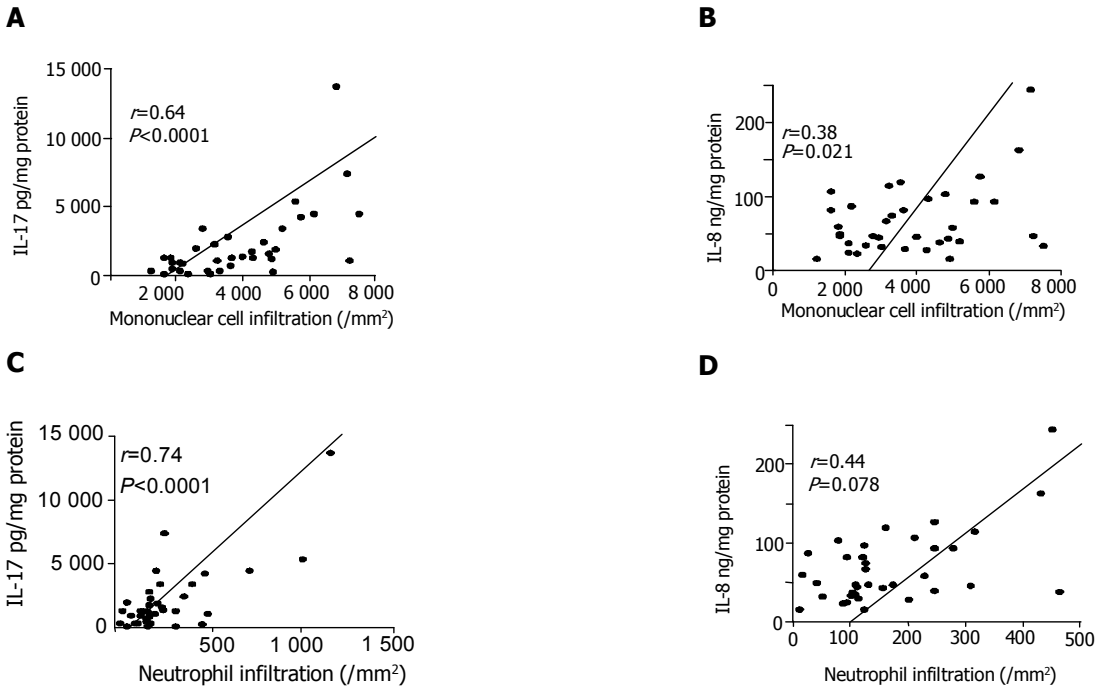

Figure 4 Relationship between IL-17 (**A** and **C**) or IL-8 (**B** and **D**) levels and mononuclear cell infiltration or neutrophil infiltration at ulcer sites.

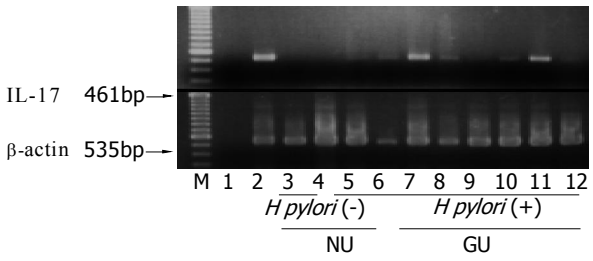

Figure 5 RT-PCR analysis of IL-17 and β-actin mRNA. M: 100-bp ladder marker; lane 1: negative (no cDNA sample); lane 2: positive control (PBMC stimulated by PHA for 3 h); lanes 3 and 4: antral biopsies from *H pylori*-negative NU patients with endoscopically normal mucosa; lanes 5 and 6: antral biopsies from *H pylori*-positive NU patients with gastritis; lanes 7, 9, and 11: antral biopsies from *H pylori*-positive GU patients; lanes 8, 10, and 12: mucosal biopsies from the ulcer site of *H pylori*-positive GU patients.

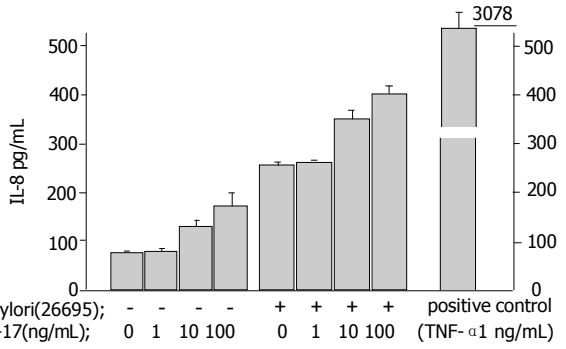

Figure 6 IL-8 levels in culture supernatants of AGS cells co-cultured with graded doses of rhIL-17, *H pylori* strain 26 695, or both.

supernatants. The addition of *H pylori* strain 26 695 to the cell culture at any concentration of rhIL-17 produced a further increase in IL-8 production.

Assessment of H pylori cagA and vacA status

Determination of genotype of *H pylori* strains isolated from GU and NU patients by LiPA confirmed that all 51 strains (GU, n = 36; NU, n = 15) were *cagA*-positive *vacA*s1/m1 (Table 2). Most strains were *vacA* subtype s1c, while the rest were *vacA* s1a. Thus, GU and NU patients had a similar *cagA* and *vacA*s1/m1 status.

DISCUSSION

On the basis of previous findings that IL-8 production increases at the ulcer site in patients with GU[12] and that IL-17 has the ability to stimulate IL-8 production in both epithelial cells[27] and fibroblasts[22], we investigated the production of IL-17 at ulcer and exogenous NU sites in GU patients. Among 36 GU patients, the ulcer was located in the corpus in 27 and in the antrum in 9. In preliminary studies to determine the site of biopsy for IL-17 measurement, IL-17 production in the antrum, corpus, and ulcer site was compared in 10 patients (5 GU and 5 gastritis). Because specimens from the corpus and the antrum showed no significant difference in IL-17 production (data not shown), specimens for comparison to the ulcer site were limited to the antrum to reduce the number of gastric biopsies. Our results show that IL-17 and IL-8 activities in organ cultures of biopsy specimens from the antrum are substantially higher in *H pylori*-positive patients than in *H pylori* -negative patients, and that among *H pylori*-infected GU patients, the gastric mucosa at the ulcer sites contains significantly more IL-17 and IL-8 than the mucosa of the antrum.

Further, IL-17 and IL-8 levels were significantly correlated with the number of infiltrating mononuclear cells

Table 2 *H pylori cagA* and *vacA* gene status

		cagA status		*vacA* status					
				Signal region				Middle region	
	n	Positive	Negative	s1a	s1b	s1c	s2	m1	m2
GU	36	36	0	5	0	31	0	36	0
NU	15	15	0	2	0	13	0	15	0
Total	51	51	0	7	0	44	0	51	0

and neutrophils at both antral and ulcer sites, suggesting that IL-17 and IL-8 generated locally within the gastric mucosa, may be relevant to the background histological gastritis caused by *H pylori* infection. IL-17 and IL-8 levels in the antrum showed significant associations with the number of infiltrating mononuclear cells and neutrophils. At the ulcer site, however, IL-17 had a stronger correlation with mononuclear cells and neutrophils than IL-8, and a stronger correlation with neutrophils than with mononuclear cells. IL-17 and IL-8 have been reported to cause neutrophil recruitment[44], and neutrophils are known to cause damage to tissues they infiltrate[27]. On the basis of these results, we hypothesize that, together with IL-8, IL-17 might contribute to ulcerogenesis in GU patients as a result of its induction of neutrophil recruitment at the ulcer site.

When IL-17 and IL-8 levels in gastric mucosa at the ulcer site were compared between GU patients in the active stage and those in the healed stage, no significant difference was seen. Moreover, comparison of infiltrating neutrophils and mononuclear cells at ulcer site between ulcer stages showed no significant difference in IL-17 and IL-8 levels (data not shown). These results suggest that immunological background might not differ by GU stage, but might rather be fundamentally the same, regardless of stage.

Another important finding is the significant correlation between IL-17 and IL-8 levels at both the antrum and ulcer site. As this indicates a likely association between IL-17 and IL-8, we subsequently examined the effect of IL-17 as well as *H pylori* on IL-8 production by AGS cells. Co-culture of AGS cells with *H pylori* strain 26 695, in the presence or absence of rhIL-17, showed that both *H pylori* strain 26 695 and rhIL-17 stimulated IL-8 production from AGS cells.

Consistent with the increased secretion of IL-17 protein in organ cultures, biopsies from *H pylori*-positive GU and NU patients contained mRNA for this cytokine in all samples tested, but no expression in samples from the antrum of *H pylori*-negative controls. We previously reported that IL-8 mRNA expression is often detected in gastric biopsy tissues from *H pylori*-positive patients, but rarely in those from *H pylori*-negative controls[7], indicating that gastric mucosa is an active site for the synthesis of both IL-17 and IL-8 in *H pylori*-infected GU patients. Considering that IL-17 and IL-8 induce exocytosis and a respiratory burst in neutrophils[46], we hypothesize that locally secreted IL-17 and IL-8 are biologically active key chemotactic factors for the recruitment and activation of neutrophils, particularly at ulcer sites in *H pylori*-infected GU patients. We additionally speculate that enhanced synthesis and secretion of IL-17 and IL-8 may contribute to ulcerogenesis in *H pylori*-infected patients.

In conclusion, IL-17 and IL-8 may play an important role in the inflammatory response to *H pylori* colonization, and may ultimately influence the outcome of *H pylori*-associated diseases arising within the context of gastritis. Further studies are necessary to determine the mechanisms of this elevation in mucosal IL-17 and IL-8 activity in *H pylori* infection.

Abstract

AIM: To investigate their expression and activity in the rat ileum after exposure to ionizing radiation along with that of the cellular effectors and molecular mediators involved in the regulation of MMPs.

METHODS: Rats were exposed to a single 10-Gy dose of X-rays delivered to the abdomen. A combination of methods, such as zymography, immunohistochemistry and real time reverse transcriptase-polymerase chain reaction, were used to localize and quantify MMPs and the molecules involved in MMP activating and inhibitory pathways (plasmin/plasminogen, TIMPs), CD8+, as well as inflammatory (interleukin (IL)-1β, IL-8, tumor necrosis factor-α, TNF-α) and fibrogenic mediators (transforming growth factor-β1-3) within ileal tissue at 1, 3, and 7 d after irradiation.

RESULTS: A marked increase in MMP-2 and -14 mRNA and protein levels associated with an increased activity of MMP-2 was observed in irradiated ileal tissue. MMP-2 and -14 expression was mainly observed in inflammatory, epithelial, and mesenchymal cells, whereas a slight increase in MMP-3 expression was detected in the few infiltrating macrophages at d 1 after irradiation. Conversely, MMP-1, -7, and -9 mRNA levels were not found to be affected by abdominal irradiation. Irradiation was found to induce disappearance of CD8+ cells. Furthermore, we have observed that TNF-α and IL-1β protein levels increased 6 h after irradiation, whereas those of IL-8 only increased after 3 d and was concomitant with neutrophil infiltration. In addition, the expressions of molecules involved in MMP activating and inhibitory pathways (urokinase-type plasminogen activator and tissue-type plasminogen activator; TIMP-1, TIMP-2, and plasminogen activator-inhibitor-1) were found to be increased after abdominal irradiation.

CONCLUSION: This study showed that abdominal irradiation induces an acute remodeling of the ileum associated with an increased expression of MMPs and TIMPs that do not involve CD8+ T cells but involve mesenchymal and epithelial cells, although to a lesser extent, and probably even soluble inflammatory and fibrogenic mediators.

INTRODUCTION

Acute intestinal toxicity may occur in response to therapeutic or accidental exposure to ionizing radiation. At the histopathological level, it is characterized by a decrease in the depth of the intestinal crypts and the height of the villi. It is associated with basement membrane degradation, and ultimately leads to mucosal barrier breakdown and ulceration. Classical radiation-induced toxicity symptoms include diarrhea, malabsorption, and protein losing enteropathy[1]. Depending on the delivered dose of radiation, a restoration phase involving desquamation and re-epithelialization may occur. This requires extracellular matrix (ECM) remodeling, a process in which proteases and especially matrix metalloproteinases (MMPs) play an essential role[2], and which is associated with the overexpression of inflammatory and fibrogenic cytokines, such as interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α) and transforming growth factor-β (TGF-β)[3,4].

Cell adhesion, migration, proliferation, and differentiation are required for complete wound healing and rely on interactions between cells and the ECM. Normal wound–ECM interactions are therefore essential to wound healing. The rate, quality/effectiveness, and organization of this process are determined

by a dynamic balance between overall matrix synthesis, deposition, and degradation. Disruption of this balance likely induces abnormal matrix degradation or accumulation. MMPs are a large family of zinc-dependent matrix degrading enzymes, involved in the fine tuning of ECM homeostasis. MMPs are classified, based on their substrate specificity and structural features, into six categories: gelatinases (MMP-2 and -9), stromelysins (MMP-3, -10, and -11), elastases (MMP-12), collagenases (MMP-1, -8, -13, and -18), matrilysins (MMP-7 and -26) and membrane-type MMPs (MMP-14, -15, -16, and -17)[2]. The primary regulatory mechanism of MMP activity occurs at the transcriptional level and consists of a variety of extracellular signals involving cytokines, growth factors, and cell–matrix interactions[5,6]. MMPs are then secreted as zymogens, which require prior proteolytic activation. *In vivo* activation of pro-MMPs is mainly mediated through the plasminogen–plasmin system, but MMPs themselves may also be involved. The third level of regulation is ensured by the physiological inhibitors of MMPs, which include tissue inhibitors of metalloproteinases (TIMPs). Four subtypes of TIMPs (TIMP 1-4) have been identified so far[7]. TIMP-1 inhibits several MMPs, while TIMP-2 seems to specifically inhibit MMP-2.

Overexpression of MMPs has been known to occur in both physiological and pathological conditions and to involve tissue restoration and/or destruction. Many studies reported that the alteration of ECM remodeling and MMP/TIMP expression occur in inflammatory bowel diseases[8-12]. Furthermore, some studies showed that T cells play a central role in the activation of MMPs in inflammatory bowel diseases[13,14]. However, few studies have examined the role of MMPs in radiation-induced gastrointestinal disorders. After intraoperative irradiation, Seifert *et al.*[15], observed a prolonged gelatinolytic activity in rat colonic anastomoses. Two clinical studies conducted in patients reported controversial data. Hovdenak *et al.*[16], observed increased MMP-2 and MMP-9 expression after irradiation, while Kumar *et al.*[17], did not. In this study, we aimed at confirming that observations made on gelatinases also applied to other types of MMPs. We investigated the expression of MMPs after abdominal X-irradiation and their activating and inhibitory systems (i.e., plasminogen/plasmin and TIMP-1 and -2). We simultaneously investigated the stimulatory signals and focused on the expression of pro-inflammatory (TNF-α, IL-1β) and fibrogenic cytokines (TGF-β) in the ileum after irradiation. Finally, we investigated the involvement of CD8a+T cells in MMP activation after irradiation. The results presented in this study show that irradiation induces a moderate inflammatory state, a significantly increased expression of MMP-2, MMP-14, TIMP-1, and TIMP-2, and the disappearance of CD8a+T cells.

MATERIALS AND METHODS

Animals and irradiation conditions

Experiments were performed using male Wistar rats (Janvier, Le Genest Saint Isle, France), weighing initially between 225 and 250 g. Prior to irradiation, rats were anesthetized by groups of six with 2.5% isoflurane, administered at a rate of 0.4 L/min (Abbott, Rungis, France). A protective lead screen (5 mm thick) was placed over each animal to cover them from the top of the head to 1 cm below the ribs. The given dose was 10 Gy at a rate of 0.62 Gy/min (Phillips, 250 MeV, 0.2-mm Cu filter). Sham-irradiated rats were placed within the apparatus and anesthetized, but were not exposed to X-rays. Animals were weighed and food intake was measured 10 d before exposure to radiation and daily during the week following irradiation. All experiments were conducted according to the French regulations on animal experimentation (Ministry of Agriculture, Act No. 87-848, October 19, 1987).

Tissue collection

One, three, and seven days after irradiation, rats were anesthetized with 2.5% isoflurane and the terminal ileum was removed before euthanasia (sodium pentobarbitone, 100 mg/kg, ip; Sanofi, La Ballastière, France) and rinsed with sterile physiological saline. The ileum was cut into three equal pieces immediately after resection: The tissue samples were formalin-fixed for histology, frozen in liquid nitrogen, and crushed into powder for RNA and protein extraction.

Histology

Samples were fixed in 40 g/L formaldehyde (Carlo Erba, Rueil Malmaison, France) for 3 d at room temperature. They were then dehydrated, paraffin-embedded, and cut into 4-μm-thick sections. Slides were stained with hematoxylin, eosin, and saffron for histological analysis.

Immunostaining

MMP and TIMP antibodies were purchased from Chemicon (Euromedex, Mundolshiem, France) and used as follows: anti-MMP-1 (41-1E5, 1:15 000), anti-MMP-2 (42-5D11, 1:200), anti-MMP-3 (SL-1 IIIC4, 1:200), anti-MMP-7 (ID-2, 1:300), anti-MMP-14 (113-5B7, 1:500), anti-TIMP-1 (102B1, 1:50), and anti-TIMP-2 (67-4H11, 1:1 000). The anti-myeloperoxidase antibody was from Novocastra (Tébu, Le Perray en Yvelines, France; NCL MYELOp, 1:300) and the anti-CD8a antibody was from Cedarlane (Tébu; CL004AP, 1:600).

Following deparaffinization and rehydration, endogenous peroxidase activity was inhibited with 30 mL/L hydrogen peroxide in PBS. In order to detect MMP-3, MMP-7, and CD8a epitopes, sections were placed in 0.01 mol/L hot citrate buffer (pH 6.0). The protein block serum-free blocking solution (Dako, Trappes, France) was used to inhibit non-specific staining. Primary antibodies were diluted in antibody diluent (Dako). Antibodies against MMP-1, MMP-2, and TIMP-1 were detected using the LSAB2-HRP system (Dako), whereas antibodies against CD8a, MMP-3, MMP-7, MMP-14, and TIMP-2 were detected using the StrepABC-HRP system (Dako) for myeloperoxidase. Immunostaining was performed using the Vector NovaRED substrate kit for peroxidase (Biovalley, Conches, France, for Vector Laboratories, USA). Sections were counterstained with differentiated Mayer's Hemalum (Merck for VWR, Fontenay-sous-bois, France). Slides were rinsed between each stage with Tris HCl-NaCl-Tween (50 mmol/L, 0.3 mol/L, 1 g/L). Control staining, without the primary antibody and using an irrelevant mouse IgG, was performed concomitantly with each immunostaining to ensure staining specificity. A semiquantitative analysis of MMP-2, MMP-3, MMP-14,

TIMP-1, and TIMP-2 expression was performed. Mean staining intensity scores, which reflected staining intensity in the epithelium, lamina propria, submucosa, blood vessels, and muscularis propria, were attributed. The following scoring system was used: no staining (-); weak staining intensity (+); moderate staining intensity (++); strong staining intensity (+++); and very strong staining intensity (++++).

Gelatin zymography

Crushed tissue samples were homogenized in 50 mmol/L Tris-HCl buffer (pH 7.6) containing 150 mmol/L NaCl, 10 mmol/L $CaCl_2$, 10 g/L Triton X-100, and protease inhibitors (Sigma-reverse Aldrich, St. Quentin Fallavier, France). Protein concentration was determined using the Lowry method.

Zymography was performed as previously described[18]. Briefly, samples (4 μg protein) and MMP-2/9 standards (CC073 Chemicon, Euromedex, Mundolsheim, France) were separated by electrophoresis on 80 g/L SDS-polyacrylamide gels copolymerized with 1 g/L gelatin (Type A from porcine skin; Sigma-Aldrich, St. Quentin Fallavier, France). Gels were washed in 25 g/L Triton X-100, incubated in a buffer containing 50 mmol/L Tris–HCl (pH 7.8), 5 mmol/L $CaCl_2 \cdot 2H_2O$, 50 mmol/L NaCl, 0.1 g/L Brij 35, and 0.2 g/L NaN_3 at 37 ℃, stained with 5 g/L Coomassie blue in 250 mL/L isopropanol/100 mL/L acetic acid, and destained in a 100 mL/L methanol/100 mL/L acetic acid solution. Gelatinolytic bands appeared as clear zones against the blue background. Gelatinases were identified by their molecular weight and after inhibition using 20 mmol/L EDTA or 1 mmol/L *o*-phenanthroline. Densitometric analyses were performed using an imaging workstation (Biocom, Les Ulis, France) interfaced with the Phoretix image analysis software (Nonlinear Dynamics, Newcastle upon Tyne, UK).

RNA extraction and quantitative RT-PCR

Total RNA was extracted from crushed tissue samples by homogenization in 4 mol/L guanidine isothiocyanate, purified using the method of Chomczynski and Sacchi and quantified by spectrophotometry (A_{260}/A_{280}). RNA was treated with RNase-free DNase (0.5 U/μL) to remove contaminating genomic DNA. RNA integrity was assessed by denaturing agarose-gel electrophoresis and staining with ethidium bromide.

Real-time reverse transcriptase-polymerase chain reaction (RT-PCR) was used to quantify the levels of MMP-2, -9, -14, TIMP-1, -2, plasminogen, urokinase-type plasminogen activator (u-PA), tissue-type plasminogen activator (t-PA), plasminogen activator-inhibitor-1 (PAI-1), IL-8, TGF-β1, TGF-β2, and TGF-β3 RNA transcripts as previously described[19]. Primers were generated with the Primer Express software (Applied Biosystems, Courtaboeuf, France) and purchased from Invitrogen (Cergy-Pontoise, France): MMP-2 5'-ACCGTCGCCCATCATCAA-3' (forward), 5'-CCTTCAGCACAAAGAGGTTGC-3' (reverse); MMP-9 5'-TGTCCAGACCAAGGGTACAGC-3' (forward), 5'-GAAGAATGATCTAAGCCCAGCG-3' (reverse); MMP-14 5'-GAGGGTCATGAGAAGCAGGC-3' (forward), 5'-TCAAAGGGTGTGCTGTCGC-3' (reverse); TIMP-1 5'-AGAAGGGCTACCAGAGCGATC-3' (forward), 5'-ATCGAGACCCCAAGGTATTGC-3' (reverse); TIMP-2 5'-CTACATCTCCTCCCCGGATGA-3' (forward), 5'-GGTGCCCATTGATGCTCTTC-3' (reverse); plasminogen 5'-CTGAGTATCTAAACAACAGAGTCAAATCC-3' (forward), 5'-TCGAAGCAAACCAGAGGTCC-3' (reverse); PAI-1 5'-ATGGCTCAGAACAACAAGTTCAAC-3' (forward), 5'-CAGTTCCAGGATGTCGTACTCG-3' (reverse); t-PA 5'-GACGTGAAGCCCTGGTGC-3' (forward), 5'-CAAGCCGGCGTGCTG-3' (reverse); u-PA 5'-GTTTGAGGTGGAGCAGCTCAT-3' (forward), 5'-GCTATGTCATTATGGAAGGCCAG-3' (reverse); TNF-α 5'-ATCCGAGATGTGGAACTGGC-3' (forward), 5'-CGATCACCCCGAAGTTCAGTA-3' (reverse); TGF-β1 5'-AGTCCCAAACGTCGAGGTGA-3' (forward), 5'-CCATGAGGAGCAGGAAGGG-3' (reverse); TGF-β2 5'-TGCTGAGAACCTTTTTGCTCC-3' (forward), 5'-GTCGAGGGTGCTGCAGGTA-3' (reverse); TGF-β3 5'-CAAGCAGCGCTACATAGGTGG-3' (forward), 5'-CAGTGACATCGAAGGACAGCC-3' (reverse); IL-8 5'-GACTGTTGTGGCCCGTGAG-3' (forward), 5'-CCGTCAAGCTCTGGATGTTCT-3' (reverse), and IL-1β 5'-CAACAAAAATGCCTCGTGC-3' (forward), 5'-TGCTGATGTACCAGTTGGG-3' (reverse).

Cytokine immunoassays

Crushed tissue was weighed and homogenized in 10 mmol/L phosphate buffer (pH 7.4) supplemented with protease inhibitors, such as 2 mmol/L PMSF, 10 μg/mL pepstatin A, 1 μg/mL aprotinin, 10 μg/mL leupeptin, and 0.5 mg/mL EDTA (Sigma-Aldrich, St. Quentin Fallavier, France). Protein concentration was measured using a modified version of the Bradford method (Bio-Rad Laboratories, Marne-la-Coquette, France). Concentration of IL-1β and TNF-α was determined by ELISA (R&D Systems, Minneapolis, MN, USA). All data were expressed in picogram per milligram of protein.

Statistical analysis

Each real-time RT-PCR and cytokine immunoassay were done in six animals and results were expressed as mean±SE. The ANOVA and Student-Newman-Keuls test were used to determine whether the difference between the values obtained with the control group and the irradiated group was statistically significant. P value <0.05 was considered statistically significant.

RESULTS

Abdominal X-irradiation (10-Gy) induced the inhibition of food intake and decrease in body weight. Diarrhea was observed between d 3 and 5 after irradiation.

Alteration of structure of ileal tissue by a single 10-Gy dose of X-rays

Histopathological changes after irradiation are shown in Figure 1. No significant histological changes were seen 24 h after irradiation, whereas a marked alteration of the intestinal mucosa was observed 3 d after irradiation. A significant decrease in the thickness of the mucosa (-15%, P<0.01), the sloughing of epithelial cells at the top of the villi, associated

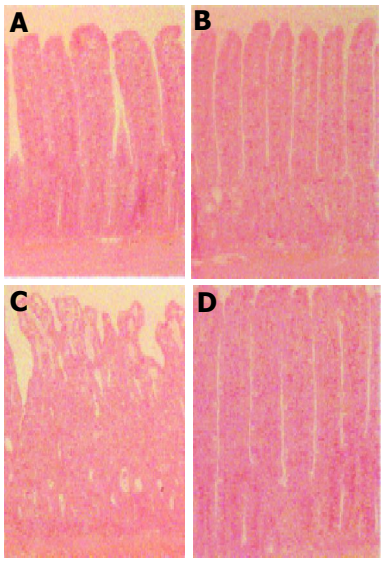

Figure 1 Histopathological study in ilea after X-irradiation with a single dose of 10 Gy. Ileal structure before (**A**) and one (**B**), three (**C**) and seven (**D**) days after abdominal X-irradiation. Magnification x100.

with an atrophy of the villi, dilation of the crypts, and absence of mucus secretion were observed. Muscle layers, on the other hand, appeared normal. Seven days after irradiation, the ileal epithelium seemed to be regenerated. We observed a significant increase in the thickness of the mucosa of irradiated mice compared to controls (+14%, $P<0.01$), with an increase in the number of epithelial cells located in the villi. Some crypts were still dilated at this time.

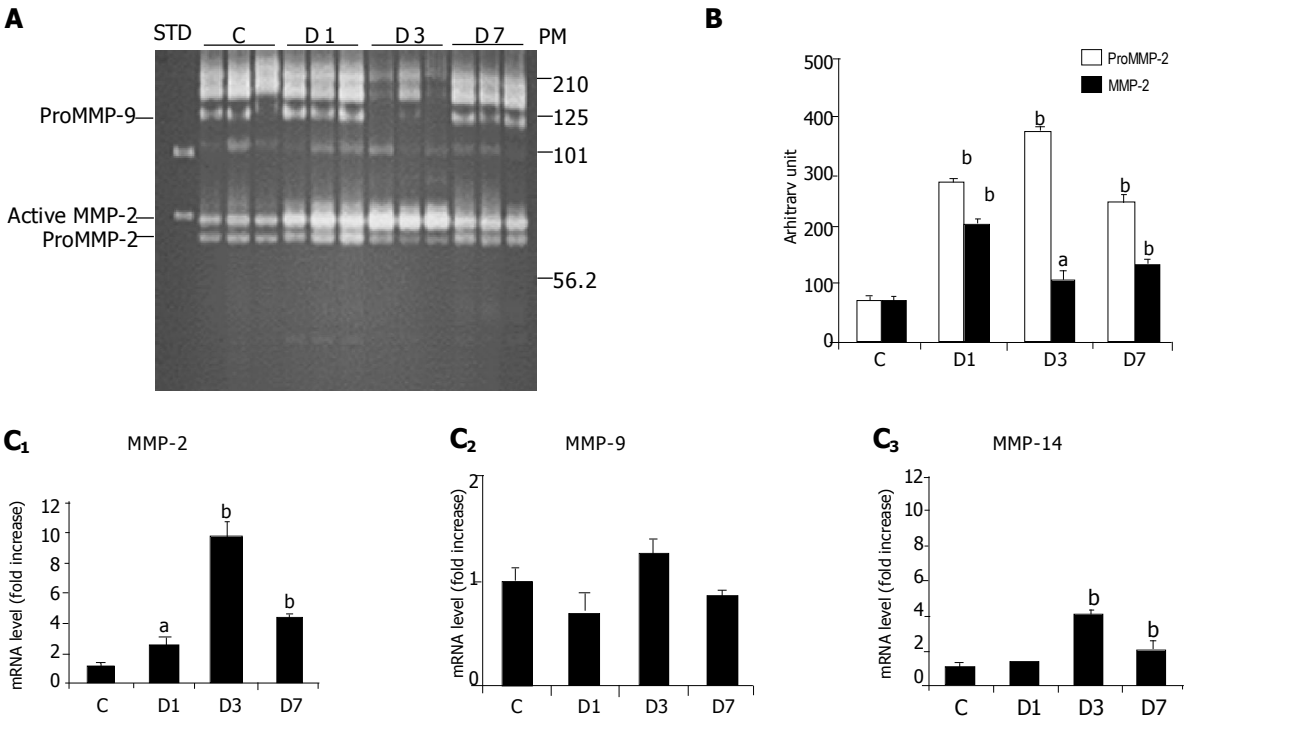
Increase in the expression and activity of gelatinase A by a single 10-Gy dose of X-rays

Gelatin zymography allowed the detection of both active and pro-forms of gelatinases (Figure 2A). Equal amounts of pro- (72 ku) and active (62 ku) MMP-2 were detected in control ileal tissues (Figure 2B). The pro-MMP-2 band significantly increased from d 1-7 (×3.8 on d 1; ×5.0 on d 3; ×4.0 on d 7, all $P<0.01$) after irradiation. Induction of active MMP-2 peaked on d 1 (×2.9, $P<0.01$) and was still higher than control values on d 3 (×1.5, $P<0.05$) and 7 (×1.8, $P<0.01$). We observed a weak gelatinolytic band with a molecular weight, which corresponded to that of pro-MMP-9, but as it was not inhibited by EDTA, it could not be attributed to MMP-9. The high molecular weight bands (125 and 200-220 ku) were, on the other hand, completely inhibited by EDTA and phenanthroline. These gelatinolytic activities, which might have MMP-9 dimers or an MMP-9-lipocalin complex, were equivalent on d 1 and 7 after irradiation, but weaker on d 3 (Figure 2B).

Irradiation-induced transcriptional activation of MMP-2 was confirmed by real-time RT-PCR. MMP-9 mRNA levels, however, were not significantly altered (Figure 2C). Since MMP-14 is involved in the activation of MMP-2, we studied the alterations in MMP-14 mRNA levels. We found that MMP-14 was induced 3 and 7 d after irradiation (Figure 2C).

Tissue localization of gelatinase A and other MMPs after X-irradiation with a single dose of 10 Gy

Immunohistochemistry was used to investigate the cell



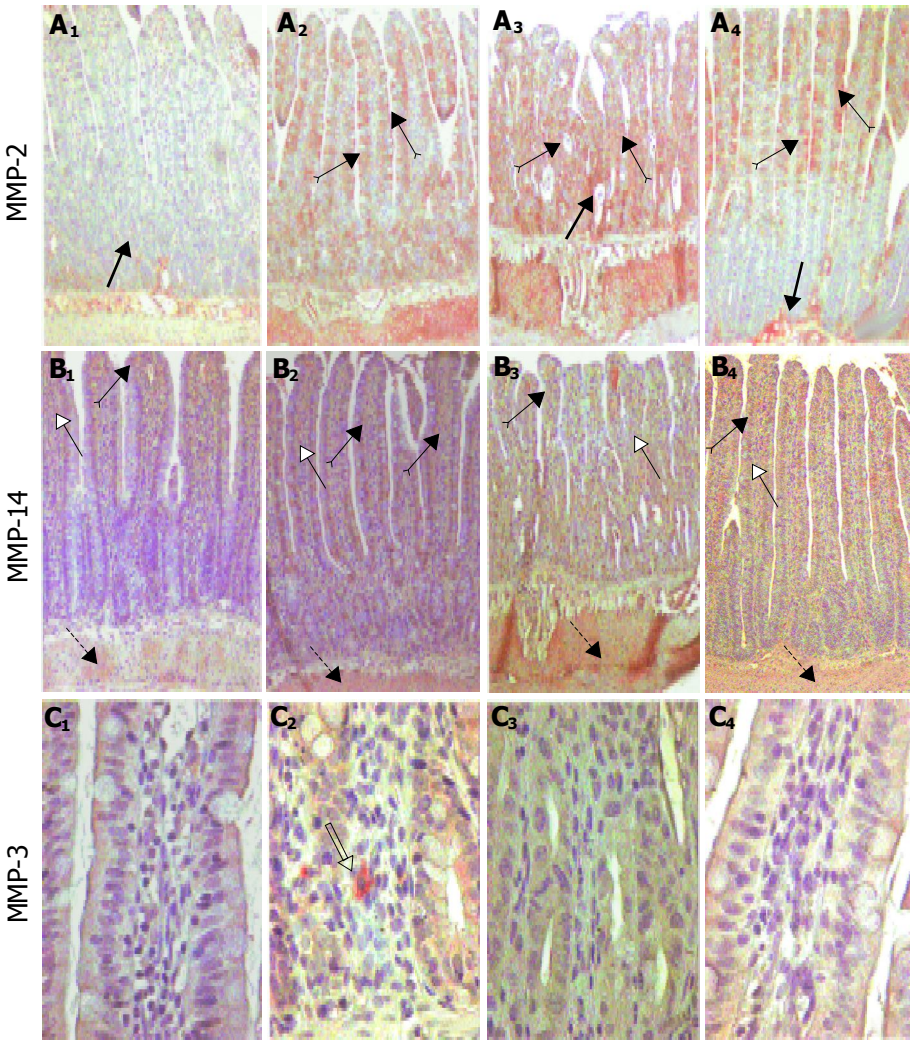


Figure 2 Gelatinases activities in ilea after X-irradiation with a single dose of 10 Gy. **A:** Study of gelatinases activities by zymography. Lane STD shows MMP-2 and MMP-9 standards, lane 2-4, 5-7; 8-10; 11-13 shows gelatinase activities in ilea from control rats (C) and one (D1), three (D3) and seven (D7) days after X-irradiation respectively; **B:** Densitometric analysis of zymography. Results are mean±SE, significantly different from controls: $^{a}P<0.05$, $^{b}P<0.01$ *vs others*. **C_{1-3}:** Analysis of MMP-2, MMP-9 and MMP-14 gene expression. mRNA levels were measured by real time RT-PCR in control ilea from control rats (C) or one (D1), three (D3) and seven (D7) days after X-irradiation respectively. Results are mean±SE, significantly different from controls: $^{a}P<0.05$, $^{b}P<0.01$ *vs others*.

types that expressed gelatinase after irradiation. A weak MMP-2 staining restricted to the pericryptal sheath myofibroblasts, inflammatory cells, and smooth muscle cells was observed in the control ileal tissues (Figures 3A and B). A significant transmural increase in MMP-2 staining was, however, found on d 1 after irradiation in smooth muscle and epithelial cells, and on d 3 in smooth muscle cells, epithelial cells of the villi, and in pericryptal sheath myofibroblasts. MMP-2 staining decreased on d 7.

In control samples, MMP-14 staining was observed in epithelial cells at the top of the villi, inflammatory cells in the lamina propria, and smooth muscle cells. As for mRNA, in irradiated samples, MMP-14 staining was unchanged on d 1, but had increased on d 3 and had spread to the whole tissue. On d 7, however, MMP-14 staining in irradiated and control samples was equivalent except in epithelial cells at the top of the villi, which exhibited weak MMP-14 staining (Figures 3A and B).

Figure 3 Tissue localization of gelatinase A and other MMPs in ilea after X-irradiation with a single dose of 10 Gy. **A_2:** MMP-2, MMP-14 and MMP-3 immunostaining. In control ilea, MMP-2 staining was observed in the pericryptal myofibroblast sheath, inflammatory cells and smooth muscle cells (A_1, x100). On day one and three (A_2; A_3, x100), increased MMP-2 staining was found in all of the layer of the bowel particularly in smooth muscle cells and in epithelial cells. On day seven (A_4, x100) MMP-2 staining was weaker and found in smooth muscle cells, epithelial cells of the villus only and pericryptal myofibroblast sheath. In control ilea, MMP-14 staining was observed in the inflammatory cells of the lamina propria, smooth muscle cells and some epithelial cells of the top of the villi (B_1, x100). No significant modification in MMP-14 staining was found in irradiated ilea on day one (B_2; x100), whereas on day three MMP-14 staining spread to the whole tissue (B_3, x100). On day seven (B_4, x100), MMP-14 staining return to control level except in the epithelial cells of the top of the villus. In control ilea, no MMP-3 staining was observed (C_1, x400), but a staining was observed in mononuclear infiltrated cells day one after X-irradiation (C_2, x400); **D:** MMPs immunostaining scoring. (-) represent no staining, (+) weak staining, (++) moderate staining, (+++) important and (++++) strong staining.

Furthermore, we focused on the expression and immunolocalization of MMP-1, -3, and -7. MMP-1 and -7 were found to be expressed in control ileal tissue, and no changes were observed after irradiation (Figure 3B). MMP-3 was not detected in control samples, but staining was observed at d 1 in some infiltrating mononuclear cells, which were morphologically similar to macrophages (Figures 3A and B).

Disappearance of CD8+T lymphocytes from the ileum after X-irradiation with a single dose of 10 Gy

To investigate whether T cells could be involved in MMP activation after X-irradiation, a subset of peripheral T cells, the majority of natural killer (NK) cells, and granular intraepithelial leukocytes of the small intestine were stained with an antibody directed against an antigen present on the surface of thymocytes. This antigen is the rat homolog of the human CD8. Figure 4 shows that X-irradiation of the abdomen with a dose of 10 Gy caused a marked decrease in the number of CD8+ cells as early as 1 d after exposure, which was also observed on d 3 and 7.

Increase in the number of polynuclear neutrophils and expression of inflammatory and fibrogenic factors after irradiation with a single dose of 10 Gy

Neutrophil infiltration after abdominal X-irradiation was quantified based on myeloperoxidase staining. While we observed a slight increase in myeloperoxidase staining at d 1 and 3 after irradiation, the number of positive cells returned to control values at d 7 (Figure 5A).

Pro-inflammatory cytokines and fibrogenic growth factors are potent inducers of MMPs expression and activity. Thus, expressions of TNF-α, IL-1β, IL-8, and TGF-β1, -2, and -3 were assessed after X-irradiation. Tissue concentration of pro-inflammatory cytokines TNF-α and IL-1β significantly increased 6 h after irradiation (2.3-fold and 2.3-fold, respectively, $P<0.01$) as shown in Figure 5B. This early increase was followed by an increase in IL-8 at d 3 (6.4-fold, $P<0.01$) as shown in Figure 5B.

TGF-β1 and -3 mRNA levels increased 3 d after irradiation (2.5-fold and 1.5-fold, respectively, $P<0.01$). Furthermore, an increase in TGF-β1 and -3 mRNA levels was also seen on d 7 (2.8-fold, $P<0.01$; and 1.6-fold, $P<0.05$, respectively). TGF-β2 mRNA level, on the other hand, increased at d 1 and remained significantly high thereafter (2.1-fold on d 1, 3.2-fold on d 3, and 1.8 fold on d 7, all $P<0.01$) as shown in Figure 5C.

Expression of MMP activating factors after X-irradiation with a single dose of 10 Gy

Because the plasminogen system is known to regulate MMP activation, we investigated variations in the mRNA levels of plasminogen, t-PA, u-PA, and PAI-1 after irradiation (Figure 6). Irradiation induced a significant decrease in plasminogen mRNA level on d 7, and a marked increase in u-PA (6.1-fold, $P<0.01$), t-PA (21-fold, $P<0.01$), and PAI-1 (19-fold, $P<0.01$) on d 3, which was also observed on d 7.

Expression of gelatinase inhibitors after X-irradiation with a single dose of 10 Gy

We investigated TIMP-1 and -2 expression, i.e., intensity and localization, in the sections of X-irradiated rat ileum. In control ileal tissue, a moderate TIMP-1 staining was observed in only a few epithelial cells, in inflammatory cells in the lamina propria, and in smooth muscle cells (Figure 7A). TIMP-1 staining increased in all of the layers of the bowel 1 d after irradiation; the most intense staining was observed in epithelial cells. Staining intensity peaked on d 3 after irradiation (Figure 7A). TIMP-1 expression pattern after irradiation was confirmed by the analysis of mRNA level (Figure 7A).

A weak TIMP-2 staining was observed in control ileal tissues (Figure 7B). A slight increase in TIMP-2 staining intensity was observed in epithelial, inflammatory, and smooth muscle cells 1 d after irradiation and could still be observed on d 3 and 7 (Figure 7B). This increase in TIMP-2 mRNA level only reached significance 3 d after irradiation (fourfold increase, $P<0.01$, Figure 7B).

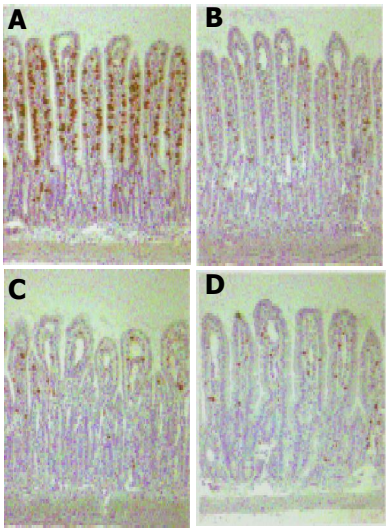

Figure 4 CD8a positive T cells after X-irradiation with a single dose of 10 Gy. Immunostaining for CD8a positive cells in control ilea (**A**) and one (**B**), three (**C**) and seven (**D**) days after X-irradiation. Magnification x100.

DISCUSSION

In this study, we have shown that abdominal X-irradiation with a dose of 10 Gy simultaneously enhances synthesis and activity of MMP-2 and -14. This enhancement is concomitant with an induction of pro-inflammatory cytokines, fibrogenic growth factors, and plasminogen system, which suggests that a complex interplay of factors actually controls radiation-induced activation of MMPs in the intestine. Inhibitory pathways are simultaneously activated as the expression of TIMP-1 and -2 increases, which is suggestive of an irradiation-induced alteration of ECM remodeling. Finally, we observed a decrease in the number of T cells after abdominal irradiation. Our data on radiation-induced induction of gelatinase are in agreement with a previous report by Seifert *et al*.[15], who observed a prolonged gelatinolytic activity in rat colonic anastomoses after intraoperative irradiation. Our results concerning the absence of T cells during radiation-induced ECM remodeling, however, markedly differ from those obtained in models of inflammatory bowel diseases. Our study shows that T lymphocytes are not directly involved in

radiation-induced mucosal injuries, suggesting that radiation-induced mucosal breakdown may be promoted by specific cellular pathways and specific molecular signals, which have been investigated further in this study.

Direct evidence of an important T cell-mediated process in the pathogenesis of mucosal lesions has been shown in *in vivo* and *ex vivo* models, in which T cells are activated by pokeweed mitogen or anti-CD3 and IL-12 in explants of human fetal intestine[13]. In these models, a severe tissue injury occurs following a massive increase in MMP synthesis (mainly MMP-3 and -9). De Winter *et al*.[22], provided evidence of a cross-talk between lymphocytes and epithelial cells *in vivo*. This cross-talk is mediated through cytokines that are locally produced by epithelial cells, which regulate immune responses in the intestine. Using the MRC OX8 antibody, specific for T cytotoxic/suppressor cells, granular intraepithelial leukocytes, and NK cells[23], we sought to determine whether T cells were present in the ileal wall. We observed that CD8+ staining completely disappeared 24 h after irradiation, possibly due to radiation-induced apoptosis. Specific target cells are activated after abdominal irradiation, and neutrophils, epithelial, and mesenchymal cells are responsible for the increased expression of MMPs.

Molecular mediators potentially involved in this radiation-induced enhancement of MMP expression were therefore investigated. We focused on the pro-inflammatory cytokines IL-1β and TNF-α as they are seemingly the mediators that are most frequently reported to be involved in bowel inflammatory diseases[24]. In agreement with a previous study[4], levels of IL-β1 and TNF-α increased as soon as 6 h after irradiation, and were returned to control values on d 1, 3, and 7 after irradiation (data not shown). The early increase in IL-β1 and TNF-α may be due to radiation-induced mast-cell degranulation[25]. This increase likely promotes IL-8 induction, leading to leukocyte recruitment and granulocyte infiltration. The radiation-induced inflammatory status, however, appeared to be moderate (twofold increase in TNF-α and IL-β1 protein levels)[4] in comparison to what was reported in Crohn's disease by Louis *et al*.[11], (10- and 8-fold increase, respectively). This weak inflammatory status may account for the weak MMP-3 stimulation observed in the irradiated ileum. This hypothesis is supported by Mengshol *et al*.[26], who reported that high levels of pro-inflammatory cytokines are required to stimulate MMP-3 secretion by subepithelial

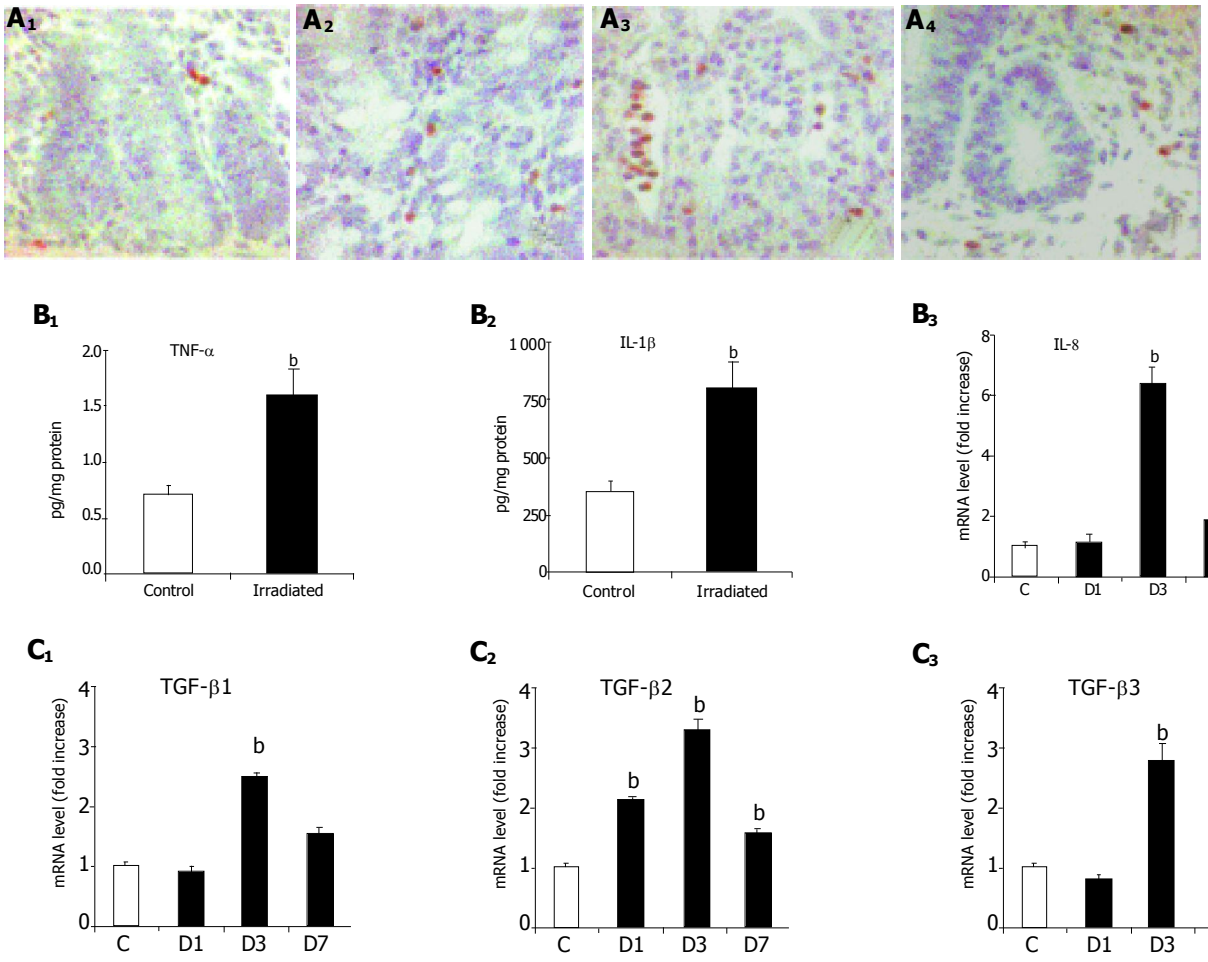

Figure 5 Radiation-induced inflammation. **A:** Myeloperoxidase positive cells in X-irradiated ilea. Immunostaining for myeloperoxidase positive cells in control ilea (A_1) and one (A_2), three (A_3) and seven (A_4) days after X-irradiation respectively. Magnification x 400; **B_{1-3}:** Concentration of TNF-α and IL-1β six hours, and IL-8 mRNA level one to seven days, after X-irradiation with a single dose of 10 Gy. Results are mean±SE, significantly different from controls: $^aP<0.05$, $^bP<0.01$ *vs* others; **C_{1-3}:** TGF-β1, β2 and β3 mRNA level after X-irradiation with a single dose of 10 Gy. Gene expression of TGF-β1, TGF-β2 and TGF-β3, was determined by real-time RT-PCR in control ilea (C) one (D1), three (D3) and seven (D7) days after X-irradiation respectively. Results are mean±SE, significantly different from controls: $^aP<0.05$, $^bP<0.01$ *vs* others.

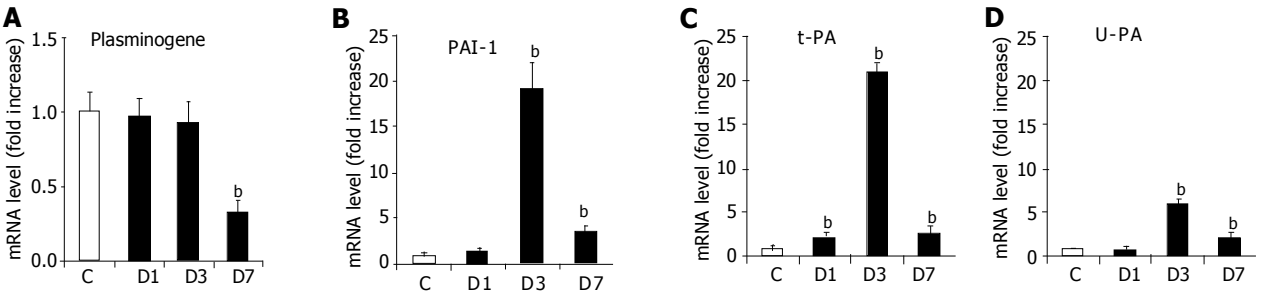

Figure 6 Plasminogen, U-PA, t-PA and PAI-1 mRNA level after X-irradiation with a single dose of 10 Gy. Gene expressions of plasminogen, U-PA, t-PA and PAI-1 were determined by real-time RT-PCR measured in control ilea (**C**) and one (D1), three (D3) and seven days (D7) after X-irradiation. Results are mean±SE, significantly different from controls: [a]*P*<0.05, [b]*P*<0.01 *vs* others (**A-D**).

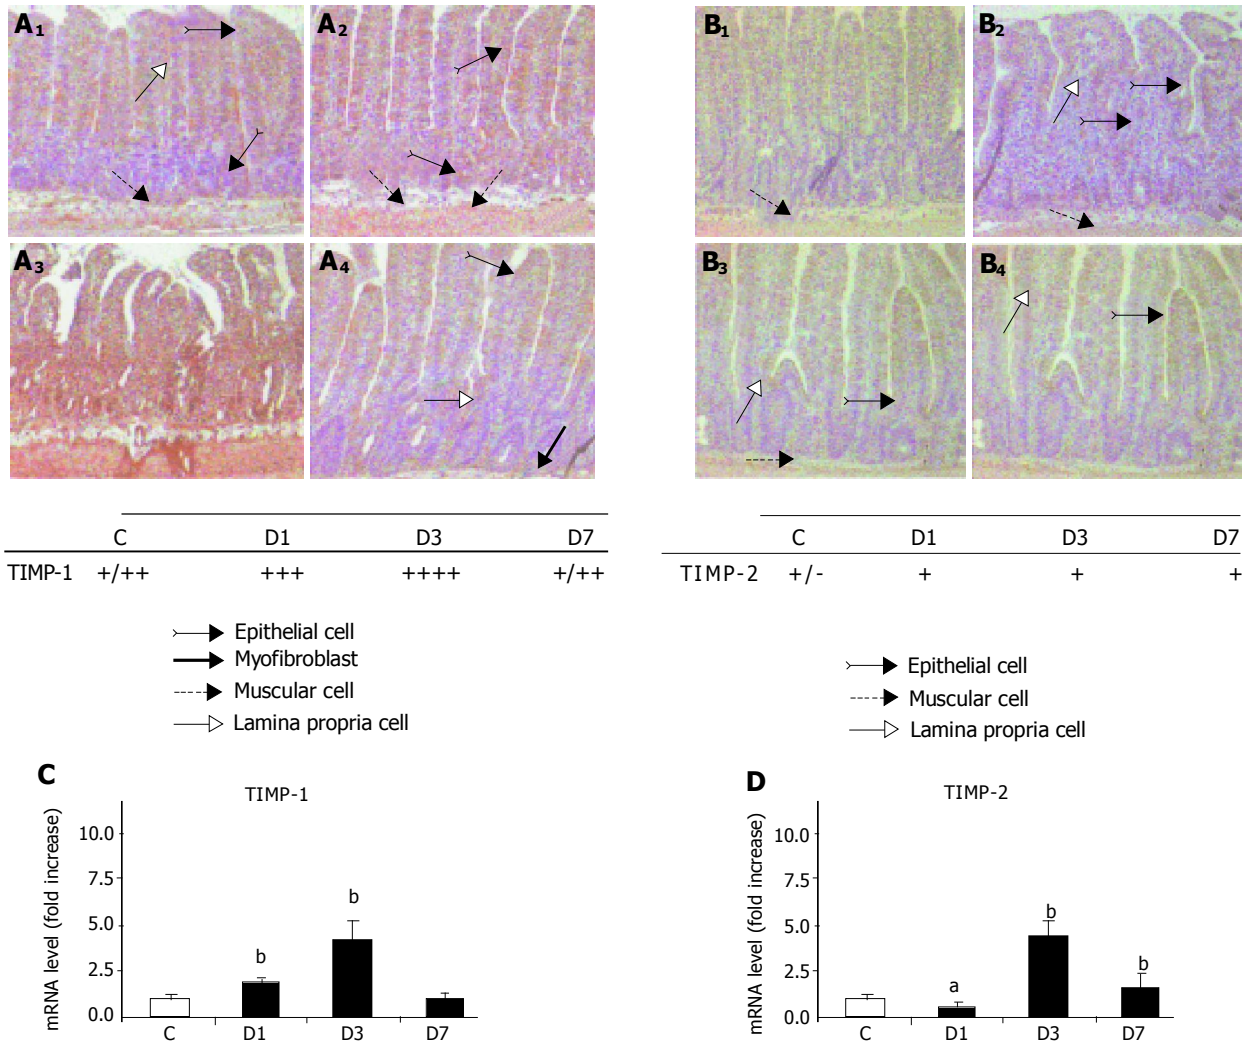

Figure 7 TIMP expression after X-irradiation with a single dose of 10 Gy. **A:** In control ilea, TIMP-1 staining was observed in the inflammatory cells of the lamina propria, smooth muscle cells and some rare epithelial cells of the crypt and of the top of the villus (A_1, x100). On day one (A_2, x100), TIMP-1 staining was found in all layers of the bowel and particularly in epithelial cells and in smooth muscle cells . On day three (A_3, x100), the staining spread to the whole tissue. On day seven (A_4, x100), TIMP-1 staining was found in smooth muscle cells, epithelial cells of the villus only , in pericryptal myofibroblast sheath and in inflammatory cells of the lamina propria. Gene expression of TIMP-1, determined by real-time RT-PCR was measured in control ilea (**C**) one (D1), three (D3) and seven (D7) days after X-irradiation respectively. Results are mean±SE, significantly different from controls: [a]*P*<0.05, [b]*P*<0.01. **B:** In control ilea, weak TIMP-2 staining was observed in smooth muscle cells (B_1, x100). On day one (B_2, x100) and day three (B_3, x100) after X-irradiation, a slight TIMP-2 increase was found in smooth muscle cells, in epithelial cells and in inflammatory cells of the lamina propria. On day seven (B_4, x100),(**C,D**) TIMP-2 staining was observed in epithelial cells on the top of the villus, inflammatory cells of the lamina propria. Gene expression of TIMP-2, determined by real-time RT-PCR was measured in control ilea (**C**) one (D1), three (D3) and seven (D7) days after X-irradiation respectively. Results are mean±SE, significantly different from controls: [a]*P*<0.05, [b]*P*<0.01 *vs* others.

myofibroblasts *in vitro*. Fibrogenic growth factors, such as TGF-β, are also involved in the regulation of cell proliferation, inflammation, immune response, and ECM deposition, which are important parts of the healing process [27,28]. Furthermore, previous studies have suggested that all three TGF-β isoforms are overexpressed during the early phase of radiation-induced injury, while TGF-β1 appears to be predominant in the late phase[29,30]. In this study, we observed an early peak of TGF-β2 induction at d 1, while the other two isoforms (TGF-β1 and TGF-β3) were overexpressed after 3 d, at the onset of the restoration phase. We also observed that induction of MMP-2 mRNA synthesis was concomitant with that of the two TGF-β isoforms. The modulation of MMP-2 expression by TGF-β has already been reported in other models[31,32], and the present results likewise support the hypothesis that the TGF-β family is involved in the regulation of MMP-2 expression after radiation-induced injury.

We investigated the plasminogen-plasmin system, an another activating pathway that is known to regulate MMP activity[2]. This system is a key regulator of fibrinolysis and ECM degradation[33]. Generation of plasmin from plasminogen is regulated by complex interactions between various activators and inhibitors. Classically, plasminogen is known to be activated by u-PA and t-PA. In this study, both u-PA and t-PA were found to be overexpressed 1 d after irradiation, suggesting that the plasmin system is acutely activated after abdominal irradiation. These results are in accordance with the previous reports[34-36] that showed an increase in the fibrinolytic activity in the intestinal mucosa after irradiation. At d 3 and 7, however, the increased expressions of u-PA and t-PA were associated to an increased expression of the inhibitor PAI-1, which may limit plasminogen activation.

Furthermore, we studied the expression of TIMP-1 and TIMP-2, the physiological inhibitors of MMPs. The involvement of TIMPs in inflammatory bowel diseases is still controversial. Heuschkel *et al*.[10], have shown that MMP-3 is overexpressed while TIMP-1 is not. von Lampe *et al*.[37], observed an increase in the level of TIMP-1 mRNA and no modification of the level of TIMP-2 mRNA, suggesting a net increase in the proteolytic activity in inflamed mucosa. Our observations seem consistent with these data obtained in human beings. Induction of TIMP-1 was observed after 1, 3, and 7 d of irradiation, whereas an upregulation of TIMP-2 was seen on d 3 after irradiation. MMP induction rates, however, significantly exceeded TIMP-1 induction. TIMP-2 has been reported to have a bimodal function and to promote activation of MMP-2 when associated with molecules, such as pro-MMP-2 and MMP-14, into large molecular complexes[38]. In this case, synthesis of MMP-14 seems to be the major rate-limiting factor of MMP-2 activation[39]. In this study, expression of both MMP-14 and TIMP-2 was increased after irradiation. Furthermore, MMP-14/TIMP-2 and MMP-2/TIMP-2 mRNA ratios suggested that activation of pro-MMP-2 must have occurred, since a marked increase in the level of active MMP-2 was observed at d 1 after exposure.

In conclusion, the molecular cascades induced by ionizing radiation are complex and are likely to involve more molecules than those studied here. These observations, however, bring new insights on radiation-induced ECM remodeling in the intestine. The fact that CD8a+ cells disappear after abdominal irradiation suggests that specific cellular effectors are involved in radiation-induced activation of MMPs.

Abstract

AIM: To determine the effect of pioglitazone, a specific peroxisome proliferator-activated receptor-γ (PPARγ) ligand, on the development of acute pancreatitis (AP) and on the expression of heat shock protein 70 (HSP70) in the pancreas.

METHODS: AP was induced in rats by subcutaneous infusion of cerulein for 5 h. Pancreatic blood flow was measured by laser Doppler flowmetry. Plasma lipase activity, interleukin-1β (IL-1β) and IL-10 were determined. Pancreatic weight and histology were evaluated and pancreatic DNA synthesis and blood flow as well as pancreatic mRNA for IL-1β and HSP70 were assessed in rats treated with pioglitazone alone or in combination with cerulein.

RESULTS: Pioglitazone administered (10-100 mg/kg i.g.) 30 min before cerulein, attenuated dose-dependently the pancreatic tissue damage in cerulein-induced pancreatitis (CIP) as demonstrated by the improvement of pancreatic histology, reduction in plasma lipase activity, plasma concentration of pro-inflammatory IL-1β and its gene expression in the pancreas and attenuation of the pancreatitis-evoked fall in pancreatic blood flow. CIP increased pancreatic HSP70 mRNA and protein expression in the pancreas and this effect was enhanced by pioglitazone treatment.

CONCLUSION: Pioglitazone attenuates CIP and the beneficial effect of this pioglitazone is multifactorial probably due to its anti-inflammatory activities, to the suppression of IL-1β and to the overexpression of HSP70. PPARγ ligands could represent a new therapeutic option in the treatment of AP.

INTRODUCTION

Acute pancreatitis (AP) is associated with high morbidity and mortality. Approximately 25% of patients develop severe inflammation with pancreatic and peripancreatic fat necrosis that requires intensive care. AP is a multifactorial disease associated with the release of digestive enzymes to the pancreatic interstitium and to the systemic circulation as well as with the increased cytokine production and release, which can ultimately lead to deleterious local and systemic effects[1].

In general, the pathomechanism of AP is still poorly understood. Recently, the modulatory role of peroxisome proliferator-activated receptors (PPARs) has been proposed in the inflammatory response of different organs[2]. The PPAR family consists of at least three different isoforms; PPARα, PPARδ, and PPARγ[3]. PPARγ is predominantly detected in adipose tissue, but it is also expressed in other tissues, including pancreatic tissue. When activated by a specific ligand, PPARs heterodimerize with retinoid X receptor and then bind to peroxisome proliferator response element leading to the change in the transcription of target genes involved in lipid metabolism, glucose homeostasis, cell proliferation and differentiation, and inflammatory response. PPARs are activated by natural ligands such as fatty acids, eicosanoids, oxidized fatty acids, and by pharmacological compounds such as glitazones. Pioglitazone is a member of glitazones and it has been clinically used to increase the sensitivity to insulin[4].

Several reports have demonstrated an anti-inflammatory action of the specific ligands of PPARγ. Activators of

PPARγ inhibit the generation of pro-inflammatory cytokines such as interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α) and interleukin-6[5] and this effect seems to be dependent on the inhibition of nuclear factor-κB (NFκB) pathway[6].

Heat shock-proteins (HSPs) are a group of cytoprotective proteins that help to maintain the metabolic and structural integrity of cells. HSPs are produced in many cell types in response to a variety of stresses, including heat, free radicals, and toxins[7]. HSPs are highly conserved proteins and play essential functions in protein folding, transport, translocation, degradation, and assembly[8]. In the pancreas, HSPs have been shown to provide the protection against cerulein- and arginine-induced pancreatitis[9,10]. HSP70 (also referred as HSP72 or inducible HSP70) is perhaps the most well-studied member of HSPs. However, it is not known whether PPARγ ligands interact with HSP70 and what is the biological consequence of this potential interaction.

The aim of the present study was: (1) to determine the effect of pioglitazone, a specific PPARγ ligand, on the development of acute cerulein-induced pancreatitis (CIP); (2) to assess the effect of treatment with pioglitazone on pancreatic expression of HSP70; and (3) to evaluate the effect of pre-treatment with pioglitazone on pancreatic synthesis and plasma level of IL-1β.

MATERIALS AND METHODS

Experimental model of pancreatitis

Studies were performed on male Wistar rats weighing 150-200 g, in accordance with the experimental protocol approved by the Committee for Research and Animal Ethics of Jagiellonian University College of Medicine, Cracow, Poland. Animals were housed in cages under standard conditions, on a commercial pellet chow, at room temperature with a 12-h light-dark cycle. Prior to the start of experiments, rats were deprived of food, while drinking water was available *ad libitum*. AP was induced by cerulein that was diluted in saline and infused subcutaneously (s.c.) for 5 h at a dose 10 μg/kg/h as described earlier[11].

To study the effect of pioglitazone on the development of AP, the rats were divided into following groups: (1) rats infused with 0.9% vehicle saline s.c. for 5 h (control); (2) rats infused with 0.9% saline s.c. for 5 h and pretreated with pioglitazone (10-100 mg/kg i.g., 30 min before saline infusion); (3) rats infused with cerulein (10 μg/kg/h) s.c. for 5 h; and (4) rats infused with cerulein (10 μg/kg/h) s.c. for 5 h and pretreated with pioglitazone (10-100 mg/kg i.g., 30 min before cerulein infusion). Animals were anesthetized and killed after 5 h of saline or cerulein infusion. This particular dose of pioglitazone 50 mg/kg was used because, in our previous studies, similar dose was highly effective in speeding up of the healing rate of gastric ulcer[12].

Determination of pancreatic blood flow

Following the infusion of saline or cerulein, animals were anesthetized with ketamine (50 mg/kg i.p., Bioketan, Biowet, Gorzów, Poland) and the abdomen was opened. The pancreas was exposed for the measurement of the blood flow by laser Doppler flowmeter, using PeriFlux 4001 Master monitor (Perimed AB, Järfälla, Sweden) as described previously[13]. The pancreatic blood flow was presented as percent change from the value obtained in rats infused with saline.

Determination of plasma lipase, IL-1β, and IL-10 concentration

Immediately after the measurement of pancreatic blood flow, the abdominal aorta was exposed and blood was taken for the determination of plasma lipase activity, and plasma IL-1β and IL-10 concentrations as described before[14].

Plasma lipase activity was determined with a Kodak Ectachem DT II System analyzer (Eastman Kodak Company, Rochester, NY, USA). The values of plasma lipase activity were expressed as units per liter.

The values of plasma IL-1β and IL-10 were measured in duplicate, using the Biosource Cytoscreen rat IL-1β and IL-10 kit based on a solid phase sandwich ELISA (BioSource International Inc., Camarillo, CA, USA) according to the manufacturer's instructions. Concentrations were expressed as picogram per milliliter.

Histological examination

After the collection of blood samples, the pancreas was dissected out and divided into samples for analysis of pancreatic mRNA, pancreatic protein, measurement of pancreatic DNA synthesis, and histological examination. Samples of pancreatic tissue for histological examination were fixed in 40 g/L formaldehyde and stained with hematoxylin and eosin. The histologic grading of edema was made using a scale ranging from 0 to 3; 0 = no edema, 1 = interlobular edema, 2 = interlobular edema and moderate intralobular edema, and 3 = interlobular edema and severe intralobular edema. Leukocytic infiltration was graded from 0 (absent) to 3 for maximal alterations (diffuse infiltration in the entire pancreatic gland). Grading of vacuolization was based on the appropriate percentage of cell involved; 0 = absent, 1 = less than 25%, 2 = 25-50%, and 3 = more than 50%.

Determination of pancreatic DNA synthesis

The rate of DNA synthesis in samples of pancreatic tissue was determined as described previously[15]. Briefly, the minced pancreatic tissue was incubated at 37 ℃ for 45 min in 2 mL of medium containing 8 μCi/mL of [^{3}H]thymidine ([6-^{3}H]thymidine, 20-30 Ci/mmoL; Institute for Research, Production and Application of Radioisotopes, Prague, Czech Republic). DNA concentration was determined by the Giles and Myers[16] procedure. The incorporation of mL [^{3}H] thymidine into DNA was determined by counting 0.5 mL DNA-containing supernatant in a liquid scintillation system. DNA synthesis was expressed as [^{3}H]thymidine disintegrations per minute per microgram DNA.

Determination of pancreatic mRNA for IL-1β and HSP70

Samples of pancreatic tissue for reverse transcriptase-polymerase chain reaction (RT-PCR) were snap-frozen in liquid nitrogen, and then stored at -80 ℃ until the time of RNA extraction. Total RNA was extracted from the pancreatic samples using the extraction kit from Stratagene (Heidelberg, Germany). Following precipitation, RNA was

resuspended in RNAse-free water and its concentration was estimated by absorbance at 260 nm wavelength. RNA samples were stored at -80 ℃ until analysis.

Single stranded cDNA was generated from 5 μg of total cellular RNA using Moloney murine leukemia virus reverse transcriptase (Stratagene, Heidelberg, Germany) and oligo-(dT)-primers (Stratagene, Heidelberg, Germany) in accordance with the procedure described by our group previously[17]. The resultant cDNA (2 μL) was amplified in 50 μL reaction volume containing 2 U Taq polymerase, dNTP (200 μmol/L each), 1.5 mmol/L $MgCl_2$, 5 μL 10× PCR buffer (100 mmol/L KCl, 20 mmol/L Tris-HCl, pH 8.3) and specific primers used at a final concentration of 1 mmol/L (all reagents were obtained from Takara, Shiga, Japan). The reaction mixture was amplified in a DNA thermal cycler (Perkin-Elmer-Cetus, Norwalk, CT, USA) and the incubation and thermal cycling conditions were as follows: denaturation at 94 ℃ for 1 min, annealing at 60 ℃ for 45 s and extension at 72 ℃ for 2 min. The number of cycles was 28 for GAPDH, 30 for HSP70, and 33 for IL-1β. The nucleotide sequence of the primers for GAPDH, IL-1β, and HSP70 were based on the sequences of the published cDNAs as described previously[18,19]. The primer sequence for IL-1β was: sense 5'-GCT ACC TAT GTC TTG CCC GT-3'; antisense 5'-GAC CAT TGC TGT TTC CTA GG-3'. Primer pair for IL-1β produced a 543-bp product according to the cDNA sequence. The primer sequence for HSP70 was: sense 5'-GTG AAG ATC TGC GTC TGC TTG-3'; antisense 5'-TTTGACAACAGG CTGGTG AAC C-5'. The expected length of the product was 590 bp. GAPDH primers were same as previously published by our group[17]. All primers were synthesized by GIBCO BRL/Life Technologies (Eggenstein, Germany). PCR products were detected by electrophoresis on a 1.5% agarose gel containing ethidium bromide. Location of a predicted product was confirmed by using 100-bp ladder (Takara, Shiga, Japan) as a standard size marker.

Protein extraction and analysis of pancreatic HSP70 expression by Western blot analysis

Shock frozen tissue from rat pancreas was homogenized in a lysis buffer (100 mmol/L Tris-HCl, pH 7.4, 15% glycerol, 2 mmol/L EDTA, 2% SDS, 100 mmol/L DDT) by the addition of 1:20 dilution of aprotinin and 1:50 dilution of 100 mmol/L PMSF. Insoluble material was removed by centrifugation at 12 000 *g* for 15 min. Approximately 50 μg of total protein extracts were loaded on SDS-polyacrylamide gels and run 40 mA, followed by transfer on nitrocellulose membrane (Protran, Schleicher & Schuell, Germany) by electroblotting. Three percent of BSA (Sigma-Aldrich, Germany) in TBS/Tween-20 buffer (137 mmol/L NaCl, 20 mmol/L Tris-HCl, pH 7.4, 0.1% Tween-20) was used to block filters for at least 1 h at room temperature. Specific primary antibody against HSP70 (mouse monoclonal, 1:200 dilution; Stressgen Biotechnologies Corp., Canada), or β-actin (mouse monoclonal, dilution 1:5 000; Sigma-Aldrich, Germany) was added to the membrane, followed by an anti-mouse-IgG HRP conjugated secondary antibody (dilution 1:20 000; Promega, USA) dissolved in 1% non-fat milk in TBS-Tween-20 buffer. Incubation of primary antibody was followed by washing thrice with TBS-Tween-20 buffer for 10 min. Incubation of the secondary antibody was followed by five washes for 10 min. Immunocomplexes were detected by the SuperSignal West Pico Chemiluminescent Kit (Pierce, USA). Thereafter, the developed membrane was exposed to an X-ray film (Kodak, Wiesbaden, Germany). Comparison between different treatment groups was made by determining the examined protein/β-actin ratio of the immunoreactive area by densitometry as described elsewhere[18].

Statistical analysis

Comparison of the difference between the mean values of various groups of experiments was made by analysis of variance and the Student's *t*-test for unpaired data. A difference with a *P* value of less than 0.05 was considered statistically significant. Results are expressed as mean±SE.

RESULTS

Effects of pioglitazone on the development of cerulein-induced pancreatitis and pancreatic blood flow

Four criteria were used to confirm the AP in rats infused with cerulein at a total dose of 50 μg/kg (10 μg/kg/h s.c. ×5 h): macroscopic and microscopic signs of AP, pancreatic edema leading to the increase in pancreatic weight and the rise in serum lipase activities. All these criteria were fulfilled in all rats treated with cerulein.

After the infusion of cerulein, the pancreas was enlarged with a visible collection of edematous fluid and the pancreatic mass was almost doubled (Figure 1). At light microscopic level, profound interlobular and intralobular edema, vacuolization of acinar cells, and moderate perivascular and scare diffuse leukocyte infiltration were observed. In rats pretreated with pioglitazone before the start of cerulein infusion, the inflammatory changes in the pancreas were significantly less pronounced when compared to changes observed in rats treated with cerulein alone (Figure 2 and Table 1). Treatment with pioglitazone alone had no effect on morphological features of the pancreas.

Plasma lipase activity in control, saline-infused rats, reached 57.0±6.0 U/L. In rats infused with cerulein, plasma lipase activity was almost increased eightfold, compared to the level obtained from control rats infused with saline. In rats pretreated with pioglitazone before cerulein, a significant and dose-dependent reduction in plasma lipase activity was

found (Figure 3 and Table 2).

In saline-infused control rats, total pancreatic DNA synthesis reached 58.8±1.6 dpm/μg DNA (Figure 4). Treatment with pioglitazone alone did not affect pancreatic DNA synthesis in animals infused with saline. The induction of AP by cerulein was associated with a significant fall in DNA synthesis in the pancreas for about 44%. This effect was partly, but significantly reversed by the treatment with pioglitazone.

Pancreatic blood flow measured in rats with CIP was reduced by about 40% as compared to the control group (Figure 5). Treatment with pioglitazone did not affect pancreatic blood flow in animals infused with vehicle saline. In contrast, in rats given a cerulein infusion, pretreatment with pioglitazone was associated with a significant reverse in the cerulein-induced fall in the pancreatic blood flow.

The measurement of plasma level of IL-10 showed no significant changes in rats with CIP or treated with pioglitazone as compared to control group (Figure 6). In contrast, IL-1β was significantly increased in rats with CIP. Pretreatment with pioglitazone did not significantly affect plasma IL-1β concentration in rats infused with saline, but pretreatment with pioglitazone caused a significant and dose-dependent reduction in plasma level of this important pro-inflammatory cytokine in animals with CIP.

In tissue samples taken from control pancreas without CIP, a weak but detectable signal for IL-β1 mRNA was observed (Figure 7). The expression of GAPDH was well preserved in all the samples. After the induction of CIP, a significant increase in IL-1β mRNA was found. This effect was strongly attenuated in rats pretreated with pioglitazone.

The analysis of mRNA expression of HSP70 showed a detectable signal of HSP70 in the samples of the pancreas obtained from control group (Figure 8). After the induction of CIP, a strong upregulation of mRNA for HSP70 was observed. Interestingly, the treatment with pioglitazone caused a further increase in mRNA expression for HSP70.

At the protein level, similar results were observed; a weak signal for HSP70 in control pancreas, a significant increase of the signal in CIP, and a further increase in HSP70 expression in rats with CIP pretreated with pioglitazone (Figure 9).

DISCUSSION

We have reported in this study that the pre-treatment of rats with pioglitazone, a specific PPARγ ligand, significantly and dose-dependently attenuated the development of CIP. This result is in accordance with the earlier report that natural PPARγ ligand, 15d-PGJ2, reduced the severity of CIP[19]. The mechanisms underlying the protective effect of pioglitazone on the CIP remain unclear. First of all, the beneficial effect of pioglitazone on the pancreas subjected to acute injury by cerulein over-stimulation could be due to its local and systemic anti-inflammatory properties. Previous reports indicated that PPARγ agonists exhibit anti-inflammatory effects both in *in vitro* and *in vivo* studies[5,19]. This anti-inflammatory effect seems to be related to multiple mechanisms. Ricote *et al.*[20], demonstrated that PPARγ ligands inhibit macrophage activation and inflammatory cytokine production. Our previous studies showed that pioglitazone reduces acute and chronic gastric mucosal lesions due to the inhibition of TNF-α and IL-1β expression[12]. Furthermore, Meier *et al.*[21], showed that PPARγ ligands exert anti-inflammatory activity by inducing the production

of IL-1 receptor antagonist. One of the important mechanisms by which pioglitazone inhibits the inflammatory reaction is the reduction in activation of the transcription factor, NFκB, by the IκB-dependent mechanism[19]. Moreover, Imamoto *et al*.[22], found that pioglitazone exerts a strong inhibitory effect on the expression of adhesion molecule VCAM-1 on neutrophils and endothelial cells, thus reducing the leukocyte recruitment in the inflamed tissue. There is also clinical evidence for the anti-inflammatory effects of glitazones. Haffner *et al*.[23], reported that treatment of type 2 diabetes mellitus patients with rosiglitazone resulted in a reduction of serum concentration of C-reactive protein and WBCs count. All these reports underline the importance of PPARγ ligands in the modulation of inflammatory reaction in different organs, particularly in reducing the cerulein-induced oxidative stress in pancreatic tissue[24].

Our present study confirms and extends previous findings[25-27] by showing that inflammatory infiltration of pancreatic tissue caused by CIP is accompanied by a significant increase in pancreatic mRNA expression of IL-1β and increased release of this cytokine in rats infused for 5 h with supramaximal dose of cerulein. The new finding of our present study is that pretreatment with pioglitazone at a dose of 50 mg/kg significantly suppresses the gene expression and plasma level of IL-1β, as well as reduces leukocyte infiltration of pancreatic tissue in the course of CIP. This observation indicates that pioglitazone, a specific PPARγ ligand, is a powerful modulator of inflammatory response.

In contrast to IL-1β, IL-10 is found to be a major anti-inflammatory cytokine[28]. It reduces activation of macrophages and inhibits the production of reactive oxygen species and pro-inflammatory cytokines[28]. Van Laethem *et al*.[29], showed that administration of IL-10 before and during the induction of AP decreases the severity of this pancreatitis. Also, administration of some growth factor such as hepatocyte growth factor[30] or insulin-like growth factor-1[13] increases a plasma level of IL-10 and inhibits the development of AP. In our present study, we did not observe any alteration in plasma IL-10 concentration after the development of acute CIP or pretreatment with pioglitazone at various doses. This result suggests that the anti-inflammatory action of pioglitazone does not depend upon the release of IL-10.

The most important finding of this study is the observation that pioglitazone increased significantly the expression of HSP70. HSPs are highly conserved cytoprotective proteins that have essential functions in protein folding, transport, degradation, and assembly. HSPs are classified into six major families (small HSP, HSP40, HSP60, HSP70, HSP90, and HSP100) depending on their molecular weight[7]. HSP70 is the best studied member of HSPs family. Previous studies demonstrated that both thermal and non-thermal stress protects against CIP and prevents trypsinogen activation in the pancreas and this effect is mediated by HSP70[31]. The potential protective mechanisms of HSPs on pancreas

include: stabilization and refolding of damaged proteins, resistance of the cells to apoptosis or necrosis, decrease in the level of pro-inflammatory cytokines and antioxidant effects and interference with intra-acinar zymogen activation[7,31-33]. Our results are in accordance with the previous studies showing an increase of HSP70 at mRNA and protein level after induction of CIP. The major finding is, however, the observation of the further increase in HSP70 expression in rats pretreated with pioglitazone. This indicates that the protective effects of pioglitazone could be mediated, at least in part, through increased HSP expression. This issue needs to be clarified in further studies, especially in *in vitro* studies.

Administration of pioglitazone alone did not affect pancreatic DNA synthesis. Induction of AP by cerulein caused a reduction in the pancreatic DNA synthesis, that is in agreement with our previous observation[34], and may be considered as an index of pancreatic damage. In rats with the induction of pancreatitis by cerulein, the pretreatment with pioglitazone attenuated the pancreatitis-evoked fall in pancreatic DNA synthesis. This observation is an additional evidence of protective effect of pioglitazone against pancreatic damage in CIP.

It is well known that the development of AP is associated with the reduction in pancreatic blood flow[35-37], whereas vasodilatation and the improvement of pancreatic blood flow reduces the development of AP[37]. Our results are in accordance with these observations. Administration of cerulein induced acute edematous pancreatitis and reduced the pancreatic blood flow. Pretreatment with pioglitazone partly reversed cerulein-induced fall in pancreatic blood flow, suggesting that the improvement of pancreatic microcirculation might contribute to the protective effect of pioglitazone administration. The mechanism of vascular effects of pioglitazone administration is unclear. Pioglitazone given alone without cerulein infusion had no effect on pancreatic blood flow. This observation indicates that pioglitazone acts indirectly on pancreatic blood flow, probably by the reduction of cerulein-induced pancreatic edema and reduction of leukocyte activation.

The fact that pioglitazone strongly inhibits the inflammatory reaction in CIP, suggests that this compound may offer a new treatment opportunity, especially in the prophylaxis of pancreatitis in human beings. This issue should be studied in the prospective protocol in human beings. Moreover, the protective effect of pioglitazone should be checked in other acute and chronic experimental models of pancreatitis.

In summary, our study provides evidence that pioglitazone, a specific PPARγ ligand, ameliorates significantly the pancreatic damage associated with the CIP confirmed by the improvement of pancreas histology and the reduction in plasma lipase activity. Treatment with pioglitazone significantly inhibited the production and release of IL-1β and enhanced the expression of pancreatic HSP70. These observations indicate that the treatment with pioglitazone may offer a new therapeutic option in the treatment or prophylaxis of pancreatitis.

Abstract

AIM: To analyze the distinct immune responses induced by *Lactobacillus* peptidoglycan (PG).

METHODS: BALB/c mice were intraperitoneally injected with PG once a day for three consecutive days. Peritoneal macrophage and splenocyte mRNA was extracted and the gene expression profile was studied using high-density oligonucleotide microarrays. Inhibitory effects of *Lactobacillus* PG on colon tumor tissue were studied *in vitro* and *in vivo*.

RESULTS: The gene expression profiles revealed that the TLR-NF-κB and Jak-STAT signaling pathways were highly activated. An inflammatory phenotype was induced when peritoneal macrophages were initially exposed to *Lactobacillus* PG and switched to a more complex phenotype when BALB/c mice were treated with three doses of *Lactobacillus* PG. A protective physiological inflammatory response was induced after three consecutive days of PG treatment. It was tending toward Th1 dominant immune response. *Lactobacillus* PG also appeared to induce a significant *in vivo* anti-colon tumor effect.

CONCLUSION: *Lactobacillus* PG is responsible for certain immune responses induced by *Lactobacilli*. Anti-tumor effects of *Lactobacilli* are likely to attribute to the activation of macrophages by PG expressed on the bacterial cell surface.

INTRODUCTION

Lactobacilli have been shown to affect selected aspects of immune function that may involve one or several components of the humoral, cellular or nonspecific immunity[1]. These functions suggest that the potential use of *Lactobacilli* in foodstuffs or medicines can prevent infection of pathogenic bacteria[2] or induction of cancer[3-5]. It is not known entirely, however, how *Lactobacilli* affect the immune system and exert these immunostimulative effects. It has been suggested that *Lactobacilli* activate innate immunity response and mediate a protective inflammatory response in the gut. The first defense mechanism in inflammation is innate immunity and involves epithelial barrier, phagocytes and release of cell-derived inflammatory mediators (i.e. cytokines). Innate immunity activates rapidly after exposure of the host to inflammatory stimuli. It has been found that pathogenic microbes express highly conserved molecular structures called pathogen-associated molecular patterns (PAMPs)[6]. PAMPs include microbial cell wall components such as lipopolysaccharide (LPS), lipoteichoic acid and peptidoglycan (PG)[7]. Active innate immune cells express pattern-recognition receptors (PRRs) which are capable of recognizing common features of PAMPs. Toll-like receptors (TLRs) are important PRRs involved in the activation of pro-inflammatory reactions[6]. TLR2 is an important TLR member that recognizes PG. Binding of bacteria or bacterial products (i.e. PG) to TLRs leads to activation of intracellular signaling cascades, resulting in the activation of transcription factors, including nuclear factor κB (NF-κB), which regulates a wide variety of innate immunity responses. Activation of NF-κB has been found to induce the expression of several inflammatory mediators such as pro-inflammatory cytokines and cell adhesion proteins[8]. These factors acting alone, sequentially, or in combination, stimulate and amplify the inflammatory response. Recent studies indicate that, in addition to pathogenic microbes and their products, immune responses can be primed or activated by non-pathogenic commensal bacteria, including the probiotics such as *Lactobacillus* and *Bifidobacteria* species[1]. Probiotics share distinct commensal-associated molecular patterns (CAMPs)[9], which enhance epithelial barrier function in the gut, activate NF-κB and cytokine production in monocytes/macrophages and natural killer (NK) cells and induce phagocytic activity in neutrophils[10].

Rakoff-Nahoum *et al.*[11], demonstrated that the beneficial effects of commensal bacteria or probiotics are due to recognition of their surface molecules by TLRs. This recognition triggers TLRs to regulate genes that foster homeostasis of the intestinal epithelium. It also confers a protective effect on these cells and induces tissue repair. Elucidating the interaction between host and probiotic cell surface molecules is the key to this protective effect. However, there are few reports on systematic investigation of host cell responses to CAMPs from various probiotic strains. In an earlier study[12], we found that *Lactobacillus* PG, a type of CAMP, enhances immune surveillance in mice. To delineate this response in a more comprehensive way, we undertook a genome-wide analysis of the immune response to *Lactobacillus* PG. The results reveal that the transcription of most genes participating in the immune response is modulated after PG treatment. Many of these genes are involved in the activation of TLR-NF-κB and Jak-STAT signaling pathways. Activation of these signaling pathways is likely to invoke pro-helper T type-1 immune/cell-mediated immune response (Th1/CMI). Due to this induced response, anti-colon tumor effects of *Lactobacillus* PG were also studied and the results suggest that *Lactobacillus* PG can be used as a potential mediator in cancer immunotherapy.

MATERIALS AND METHODS

Preparation of peptidoglycan

A livestock feces derived *Lactobacillus* strain, *Lactobacillus* sp., was used. The strains were maintained at -80 ℃ as 15% glycerol stocks and subcultured in MRS broth or on MRS agar plates at 37 ℃. *Lactobacillus* PG was prepared as previously described[13] with minor modifications. Briefly, *Lactobacillus sp.* was grown in MRS liquid medium for 48 h at 37 ℃ without shaking. The culture was quickly chilled in an ice bath and the bacteria were harvested by centrifugation (2 000 r/min, 10 min, 4 ℃) and washed several times with water. The cells were placed in a boiling water bath for 20 min before they were broken by sonication. The suspension was centrifuged at 1 000 r/min for 15 min to sediment unbroken bacteria and the supernatant containing the cell walls was decanted. After the centrifugation at 10 000×*g* for 10 min, the pelleted cell walls were incubated in 2% sodium dodecyl sulfate for 30 min at 60 ℃. After being washed four times with water and twice with dehydrated alcohol, covalently bound proteins were digested with 0.02% trypsin in 0.1 mol/L Tris-HCl buffer (pH 7.5) for 20 h at 37 ℃. The walls were washed several times with water and lyophilized, resuspended in 10% trichloroacetic acid and stirred for 20 min at 60 ℃. PG was concentrated by centrifugation (10 000×*g*, 20 min) and washed extensively with water. All reagents used were sterile, and disposable plasticware or glassware baked at 180 ℃ was used to avoid contamination with endotoxin.

PG administration and preparation of macrophages and splenic lymphocytes

Three groups of BALB/c mice (three per group) were injected ip with either 0.5 mL of PBS (control) or PG (25 mg/kg weight in 0.5 mL PBS) once a day for one day or three consecutive days. Mice were killed after administration of PG. Peritoneal macrophages and splenic lymphocytes were isolated and mixed together (1×10^7 cells each) for each treatment and stored at -70 ℃ in 2 mL TRIzol reagent for future use.

Analysis of gene expression by high-density oligonucleotide arrays

Gene expression analysis was performed using the Affymetrix MOE430A GeneChip system according to the manufacturer's instructions (Protocol for Eukaryotic Sample and Array Processing in http://www.Affymetrix.com). Briefly, total RNA was isolated using the RNeasy Mini Kit from QIAGEN. Double-stranded cDNA was synthesized using 0.2 μg poly (A)-RNA. Biotin-labeled cRNA was synthesized using the BioArray high-yield RNA transcript-labeling kit (Enzo Biochem) and equal amounts of fragmented RNA (30 μg) were hybridized to each array. The arrays were washed using the EukGW2 protocol on the GeneChip Fluidics Station 400 series and scanned using the GeneArray scanner.

Colon tumor inhibition by peptidoglycan

In order to determine *in vitro* inhibition of colon tumors by PG, CT26 colon tumor cells were collected in log phase, treated with 0.25% trypase, washed twice, and resuspended to 5×10^4 cells/mL in RPMI 1640 medium. The cell suspension (0.1 mL), and 0.1 mL of RPMI 1640 medium, with or without PG (100 μg/mL or 2 000 μg/mL), were added to each well of 40-well flat plates. After incubation for 48 h at 37 ℃ in a humidified atmosphere containing 50 mL/L CO_2 and 95% air, the cell supernatant was discarded and 100 μg methyl thiazolyl tetrazolium was added to each well. After another 4-6 h incubation, the suspension was centrifuged at 162 r/min at 4 ℃ for 5 min, the supernatant was discarded, and 100 μL dimethyl sulfoxide was added before A_{192} was determined.

To determine inhibition of colon tumors by PG *in vivo*, 30 BALB/c mice were inoculated with 0.2 mL CT26 cells (5×10^4 cells/mL) into the wall of left posterior limb and randomly allocated to three groups averagely. Mice were then administered ip with 0.5 mL physiologic saline, 0.1 or 0.5 mg PG in 0.5 mL physiologic saline, once in 2 d for 16 d. On d 17, tumor tissue and spleen were removed and stored at -80 ℃ for measurement of tumor weight, spleen weight, and analysis of tumor DNA by agarose gel electrophoresis.

Statistical analysis

The gene expression data were normalized and further processed using GeneChip analysis Microarray Suite 5.0 (Affymetrix) and Data Mining Tool Version 2.0 (Affymetrix). The GeneChip software performed statistical analysis of array data and generated signal intensity values representing the relative expression levels of each gene on the array. A comparison analysis was performed that directly compared probe pairs from one GeneChip to another. The signal log ratio (SLR) was used to estimate the change in expression level for a transcript between baseline and an experiment

array. This change was expressed as the $\log_2$ ratio. The fold change was calculated from the log ratio formula as follows: fold change = $2^{\text{single log ratio}}$ (if single log ratio $\geqslant 0$) or $(-1)\times 2^{-\text{single log ratio}}$ (if single log ratio<0). Therefore, a $\log_2$ ratio of 1 has a fold change of 2.

For annotation of genes, known or putative gene functions were ascertained from gene ontology (GO) classifications (provided at http://www.NetAffx.com). Probe sets can be found at http://www.NetAffx.com that provides oligonucleotide sequences of the probes and links to UniGene and other descriptive information. Pathways in KEGG (http://www.genome.ad.jp/kegg/) were analyzed to provide speculation on the possible biological pathways activated by PG, as suggested by the GeneChip data.

Inhibitions of colon tumors were analyzed using the SAS program. The statistical significance of the differences between group means was calculated by Student's two-tailed *t*-test for two groups, by single factor ANOVA, or by Tukey's test for three or more groups.

RESULTS

Global view of differentially expressed genes

To study the interaction between host cells and *Lactobacilli*, BALB/c mice were injected ip with PG derived from *Lactobacillus sp.* once a day for three consecutive days, and peritoneal macrophage and splenic lymphocyte mRNA was harvested. These mRNA samples were hybridized to oligonucleotide arrays containing 22 690 oligonucleotide probe sets (MOE430A GeneChip), each representing an expressed gene. The general information of gene expression is presented in Figure 1. Changes in gene expression were generally more marked after mice were treated once (e.g., expression of 5 085 genes was changed) than after three administrations during which only 3 995 genes were differentially regulated. When mice were treated once, a rapid and widespread response was triggered resulting in substantial changes in 3 332 genes (SLR was more than 1) and the total number of upregulated genes (1 762) was less than the number of genes whose expression was suppressed (3 323). When treated thrice, however, a slow but more specific response was induced resulting in transcriptional changes of 857 genes (SLR was more than 1) (Figure 1A). The total number of upregulated genes (1 846) was similar to that of genes whose expression was suppressed (2 149). Of the 3 332 or 857 genes (absolute values of SLR were more than 1) in two different stimulating procedures, at least 125 upregulated and 191 downregulated genes of the mouse genome were mobilized in response to one or three times of stimuli (Figure 1B). Of these PG-responsive genes, 86 upregulated genes and 128 downregulated genes encoded proteins with known biological functions. These genes were divided into 10 functional categories (Figure 2) as defined by the Gene Ontology Consortium (http://www.geneontology.org/). The three categories of response to stress, signal transduction, and metabolism, accounted for 59% of the PG-responsive genes. Genes playing a role in defense and immunity (response to stress) or signal transduction comprised 44% of the PG-induced genes but only 14% of the downregulated genes. In contrast, genes with functions in intermediary metabolism made up 42% of the genes whose expression was suppressed by PG, but only 9% of the induced genes.

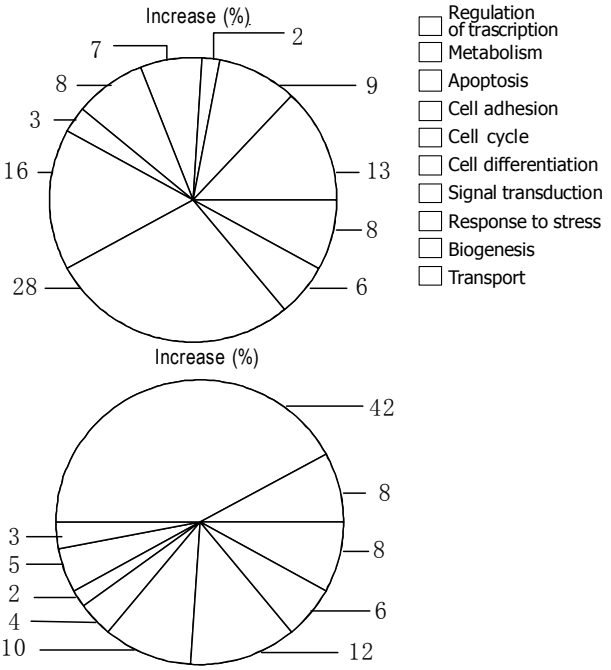

Figure 2 Functional profiles of expression changed by PG derived from *Lactobacillus sp.* in peritoneal macrophages and splenic lymphocytes.

I: One dose of PG treatment. II: Three doses of PG treatment.

Effects of peptidoglycan on genes involved in NF-κB pathway

At least 361 and 57 stress response genes responded to PG when mice were treated once or thrice (absolute value of SLR was more than or equaled to 1). Expressions of 17 genes encoding important proteins that participate in TLR-NF-κB pathway were regulated in different patterns after both treatments. According to the pathways defined at the KEGG database, a possibly regulated branch of TLR-NF-κB signaling pathway is shown in Figure 3A. TLR2 could mediate response to PG and cell wall components of Gram-positive bacteria[14]. Gene expression profile indicated that expression of TLR2 was only upregulated significantly after mice were treated with PG thrice. According to the findings of Anderson[15], the strong expression of TLR2 would present in antigen presenting cells such as peritoneal macrophages. Different expressions of TLR2 in different treatments revealed that, in certain tissues, expression of certain TLR was different according to the time or frequency of cell interaction with particular probiotic CAMPs.

Several intracellular signal transduction pathways were activated when TLRs reacted with microbial products. The most prominent and best characterized of these is the NF-κB signaling pathway[16]. Expressions of downstream genes of TLR signal were analyzed. Results revealed that only certain branches of NF-κB pathway were impacted by PG stimulation. Specifically, expression of toll-interleukin 1 receptor domain containing adaptor protein decreased after both PG treatments, suggesting that the cytoplasmic domain of TLRs was modified, affecting recruitment of myeloid differentiation primary response gene 88 (MyD88). Expression of thymoma viral proto-oncogene 1 (Akt1) was suppressed after a single PG dose. Expression of interleukin-1 receptor-associated kinase 1 (Trak1) was activated after a single PG stimulation. Expressions of Tnf receptor-associated factor 6 (Traf6) NF-κB1 and NF-κB2 were only induced after chronic stimulation. Furthermore, expression of mitogen-activated protein kinase 14 (P38) was upregulated after PG treatment.

It was demonstrated that once activated, Irak released from the receptor, and bound to and activated Traf6[17]. In that study, increased expression of Irak was linked to the activation of Traf6. We postulate that the expression of Traf6 was induced during the later time of Irak stimulation. Akt1 is another important protein, which can directly phosphorylate inhibitor of kappaB kinase α (IKKa) and mitogen-activated protein kinase kinase 6 (MKK6), leading to the activation of both Jun amino-terminal kinase (JNK)/p38 and NF-κB signaling pathways[18]. After single administration of PG, Akt1 expression decreased, indicating that in early period of stimulation Traf6 was a primary mediator of Ikk phosphorylation and led to nuclear transferring of NF-κB. In three-dose stimulation, however, both TRAF6 and Akt1 took part in nuclear transport of NF-κB. Perhaps the differential expression of Traf6 and Akt1 could lead to differential expression of products of NF-κB signaling pathway. Many components of the NF-κB pathway were stimulated only after the mice were treated thrice with PG. This finding could imply that constitutively expressed proteins comprising the NF-κB pathway were sufficient for early defense responses. Additional proteins might undergo degradation after initial PG stimulation. A series of genes encoding proteins of ubiquitin-proteasome proteolytic pathway were activated as shown in Table 2. Products of these genes could mediate destruction of NF-κB pathway memberships. Tollip is a negative regulatory molecule in TLR signaling[19]. In the present study, expression of Tollip was downregulated after acute injection of PG and the expression was resumed after mice received chronic PG treatment.

Some genes encoding products of NF-κB pathway were upregulated (e.g., IL-1, IL-6, CD80, CD86) after PG treatment. IL-12 was only upregulated after acute PG treatment. It was reported that tumor necrosis factor (TNF) and IL-2 are molecules induced by some pathogens or probiotics exposed to macrophages[16]. Our previous study suggested that PG could cause production of TNF in macrophages of cyclophosphamide-treated mice whose immune system was inhibited[12]. In the present study, TNF gene expression was only upregulated when mice were treated chronically with PG. IL-2 expression, however, was not similarly induced. Therefore, expression of these molecules could be differentially regulated in healthy individuals compared to immune-compromised individuals. Because the expression of several cytokines such as interleukin-2 (IL-2), interferon-γ (IFN-γ), TNF-α and IL-3, as well as several growth factors, have been shown to be regulated by stabilization/destabilization of mRNA[20], and IL-2 expression was not significantly affected by PG treatment in this study. IL-2 mRNA might go degradation, and was beneficial for the control of host immune response. After PG treatment, no change in iNOS (also named as NOS2 encoding a protein responsible for induced production of nitrogen monoxidum) mRNA levels was found. Although basic production of nitrogen monoxidum (NO) was beneficial for host to regulate defense response, too much NO induced a severe inflammatory response that might lead to tissue damage[21]. *Lactobacillus* PG did not induce NO production, implying that inflammatory response induced by *Lactobacillus* was solely for enhancement of host immune surveillance.

Possible macrophage phenotype induced by PG

On the basis of macrophage gene expression patterns, Stoy[22] has functionally classified macrophages into various phenotypes. External triggers, acting via cell membrane receptors (e.g., TLR2), and activation of the NF-κB-dependent intracellular signaling pathway in macrophages, might be the most important determinants leading to the pro-inflammatory phenotype. NF-κB could increase the release of cytokines (e.g., TNF-α, IL-1, IL-6, IL-12 and interferons), as well as amyloid A, adhesion molecules (e.g., Vcam-1 and Icam-1)[23], chemokines, major histocompatibility complex (MHC) class I and II molecules[24] from macrophages and a variety of other mammalian cell types. PG-induced proteins related to pro-inflammatory response and ant-inflammatory response are listed in Table 1. The innate response induced by *Lactobacillus* PG, reinforced over a limited period of time (one dose), sustained an elevation of IL-1 expression, increased IL-1 receptor type 2 mRNA

Table 1 Relationship between *Lactobacillus* PG-induced expression of proteins and pro-inflammatory and anti-inflammatory response

and induced (three doses) expression of PRRs, such as TLR2.

Serum amyloid (A1 and A2), intercellular adhesion molecules (Vcam1 and Icam2) increased after PG treatment. Icam4 was only induced after acute treatment. The majority of class II MHC genes were induced during the early period of stimulation with PG (SLR>1). Expressions of H2-T24, H2-K, H2-Q1 were induced during the later time period of stimulation with PG. H2-D1 and H2-b1, however, were induced after PG treatments. Eleven of C-C family chemotactic factors were inconsistently induced or suppressed after either treatment. Expressions of seven C-X-C chemotactic factors were induced consistently after chronic PG treatment. These induced proteins, in addition to the pro-inflammatory cytokines (Figure 3A), were produced by activated macrophages and maintained the activated state. Upregulated expression of IL-12 and class II MHC genes mediated the initiation of the adaptive immune response of *Lactobacillus* PG by $CD4^+$ T cells (Th cells). Studies have demonstrated adjuvant-like activity of *Lactobacillus*[27], and factors induced by *Lactobacillus* PG in this study contributed to the enhancement of immune surveillance PG. Compared to one dose of PG treatment, a greater number of inflammatory genes were upregulated after three doses of PG treatment. Anti-inflammatory cytokines, such as TGF, were also upregulated during chronic PG treatment. This complex cytokine profile could lead to differential activation of helper T cells. Consequently, activated macrophages displayed an inflammatory phenotype, which switched to a complex phenotype induced by both inflammatory and anti-inflammatory factors. This differential response revealed the plasticity of macrophages when they were affected by *Lactobacillus* PG.

Immune processes underlying PG-mediated pro-Th1 signaling

One of the important signaling pathways induced by cytokines was involved in Janus tyrosine kinases (Jak kinases), signal transducers and activators of transcription (STAT proteins). At least 30 genes relating to T-cell proliferation and differentiation were observed to undergo significant alterations in expression after treatment. The Jak-STAT pathway was coordinately upregulated (Figure 3B), especially

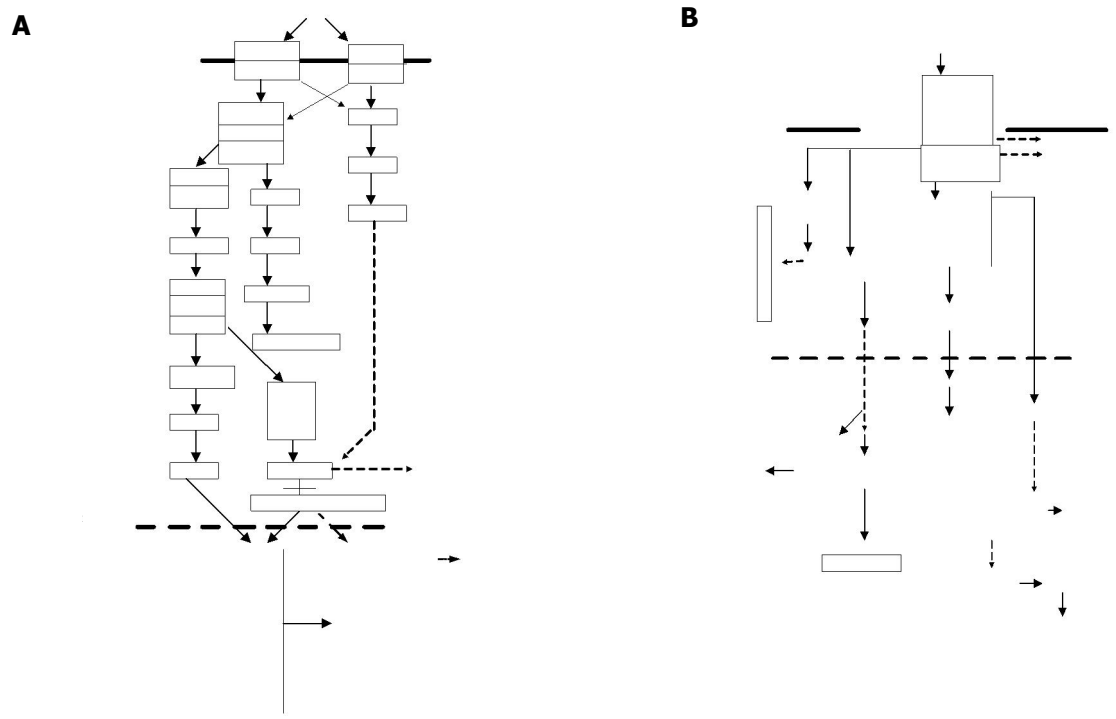

Figure 3 Functional mapping of genes to pathways for products of pro-inflammatory cytokines (**A**) and IFN-γ and T-cell proliferation (**B**).

after consecutive PG treatment. After PG treatment, IL-2 receptor and proto-oncogene (Myb and Myc) were upregulated, essential for T-cell proliferation. This finding is coincident with those from our previous study[12] in which proliferation of splenic lymphocytes was stimulated after single injection (ip) of *Lactobacillus* PG. Experimental evidence indicates that pro-Th1 immunoregulation is dependent on the ability of *Lactobacillus* to promote interferon production[26], which in turn drives the production of pro-interferon monokines (principally IL-12 and IL-18). One dose PG treatment greatly induced expression of IL-12 and Stat4 (SLR was 1.9 and 2.6 respectively). Furthermore, expression of CD3 was also upregulated stimulating naive $CD4^+$ T cell differentiated into type 1 helper T cells. It has been demonstrated that differentiation of T cells occurs 48-72 h after stimulation[27]. In this experiment, upregulated expression of IFN-γ was observed after chronic PG treatment (about 72 h), suggesting the polarization of naive $CD4^+$ T cells toward Th1 cells and the activation of the IL-12/IFN-axis. After either treatment, the gene encoding IL-18 receptor was also upregulated and served to maintain the development of CMI/Th1 response. Many downstream proteins involved in cytokine/cytokine receptor interaction within the Jak-STAT pathway were strongly activated after chronic PG treatment (Figure 3B). The major genes affected were Jak, Stat, cytokine inducible SH2-containing protein (cish), and pim-1 oncogene (Pim), suggesting that only certain branches of Jak-STAT pathway are activated. It should also be noted that continuous stimulation of mice with PG induced production of IL-10 and its receptor, likely to protect host from damage by CMI response. On the other hand, both Stat1 and Stat3 are activated by IL-6, IL-10[28,29], which may lead to proliferation or differentiation of macrophages or lymphocytes via activation of the Jak-STAT pathway.

Colon tumor suppression by Lactobacillus PG

Microarray analysis indicated that peritoneal macrophages were activated by *Lactobacillus* PG. We studied whether activation of macrophages could induce tumoricidal activity against CT26 colon cancer cells. Results indicated that there was a dose-dependent inhibition of CT26 colon cancer development in mice treated with PG ($P<0.01$) (Figure 4B). The inhibition ratio of high PG dose was 54.2%. A DNA ladder appeared in the apoptosis analysis (Figure 5), indicating that cancer apoptosis was induced by PG. On the other hand, cancer cell line growth *in vitro* following PG treatment showed no direct inhibitory effect (Figure 4A), suggesting that PG-induced immune responses might be primarily responsible for these anti-tumor effects.

DISCUSSION

A recent study has shown that cytokine production by cells of the immune system can be altered by *Lactobacillus* strain[1]. In the present study, immune response induced by *Lactobacillus* PG agreed with results induced by these *Lactobacillus* strains, indicating that *Lactobacillus* PG is responsible for certain immune responses induced by this type of important probiotic organism. *Lactobacillus* PG, as a distinct CAMP, could modulate the production of cytokines and other immunoregulatory factors of macrophages. Through these factors, macrophages play a pivotal immunoregulatory role in the Th1 and Th2 cell balance. In the present study, one dose of PG induced a temperate inflammatory reaction, and three doses of PG enhanced antigen presentation and T-cell differentiation. One dose of *Lactobacillus* PG induced the expression of IL-12 and

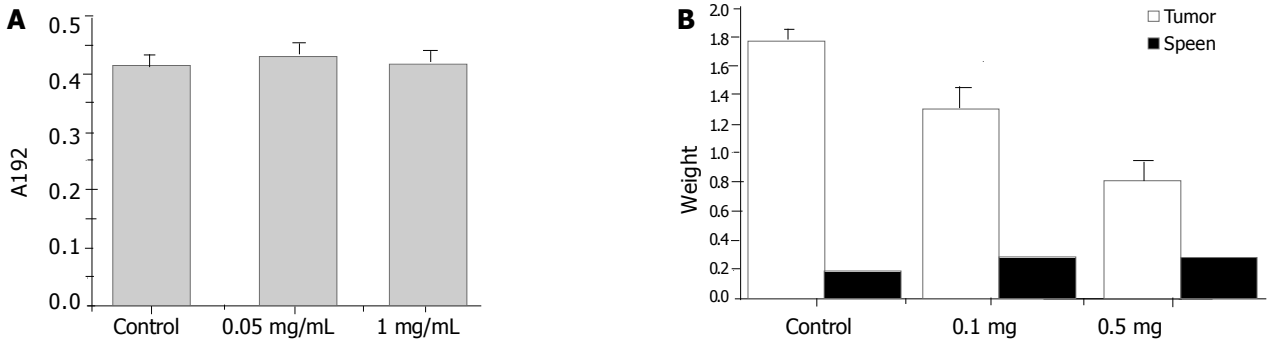

Figure 4 *In vitro* (**A**) and *in vivo* (**B**) inhibitory effects of PG on growth of CT26. Values are mean±SD.

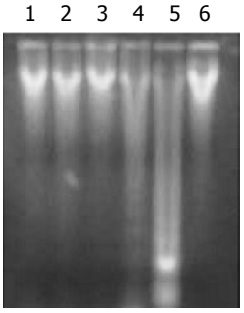

Figure 5 DNA of inoculated colon tumor in 2% agarose gel. Lane 1-3 and 6: control; lane 4: tumor-inoculated mice treated with low doses of PG; lane 5: tumor-inoculated mice treated with high doses of PG.

three doses of PG increased the expression of IFN-γ, suggesting that the induced immune response may develop toward Th1 immune response (CMI response). CMI response is important for tumor inhibition. The present study demonstrated that *Lactobacillus* PG could inhibit CT26 colon cancer development *in vivo*, which was mediated by increased CMI.

Enhanced phagocytic activity, NK cell activity, T- and B-cell function, and antigen-specific antibody responses are likely to result in an increased resistance to tumor incidence. All these types of tumoricidal activity require macrophage activation[30]. Interaction between PAMPs and cell surface PRRs induce macrophage activation[31]. Macrophages are important antigen-presenting cells that present throughout the gastrointestinal tract. Macrophages under lamina propria may be targets for modulation by gut microbes, including ingested probiotics. It has been found that foreign *Lactobacillus murinus* and cell fragments can penetrate the gut wall by translocation through the epithelial layer or through Peyer's patches[31]. Indigenous intestinal bacteria including *Lactobacilli* are also able to cross the intestinal mucous layer and can survive in the spleen or in other organs for many days where they stimulate phagocytic activity. It is possible that physiologically translocated *Lactobacilli* carry PG or other CAMPs to macrophages in gut or other sites and can induce the production of modulatory molecules.

An important finding revealed by gene expression assay is that different doses of PG induce different cytokine profiles. In the present study, expression of Traf6 and Tollip was changed by different doses of *Lactobacillus* PG, suggesting that expression of cytokine is regulated by activation or inhibition of Traf6 or Tollip expression. Zhang and Ghosh[19] reported that overexpression of Tollip causes interaction with TLR2 and TLR4 and inhibits TLR signaling, indicating that Tollip plays a negative regulatory role in TLR signaling. These findings imply that *Lactobacillus* PG can modulate the activating state of TLR signaling partly, although it may change the expression of inhibitory molecules. On the other hand, in mammals, Traf proteins are key components in various NF-κB activating pathways and overexpression of Traf2 or Traf6 activates NF-κB[32]. Traf6 knockout mice exhibit defects in IL-1 and LPS-induced NF-κB activation[33]. In the present study, three doses of *Lactobacillus* PG-induced high activation of TLR-NFκB signaling might be a result of increased expression of TRAF6.

Although used widely, different strains of *Lactobacillus* can induce increased systemic or mucosal immune response at different levels of stimulation, and the stimulation is also dose-dependent[27]. Maassen *et al*.[34], have also found that the growth phase of orally administered individual *Lactobacillus* strains can differentially affect antigen-specific antibody subclasses IgG1 and IgG2a. This differential antibody response is likely due to growth phase-dependent differences in bacterial cell compositions[31]. In the present study, we found that different doses of *Lactobacillus* PG led to different immune responses, suggesting that difference in CAMPs compositions and amount of CAMPs reaching to macrophages influences immune stimulatory effect of *Lactobacilli*.

In conclusion, the *Lactobacillus* PG-induced response is dominant in Th1, and a stimulatory effect is dose-independent. *Lactobacillus* PG influences the expression of signaling regulatory molecules modulating the cytokine profile and activation of lymphocytes. Pro-Th1 immune signals generated by probiotic *Lactobacilli* at the gut mucosal interface (and in some cases at other mucosal sites) can stimulate systemic CMI responses relating to cancer immunotherapy[35].

Abstract

AIM: Recent studies demonstrating the direct involvement of dendritic cells (DC) in the activation of pathogenic T cells in animal models of inflammatory bowel disease identify DC as important antigen presenting cells in the colon. However, very little is known about the properties of colonic DC.

METHODS: Using immunohistochemistry, electron microscopy and flow cytometry we have characterized and compared colonic DC in the colon of healthy animals and interleukin-2-deficient ($IL2^{-/-}$) mice that develop colitis.

RESULTS: In the healthy colon, DC resided within the lamina propria and in close association with the basement membrane of colonic villi. Type 1 myeloid ($CD11c^+$, $CD11b^+$, $B220^-$, $CD8\alpha^-$) DC made up the largest (40-45%) population and all DC expressed low levels of CD80, CD86, and CD40, and had high endocytic activity consistent with an immature phenotype. In colitic $IL2^{-/-}$ mice, colonic DC numbers increased four- to five-fold and were localized within the epithelial layer and within aggregates of T and B cells. They were also many more DC in mesenteric lymph nodes (MLN). The majority (>85%) of DC in the colon and MLN of $IL2^{-/-}$ mice were type 1 myeloid, and expressed high levels of MHC class II, CD80, CD86, CD40, DEC 205, and CCR5 molecules and were of low endocytic activity consistent with mature DC.

CONCLUSION: These findings demonstrate striking changes in the number, distribution and phenotype of DC in the inflamed colon. Their intimate association with lymphocytes in the colon and draining lymph nodes suggest that they may contribute directly to the ongoing inflammation in the colon.

INTRODUCTION

There is increasing evidence that inflammatory bowel disease (IBD) is the result of dysregulated immune and T cell responses to the intestinal bacterial microflora resulting in chronic intestinal inflammation[1,2]. However, it is not clear how antigen is taken up and processed in the colon. In the small intestine antigen uptake is believed to occur via specialized epithelial cells, or M cells, located in Peyer's patches[3]. Peyer's patches represent a relatively small area of the small intestine and no equivalent to the M cell has yet been described in the colon resulting in the speculation as to whether cells such as epithelial cells and lamina propria (LP) dendritic cells (DC) may contribute to antigen uptake and presentation. However, little is known about the nature of antigen presentation in the colon.

It is likely that DC play a pivotal role in both the initiation and regulation of immune responses in the intestinal tract. Our recent studies, using the interleukin 2-deficient ($IL2^{-/-}$) mouse model of ulcerative colitis (UC), demonstrated the direct involvement of colonic DC in the activation of pathogenic T cells[4]. Both colitis as well as spontaneous bone loss in these animals were caused by increased production of the TNF family member, receptor activator of NFκB ligand (RANKL) by activated $CD4^+$ T cells. Modulation of the interaction of RANKL with its receptor RANK by the administration of osteoprotegerin, a soluble decoy receptor for RANKL, resulted in reduced intestinal inflammation and ablation of colonic DC. However, a detailed analysis of the phenotype and function of these cells in the murine colon in healthy and inflamed tissue is lacking.

DC derived from murine Peyer's patches have been extensively characterized and comprise at least three populations: (1) MAC-1^+ (CD11b) myeloid DC in the subepithelial dome; (2) CD8α lymphoid DC in the interfollicular T cell regions and: (3) $CD11b^-$ $CD8\alpha^-$ in both areas[5,6]. In contrast, little is known about the phenotype of colonic DC. DC from human colonic biopsies of normal and inflamed colon have been described as a heterogenous population of immature cells[7]. In contrast, preliminary

analyses of DC from normal and colitic mice have suggested that DC are immature in the normal colon but mature in the diseased colon[3,8].

The observation that DC are key to the development of colitis in IL2$^{-/-}$ model[3] makes it important to elucidate their phenotype and function to gain a greater understanding of their role in driving immune responses within the colon. In the current study, we have used immunohistochemistry, electron microscopy and flow cytometry to characterize and compare the DC present in colonic tissue from healthy and inflamed murine colon. This study represents the first attempt to characterize colonic DC in the IL2$^{-/-}$ model of UC.

MATERIALS AND METHODS

Materials

Animals C57BL/6 and C57BL/6-IL2$^{-/-}$ transgenic mice were purchased from Jackson Laboratory (Bar Harbor, ME) and housed under specific pathogen free conditions at the University of Leeds. IL2$^{-/-}$ mice were obtained from heterozygote matings and were identified by PCR analysis of tail DNA samples[2]. Mice were killed at 7-8 wk of age. Sentinel mice were routinely screened for common mouse pathogens and none were detected.

Methods

Immunohistochemistry Colonic tissue from the distal, mid, and proximal colons of C57BL/6- IL2$^{-/-}$ mice and age-matched littermate controls were snap frozen in OCT medium. Sections (6 μm) were fixed in cold acetone and stained for cell-specific markers using the tyramide amplification method (Perkin Elmer, Berkshire) as described previously[6]. Sections were stained with antibodies to F4/80, CD11c, MAC-1, CD4, B220, (all supplied by Becton Dickinson, Cowley, Oxford), and cytokeratin (Sigma, Poole, Dorset) and then counterstained with 4'-6-diamidino-2-phenolinodole dihydrochloride (DAPI) to visualize cell nuclei. Slides were mounted with Mowiol and analyzed with a Zeiss Axioplan u.v. microscope.

Cell isolation Colonic LP cells were isolated as described previously[4]. Briefly, colons were opened longitudinally, washed, and finely minced. LP cells were released from the tissue by incubation for 2 h under gentle agitation at 37 ℃ with collagenase I (4 mg/mL) in RPMI containing 10% FBS. The resultant cells were washed, resuspended in a 40% solution of Percoll (Amersham, Buckinghamshire) and gently layered onto a 60% Percoll gradient (400 g, 30 min). The cells were collected at the gradient interface, washed and prepared for analyses by flow cytometry or electron microscopy as described below. Mesenteric lymph node (MLN) cells were excised from C57BL/6 and C57BL/6- IL2$^{-/-}$ mice and homogenized to obtain a suspension of mononuclear cells.

Flow cytometry MLN and colonic LP cells were analyzed by flow cytometry on a FACScan flow cytometer using CELLQuest software (Becton Dickinson). Cells were stained with fluorochrome and/or biotin conjugated antibodies to CD45, B7.1 (CD80), B7.2 (CD86), CD40, CD8α, CD4, B220 (CD45R), GR-1, F4/80, MAC-1 (CD11b), I-A/I-E, CD11c, CCR5 (Becton Dickinson), DEC205 (Serotec Ltd, Oxford) and streptavidin conjugated to Alexa Fluor 633 (Molecular Probes, OR, USA). Isotype-matched antibodies of irrelevant specificity were used to determine the level of non-specific staining and frequency of cells stained with test antibodies.

Electron microscopy CD11c$^+$ LP cells from C57BL/-IL2$^{-/-}$ and C57BL/6 littermate controls were enriched by negative immunomagnetic selection to deplete the cell preparation of T (CD3$^+$) and B (CD19$^+$) cells prior to preparing the samples for electron microscopy. Between 1-5×10^5 cells were fixed in 0.1 mol/L sodium phosphate buffer, pH 7.4 containing 3% glutaraldehyde for at least 12 h at 4 ℃. After washing in sodium phosphate buffer, the cells were embedded as a pellet in low gelling temperature agarose (Sigma). The pellet was washed thoroughly and post-fixed for 1 h in 1% osmium tetroxide, washed and left overnight in dH_2O prior to being stained for 2-4 h in 2% uranyl acetate. After washing in dH_2O, the cells were dehydrated using an acetone gradient, embedded in araldite resin prior to curing for 18 h at 65 ℃. Ultrathin sections (100 nm thick) were cut on a Reichert-Jung Ultracut E microtome and collected on a 200 mesh copper grid. After staining with Reynold's lead citrate, the grid was carbon coated and visualized using a JEOL 1200 EX electron microscope. All samples analyzed by electron microscopy were also analyzed by flow cytometry to confirm the presence of DC in the cell samples.

Endocytosis assay Endocytic activity was assessed by measuring the uptake of FITC-dextran (Sigma). Freshly isolated MLN and LP cell preparations (2×10^5 cells/mL) from C57BL/6 and C57BL/6-IL2$^{-/-}$ mice were incubated at 37 ℃ with FITC-DX (1 mg/mL, Sigma) for 1 h. Control samples were incubated at 4 ℃. Incubation was stopped by washing in ice-cold PBS, stained with antibodies to CD11c or F4/80 as described above, fixed in 1% paraformaldehyde and permeabilized in 0.1% saponin and analyzed by flow cytometry as described above. Results are expressed as the proportion of cells (F4/80$^+$ or CD11c$^+$) which have specifically taken up the FITC-DX minus the background staining (cells incubated at 4 ℃).

Statistical analysis

Data are presented as mean±SE. Statistical significance was evaluated using a Mann-Whitney test.

RESULTS

Distribution of colonic DC is altered in the inflamed colon

A comparative analysis of the localization and type of DC and macrophages within the colons of normal (7 wk old C57BL/6) and colitic (7 wk old C57BL/6-IL2$^{-/-}$) mice was carried out using a three fluorochrome immunohistochemical procedure. The relatively few CD11c$^+$ DC present in the normal colon (Figure 1C) were mostly found within the LP and in close association with the basement membranes of the colonic villi (Figure 1C). Similarly, F4/80$^+$ macrophages were also found located within the LP and basement membrane of the normal colon (Figure 1A). F4/80$^+$ macrophages outnumbered CD11c$^+$ DC in the normal, healthy colon.

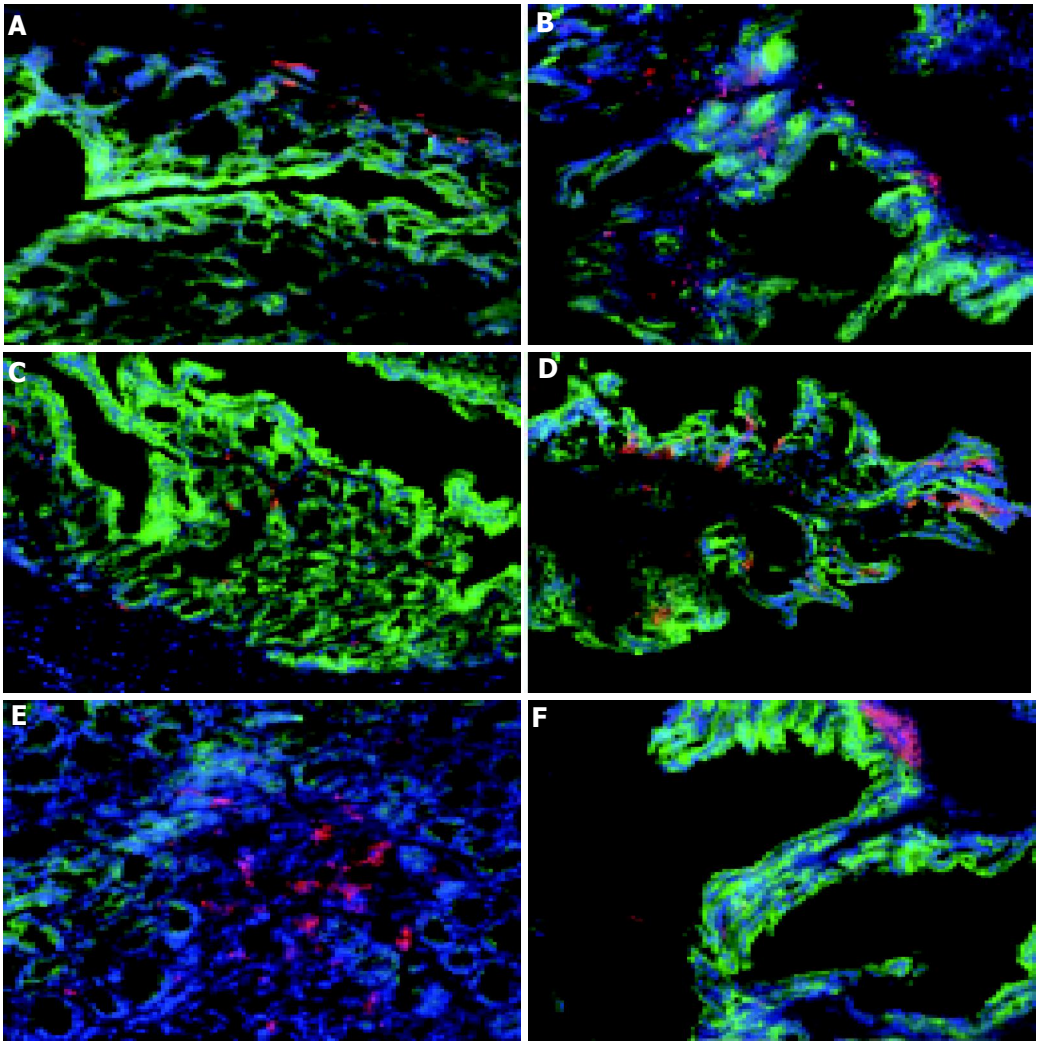

Figure 1 Distribution of macrophages and DC in normal and colitic colon. Sections of cryopreserved colon from normal C57BL/6 (**A, C,** and **E**) and colitic C57BL/6-IL2$^{-/-}$ mice (**B, D,** and **F**) were labeled with F4/80 and Cy-3 to identify macrophages (**A** and **B**), CD11c and Cy-3 to identify DC (**C**-**F**) and cytokeratin-FITC to identify epithelial cells (**A**-**F**) and counterstained with DAPI. Although there were increased numbers of macrophages in colitic animals, their distribution was unaltered (**A** and **B**). The number of DC was increased in the inflamed colon and their distribution was altered with DC being found in close proximity to the epithelium (**C** and **D**). Aggregates of CD11c$^+$ DC were also observed at the base of villi of both normal and colitic colons (**E** and **F**). Magnification, ×160. Tissue was analyzed from the colons of 5 C57BL/6-IL2$^{-/-}$ and 4 C57BL/6 animals.

In contrast, there were changes in both the number and distribution of F4/80$^+$ macrophages and CD11c$^+$ DC in the colon of colitic IL2$^{-/-}$ mice. C57BL/6-IL-2$^{-/-}$ mice spontaneously develop a progressive form of intestinal inflammation that is restricted to the colon and histopathologically resembles human UC[9], and has been shown to be triggered by commensal gut bacteria[9,10]. There were more macrophages (82.5±40.2 compared with 106.1±27.1 per field of view) and colonic DC (52.5±5.2 compared with 80.2±16.1 per field of view) in the inflamed colons of IL2$^{-/-}$ mice compared to the normal healthy colon (Figures 1B and D). Furthermore, the distribution of colonic CD11c$^+$ DC was altered in colitic animals with the majority of DC found in close association with the luminal surface, adjacent to the colonic epithelia (Figure 1D). This suggests that in colitic animals, colonic DC are mobile and migrate to the epithelial layer perhaps in response to epithelial derived signals or microbial antigens from the gut lumen. Of note, in the inflamed colon was the accumulation of CD11c$^+$ in aggregates, or lymphoid follicle like structures, at the base of crypts beneath the epithelial layer (Figure 1F). Although, similar clusters of colonic DC were also found in the colons of normal animals (Figure 1E), they were less well organized and much rarer.

To ascertain if colonic DC were restricted to specific parts of the colon, sections of the distal, mid, and proximal colon of both normal and colitic animals were analyzed. CD11c$^+$ cells were detected throughout the entire colon (Figures 2D-F) in both normal and colitic animals. Of note, a greater proportion of the aggregates of CD11c$^+$ were observed in the mid and distal areas compared to the proximal area of the colon in IL2$^{-/-}$ mice. The number of DC aggregates varied from mouse to mouse with 2-4 being observed in the sections of tissue from IL2$^{-/-}$ mice.

The phenotype of colonic DC was determined by immunolabeling with antibodies specific for MAC-1 (CD11b) and B220. The majority of CD11c$^+$ cells co-expressed MAC-1$^+$ (Figures 2A-C) consistent with them being myeloid DC. A small proportion (approximately 5%) of the colonic CD11c$^+$ cells within the lymphoid aggregates of IL2$^{-/-}$ animals co-

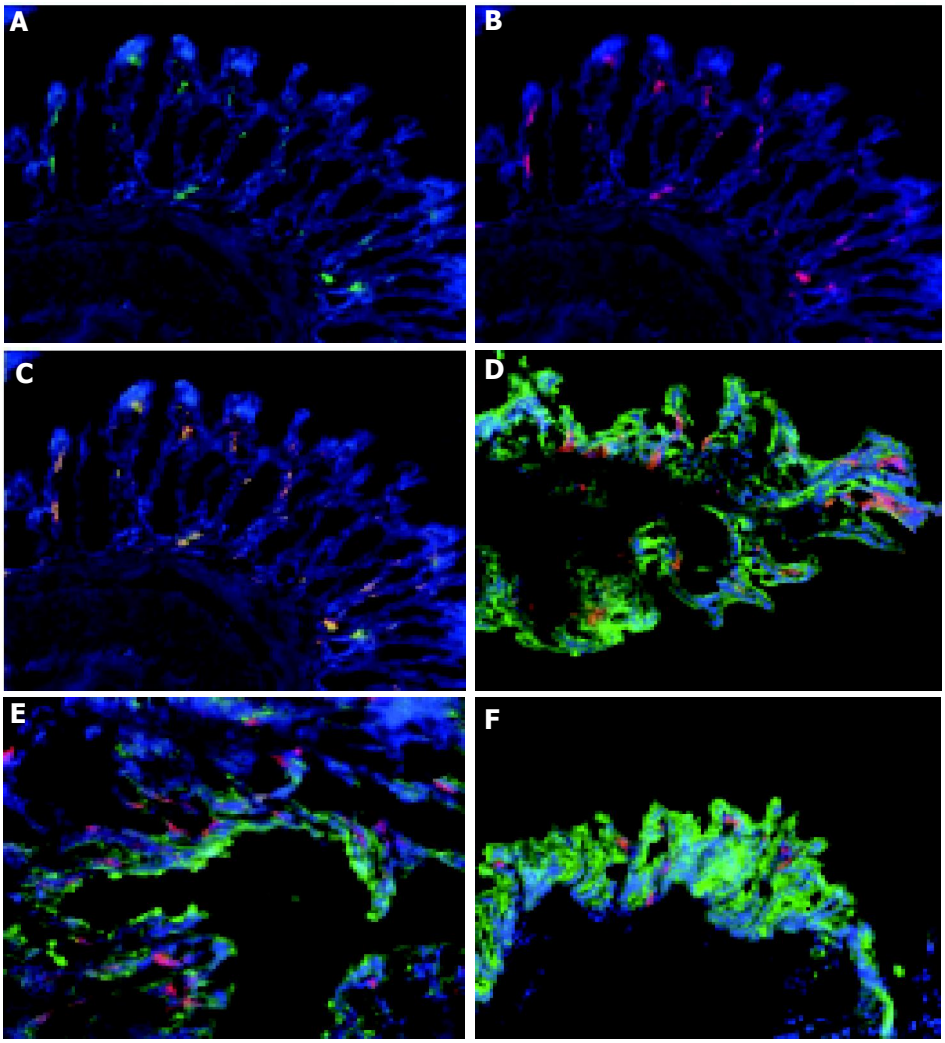

Figure 2 Colonic DC are myeloid DC which are distributed throughout the colon. Frozen sections of normal colon were stained with MAC-1 and FITC (**A**), CD11c and Cy3 (**B**) and counterstained with DAPI. The overlay of the combined images (**C**) shows that CD11c and MAC-1 co-localized (yellow) consistent with these cells being MAC-1$^+$, CD11c$^+$ myeloid DC. Tissue from the proximal (**D**), mid (**E**), and distal (**F**) colon of normal animals were immunolabeled with CD11c-Cy.3 to identify DC, cytokeratin-FITC to identify epithelial cells and counterstained with DAPI. DC were distributed throughout the colon. Magnification, ×160. Tissue was analyzed from the colons of 5 C57BL/6-IL2$^{-/-}$ and 4 C57BL/6 animals.

expressed B220 (see below, Figures 3G-I) suggesting that they may be plasmacytoid DC. The majority of CD11c$^+$ cells in the lymphoid aggregates were MAC-1$^+$ myeloid DC (data not shown).

The distribution of CD11c$^+$ cells in lymphoid aggregates within the colons (Figure 3) of colitic animals was analyzed next. These follicular-like structures were found at the base of crypts, with up to four being found per section with the exact number varying between individual mice. In IL2$^{-/-}$ mice these follicular structures were comprised of tightly packed groups of CD11c$^+$ cells which were particularly evident at the margins of these follicular structures (Figures 1F and 3). The cellular composition of these follicle-like structures was determined by immunolabeling with antibodies specific for B220 and CD4. Whereas, CD11c$^+$ cells were primarily localized to the outer edges of the structures, B220$^+$ B cells and CD4$^+$ T cells were found in the centre (Figure 3). There was also evidence of co-localization of CD4 and CD11c antibody staining (Figures 3A-C) indicating that either some CD11c$^+$ cells were also CD4$^+$, as described in the small intestine[11] and colon[8], or that some CD11c$^+$ cells are in intimate contact with CD4 T cells. Such close contact of CD11c$^+$ cells with CD4$^+$ T cells would suggest that local activation of T cells may be occurring within these sites. Although the majority of CD4$^+$ cells were found in the follicular structures, smaller numbers of positive cells were also seen in the LP of the villi and in blood vessels. B220$^+$ B cells were almost entirely restricted to the lymphoid follicle-like structures (Figures 3D-F). A small proportion of B220$^+$ cells co-localized with CD11c$^+$ cells within the lymphoid follicle (Figures 3G-I), which may represent plasmacytoid DC. CD11c$^+$, B220$^+$ cells were found primarily at the interface of the B220$^+$ cells in the centre of the lymphoid follicle and CD11c$^+$ cells at the aggregate margin.

The identity and type of DC present in the colons of normal C57BL/6 and colitic C57BL/6 IL2$^{-/-}$ mice was confirmed by electron microscopy (Figure 4). Of the total cells analyzed from C57BL/6 mice, DC represented approximately 2-4% of the cells counted. DC have been classified into three types by electron microscopy[12,13]. Type 1 DC are small, irregularly shaped cells with small cell surface

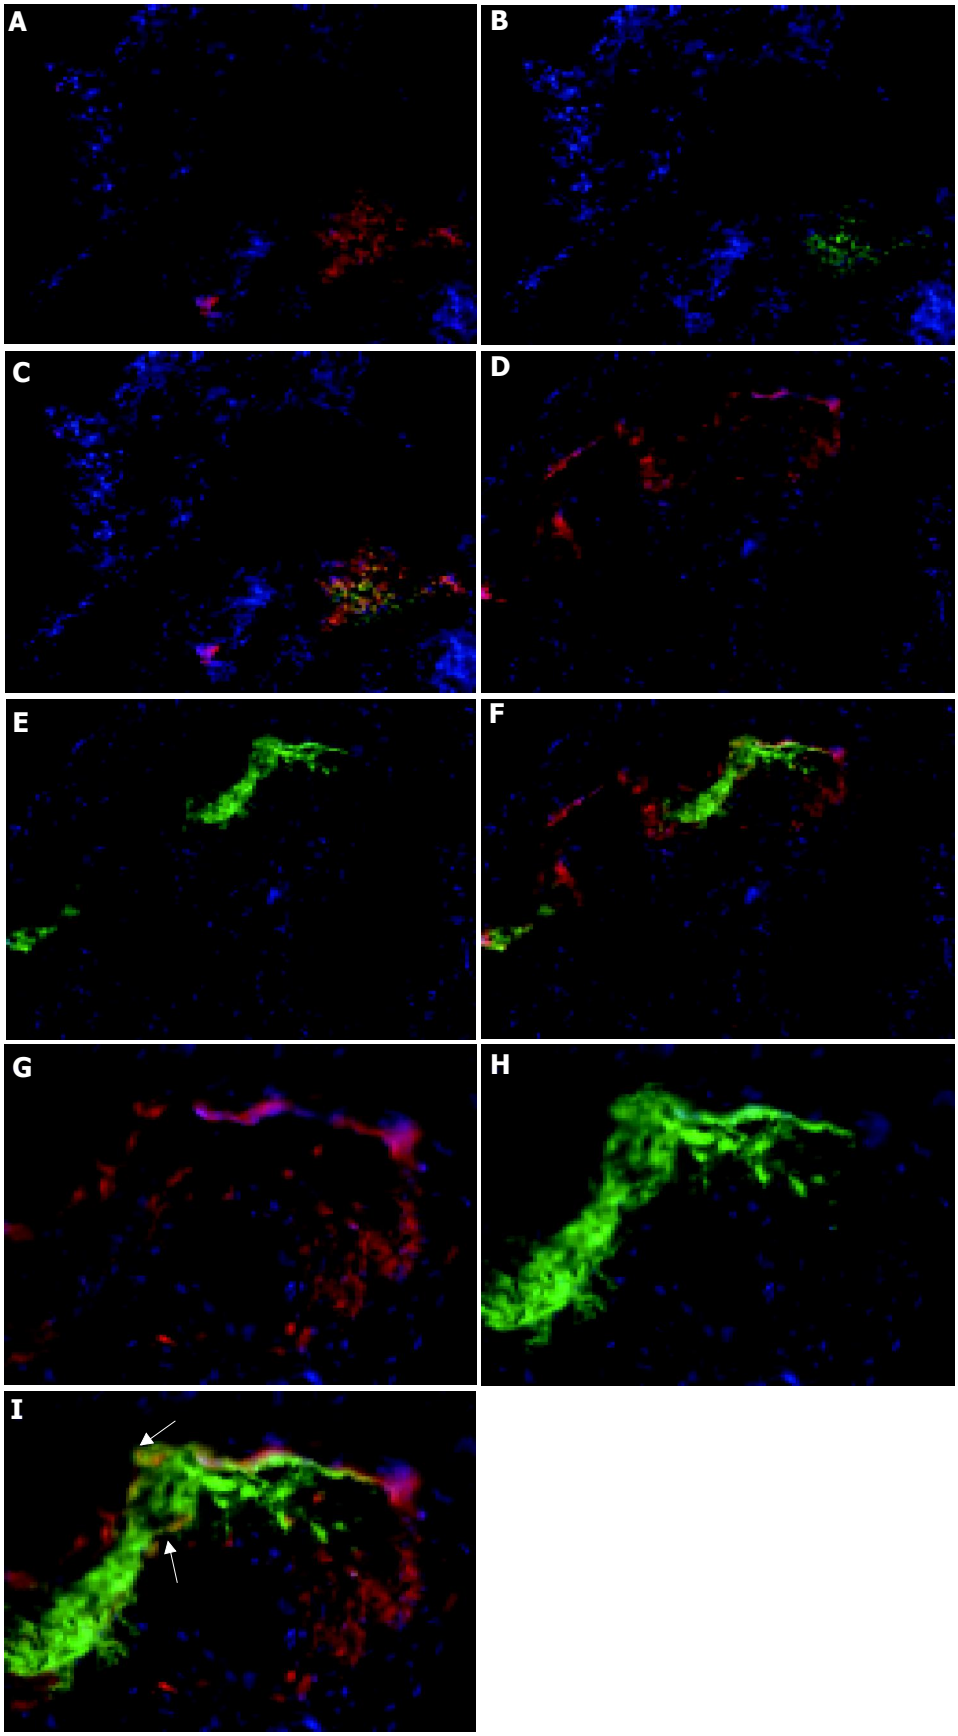

Figure 3 Lymphoid follicles in the colon. Colon sections were immunolabeled with CD11c and Cy3 to identify DC (red, **A, C, D, F, G,** and **I**), CD4 and FITC to identify Th cells (**B** and **C**) and B220 and FITC to identify B cells (**E, F, H,** and **I**) and counterstained with DAPI. Magnification, ×160. The bottom panel shows that there are $B220^{+}$ $CD11c^{+}$ cells (yellow) within the lymphoid follicles of colitic mice (magnification, ×400). The dual stained cells have been arrowed to indicate their localization. Tissue was analyzed from the colons of 5 C57BL/6-$IL2^{-/-}$ and 4 C57BL/6 animals.

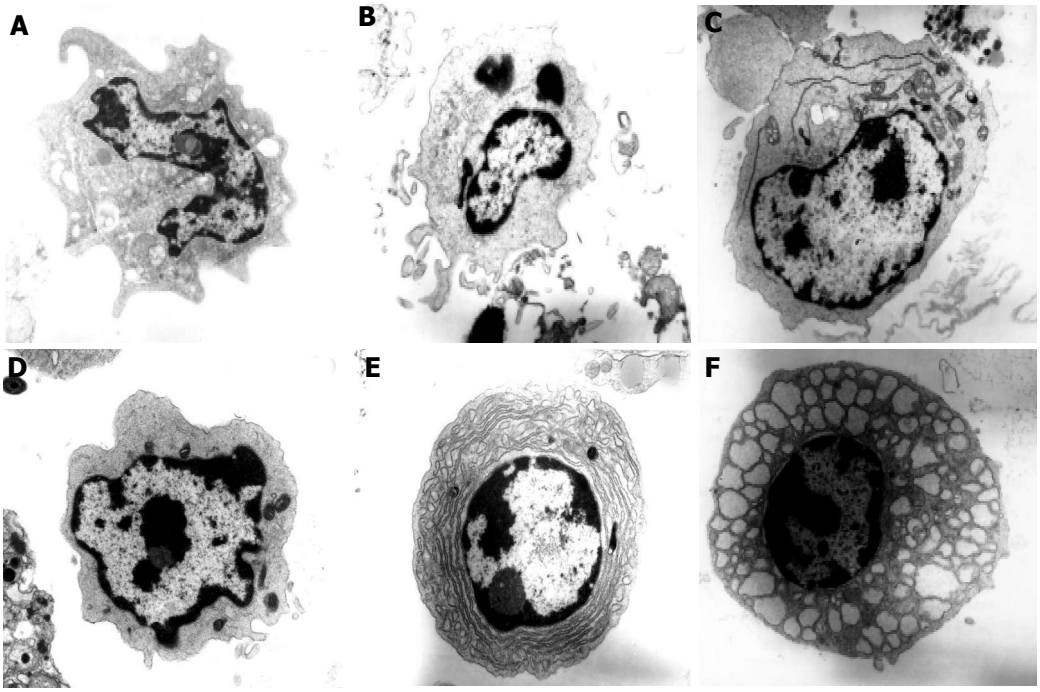

Figure 4 Electron micrographs of colonic DC from normal and colitic mice. Electron micrographs of cells from the colonic LP of normal C57BL/6 and colitic C57BL/6-IL2$^{-/-}$ mice showing (**A**) dendritic cell type 1 (myeloid DC) from a C57BL/6 mouse (×17 250), (**B**) dendritic cell type 1-2 from C57BL/6-IL2$^{-/-}$ mouse (×17 250), (**C**) dendritic cell type 2 (plasmacytoid DC) from C57BL/6-IL2$^{-/-}$ mouse (×13 800) with prominent RER, (**D**) dendritic cell type 1 (myeloid DC) from C57BL/6-IL2$^{-/-}$ mouse (×23 000), (**E**) plasma cell from C57BL/6-IL2$^{-/-}$ mouse (×17 250) and (**F**) Mott cell from C57BL/6-IL2$^{-/-}$ mouse (×17 250). Tissue was analyzed from the colons of 3 C57BL/6-IL2$^{-/-}$ and 3 C57BL/6 animals.

projections and heterochromatic nuclei with the chromatin found in a thick band at the nuclear margin and also in small condensed areas. Type 2 DC are larger than type 1 cells and have fewer projections and a euchromatic nucleus with disaggregated chromatin which is also found as a thin band at the nuclear margin. DC especially type 2 DC can have a prominent rough endoplasmic reticulum. Some cells appear to have features of both types 1 and 2 DC and have been termed type 1-2. Type 3 DC have a veiled appearance and euchromatic nuclei.

Colonic DC from normal C57BL/6 mice were mostly Type 1 (Figure 4A) with approximately 1% representing type 3 DC. However, some DC type 1 can have long projections making them appear similar to type 3 DC so this small subset of cells may in fact represent DC type 1. In comparison with normal colonic DC, many more colonic DC were identified in IL2$^{-/-}$ mice (13% compared with 2%) confirming our immunohistochemical findings. Colonic DC in the IL2$^{-/-}$ mice were comprised of type 1 DC (7-9%), type 1-2 (2%) and type 2 (2-3%, Figures 4B-D). Some of the DC (Figure 4C) had a prominent rough endoplasmic reticulum characteristic of plasmacytoid DC [14]. This would appear to confirm our immunohistochemical finding that there are small numbers of B220$^+$ CD11c$^+$ plasmacytoid DC within the colonic mucosa of IL2$^{-/-}$ mice. No type 3 DC were detected in the IL2$^{-/-}$ sample. Of the type 1 DC, half had undeveloped cytoplasm and may therefore represent a more immature population. Overall, these results confirm and extend our immunohistochemical findings that the majority of CD11c$^+$ DC detected by immunohistochemistry were CD11b$^+$ myeloid DC.

The presence of B220$^+$ B cells within the lymphoid follicular structures in the colons of IL2$^{-/-}$ mice was also confirmed by electron microscopy. Plasma cells represented approximately 10% of cells counted (Figure 4E) in the IL2$^{-/-}$ sample. The majority of plasm a cells detected had a dilated rough endoplasmic reticulum with vacuoles containing protein (Russell bodies). These are known as Mott cells and make more immunoglobulins than they are able to secrete[15]. The presence of plasma cells within the colonic lymphoid follicles suggests that the follicles are functional and that lymphocyte activation may occur locally within the colon, contributing to the chronic inflammation seen in these animals.

Phenotype of colonic DC from healthy and inflamed colonic tissue

The phenotype of DC was further analyzed by flow cytometry. There was approximately a five fold increase in the number of colonic DC in colitic animals with colonic CD11c$^+$ DC representing $3.0\pm1.3\times10^5$ of the total cells in IL2$^{-/-}$ mice compared with $6.0\pm1.4\times10^4$ cells in normal colons. These numbers were calculated by evaluating the CD45$^+$ CD11c$^+$ cells as a proportion of the absolute cell numbers and were generated from four different age- and sex-matched pairs of mice. These results confirm the increase in numbers of colonic DC in colitic mice seen by both electron microscopy and immunohistochemistry.

Expression of co-stimulatory molecules (CD40, CD80, and CD86) on CD11c$^+$ cells was compared on DC from C57BL/6 and C57BL/6-IL2$^{-/-}$ mice. Cell surface expression

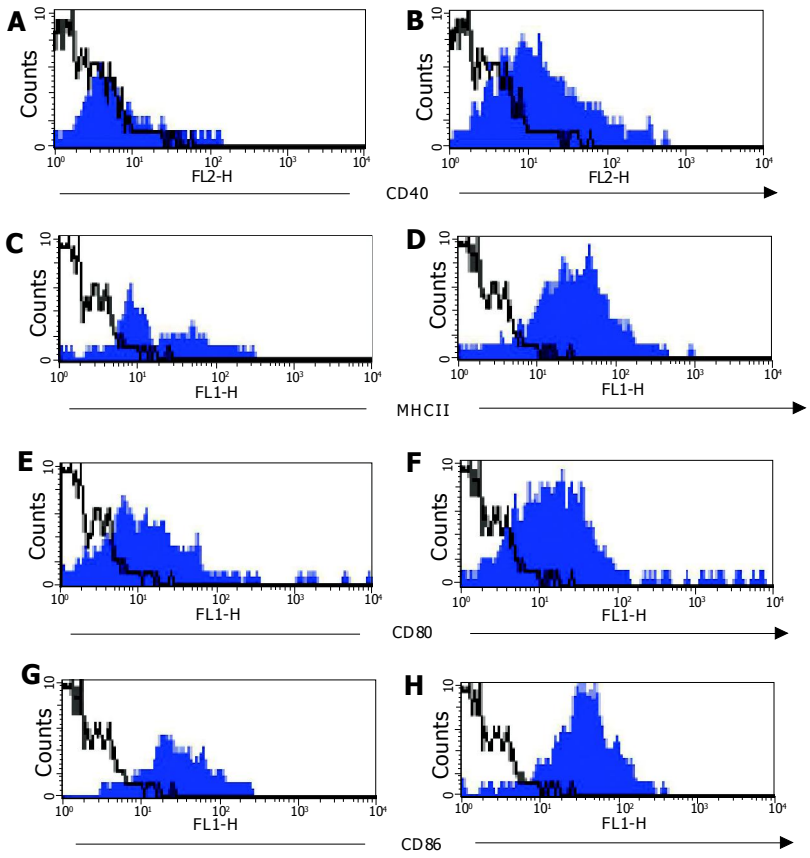

Figure 5 Co-stimulatory molecule expression on colonic LP DC. Expression of CD40 (**A+B**), MHCII (**C+D**), CD80 (**D+E**), and CD86 (**G+H**) was analyzed on CD11c$^+$ colonic LP DC from normal C57BL/6 (filled histogram left hand panel) and C57BL/6-IL2$^{-/-}$ (filled histogram right hand panel) mice by flow cytometry. Isotype control staining is represented by the open histograms with a dotted line. Data shown is a representative experiment from a total of six independent experiments.

of MHCII and CD40 was low, and CD80 and CD86 was low to moderate on CD11c$^+$ cells derived from normal colons (Figure 5). In contrast, expression of CD40, MHCII, CD80, and CD86 were all higher on DC derived from colitic animals (Figure 5). Furthermore, DC from colitic animals also expressed high levels of DEC205 (data not shown). CD11c$^+$ cells from both C57BL/6 and C57BL/6-IL2$^{-/-}$ mice all expressed high levels of the chemokine receptor CCR5 (data not shown).

The myeloid phenotype of the majority of colonic DC was also confirmed by flow cytometry with CD11c$^+$ cells being uniformly MAC-1$^+$ and CD8α. A small proportion of CD11c$^+$ DC were B220$^+$ confirming the immunohistochemical observations that there were small numbers of plasmacytoid DC present in the colons of colitic animals.

Phenotype of DC from mesenteric lymph nodes of healthy and colitic mice

In parallel to analyzing DC from the colonic LP, MLN cells were analyzed from normal and colitic animals. There were many more DC in the MLN of colitic C57BL/6-IL2$^{-/-}$ ($3.0\pm0.9\times10^5$) compared with normal C57BL/6 ($9.7\pm2\times10^4$) mice. MLN DC expressed high levels of MHCII and CD86, and moderate levels of CD40 and CD80. Furthermore, MLN DC from both C57BL/6 and C57BL/6-IL2$^{-/-}$ animals all expressed the marker DEC205. It was interesting to note that in the MLN of IL2$^{-/-}$ animals, there was an enrichment of DC populations, which expressed lower levels of MHCII (Figure 6B) and CD86 (Figure 6D). In normal mice, myeloid DC represented approximately 40-45% of DC detected in the MLN whereas in IL2$^{-/-}$, they represented up to 87% of the total DC detected. As for LP DC, all MLN DC expressed CCR5.

Endocytic activity of colonic DC

That colonic DC from normal C57BL/6 and colitic C57BL/6-IL2$^{-/-}$ animals are immature and mature, respectively, was confirmed by analyzing their endocytic activity (Figure 7). Colonic DC from normal animals were significantly more endocytically active ($P<0.001$) compared with DC from colitic animals (Figure 7A) consistent with their immature and mature status, respectively. Compared to DC, colonic macrophages were more endocytically active and took up a greater proportion of the FITC-dextran (Figure 7B). Macrophages from colitic animals endocytosed slightly more FITC-dextran than those from normal C57BL/6 animals although this was not statistically significant. Contaminating epithelial cells present in the colonic LP cell preparations all demonstrated endocytic activity. Consistent with MLN DC being mature cells, they had low endocytic activity (data not shown).

DISCUSSION

This study represents the first to attempt to quantify and characterize colonic DC in the normal, healthy colon and

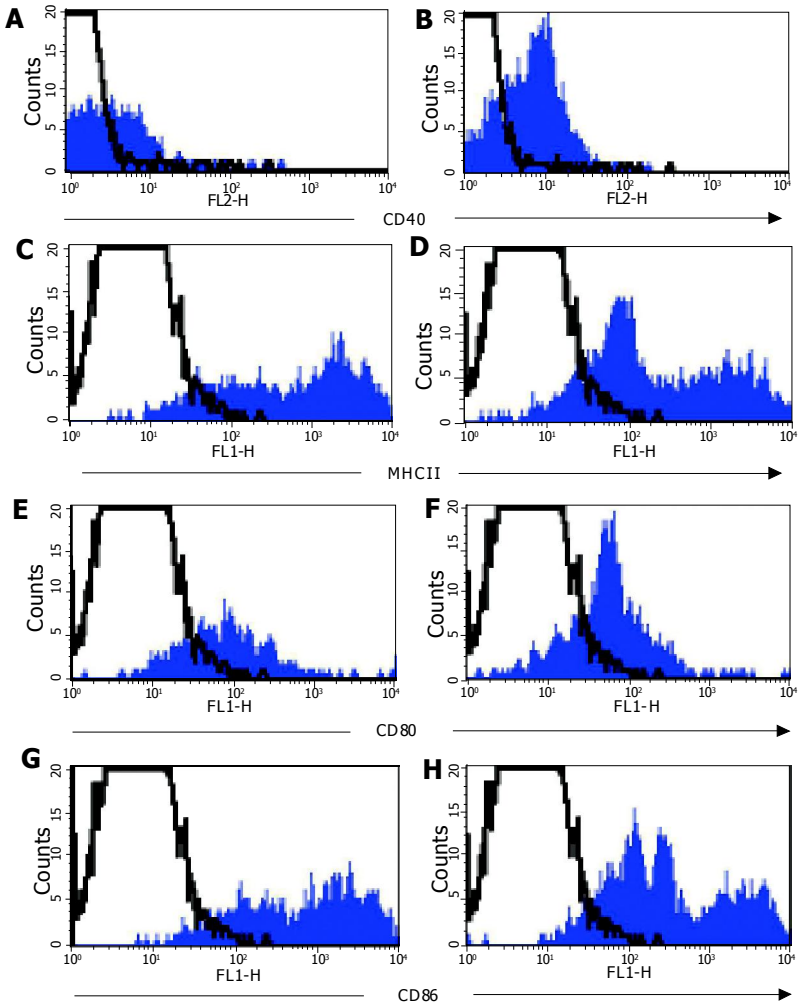

Figure 6 Co-stimulatory molecule expression on MLN DC. Expression of CD40 (**A+B**), MHCII (**C+D**), CD80 (**D+E**) and CD86 (**G+H**) was analyzed on CD11c$^+$ MLN DC from normal C57BL/6 (filled histograms left hand panel) and C57BL/6-IL2$^{-/-}$ (filled histograms right hand panel) mice by flow cytometry. Isotype control staining is represented by the open histograms with a dotted line. Data shown is a representative experiment from a total of six independent experiments.

in the colon of colitic mice. We have shown that DC in the normal colon are primarily myeloid of an immature phenotype with high endocytic activity. In contrast, colitic animal, colonic DC are mature and poor at taking up antigen. Furthermore, the redistribution and migration of DC in C57BL/6-IL2$^{-/-}$ mice and the accumulation of DC, B and T cells within lymphoid follicle-like structures suggests that activation of lymphocytes may occur locally within the colon.

There is a profound increase in the number of DC present in the inflamed colon as shown by three independent approaches. This contrasts, however, with a previous study that attempted to quantify DC in colonic biopsies from normal, UC and Crohn's patients in which it was not possible to identify any differences in the number of DC in the normal *vs* diseased colon[16]. In using, a murine model of colitis, it was possible to enumerate DC throughout the entire colon including cells within the lymphoid follicles in which many of the DC appeared to reside. By their very nature, biopsy samples may not be representative of the distribution of different cell types throughout the colon and may exclude some or all of these cells. Alternatively, these different findings may simply reflect species-specific differences.

Colonic DC are primarily myeloid DC with a small proportion of plasmacytoid DC present in the inflamed colon. This contrasts with a previous study using *rag-1*$^{-/-}$ mice transfused with CD4 T cells to induce intestinal inflammation in which CD8α CD11c$^+$ lymphoid DC were detected in the colon, which expanded two- to three-fold during inflammation[8]. This apparent difference may reflect differences in the properties of colonic DC in lymphocyte-replete *vs* lymphocyte-deficient mice, and different genetic backgrounds[17]. Alternatively, since some plasmacytoid DC have been reported to co-express CD8α the expanded population seen in CD4 T cell-transfused *rag-1*$^{-/-}$ mice may also represent an expansion of resident plasmacytoid DC which we have identified here. Although expression of the GR-1 antigen has been used to identify plasmacytoid DC in somestrains of mice[17], it was not possible to attempt this analysis here since plasmacytoid DC in C57BL/6 mice do not express GR-1.

The significance of different DC populations in normal and colitic colons is not clear. Plasmacytoid DC are associated with inflammatory responses and can secrete cytokines such as IFNα and IFNβ in response to viruses or bacterial antigens (CpG-DNA)[17,18]. Their role as APC *in vivo*, however,

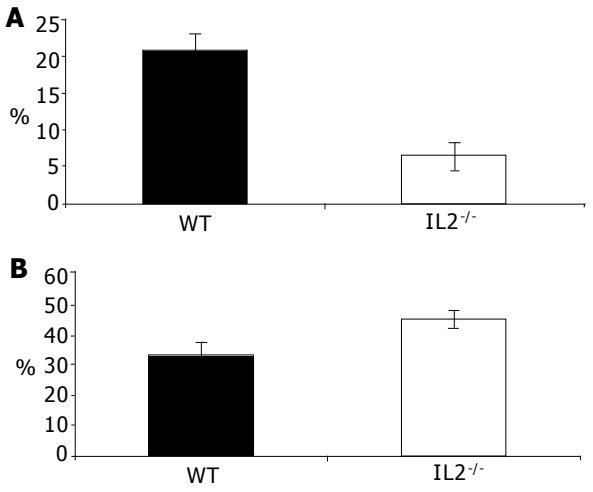

Figure 7 Increased endocytic activity by colonic DC from WT mice. Endocytic uptake of colonic lamina propria cells was measured by incubating colonic LP cells with FITC-dextran and antibodies to identify $CD11c^+$ DC (**A**) and $F4/80^+$ macrophages (**B**) from normal C57BL/6 (WT) and colitic C57BL/6-$IL2^{-/-}$ ($IL2^{-/-}$) mice. DC from colitic $IL2^{-/-}$ mice took up less FITC-dextran than their WT counterparts ($P<0.001$) consistent with them being mature DC. In contrast, colonic macrophages from $IL2^{-/-}$ mice took up more antigen than their WT counterparts although this was not significant (**B**). Results are from three independent experiments.

remains controversial with evidence of their involvement in the induction of tolerance[18-20]. Interestingly, they have also been associated with human plasma cell differentiation[21] and our observation that they localize to lymphoid follicles suggests that they may also be involved in plasma cell differentiation in the mouse. Myeloid DC may be important in promoting T regulatory/tolerogenic responses. Peyer's patch myeloid DC preferentially produce IL-10 in response to *S. aureus* and prime T cells to synthesize IL4 and IL-10 whereas lymphoid and $CD8\alpha^-CD11b^-$ DC primed IFNγ production by T cells [11]. However, our findings that myeloid DC are present in lymphoid follicle structures in the colon and comprise the major DC population in colitic animals suggests that they may promote local immunogenic or pathogenic rather than tolerogenic responses. Their ability to promote Th2 CD4 T cell responses[11] may be important for B cell class switching and contribute to the activation of the plasma cells observed in the lymphoid follicles of colitic $IL2^{-/-}$ mice. It is important to note, however, that DC from the colon and small intestine may not possess the same functional properties. For example, it has been shown that treatment of mice with RANKL promotes tolerogenic T cell responses in the small intestine[22] whereas excessive RANKL in the colon drives colonic inflammation by promoting DC maturation and survival[23, 24]. Furthermore, the nature of the signals that promote DC maturation can have a significant impact on the resultant immune response. Signaling through different toll-like receptors (TLR) generates distinct biological responses and differential expression of TLR by different DC subsets enables them to respond to distinct microbial structures in a specific manner[25,26]. Therefore, ligation of pattern recognition receptors by different bacteria may promote different types of T cell responses, including tolerogenic responses, and differences in small intestine and colonic DC function may therefore be due to different environmental influences[22,27,28]. For example, the interaction of DC with other cell types in the colon may be of significance, since colonic epithelial cells (CEC) can suppress T-cell activation even in the presence of professional APC[29]. Thus, the interactions of different cell types in the colon and the influence of the cell environment may have profound effects on the immune response generated.

The localization of colonic DC was altered in colitis. DC in $IL2^{-/-}$ animals were found adjacent to the colonic epithelium and may therefore access the lumen. This is not the case in normal animals, in which the colonic DC were found exclusively within the LP. DC have been reported as forming tight junctions with epithelial cells[30] enabling them to sample luminal antigens. However, our observation that, DC in the normal colon although capable of endocytosis are excluded from the epithelial layer, suggests that colonic DC may not normally sample luminal antigens in healthy mice. By contrast, in colitic mice DC are well positioned to take up luminal antigen although as mature cells they had low endocytic activity. Interestingly, we also found that CEC are strongly endocytic which may support the hypothesis that they are the primary cells involved in sampling luminal antigens within the colon. Based on this assumption we would propose that DC interact directly with CEC. Indeed, we have found that colonic DC express CCR5 and CEC secrete a variety of chemokines including ligands for CCR5 (MCP-1, MIP1α, and MIP1β) in response to different bacterial stimuli and may therefore play a role in attracting DC to the epithelial layer[31].

The number of $CD11c^+$ DC in the MLN of colitic mice was increased compared to normal mice and a population of $MHCII^{int}$, $CD86^{int}$ DC were expanded in the MLN, corresponding to the phenotype of mature LP DC which suggested that some colonic LP DC may have migrated from the colonic mucosa to the MLN. In addition to T-cell activation occurring within the MLN, there may also be local activation of lymphocytes within the colon as we found organized aggregates of DC at the base of the crypts in the inflamed colon, which primarily comprised DC, B cells, and T cells. The presence of plasma cells including Mott cells, which were identified by electron microscopy, in the colonic LP of $IL2^{-/-}$ animals adds weight to this hypothesis. Of note, similar aggregates of DC, B, and T cells have been described in human UC[32]. The formation of lymphoid aggregates may also contribute significantly to the pathology of IBD as DC which mature in inflamed tissue and fail to migrate to the lymph nodes are thought to act as nucleation sites to organize lymphoid structures which can sustain chronic inflammation[33].

In conclusion, we have characterized the phenotype of colonic DC in normal mice and mice with colitis. There is a dramatic increase in DC numbers within the colonic LP of the inflamed colon which have an altered phenotype and localization. Furthermore, we have described the formation of lymphoid aggregates which may contribute directly to the ongoing inflammation. Further study of these cells may

be informative in understanding the etiology of colitis and persistence of chronic inflammation.

Abstract

AIM: To provide the useful information for the diagnosis of liver cirrhosis by observing the morphology of peripheral hepatic vessels and the hemodynamics of microbubble arrival time in these vessels.

METHODS: Twenty-one subjects including 5 normal volunteers and 16 patients (liver cirrhosis, n=10; chronic hepatitis, n=6) were studied by contrast-enhanced coded phase inversion harmonic sonography (GE LOGIQ 9 series) using a 6-8 MHz convex-arrayed wide-band transducer. The images of peripheral hepatic artery, portal and hepatic vein were observed in real-time for about 2 min after intravenous injection of Levovist. The time when microbubbles appeared in the peripheral vessels (microbubble arrival time) was also recorded. The morphologic changes of peripheral hepatic vasculature were classified as marked, slight, and no changes based on the regularity in caliber, course, ramification, and the delineation of vessels compared to normal subjects.

RESULTS: The microbubble arrival time at peripheral artery, portal, and hepatic vein was shorter in cirrhotic patients than in chronic hepatitis patients and normal subjects. The marked, slight and no morphologic changes of peripheral hepatic vasculature found in 5 (5/6, 83.3%), 1 (1/6, 16.7%), and 0 (0/6, 0%) liver cirrhosis patients, respectively, and in 1 (1/10, 10%), 6 (6/10, 60%), and 3 (3/10, 30%) chronic hepatitis patients, respectively. There was a significant difference between the two groups (P<0.001).

CONCLUSION: Evaluation of the hemodynamics and morphology of peripheral hepatic vasculature by contrast-enhanced coded pulse inversion harmonic sonography can provide useful information for the diagnosis of liver cirrhosis.

INTRODUCTION

Ultrasonography (US) is widely used for the purpose of screening for liver tumors. However, it has a limited value for the diagnosis of liver cirrhosis due to its low sensitivity and specificity[1].

With the advent of ultrasound contrast agent and associated ultrasonic technologies, drastic improvements have been achieved in the diagnosis and treatment of hepatic tumors[2]. However, application of contrast-enhanced US in the evaluation of diffused liver diseases is rare. Recently, using spectral Doppler US with time-intensity analysis software to measure the arrival time of microbubble agent, Levovist, in hepatic vein, Albrecht *et al*.[3] found a much earlier onset of microbubble enhancement in cirrhotic patients than in normal controls or non-cirrhotic patients, and stressed that this method is a sensitive non-invasive test for liver cirrhosis. However, this technique is based on the Doppler US that has limitations in detecting slow blood signals in small vessels. Furthermore, it is not easy to perform continuous spectral Doppler tracing.

Microbubble-specific technologies, such as phase/pulse inversion harmonic imaging (PIHI) and coded harmonic angio, can display microbubble signals in blood vessels on a gray-scale background in real time[4]. Theoretically,

microbubble arrival time can be measured using such gray-scale harmonic imaging techniques by direct visualization of microbubble enhancement in hepatic vessels, that is both hemodynamics and morphology of hepatic vessels can be evaluated simultaneously. Bang *et al*.[5] recently used the pulse inversion imaging technique to assess the arrival time of microbubbles in hepatic vein and compared it with the spectral Doppler tracing method[3]. They noticed that there is no significant difference between these two methods.

On the assumption that the evaluation of hepatic vascular morphology when observing the hemodynamics of microbubble arrival time in hepatic vessels may provide more information for the diagnosis of liver cirrhosis, we conducted a study to observe the morphology of and microbubble arrival time in peripheral hepatic vessels in patients with liver cirrhosis and chronic hepatitis using contrast-enhanced coded harmonic angio mode, which is a real-time vascular imaging technique that combines PIHI with coded technology. The purpose of this preliminary study was to evaluate whether it is possible to provide useful information for the diagnosis of liver cirrhosis by observing the morphology and hemodynamics of hepatic vessels using contrast-enhanced coded harmonic angio technique.

MATERIALS AND METHODS

Patients

This study consisted of 5 normal volunteers (4 men and 1 woman; age range 28-38 years, mean age 31 years) and 16 patients (12 men and 4 women; age range 18-73 years, mean age 54 years). Among the 16 patients, 10 had chronic hepatitis (hepatitis C, n=7; hepatitis B, n=3), 6 had liver cirrhosis (hepatitis C-related cirrhosis, n=3; hepatitis B-related cirrhosis, n=3). In addition, 4 patients (3 with cirrhosis and 1 with chronic hepatitis) were accompanied with hepatocellular carcinoma (HCC) with 1 (n=3) or 2 (n=1) nodules (less than 4 cm in diameter) in the right (n=3) or left (n=1) liver lobe. The diagnosis of chronic hepatitis (n=9) and liver cirrhosis (n=1) was made by histology in 10 patients. Other patients were diagnosed on the basis of clinical, biochemical and imaging findings on US (n=6), CT (n=5), MRI (n=3) and/or angiography (n=2). Normal subjects had no history or clinical signs of liver diseases. The Institutional Ethics Board of our university approved the study protocol and informed consent was obtained from all subjects.

Methods

In this study, we used Levovist (Schering, AG, Berlin, Germany) as a contrast agent, an intravenous microbubble agent consisting of 99.9% D-galactose and 0.1% palmitic acid. In brief, 2.5 g Levovist suspension at a concentration of 400mg/mL was prepared according to the manufacturer's introductions. The suspension was injected via a 21- gauge cannula placed in the antecubital vein at a speed of 1 mL/s, and followed by a 10 mL normal saline flush.

Contrast-enhanced US study was carried out using GE LOGIQ 9 series (General Electric Medical System, Milwaukee, WI). A M7C convex-arrayed wide-band transducer with a frequency of 6-8 MHz was used. All subjects were fasted for at least 5 h before examination. Before contrast-enhanced study, fundamental B-mode imaging was performed to screen for any local lesions. Patients who had multiple (more than two nodules) and large (larger than 4 cm in diameter) nodules of solid occupying lesions were excluded in this study. The scanning section was selected at the right liver lobe through an intercostal approach. A non-tumor section was chosen to avoid the interference of the tumor for patients with HCC. Color Doppler imaging was also performed before the contrast study to ascertain the location and course of different liver vessels (especially the portal and hepatic vein) for the reference of identifying these vessels on contrast-enhanced images.

Contrast-enhanced US was then studied using coded harmonic angio mode with the mechanical index (MI) of 0.4-0.5, dynamic range of 72 decibels, main gain of 35-40 G and frame rate of 6-7 Hz. The scanning depth was maintained within 6-8 cm from the body surface. Single focus point was set at 1-2 cm beneath the liver surface. After the administration of Levovist, an inner time-meter was switched on. All the subjects were asked to breathe gently during examination. Real-time scanning with no background display was used to observe the vessel images of hepatic vasculature from the level equal to the origin of the third order branches of portal vein (segment level) to the liver surface, for about 2 min after injection. Simultaneously, the time when microbubbles appeared in the hepatic artery, portal and hepatic vein (microbubble arrival time) in the area described above was measured.

Real-time data were recorded on S-VHS videotapes and stored in the cine memory of the machine, which could load more than 2 000 frames of images (about 5 min in real time), and then saved to the hard disk for later review. After the examination, the dynamic contrast-enhanced images were replayed in the cine loop derived from the hard disk frame and series pictures were printed in the time sequence for later analysis.

Data analysis

Contrast-enhanced US studies were performed by the same operator using the same protocol in order to minimize the variations from the operators and condition settings. Another two authors reviewed the series pictures and evaluated the results without any knowledge of the subjects' clinical data.

Referring to the evaluation method used in hepatic venography[6] and transhepatic portography[7], the morphologic changes of peripheral hepatic vasculature in patients with chronic liver disease were classified as marked, slight and no changes based on the regularity in caliber, course, ramification, and the delineation of vessels compared to normal subjects.

The peripheral vascular morphologic changes were compared among different groups using chi-square test, while the microbubble arrival time at different hepatic vessels was compared using Mann-Whitney test. $P<0.05$ was considered statistically significant.

RESULTS

The peripheral artery could not be seen on coded harmonic angio mode before contrast, while the relative large portal and hepatic veins could be visualized during respiration (Figure 1A). After injection of contrast medium, microbubbles in the peripheral hepatic artery were displayed as small bright dots (Figure 1B). When enhanced by the contrast medium, the portal and hepatic vein became more echogenic than they were on pre-contrast images (Figure 2). In some subjects, the microbubble arrival time at different vessels could not be measured because of inadequate section showing no target

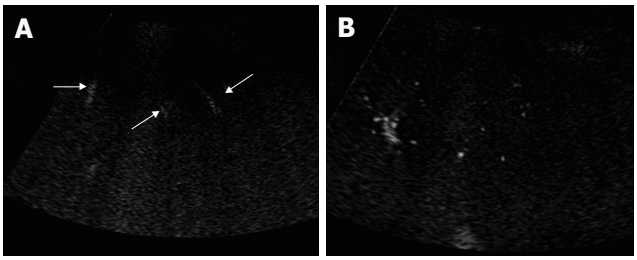

Figure 1 Pre-contrast image in a 32-year-old normal control (**A**) and contrast-enhanced US image in a 64-year-old cirrhotic patient (**B**).

vessels, or interference with deep breath of the subjects.

In the normal subjects, microbubbles appeared in the peripheral hepatic artery in about 16-28 s after Levovist injection. Arterial vessels were thin and regular in the early arterial phase in which only intraheaptic arterial vessels were visualized on contrast-enhanced images (Figure 3A). Portal venous vessels were enhanced by microbubbles in about 28-39 s, and then hepatic venous vessels were stained in about 35-71 s. In the vascular phase, intrahepatic portal and hepatic veins were visualized on contrast-enhanced images, peripheral hepatic vessels were regular in caliber, course and ramification, tapering smoothly as they run to the periphery (Figures 3B and 3C). When the vessel images on contrast-enhanced US were evaluated by another two authors blindly, all the normal subjects were regarded to having no abnormal morphologic changes.

The microbubble arrival times at peripheral artery, portal and hepatic vein were shorter in cirrhotic patients than in chronic hepatitis patients and normal subjects. However, it showed statistical significant differences only in hepatic venous arrival time ($P<0.05$) (Table 1). Whereas, there were no significant differences in arrival times at different vessels between chronic hepatitis patients and normal controls (Table 1). Markedly morphologic changes of peripheral hepatic vessels including poor delineation

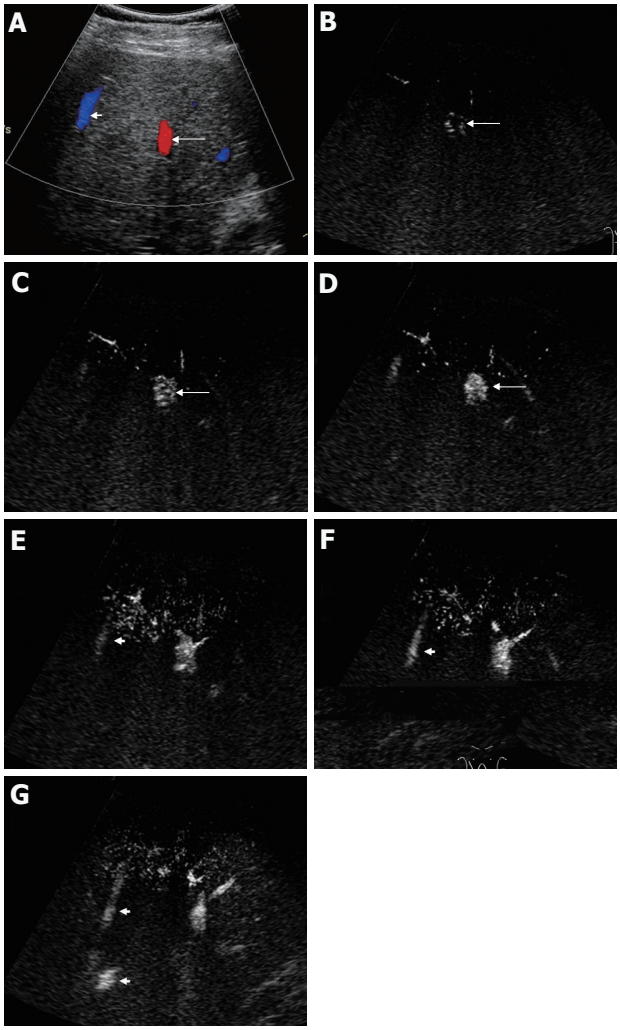

Figure 2 Contrast-enhanced US images in a 32-year-old normal control. **A:** Before contrast, color Doppler US was performed to show the location and course of the portal vein (arrow) and hepatic vein (arrowhead); **B:** In the early arterial phase, the portal vein was not enhanced, while the parallel running artery was displayed by microbubble enhancement (arrow); **C:** Twenty-eight seconds after injection of Levovist, bright dots of microbubbles began to fill in the portal vein (arrow); **D:** Four seconds later, the portal vein was obviously enhanced by microbubbles (arrow); **E:** Before microbubbles arrived, the hepatic vein (arrowhead) was mildly echogenic; **F** and **G:** Thirty-seven seconds after injection of contrast medium, the hepatic vein (arrowhead) became more echogenic (**F**) than it was on **E**, indicating enhancement by microbubbles, and 4 s later the proximal part of hepatic vein was also clearly seen (arrowheads) (**G**).

of vessels, irregularity in caliber, course, and ramification without tapering of vessels (Figure 4A), or visualization of abnormal structures such as ring-like vessels (Figure 4B), were found in 5 of the 6 cirrhotic patients (5/6, 83.3%) Slight morphologic changes were identified in one cirrhotic patient (1/6, 16.7%). Marked, slight and no morphologic changes were found in 1 (1/10, 10%), 6 (6/10, 60%), and 3 (3/10, 30%) chronic hepatitis patients, respectively ($P<0.001$, Table 2). If marked morphologic changes of peripheral hepatic vessels were taken as a criterion for the diagnosis of liver cirrhosis, the diagnostic sensitivity and specificity were 83.3% and 93.3%, respectively.

The microbubble arrival time at hepatic vein was shorter in cirrhotic patients who had marked morphologic

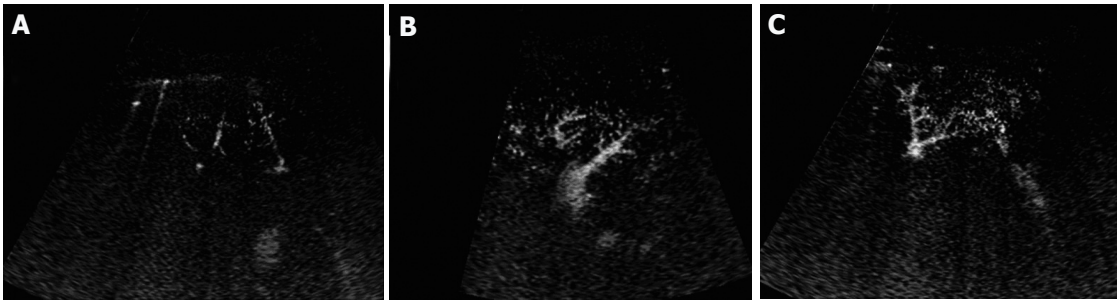

Figure 3 Contrast-enhanced US images in normal controls. **A:** In the early arterial phase, only the peripheral arteries were displayed, they were thin and regular; **B** and **C:** In the vascular phase of contrast-enhanced US, the peripheral portal vein (**B**) and hepatic vein (**C**) were portrayed as regular in caliber, course, and ramification, tapering smoothly as they run to the liver surface.

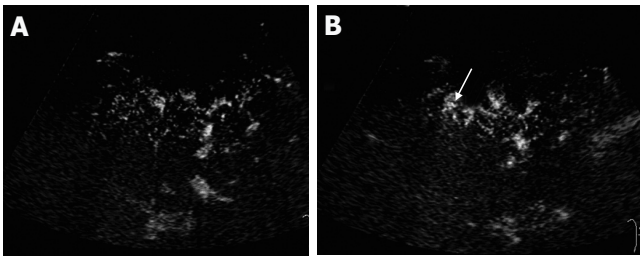

Figure 4 Contrast-enhanced US images in cirrhotic patients. **A** and **B:** On contrast-enhanced US images, the peripheral vessels had poor delineation and were irregular (**A**). There was no tapering of the vessels. Small branches of the vessels were rarely seen (**A**), while abnormal ring-like structure (**B**, arrow) was displayed.

changes than in those who had slight morphologic changes of peripheral hepatic vasculature (16-25 s *vs* 37 s). In one of the cirrhotic patients without HCC, the arterial arrival time was short (11 s). During the early arterial phase, one distal portal vein branch was enhanced by microbubbles (14 s) prior to the enhancement of proximal portal vein and other branches at the same level (Figure 5A). An adjacent peripheral hepatic vein was also stained (16 s) (Figures 5B and 5C). A small intrahepatic arterioportal shunt was suspected. Unfortunately, the patient did not undergo hepatic angiography.

DISCUSSION

In liver cirrhosis, circulatory changes play an important role in the progression of regenerative nodular formation and extensive stromal fibrosis and vice versa[8]. Microscopically, these circulatory changes in the liver, such as capillarization

Table 2 Abnormal morphologic changes of peripheral hepatic vasculature on contrast-enhanced US

	Marked (%)	Slight (%)	None (%)	Total
Cirrhosis	5 (83.3)	1 (16.7)	0	6

Normal control	0	0	5 (100)	5

^{b}P<0.001 *vs* cirrhosis, chronic hepatitis and normal control.

of sinusoids, arterialization, and intrahepatic shunts[9-11], can be observed by microcirculation evaluation methods such as microvascular casts[8], color gelatin injection postmortem[11]. Macroscopically, circulatory morphological changes in liver cirrhosis can be demonstrated by different angiographic techniques, such as hepatic angiography, arterial portography or transhepatic portography and hepatic venography[7]. However, angiographic techniques are invasive and cannot be used routinely. Color and power Doppler ultrasonography can also be used in the evaluation of hepatic vasculature. However, they can not achieve satisfactory results due to their limitations in detecting slow blood flow signals in fine vessels.

Contrast-enhanced code harmonic angio is an advanced microbubble-specific technique that combines PIHI with coded technology, which amplifies the wide-bind signals from microbubbles and suppresses signals from the tissue[2,4]. It provides the possibility to assess the morphology of hepatic vessels in real time under physiological conditions. In this study, the morphology of peripheral hepatic vasculature was clearly demonstrated by a high frequency probe, which has high resolution in showing superficial structures. Compared to normal subject, marked morphologic changes including poor delineation of vessels, irregularity in caliber, course, and ramification without tapering of the vessels, or visualization of abnormal structures, were portrayed in most cirrhotic patients (83.3%), while few of chronic hepatitis patients (10%) and none of normal subjects had marked morphologic changes of peripheral hepatic vasculature, suggesting that it has a relatively high sensitivity and specificity for the diagnosis of liver cirrhosis. The results indicate that contrast-enhanced code harmonic angio can recognize the differences in peripheral vasculature between cirrhotic and non-cirrhotic subjects,

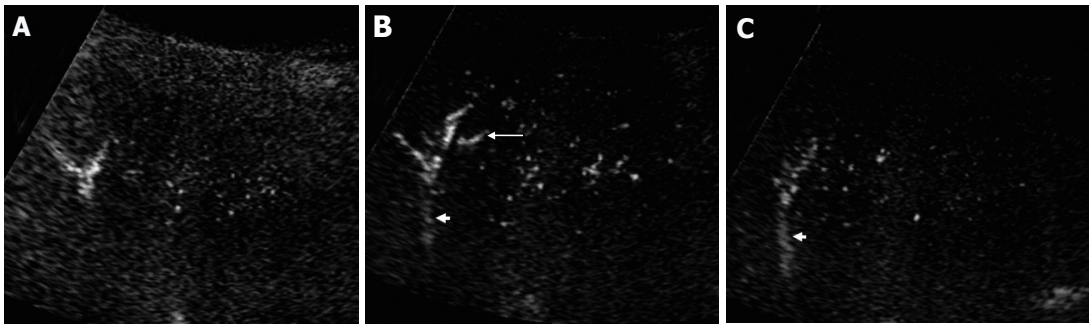

Figure 5 Contrast-enhanced US images in a 64-year-old cirrhotic patient. **A:** In the early arterial phase 14 s after Levovist injection, a "Y"-shaped distal portal venous branch was enhanced by microbubbles (arrow), while the proximal portal vein and other portal venous branches at the same level were not seen; **B** and **C:** An adjacent hepatic venous branch was enhanced by contrast medium at 16 s after injection of Levovist (arrows).

and might provide useful information for the diagnosis of cirrhosis.

In addition, evaluation of peripheral hepatic vasculature might facilitate the differential diagnosis of pseudotumors caused by intrahepatic arterioportal shunt, which is not rare in liver cirrhosis especially in peripheral area of the liver[7,12,13]. It was reported that these pseudolesions mimic hypervascular tumors on hepatic imaging and bring about problems of differential diagnosis in cirrhotic patients especially when they are round or nodular in shape[12,13]. Usually, intrahepatic arterioportal shunts are confirmed by hepatic angiography. However, when the arterioportal shunt-induced pseudolesion is small (less than 1 cm in diameter), it can hardly be visualized on hepatic angiogram because of the limited spatial resolution and overlapping of liver parenchyma[13]. In this situation, contrast-enhanced US may show the small intrahepatic arterioportal shunt in peripheral area of the liver. Theoretically, when distal portal venous branches are enhanced earlier in the early arterial phase before microbubbles arrive at the proximal branches, an intrahepatic arterioportal shunt can be diagnosed by hepatic angiography. In addition, the abnormal ring-like structures on contrast-enhanced US images in some cirrhotic patients might also indicate small intrahepatic shunts or abnormal anastomoses in artery, portal or hepatic vein. Unfortunately, this assumption was not confirmed in this study because we did not perform any prospective angiography. Further investigations are needed to validate the possibility.

Compared to angiography, contrast-enhanced coded harmonic angio imaging has several advantages in showing morphologic changes of peripheral vessels. First, it is non-invasive. Second, peripheral vessels including hepatic artery, portal and hepatic vein, can be seen. Third, the kinetics of microbubble contrast agent in peripheral hepatic vessels can be evaluated simultaneously. However, it has some disadvantages. The morphologies of different hepatic vessels displayed on contrast-enhanced US are not so clear compared to angiography because of overlapping of different vessels. In addition, the visual fields on contrast-enhanced US cannot display the whole vascular tree.

We could also assessed the microbubble arrival time at different peripheral vessels in some subjects using contrast-enhanced coded harmonic angio mode. The results showed that hepatic venous arrival time was shorter in cirrhotic patients than in other subjects, which is in accordance with those observed by Albrecht *et al*.[3] Furthermore, the venous arrival time was shorter in cirrhotic patients who had marked morphological changes of peripheral hepatic vasculature, indicating that hemodynamic changes in liver cirrhosis are due to the morphologic changes of hepatic circulation. We also noticed that not only the hepatic venous arrival time, but also the arterial and portal venous arrival time were shorter in cirrhotic patients than in chronic hepatitis patients and normal controls, though there was no statistically significant difference, suggesting that both intrahepatic and extrahepatic hemodynamic changes such as pulmonary arteriovenous shunt and systemic hyperdynamic circulatory state may occur in liver cirrhosis[3], which might contribute to the early arrival of microbubbles in hepatic artery and portal vein.

Except for the evaluation of hemodynamics changes in chronic liver disease, assessing microbubble arrival time at different hepatic vessels might help to study the time phases on contrast-enhanced US images, which is important in the diagnosis and differential diagnosis of liver tumors.

There are several limitations in this preliminary study. First, the number of patients with liver cirrhosis was not large enough. Second, angiography examinations were not prospectively studied, lacking of data to validate the findings on contrast-enhanced the United States. Third, the microbubble arrival time was not available in some subjects because of several interfering factors. Furthermore, we did not use the time-intensity analyzing software to measure the microbubble arrival time, the accuracy was certainly not very high. However, the results obtained in our study and other studies[5] are not significantly different from those obtained using time-intensity analyzing software[3].

In conclusion, contrast-enhanced coded pulse inversion harmonic imaging can evaluate the hemodynamics and morphology of peripheral hepatic vasculature and provide useful information for the diagnosis of liver cirrhosis.

Abstract

AIM: To evaluate the imaging findings of biliary hamartomas (von Meyenburg complexes, VMCs) and discuss the differential diagnosis with other related diseases.

METHODS: Imaging findings of biliary hamartomas on ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), MR cholangiopancreatography (MRCP)and hepatobiliary scintigraphy were retrospectively analyzed in six patients.

RESULTS: On ultrasound images, five of the six cases showed multiple small hyper- and hypo-echoic lesions with comet-tail echoes, especially when magnified by US with the usage of zoom function. In all the six cases, multiple tiny hypodense lesions less than 10 mm in diameter were revealed as scattered throughout the liver with no enhancement on CT. These tiny lesions were demonstrated to be hyper- and hypo-intensity on T2- and TI-weighed images, respectively, in three patients who underwent MRI examinations. MRCP was performed in two patients, and clearly showed multiple tiny irregular- and round-shaped hyper-intensity lesions. MRCP and hepatobiliary scintigraphy showed normal appearances of intra- and extra-hepatic bile ducts in two and one patients, respectively.

CONCLUSION: Imaging modalities are useful in the diagnosis and differential diagnosis of VMCs. A correct diagnosis might be obtained when typical imaging findings are present even without a histological confirmation.

INTRODUCTION

Biliary hamartomas also called as von Meyenburg complexes (VMCs) are benign liver malformations that histologically contain cystic dilated bile ducts within 10 mm in diameter surrounded by abundant fibrous stroma[1,2]. They are usually uncovered by autopsy as an incidental finding. Detecting by imaging modalities is thought to be uneasy because of their asymptomatic nature and small size[3]. To our knowledge, except for a few case reports, there are only two imaging studies on VMCs with small series of cases that have been published in the literature so far[1,3]. Although VMCs are rare, they are easily confused with metastatic diseases of the liver on imaging[4]. Therefore, discerning the imaging characteristics of VMCs is desirable for the differential diagnosis, and thus reducing the needs for invasive methods such as biopsy or laparotomy[5].

Herein, we retrospectively analyze the imaging findings of VMCs on ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), MR cholangiopancreatography (MRCP), and hepatobiliary scintigraphy in six patients, and discuss the differential diagnosis with other related diseases.

MATERIALS AND METHODS

Materials

There were four men and two women with ages ranging from 29 to 72 years (mean, 54 years). Hepatic lesions were found incidentally when the patients underwent routine physical checkup by US (n=2), screening for liver metastasis of a known ovary carcinoma by US and CT (n=1), and abdominal US examinations for Hashimoto disease associated with abnormal liver function tests (n=1), as well as diabetes (n=2). All imaging studies including US, CT, and MRI were performed in three patients. Among them, additional MRCP was performed in two patients; hepatobiliary scintigraphy was carried out in another patient. Both US and CT scans were available in another three patients. Three- to ten-time follow-up US and/or CT examinations were obtained in all the six patients for over a period of 7–100 months. Histologic

confirmation was acquired in three patients.

Methods

US examinations were performed by using GE LOGIQ 700 EXPERT series and LOGIQ 500 MD series (GE Medical System, Milwaukee, WI, USA), Toshiba Powervision 8000 (Toshiba Medical System) with convex probes at the frequency of 3.0–4.4 MHz. A helical CT system (Toshiba X-vigor) was used for CT scans. The section thickness was 7 mm with no interslice gap. Both plain and enhanced CT scans were carried out in five patients. For enhanced CT, a total of 100 mL of Iopamiron (Iopamidol, Nihon Schering) was intravenously injected with the iodine concentration of 370 mg/mL. MRI was performed by using a 1.5 T MR unit (VISART HYPER, Toshiba) with 160 × 256 matrix. SE T1- and T2-weighed images were acquired by using 500/15 ms (TR/TE) and 3 000/80 ms (TR/TE), respectively, with two excitations. Slice thickness was set to 8 mm, and interslice gap of 1 mm. Fast SE MRCP was performed with 6 000/250 ms (TR/TE), and 4–8 mm slice thickness. Hepatobiliary scintigraphy was carried out by using 99mTC-N-pyridoxy 1-5-methyl tryptophan (99mTC-PMT).

RESULTS

Multiple hepatic lesions were scattered throughout both the right and left liver lobes in five patients, distributed predominantly in the right liver lobe in one case. Of the five patients with scattered distribution of the lesions, apparent location of the lesions in the subcapsular areas was observed in four cases. The lesion size measured within 10 mm in five cases. In another case, most of the lesions were less than 10 mm in diameter; in addition, four to five typical cysts with round or oval shape in the right liver measuring from 11 to 25 mm were noted in one case. Multiple right renal cysts (3 in number and 10-20 mm in diameter) together with one cyst (10 mm in diameter) in the left kidney were detected in one case.

On US images, five cases showed multiple small hyper- and hypo-echoic lesions with comet-tail echoes (Figure 1A). Liver echo textures were heterogeneous. When zoom function was used, some small hyper-echoic dot-like lesions were showed to be tiny cystic lesions with distal acoustic enhancement (comet-tail echoes) (Figures 2A and 3A). One case was revealed as multiple hypo-echoic lesions. In five cases, three- to ten-time follow-up US examinations were performed for 19-100 mo, and no remarkable changes were found.

On plain CT, multiple hypodense lesions with irregular and round shape were observed in six cases (Figures 1B and 3B). After intravenous administration of contrast medium, all the lesions showed no enhancement in either the periphery or the center areas, and the delineation of all the lesions became more conspicuous than on plain CT (Figures 1C and 3C). Three- to six-time follow-up CT scans performed for 7-84 months in three patients revealed no obvious changes of the lesions when compared with the findings on the first time CT images.

MRI was performed in three cases. Multiple small hepatic lesions were demonstrated to be of low signal intensity on T1-weighed images and high signal intensity on T2-weighed images (Figures 1D, 3D, and E). After gadolinium administration was performed in one case, no enhancement was noted on T1-weighed images (Figure 1E). In two cases, MRCP clearly portrayed numerous

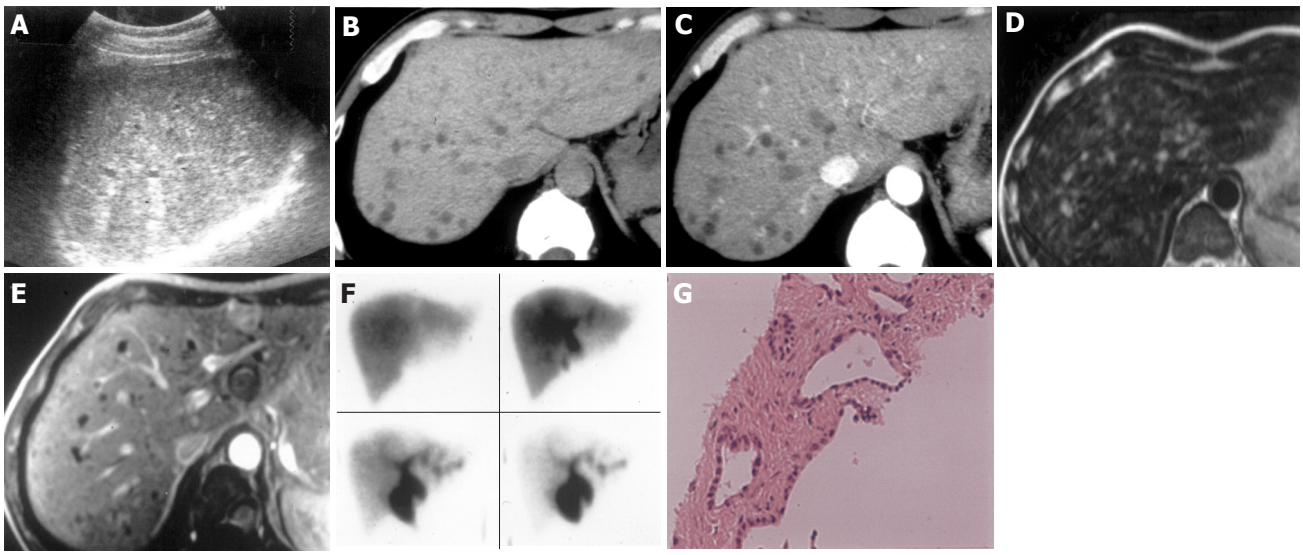

Figure 1 A 51-year-old man with VMCs. **A:** B-mode US showed multiple small hyper- and hypoechoic lesions less than 10 mm in diameter with multiple comet-tail echoes; **B:** On plain CT, multiple small hypodense lesions scattered in the whole liver especially in the subcapsular area of posterior segment of the right liver lobe; **C:** On enhanced CT, the small lesions became well delineated when compared with that on plain CT. No enhancements were noted in these lesions; **D:** T2-weighed image revealed multiple small lesions with high signal intensity; **E:** After gadolinium administration on T1-weighed image, hypo-intensity of the lesions was clearly shown without contrast medium enhancement; **F:** Hepatobiliary scintigraphy by using 99mTC-PMT showed normal appearances of biliary system without pooling areas; **G:** On histology, multiple irregularly dilated bile ducts lined by a single layer of cubic epithelium were shown.

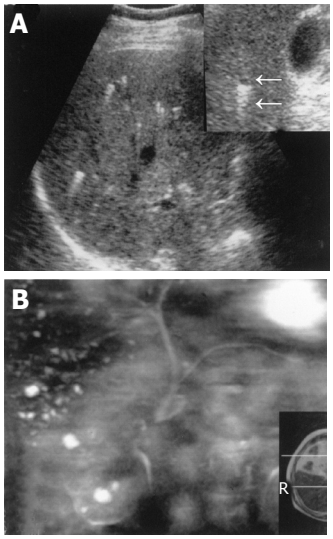

Figure 2 A 72-year-old man with VMCs. **A:** On B-mode US, multiple small hyperechoic lesions were shown, while hypo-echoic lesions were not evident on the conventional scanning plan. However, with the use of zoom function, the hypoechoic lesion with comet-tail echo was clearly shown (arrows); **B:** On MR cholangiopancreatography, multiple small hyper-intensity lesions were revealed except for the demonstration of normal intrahepatic and extrahepatic bile ducts. In addition, several small cysts in the right kidney were also shown.

tiny irregular-shaped and few round-shaped small hyperintense nodules (Figures 2B and 3F). The lesions were displayed more distinctly and in more numbers on MRCP than on CT and MRI (Figure 3). Intra- and extra-hepatic bile ducts were normal (Figures 2B and 3F). Hepatobiliary scintigraphy performed in one case showed no obvious pooling in the liver, which was found in Caroli's disease. The biliary system excreting function of radioisotope was normal (Figure 1F).

US guided liver biopsy was performed in three cases. On histology, multiple dilated bile ducts lined by a single layer of cubic epithelium (Figure 1G) were revealed in two cases, and the diagnosis of VMCs was confirmed. The patient with ovary carcinoma underwent operations twice for hysterectomy plus ovariotomy, and secondary omentectomy, respectively. During the operation, liver metastasis was suspected by the palpation of the liver surface. However, US and CT displayed multiple small typical cystic lesions without any changes on three-time follow-up CT scans performed for over 7 mo period. US guided liver biopsy was performed without demonstrating any malignant cells, although VMC findings were also not found. Liver metastases were not considered according to imaging findings. VMCs were thought to be the most possible diagnosis. The patient died from severe complications after secondary omentectomy later.

The details of the six cases with VMCs are summarized in Table 1.

DISCUSSION

VMCs are considered as congenital bile duct malformations due to the failure of embryonic involution[2,4,6]. Macroscopically, the lesions present as gray-white to gray-yellow or black nodules mostly uniform in size measuring less than 5 mm, some up to 10 mm in diameter[3,7,8]. They are usually scattered throughout both of the liver lobes, especially in the subcapsular region of the liver[8]. Microscopically, VMCs are generally well defined, irregular or round in shape, consisting of a variable number of dilated, tortuous or branching bile ducts that were lined by a single layer of cuboidal cells and embedded in a fibrocollagenous stroma[4,8,9]. The lumina of these dilated bile ducts sometimes contain bile-stained granular or amorphous materials[4,8]. Some VMCs contain sclerotic arteries, however, most of them are not associated with vascular proliferation, and some are even devoid

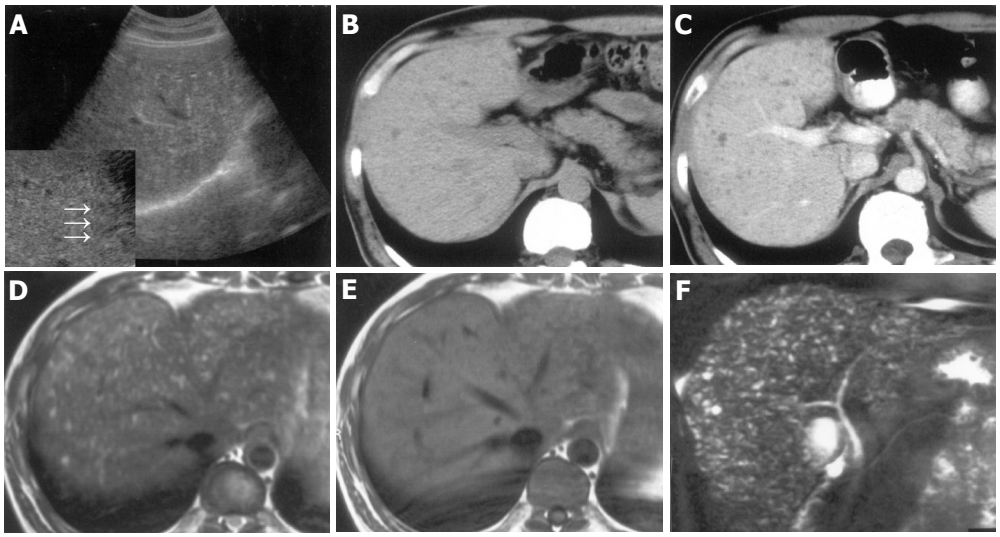

Figure 3 A 44-year-old man with VMCs. **A:** B-mode US scan with routine depth showed a vague image of multiple small hyper- and hypoechoic lesions. When magnified by using zoom function, the tiny hypoechoic lesion and the comet-tail echo were clearly seen (arrows); **B,C:** Multiple tiny hypodense lesions were displayed more conspicuously on enhanced CT (**C**) than on plain CT (**B**), and no enhancements were found in the lesions (**C**); **D,E:** the lesions.

Table 1 Details of six patients

No	Sex/age (yr)	Clinical Background	Imaging findings										Histological diagnosis
			Size (mm)	Number	Distribution	US	CT		MRI		MRCP/ scintigraphy	Associated findings	Follow-up. (time: month)	
							Attenuation	enhancement	T1	T2				
1	M/51	No symptoms	<10	Multiple	Scattered, whole liver	Hyper- and hypoechoic, with comet-tail echoes	Low	No	Hypo-intensit y	Hyper-intensity	Normal bile ducts	No	US for 52 mo, no change	VMCs
2	F/61	Ovary carcinoma	most lesions <10, several cysts 11-25	Multiple	Scattered, whole liver	Hyper- and hypoechoic, with comet-tail echoes	Low	No				Hepatic cysts	CT for 7 mo, no change	No
3	F/68	Hashimoto disease with liver damage	<10	Multiple	Scattered, whole liver	Hypoechoic	Low	No				No	US/CT for 19–48 mo, no change	
4	M/72	No symptoms	<10	Multiple	Predominant in the right lobe	Hyper- and hypoechoic, with comet-tail echoes	Low	No	Hypo-intensity	Hyper-intensity	Hyperintensity, normal bile ducts(MRCP)	Right and left renal cysts	US/C T for 27–84 mo, no change	
5	M/44	Diabetes	<10	Multiple	Scattered, whole liver	Hyper- and hypoechoic, with comet-tail echoes	Low	No	Hypo-intensity	Hyper-intensity	Hyperintensity, normal bile ducts (MRCP)	No	US for 25 mo, no change	VMCs
6	M/29	Diabetes	<10	Multiple	Scattered, whole liver	Hyper- and hypoechoic, with comet-tail echoes	Low	No				No	US for 100 mo, no change	

AUPBD: anomalous union of the pancreatic and biliary ducts.

of vessels[4,8]. The incidence of VMCs was estimated at 0.69-5.6% in autopsy series[8,10], and 0.6% in needle biopsy series[9]. In some cases, association with polycystic liver and kidney diseases, simple liver cysts or pancreatic cysts were reported in the literature[2-4,6,7,10]. Although VMCs are generally considered to be benign liver lesions without clinical manifestations, less frequent association with malignant transformation was also described[11,12]. However, the most important clinical significance is that VMCs are easily misdiagnosed as multiple liver metastases on imaging[2,6,13,14] or even on gross examination[8].

Imaging manifestations of VMCs are various[2-6,14-17] and have not been well illustrated yet. US findings have been described as hypoechoic, hyperechoic or mixed heterogenic echoic structures[6,7,13-15]. These variations might reflect the histologic features of VMCs including dilated bile ducts and fibrocollagenous stroma. Luo *et al*[3] described the sign of multiple comet-tail echoes, and speculated that it might be the specific US finding of VMCs. However, this sign was observed only in one case of their study. In our series, multiple small comet-tail echoes appeared in all but one case. It manifested as posterior echo enhancement of the lesions, which might be due to the cystic feature of dilated bile duct and therefore resulted in good transmission of the sound beam. Especially when magnified by US, some small hyperechoic lesions were actually found to be tiny cystic lesions with comet-tail echoes. This evidence strongly suggests that the sign of multiple small comet-tail echoes is a unique US feature of VMCs, which have diagnostic value.

On plain CT images, almost all VMCs that had been reported were demonstrated to be multiple small hypodense lesions[1-5,7,13,14,16,17]. While on enhanced CT images, although homogeneous enhancement of the lesions was noted in two case reports[2,17], no enhancement of the lesions was observed in most of the reported cases after intravenous administration of contrast medium[1,3–5,13,14,16], as in our series. This phenomenon might correlate to the poor vascularity of VMCs described on histology[4].

On MRI, VMCs, including our series, were revealed as hypo-intense on T1-weighed images and hyper-intense on T2-weighed images when compared with surrounding liver parenchyma[3,5,7,17–19]. Recently, MRCP has been considered to be highly sensitive in depicting intra- and extrahepatic bile duct anomalies and cystic lesions of the liver as well as their relationship with bile duct system[5,20], which is superior to the sensitivity of CT[20]. In the two cases of our study, MRCP displayed the VMC lesions more clearly than CT and MRI concerning both the lesion number and shape. As for the superior sensitivity of MRCP, this may be partially due to the relatively large slice thickness used in CT and MRI scans in our study, resulting in overlooking of lesions smaller than the slice thickness. In addition, the poor MR imaging quality in our study also accounts for one of the reasons.

Some authors claimed that imaging findings of VMCs were not specific and liver biopsy was needed for a definitive diagnosis[1,4]. However, with the use of advanced imaging modalities and long-term imaging follow-up, some authors pointed out that it might be possible to make a correct diagnosis of VMCs by imaging[4,5]. This view is supported by our studies. When typical imaging findings appear, such as multiple small comet-tail echoes on US, multiple tiny hypodense lesions scattered throughout the liver with no enhancement on CT, and cystic appearance with normal extra- and intrahepatic bile duct on MRI and MRCP, a diagnosis of VMCs can be considered. Liver biopsy may have limitations such

as sample errors and performance difficulties due to the very small size of the VMCs, which was reflected by the fact that the reported incidence (0.6%)[9] of VMCs in a series of needle biopsy was relatively lower than that of autopsy (0.69–5.6%)[8,10]. Therefore, long-term follow-up by imaging examinations may have the same important significance in the diagnosis of VMCs. Although histological confirmation was obtained in only three cases in our series, typical imaging findings and relative long-time imaging follow-up that showed identical findings are strongly suggestive of VMCs. However, the case number in our series is small. Further observations on large series are still needed to clarify our stand.

The spectrum of differential diagnosis of VMCs is fairly wide. However, the most important one is liver metastasis especially in patients with extrahepatic malignant tumors. Usually, multiple small metastases are ill defined on plain CT, and show various degrees of enhancement (such as rim enhancement) after intravenous administration of contrast medium. However, for difficult patients, final exclusion of metastatic lesions should still depend on liver biopsy or follow-up imaging studies. Diffuse primary hepatocellular carcinoma usually occurs in cirrhotic patients, and is seldom revealed to be a cystic lesion on US and CT. Simple hepatic cysts are variable in number, size, and location, and usually round in shape[3]. As VMCs may coexist with simple hepatic cysts or polycystic liver and kidney diseases[2-4,6,7,10], sometimes it is difficult to make a definitive differentiation especially from polycystic liver disease on imaging. We are likely to approve simple hepatic cysts, when the lesions are larger than 10 mm in diameter and round in shape, as in one case of our series, since most VMCs were reported to be less than 10 mm in diameter[1-5]. Peribiliary cysts are multiple small cystic dilatations of the intrahepatic extramural peribiliary glands[21] and should also be included in the differential diagnoses of VMCs. However, they are located exclusively in the hepatic hilum and along the larger portal tract[21], which is different from the scattered distribution of VMCs. In addition, some peribiliary cysts were reported to be gradually increasing in size and number[20], which has never been described in VMCs. Microabscesses of the liver can be differentiated from VMCs by means of clinical and radiological data, such as having a history of immuosuppression, symptoms of fever and epigastralgia, multiple round or loculated hypodense lesions on CT[4,16,22], and "target" appearance on US[22]. Furthermore, intrahepatic bile duct anomalies such as dilated bile ducts and Caroli's disease can be readily distinguished from VMCs by imaging, especially when MRCP is performed for this purpose[5], as MRCP offers optimal visualization of the spatial relationship between hepatic lesions and intrahepatic bile ducts[5,20]. Besides, biliary scintigraphy also facilitates the differentiation.

In conclusion, imaging modalities are useful in the diagnosis and differential diagnosis of VMCs. Imaging findings, such as multiple small comet-tail echoes on US, multiple tiny hypodense lesions scattered throughout the liver with no enhancement on CT, and cystic nature with normal extra- and intrahepatic bile duct on MRI and MRCP, can be considered as typical or highly suggestive manifestations of VMCs. A correct diagnosis might be obtained when typical imaging findings are present even without a histological confirmation. However, in patients with extrahepatic malignant tumors, follow-up imaging examinations or liver biopsy are needed.

Abstract

AIM: To investigate the roles of mucin histochemistry, cytokeratin 7/20 (CK7/20) immunoreactivity, clinical characteristics and endoscopy to distinguish short-segment Barrett's esophageal (SSBE) from cardiac intestinal metaplasia (CIM).

METHODS: High iron diamine/Alcian blue (HID/AB) mucin-histochemical staining and immunohistochemical staining were used to classify intestinal metaplasia (IM) and to determine CK7/20 immunoreactivity pattern in SSBE and CIM, respectively, and these results were compared with endoscopical diagnosis and the positive rate of gastroesophageal reflux disease (GERD) symptoms and *H pylori* infection. Long-segment Barrett' s esophageal and IM of gastric antrum were designed as control.

RESULTS: The prevalence of type III IM was significantly higher in SSBE than in CIM (63.33% *vs* 23.08%, $P<0.005$). The CK7/20 immunoreactivity in SSBE showed mainly Barrett's pattern (76.66%), and the GERD symptoms in most cases which showed Barrett' s pattern were positive, whereas *H pylori* infection was negative. However, the CK7/20 immunoreactivity in CIM was gastric pattern preponderantly (61.54%), but there were 23.08% cases that showed Barrett's pattern. *H pylori* infection in all cases which showed gastric pattern was significantly higher than those which showed Barrett' s pattern (63.83% *vs* 19.30%, $P<0.005$), whereas the GERD symptoms in gastric pattern were significantly lower than that in Barrett's pattern (21.28% *vs* 85.96%, $P<0.005$).

CONCLUSION: Distinction of SSBE from CIM should not be based on a single method; however, the combination of clinical characteristics, histology, mucin histochemistry, CK7/20 immunoreactivity, and endoscopic biopsy should be applied. Type III IM, presence of GERD symptoms, and Barrett's CK7/20 immunoreactivity pattern may support the diagnosis of SSBE, whereas non-type III IM, positive H pylori infection, and gastric CK7/20 immunoreactivity pattern may imply CIM.

INTRODUCTION

The incidence of adenocarcinoma at the distal esophagus and gastric cardia has been increasing rapidly for more than two decades in the Western world, but the adenocarcinoma of distal stomach is decreasing gradually. This phenomenon has so far not been satisfactorily explained. These gastroesophageal junction (GEJ) carcinomas appear to arise from intestinal metaplasia (IM) foci that develop either in the distal esophagus or in the proximal stomach (gastric cardia). Some studies indicate that short-segment Barrett's esophageal (SSBE) and cardiac intestinal metaplasia (CIM) are precancerous conditions of the adenocarcinoma at GEJ[1,2]. However, the potential carcinogenesis, and the roles in the development of adenocarcinoma at GEJ are probably the differences between them[3]. Some studies have shown that the risk of malignancy is substantially higher for IM in the SSBE than CIM[4], and medical societies, therefore, have recommended endoscopic cancer surveillance routinely for patients with SSBE, but not for patients with CIM[5]. A recent study has shown that biopsy specimens taken from the GEJ frequently show specialized IM, even in patients who have no esophageal symptoms and a normal-

appearing distal esophagus[6,7]. Therefore, it is necessary to distinguish SSBE from CIM. However, there are not precise criteria in endoscopy and histology, and reliable methods in distinguishing SSBE from CIM have not yet been established[8]. Ormsby *et al*[9] once observed a specific pattern of immunoreactivity for cytokeratin 7 and 20 (CK7/20), defined as Barrett's CK7/20 pattern, which seemed to be distinctive for Barrett's esophageal, but this method has been disputed by others[10,11].

In this study, we used high iron diamine/Alcian blue (HID/AB) mucin-histochemical methods and CK7/20 immunoreactivity, combined with clinical characteristics and endoscopic appearances, to diagnose SSBE and CIM strictly, and long-segment Barrett's esophageal (LSBE) and intestinal metaplasia of gastric antrum (GA-IM) were designed as control. We aimed to investigate the roles of these methods in distinguishing SSBE from CIM.

MATERIALS AND METHODS

Patients

The study group consisted of 118 patients who underwent endoscopies because of a variety of upper gastrointestinal complains. All patients were required to record complete clinical, histological, and endoscopic data.

Clinical data included age, gender, complains, and symptoms of gastroesophageal reflux disease (GERD), which included heartburn, reflux acid, and regurgitation. The diagnostic criteria of GERD were as follows: there were at least twice of aforementioned symptoms within 1 week, and persisted at least 6 months, and all symptoms could be relieved significantly with H2 receptor blocker or proton pump inhibitor.

Histological data required presence of IM, which was proved with hematoxylin–eosin (HE) staining, and excluded dysplasia or adenocarcinoma.

Endoscopic data included precise biopsy location, precise site of squamocolumnar junction (SCJ) and GEJ, and presence or absence of hiatus hernia.

The patients who were classified into four groups according to histological and endoscopic data are as follows:

LSBE with IM: Twenty-eight patients with IM in LSBE, which was defined as 3 cm or more of columnar mucosa in the esophagus. Biopsies were taken from reddish island-like or long tongue-like columnar mucosa in distal esophagus.

SSBE with IM: Thirty patients with IM in SSBE, which was defined endoscopically as tongues less than 3 cm in length above GEJ with its resemblance to small intestine having well-formed microvilli, and biopsies were taken from red, velvet-like columnar mucosa in distal esophagus.

CIM: Twenty-six patients with SCJ coincided precisely with GEJ, and biopsies were obtained within 2 cm below GEJ.

GA-IM: Thirty-four patients who underwent biopsies from gastric antrum.

On the other hand, eight normal distal esophagus mucosa and cardiac mucosa were selected as normal controls, which were defined as such by the combination of a normal endoscopic appearance of the mucosa and the absence of acute or chronic inflammation, IM, and dysplasia or adenocarcinoma.

HID/AB mucin-histochemical staining

Each endoscopic biopsy was sliced into three sections with a thickness of 4-5 μm to carryout histological examination. Biopsies with IM were stained with HID/AB to identify neutral mucins, sialomucins, and sulfomucins. Briefly, slides were immersed into HID solution for more than 18-24 h (includes 6–8 h in warm-box at 60 °C). Slides were then stained with 10 g/L Alcian blue solution (pH 2.5) for 30 min. Finally, the slides were stained with 10 g/L neutral red solution for 2 min.

Immunohistochemical staining for CK7/20

Slides were deparaffinized and rehydrated through graded alcohols. Antigen retrieval was performed by using citrate buffer in a microwave, both for CK7 and CK20 at 92-96 °C. Slides were incubated in 30 mL/L hydrogen peroxide/methanol for 20 min to block nonspecific background staining due to endogenous peroxidase. Using the standard streptavidin–biotin–peroxidase complex (ABC) method, the slides were incubated with primary antibodies CK7 (1:50 dilution) and CK20 (1:30 dilution). The slides were further incubated for 30 min in a secondary antibody solution. Diaminobenzidine served as the chromogen. The slides were counterstained with hematoxylin. The samples of breast carcinoma and colon carcinoma were used as positive controls for CK7 and CK20, respectively. Negative controls were produced with the same tumor samples and staining methods by omitting the primary antibodies.

Giemsa staining

Giemsa staining was used to assess *H pylori* infection.

Histological diagnostic criteria

Classification of IM IM was classified into three subtypes as previously described by El-Zimaity *et al*[12]: complete type (type I); incomplete small intestinal type (type II); and incomplete colonic type (type III). Type I: non-secretory absorptive cells and sialomucin-secreting goblet cells. Type II: few absorptive cells, columnar cells secreting neutral and acid sialomucin, and goblet cells secreting mainly sialomucin but occasionally sulfomucin. Type III: columnar cells secreting predominantly sulfomucin and goblet cells secreting sialomucin or sulfomucin. The HID/AB method stains sialomucins blue and sulfomucin brown (Figure 1). Normal colonic mucosa served as a positive control for this stain. Type I was classified as complete IM, and type II and III were grouped into incomplete IM.

CK7/20 immunoreactivity staining pattern

Three types of CK7/20-staining patterns were recognized in areas of IM, similar to those described by Ormsby *et al*[9]. Barrett's CK7/20 pattern was defined as staining of both superficial and deep metaplastic epithelium for CK7, and staining of the superficial epithelium for CK20 (Figures

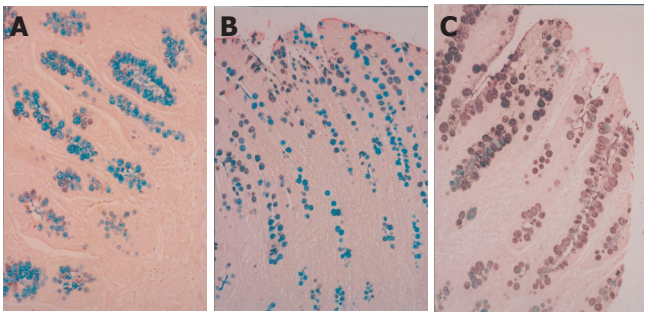

Figure 1 Classifications of IM(HID-AB). **A:** Complete type (Type Ⅰ, ×100); **B**: Incomplete small intestinal type (Type Ⅱ, ×100); **C**: Incomplete colonic type (Type Ⅲ, ×200)

2A and B). Gastric CK7/20 pattern that depended on the histochemical type of IM are as follows: complete IM was characterized by absence of CK7 immunostaining and strong diffuse CK20 immunostaining (Figures 2C and D), whereas incomplete IM was characterized by weak patchy CK7 staining and moderate patchy CK20 immunostaining. All the patterns that did not belong to Barrett's or gastric pattern were defined as other patterns.

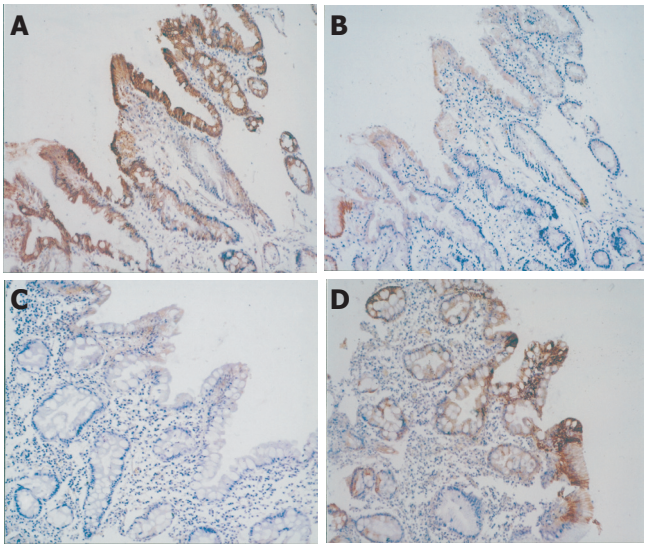

Figure 2 Barrett's(**A**,**B**) and gastric(**C**,**D**) CK7/20 immunoreactivity staining pattern (SABC). **A**: CK7: Strong staining of both superficial and deep metaplastic epithelium (×200); **B**: CK20: Weak staining of the superficial epithelium (×200);**C**: Absent immunostaining of both superficial and deep metaplastic epithelium (×400); **D**: CK20: Strong diffuse immunostaining (×400).

Statistical analysis

Using software SPSS 10.0 for Windows, statistical analyses were performed. The comparison of prevalence at different sites was performed using $\chi 2$ test. A P value <0.05 was considered statistically significant.

RESULTS

HID/AB mucin-histochemical staining

The classifications of IM at different sites are shown in Table 1.

Table 1 Phenotype of IM at different sites

Site of IM	*n*	subtype of IM		
		type I (%)	type II (%)	type III (%)
LSBE	28	3(10.71)	4(14.29)	21(75.00)[a,c]
SSBE	30	7(23.33)	4(13.33)	19(63.33)[a,b]
CIM	26	11(42.31)	9(34.62)	6(23.08)
GA-IM	34	18(52.94)	10(29.41)	6(17.65)

[a]P<0.005 *vs* GA-IM; [b]P<0.01, [c]P<0.005 *vs* CIM

The prevalence of type III IM in SSBE was 63.33%, similar to LSBE (75.00%), but significantly higher than CIM (23.08%) and GA-IM (17.65%, P<0.005). However, there was no statistical difference between CIM and GA-IM. On the contrary, the preponderant subtype of IM in CIM and GA-IM were type I and type II. These results indicated that the LSBE and SSBE mainly contained type III subtypes of IM, whereas there were low incidence of type III in CIM and GA-IM.

CK7/20 immunoreactivity staining

The CK7/20 immunoreactivity patterns at different sites are shown in Table 2.

Table 2 CK7/20 immumoreactivity pattern of IM at defferent site

Site of IM	*n*	Barrett's CK7/20 pattern	Gastric CK7/20 pattern	
LSBE	28	22(78.57%)[a]	4(14.29%)[a]	2(7.14%)
SSBE	30	22(73.33%)[a]	4(13.33%)[a]	4(13.33%)
CIM	26	7(26.92%)	15(57.69%)	4(15.38%)
GA-IM	34	6(17.65%)	24(70.59)	4(11.76%)

[a]P< 0.005 *vs* CIM

There were significant differences in CK7/20 immunoreactivity staining among LSBE, SSBE, CIM, and GA-IM (P<0.005). The CK7/20 immunoreactivity pattern in SSBE was mainly Barrett's pattern (73.33%), similar to LSBE (78.57%). On the contrary, the preponderant CK7/20 immunoreactivity pattern in CIM was gastric pattern (57.69%), similar to GA-IM (70.59%), but there were still 26.92% cases in CIM, which showed Barrett' s pattern. These results implied that although there was a significant difference in CK7/20 immunoreactivity pattern between SSBE and CIM, there were also several cases, which did not belong to either Barrett's pattern or gastric pattern. Therefore, CK7/20 immunoreactivity pattern alone could not distinguish all SSBE and CIM reliably. No difference in CK7/20 immunoreactivity pattern was observed between types II and III IM at any site. However, all cases with type I IM were stained with gastric CK7/20 immunoreactivity pattern.

Relationship between CK7/20 immunoreactivity pattern and symptoms of GERD and H pylori infection (Table 3)

Comparing the differences between the expression of CK7/20 immunoreactivity pattern and the positive prevalence of GERD and *H pylori* infection at different sites of IM, comprehensively, we observed that the

positive prevalence of GERD in the cases with Barrett's CK7/20 pattern was significantly higher than those with gastric CK7/20 pattern. On the contrary, the positive prevalence of *H pylori* infection in the cases with gastric CK7/20 pattern was significantly higher than those with Barrett's CK7/20 pattern. Furthermore, the symptoms of GERD in the cases with LSBE and SSBE that showed Barrett's pattern were all positive, whereas the *H pylori* infection in 60% (6/10) cases that showed gastric pattern was positive. H pylori infection in all the cases that showed gastric pattern in CIM was positive, and accompanied with chronic atrophic gastritis, whereas the symptoms of GERD in six cases with Barrett's pattern were all positive. These results implied that LSBE and SSBE were probably associated with GERD, whereas CIM was mainly associated with *H pylori* infection, but the CK7/20 immunoreactivity pattern showing Barrett's pattern in CIM was probably associated with GERD. Furthermore, these results suggested that the CK7/20 immunoreactivity pattern could be used to distinguish CIM caused by GERD from that was caused by *H pylori* infection.

Table 3 Relationships betweeen CK7/20 immunoreactivity patterns and symptoms of GERD and *H pylori* infection

	Barett's CK7/20 pattern(=57)(%)	Gastric CK7/20 pattern (=47) (%)	Other pattern (=14)(%)
Symptoms of GERD	49(85.96)[a]	10(21.28)	3(21.43)
H pylori infection	11(19.30)[a]	30(63.83)	4(28.57)

DISCUSSION

IM may develop in GEJ in patients either with SSBE or carditis, which is defined as CIM. Distinction between these two entities is important, since the etiology and risk of developing adenocarcinoma are different[13,14]. SSBE is believed to be caused by GERD, and associated with an increased risk of esophageal adenocarcinoma, similar to LSBE[15-17], whereas the etiology and clinical importance of CIM are unclear. Therefore, it is necessary to distinguish them from each other. However, because there are not precise criteria used to diagnose SSBE and CIM in histology, as well as in endoscopy, it is not so easy to distinguish them precisely.

The best criterion for the distinction between SSBE and CIM is the precise knowledge that the biopsy specimens are from the esophagus or the stomach, but because of the effects of the anatomic variation of GEJ and SCJ, inflammation and hiatus hernia, this is not always possible in endoscopy. In histological morphology, there is also no significant difference between SSBE and CIM. Although few scholars have reported that the areas adjacent to CIM show normal foveolar epithelium, whereas those of Barrett's epithelium contain pre-goblet cells that can be stained positive by Alcian blue method[18], these characteristics do not exist in all biopsy specimens. Therefore, it is not reliable to distinguish SSBE from CIM histologically. HID/AB staining have also been used to distinguish SSBE from CIM. IM at GEJ (or ultra-short-segment Barrett's esophagus) has been more frequently found to express sulfomucins, which is defined as type III in classification of IM, and to involve the surface glandular epithelium than CIM[19,20]. Piazuelo *et al*[21] also found that the area covered with incomplete type of IM and the proportion of sulfomucins were significantly higher in the esophagus compared to the stomach. In our study, we found that the prevalence of type III IM in SSBE was 63.33%, similar to LSBE, but significantly higher than CIM (23.08%). Therefore, we think that the HID/AB method could be used to distinguish SSBE from CIM initially, based on the different expressions of neutral mucins, sialomucins, and sulfomucins.

Cytokeratins (CK) are a family of at least 20 structural proteins found in the cytoskeletons of epithelial cells. Certain epithelia exhibit characteristic patterns of CK expression depending on the type, location, and differentiation of the epithelium. CK7, essentially, is not expressed in normal epithelium of the gastrointestinal tract, whereas CK20 is expressed in intestinal epithelium, gastric foveolar epithelium, and endocrine cells in the upper portions of the pyloric glands[22]. Ormsby *et al*[9] observed a pattern of immunoreactivity for CK7 and CK20 that seemed to be distinctive for Barrett's esophagus, which was defined as staining of the superficial epithelium for CK20 and staining of both superficial and deep metaplastic epithelium for CK7. This so-called "Barrett' s CK7/20 pattern" was found in 100% esophageal biopsy specimens from LSBE, but none of the specimens of IM were from the stomach. Ormsby *et al*[23] later found that this Barrett's CK7/20 pattern was present in 82% of patients with SSBE. Studies by Sarbia *et al*[24], Glickman *et al*[20] and Jovanovic *et al*[25] confirmed findings of Ormsby *et al*[9] in 90.3%, 91%, and 94% of their cases with LSBE, respectively. However, some other studies did not support the findings of Ormsby *et al*[9]. In addition, Mohammed *et al*[10] and by El-Zimaity *et al*[11] demonstrated that the proposed Barrett's CK7/20 pattern was observed only in 54% and 39% of patients with LSBE, respectively. Differences in patient populations and endoscopic biopsy techniques may have contributed to the discrepancies among these studies, especially, the sites of the biopsies. Previous anatomic and endoscopic studies have shown the gastric cardia to be a small structure varying from about 0 to 10 mm in length (mean length 3 mm) beneath the GEJ[26], but there are no agreement on the precise distal extent of the cardia[5]. In our study, we have defined the distal extent of the cardia as less than 2 cm beneath the GEJ, which is accepted by most scholars at present, and applied an anterograde approach to obtain biopsies by avoiding biopsy across the SCJ, aiming to eliminate biopsy error to most extent. On the other hand, we compared the results of SSBE and CIM with LSBE and GA-IM. The results indicated that 73.33% of SSBE showed Barrett's CK7/20 immunoreactivity pattern, which was similar to LSBE; whereas 57.69% of CIM showed gastric CK7/20 pattern, which was similar to GA-IM. These results implied that CK7/20 immunoreactivity pattern could be

used to distinguish most of SSBE from CIM. However, there were a large number of cases, which belonged to neither Barrett's pattern nor gastric pattern, since they showed some controversial results; therefore, we have simply based our study on the CK7/20 immunoreactivity pattern, and could not distinguish all SSBE from CIM.

The etiology and pathogenesis of SSBE and CIM are unclear until recently. Recent data have suggested the cause of SSBE, like that of LSBE, is probably related to chronic GERD, and not to *H pylori* infection[14,27,28]. However, the cause of CIM is still controversial. Schnell *et al*[29] suggest GERD as a probable cause, whereas Dulai *et al*[30] have found an association with *H pylori* infection. Few scholars even think that CIM has dual etiologies: gastroesophageal reflux in some and *H pylori* infection in others[31,32]. A recent report has described findings in biopsies of the cardia that are said to distinguish between gastroesophageal reflux and *H pylori* as the etiology[33]. On the basis of these findings, some scholars have proposed that the CK7/20 immunoreactivity patterns with gastroesophageal reflux symptoms and the status of the remainder of the gastric mucosa, including *H pylori* infection, can distinguish IM caused by GERD from that caused by *H pylori* infection. Balaji *et al*[31] found that there were two different patterns of CK7/20 staining in patients with CIM, which support the concept of dual etiologies for CIM. A Barrett's staining pattern was associated with objective evidence of gastroesophageal reflux and the absence of *H pylori*, suggesting that CK7/20 immunostaining is useful to determine the likely etiology of CIM. Couvelard *et al*[34] also found that the Barrett's type CK7/20 pattern was related to a high frequency of gastroesophageal reflux symptoms and normal endoscopic appearance of the stomach, but the gastric type CK7/20 pattern was linked to high frequency of *H pylori* infection, antral inflammation with atrophy and IM. In the present study, we found that the symptoms of GERD were all positive in some cases of LSBE and SSBE, which showed the Barrett's type CK7/20 pattern, whereas in other cases that showed gastric CK7/20 pattern, the symptoms of GERD were all negative, but *H pylori* infection was positive conversely. In contrast, in the CIM cases that showed gastric type CK7/20 pattern, *H pylori* infection was all positive, and the symptoms of GERD were mostly negative, whereas in other cases which showed Barrett' s type, the symptoms of GERD were all positive. These results indicate partly that the CK7/20 immunoreactivity patterns, combined with gastroesophageal reflux symptoms and statuses of *H pylori* infection, could imply the probable cause of SSBE and CIM, and even help to distinguish from each other. However, although GERD symptoms were significantly more common among the patients with IM showing a Barrett's CK7/20 pattern, Couvelard *et al*[34] also found that most of those patients (57%) had no symptoms of GERD. Conversely, although H pylori infection was found significantly more often in gastric biopsy specimens from patients with IM showing a gastric CK7/20 pattern, 34% of those patients had no demonstrable *H pylori* infection. Our findings are also in agreement with the above results. Thus, the concept that CK7/20 immunoreactivity patterns can distinguish IM caused by GERD from that caused by *H pylori* infection is appealing, and further investigations are needed to resolve this dispute.

Therefore, on the basis of our results, we conclude that the distinction of SSBE from CIM should not be based on a single method or factor or characteristic, but the combination of clinical characteristics, histological results, mucin-histochemistry, CK7/20 immunoreactivity, and especially precise endoscopic biopsy. Type III IM, presence of GERD symptoms and Barrett's CK7/20 immunoreactivity pattern may support the diagnosis of SSBE, whereas non-type III IM, presence of *H pylori* infection and gastric CK7/20 immunoreactivity pattern may support the diagnosis of CIM.

ACKNOWLEDGMENT

We thank Professor Wei Ding, Department of Pathology, the First Affiliated Hospital, Medical College of Zhejiang University, for gifting us the reagent of HID/AB.

Abstract

AIM: To establish the most common *vacA* alleles in *Helicobacter pylori* (*H pylori*) strains isolated from Chilean patients and its relationship with gastritis and gastroduodenal ulcers.

METHODS: Two hundred and forty five *H pylori* clinical isolates were obtained from 79 biopsies from Chilean infected patients suffering from gastrointestinal diseases. An average of 2-3 strains per patient was isolated and the *vacA* genotype was analyzed by PCR and 3% agarose electrophoresis. Some genotypes were checked by DNA sequencing.

RESULTS: The most prevalent *vacA* genotype in Chilean patients was s1b m1 (76%), followed by s1a m1 (21%). In contrast, the s2 m2 genotype was scarcely represented (3%). The s1b m1 genotype was found most frequently linked to gastropathies ($P<0.05$) rather than ulcers. Ulcers were found more commonly in male and older patients. Curiously, patients living in cities located North and far South of Santiago, the capital and largest Chilean city, carried almost exclusively strains with the s1b m1 genotype. In contrast, patients from Santiago and cities located South of Santiago carried strains with either one or both s1a m1 and s1b m1 genotypes. Regarding the s2 m2 genotype, comparison with GenBank sequences revealed that Chilean s2 sequence was identical to those of Australian, American, and Colombian strains but quite different from those of Alaska and India.

CONCLUSION: Differences in geographic distribution of the s and m *vacA* alleles in Chile and a relationship of s1b m1 genotype with gastritis were found. Sequence data in part support a hispanic origin for the *vacA* genotype. Asymmetric distribution of genotypes s1b m1 and s2 m2 recedes *H Pylori* strain distribution in Spain and Portugal.

INTRODUCTION

Helicobacter pylori (*H pylori*) is a curved Gram-negative bacterium frequently present in the human stomach. Once the host has been colonized, this microorganism persists for years or decades[1]. This microorganism has a worldwide distribution and its prevalence increases with age[2], and is a major etiological agent in the development of peptic ulcer and gastric cancer[3,4]. Several potential virulence factors have been suggested to play a role in the pathogenesis caused by this microorganism. The most studied *H pylori* virulence factors are CagA and VacA. The first one, called the cytotoxin associated antigen[5] is one of the proteins encoded by the pathogenicity island, a unique genomic fragment containing about thirty genes and some of them encode the machinery required for the secretion of the CagA protein. Strains carrying a functional *cagA* gene have been associated with a variety of clinical outcomes[5].

VacA is a vacuolating cytotoxin which induces cytoplasmic

vacuolation in a variety of mammalian cell lines *in vitro*[6]. It is responsible for the gastric epithelial damage and causes mucosal ulceration when administered intragastrically to mice[7]. Recently, the VacA cytotoxin has been described as a permease that promotes urea diffusion across the epithelia[8] providing an additional source of nutrients to sustain *H pylori* growth *in vivo*. It has been recently reported that the cytotoxin is able to induce apoptosis in epithelial cells as well as a specific inhibition of the immune response[9,10]. Different allelic variants in the *vacA* sequence in two regions of the gene have been described: the s allele located in the region encoding the N-terminal signal region which may occurs as the alleles s1- (s1a or s1b) or s2 type, and the m allele located at the middle of the *vacA* gene, which is present as m1 or m2 type[11]. The variable structure resulting of different arrangements of these alleles in the gene has been related to the differences in the level of cytotoxin production and to distinct clinical outcomes of the *H pylori* infection[12-14].

In Chile, a country with one of the higher mortality rates of gastric cancer, gastroduodenal diseases are common causes of medical consultations[15]. Serological studies have indicated that over 70% of asymptomatic adults older than 35 years old are infected by *H pylori*[16]. Our previous studies[17] have revealed that 83% of Chilean infected patients from Santiago have antibodies against VacA or CagA virulence factors determined by Western blot using purified recombinant proteins and by ELISA tests based on the detection of CagA and VacA antibodies[17].

Few studies have been carried out on strains from the South Cone and in particular from Chilean patients[18]. Recent data from *H pylori* strains from Argentina have revealed that most of the *vacA* alleles are s1b m1[19]. Reports about the characterization of strains isolated from Brazilian children indicated that s1 allele is associated with the presence of peptic ulcer[20] and genotype *cagA*+*vacA* s1b m1 is the most frequent in Brazilian adults with non-mixed infections[21]. Recent studies done with strains from 63 patients from the central area in Santiago, Chile, found that s1m1 is also the most common allele associated to ulcer patients[22].

Since information in Latin American countries is rather scarce, the present study adds new pieces of information in this respect and it has been focused on the distribution of *vacA* alleles of *H pylori* strains obtained from infected patients along this country (more than 5 000 kilometers long) to identify, as a preliminary study, the most frequent *vacA* alleles in this population and their relationship with different pathologies.

MATERIALS AND METHODS

Strains, growth and collection of clinical specimens

E. coli DH5α was used as a host for cloning experiments. *Campylobacter yeyuni* VPI H840 (ATCC 29428), kindly provided by Dr. H. Fernández (Universidad Austral de Chile) was used as DNA source of a negative *vacA* genotype control. Strains 26695 (ATCC 700392), 60190 (ATCC 49503), T×30a (ATCC 51932), NCTC 11637 (ATCC 43504) and J99 (ATCC 700824) were used as well characterized *vacA* alleles sources.

H pylori clinical strains were isolated from human gastric biopsies obtained from each patient who underwent upper gastrointestinal endoscopy for medical indication. Patients were recruited from different hospitals and clinics from 10 Chilean cities. Biopsies were transported to Santiago as frozen samples in dry ice and immediately after arrival suspended in PBS (500 μL), manually grinded and plated on *Brucella* agar plates. This medium contained 5% fresh horse blood, 5 mg vancomycin, 2.5 mg cefsulodin, 2.5 mg trimethoprime lactate, 2.5 mg amphotericin B, and 1.5 g agar per 100 mL of medium. Colonies were grown for three to four days under microaerophilic conditions using the microaerophilic system envelopes with palladium catalyst. Two or three specimens per biopsy were obtained and a total of 245 isolates were characterized.

Patients

Seventy- nine consent patients who gave informed consent including 35 males and 44 females aged between 3 and 79 years old with symptoms warranted upper gastrointestinal endoscopies. Twenty- two patients from Iquique (IQ), 1 from La Calera (LC), 3 from Quillota (QU), 6 from Valparaíso (VA), 12 from Santiago (SA), 5 from Linares (LI), 6 from Los Angeles (LA), 2 from Temuco (TE), 8 from Valdivia (VD) and 14 from Punta Arenas (PA) were analyzed in this study.

Criteria for enrollment included nocturnal or burning abdominal pain, chronic vomiting, hematemesis or history of recurrent abdominal pain plus a first degree relative with an endoscopically proven diagnosis of peptic ulcer disease. Exclusion criteria included hemodynamically unstable patients and recent antibiotic therapy, antisecretory drugs or bismuth compounds in the last 4 wk. Signed informed consent forms by the patients or their parents in the case of minors were obtained. The institutional Review Board of the local participating institutions reviewed and approved the study.

Endoscopy, histology and criteria of H pylori infection

The endoscopic findings in the esophagus, stomach and duodenum were described in a standardized protocol. The macroscopic appearance was recorded according to the presence of nodularity, erosion or ulceration. Diagnosis of gastritis and duodenitis were done on histological basis. Gastropathy was diagnosed when abnormalities such as erosions or nodularity were observed. Ulcer was diagnosed when either a circumscribed break in the gastroduodenal mucosa that measured at least 5 mm in diameter or a scar was observed. Two biopsies were obtained from the distal antrum of each patient to determine *H pylori* status. One of the biopsies was used for rapid urease test (Hepy test, BiosChile).

Serial sections of formalin-fixed and embedded in paraffin gastric tissue from the second antrum biopsy of each patient were stained either with Warthin-Starry silver or H&E stain and examined for the presence of *H pylori* and associated pathology for pathologists who were unaware of the results of other tests. Bacteria were defined as *H pylori* on the basis of size, spiral morphology, and tissue location. A subject was considered colonized by *H pylori* when both invasive diagnostic techniques (rapid urease test and *H pylori* staining) were positive. A patient was considered negative for *H pylori* when both invasive diagnostic tests were negative. We confirmed this assignment in most of the cases by isolation of colonies which gave positive for urease, catalase, and peroxidase enzyme tests.

Isolation of H pylori chromosomal DNA

DNA was obtained by using the method described by Owen

and Bickley[28], with CTAB (Cetyltrimethylammonium bromide) as the detergent for cell lysis. Briefly, single colonies were grown in plates as described above. Cells coming from half a plate were collected and transferred to an Eppendorf tube using a sterile loop and processed as described[23].

PCR reactions, primers, cloning and sequencing

Reactions were done according to the conditions established by Atherton *et al*.[11,12]. Cloning of s1a, s1b, s2, m1, m2 PCR fragments from some isolates were done by ligation into the pGEM-T vector (Promega) and electroporation into *E. coli* DH5α cells which were plated on Luria agar plates containing ampicillin 50 μg/mL. Some cloned PCR fragments were sequenced by using ABI Prism-3 100 genetic analyzer (Applied Biosystems).

Study groups and statistical analysis

H pylori infected patients were assigned to one of three groups according to their endoscopical or histological findings as follows: Chronic Active Gastritis group (CG) included patients with normal or non-specific endoscopic findings, plus chronic gastritis by histology; Gastropathy Group (GG) included patients with significant endoscopic abnormalities (nodularity, polyps or erosions but not ulcers) and chronic gastritis by histology; and Peptic Ulcer Disease group (PUD) included patients with gastric or duodenal ulcer at endoscopy and chronic gastritis by histology.

To asses whether the presence or absence of ulcers in infected patients could be related with the gender, age, or allele type, cross tabulation and χ^2 test were performed using the Minitab release 12 program (State College, PA, USA). A P value < 0.05 was considered significant. The s2 m2 strains were not included in this analysis due to its low frequency (3%).

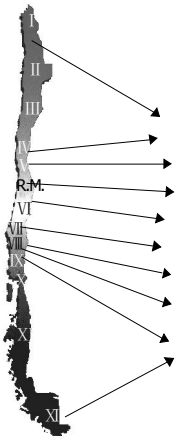
RESULTS

Detection of the m1 and m2 alleles in Chilean H pylori strains



Seventy nine biopsies from *H pylori* infected patients living at 10 Chilean cities were used as a source to isolate 245 *H pylori* colonies. Amplification of the m2 *vacA* allele was obtained for two patients from Iquique and one from Santiago. Among the 245 studied strains, 97% of them harbored the m1 allele and 3% the m2 allele. Hybrids corresponding to m1/m2 alleles or non-typable alleles were not detected.

Detection of the s1 and s2 alleles in Chilean H pylori strains

Most of the strains carried the s1 allele (97%). The 72.1% of these was s1b and 24.1% was s1a. A summary of these results according to the strain origin (city) and the s and m alleles is displayed in Figure 1.

Identification of the m1 and m2 alleles of Chilean strains by DNA sequencing

Strain CHCTX-1 and LA-12 were utilized to amplify the m1 *vacA* allele. The PCR fragments were cloned in the pGEM-T vector and then sequenced. The results are shown in Figure 2A. After the alignment of the amino acid sequences with those available at in the GenBank, we found that the Chilean m1 sequences were similar to the Indian m1 deposited sequences. Seven strains out of 245 isolates presented the genotype s2m2. A further characterization

Figure 2 Alignment of s and m alleles as *vacA* amino acid partial sequences. **A:** Alignment of amino acid sequences corresponding to the amplified m1 *vacA* allele of Chilean strains CH-CTX1 and LA-12 with other representative m1 Indian sequences obtained from the GenBank; **B:** Alignment of amino acid sequences corresponding to the amplified m2 *vacA* allele and other representative m2 sequences obtained from the GenBank. The m2 allele from strain SA-64 was amplified using primers VA4F and VA4R and both strands were sequenced. The oligonucleotide sequence was translated (126 amino acids) and compared with other representative m2 allele sequences. These m2 sequences were obtained from GenBanK and corresponded to strains 95-54 from Italy, India 90, 97-203 from USA and V-296 from Taiwan; **C:** Alignment of amino acid sequences corresponding to Chilean strains having the s1a allele (CH-CTX1 and LA-12) and comparison with a s1a sequences from China. Sequences of Chilean s1b strains (IQ-61, QU-31 and QU-61) and comparison with other s1b sequences obtained from the GenBank from Argentinean strains AR-312 and AR-710; **D:** Alignment and comparison of amino acid sequences corresponding to the s2 sequence of the Chilean strain SA-64 and other sequences obtained from the GenBank of strains isolated in different locations. Sequences of the s2 *vacA* allele from different strains were aligned starting from amino acid position 30 in the *vacA* precursor sequence and the segment was fit with the ends defined by the Atherton primers for amplification of the s2 allele. ◆ Includes identical s2 sequences for strains: SA-64 from Chile, USA2781 from Arizona, USA, SS-1 from Australia, NA2010 and NA1986 from Colombia. ●Represents identical s2 sequences from strains NA1995, NA1992 and NA1685 from Colombia, India 3 and Alaska 5 from USA. Accession numbers are displayed in Materials and methods.

of the m2 *vacA* allele was done on strain SA-64 by DNA sequencing the amplified cloned fragment. Comparison of this m2 allele sequence (Figure 2B) with other m2 sequences taken from the GenBank revealed almost identical amino acid sequences (one amino acid difference) with the m2 sequence of the Italian strain 95-54. Conversely, we found 45% amino acid identity for the SA-64 m2 sequence when compared to the Taiwanese strain V 296 as displayed in Figure 2B. These findings put the Chilean strain SA-64 closer to the strains that share a common ancestor from hispanic origin and far from those strains isolated from Asiatic patients.

Sequences of the s2 and s1 alleles of Chilean strains

Strains CHCTX-1 and LA-12 were used as DNA source for amplification and sequencing of the s1a alleles, strains IQ-61, QU-31 and QU-61 for sequencing s1b allele (Figure. 2C), and strain SA-64 for sequencing the s2 allele (Figure. 2D). Comparison with other s1a, s1b, and s2 sequences available at the GenBank are displayed in Figures 2C and D. It was found that the s2 allele sequence from Chilean strain SA-64 was identical to those reported for American (USA2781), Australian (SS-1) and Colombian (NA2010) strains but far away from those of Alaskian (Alaska 4) and Indian (India 27) strains (in a segment of 66 amino acids there were 8 and 6 amino acid differences, respectively).

Correlation of vacA *alleles and patient gastric diseases*

The s1bm1 allele combination was more common in patients with chronic gastritis without ulcers and other endoscopic findings ($P<0.05$). The s1am1 has a homogeneous distribution among patients with chronic gastritis, gastrophaties or peptic ulcer diseases (Figure 3A). Figure 3B shows patient gender and disease occurrence. There was not significant difference between males and females regarding different clinical outcomes (Figure 3B). There was an age dependent increase in the frequency of peptic ulcer disease and an age dependent decrease in the frequency of chronic gastritis, without reaching statistical significance (Figure 3C).

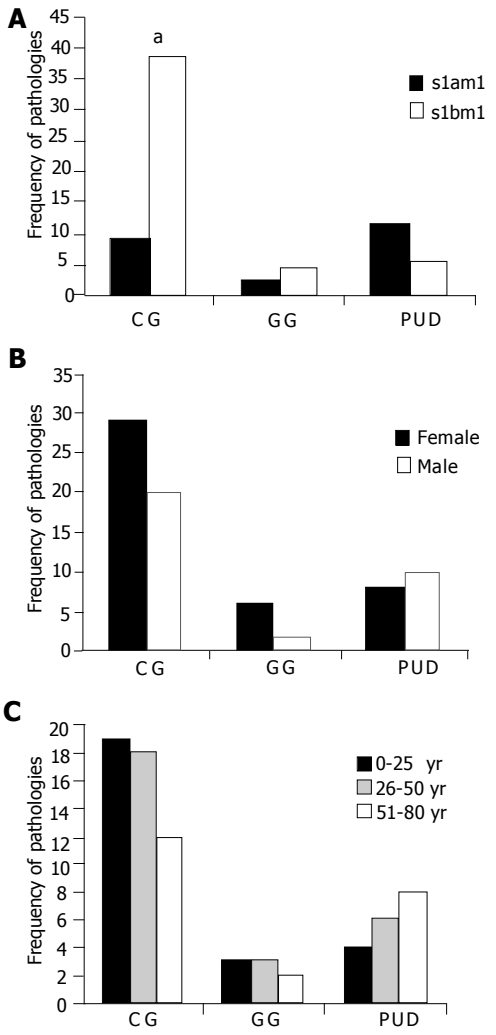

Figure 3 Analysis of gastropathies outcome frequencies respect to *VacA*. genotype, gender and patient age; **A:** Relationship between pathologies and alleles. Minitab Release 12 PA.USA and χ^2 test for categorical variables was used ($P<0.05$). $P<0.05$ was considered significant. The s2m2 allele was excluded of the statistics test due a low frequency (3%); **B:** Relationship between gastropathies and gender. F: female, M: male. A total of 43 females and 32 males were studied ($P>0.5$), four patients carrying strains with s2 m2 allele were excluded from this study; **C:** Relationship between gastropathies and patient age ($P>0.5$).

DISCUSSION

A variety of structural and functional characteristic of the *H pylori* virulence factors have been used for strain genotyping, since they define a particular genotype which can be associated with an increased risk of peptic ulcer in human beings. Among these, genes of virulence factors such as *cagA*, *vacA*, *hpaA, iceA and babA* have been used before for classification purposes[24]. However one of the most extensively studied has been the *vacA* cytotoxin genotypes. This gene has a mosaic-like structure which is very uncommon in bacterial cytotoxins. Moreover, it is also unique for *H pylori* because the VacA polypeptide precursor promotes its own secretion. A similar auto-promoted mechanism has been observed for IgA proteases secreted by *Neisseria gonorrhoeae* and *Haemophilus influenzae*[25,26]. Some *vacA* gene regions have been used for genotyping and to evaluate the relationship between some *vacA* allele and a particular disease caused by *H pylori*[22].

We have studied 245 *H pylori* Chilean strains collected from patients belonging to different cities along the country. Most of the samples were collected from patients living at the central valley and some from the North and South regions as displayed in Figure 1. It should be noted that to the North of Chile is located the Atacama desert, one of the driest places in the world and this region do not support the development of cities. On the other hand, Southern Chile is under-populated because vast areas are preserved as ecological native resources and inhabited zones are rather minimal. Northern Chile also includes indigenous population. We included in the group of patients living in IQ, some strains isolated from native descendants from ancestral *Aimara* population. Curiously, all strains isolated from these patients had s1bm1 genotype. Also, a "*Mapuche*" native from Valdivia city (Southern Chile) presented the same genotype. A *Mapuche* autochthonous is considered a descendant of native Chileans before Hispanic colonization. Further analyses will be required to establish if the *vacA* genotype and other virulence markers

within the autochthonous population remain homogeneous.

The analysis of the signal sequence s region showed that barely 3% of the isolated strains exhibited the s2 allele (just 7 out of 245 strains) and 97.1% was classified as s1 type. Therefore, most of the strains were classified either as s1a or s1b alleles. The analysis of the medium region ("m" alleles) revealed that only 3% was m2 type, which was always associated to the s2 allele. Considering simultaneously both "s" and "m" alleles, 72% of all characterized strains was s1b m1 and 25.1% was s1a m1. These results are quite different from those reported by Martínez *et al*.[27], in particular to the frequency of the s2 and m2 alleles for one Chilean city Concepción, not included in our study. They found a higher proportion (44%) of this genotype in 34 infected patients and, considering each allele independently, 32% was s2 and 58% was m2 in an extended study for this city with 50 patients. Compared to our data, this could be an overestimation of the s2m2 genotype, since the screened patients were all recruited from a single city. In addition, they used in some cases a different set of primers to detect the m2 allele, based on a 6 bp difference in fragment length (m1 = 116 bp; m2 = 122 bp) which is difficult to distinguish even in a 3% agarose gel. Moreover, their results were not confirmed by DNA sequencing of the amplified alleles. In any case, our data support the idea of a putative hispanic origin for the Latin American strains, considering that the preferred s1bm1 allele distribution was also detected in the strains from patients from Spain and Portugal, as reported by van Doorn *et al*.[28]. In addition, it is noticeable that the allele s2 m2 that we described for 7 Chilean strains has not frequently been described in other South American countries yet. Also, the s2 and m2 alleles occur in the lowest proportion in Spain and Portugal[28]. The s2 m2 Chilean allele seemed to be interesting to sequence since, as mentioned, it represents a local uncommon *vacA* genotype. The m2 allele cloned from strain SA-64 was sequenced. The amino acid sequence revealed a closer similarity to the m2 allele of strain 95-54 isolated from an Italian patient (one aminoacid difference). A feasible explanation for the low occurrence of this genotype could be that this allele may confer a disadvantage for natural *in vivo* selection of the strain such as a lower VacA activity, a feature proposed by some authors[11,29]. Alternatively, it may have resulted from a recombination event that actually occurs at very low frequency. The latter argument is sustained in part by the finding that some patients infected with multiple *H pylori* strains allow the exchange of bacterial DNA along the course of the disease[30,31].

Results of *H pylori* strain typing based on *vacA* allele done in other countries indicate that differences between m1 and m2 strains raise diversity in the level of cytotoxin activity. However, at present it is not clear if differences between s1 and s2 phenotypes also affect the level of cytotoxin expression by a reduction in the amount of exported cytotoxin. One hypothesis strongly proposes that S2 type allele containing a different signal sequence exports a cytotoxin precursor through the inner membrane in a less efficient way[13]. On the other hand, it has been demonstrated that when a short oligonucleotide extension encoding 12 amino acids (as part of the s2 allele) is transferred to a *vacA* gene displaying the s1 genotype. This completely abolishes the vacuolating activity but has no effect on VacA cytotoxin production[11,29].

A strong correlation between the severity of the clinical diagnosis and *vacA* genotype has been proposed by several authors. For instance, in South African patients, the allele s1m1 is associated to ulcer disease[32] and in other cases to gastric cancer, as described for German patients[33]. The s2 allele has also been associated with the lack of peptic ulcer[11]. Indeed, in the present analysis those strains whose s2 and m2 alleles were sequenced and reported here were isolated from patients suffering from mild gastritis and corresponded to supposedly less aggressive genotypes. However, one patient had a mixed infection carrying, in addition to the genotype s2m2, other strains with the s1am1 and s1bm1 genotypes. It remains to be established if the strains with genotype s2m2 are actually producing a VacA protein with attenuated cytotoxic properties.

We have reported here that most of the patients carrying the s1b m1 VacA allele suffered chronic gastritis (females mainly) and this genotype was preponderant in patients living in cities located to the north of Santiago. The s1am1 genotype was most frequently associated to isolates from patients suffering from ulcers (mild male predominance). Patients from Santiago and cities located south of Santiago (Central Chile) carried strains with either one or both s1am1 and s1bm1 genotypes. It should be noted that Santiago, as the Chilean capital city, attracts immigrants not only from the neighboring countries but also from Asian countries, and in a lesser extent, natives from Northern and Southern cities searching for jobs, a fact that may explain a mixed allele distribution found in strains isolated from patients living in Santiago.

Finally, this study supports the fact that *H pylori* is actually one of the microorganisms with the highest genetic variability and this feature may complicate genotyping[34]. The genomic variability is so high that some researchers consider *H pylori* as a *quasi* strain[34]. Also, in some cases, mutations in other genetic loci may be responsible for the generation of unexpected and more virulent strains.

Abstract

AIM: To determine how glucocorticoids (GCs) may affect the growth and chemosensitivity of common carcinoma cells.

METHODS: The effect of dexamethasone (DEX) on growth and chemosensitivity was assessed in 14 carcinoma cell lines. The function of GC receptors (GR) was assessed by MMTV reporter assay. Overexpression of GR was done by *in vitro* transfection and expression of a GR-expressing vector. Immunohistochemical stain of tissues and cells were done by PA1-511A, an anti-GR monoclonal antibody.

RESULTS: DEX inhibited cell growth of four (MCF-7, MCF-7/MXR1, MCF-7/TPT300, and HeLa), increased cisplatin cytotoxicity of one (SiHa), and decreased cisplatin cytotoxicity of two (H460 and Hep3B) cell lines. The GR content of the seven cell lines affected by DEX was significantly higher than those of the seven cell lines unaffected by DEX ($5.2\pm2.5\times10^4$ sites/cell *vs* $1.3\pm1.4\times10^4$ sites/cell, $P = 0.005$). Only two DEX-unresponsive cell lines (NPC-TW01 and NPC-TW04) contained high GR amounts in the range ($1.9\text{-}8.1\times10^4$ sites/cell) of the seven DEX-responsive cell lines. The GR function of NPC-TW01 and NPC-TW04, however, was found to be impaired. The importance of high cellular amount of GR in mediating DEX susceptibility of the cells was further exemplified by GR dose-dependent drug resistance to cisplatin of AGS, a cell line with low GR content and was unaffected by DEX before transfection of GR-expressing vector. Immunohistochemical studies of human cancer tissues showed that 5 of the 45 (11.1%) breast cancer and 43 of the 85 (50.6%) non-small cell lung cancer had high GR contents at the ranges of the GC-responsive carcinoma cell lines.

CONCLUSION: The growth and chemosensitivity of human carcinomas with high GR contents may be affected by GC. However, in light of the heterogeneous and even contradictive effects of GC on these cells, routine examination of GR contents of human carcinoma tissues may not be clinically useful until other markers that help predict the ultimate effect of GC on individual patients are identified.

INTRODUCTION

Although glucocorticoids (GCs) are effective in inducing apoptosis via uncharacterized pathways in many hematological malignancies[1], they are generally thought to be ineffective in the treatment of non-hematological solid tumors. However, in the treatment of patients with solid tumors, co-administration of GC with anti-cancer drugs is a common clinical practice to prevent drug-induced allergic reaction or nausea/vomiting. Although GC receptors (GRs) are ubiquitous in cancer cells and have been linked to signal transduction pathways pertinent to their growth, defense, and apoptosis[2-4], little is known regarding the effects of GC on the growth and chemosensitivity of common human carcinomas. Several studies have shown diverse effects of GC on chemosensitivity in non-hematological neoplastic cells. GC has been reported to inhibit cell growth[5-7] and affect

the chemosensitivity[8-12] in some sarcoma and carcinoma cell lines. Further, the pretreatment with dexamethasone (DEX) may increase antitumor activity of carboplatin and gemcitabine in tumor xenografts due to increased intra cancer cell drug accumulation was also reported[13]. More comprehensive study is needed to clarify the role of GC on chemosensitivity of non-hematological neoplastic cells. In the present study, we examined the effects of DEX on the chemosensitivity of 14 carcinoma cell lines. We found that GC exerted a GR-related differential effect on the growth or chemosensitivity of half of carcinoma cells. Further, we have demonstrated that a substantial portion of human carcinomas do contain high GR contents and, therefore, the tumor response to chemotherapy may be affected by the co-administered GC.

MATERIALS AND METHODS

Cell culture and chemicals

SiHa, HeLa, Caski (human cervical carcinoma), H460 (human lung carcinoma), Hep3B, Huh 7 (human hepatocellular carcinoma), and MCF-7 (human breast cancer) were obtained from the American Type Culture Collection (Rockville, MD, USA). MCF-7/MXR1 and MCF-7/TPT300 cells were derived from MCF-7 cells by selection for growth in increasing the concentrations of mitoxantrone or topotecan, respectively. MCF-7/MXR1 cells were gifts from Dr. Kenneth Cowan (National Cancer Institute, USA). MCF-7/TPT300 cells were selected as previously described[14]. NPC-TW01 and NPC-TW04 (nasopharyngeal cancer) were obtained as previously described[15,16]. They were maintained in Dulbecco's modified Eagle's medium supplemented with 2 mmol/L glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin (Sigma Chemical Co., St. Louis, MO, USA), and 10% heat-inactivated fetal bovine serum (Life Technologies, Inc., Gaithersburg, MD, USA). AGS, N87, and SNU1 cells (human gastric cancer) were obtained from the American Type Culture Collection (Rockville, MD, USA) and maintained in RPMI 1640 (Sigma Chemical Co.) supplemented with 2 mmol/L glutamine, 10% fetal bovine serum, 100 U/mL penicillin, and 100 μg/mL streptomycin. Cisplatin was obtained from Pharmacia-Upjohn (Kalamazoo, MI, USA). DEX was purchased from Sigma Chemical Co., and [^{3}H] DEX (specific activity 35-50 Ci/mmol) was from Blossom Biotechnologies Inc. (Blossom, TX, USA).

Cytotoxicity assay

The *in vitro* growth inhibitory effects of the drugs in 14 carcinoma cell lines were determined by the MTT assay as previously described with slight modification[17]. Briefly, cells were plated in 96-well plates at 5×10^3 cells/well. After overnight incubation, various concentrations of drugs were added in triplicate samples to each culture. Cells were exposed to drugs continuously. After 3-4 d of culture, when cells in drug-free wells reached 90% confluency, 50 μL of 2.5 mg/mL MTT (Sigma Chemical Co.) in PBS was added to each well, followed by incubation for 4 h at 37 ℃. The formazan crystals were dissolved in DMSO. The absorbance was determined with an ELISA reader at 540 nm. Absorbance values were normalized to the values obtained for the vehicle-treated cells to determine the percentage of surviving cells. Each assay was performed in triplicate.

Measurement of GR content of cancer cell lines by [^{3}H]-labeled ligand binding assay

The GR content was measured by a whole-cell binding assay as previously described with minor modification[18]. Briefly, cells with 90% confluency were subcultured and allowed to grow overnight, and then trypsinized and suspended in a culture medium containing 10% fetal bovine serum (pH 7.2) to a density of $1\text{-}10\times10^6$ cells/mL. Cells were exposed to various concentrations of [^{3}H] DEX from 1 to 100 nmol/L in the presence or absence of 10 μmol/L unlabeled DEX, followed by incubation for 1 h at 37 °C, and harvested by centrifugation at 1 200 r/min for 1 min. Cells were then washed thrice in 3.0 mL of Hank's balanced salt solution and finally suspended in 1.6 mL of the same solution. A 0.2-mL aliquot of this suspension was used for the determination of cell number, and 1.0 mL was assayed for radioactivity by a liquid scintillation counter. The presence of at least 200-fold excess of unlabeled DEX effectively competed out all of the binding of [^{3}H] DEX to specific GR. The binding of [^{3}H] DEX to specific GR was represented as the difference in disintegrations per minute per cell between those samples incubated with [^{3}H] DEX alone and those with at least 200-fold excess of unlabeled DEX. Using the specific activity of [^{3}H] DEX, the number of receptors per cell was calculated, assuming that each receptor binds to one DEX molecule.

Examination of endogenous GR function by MMTV reporter assay

The human GR-expressing plasmid, pS-hGR, and the luciferase reporter plasmid, MMTV reporter plasmid were gifts from Prof. Chawnshang Chang (George H Whipple Laboratory for Cancer Research, University of Rochester, Rochester, NY, USA). The MMTV reporter plasmid contains the 1.4-kb MMTV LTR which encompasses the natural GRE sequences[19]. MCF-7, TW01, and TW02 cells were either transiently transfected with MMTV reporter plasmid cells, or co-transfected with MMTV reporter plasmid and pS-hGR (in a ratio of 5∶1) by Lipofectamine 2000 (Life Technologies, Inc. [GIBCO BRL], Gaithersburg, MD, USA) according to the manufacturer's protocol. Forty-eight hours after transfection, 1×10^5 transfected cells were stimulated with 1 μmol/L DEX and incubated for an additional 6 h. Reporter gene activity was determined with the Luciferase Reporter Assay System (Packard, the Netherlands).

Transfection of GR-expressing vector into cancer cell lines with low GR content

AGS cells were transfected with the pS-hGR by Lipofectamine 2000 (Life Technologies, Inc. [GIBCO BRL], Gaithersburg, MD, USA) according to the manufacturer's protocol. The stable clones were selected by 400 μg/mL hygromycin for 20 d. Single cell clones were obtained by limiting dilution of the hygromycin-resistant cells. The success of transfection was verified by Western blot analysis of GR and β-actin using rabbit polyclonal antibodies purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA) with signals

visualized by an enhanced chemiluminescence kit followed by exposure to X-ray films. The GR number in different clones of transfected cells was measured by [^{3}H]-labeled ligand binding assay.

GR immunohistochemistry study in cell lines and human cancer tissue samples

The GR immunocytochemistry study was performed in the 14 carcinoma cell lines. Cells with 90% confluency were subcultured and allowed to grow overnight, then were harvested and centrifuged at 400 r/min for 1 min. The cell pellets were fixed in 4% buffered formalin and embedded in paraffin.

Eighty-five human non-small cell lung cancer and 45 breast cancer tissue specimens which had been fixed in 4% buffered formalin and embedded in paraffin were used for immunohistochemistry study. Use of these tissue materials had followed the regulation of the research ethical committee of the National Taiwan University Hospital.

Five micrometers of paraffin-embedded cell block sections prepared on coated slides (DAKO Ltd.) were dewaxed and rehydrated, and endogenous peroxidase activity was blocked by incubation with 3% H_2O_2-methanol solution for 10 min. Heat retrieval was used for antigen retrieval. Endogenous biotin was blocked by normal goat serum (DAKO Ltd). Slides were then incubated with anti-GR antibody (PA1-510A, 511A and 512, Affinity BioReagents, Golden, CO, USA). The DAKO Envision system (Copenhagen, Denmark) was used to further avoid endogenous biotin contamination. Sites of bound peroxidase were visualized using liquid 3',5'-diaminobenzidine (DAKO, Glostrup, Denmark) and counterstained with hematoxylin. Under this staining condition, only the carcinoma cells with high (>10 000 sites/cell) GR content were positively stained. Tumor tissue samples were considered to be having high GR expression, when more than 20% of tumor cells were positively stained.

Statistical analysis

Independent *t* test was used to assess the correlation of GR content with the effect of DEX.

RESULTS

DEX affects either growth or chemosensitivity in 7 of the 14 carcinoma cell lines

DEX (0.01-1.0 μmol/L) inhibited cell growth in MCF-7, MCF-7/MXR1, MCF-7/TPT300, and HeLa cells (Figure 1A). However, DEX alone, up to 20 μmol/L, had no effect on the growth in the other 10 cell lines, including AGS, N87, SNU1, SiHa, Caski, Hep3B, Huh 7, TW01, TW04, and H460 (representative data shown in Figure 1A). The latter 10 carcinoma cell lines were further tested for the effect of GC on the chemosensitivity of carcinoma cells toward cisplatin. Pretreatment of SiHa cells with 1 μmol/L DEX for 3 h decreased the IC_{50} of cisplatin from 18.6±1.9 to 9.7±2.0 mmol/L (Figure 1B). This cytotoxicity-enhancing effect could be observed even when the concentration of DEX was as low as 1 nmol/L (data not shown). In contrast, DEX slightly increased cisplatin resistance in H460 and Hep3B cells (Figures 1C and D). DEX had no effect on the chemosensitivity of AGS, N87, SNU1, Huh-7, Caski, NPC-TW01, and NPC-TW04 cells (representative data shown in Figure 1E).

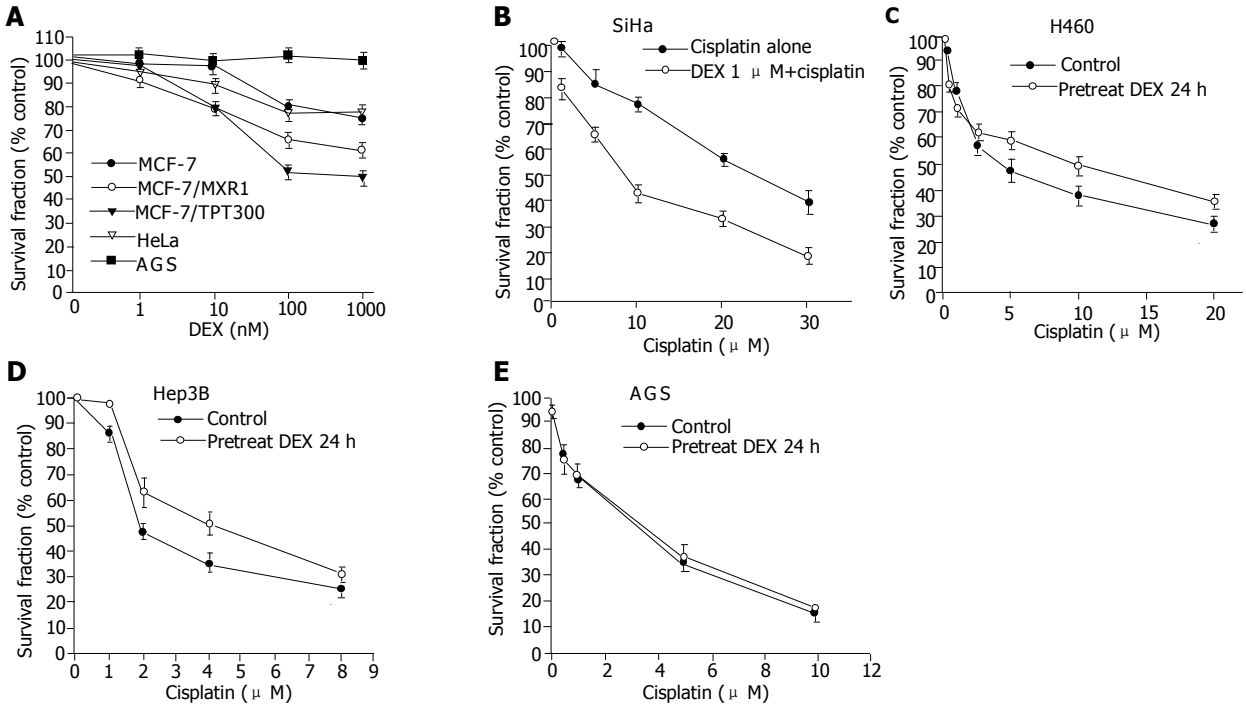

Figure 1 Effect of DEX on the growth and chemosensitivity in carcinoma cell lines. Cell numbers were measured by MTT assay and were plotted as a percentage of the control (cells not exposed to drugs); **A:** Growth of MCF-7, MCF-7/MXR1, MCF-7/TPT300, and HeLa cells were suppressed by DEX. Data of AGS represent the other 10 cell lines, growth of which was not affected by DEX; **B:** SiHa cells pretreated with DEX for 3 h were more sensitive to cisplatin; **C** and **D:** Pretreatment with DEX 1 μmol/L for 24 h diminished cisplatin cytotoxicity in H460 cells and Hep3B cells; **E:** Data of AGS represent the seven cell lines (AGS, N87, Caski, Hut 7, SNU1, NPC-TW01, and NPC-TW04), of which cytotoxicity of cisplatin was not affected by DEX. All values represent mean±SD of six separate wells.

Effects of GC correlate well with GR content of the cells

The GR contents of these 14 cell lines are listed in Table 1. The GR contents of the seven cell lines affected by DEX were significantly higher than those of the other seven cell lines unaffected by DEX ($5.2\pm2.5\times10^4$ sites/cell *vs* $1.3\pm1.4\times10^4$ sites/cell, $P = 0.005$) suggesting GR is one of the pivotal mediators of the effect of DEX on carcinoma cell. The GR content of human lymphocytes, the internal control for these experiments, was tested parallel and was within the reported range (2 500-5 400 sites/cell)[20].

GC-unresponsive GR-rich carcinoma cells have dysfunctional GR

As shown in Table 1, DEX had no effect on NPC-TW01 and NPC-TW04, two cell lines with GR content as high as that of the seven GC-responsive cell lines. The function of the GR in these two cell lines was further examined. As shown in Figure 2, MCF-7 cells contained endogenous DEX-responsive GR, while NPC-TW01 and NPC-TW04 cells did not. Further, when NPC-TW01 and NPC-TW04 cells were co-transfected with MMTV reporter plasmid and pS-GR, which contains functional human GR gene, the response to DEX were restored (Figure 2). These data strongly suggested that the function of endogenous GR of NPC-TW01 and NPC-TW04 cells was probably impaired.

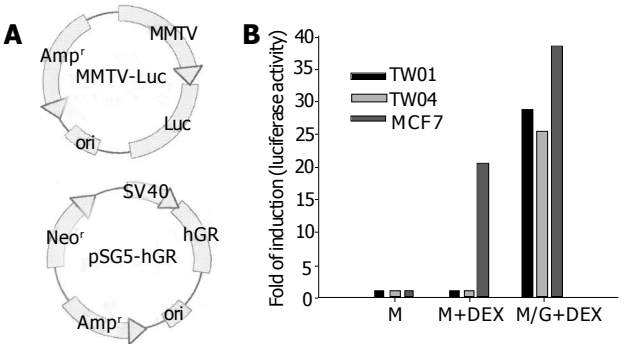

Figure 2 Functional assay of the GR in NPC-TW01 and NPC-TW04 cells. NPC-TW01, NPC-TW04, and MCF-7 cells were transiently transfected with MMTV reporter plasmid (lanes M and M+DEX) or co-transfected with MMTV reporter plasmid and pS-hGR (lane M/G+DEX). The cells were then treated with 1 μmol/L DEX for 6 h (lanes M+DEX and M/G+DEX). Then the luciferase activity was assayed and represented in terms of folds of the induction activity of the control (lane M). All values represent mean±SD of three experiments(**A**,**B**).

Expression of GR in GR low-expressing cells increases their responsiveness to DEX

To further examine whether the GR content is pivotal in mediating the susceptibility to DEX in carcinoma cell, pS-hGR was transfected into AGS cells, a GR low-expressing cell line. The GR content in empty vector-transfected AGS cells, and pooled stably pS-hGR-transfected AGS cells were 5.2×10^3 and 1.42×10^4/cell, respectively. The GR contents of clone 1, 2, and 3 were 1.54×10^4, 1.32×10^4, and 5.8×10^3/cell, respectively. Treatment of DEX alone had no effect on cell growth in these cells (data not shown). However, as shown in Figure 3, pS-hGR transfected AGS cells that expressed high GR content became susceptible to the effect of DEX with increasing drug resistance toward cisplatin. The cells that express higher GR content (pooled cells, clones 1 and 2) were more resistant toward cisplatin, while cells with lower GR content (empty vector and clone 3) remained non-susceptible to DEX treatment.

Tumor tissues of common human carcinomas may express high level of GR

GR expression was examined by immunohistochemical stain in the carcinoma cell lines (Figure 4A), and tumor tissue samples of human breast cancer and human non-small cell lung cancer (Figure 4B). Positive GR immunoreactivity (representing high GR content) was observed in 5 of the 45 tumor samples (11.1%) of breast cancer and 43 of the 85 tumor samples (51%) of non-small cell lung cancer patients.

DISCUSSION

This study has demonstrated that GC affects either growth or chemosensitivity in a substantial portion of carcinoma cells. Since GC is commonly co-administered with anticancer drugs such as taxanes and platinums, how GC alters the effect of chemotherapy may have to be taken into consideration in clinical practice. As shown in this study, it may not be difficult to identify those carcinoma patients of whom tumor response is going to be affected by GC, since only cells with high GR content are affected. However, how GC will actually

Table 1 Correlation of GR content with the effect of DEX in carcinoma cells

Cells	Origin	Effect of DEX	GR (sites/cell)
MCF7	Breast	Growth inhibition	6.37×10^4
MCF7/TPT300	Breast	Growth inhibition	7.43×10^4
MCF7/MXR1	Breast	Growth inhibition	5.9×10^4

DEX: dexamethasone; GR: glucocorticoid receptor.

affect the growth of tumors of these cancer patients remains uncertain since the effects of GC, as disclosed in this study, are extremely diverse and even contradictory.

A direct correlation between GR content of the cells and the magnitude of physiologic response to GC has been reported in hematologic malignancies[21]. The sensitivity of many lymphoid cell lines to GC-induced growth arrest and apoptosis is directly proportional to intracellular receptor content[22-24]. Several studies also identified a correlation between reduced GR expression and a poor treatment response as well as poor prognosis in patients with acute lymphocytic leukemia, suggesting that reduced GR expression could lead to clinical GC resistance[22,25-27]. Our study demonstrated that the susceptibility to the effect of DEX on cell growth or chemosensitivity in carcinoma cells also correlate well with the level of GR content. However, the GR contents of the GC-responsive carcinoma cells are almost 10 times higher than that of lymphoid cells[27-29], suggesting that the cellular contexts or the signal transduction pathways for the interaction of GC and GR are probably different between epithelial and lymphoid malignant cells.

In this study, the only two cell lines, NPC-TW01 and NPC-TW04, which have relatively high GR content but not susceptible to the growth regulatory effect of DEX, were found to have non-functional endogenous GR. Previous studies on both human and mouse cell lines have shown that somatic mutation in the GR gene is the principal mechanism for *in vitro* acquisition of GC resistance[28-30]. However, we failed to detect GR gene mutations in NPC-TW01 and NPC-TW04 (data not shown). Beside the GR number and GR gene mutations, the phosphorylation status of GR has also been reported to be correlated with GR resistance[31]. The expression level of GR co-regulators was also important to normal GR function[32]. Therefore, there should be other mechanisms associated with the malfunction of GR in these two cell lines.

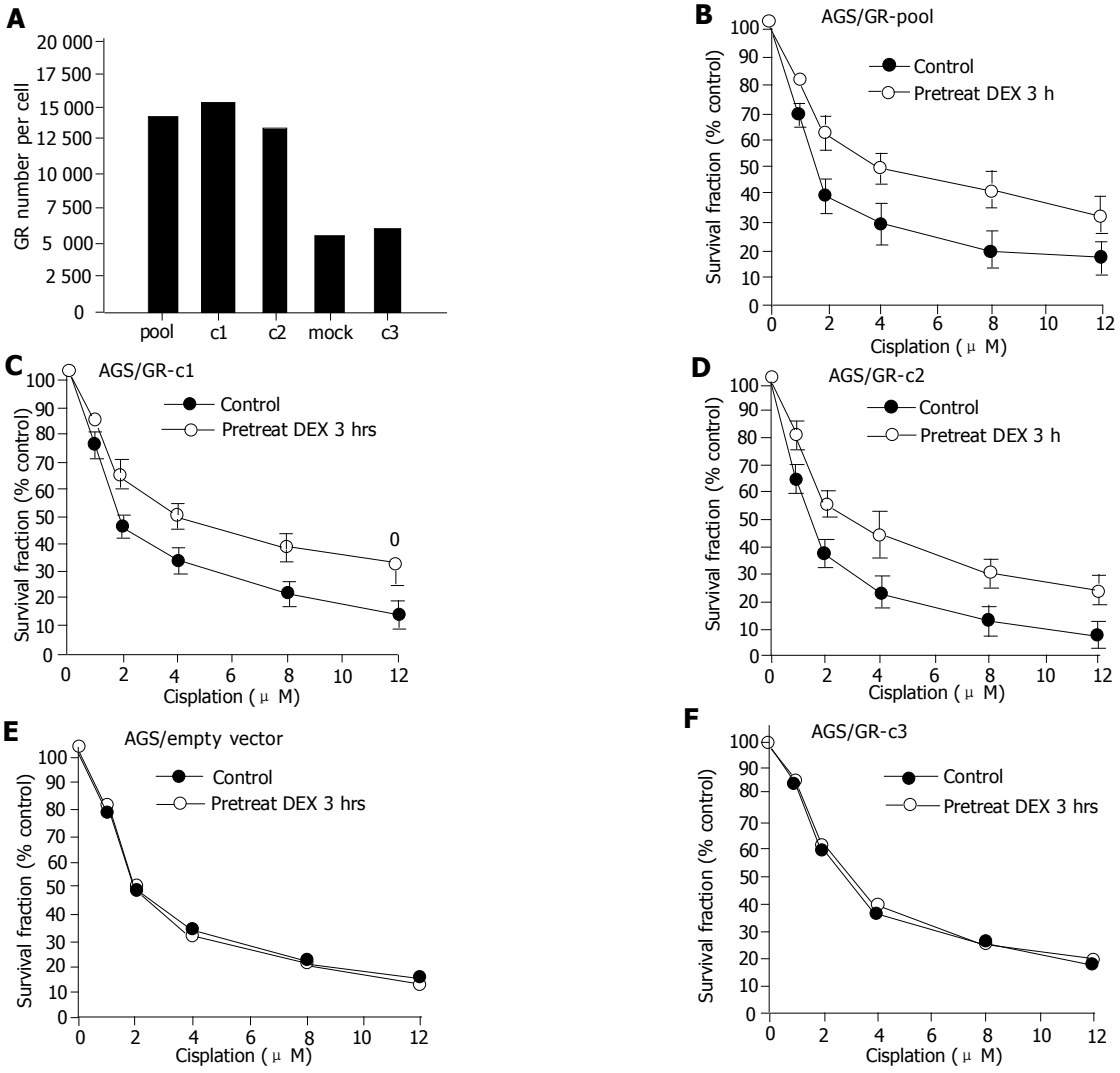

Figure 3 Increased drug resistance to cisplatin in pS-hGR-transfected AGS. AGS cells were transfected with pS-hGR and MTT assay were performed. **A:** GR number measured by [^{3}H]-labeled ligand binding assay. Pool: AGS/GR-pool; AGS cells transfected with pS-hGR, pooled cells. c1: AGS/GR-c1; AGS cells transfected with pS-hGR, single cell cloned, clone 1. c2: AGS/GR-c2; AGS cells transfected with pS-hGR, single cell cloned, clone 2. Mock: AGS/empty vector; AGS cells transfected with empty vector. c3: AGS/GR-c3; AGS cells transfected with pS-hGR, single cell cloned, clone 3; **B-D:** Pretreatment with DEX 1 μmol/L for 3 h diminished cisplatin cytotoxicity in AGS/GR-pool, AGS/GR-c1, and AGS/GR-c2 cells; **E** and **F:** Pretreatment with DEX 1 μmol/L for 3 h had no effect on the cisplatin cytotoxicity in AGS/empty vector cells and AGS/GR-c3. All values represent mean±SD of six separate wells.

Activated GR may activate or suppress gene expression through interaction with respective positive or negative *cis*-acting regulatory elements in the promoters regions[33,34]. Activated GR can also regulate the expression of GC responsive genes indirectly through protein-protein interactions with other transcription factors such as NF-κB and AP-1[35-37]. Inactivation of NF-κB or AP-1 has been shown to alter the vulnerability of cancer cells to several cytotoxic agents[38,39]. Our preliminary data have indicated that suppression of NF-κB by GC is one of the major mechanisms of increasing cisplatin sensitivity in SiHa cell[40]. Some studies have demonstrated variable potential other mechanisms of GC related growth arrest in non-hematologic cancer cells that included upregulation of p21Cip1[7], p57 Kip2[8], and inhibition of ERK/MAPK kinase pathway[9], and mechanisms of GC related chemosensitivity alteration include induction of GC-inducible protein kinase-1 (SGK-1) and mitogen-activated protein kinase phosphatase-1 (MKP-1)[14], and modulation of bcl-x expression[11]. However, it remains difficult to explain the diverse and even contradictive effect of GC on GR-rich carcinoma cells. The possibilities that the specific presence of certain co-regulators of GR in different carcinoma cells may dictate the ultimate effect

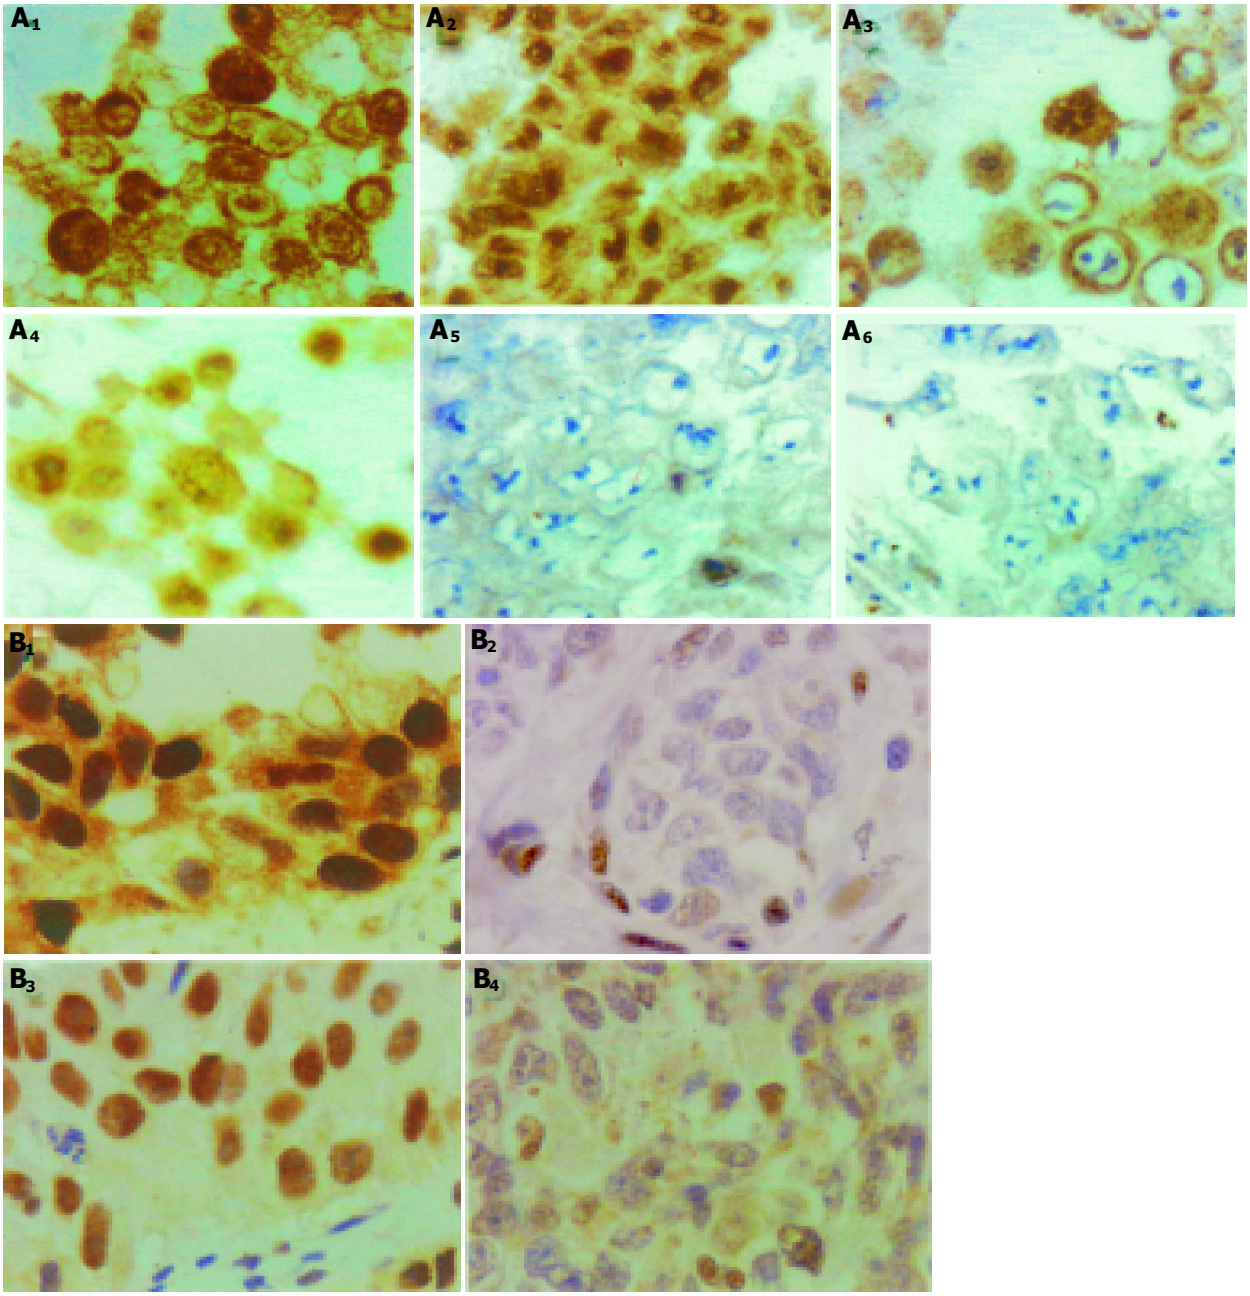

Figure 4 A: Immunocytochemical stain for GR expression in representing carcinoma cell lines. (A_1) and (A_2): SiHa cells, which had GR content about 8.1×10^4/cell according to ligand binding assay; (A_3) and (A_4): HeLa cells, with GR content about 1.97×10^4/cell; (A_5) and (A_6): N87 cells, with GR content about 5.0×10^3/cell. (A_2), (A_4), and (A_5): cells treated with DEX for 3 h before harvest. In (A_1) and (A_3), the GR immunoreactivity localized in cytoplasm. After DEX treatment, the immunoreactive GR translocalized to nuclei (A_2) and (A_4). The low GR content cancer cells N87 showed negligible immunoreactivity. **B:** Immunohistochemical stain for GR expression in human carcinoma tumor tissue samples. Non-small cell lung cancer tumor samples, with high GR expression (B_1), and low GR expression (B_2). Breast cancer tumor samples, with high GR expression (B_3), and low GR expression (B_4).

of GC needs to be clarified.

The [^{3}H] labeled DEX ligand binding assay has been the standard method to measure the GR content in cell lines and *in vivo* human leukemia samples. The GR amount measured by [^{3}H] labeled DEX ligand binding assay is expressed as GR number per cell. However, this method is hard to apply to solid tumor tissue samples, since it is difficult to quantify the cell number in tissue samples. There were other methods to detect the expression of GR in the *in vivo* solid tumor samples, including cytosol DCC-competitive (dextran-coated charcoal) protein binding assay[41,42], and RT-PCR[43]. These methods all use tissue homogenizer and the results were normalized by the total protein or RNA amount. Therefore, the result was the average of the GR content of the whole tissue sample, which includes the cancer cells as well as the stroma cells and adjacent normal tissues component. Besides, the cytosol DCC-competitive protein binding assay required fresh frozen tissue which limited its applicability. In this study, we have shown an ideal staining condition by which only cancer cells with high GR content were stained positively (Figure 4). We have also demonstrated that a substantial portion of common human carcinoma do express high level of GR, and therefore are potentially susceptible to the growth and chemosensitivity-regulatory effect of GC.

Clinically, the serum concentration of DEX was found to be around 0.12 μmol/L, lasting for 1-3 h, after a single oral dose of 7.5 mg of DEX[44]. However, the serum concentration of DEX may reach 2 μmol/L after a single intravenous infusion of 80-100 mg of DEX[45]. Since the administration of relatively high-dose DEX, at the range of 10-50 mg/d, or its equivalents, has been widely used for the prevention of cisplatin-induced nausea/vomiting and taxanes-induced allergic reactions, the possible effect of GC on the chemosensitivity of some cancer patients needs to be seriously considered.

In summary, the results of this study suggest that GC exerts a GR-dependent effect on the growth or chemosensitivity in a substantial portion of carcinoma cells. The clinical relevance and the cellular mechanisms that dictate the disparate effects of GC need to be further clarified.

Abstract

AIM: To investigate the apoptotic effects of nucleosides on the human hepatoma HepG2.

METHODS: The nucleosides included inosine (I), cytidine (C), uridine (U), thymidine (T), adenosine (A), and guanosine (G). Cells were incubated by the mediums with or without nucleosides at 37 ℃ in a 50 mL/L CO_2 humidified atmosphere.

RESULTS: It was found that the cell viabilities were significantly decreased, when cells were treated with 30 mmol/L I, 30 mmol/L C, 30 mmol/L U, 30 mmol/L T, 0.5 mmol/L A, and 0.5 mmol/L G after 12 h incubation ($P<0.05$). About the apoptotic phenomenon, the cell percentages of sub-G_1 cells were significantly increased in the mediums containing nucleosides such as C, U, T, A, and G ($P<0.05$). Furthermore, the caspase-3 activity was increased, when the cells were incubated with T ($P<0.05$). The protein expressions of p53 and p21 showed no difference in each group. To investigate the mechanism of apoptosis induced by nucleosides, it was found that the contents of soluble Fas ligand contents were increased in HepG2 cells following I, U, T, and A treatment ($P<0.05$). But, TNF-α and cytochrome *c* were undetectable.

CONCLUSION: Thymidine may induce the apoptosis in HepG2, but the effective dosages and reactive time must be investigated in the future study. However, the apoptosis-inducing abilities of other nucleosides were still unclear in this study.

INTRODUCTION

According to the statistics tabulated by the Department of Health, Taiwan in 2003, cancer is the first leading cause of death in Taiwan. Among the various cancers, the morbidity of hepatoma is the highest in Taiwanese. The great medical expenses covering not only drugs but also in providing nutritional supplements for treating or preventing the liver diseases and hepatoma are the heavy burdens of Taiwanese. Food-derived inducers of apoptosis may be significant as exogenous anti-tumor substances in the control of malignant cell proliferation despite little understanding about their molecular and cellular basis of action. Many healthy foods that are rich in nucleosides have anti-carcinogenic effects, such as the hot water extract of chlorella[1–3]. Current evidence suggests that nucleosides induce cell death by apoptosis[4-6]. Nucleosides that act as signaling molecules are well documented and are mostly released from cells, when cells are under stress, such as anoxia or injury[7-9]. In addition, it has been presumed that a vast majority of tumor promoters are potent inhibitors of apoptosis, and cancer cells did not produce apoptosis-inducing nucleosides[10]. However, little is known about the signaling or the biochemical mechanisms of nucleosides-mediated cell death.

Thus, the purpose of this study was to investigate the apoptosis-inducing ability and the molecular mechanisms of nucleosides in human hepatoma HepG2.

MATERIALS AND METHODS

Cell culture and treatment

The human hepatoblastoma cell line, HepG2 (HB-8065), was obtained from the American Type Culture Collection. Cells were cultured in MEM supplemented with 5% FBS. Cells were grown in a humidified incubator under 50 mL/L CO_2 at 37 ℃ and medium was changed every 2 d. When the cell status was stable after several passages, the experiments started. Cells were seeded in 100-mm dishes at a density of 1×10^6 cells/well. They were incubated with defined concentrations of nucleosides for 12 h. The cells and media were collected and analyzed after incubation. The nucleosides included inosine (I), cytidine (C), uridine (U), thymidine (T), adenosine (A), and guanosine(G).

Cell viability assay

The cell viability was determined using CellTiter^{R}96 Aqueous One Solution Cell Proliferation Assay (Promega, Madison,

WI, USA). The assay is an MTT-based method, which measures the ability of metabolically active cells to convert tetrazolium salt into a cleavage product and its absorbance is recorded at 490 nm[11].

Flow cytometric analysis

Cells were harvested by 0.25% trypsin release, washed twice with PBS, permeated with 75% ethanol, treated with 3 μL RNase A and finally stained with 1 mL propidium iodide (40 μg/mL final concentration). Distribution of cell-cycle phases with different DNA contents was determined using FACScan flow cytometer (Becton Dickenson, San Jose, CA, USA). Cells that were less intensely stained than G_1 cells (sub-G_1 cells) in flow cytometric histograms were considered as apoptotic cells.

Caspase-3 activity and soluble Fas ligand content

After treatment for 12 h, cells were collected and lysed with 50 μL cell lysis buffer. Then, the cell lysate was centrifuged and the supernatants were retained to determine the caspase-3 activity with Caspase-3/CPP32 Colorimetric Kit (Biosource International, Camarillo, CA, USA). Furthermore, the soluble Fas ligand contents (sFas-L) in the medium were detected with Human sFas Ligand ELISA kit (Biosource International).

Protein extraction and Western blot assay

Cell proteins were extracted from cells in a buffer containing 50 mmol/L Tris-HCl, pH 7.5, 150 mmol/L NaCl, 1% Nonidet P-40, 0.5% sodium deoxycholate, 4% protease inhibitors, and 1% phosphatase inhibitors. The cell lysate was rotated at 4 ℃ for 30 min, centrifuged at 10 000 r/min for 10 min and the precipitates were discarded. Protein contents were determined by the DC Bio-Rad protein assay kit using bovine serum albumin as a standard. The cell proteins were added to an equal volume of 2× sample buffer containing 0.125 mol/L Trizma base, 4% sodium dodecyl sulfate (SDS), 20% glycerol and 10% 2-mercaptoethanol and boiled during 3 min at 100 ℃. Then, proteins (100 μg) were separated by 12% SDS-polyacrylamide gels and transferred onto polyvinylidene difluoride membranes (Schleicher & Schuell BioScience, Keene, NH, USA), which was then incubated with primary antibody, such as p53 mouse monoclonal IgG_2a (Santa Cruz Biotechnology, Santa Cruz, CA, USA) and F-5 mouse monoclonal IgG_2b (Santa Cruz Biotechnology). HRP-conjugated goat anti-mouse IgG (Santa Cruz Biotechnology) was used as a secondary antibody. The immunoreactive bands were washed four times in PBS-T (PBS in 0.2% Tween 20), dried and exposed to Kodak film. The relative intensity of the bands was analyzed by densitometry.

Statistical analysis

All data are expressed as the mean±SD. One-way analysis of variance and Fisher's least significant difference test were used to compare the differences of means using the SAS software (v.6.12, SAS Institute, Cary, NC, USA). Statistical significance was assigned at the 0.05 level.

RESULTS

Cell viability assay

The cell viabilities were significantly decreased when cells were treated with defined concentrations of nucleosides after 12-h incubation (Table 1). The most effective dosages were 30 mmol/L for I, C, U, and T, 0.5 mmol/L for A and G. Thus, these effective concentrations were used in later experiments.

Flow cytometric analysis

Figure 1 is the example of flow cytometer graph from all results in each group. The quantity of various phase percentages is shown in Table 2. About the apoptotic phenomenon, the cell percentages of sub-G_1 phase were significantly increased in the media containing nucleosides such as C, U, T, A, and G (Table 2). In particular, thymidine induced the highest cell percentages of sub-G_1 phase among the nucleosides. The cell-cycle progression of I, A, and G groups was similar to that of control group. Moreover, C and U treatments caused an increase in the cell numbers in the G_0/G_1 phase of the cell cycle. Certainly, the cell numbers of S phase in C and U groups were significantly decreased.

Caspase-3 activity and soluble Fas ligand content

Caspase-3 activity was increased when the cells were incubated with T (Table 2). To investigate the mechanism of apoptosis induced by nucleosides, it was found that the contents of sFas-L contents were increased in HepG2 cells following I, U, T, and A treatment (Table 2). But, TNF-α and cytochrome *c* were undetectable (data not shown).

Western blot assay

HepG2 is the wild type hepatoma with p53 gene. The expressions of p53 and p21 showed no difference in each group (Figure 1). The densitometric result was also unchanged (Figure 2).

Table 1 Effects of nucleosides on HepG2 cell viability by MTS assay[1]

Treatment	Inosine (%)	Cytidine (%)	Uridine (%)	Thymidine (%)	Adenosine(%)	Guanosine(%)
0 mmol/L	103.9±3.5[a]	101.8±1.6[a]	103.5±3.5[a]	102.2±1.9[a]	101.3±1.2[a]	103.1±2.7[a]
7.5 mmol/L	94.0±1.2[a]	92.0±3.8[a]	100.6±6.6[a]	101.5±5.1[a]		
15 mmol/L	69.5±1.8[a]	75.6±1.7[a]	99.1±2.8[a]	99.0±0.3[a]		
30 mmol/L	67.7±0.7[a]	61.4±5.9[a]	86.1±1.3[a]	84.5±3.2[a]		
0.1 mmol/L					93.0±5.2[a]	86.3±3.5[a]
0.3 mmol/L					80.9±2.0[a]	89.4±2.1[a]
0.5 mmol/L					78.4±1.8[a]	86.3±3.3[a]

[1] Cells were incubated with different treatments for 12 h. Cell viability was measured with MTS assay kits. Values are expressed as the mean±SD of six independent experiments. [a]$P<0.05$ *vs* 0 mmol/L.

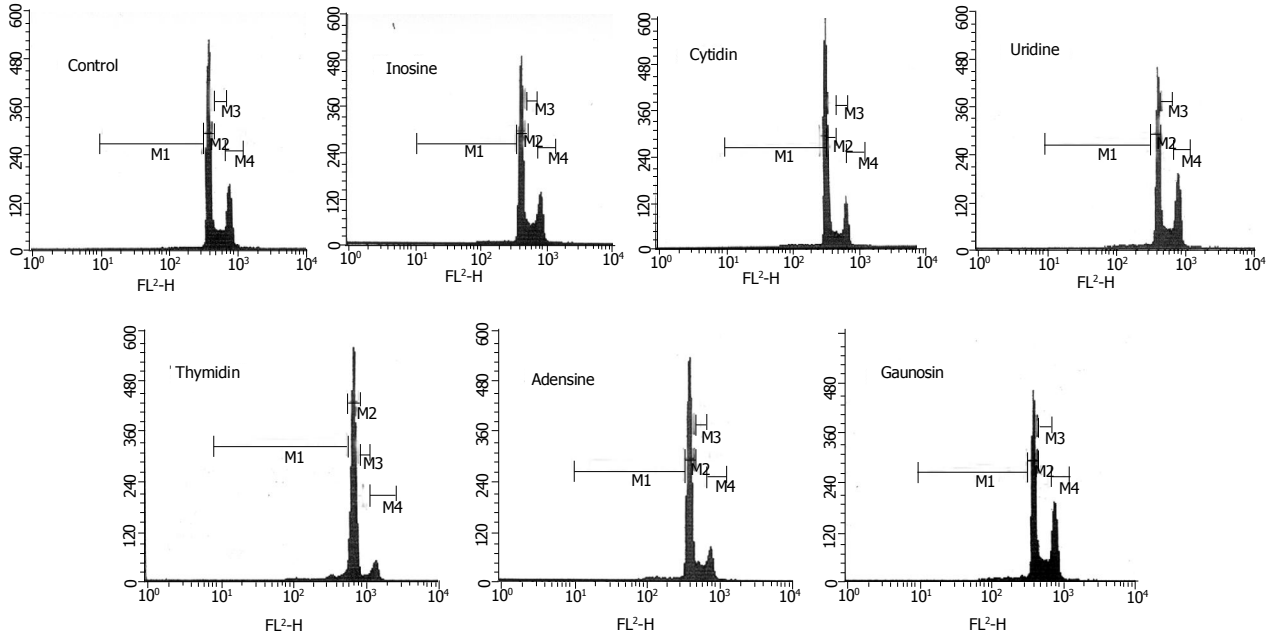

Figure 1 Effects of nucleosides on the cell cycle progression of HepG2 cells. HepG2 cells untreated (control) or treated with nucleosides were stained with propidium iodide and analyzed using a flow cytometer. The contents of inosine, cytidine, uridine, and thymidine in mediums were 30 mmol/L, respectively. And, the contents of adenosine and guanosine were 0.5 mmol/L. This experiment was repeated thrice and obtained similar results were obtained. Figure 1 was the example from all results in each group. M1, M2, M3, and M4 represented Sub G1, G0/G1, S, and G2/M phases, respectively (A-G).

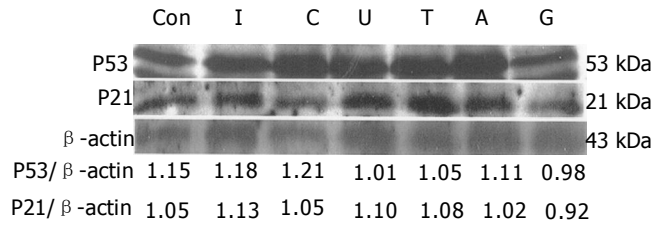

Figure 2 Effects of nucleosides on the p53 and p21 protein expressions in HepG2 cells. One hundred μg of cytosolic proteins were separated by SDS-PAGE, and P53, P21, and β-actin protein were detected, respectively. This experiment was repeated thrice and similar results obtained.

DISCUSSION

The cytotoxicity of nucleosides at defined concentrations in human hepatoma HepG2 cells was proved in this study. However, it has been reported that 1 mmol/L I, C, U, and T did not inhibit the proliferation of HL-60 and Caco-2 cells[12]. In addition, the inhibition effects were observed after 1 mmol/L A and G treatment[12]. Thus, it was speculated that the different cell type of tumor might lead to completely opposite influences.

The cell percentages of sub-G_1 phase were increased after C, U, T, A, and G treatment. However, the variation of sub-G_1 phase in C, U, A, and G groups was weaker than other apoptosis-related researches[13,14]. More apoptotic indicators or treatment dosages of nucleosides must be investigated further.

Thymidine increased the caspase-3 activity in HepG2 cells. Moreover, the sFas-L was also increased when cells were cultured with thymidine. However, these effects were not extremely obvious. These results indicated that thymidine might have the potential to induce the apoptosis, but the effective dosage and reactive time must be investigated further.

The cell percentages of sub-G_1 phase and caspase-3 activities were still unchanged despite sFas contents were higher after inosine and uridine treatments. Similarly, cytidine did not increase the caspsase-3 activity and sFas-L contents,

Table 2 Effects of nucleosides on the cell cycle progression, caspas-3 activity and sFas-L content in HepG2 cells[1]

Treatment	Control	Inosine	Cytidine	Uridine	Thymidine	Adenosine	Gaunosine
SubG1 (%)	2.6±0.8[a]	3.2±0.3[a]	6.9±0.2[a]	6.5±1.5[a]	26.8±2.3[a]	9.6±1.5[a]	5.7±1.2[a]
G0/G1(%)	67.7±1.1[a]	69.2±0.1[a]	74.1±1.3[a]	84.8±2.6[a]	54.4±1.8[a]	64.8±1.4[a]	68.0±1.9[a]
S (%)	15.7±0.0[a]	18.8±0.3[a]	8.5±0.2[a]	3.1±0.3[a]	12.0±0.2[a]	10.6±0.4[a]	17.3±0.7[a]
G2/M (%)	14.0±1.9[a]	8.8±0.1[a]	10.5±1.0[a]	5.7±0.8[a]	6.8±0.8[a]	15.0±0.9[a]	9.0±1.3[a]
Caspase-3 (%)[2]	100±0[a]	101±5[a]	97±6[a]	98±5[a]	148±2[a]	104±4[a]	100±3[a]
sFas-L (pg/mL)	0.11±0.01[a]	0.14±0.01[a]	0.08±0.03[a]	0.15±0.03[a]	0.17±0.02[a]	0.15±0.07[a]	0.10±0.03[a]

[1]Cells were treated with or without nucleosides for 12 h. The contents of inosine, cytidine, uridine, and thymidine in the mediums were 30 mmol/L, respectively, and, the contents of adenosine and guanosine were 0.5 mmol/L. Values are expressed as the mean±SD of four independent experiments. [a]$P<0.05$ *vs* others.
[2]Caspase-3 activity was shown as percentage to compare with control group.

but raised the cell percentages of sub-G_1 phase. Insufficient data indicated the apoptosis-inducing action of inosine, uridine, and cytidine. There are two possibilities, which can explain these results. One is that the apoptosis induced by inosine, uridine, and cytidine might occur later than 12-h incubation. The other is that the cell death induced by inosine, uridine, and cytidine, which showed in MTS assays, was necrosis not apoptosis. Besides, the cell cycle progressions of uridine and cytidine were different from those of other nucleosides. It was observed that uridine and cytidine induced G_0/G_1 phase arrest in HepG2 cells. This effect may be associated with the growth inhibitory action of uridine and cytidine.

Chow *et al*. indicated that adenosine induced apoptosis of HL-60 cells by activating the G protein and increasing the cytosolic Ca^{2+} concentration when adenosine combined with its receptors, P1[15,16]. Moreover, guanosine appears to improve the release of adenosine from cell, and induce cell death via the action of adenosine[17]. But, in this study, the apoptotic-related signals, such as sFas-L content and caspase-3 activity, were not altered in cells after adenosine and guanosine treatments. Thus, the treatment concentration and time point must be reconsidered.

The tumor suppressor p53 is the most commonly mutated gene in human cancers. Cells can respond to the activation of the tumor-suppressor protein p53 by undergoing apoptosis[18,19]. Active p53 is able to stimulate the transcription of a variety of genes including p21, which is a universal inhibitor of the cyclin-dependent kinases (CDK)[20-22]. There were few researches that investigated the relationships between the p53 and nucleosides. In this study, it was found that nucleotides did not alter the expression of p53 and p21 after 12-h incubation with cells.

In conclusion, thymidine might have the potential to induce the apoptosis; however, the apoptosis-induced abilities of other nucleosides were still unclear in this study. It is necessary to recheck the dosage and time of treatment and measure more apoptotic indicators, such as DNA fragmentation and morphological analysis.

Abstract

AIM: To investigate the effect and mechanism of action of the nitric oxide synthase (NOS) inhibitor NG-nitro-L-arginine methyl ester (L-NAME) on invasion and metastasis of human colorectal cancer cell line SL-174T.

METHODS: Human colorectal cancer cell line SL-174T was cultured and treated separately with four different dosages of L-NAME for 72 h. Nitric oxide (NO) production was measured with Griess reagent. The effect of L-NAME on invasion and migration of SL-174T cells were evaluated by using Transwell chambers attached with polycarbonate filters and reconstituted basement membrane (Matrigel). RT-PCR was performed to determine the mRNA levels of matrix metalloproteinase-2 (MMP-2) and tissue inhibitor metalloproteinase-2 (TIMP-2).

RESULTS: L-NAME could significantly inhibit NO production of SL-174T in a dose-dependent manner. After being treated for 72 h with 0.2, 0.4, 0.8, and 1.0 mmol/L L-NAME, respectively, the ability of the L-NAME treated SL-174T cells to invade the reconstituted basement membrane decreased significantly (t = 8.056, P<0.05; t = 14.467, P<0.01; t = 27.785, P<0.01; and t = 29.405, P<0.01, respectively) and the inhibition rates were 10.29%, 19.62%, 34.08%, and 42.23%, respectively. Moreover, L-NAME could inhibit migration of SL-174T cells, and the inhibition rates were 20.76%, 24.95%, 39.43%, and 46. 85% for L-NAME at 0.2, 0.4, 0.8, and 1.0 mmol/L, respectively (t = 15.116, P<0.01). In addition, after treatment with L-NAME, expression of MMP-2 mRNA was significantly decreased (t = 71.238, P<0.01) and that of TIMP-2 mRNA was markedly increased (t = -13.020, P<0.01).

CONCLUSION: L-NAME exerts anti-invasive and anti-metastatic effects on SL-174T cell line via downregulating MMP-2 mRNA expression and upregulating TIMP-2 mRNA expression.

INTRODUCTION

Colorectal cancer is one of the leading causes of cancer deaths in men and women, and more effective and potent agents for chemotherapy of colorectal cancer are urgently needed. A number of *in vitro* and *in vivo* investigations have indicated the possible involvement of nitric oxide (NO) in promoting tumor carcinogenesis, migration, invasiveness, and angiogenesis. NO is produced from L-arginine, catalyzed by three isoforms of nitric oxide synthases (NOS): (1) calmodulin- and Ca^{2+}-dependent endothelial NOS (eNOS); (2) neuronal NOS (nNOS); and (3) calmodulin- and Ca^{2+}-independent endothelial NOS (iNOS)[1]. An NOS inhibitor NG-nitro-L-arginine methyl ester (L-NAME) has been reported to exert anticancer effects against human head and neck cancer and mammary tumor *in vitro*[2,3]. However, the effects of this agent against colorectal cancer remain to be determined. In the present study, we, therefore, examined the anticancer effects and mechanisms of L-NAME in highly metastatic colorectal cancer cell line SL-174T.

MATERIALS AND METHODS

Cell line and treatment

The human colorectal cancer cell line SL-174T was purchased from Cancer Research Institute of Harbin Medical University and maintained in RPMI 1640 medium (Gibco/BRL), supplemented with 100 mL/L heat-inactivated fetal calf serum (Gibco) and 10 g/L penicillin-streptomycin solution (10 000 U/mL). The cells were incubated in plastic tissue culture flasks (Falcon) at 37 ℃ in a humidified atmosphere containing 50 mL/L CO_2 in air. In the experiments designed to block NO synthesis, L-NAME (Sigma) was added to the medium at various concentrations (0.2, 0.4, 0.8, and 1.0 mmol/L).

NO production assay

Using a microplate assay with Griess reagent, NO production was determined by measuring nitrite accumulation in culture supernatants. After the cells were treated with different

concentrations of L-NAME (0.2, 0.4, 0.8, and 1.0 mmol/L) for 72 h, NOS activity was assessed by measuring nitrite production following the manufacturer's instructions. Cell supernatants (1 000 μL) were mixed with 1 000 μL of the Griess reagent. After 10-min incubation at room temperature, the absorbency was read at 540 nm on a spectrophotometer.

Tumor cell invasion and migration assays

The ability of cells to migrate through control (migration) or invade through Matrigel-coated filters (invasion) was measured in a Transwell chamber (Costar). Eight-micron Transwell filters, which were coated with or without 5 μg Matrigel (Becton Dickinson) and 5 μg fibroblast (Promega), were placed in the lower chamber as a chemoattractant. Then SL-174T cells, treated with different concentrations of L-NAME for 72 h, were added into the upper room and incubated for additional 4 h at 37 ℃ in a humidified atmosphere containing 50 mL/L CO_2 in air. The cells that had not penetrated the filter were wiped out with cotton swabs, and the cells that had migrated to the lower surface of the filter were examined using bright field microscopy, and photographed. The values for invasion were determined as the average number of migrated cells bound per microscopic field over four fields per assay and expressed as average values for triplicate experiments.

Detection of MMP-2 mRNA and TIMP-2 mRNA expression

After the cells were treated with different concentrations of L-NAME (0.2, 0.4, 0.8, and 1.0 mmol/L) for 72 h, total RNA was extracted from SL-174T cells with the TRIzol reagent (Gibco/BRL, Life Technologies Inc.) according to the manufacturer's instructions. The primers were designed using Primer Premier 5 software. The primers used for PCR amplification of matrix metalloproteinase-2 (MMP-2) were 5'-TCTTCAAGGACCGGTTCATTTG-3' (sense) and 5'-GATGCTTCCAAACTTCACGCTC-3' (antisense), 500 bp long. The primers used for PCR amplification of tissue inhibitor metalloproteinase-2 (TIMP-2) were 5'-ACC TGGATGCCGTCGTGGAC-3' (sense) and 5'-TGTGGCAGCACCAGGGCAGC-3' (antisense), 376 bp long. The primers used for β-actin PCR amplification were 5'-TACATGGCTGGGGTGTTG AA-3' (sense) and 5'-AAGAGAGGCATCCTCACCCT-3' (antisense), 218 bp long. PCR primers were synthesized by Biology Engineering Corporation of Shanghai. Ten-microliter aliquots of the PCR product were loaded on 20 g/L polyacrylamide gel. Absorbency ratios of MMP-2 and TIMP-2 to control β-actin mRNA expression were considered as expression indices of the former two genes and used for semi-quantitation.

Statistical analysis

SAS for Windows 6.12 was used to solve the data. The data were mean value of at least three different experiments and expressed as mean±SD. The LSD-*t* test and Dunnett's *t* test were used to compare the data. $P<0.05$ was considered statistically significant.

RESULTS

Effect of L-NAME on NO production

NO production was significantly decreased after the treatment with different dilutions of L-NAME. We observed significant differences in NO levels between control group and treatment groups (Table 1).

Table 1 Effect of different concentrations of L-NAME on NO production by SL-174T cells (mean±SD)

Concentration mmol/L	No. of experiments	NO (μmol/L) 72 h
Control	3	147.80±0.78[b]
0.2	3	135.66±0.45
0.4	3	95.73±0.23
0.8	3	59.80±0.65
1.0	3	56.43±0.64

[b]$P<0.01$, *vs* control.

Influence of L-NAME on invasion and migration of SL-174T cells

Compared with the control group, SL-174T cells treated with different concentrations of L-NAME for 72 h had decreasing tendency for invasion and the inhibition rates were 10.29%, 19.62%, 34.08%, and 42.23% for L-NAME at 0.2 mmol/L ($P<0.05$), 0.4, 0.8, and 1.0 mmol/L ($P<0.01$), respectively. In addition, L-NAME could markedly inhibit SL-174T cells migration, and the inhibition rates were 20.76%, 24.95%, 39.43%, and 46.85% for L-NAME at 0.2, 0.4, 0.8, and 1.0 mmol/L ($P<0.01$), respectively (Figures 1 and 2A-D).

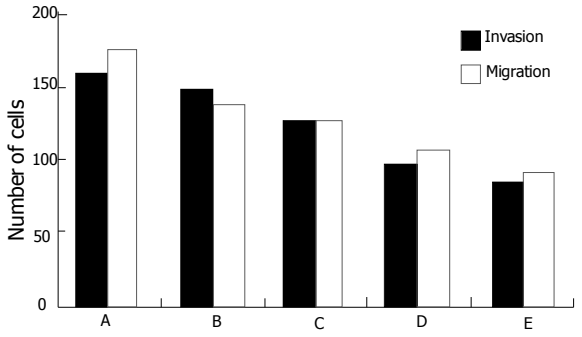

Figure 1 SL-174T treated with different concentrations of L-NAME. **A:** Control; **B:** 0.2 mmol/L; **C:** 0.4 mmol/L; **D:** 0.8 mmol/L; **E:** 1.0 mmol/L. Data are represented as mean±SD of triplicate determinations.

Expression of MMP-2 mRNA and TIMP-2 mRNA

After the treatment with L-NAME for 72 h, expression of MMP-2 mRNA and TIMP-2 in SL-174T cells is shown in Figures 3A and B. The expression of MMP-2 mRNA was significantly decreased in the treatment groups as compared to the control ($P<0.05$). On the contrary, the expression of TIMP-2 mRNA was significantly higher in the treatment groups as compared to the control ($P<0.05$).

DISCUSSION

NO has dual action on tumor growth that may be dependent on local concentrations, type of tumor, and susceptibility of tumor cells to NO. Over production of endogenous

NO would cause tumor toxicity, induce cell apoptosis, and prevent tumor angiogenesis. NO level produced in tumor microenvironment usually was up to two orders of magnitude lower than that associated with NO-dependent tumor apoptosis. Endogenous NO produced by blood vessel endothelial cells and tumor cells plays an important role in supplying tumor blood and maintaining tumor growth, also in dilating blood vessel and increasing angiogenesis[4,5]. NO can dilate arteriola, decrease leukocyte-endothelial interactions, and enhance vascular permeability in solid tumor. Much scientific research has focused on the role of NO in tumor progression; although two apparently conflicting views exist, overall an overwhelming amount of clinical and experimental evidence supports a positive association between NO production and tumor progression. The level of NOS protein and/or activity in the tumor has been shown to be positively correlated with the degree of malignancy for tumors of the human reproductive tract[6], breast[7,8], central nervous system[5], lung cancer[10], and prostate carcinomas[11]. Several studies have shown an increase of iNOS expression in colorectal cancer tissue when compared to normal mucosa and its extent correlates with tumor metastasis[12,13]. A specific cause-effect relationship between the upregulation of the iNOS gene and colon cancer has been recently demonstrated by Ahn and Oshima[14]. It has been demonstrated that tumors derived from human colon adenocarcinoma cells engineered to generate NO continuously (iNOS-19) are significantly more vascularized and more invasive than the wide controls.

This study clearly demonstrated that human colorectal cancer cell line SL-174T exhibited a strong ability to invade Matrigel and the NOS inhibitor L-NAME markedly decreased the invasion and migration. We explored the mediators of the NO-stimulated invasion, which lead to essential steps as migration and matrix degradation. MMPs and TIMPs have the ability to modulate the structure of the extracellular matrix (ECM), and changes of their expression level or activation of MMPs weaken the integrity of the ECM, which is a prerequisite for invasion and metastasis. Our study demonstrated that NOS inhibitor L-NAME reduced invasive and migratory capacities of cell line SL-174T by downregulation of MMP-2 mRNA and upregulation of TIMP-2 mRNA expression. Further work needs to demonstrate a corresponding shift in the activities

of the enzyme and its inhibitors at the protein level. Additional mechanisms underlying NO-mediated stimulation of cellular invasiveness may exist. For example, NO has been shown to upregulate urokinase-type plasminogen activator (uPA) in endothelial cells of post-capillary venules during NO-mediated stimulation of angiogenesis[15]. Since uPA converts plasminogen to plasmin, which can activate numerous MMPs, this may represent another pathway of NO-mediated stimulation of matrix degradation.

In conclusion, the NOS inhibitor L-NAME can reduce invasive and migratory capacities of SL-174T cell line via downregulating MMP-2 mRNA expression and upregulating TIMP-2 mRNA expression. Thus, NOS inhibitors may prove to be important components of combination therapy protocols in human tumors, including colorectal cancer.

Abstract

AIM: To insert the constructed TGF-β1 epitope gene into the el loop of C-terminus of truncated hepatitis B core antigen to increase TGF-β1 antigenicity in its prokaryotic expression system and to identify immunity of the expressed recombinant protein in order to exploit the possibility for obtaining anti- TGF-β1 vaccine.

METHODS: The TGF-β1 encoding epitope gene (the mature TGF-β1 from 78-109 amino acid residues, TGF-β_1^{32}) was amplified by polymerase chain reaction from the recombinant pGEM-7z/ TGF-β_1^{32} vector. The HBcAg gene fragments (encoding HBcAg from 1-71 and 89-144 amino acid residues) were amplified from PYTA1-HBcAg vector. The recombinant vector pGEMEX-1 was used to insert HBcAg1-71, TGF-β_1^{32} and HBcAg89-144 into restrictive endonuclease enzyme and ligated with T_4 ligase. The fusion gene fragments HBcAg1-71-TGF-β_1^{32}-HBcAg89-144 were recloned to pET28a(+) and the DNA sequence was confirmed by the dideoxy chain termination method. The recombinant vector pET28a (+)/CTC was transformed and expressed in *E. coli* BL21 (DE3) under induction of IPTG. After purification with Ni^{+2}-NTA agarose resins, the antigenicity of purified protein was detected by ELISA and Western blot and visualized under electron microscope.

RESULTS: Enzyme digestion analysis and sequencing showed that TGF-β1 epitope gene was inserted into the el loop of C-terminus of truncated hepatitis B core antigen. SDS-PAGE analysis showed that relative molecular mass (Mr) of the expressed product by pET28a (+)/CTC was Mr 24 600.The output of the target recombinant protein was approximately 34.8% of the total bacterial protein, mainly presented in the form of inclusion body. Western blotting and ELISA demonstrated that the fusion protein could combine with anti-TGF-β1 polyclonal IgG but not with anti-HBcAg. The purity of protein was about 90 % and the protein was in the form of self-assembling particles visualized under electron microscope. This fusion protein had good anti-TGF-β1 antigenicity and could be used as anti-TGF-β1 vaccine.

CONCLUSION: A recombinant prokaryotic expression system with high expression efficiency of the target TGF-β1 epitope gene was successfully established. The fusion protein is in the form of self-assembling particles and HBcAg can increase the antigenicity of TGF-β1. The expressed TGF-β1 epitope gene shows good immunogenicity and antigenicity.

INTRODUCTION

Liver fibrosis is commonly resulted from diverse liver injuries. Liver fibrosis can be reversed while liver cirrhosis is irreversible[1]. However, no efficient therapy is available at present for this disease[2]. Searching for a new therapy seems very important. Transforming growth factor (TGF-β), especially TGF-β1, plays a pivotal role in the fibrogenesis of liver fibrosis and cirrhosis. TGF-β1, a major cytokine, can regulate the production, degradation, and accumulation of ECM[3-6]. Over expression or activation of TGF-β1 for a prolonged period of time after tissue damage may induce a fibrosis proliferating response and deposition of ECM, resulting in fibrosis in vital organs[7-9]. Inhibition of TGF-β1 can prevent progression of liver fibrosis and enhance hepatocyte regeneration. Blockage of TGF-β1 may have therapeutic effects on liver fibrosis[10-14].

Anti-cytokine vaccination is a safe and effective pathway to blockage hepatic lesions as long as high antibody levels

are maintained[15]. It is difficult to induce high titer antibody since TGF-β_1 is a self-protein and B cells are immune silence. Fusion peptide epitope-encoded sequences of HBcAg can enhance TGF-β_1 immunogenicity, because HBcAg components help T-cells, and the fusion proteins retain the polymeric or the particulate nature of HBcAg[16].

In this paper, fusion protein sequences carrying the TGF-β_1 epitope inserted into the el loop of C-terminus of truncated HBcAg were expressed in *E.coli BL21*. The fusion protein can form particles. HBcAg has the potential to increase the TGF-β_1 antigenicity and immunogenicity. Our results indicate that the fusion protein can be used as an effective anti-TGF-β_1 vaccine.

MATERIALS AND METHODS

Materials

Recombinant vector pGEM-7z/TGF-β_1^{32} (TGF-β_1^{32} is the encoding gene of mature TGF-β_1 79-108 amino acid residues)[17] and vector pET28a (+) were provided by Dr Zhi-Ming Hao (Novagen). Top10 and *E.coli BL21*strains were provided by Xi'an Huaguang Biology Company. Plasmid pYTA1-HBcAg was constructed by Institute of Virology of Chinese Academy of Preventive Medicine. Rabbit anti-human TGF-β_1-IgG was purchased from Santa Cruz. Restriction endonuclease enzymes (*Eco*RI, *Hind* III, *Bam*HI, *Xho*l),TagDNA polymerase and T_4 DNA ligase were purchased from Huamei Company and TaKaLa Company. dNTP and isopropyl-β -D-thiogalactopyranoside (IPTG) were obtained from Sigma and oligonucleotide primers were obtained from Shanghai Shenggong Company.

Cloning of target genes

The encoding genes of TGF-β_1 epitope (mature TGF-β_1 amino acid residues from 79-108) and HBcAg were cloned from amino acid residues 1-71 and 89 - 144.

Oligonucleotide primers were designed to amplify the encoding genes based on GenBank TGF-β_1^{32} was cloned from the recombinant plasmid pGEM-7z/ TGF-β_1^{32} as the PCR fragment template. The primers have a Xhol site incorporated into the 5' end and a BamHI site at the 3' end and their sequences are as follows (5'-3'): CC CTC GAG TGC GTG CCG CAG GCG CTG (forward) and CC GGA TCC GCA GGA GCG CAC GAT CAT (reverse). HBcAg gene was amplified by PCR from the vector pYTA1-HBcAg as the template (constructed by Institute of Virology, Chinese Academy of Preventive Medicine).The primers of $HBcAg_{(1-71)}$ have a EcoR Ⅰ site incorporated into the 5' end and a Xhol site at the 3' end and their sequences are as follows (5'-3'): GGAATTCAT GATTACGCCAAGCTTGGCTGCAGAGTTCCATATG (forward) and CCCTCGAGTCCACCCCAGGTAGCT AGAGTC (reverse) .The primers of $HBcAg_{(89-144)}$ have a BamH Ⅰ site incorporated into the 5' end and a *Hind*Ⅲ site at the 3' end and their sequences are as follows (5'-3'): CGGATCCGGTGGAGTCAACAACACTAATATGGG C (forward) and CCAAGCTTCCGCGGAAGTGTTGA TAGGAT (reverse). Total volume per PCR was 100 mL containing 2.5 mol/L each dNTP, 250 nmol/L each of the 2 primers, 15 mol/L $MgCl_2$, 3.0U Taq-plus polymerase, 100 ng DNA template and 1×PCR buffer. The PCR consisted of 30 cycles of denaturation at 94 °C for 60 s, annealing at 52 °C for 30 s, and extension at 72 °C for 30 s. The products were visualized on 10 g/L agarose gel under UV light, pre-stained with ethidium bromide. The PCR products were digested respectively using *Eco*R/*Xho*l , *Xho*I/*Bam*HI, *Bam*H Ⅰ/*Hind*Ⅲ. After digestion with the restriction endonuclease enzymes simultaneously, the expected sizes of target amplification fragments $HBcAg_{1-71}$, TGF-β_1^{32} and $HBcAg_{89-144}$ was 268, 96 and 177 bp, respectively.

Construction of recombinant prokaryotic expression vector

The PCR products were digested respectively using *Eco*R Ⅰ/*Xho*l, *Xho*I /*Bam*HI, *Bam*H Ⅰ/*Hind*Ⅲ and ligated into the cloning vector pGEM-Teasy. The resulting fragments were cloned into the vector pGEMEX-1. The purified products were cloned into the compatible sites of the vector pGEMEX-1 (Promega, USA) using T4 DNA ligase at a molar ratio of 4:1 at 4 °C overnight. The recombinant plasmid clones pGEMEX-1/ $HBcAg_{1-71}$- TGF-β_1^{32}-$HBcAg_{89-144}$ [$HBcAg_{1-71}$-TGF-β_1^{32}-$HBcAg_{89-144}$ (CTC)] were sequenced using the dideoxy chain termination method. After digestion with the restriction endonuclease enzymes *Eco*RI and *Hind*Ⅲ simultaneously, the fusion gene fragments CTC were cloned into the compatible sites of the prokaryotic expression vector pET-28a(+), downstream of the 6-His tag to facilitate the protein purification using T4 DNA ligase at a molar ratio of 4:1 at 4 °C overnight. The recombinant vector pET28a(+)/ CTC was selected and identified by enzyme digestion and sequencing. IPTG at the dose of 1.0 mmol/L could efficiently induce pET28a/CTC in *E.coli BL21(DE3)* to express the fusion gene composed of 606 base pairs and encode objective polypeptides of 201 amino acid residues(Figure 1).

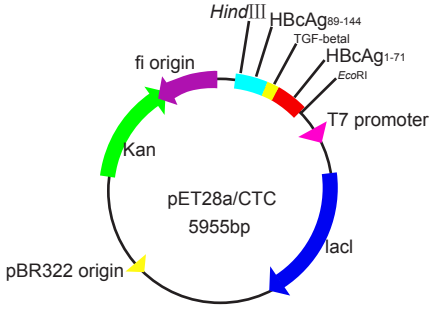

Figure 1 Schematic construction of plasmid pET28a(+)/CTC.

Extraction and expression of recombinant plasmids

The single bacterial colony (Top10/pET28a(+)/CTC) was picked and incubated in 2 mL LB containing 100 g/L of Kanamycin, at 300 r/min overnight at 37 °C, then recombinant plasmids were extracted according to the manufacturer's instructions and identified by PCR and restriction endonuclease enzyme digestion. *E.coli BL21 (DE3)* strains containing recombinant plasmids were grown until mid-log phase (optical density at 600 nm=0.5-1.0), and then induced to express recombinant fusion protein by adding 1 mmoL/L IPTG for 8 h. Bacteria were harvested by centrifugation at 12 000 *g* for 2 min, resuspended in protein-buffer and seethed for 5 min. Total protein was electrophoresed on 150 g/L SDS-PAGE gel and stained with Coomassie. The rate of recombinant fusion protein to total protein was deduced by Image Master Band Leader 3.0 software.

Purification of pET28a(+)/CTC fusion protein

Due to C end of the recombinant fusion antigen with six histidines, Ni^{2+}-NTA agarose resin was used to purify the recombinant fusion antigen. Briefly, 500 ml of cultivated bacterial suspension was prepared, centrifuged, resuspended with the buffer liquid (50 mmoL/L phosphate, 300 mmoL/L NaCl, pH 7.0), and sonicated by ultrasonic wave with the energy of 600 W for 30 min, and ultracentrifuged for 15 min at 10 000 *g* at 4°C. The sonicated recombinant fusion antigen was purified by Ni^{2+}-NTA agarose resin with abluent (50 mmoL/L phosphate, 300 mmoL/L NaCl, 20 mmoL/L imidazole, pH 7.80) and lavation (50 mmoL/L phosphate, 300 mmoL/L NaCl, 250 mmoL/L imidazole, pH 7.80) respectively, and quantified. pET28a(+)/HBc-TGF-β_1^{32} fusion protein was expressed and purified by SDS-15% PAGE. In contrast with the induced product of pET-28a(+) (negative control), a recombinant protein with expected molecular weight of 24.6X103Da was expressed in *E. coli BL21 (DE3)* as shown by SDS-PAGE.

Immunoblotting analysis of recombinant fusion protein

ELISA The expressed fusion protein was stabilized as antigen at the coated concentration (1:100, 1:200, 1:400, 1:800, 1:1600 dilution) with CBS buffer overnight at 4 °C, and blocked with 100 g/L bovine serum albumin (BSA) for 1 h at room temperature, incubated with the anti-TGF-β_1 antibody and HBc antibody as the first antibody respectively for 2 h at room temperature. After a washing, the proteins were detected by incubating in HRP-goat anti-rabbit IgG antibody(1:1000 dilution) (Zhongshan, Beijing) and anti-human IgG (Xi'an Huagguang) as the second antibody respectively for 1 h at room temperature. The first antibodies were replaced by PBS and used as negative control. The result of ELISA for the sample was considered as positive if the A value at 490 nm (A_{490}) was over the mean plus 2.1 SD of the negative samples.

Western blot

After bacteria BL21/pET-28a(+)/CTC were incubated by adding of 1 mmol./L IPTG for 8 h, 1 ml of cultivated medium was ultracentrifuged, resuspended in protein-buffer and seethed for 5 min. Total protein was electrophoresed on 150 g/L SDS-PAGE gel, and then the proteins of SDS-PAGE-separated (150 g/L acrylamide) were transferred to 0.45 mm pore size PVDF membrane. Following a 30-min washing in tris-saline blotting buffer, antigen-impregated PVDF strips were incubated with anti-TGF-β_1 antibody and anti-HBc antibody respectively for 2 h at room temperature. After a washing, the proteins were detected by incubating the strips in alkaline phosphatase-conjugated goat anti-rabbit IgG antibody and anti-human IgG respectively for 1 h at room temperature.

RESULTS

Sequence analysis of recombinant vectors nucleotide and open reading frame (ORF)

The recombinant vectors pGEMEX-1/ CTC and pET28a(+)/CTC were identified by restriction enzyme digestion in 10 g/L agarose gel electrophoresis. The recombinant vector clones were sequenced using dideoxy chain termination method. The inserted 6xHis- $HBcAg_{1-71}$-TGF-β_1^{32}-$HBcAg_{89-144}$ had the correct open reading frame in the expression vector and correctly sequenced DNA. The nucleotide sequence of the fusion genes was analyzed. Recombinant vector pET-28a(+)/CTC was digested by bi-enzyme digestion with *Hind*III,*Eco*RI, then digestive products were visualized on 10 g/L agarose gel (Figure 2). The amplified fused $HBcAg_{1-71}$-TGF-β_1^{32}-$HBcAg_{89-144}$ DNA fragments were confirmed by restriction enzyme digestion and contained the objective gene.

Analysis of recombinant fusion protein

Total protein was electrophoresed on 150 g/L SDS-PAGE gel and stained with Coomassie. Its molecular mass was Mr 24 600 as demonstrated by 150 g/L SDS-PAGE gel analysis. The fusion protein was about 34.8 % of total cellular protein. After purification by Ni^{2+}-NTA agarose

resin columniation, the purity of recombinant fusion protein was about 90% (Figure 3).

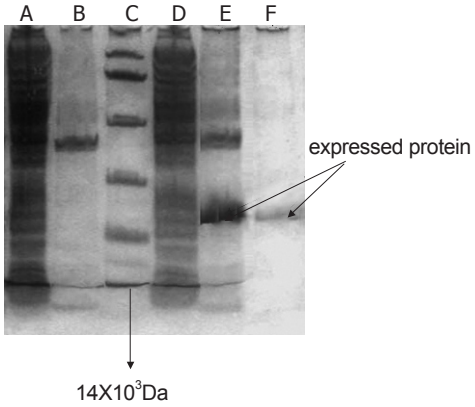

Figure 3 Expressed and purified pET28a/CTC fusion protein by 150 g.l-1 SDS –PAGE in combination with Coomassie blue staining. Lane A: Bacterial protein expressed in the supermatant fraction of pET-28a(+) vector after induction with IPTG; lane B: Bacterial protein expressed in the precipitation of lysate of fraction of pET-28a(+) vector after induction with IPTG; lane C: Standard protein low-molecular-mass marker (Mr 97.4, 66.2, 43.0, 31.0, 20.1, and 14KD); lane D: Bacterial protein expressed in the supernatant fraction of the vector pET-28a(+)/CTC after induction with IPTG; lane E: Bacterial protein expressed in the precipitation of lysate of fraction of the vector pET-28a(+)/ CTC after induction with IPTG; lane F: Purity of recombinant fusion protein.

Antigenicity of recombinant fusion protein

The antigen-impregated PVDF strips of *BL21*/pET32a(+)/CTC were recognized by anti-TGF-β_1 antibody, showing brown strips corresponding to the site of the recombinant fusion protein. They could not be recognized by HBc antibody, showing no brown strips corresponding to the site of the fusion protein (Figure 4).

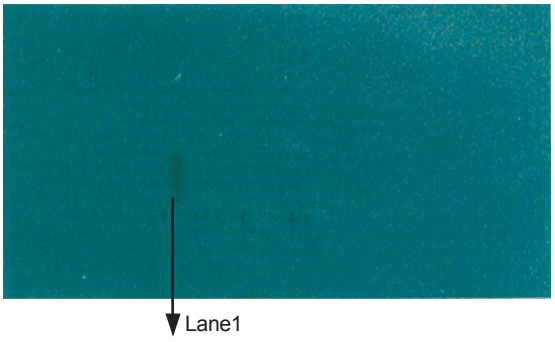

Figure 4 Antigenic analysis of the expression of recombinant vector by Western blot. Lane 1: BL21/pET28a(+)/CTC.

Antigenicity of fusion protein displayed in ELISA

Staining was positive in the fusion protein and negative in the negative controls. The expressed fusion protein did not react with anti-HBc polyAb and mAb. The expressed protein reacted with anti-TGF-β_1 antibody.

Electron microscopy

The expressed proteins by the constructs formed core particles observed under electron microscope, which were bigger than HBcAg core particles (Figure 5).

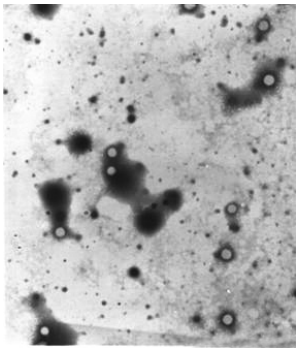

Figure 5 Electron microscopy of the core-like particles formed in fusion protein.

DISCUSSION

Anti-cytokine vaccination is a safe and effective therapy[19]. Imbalance in cytokine production or cytokine receptor expression and /or dysregulation of cytokine production provides the basis for generating pathological disorders. Cytokine production by effector cells (induced by activation but controlled by negative feedback regulation) does not accumulate in the extracellular compartment under physiologic conditions. The anti-cytokine therapeutic vaccine is to raise antibody levels over the background levels of natural antibodies while enhancing their affinity and neutralizing activity block the accumulation of overproduced cytokines, thereby inhibiting its pathogenic effects. In contrast, the neutralizing Abs do not interfere with cytokine production in normal tissues. Since it has no side effects in normal tissues, high-affinity Abs can be induced safely and effectively.

The TGF-β_1 is chosen as an antifibrosis vaccine because it is a key cytokine in hepatic fibrosis and blockade of TGF-β_1 prevents liver fibrosis. It is difficult to induce high titer antibody since TGF-β_1 is a self-protein. T cells undergo a thymic-negative clonal selection against self-cytokines though anti-cytokine B cells still exist. HBcAg is an attractive candidate for induction of cytokine foreign epitopes because the HBcAg component helps T-cells and the fusion proteins retain the polymeric or the particulate nature of HBcAg. HBcAg behaves as highly immunogenic TI and TD antigens[18,19]. In recent years epitopes of various origin have been inserted into the core antigen of hepatitis B virus (HBV) allowing formation of chimeric HBV core particles. Chimeric core particles carrying the protein can induce protective immunity.

The high immunogenicity of HBcAg depends both on its structure with repetitive spikes on the surface to induce TI responses and on the efficient presentation of HBcAg by B cells to induce TD responses[20]. Fusion

of peptide epitope sequences to HBcAg can enhance their immunogenicity. Virus-like particles generated by the heterologous expression of virus structural proteins are able to potentiate the immunogenicity of foreign epitopes presented on their surface. Several foreign epitopes from hepatitis B virus, Papillomavirus, Plasmodium falciparum and hantavirus[21-24] have been introduced successfully into HBcAg capsids, and immunogenicity of the new epitopes has been demonstrated.

Foreign epitope sequence of varying length was inserted into HBcAg in various protein regions, including the N-,C-termini and some internal sites including immunodominant el loop without loss of the self-assembly properties of HBcAg[25].It has been demonstrated that the loop in the main determinant of the core antigen is the most promising insertion site from the immunological point of view. Epitopes inserted there possess higher antigenicity and immunogenicity than anywhere. But not all chimeric proteins are able to be particulated. The ability of chimeric HBcAg to self-assemble is most likely to depend on the physical and chemical properties of the amino acid residues forming the inserted foreign peptide.

The fusion of sequences carryies the epitope of the TGF- β_1 (mature encode zone amino acids 78-109)[26] to the el loop of C-terminus of truncated HBcAg, produced in *E. coli. BL21 (DE3)*. The expressed fusion protein is in the form of self-assembling particles observed under electron microscope. The results demonstrate that recombinant fusion protein has a good anti-TGF- β_1 antigenicity. Mr 24 600 recombinant fusion protein has HBcAg characteristics and possesses TGF- β_1 antigen specialty. The fusion proteins carrying the TGF- β_1 antigen-dominant fragment induce antibodies that react effectively with native TGF- β_1, suggesting that the recombinant fusion protein can be used as a true vaccine candidate. In the present study, recombinant plasmid was constructed and expressed in *BL21(DE3)* to explore the possibility for obtaining a vaccine conferring protection against liver fibrosis. We are going to use it in the hepatic fibrosis model as an anti-fibrosis vaccine. Further study is needed to detect its anti-fibrosis effect as a therapeutic vaccine.

Abstract

AIM: To investigate the treatment efficacy of radiofrequency ablation (RFA) of hepatic malignant tumor and the relevant complications.

METHODS: A total of 338 patients with 763 hepatic tumors underwent ultrasound-guided RFA (565 procedures). There were 204 cases of hepatic cellular carcinoma (HCC) with 430 tumors, the mean largest diameter was 4.0 cm. Of them, 48 patients (23.5%) were in stages I-II (UICC Systems) and 156 (76.5%) in stages III-IV There were 134 cases of metastatic liver carcinoma (MLC), with 333 metastases in the liver, the mean diameter was 4.1 cm, the liver metastases of 96 patients (71.6%) came from gastrointestinal tract. Ninety-three percent of the 338 patients were treated using the relatively standard protocol. Crucial attention must be paid to monitor the abnormal changes in ultrasound images as well as the vital signs of the patients to find the possible hemorrhage and peripheral structures injury in time. The tumors were considered as ablated completely, if no viability was found on enhanced CT within 24 h or at 1 mo after RFA. These patients were followed up for 3-57 mo.

RESULTS: The ablation success rate was 93.3% (401/430 tumors) for HCC and was 96.7% (322/333 tumors) for MLC. The local recurrence rate for HCC and MLC was 7.9% (34/430 tumors) and 10.5% (35/333 tumors), respectively. A total of 137 patients (40.5%) underwent 2-11 times of repeated ablations because of tumor recurrence or metastasis. The 1st, 2nd, and 3rd year survival rate was 84.6%, 66.6%, and 63.1%, respectively; the survival rate from 48 patients of I-II stage HCC was 93.7%, 80.4%, and 80.4%, respectively. The major complication rate in this study was 2.5% (14 of 565 procedures), which consisted of 5 hemorrhages, 1 colon perforation, 5 injuries of adjacent structures, 2 bile leakages, and 1 skin burn.

CONCLUSION: RFA, as a minimally invasive local treatment, has become an effective and relatively safe alternative for the patients of hepatic malignant tumor, even of advanced liver tumor, tumor recurrence, and liver metastases. Knowledge about possible complications and their control may increase the treatment efficacy and help to promote the use of RFA technique.

INTRODUCTION

The treatment efficacy of radiofrequency ablation (RFA) of liver tumors has been confirmed by sufficient quantity of clinical results[1-4]. With the improvement in both equipments and treatment skills, RFA has gradually been developed in China to treat large tumors[5,6], and provided an efficient alternative for the tumors which were difficult to manage with conventional treatments. With the wide adoption of the RFA technique, the complications increased accordingly, which drew a very important clinical attention. Large tumor and advanced tumor were commonly seen in China. Taking into consideration the characteristics of the tumors of our contrary study, this research aimed to summarize the treatment efficacy of RFA in 338 malignant liver tumors and explore the effective measures for complications.

MATERIALS AND METHODS

Patients

From 1999 to 2004, 338 patients with 763 hepatic tumors underwent 565 US-guided percutaneous RFA. All patients were diagnosed by biopsy at least on one lesion. Two hundred and forty-four patients were men (mean age, 59.1 years; age range, 24-87 years) and 94 were women (mean age, 58.6 years; age range, 32-86 years). Two hundred and four were hepatic cellular carcinoma (HCC) patients (430 tumors), with mean diameter of 4.0 cm (range, 1.2-10.8 cm). Of these 204 HCC patients, 96, 95, and 13 had Child-Pugh class A, B, and C cirrhosis, respectively. According to the UICC-TNM staging system, 48 patients (23.5%) were

in stages I-II, 156 were in stages III-IV. In the 204 HCC patients, 29 were given palliative treatment because of large size, unclear tumor border, invasion to the surrounding anatomical structure or multi-tumor occurrence. One hundred and thirty-four patients (333 tumors) had metastatic liver carcinomas (MLCs) with mean diameter of 4.1 cm (range, 1.0-10.0 cm). The primary tumors were from gastric and colorectal tract (n = 96, 71.6%), breast cancer (n = 16), lung cancer (n = 10), pancreatic cancer (n = 5), other organs (n = 7), respectively. Nine of them were given palliative treatment because of large size or multi-tumors. Eleven patients were found to have extrahepatic metastases when the first RFA was performed. The tumors larger than 3.5 cm, accounted for 61.8% (209/338 patients) in this study. There were 51 patients (15.1%) with 54 tumors adjacent to the gastrointestinal tract and 46 patients (13.9%) with 51 tumors adjacent to the gallbladder in this group.

Equipment

The RF system used in this study was a 460-kHz generator (Model 1500; RITA Medical System, Mountain View, CA, USA) that is capable of delivering a maximum power of 150 W through a 14-G electrode. The electrode contained nine hook-shaped prongs that could be deployed from the cannula, when the cannula was inserted into the surface of the tumor. The high-frequency electric current was passed through the deployed prongs to the tumor tissue, causing the vibration and friction of ions in the tissue, resulting in the temperatures of up to 100 ℃, which produced a sphere-like coagulation area of 2.0-5.0 cm in diameter. The time to produce a 5-cm ablation sphere was about 20 min. If multiple-overlapping ablations were required to ablate large tumors, much more time was needed.

Methods

Ninety-three percent of the patients were treated using the established protocol. The ablation area should cover the tumor and at least 0.5-1.0 cm of the surrounding tissue, and the margin should even be more than 1 cm when the tumor border was unclear. The treatment protocol was decided according to the ablation range. The ablation number and relevant placement mode should be decided, if the ablation range was greater than 4.5 cm in diameter[6]. For example, a regular tetrahedron overlapping mode with 4 ablations should be used, if the ablation range was 5.1-5.3 cm; the regular three- to six-sided prism overlapping mode with 5-8 ablations should be adopted, if the ablation range was 5.4-6.6 cm; the three segment overlapping ablation mode with 12 ablations was needed, if the ablation range was 6.7-7.5 cm. Furthermore, the sequence of the ablations and the skill of electrode placement were also crucial[7].

During the ablation process, real-time ultrasound scan was performed to monitor the electrode placement and the ablation, and post-ablation ultrasound was performed to find the potential complications so that the corresponding measures could be carried out in time[8].

Anesthesia

All patients underwent percutaneous RFA under general anesthesia or conscious sedation. Conscious sedation was induced with intravenous administration of 2.5-5.0 mg of midazolam (Roche; Basel, Switzerland) and 50-100 μg of fentanyl (Fentaini; Renfu, Yichang, China). Local infiltration anesthesia was induced by 5-15 mL of 1% lidocaine (Liduokayin; Yimin, Beijing, China). When tumors were adjacent to the diaphragm or the liver surface, an intravenous bolus of propofol (Diprivan; Zeneca, Macclesfield, UK, 1-2 mg/kg) and fentanyl (50-100 μg) was given to enhance anesthesia in combination with local anesthesia.

Assessment of therapeutic efficacy

For irregular tumors larger than 5 cm and near the gastrointestinal tract, enhanced CT within 24 h after the treatment was used to detect any residual viable tissue that would require a second RFA and to observe possible complications. To evaluate the tumor response to RFA therapy, contrast-enhanced CT was performed 1 mo post-ablation and the complete ablation of the tumor was considered to be achieved if the scans revealed: (1) the ablation zone was beyond the tumor borders, (2) the margin of the ablation zone was clear and smooth, and (3) no contrast enhancement was detected within or around the tumor. Subsequently, the patients were monitored regularly for intrahepatic recurrence in the outpatient clinic by a follow-up protocol including serum α-fetoprotein (AFP), abdominal US and enhanced CT every 2-3 mo for the first year, and then AFP every 2-3 mo, abdominal US and enhanced CT every 4-6 mo after the first year. Suspected intrahepatic recurrence was confirmed by percutaneous fine needle biopsy. Local recurrence was defined as tumor recurrence within or at the periphery of the ablated lesion in the follow-up CT scan. Distant intrahepatic recurrence referred to a new tumor that appeared in the liver separated from the ablated area. Patients were followed-up for 3-57 mo, follow-up rate was 91.4% (309 patients).

Statistical analysis

Cumulative survival rate of each group was calculated using the Kaplan-Meier method and compared by log-rank test. The level of significance was set at 0.05 for all tests. SPSS statistical analysis software (SPSS, Chicago, IL, USA) was used.

RESULTS

Therapeutic efficacy

The ablation success rate after the first RFA based on the CT findings were: HCC 93.3% (401/430 tumors), MLC 96.7% (322/333 tumors), the results are detailed in Table 1.

11.2% (38/338 cases) of the patients in this study had tumor residue, of which 31 cases (81.6%) were those with tumors larger than 3.5 cm; success rate for patients with tumors larger than 3.5 cm was 85.2% (178/209 cases, Figure 1). For tumor adjacent to bowel or gallbladder, the ablation success rates were 83.3% (45/54 tumors) and 86.3% (44/51 tumors), respectively. Local tumor recurrence was found in 34 of HCC patients (7.9%), 35 of MLC patients (10.5%), respectively, after the follow-up of 3-57 mo. 40.5% of patients received additional 2-11 RFA treatments because of the metastases or recurrence. The overall survival

Table 1 Therapeutic results of 338 patients after radio-frequency ablation

Tumor type	No. of patients	No. of tumors	Tumor size[1] (cm)	No. of tumors completely ablated[2] (%)	No. of local recurrence (%)
HCC	204	430	4.0 (1.2-10.8)	401 (93.3)	34 (7.9)
MLC	134	333	4.1 (1.0-10)	322 (96.7)	35 (10.5)
Total	338	763	4.1 (1.0-10.8)	723 (94.8)	69 (9.0)

[1]The largest average diameter of the tumors. [2]The ablation was considered a success, if the 1 mo CT scan showed no contrast enhancement detected within or around the tumor.

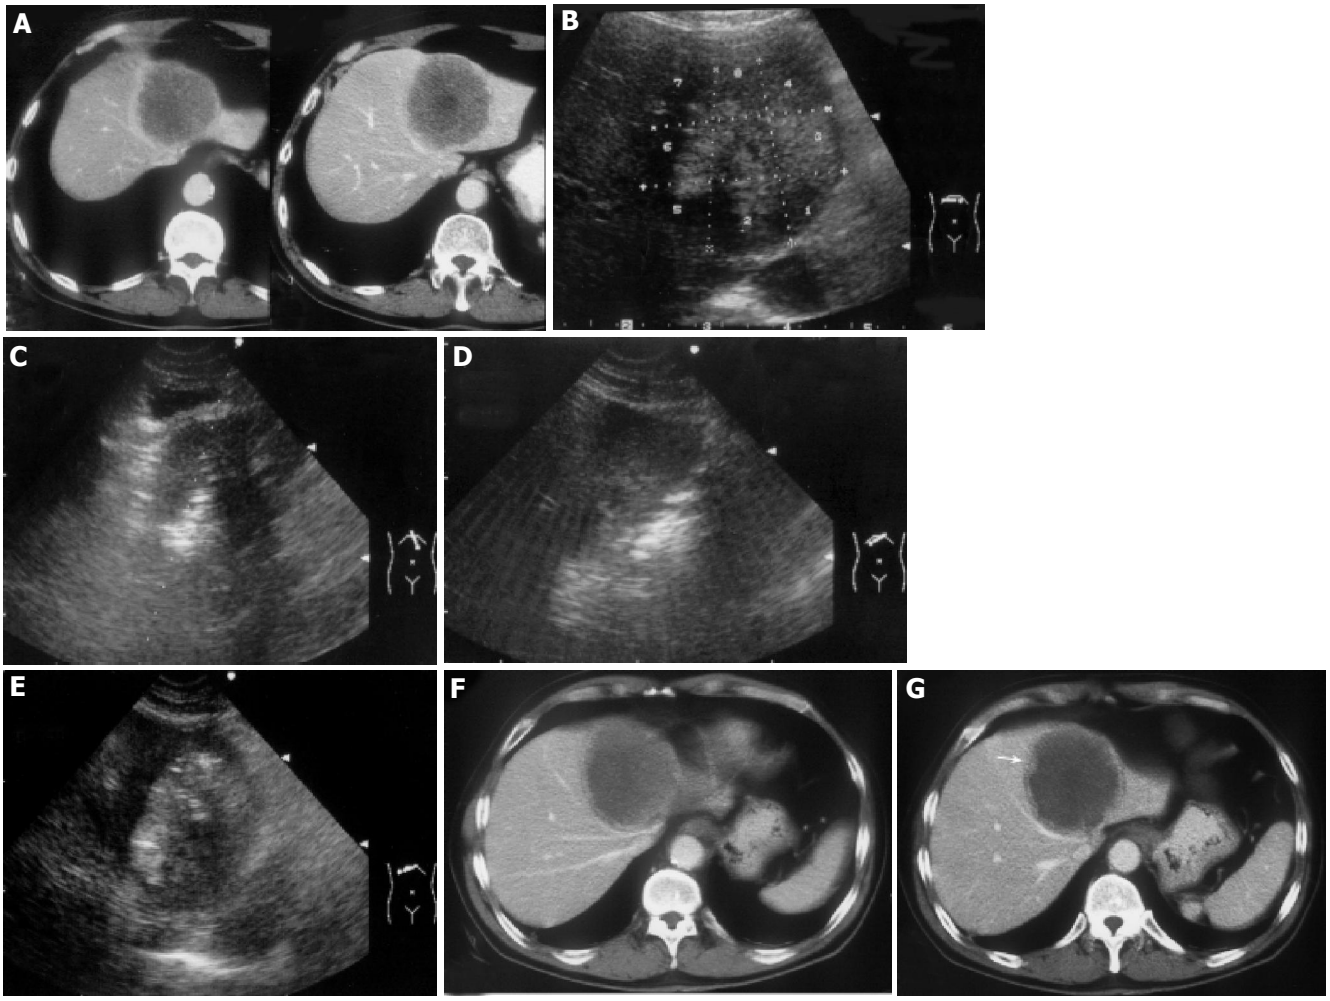

Figure 1 A 55-year-old man developed liver metastasis from colon cancer. **A:** Enhanced transverse CT scans obtained before treatment showed a spherical tumor invading into the diaphragm; **B:** The ablation protocol was designed and eight target sites were determined in this section. The tumor area near the heart and stomach were ablated first. **C:** The fourth ablation was conducted; **D:** The fifth ablation was conducted; **E:** The ablation was finished and the tumor area was presented as hyperechoic; **F:** Enhanced transverse CT scans obtained 1 d after the treatment showed that most of the tumor was coagulated and necrosis; **G:** Enhanced transverse CT scans obtained 1 d after the treatment showed slight enhancement (↑) on the lower margin of the tumor. The patient received the second treatment and achieved complete ablation.

rate of 300 patients with malignant liver tumor after RFA is shown in Table 2.

The overall survival rate was higher in HCC group than in MLC group (P<0.001), so was the survival rate in HCC group of stages III-IV than in MLC group (P<0.05); and the survival rate in HCC group of stages I-II than in HCC group of stages III-IV (P<0.001).

Complications

The occurrence rate of major complications was 2.5% (14/565 RFA procedures), including hemorrhage (n = 5, Figure 2), bile leakage (n = 2), colon perforation (n = 1), stricture of bile duct (n = 2), cholecystitis (n = 1), hemothorax (n = 2), skin burn (n = 1), minor complications consisted of bellyache, shoulder pain, breath-related right-superior bellyache, fever after RFA, transient hepatic dysfunction, etc.

DISCUSSION

All the therapeutic alternatives commonly used to treat HCC or MLC have limitations. In the recent decade, US-guided percutaneous ethanol injection (PEI) as a local therapy for

Table 2 The comparison of survival rates of 300 patients with malignant liver tumor after RFA

Tumor type	Survival rate		
	1 yr	2 yr	3 yr
MLC (n = 125)	75.3	50.2	25.1
HCC (n = 175)[b]	84.6	66.6	63.1
Stages I–II (n = 48)[b,d]	93.7	80.4	80.4
Stages III–IV (n = 127)[a]	81.3	61.7	57.2
Total (n = 300)	80.6	60.1	50.4

[a]P<0.05, [b]P<0.01 *vs* MLC; [d]P<0.01 *vs* HCC of stages III–IV , P<0.01.

hepatic tumors has gradually been replaced by intraoperative or percutaneous RFA[2,9,10], which was considered by many as superior to other existing locoregional therapies such as PEI, TACE, and microwave ablation[9,11,12]. However, the efficacy of RFA was reduced by its high recurrence rate and relevant complications, especially in the treatment of large tumors or special location tumors. Livraghi *et al*.[13], reported complications of RFA in 2 320 patients with focal liver cancer treated by a collaborative group in Italy, and demonstrated that bleeding and gastrointestinal perforation were the most common major complications which might lead to death. Thus, studies on the treatment protocol of RFA to increase its efficacy and the preventive measures of the relevant complications have become a major issue.

RFA skills

Generally, a single ablation of 5 cm in diameter could successfully destroy a liver tumor smaller than 3.5 cm plus the "safety margin" of 0.5-1.0 cm. Patients with tumors larger than 3.5 cm accounted for 61.8% (207/335 cases) of the whole population in this study. With the help of the correct electrode placement, the operation skills and the established protocol, we got a response rate of 85.2% (178/209 cases), indicating that the protocol could be used to guide the RFA of large liver tumors[7]. However, this mathematic protocol was not always easy to perform in practice because of some factors, such as deviation of needle placement or failure of full deployment of prongs, due to rigid texture of the tumor or hepatic parenchyma, limitation of puncture angle, or insufficient safe margin due to being adjacent to major structures. For treating tumors with undesirable locations such as being adjacent to diaphragm, gallbladder, and gastrointestinal tract, etc. an individualized protocol was required. Some adjunctive measures or combination treatment of multiple modalities were also adopted to deal with particular features of the tumors[7,14].

Regarding the tumors being adjacent to diaphragm, gallbladder, gastrointestinal tract, the puncture direction of the electrode should be vertical to the organs and the cannular should be lifted a little, while the prongs had been deployed, besides multiple-overlapping ablations of 2-3 cm should be performed to ablate the risky area of tumor. If necessary, enhanced CT was performed within 24 h to detect residual tumor and decided if additional ablations were required. For the tumors adjacent to the colon, most part of the tumor which was near to the center of the liver should be ablated first, stage II resection should be adopted 2-4 wk later. Combination treatments including the TACE or obstruction of the liver arteries prior RFA should be adopted, if the tumor had abound blood supply; anyway, combination treatments were very important to improve the therapeutic efficacy[15].

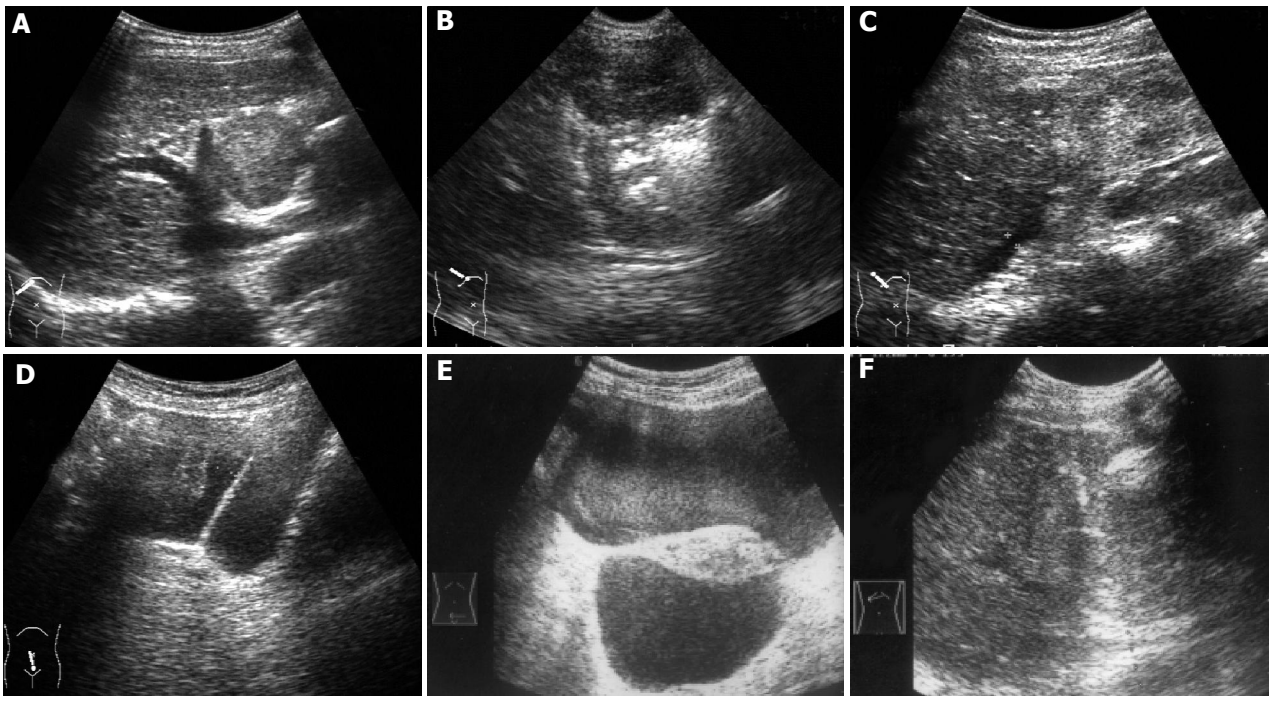

Figure 2 A 72-year-old woman developed intrahepatic recurrence 2 years after hepatic resection for HCC. **A:** US scan before treatment showed a large tumor protruding from the liver surface; **B:** US guided ablation was conducted; **C:** US scan immediately obtained after treatment showed little fluid under the liver. **D:** Five minutes later, US scan showed accumulative fluid in pelvic cavity; **E:** Nine hours later, US scan showed a great deal of hemorrhage in pelvic cavity. **F:** Ten hours later, US guided ablation of bleeding site was performed.

Analysis of therapeutic efficacy

There are many factors that can affect the therapeutic efficacy of RFA. The most important factor is the size of the tumor. Sufficient data confirmed that RFA could successfully ablate the small liver tumors. The ablation success rate of the initial RFA in this study was 94.8% (723/763 tumors). Of the 40 incompletely ablated tumors, 33 (82.5%) were larger than 3.5 cm. The ablation success rate of RFA on MLC patients reached 96.7% (322/333 tumors). It was considered that the MLC tumor was more sensitive to heat energy due to less blood supply[16]. Furthermore, in our study, most MLCs were treated with extended ablation margin as there were enough liver function reserve and surrounding liver tissue, thus contributing to a satisfactory short-term outcome of MLC in this study. In this study, six patients were found to have 1-3 MLC as well as primary stomach or colon cancer. The primary cancer had been successfully resected before RFA. Therefore, as an adjuvant therapy to the surgical resection, RFA could increase the opportunity of surgical resection of those patients with advanced liver tumor. Although additional RFA had been performed due to the new metastases in the liver after RFA, four of six patients had survived beyond 2-3 years. Although most of the HCC patients in our study were in stages III-IV, the 1-, 2- and 3- year survival rates after RFA was 84.6%, 66.6%, 63.1%, respectively, and 93.7%, 80.4%, 80.4% for HCC patients of stages I-II. These results indicated that RFA could have a similar efficacy compared with surgery resection as long as the tumors were completely ablated. However, the long-term efficacy of MLC post RFA was no good, the survival rate of 2nd, 3rd year was lower than that of HCC. Solbiati *et al*.[3], reported that the average survival of MLC patients after RFA was 35.4 mo, which was higher than that of ours. It might be explained by the reason that most MLC patients in our study had large sized tumor, multi-tumor or extrahepatic metastases.

Another major factor to affect the efficacy was the undesirable location of the tumor, such as being adjacent to hepatic hilum, diaphragm, gastrointestinal tract or invasion to large vessels, or intruding outward from the liver surface, and RFA on those tumors may more likely induce tumor residue or complications.

The management of complications

More complications about RFA have been reported as more patients have been treated, despite that RFA is a minimally invasive technique[13,17]. The major complication rate in this study was 2.5% (14/565 procedures), which consisted of mechanical and thermal injuries. It is very important to find the auspice symptoms in time and adopt appropriate management.

Two of the five cases of hemorrhage occurred during the RFA treatment. One was due to liver capsule laceration when the electrode was deployed to treat a 1-cm metastatic liver tumor near the liver surface but unfortunately was pushed deep forward, and the anechoic area of hemorrhage in front of the liver enlarged to 1-3 cm in thickness in 2 min. The other case with metastatic tumor from rectum cancer was the result of stabbing subcapsular arterial-venous shunt by the RFA electrode and the anechoic area of hemorrhage increased to 2.5 cm in thickness. The above two cases of hemorrhage were stopped by using RFA at the bleeding sites without moving and the tumors were ablated successfully at the same time. The other three cases of hemorrhage were all HCC with liver cirrhosis. One hemorrhage occurred in a small HCC patient and was controlled by ablating the bleeding site. The other two occurred in patients with large liver tumors located near the liver surface and deteriorated coagulation functions. The hemorrhage was caused by the increased abdominal pressure due to cough or sudden position change at half or 4 h after the RFA treatment. The bleeding was controlled by hemostatics intravenously and local oppression and in one case whose bleeding amount was large that the patient even received blood transfusion of 800 mL.

Colon perforation occurred in one case in our early practice. The patient with HCC located in segment VI received two sessions of RFA procedure and a new 4-cm tumor near the colon hepatic flexure was found 1 year later. Contrast enhanced US demonstrated rich blood flow within the tumor, which was adhered to the colon. Overlooking this phenomenon, the tumor was ablated aggressively. Colon perforation occurred 1 wk later and the patient underwent surgical operation. In retrospect, we reckoned that the perforation might have been avoided if an individualized treatment protocol had been adopted with greater care as follows: (A) the patients were placed in the right anterior oblique position, so that the transverse colon and intestines would migrate to the left, away from the liver. (B) During the ablation, the patients were instructed to make repeated abdominal breaths to keep the bowels moving and to avoid continual hyperthermia in the bowel wall. (C) After the ablation, the patient needs to fast for 24 h and then has semi-fluid diets for 2 d. If the patient complains about right upper abdominal pain or has thickened bowel wall demonstrated by US or CT examination 24-48 h after the treatment, ask the patient to fast longer and receive infusion and other conservative treatment. In our later series of 51 patients with liver tumors near the bowels and 3 mo later, 8 (15.7%) patients demonstrated bowel adhesion but no colon perforation occurred.

Other adjacent structure injury occurred in eight cases. One patient with gallbladder stone developed cholecystitis and recovered after antibiotic administration. For tumors near the gallbladder, RFA might lead to a series of syndromes caused by parasympathetic stimulation with decreased heart rate and pain in stomach or pericardial area. Of the 46 cases with tumors near the gallbladder, 38 (82.6%) complained of pain in stomach and pericardial area, 17 (36.9%) had decreased heart rate with the lowest being 27 per min. Enhancing anesthesia and injecting of atropine of 0.25-1.0 mg could control these disorders. Two patients with slightly dilated bile duct due to tumor invasion had jaundice and obviously dilated bile duct after the RFA. Both recovered after percutaneous transhepatic biliary drainage.

Diaphragm injury occurred in two cases. One with bloody pleural infusion was given hemostatics and drainage of pleural cavity. The other with large amount of pleural effusion and thickened diaphragm recovered after draining out pink effusion fluid.

Two cases of biliary leakage occurred in patients with metastatic tumors from pancreatic cancer within 1 wk after RFA. The tumors were located near the liver surface with the size of 3.5 and 4.5 cm. One of them recovered after 2-3 mo of percutaneous drainage but the other did not till death.

Skin burn occurred in one case. The patient had large scars in the abdominal wall due to previous operation for purulent cholecystitis. It was difficult to avoid the scar area when we inserted the RFA electrode to treat a 5-cm tumor in segment IV. The outer insulate coat of the electrode melted during the RFA and led to skin burn of the scarred area. Thus it was essential to avoid the scar while inserting the electrode.

Besides these major complications, other patients complained about some mild complications, such as fever and bellyache. The temperature could reach about 37.8-38.5 ℃, and lasted about several days to two weeks. If the temperature was too high or lasted too long, a blood test should be taken in time and relevant treatments should be adopted. The anesthetic drugs used during the RFA process could cause vomiting and nausea. The symptoms of bellyache post-RFA could be relieved within 3-7 d without any drugs; however, little acesodyne was occasionally needed. But if the tumor was close to the diaphragm, the RFA could induce an ache on the right shoulder; besides, if the intercostals nerve, peritoneum, or abdominal wall were injured, a transient breath-related pain could happen, and sometimes acesodyne was needed.

Some patients experienced transient liver dysfunction 2 wk post RFA; Western or Chinese medicines to protect liver function should be adopted to facilitate the general health and liver function.

Advantages and problems in the RFA of liver tumors

It was easy and feasible to perform RFA on liver tumors. Most RFA could be administered with local anesthesia and acesodynes on outpatient, and the rest of the patients could be discharged after 1-2 d of observation. The RITA electrode in our practice was satisfying, and the information about temperatures at the needle tip helped to control the RFA area. Another advantage was RFA could be performed repeatedly on the condition of subsequent metastases or tumor recurrence. The quality of patient life and the immune status was good after RFA treatment. One patient's with HCC was repeatedly treated 11 times and 21 tumors in total were ablated successfully, the patient has survived for more than 4 years. Another patient with liver metastases from stomach sarcoma was treated seven times and 11 metastases in total were treated, the patient has survived for 27 mo. The obvious advantage was that the whole cost of RFA was less expensive than other treatment options; RFA was minimally invasive and relatively safe, most patients experienced body weight increase, improvement of appetite and general health without serious liver dysfunction after RFA. There were seven cases who had mild to severe ascites before RFA, the ascites of two patients disappeared and that of three decreased significantly after RFA, further supporting the advantages of RFA in its minimal invasiveness and good efficacy.

Most of the liver tumor patients in China were at the very late stages when they were diagnosed, and large tumors were commonly seen. In order to develop the RFA technique effectively, we should pay enough attention to the standard protocol and the operation skill. Combination treatments may help to improve the therapeutic efficacy, including hepatic artery embolization or infusion before RFA, combined resection and RFA[15,18] and subsequent stage II surgical resection after RFA. These options will no doubt improve the therapeutic level of liver tumors.

RFA, as a minimally invasive local treatment of liver tumors, was an effective and relatively safe alternative for the advanced liver tumor patients, tumor recurrence, liver metastases which were unresectable or difficult to treat with traditional therapies. The complications usually occurred during or shortly after RFA, so we should follow them up closely to find the possible hemorrhage or periphery structures injury in time; as long as the precautious measures are taken and effective managements are carried out, the serious complication rate would be reduced to the least, so that the final goal of improvement of general health and long-term survival time could be reached.

38	Ten mL	Ten milliliters	At the beginning of a sentence
39	umol	μmol	
40	30 sec	30 s	
41	1 g/dl	10 g/L	10-fold conversion
42	OD_{260}	A_{260}	"OD" has been abandoned.
43	One g/L	One microgram per liter	At the beginning of a sentence
44	*A*260 nm	A_{260}nm	*A* should be in italic.
	$^bP<0.05$	$^aP<0.05$	In Table, no note is needed if there is no significance in statistics: $^aP<0.05$, $^bP<0.01$ (no note if $P>0.05$). If there is a second set of *P* value in the same table, $^cP<0.05$ and $^dP<0.01$ are used for a third set: $^eP<0.05$, $^fP<0.01$.
45	**F*=9.87, §*F*=25.9, #*F*=67.4	^1F=9.87,^2F=25.9, ^3F=67.4	Notices in or under a table
46	KM	km	kilometer
47	CM	cm	centimeter
48	MM	mm	millimeter
49	Kg, KG	kg	kilogram
50	Gm, gr	g	gram
51	nt	N	newton
52	l	L	liter
53	db	dB	decibel
54	rpm	r/min	rotation per minute
55	bq	Bq	becquerel, a unit symbol
56	amp	A	ampere
57	coul	C	coulomb
58	HZ	Hz	
59	w	W	watt
60	KPa	kPa	kilo-pascal
61	p	Pa	pascal
62	ev	EV	volt (electronic unit)
63	Jonle	J	joule
64	J/mmol	kJ/mol	kilojoule per mole
65	10×10×10cm^3	10 cm×10 cm×10 cm	
66	N·km	KN·m	moment
67	$\bar{x}\pm s$	mean±SD	In figures, tables or text narration
68	Mean±SEM	mean±SE	In figures, tables or text narration
69	*im*	im	intramuscular injection
70	*iv*	iv	intravenous injection
71	Wang et al	Wang *et al.*	
72	EcoRI	*Eco*RI	*Eco* in italic and RI in positive. Restriction endonuclease has its prescript form of writing.
73	Ecoli	*E.coli*	Bacteria and other biologic terms have their specific expression.
74	Hp	*H pylori*	
75	Iga	*Iga*	writing form of genes
76	*igA*	IgA	writing form of proteins
77	-70 kDa	~70 ku
