Cardiomyocytes and its purity were monitored by staining with antibody to cardiac α-sarcomeric actin according to the manufacturer's instructions (Boster). Briefly, myocytes were plated on plastic four-chamber culture slides at 1.0×10^5 cells/cm^2. The cells were fixed with 50% methanol and 50% acetone at 20 ℃ and then incubated with antigen-specific primary antibody (mouse multiclonal anti-α-sarcomeric-actin antibody diluted at 1:150). After a brief wash, the myocytes were incubated with biotinylated secondary antibody (goat anti-mouse IgM, μ-chain specific). At the addition of an extravidin peroxidase reagent, a stable avidin-biotin complex was formed with the bound biotinylated antibody. The sites of antibody deposition were visualized by the addition of freshly prepared substrate containing H_2O_2 and chromogen 3-amino-9-ethyl-carbazole. Nuclei were stained with Mayer's hematoxylin. Myocytes were visualized under a reverse microscope (Olympus).

Cytotoxicity of H_2O_2

The cytotoxicity of H_2O_2 was determined by observing cellular morphology, measuring cellular apoptosis and examining the cell viability. Observing the change of cellular morphology is a traditional method to determine the cellular injury. We observed the change of cellular morphology by reverse microscopy, when cardiomyocytes were exposed to different concentrations of H_2O_2. Cardiomyocytes were plated on six-well microplates at the density of 1×10^5 cells/well containing 1 000 μL FBS-DMEM, and cultured in a water-saturated atmosphere of 50 mL/L CO_2-95% air box for 48 h. The myocardium was treated with 0.625, 1.25, 2.5, 5, 10 mmol/L H_2O_2. A photo was taken to record the change of cardiomyocyte morphology after 3 h. The media were removed, the cells were collected and cell genome DNA were extracted, the change of genome DNA was analyzed and the process of cellular apoptosis was evaluated by electrophoresis on 1% agarose gels.

Cell viability was determined by short-term microculture MTT assay. On 96-well microplates, cardiac myocytes were plated at the density of 3×10^4 cells/well containing 150 μL FBS-DMEM. After being cultured for 48 h, the cells were exposed to different concentrations (0.075, 0.15, 0.3, 0.6 mmol/L) of H_2O_2 for 3 h, and then the media were replaced by 100 μL of DMEM and 20 μL of MTT solution (5 mg/mL). The cells were incubated for another 4 h. After being incubated for 4 h, the media and MTT solution were removed. The remaining formazan blue crystals were dissolved by MDSO. Absorbance at 570 nm was measured by Thermo Lab Systems (Multiskan MK3).

Cardioprotection of nm-haFGF

The cardio-protective effect of nm-haFGF was evaluated on the basis of its anti-oxidic effect of nm-haFGF including measuring the total activity of SOD, monitoring the injury of cells membrane, examining cell viability as well as monitoring cell apoptosis by terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL).

SOD and MDA were measured by respective assay kit (Jiancheng Bioengineering Co.). Cardiomyocytes were plated on 96-well microplates at the density of 3×10^4 cells/well

containing 100 μL FBS-DMEM, and cultured in a water-saturated atmosphere of 50 mL/L CO_2-95% air box for 48 h. The FBS-DMEM media were replaced by free-serum DMEM containing different concentrations of nm-haFGF (10, 20, 40, 80 ng/mL), and incubated in a water-saturated atmosphere of 50 mL/L CO_2-95% air for 24 h, then the cardiomyocytes were treated with 0.15 mmol/L H_2O_2. The leakage of MDA and the activity of SOD were measured after exposure to H_2O_2 for 3 h, and the cell viability of cardiomyocytes was measured by MTT.

TUNEL assay was performed. After being treated with nm-haFGF and H_2O_2, cardiomyocytes were fixed with 4% paraformaldehyde in PBS overnight at 4 ℃. The sample was washed with PBS and then permeabilized by 0.2% Triton X-100 in PBS for 5 min at room temperature. After being washed, cells were equilibrated at room temperature for 5-10 min in equilibration buffer (200 mmol/L potassium cacodylate, 0.2 mmol/L dithiothreitol, 0.25 g/L bovine serum albumin, and 2.5 mmol/L cobalt chloride in 25 mmol/L Tris-HCl, pH 6.6) and then incubated in the presence of biotinylated nucleotide mix and terminal deoxynucleotidyl transferase at 37 ℃ for 1 h in a humidified chamber. The tail reaction was terminated by 2× standard saline citrate (SSC). Then, 0.3% hydrogen peroxide was added to block the endogenous peroxidase. After being washed thrice in PBS, streptavidin HRP was added for 30 min at room temperature, and washed in PBS again. At last, DAB was added to stain the sample, until a suitable background occurred and the positive cells were mounted under a reverse microscope. At least 1 000 cells were counted, and the percentage of TUNEL-positive cells was determined.

Statistical analysis

Data were expressed as mean±SD. Statistical analysis was performed by Student's *t*-test to compare data in different groups. $P<0.05$ was considered statistically significant.

RESULTS

Neonatal mouse primary cardiomyocytes culture and identification

It was noted that the animal age should not be more than 3 d, because cardiomyocytes obtained from neonatal mice older than 3 d, did not attach to the dishes. After being separated from non-muscle cells by preculturing for 2 h, the cardiomyocytes were replated at a density of 1.0×10^5 cells/cm^2 and incubated under the condition described in Materials and methods. After being cultured for 24 h, almost all the cardiomyocytes attached to and spread on the substratum of the dishes and beat spontaneously. The culture media were changed at this time and then changed every 3 d. Forty-eight hours after culturing was completed, the myocytes were identified by the immunocytochemical assay. The cells isolated and cultured were cardiomyocytes, and the cellular morphological characteristics are shown in Figure 1. The myocyte purity averaged 94±2.25%.

Cytotoxicity of H_2O_2

Cardiomyocytes were exposed to different concentrations of H_2O_2. Morphological alteration, cardiomyocyte apoptosis and cell viability were measured as the cytotoxicity of this oxidant. As shown in Figure 2, a dramatic change of cellular morphology and a concentration-dependent injury effect could be observed. When exposed to 0.6125 mmol/L hydrogen peroxide for 3 h, there were no significant differences in cellular morphology. When the concentration increased, a dramatic change in cellular morphology was found. All the cells lost their characteristics of spontaneous beating, and cellular membrane became shrunk, cellular nuclei were contracted.

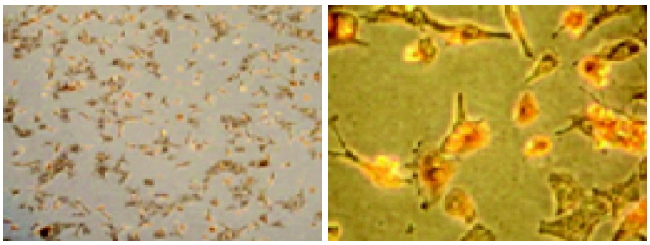

Figure 1 Cardiac myocytes identified by immunocytochemical assay.

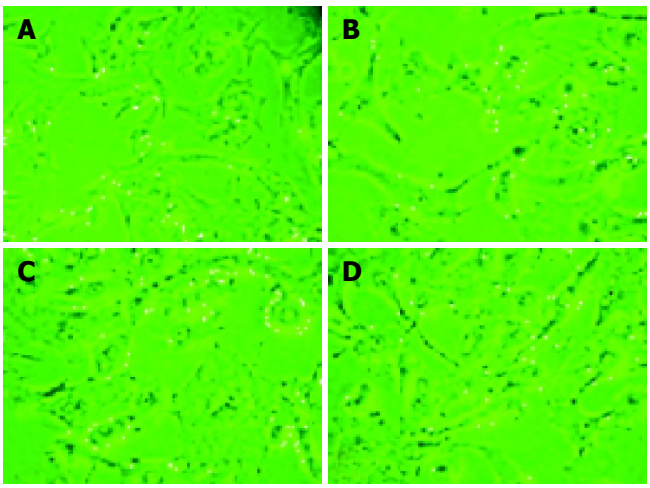

Figure 2 Cellular morphological change of cardiomyocytes after exposure to different concentrations of hydrogen peroxide for 4 h. **A:** Normal control group (magnification ×200); **B:** cardiomyocytes exposure to 1.25 mmol/L H_2O_2 (magnification ×200); **C:** cardiomyocytes exposure to 2.5 mmol/L H_2O_2 (magnification ×200); **D:** cardiomyocytes exposure to 5 mmol/L H_2O_2 (magnification ×200).

Genomic DNA was measured to indicate alterations in cardiomyocyte apoptosis, when cardiomyocytes were exposed to different concentrations of H_2O_2. As shown in Figure 3, genomic DNA remained intact after being exposed to 0.625 mmol/L H_2O_2 for 3 h; when H_2O_2 concentration was changed to 1.25 mmol/L, genomic DNA was divided into some small fragments; when H_2O_2 concentration increased to 5 and 10 mmol/L, all genomic DNAs were divided. There were electrophoresis stains, suggesting that apoptosis of cardiomyocytes occurred when they were exposed to H_2O_2.

MTT assay was used to monitor the cellular viability. There were significant differences in the cell viability at different concentrations of H_2O_2. The higher the concentration of H_2O_2, the lesser the viability of cardiomyocytes (Table 1).

Cardio-protective effect of nm-haFGF

Cardiomyocytes were exposed to a certain concentration of H_2O_2 and different concentrations of nm-haFGF. The total activity of SOD, MDA leakage, cellular viability and apoptosis were measured as the parameters for evaluating the protective effects of nm-haFGF. As shown in Table 2, the total activity of SOD dramatically increased with the concentration of nm-haFGF, the MDA leakages decreased with the concentration of nm-haFGF, and there was a significant difference between the control and experiment groups. As shown in Table 3, cellular viability increased with the increasing of concentration of nm-haFGF. All these showed that nm-haFGF had a significant cardiomyocytes protective effect on cardiomyocytes exposed to H_2O_2.

To examine the effect of H_2O_2 on apoptosis, myocytes were pretreated with different concentrations of H_2O_2. The initiating effect of H_2O_2 on cardiomyocytes apoptosis was confirmed by determining the change of DNA fragment (Figure 3). The cellular protective effect of nm-haFGF was confirmed by the same method (Figure 4). The rate of TUNEL-positive cells was 32.9±3.3% in the H_2O_2 group, and 1.1±0.26% in the normal group. But after being exposed to 0.15 mmol/L H_2O_2-DMEM, the rate of TUNEL-positive cells was 25.4±2.6% in 10 ng/mL nm-haFGF group, the cellular apoptosis rate in the 40 ng/mL nm-haFGF group was only 19.7±1.9%.

DISCUSSION

Studies indicate that intracoronary, intrapericardial or myocardial administration of FGFs, in chronically ischemic canine and porcine hearts, can stimulate angiogenesis, a process to minimize infarct size and improve cardiac function[11-13]. Although there are some promising results in the animal model trials, some questions, such as dose dependence[14], acute negative inotropic effects[10] still exist. Some investigators

wondered if there would, be a potential danger of stimulating the growth of tumor for their strong power of mitogenesis[15]. In this study, we explored nm-haFGF responding to free radical-induced injury of primary cardiomyocytes when exposed to H_2O_2, which induces cardiac apoptosis[16,17]. As shown in Figure 2, when primary cultured neonatal SD mouse cardiac myocytes were exposed to different concentrations of hydrogen peroxide, a dramatic difference of morphological alteration was found, showing a concentration-dependent injury effect. The higher the concentration of H_2O_2, the more serious injury of the cardiomyocytes. As shown in Figure 3, at the lower concentration of H_2O_2, the cellular genomic DNA remained intact, when the concentration of H_2O_2 increased, cellular genomic DNA was divided into small fragments, suggesting that H_2O_2 has a strong cytotoxicity to primary cultured cardiac myocytes.

There is evidence that FGF family protein plays an important role in cardiac protection during hypoxia and reperfusion of ischemic myocardium[18-21]. It was reported that FGF should be considered as a protector rather than a promoter of myocardium regeneration in myocardium reperfusion injury[22-25].

In this study, we isolated and cultured the neonatal SD rat cardiomyocytes, built a cardiac myocyte injury model, and observed the cardio-protective effect of non-mitogenic human acidic FGF *in vitro*. We determined the cardiac myocytes injury by exposing it to different concentrations of H_2O_2, the cellular viability and the concentration of H_2O_2 showed a dose-dependent relationship. Cellular morphology and apoptosis examination showed that H_2O_2 had strong cytotoxicity to the cultured cardiomyocytes. nm-haFGF increased the total activity of SOD, protected the integrity of cellular membrane, and decreased the leakage of MDA as well as cell apoptosis, when cardiomyocytes were exposed to a certain concentration of H_2O_2. All these suggest that nm-haFGF can weaken the injury of cardiomyocytes in a dose-independent manner.

FGF has cardio-protective action on an isolated rat heart model[23,26,27]. Myocardial preconditioning can reduce infarct size, attenuate neutrophil infiltration, reduce calcium influx into cardiomyocytes, delay ultrastructural changes, and decrease programmed cell death (apoptosis)[23,28,29]. Therefore, one of the important mechanisms that can promote cardioprotection is by decreasing myocardial cell apoptosis identified in a wide variety of cardiovascular disorders, including myocardial infarction. As shown in Figure 3, when cardiomyocytes were exposed to a high concentration of H_2O_2, almost all the cells underwent apoptosis (Figure 2), and electrophoresis analysis showed the same results. When exposed to different concentrations of nm-haFGF, TUNEL assay showed that the rate of apoptosis dramatically decreased (Figure 4). All these indicate that nm-haFGF has the anti-apoptosis effect.

In conclusion, nm-haFGF has the anti-apoptosis effect at cell level.

ACKNOWLEDGMENT

The authors thank Dr. Tan Zhi (Physiological and Pathological Department, Sun Yat-Sen University) for his excellent technical support.

Abstract

AIM: To clarify the types, regional distributions and distribution densities as well as morphological features of gastrointestinal (GI) endocrine cells in various parts of the gastrointestinal track (GIT) of four reptiles, *Gekko japonicus*, *Eumeces chinensis*, *Sphenomorphus indicus* and *Eumeces elegans*.

METHODS: Paraffin-embedded sections (5 μm) of seven parts (cardia, fundus, pylorus, duodenum, jejunum, ileum, rectum) of GIT dissected from the four reptiles were prepared. GI endocrine cells were revealed by using immunohistochemical techniques of streptavidin-peroxidase (S-P) method. Seven types of antisera against 5-hydroxytryptamine (5-HT), somatostatin (SS), gastrin (GAS), glucagon (GLU), substance P (SP), insulin and pancreatic polypeptide were identified and then GI endocrine cells were photomicrographed and counted.

RESULTS: The GI endocrine system of four reptiles was a complex structure containing many endocrine cell types similar in morphology to those found in higher vertebrates. Five types of GI endocrine cells, namely 5-HT, SS, GAS, SP and GLU immunoreactive (IR) cells were identified in the GIT of *G. japonicus, E. chinensis* and *S. indicus*; while in the GIT of *E. elegans* only the former three types of endocrine cells were observed. No PP- and INS- IR cells were found in all four reptiles. 5-HT-IR cells, which were most commonly found in the pylorus or duodenum, distributed throughout the whole GIT of four reptiles. However, their distribution patterns varied from each other. SS-IR cells, which were mainly found in the stomach especially in the pylorus and/or fundus, were demonstrated in the whole GIT of *E. chinensis*, only showed restricted distribution in the other three species. GAS-IR cells, with a much restricted distribution, were mainly demonstrated in the pylorus and/or the proximal small intestine of four reptiles. GLU-IR cells exhibited a limited and species-dependent variant distribution in the GIT of four reptiles. SP-IR cells were found throughout the GIT except for jejunum in *E. elegans* and showed a restricted distribution in the GIT of *G. japonicus* and *S. indicus*. In the GIT of four reptiles the region with the highest degree of cell type heterogeneity was pylorus and most types of GI endocrine cells along the GIT showed the peak density in pylorus as well.

CONCLUSION: Some common and unique features of the distribution and morphology of different types of GI endocrine cells are found in four reptiles. This common trait may reflect the similarity in digestive physiology of various vertebrates.

INTRODUCTION

Today more than 30 GI hormone genes and a multitude of GI hormones have been recognized, thus making the GIT the largest endocrine organ in the body[1]. GI hormones as regulatory peptides appear to be the major components of body integration and have important regulatory actions on physiological function of the GIT[2-6]. In recent years, the field of GI hormones expanding at a dazzling speed has become an important domain in gastroenterology. Some GI dysfunctions are related to GI hormones[7]. Some GI hormones have synergistic expression in gastric carcinoma and take part in the occurrence of gastric carcinoma[8,9]. Furthermore, some GI hormones in combination with their peptide analogs are helpful in developing new diagnostic and therapeutic strategies[10]. The physiological role of hormonal messengers, peptide receptors and their potential involvement in disease are under investigation.

GI endocrine cells, dispersed in epithelia and gastric gland of the GIT, are the anatomical units responsible for the production of GI hormones. Since pathological changes

of GIT also correlate with the changes of GI endocrine cells[11-15], the investigation of GI endocrine cells has been considered as an important part of GI hormone studies and can provide baseline data for basic research in gastroenterology.

It is generally accepted that GI endocrine cells are remarkably different in regional distribution, relative frequency, cell types, and each regional part of the GIT. Many studies have elucidated the regional distribution and relative frequency of different endocrine cells in the GIT of other vertebrates, such as fishes, amphibians[16,17], especially mammals[18-22]. Some studies on regional distribution and relative frequency or distribution density of GI endocrine cells of reptilian species have also been carried out[23-28], because they are centrally placed on the vertebrate phylogenetic tree.

The present study was conducted to clarify the types, regional distribution, distribution densities and morphology of GI endocrine cells in the GIT of *G. japonicus*, *E. chinensis*, *S. indicus* and *E. elegans* by specific immunohistochemical methods, and to provide baseline data not only for further morphological studies but also for physiological and pathological research on the digestive system of reptilians.

MATERIALS AND METHODS

Specimens and sections

G. japonicus (n = 5, body length: 130±14 mm) in the campus of Anhui Normal University, *E. chinensis* (n = 3, body length: 180±20 mm) in the campus of the 9th Middle School in Wuhu City, *S. indicus* (n = 5, body length: 190±18 mm) and *E. elegans* (n = 5, body length: 150±10 mm) in Langya Mountain were collected in summer and autumn. The animals were lightly anesthetized with ether and decapitated with their cardia, fundus, pylorus, duodenum, jejunum, ileum and rectum dissected and fixed in Bouin's fluid for 24 h. After being dehydrated through an ethanol-xylene series the specimens were embedded in paraffin. Sections were cut at 5 μm thickness and mounted on gelatin-coated slides.

Antisera and reagents

The details of the seven antisera and main reagents used in this study are listed in Table 1.

Immunohistochemical staining

Each representative section was deparaffinized, rehydrated and immunostained with the S-P method. Endogenous peroxidase activity was blocked by incubating the sections with 0.3% H_2O_2 in methanol for 10 min. The non-specific reaction was blocked with normal goat serum prior to overnight incubation at 4 ℃ with the primary antiserum (Table 1). After being rinsed in phosphate-buffered saline (PBS; 0.01 mol/L, pH 7.4), the sections were incubated for 15 min at room temperature with biotinylated goat anti-rabbit IgG serum for all antisera, while biotinylated goat anti-mouse IgG serum was used for insulin. They were then washed in PBS and incubated for 15 min with S-P. Peroxidase reaction was carried out in a solution of DAB containing 0.01% H_2O_2 in Tris-HCl buffer (0.05 mol/L, pH 7.6). After the being lightly counterstained with Mayer's hematoxylin, the sections were dehydrated and cover-slipped.

Experiment control

To investigate the specificity of the reactions, negative and positive controls were used. By replacement of the primary antisera with normal goat serum and PBS, negative control was set. A positive control was also established using tissue sections from the GIT of tortoise containing the hormones being studied. The positive reaction cells were colored brown.

Observation, photomicrograph and cell count

All animals were used for each of the four reptiles studied, seven specimens of each reptile were observed and photomicrographed under the Olympus BX-51 photomicroscope. The dark-brown positive reaction cells on the sections were counted under 10×40 times field. The average number of positive reaction cells from the 10 fields selected randomly in each specimen was the number of IR cells in each reptile. Then the average number of all the reptiles was again quantified as distribution density of IR cells.

Statistical analysis

Data were expressed as mean±SD and variance analysis was performed using SPSS 11.0 software. One-way analysis of variance was used for multiple comparisons, and Duncan's test was used for intra-group comparisons. $P<0.05$ was considered statistically significant.

RESULTS

Types, distributional feature of GI endocrine cells in GIT of four reptiles

Table 1 Details of antisera and main reagents used

Antisera and reagent	Donor	Code number	Working dilution	Source

S-P Kit		SP-9001	Working solution	Zhongshan Biotech Co. LTD., Beijing, China
S-P Kit		SP-9002	Working solution	Same as above
DAB		ZLI-9030	0.6 g/L	Same as above

SP-9002 was only used in detecting INS-IR cells.

Five types of endocrine cells namely 5-HT-, SS-, GAS-, SP- and GLU-IR cells were identified in the GIT of *G. japonicus*, *E. chinensis* and *S. indicus*. However, in the GIT of *E. elegans* only 5-HT-, SS-, GAS-IR cells were found. PP- and INS-IR cells were not detected in the GIT of the four reptiles. The regional distribution and distribution density of GI endocrine cells in the GIT of four reptiles are listed in Tables 2-5. No positive reactions were detected in the negative control sections.

5-HT-IR cells detected throughout the whole GIT of four reptiles were the most predominant GI endocrine cells. These cells showed the highest density in pylorus of four reptiles except for *G. japonicus* in which the most abundant cells were observed in the duodenum. However, the distribution pattern of 5-HT-IR cells in the GIT varied considerably in four reptiles (Figure 1). SS-IR cells were demonstrated in the whole GIT of *E. chinensis*, but only showed restricted distribution in the other three. They were found in stomach and duodenum of *G. japonicus* and only in stomach of *S. indicus* and *E. elegans*.

SS-IR cells were most predominant in pylorus of four reptiles except for *G. japonicus* in which most SS-IR cells were detected in fundus (Figure 2). GAS-IR cells showed limited distribution in the GIT of four reptiles and were confined to pylorus of *E. chinensis*, pylorus and duodenum of *S. indicus* and *E. elegans*, duodenum and jejunum of *G. japonicus*, respectively. In the pylorus of *E. elegans*, GAS-IR cells showed the highest density (Figure 3). GLU-IR cells were detected in the whole stomach of *G. japonicus*, in ileum and rectum of *S. indicus*, in ileum and rectum, and rarely in fundus of *E. chinensis* (Figure 4). SP-IR cells distributed throughout the GIT except for jejunum of *E. elegans*, and were found in stomach of *G. japonicus* and in rectum of *S. indicus* respectively (Figure 5). In the GIT of four reptiles, the region with the highest degree of cell type heterogeneity was the pylorus and most types of GI endocrine cells in the GIT showed the peak density in pylorus as well.

Morphological features and localization of GI endocrine cells in GIT of four reptiles

The GI endocrine system of four reptiles contained many endocrine cell types similar in morphology to those found in higher vertebrates. The endocrine cells showed the characteristic form of both open and close types. They appeared as close-type cells as they did not possess lamina contact with their apical cytoplasmic processes and as open-type cells with apical cytoplasmic processes that reached the glandular or intestinal lumen. The GI endocrine cells were round, oval, triangular, spindle-, shuttle- or flask-like in shape. They were mostly found in gastric glands and intestinal epithelium, and occasionally in gastric epithelia. In gastric glands, the GI endocrine cells were located between

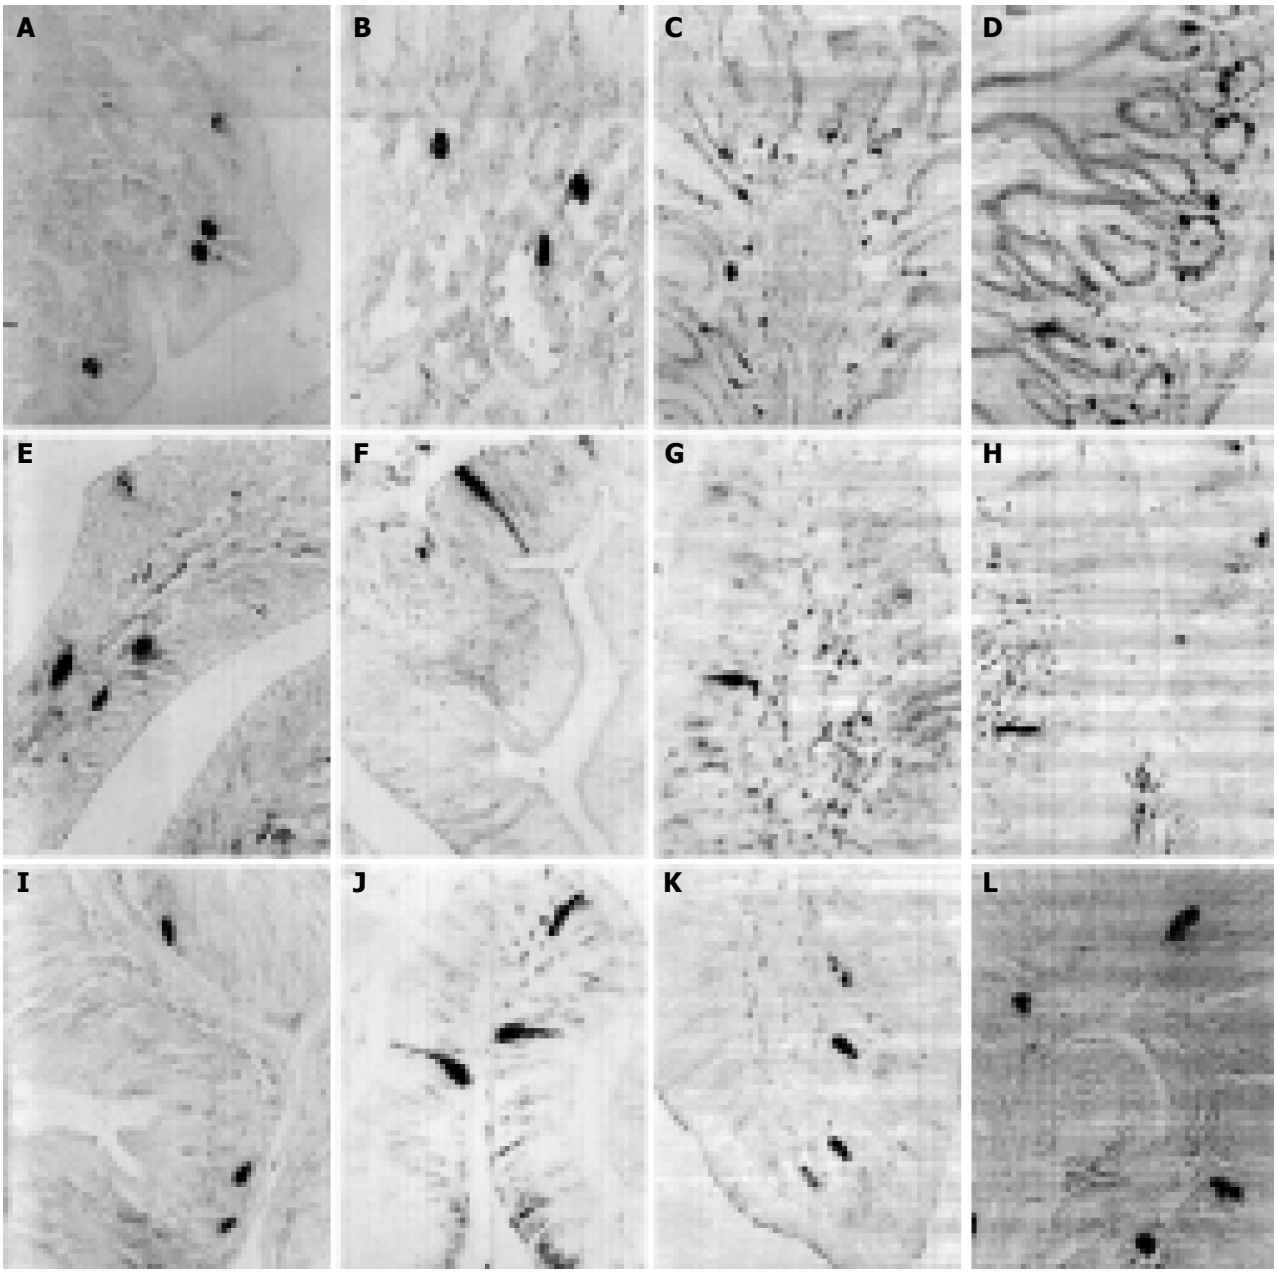

Figure 1 5-HT-IR cells in cardia of *E. chinensis* (**A**), fundus of *E. elegans* (**B**), pylorus of *S. indicus* (**C**) and *E. elegans* (**D**), duodenum of *G. japonicus* (**E**) and *S. indicus* (**F**), jejunum of *S. indicus* (**G**) and *E. elegans* (**H**), ileum of *S. indicus* (**I**) and *E. elegans* (**J**), rectum of *E. elegans* (**K**) and *E. chinensis* (**L**).

the glandular cells and the basement membrane at the basal portion of the glands. In the intestinal parts, most of these cells were situated in the basal portion of the epithelia.

DISCUSSION

The present study demonstrated that the GI endocrine system of four reptiles is a complex structure containing many endocrine cell types similar to those found in mammals except for PP-IR cells[19-22]. 5-HT-, SS-, GAS-, GLU-, SP-IR cells were identified in the GIT of four reptiles, except for *E. elegans*, in which only the former three types were found.

5-HT, a monoamine, which has a strong effect on regulation of digestive functions, is widely distributed in gastric epithelial endocrine cells, 5-HT-IR cells[4,23]. El-Salhy *et al*.[23], reported that 5-HT-IR cells are detected throughout the GIT of all species of vertebrates, suggesting that they have been established in the GIT at an early stage of vertebrate evolution. By using specific antiserum against 5-HT, these cells were detected throughout the GIT of four reptiles in the present study, further approving that 5-HT-IR cells have a wider distribution than other types of GI endocrine cells in GIT of vertebrates. Similarly to

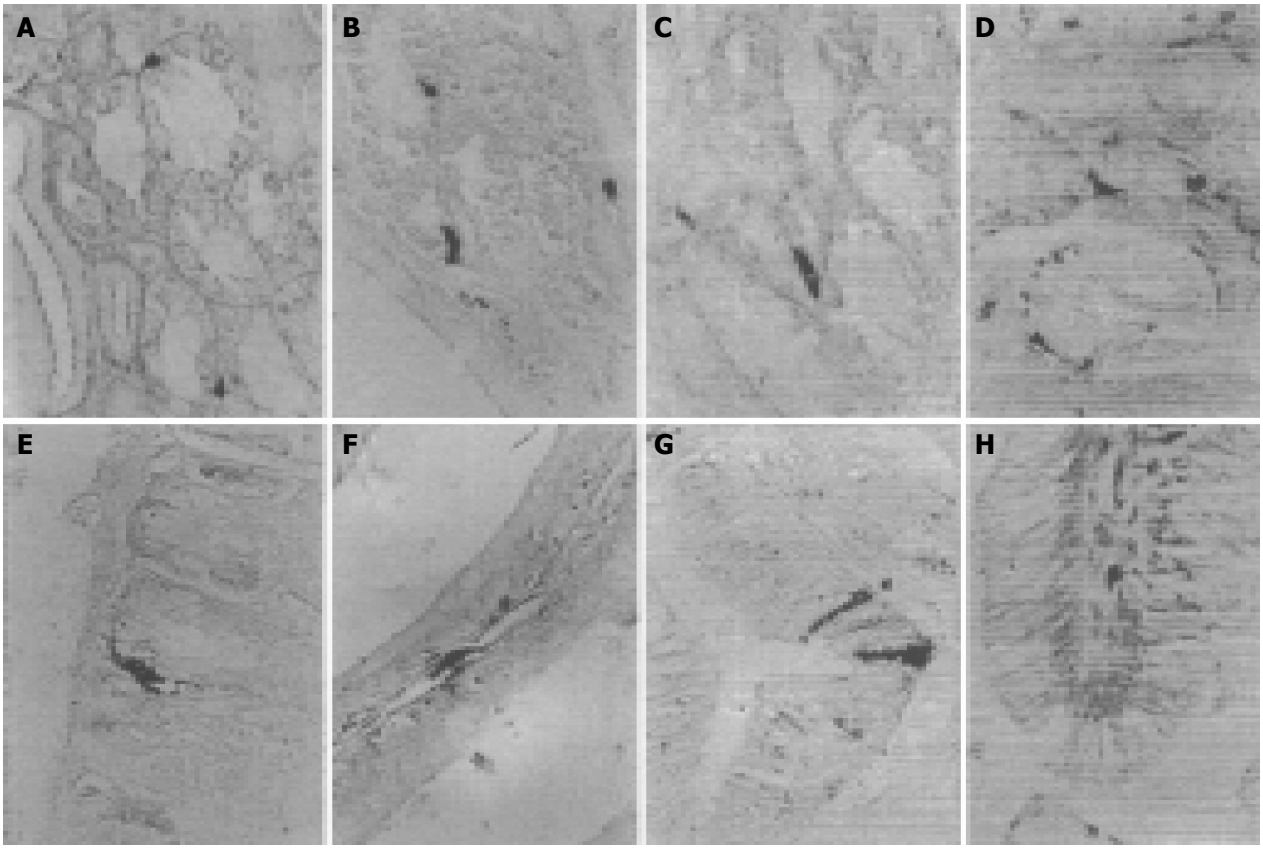

Figure 2 SS-IR cells in cardia of *S. indicus* (**A**) and *E. elegans* (**B**), fundus of *S. indicus* (**C**) and *G. japonicus* (**D**), pylorus of *G. japonicus* (**E**), duodenum of *G. japonicus* (**F**), ileum of *E. chinensis* (**G**), rectum of *E. chinensis* (**H**).

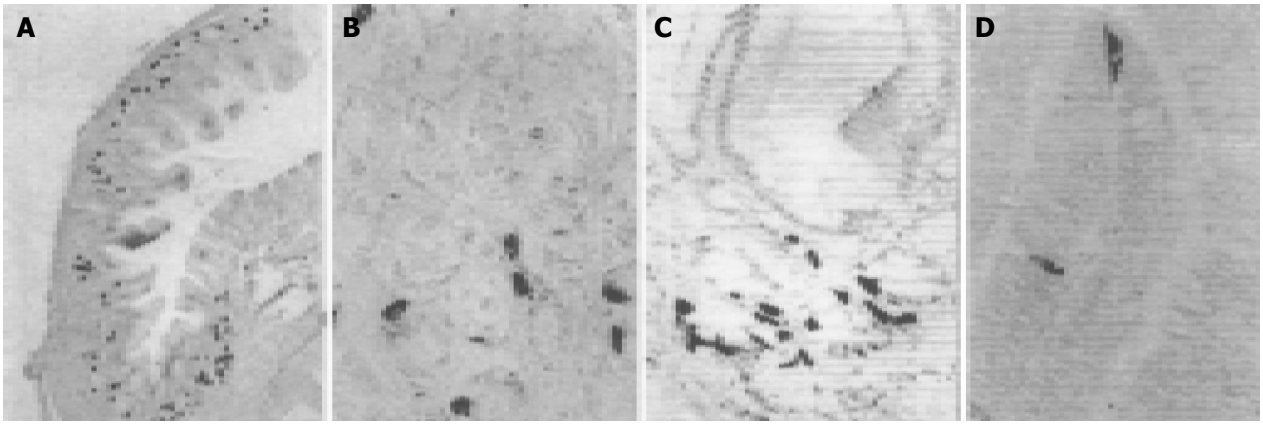

Figure 3 GAS-IR cells in pylorus of *E. elegans* (**A**) and *E. chinensis* (**B**) and *S. indicus* (**C**), duodenum of *G. japonicus* (**D**).

Ku *et al*.[29], and Arena *et al*.[30], 5-HT-IR cells are most predominant in pylorus of *E. chinensis*, *S. indicus* and *E. elegans*. In other studies[24,25,28,31,], the highest frequency of 5-HT-IR cells is in the duodenum and similar results are found in *G. japonicus*, suggesting that pylorus and/or duodenum are important parts in GIT for digestion and a great deal of 5-HT is needed to facilitate the digestive process. As for the distribution pattern (regional distribution and relative frequency or distribution density in GIT) of 5-HT-IR cells in the GIT of four reptiles, considerable variation was observed, and no one was similar to each other, suggesting that the distribution pattern of 5-HT-IR cells may vary from different species. In the present study, some 5-HT-IR cells in the stomach of four reptiles exhibited narrow apical cytoplasmic processes reaching adjacent cells or the gastric gland lumen, indicating that these cells can probably secrete 5-HT by paracrine pathway. In the intestines of four reptiles, 5-HT-IR cells with cytoplasmic processes reaching intestinal lumen were also observed, suggesting that 5-HT may be secreted by exocrine pathway to intestinal lumen.

In most mammals as well as some reptiles, SS-IR cells have a wide distribution in the GIT, except for the large intestine[29-33]. However, species-dependent variations in the distribution patterns of these IR cells have also been reported[24-28]. In the present study, SS-IR cells were demonstrated in the whole GIT of *E. chinensis*, which are in agreement with those reported in *Trimeresurus stejnegeri*, *Trionyx sinensis*, *Alligator mississippiensis* and *Caiman latirostris*[24-27]. In the other three reptiles, SS-IR cells showed restricted distribution. In the GIT of *G. japonicus*, SS-IR cells were demonstrated in stomach and duodenum, as in *Alligator sinensis*[28]. In the GIT of *S. indicus* and *E. elegans*, SS-IR cells are only restricted to the stomach, which differ from those of previous reports on other reptiles[29-33]. These studies suggest that the distribution pattern of SS-IR cells varies greatly in reptiles. On the other hand, common distribution features of SS-IR cells also exist. Studies show that in the GIT of other vertebrates especially mammals, SS-IR cells are found mainly in stomach[20,22], and this common place is also found in most reptiles[27-32]. In the present study SS-IR cells were most predominant in pylorus of *E. chinensis*, *S. indicus* and *E. elegans*. This finding is in line with those of most vertebrates[29,31]. Somewhat different from the above results, SS-IR cells were most abundant in fundus rather than in pylorus of *G. japonicus*, and this difference may be due to the different species. The results found in *G. japonicus* have also been reported in some mammals[18,19,22]. Larsson *et al*.[5], reported that in the stomach, SS-IR cells have cytoplasmic processes terminated on GAS-producing cells, and SS is secreted through cytoplasmic processes by paracrine pathway, inhibiting the secretion of GAS. In the present study, both SS- and GAS-IR cells showed the highest density in pylorus of four reptiles except for *G. japonicus*, suggesting that some relationships may exist between them. Some SS-IR cells with cytoplasmic processes extending to adjacent cells were also found, suggesting that SS-GAS paracrine regulation may exist in reptiles as in mammals.

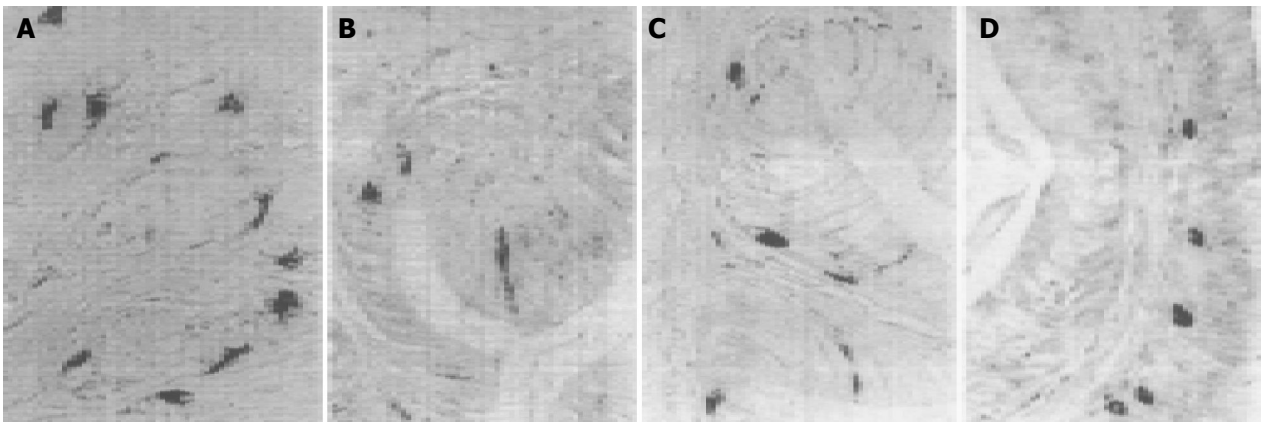

Figure 4 GLU-IR cells in fundus of *G. japonicus* (**A**), ileum of *E. chinensis* (**B**), rectum of *E. chinensis* (**C**) and *S. indicus* (**D**).

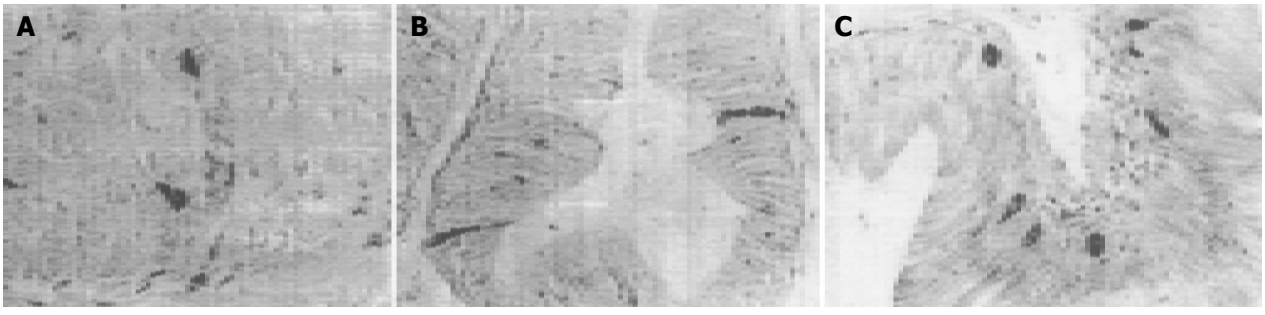

Figure 5 SP-IR cells in cardia of *G. japonicus* (**A**), ileum of *E. chinensis* (**B**), rectum of *S. indicus* (**C**).

In some reptiles, GAS-IR cells are observed in pylorus and whole small intestine of GIT[25,30-33], while in the present study, GAS-IR cells showed restricted distribution in the GIT of four reptiles and the results are similar to those reported in most mammals[18-22]. GAS-IR cells in pylorus and duodenum of *S. indicus* and *E. elegans* are reported in *Bubalus bubalis* and *Caiman latirostris*[20,27]. In the GIT of *E. chinensis*, GAS-IR cells are confined to the pylorus, corresponding to those found in C57BL/6 mice and SKH-1 hairless mice[18,19]. Interestingly, GAS-IR cells were not detected in the pylorus but in the duodenum and jejunum of *G. japonicus*, which differ from those of other three reptiles in which GAS-IR cells were numerous in the pylorus. However, this distribution is consistent with that in *Rana japonica japonica*[17]. In addition, GAS-IR cells are observed in the intestines of *Alligator sinensis* but not in the pylorus[28]. GAS secreted by GAS-IR cells, regulate gastric acid secretion[6]. In *E. chinensis*, *S. indicus* and *E. elegans*, like most vertebrates[30-32], the highest density of GAS-IR cells is found in the pylorus, and this distribution may be important for them to fulfill the regulation of digestive function. However, GAS-IR cells were detected in small intestine in *G. japonicus* but not in the pylorus. Gut hormones have been demonstrated to release into tissue spaces in a paracrine way, they can also release into the gut lumen in a partial exocrine manner or into the blood in an endocrine fashion[3]. In the present study, GAS-IR cells in the intestines of *G. japonicus* were often found with cytoplasmic processes either reaching intestinal lumen or extending to lamina propria, suggesting an exocrine or endocrine secretion of these cell types. Maybe in this way, GAS-IR cells in the intestine can regulate gastric acid secretion. Studies are required to elucidate the functional meaning of these findings.

GLU is synthesized in A cells of the pancreas and regulates serum glucose levels. GLU-IR cells have been demonstrated in various mammals and it is considered that the distribution pattern of these cells in GIT of mammals show species-dependent variation[18-22]. In the present study no GLU-IR cells were found in GIT of *E. elegans* and the findings are similar to those in *Trionyx sinensis*, *Alligator sinensis* and *Egernia kingii* and remarkably different from those in *Caiman latirostris* in which GLU-IR cells were detected throughout the GIT except for the cloaca[25,27,28,30]. In GIT of *G. japonicus*, GLU-IR cells are only found in the stomach, corresponding well with those in *Alligator mississippiensis*[26]. In GIT of *E. chinensis* and *S. indicus* GLU-IR cells are mainly localized in the ileum and rectum. The above studies suggest that the regional distribution of GLU-IR cells in the GIT varies in reptilians.

Up to date, reports on SP-IR cells in the GIT of reptiles are scarce[24,28,31,33,34]. The present study showed that SP-IR cells exhibited variant distribution patterns in GIT of four reptiles. In *E. chinensis* SP-IR cells were found throughout the GIT except for jejunum. Similar to *Lacerta lepida*[31], SP-IR cells are confined to the stomach in GIT of *G. japonicus*. The GIT of *E. elegans* is devoid of SP-IR cells, which is consistent with that in *Trimeresurus stejnegeri*, *Alligator sinensis*, *Testudo graeca* and *Mauremys caspica*[24,28,31]. In *S. indicus* SP-IR cells are only found in the rectum, which are quite different from those of previous studies[33,34].

In this study, the region with the highest degree of cell type heterogeneity was the pylorus. The distribution of most endocrine cell types in the GIT showed the peak density in the pylorus as well. The heterogeneity and concentration of endocrine cells in the pylorus may be attributed to the role of the cells in the feedback control of the function of the segment. In *G. japonicus* and *E. elegans* the spectrum of cell types in the intestine gradually narrowed. While in *E. chinensis* and *S. indicus* the spectrum gradually narrowed from duodenum to jejunum and then widened and got its minimum in jejunum and maximum in rectum.

In conclusion, some common features of the distribution and morphology of different types of GI endocrine cells are found in GIT of four reptiles. This common trait may reflect the similarity in digestive physiology of various vertebrates. Further physiological studies are required to elucidate the ways in which the distribution of GI endocrine cells may be related to the regulatory characteristics of the GIT of reptiles.

Abstract

AIM: To study the techniques of MR diffusion-weighed imaging (DWI) for normal rabbit liver.

METHODS: After 15 normal New Zealand white rabbits and one New Zealand white rabbit implanted with VX-2 tumor were anesthetized with 3% soluble pentobarbitone, DWI was performed respectively for different *b* values, repetition times (TR) or thicknesses, when other parameters were the same and magnetic resonance imaging (MRI) was performed respectively, or with different field of views (FOV) or coil when other parameters were the same. The distinction between groups was analyzed by SPSS10.0 with apparent diffusion coefficient (ADC), quality index (QI) or signal-noise ratio (SNR).

RESULTS: As *b* value increased, liver ADC, QI and SNR of DWI became smaller and simultaneously (F = 292.87, 156.1, 88.23, P<0.01). QI of DWI was high, when *b* value was 10, 50 or 100 respectively, but the distinction between them was insignificant; when *b* value was 800, QI and SNR of DWI were low. QI and SNR of DWI had no significant difference between TR = 4 000, 6 000 and 8 000. QI of DWI with 2 mm thickness was bigger than that with 5 mm thickness (t = 3.04, P<0.01), but SNR of DWI with 2 mm thickness was significantly smaller (t = -17.86, P<0.01). SNR of MRI with knee joint coil was obviously bigger than that with cranium coil [t = -5.77 (T1WI) or -4.02 (T2WI), P<0.01], but QI of MRI was smaller on the contrary [t = 7.10 (T1WI) or 3.97 (T2WI), P<0.01]. When FOV was enlarged gradually, SNR of MRI increased [F = 85.81 (T1WI) or 221.96 (T2WI), P<0.01], but QI firstly increased, then decreased [F = 68.67 (T1WI) or 69.46 (T2WI), P<0.01] and QI of MRI was the biggest when FOV was 20 cm×15 cm.

CONCLUSION: The scanning technique is very important in DWI of rabbit liver and the overall quality of DWI with *b* (100 s/mm^2), thickness (2 mm), cranium coils and FOV (20 cm×15 cm) was best in our study, when other parameters were the same.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most frequent malignant tumors[1]. Many researches on its computed tomography (CT)[2-6], ultrasonography (US)[4-8] and digital subtraction angiography (DSA)[7-9] have been performed in recent years and they have demonstrated their significant values in diagnosis or prognosis of HCC.

However, the application of MRI[10-14], especially diffusion-weighted imaging (DWI)[14-16], in diagnosing hepatic tumors and evaluating its progression is much less than that of CT and US. With the development of software and the scanning technology of MRI, common MRI, including T1WI, T2WI of the axial, the coronal or the sagittal and magnetic resonance cholangiopancreatography (MRCP), has been used widely in diagnosing and evaluating progression of hepatic tumors in recent years.

Diffusion is caused by random water molecular motion. The amount of diffusion is determined by diffusion coefficient. However, because the measurement of the diffusion coefficient (DC) *in vivo* may be affected by many factors, such as temperature, blood perfusion, magnetic susceptibility in the tissue, or other kinds of motion, more of apparent diffusion coefficient (ADC) rather than DC is used clinically[17-19]. DWI was initially used to evaluate early ischemic stages of the brain and its value has been accepted in recent years all over the world. Meanwhile, several research groups have concluded that DWI has great potential for understanding normal and pathological brain function[20-22]. But only a few researches, including that of Inoha *et al.*[23,24], and Geschwind *et al.*[14], on the value of DWI in diagnosing or evaluating the progression of hepatic lesions, especially VX-2 tumor of rabbit, have been reported.

The rabbit VX-2 tumor, today, is seen as the valued animal modality of HCC in researching its imaging characteristics, because most experiments have demonstrated that the blood supply of VX-2 tumor is similar to that of HCC and VX-2 tumor is implanted easily and grows quickly so that

the diameter of the tumor can reach 2 cm or more, 3 wk after implantation and it is able to transfer or metastasize to the liver, the lump, mediastina, etc. in the early stage, and VX-2 tumor animal models have been applied increasingly in the study of HCC[10-13,24]. Thus, it is important to study the characteristics of rabbit liver MR DWI. Geschwind *et al*.[14], have performed researches on the value of DWI in assessing VX-2 tumor cell apoptosis and histologic analysis after transcatheter arterial chemoembolization (TACE). However, the study on the characteristics of rabbit liver VX-2 tumor MR DWI has not been reported. The main reason is its poor quality of imaging which greatly limits its use in diagnosing or evaluating the progression of tumors[14-17].

The purpose of our experiment is to study the techniques of MR DWI of normal rabbit liver in order to improve its image quality and to prepare for the study of MR DWI of rabbit liver VX-2 tumor, which is an important part of the HCC study on MR DWI after TACE.

MATERIALS AND METHODS

Experimental animals

The animal studies were performed under the supervision of a veterinarian and were completely compliant with the National Institutes of Health (NIH) guidelines for the use of laboratory animals. All animals were provided by the Animal Department of the Second Xiangya Hospital and all protocols were approved by the Animal Use and Care Committee of the hospital.

Of 15 New Zealand normal white rabbits, seven were male rabbits and eight were female, their weights ranging from 1.5 kg to 2.0 kg and their ages ranging from 5 mo to 6 mo. One New Zealand white rabbit was transplanted with VX-2 tumor for 21 d, and four rabbits were for pre-experiment. All New Zealand white rabbits were healthy.

Magnetic resonance imaging protocol

After animals were anesthetized, by injecting 3% soluble pentobarbitone into auricular vein at a dose of 1 mL/kg or different dose based on different animal status in order to make sure that the breath of animals was slowest, other than for the dead ones, and stable, T1WI, T2WI or DWI was performed on a 1.5-Tesla Signa Twinspeed MR scanner (General Electron Medical Systems, USA). Our experiment was divided into seven steps.

Firstly, to clearly observe the effect of animal breathing on MRI quality and choose the most suitable dose of anesthesia, T1WI and T2WI were obtained repeatedly in pre-experiment after four rabbits (excluding 15 rabbits in formal experiment) were anesthetized with different dosage, from low to high, of 3% soluble pentobarbitone injected into auricular vein. Then we compared the quality of images with that of the images after the rabbits died from an overdose of anesthesia. From this, we concluded that the quality of the images was the best, when breathing of animals was slow and stable and this dose was the most suitable anesthetic dosage. Secondly, T1WI and T2WI of 15 rabbits were obtained respectively with the cranium coil and the knee joint coil, and the other similar parameters included fast reverse fast spin echo (FRFSE) series, T1WI [(TR) 400 ms/echo time (TE) 12.3 ms], T2WI (TR3000/TE80 ms), FOV 20 cm×15 cm, NEX 4, thickness of the layer 5 mm, spacing 0 mm, matrix 256×192 (T1WI) and 320×256 (T2WI). Thirdly, different FOVs included 24 cm×24 cm, 20 cm×15 cm, 16 cm×12 cm, while the other parameters were similar to those in step two; T1WI and T2WI of 15 rabbits were carried out respectively. Fourthly, DWIs of 15 rabbits were acquired respectively for different *b* values including 10, 50, 100, 300, 800 s/ mm^2 while other parameters remained the same (Table 1). Fifthly, DWIs of 15 rabbits were performed respectively with different TR values including 4 000, 6 000, and 8 000, while the other parameters remained the same (Table 1). Sixthly, DWIs of 15 rabbits were obtained respectively for different layer thicknesses including 2 and 5 mm, while other parameters remained the same (Table 1). Finally, DWI of VX-2 tumor rabbit was performed for a *b* value of 100 or 300 s/mm^2, TR 6 000, and a 2-mm thick cranium coil.

Data analysis

Based on the ADC value of the region of interest (ROI), QI and SNR, the distinction between different scanning parameter groups was respectively evaluated quantitatively. Of them, the ADC and SNR values were obtained through GE working station.

ADC values of 15 normal rabbit liver parenchyma were obtained by getting the ADC average value from five different ROIs at the central layer of the liver, of which each area was 50 mm^2, which was measured five times, with the help of the relative functional software in GE working station.

QI value was an image marker, which was obtained by combining SNR, the artifact and the liver anatomy manifestation of the image with the same weight after they were quantified respectively with five levels, which could reflect the image

Table 1 The parameters of normal rabbit MR DWI

Series	*b*	TR	TE	FOV	NEX	Thickness	Spacing	Matrix	Coils
SE-EPI	10	6 000	45	20×15	8	2	0.5	128×128	Cranium
SE-EPI	50	6 000	45	20×15	8	2	0.5	128×128	Cranium
SE-EPI	100	6 000	45	20×15	8	2	0.5	128×128	Cranium
SE-EPI	300	6 000	45	20×15	8	2	0.5	128×128	Cranium
SE-EPI	800	6 000	45	20×15	8	2	0.5	128×128	Cranium
SE-EPI	100	4 000	45	20×15	8	2	0.5	128×128	Cranium

SE-EPI: spin echo echo planar imaging.

quality collegiately. SNR is the contrast of SH to SD. SH was the average signal of the hepatic parenchyma from the average value of five different ROIs, each area of which was 50 mm^2 excluding biliary ducts and blood vessels. SD is standard deviation of background signal intensity in the direction of the phase coding. It was obtained by calculating the average value of five ROIs which were not only in front of the abdominal wall but in the field of the scanning as well. The values of "SNR<5", "5<SNR<10", "10<SNR <20", "20<SNR<30", "30<SNR<50" and "SNR>50" are thought of as 0, 1, 2, 3, 4 and 5 scores respectively. As far as the artifact of the images is concerned, when the artifact was the highest and the images could not be used for diagnosis, we considered it as 1 score and when the artifact was very high and it affected diagnosis seriously, we considered it as 2 scores. When the artifact of the images was general and it had some effects on manifestation and diagnosis of the lesions, we regarded it as 3 scores and when the artifact was not high and it did not affect diagnosis seriously, we regarded it as 4 scores. Then, when the artifact was little or none, we regarded it as 5 scores. As for the liver anatomy manifestation of the images, 1 score represented the poorest quality of the images which could not display, at all, the border of the organ or the intrahepatic vessels and 3 scores indicated the average quality of the images which could display the border of most organs, comparatively display the major intrahepatic vessels and vaguely display the border of stomach and bowel and, then, 5 scores showed the highest quality of the images which could distinctly display the border of most organs, clearly display the intrahepatic microvessels and that of the border of the stomach and bowel. When the quality of the images was between 1 and 3 scores, we regarded it as 2 scores and, when the quality of the images was between that of 3 scores and 5 scores, we regarded it as 4 scores.

All MR images were retrospectively analyzed by three experienced radiologists and evaluation of the images artifact and liver anatomy manifestations were obtained by average value statistical analysis, based on the above criteria.

The statistical significance was calculated using SPSS10.0 with analysis of variance (ANOVA) of the randomized block design or paired *t*-test.

RESULTS

Considering only the increase in *b* value and no other parameter, the mean ADC value of hepatic parenchyma was decreased and, at the same time, QI also decreased (Table 2). The distinction of ADC among *b* values of 100 and that of 10, 50, 300 or 800 was significant, respectively (Tukey HSD, $P<0.01$). The distinction of QI among groups of *b* values 10, 50 and 100 s/mm^2 was insignificant, and those among *b* values 100, 300 or 800 was significant (Tukey HSD, $P<0.01$), and was significant between groups of *b* values of 800 and 300 (Tukey HSD, $P<0.01$). With *b* value increase, SNR became smaller and, when *b* value was 800, SNR was no more than 10 (Table 2, Figures 1 and 2). The distinction of SNR between *b* values 100, 10, 300 or 800 was significant (Tukey HSD, $P<0.01$) and that between *b* values 100 and 50 was not significant.

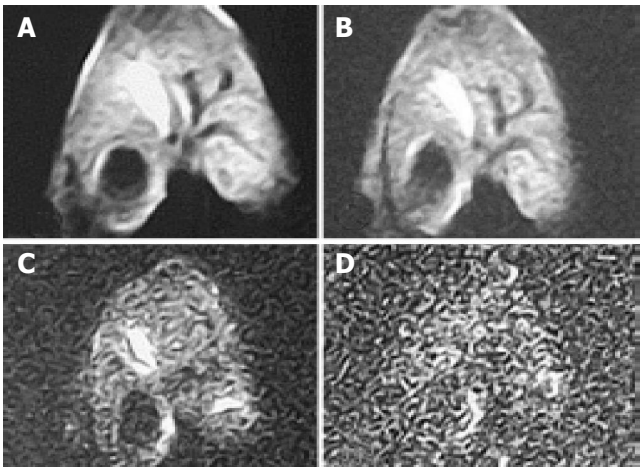

Figure 1 With *b* value, thickness, TR value, scanning coil and NEX were different, ADC value, the ability of liver anatomy manifestation or differentiation and SNR of rabbit liver on MR DWI were also different. b value were respectively 10,100, 300 and 800 s/mm^2 of the image (**A**), (**B**), (**C**) and (**D**). ADC value, SNR and the liver anatomy manifestation of the images became lower and lower with increasing b value. The distinction between b values 10 and 100 was insignificant and the diagnostic value of images at b value 800 was low.

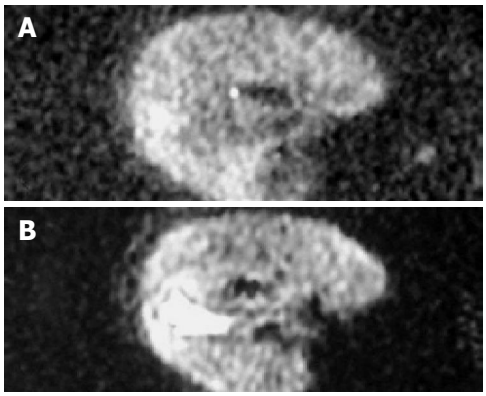

Figure 2 *b* value, the thickness and the NEX of image (**A**) were 300, 2 mm and 8 respectively while those of image (**B**) were 100, 2 mm and 1 respectively. The quality and SNR of the images were poorer than that of Figure 3.

When TR value was 4 000, 6 000 or 8 000, and other parameters were the same, ADC values of hepatic parenchyma

Table 2 DWI of normal rabbit liver with different *b* values (s/mm^2)

	b = 10	*b* = 50	*b* = 100	*b* = 300	*b* = 800	*F*	*P*
ADC[1]	3.23±0.41	2.92±0.43	2.58±0.41	1.73±0.37	0.93±0.56	292.87	<0.01
QI	12.74	12.07	11.80	7.87	3.98	156.1	<0.01
SNR	43.28	33.56	28.65	16.27	9.23	88.23	<0.01

[1](mean±SD)×10^{-3}mm^2/s.

were 2.48±0.52, 2.58±0.43 and 2.70±0.37 (F = 5.6, P<0.01) respectively, QI were 11.11, 11.80 and 10.83 (F = 3.15, P>0.05) respectively, and SNR were 26.61, 28.65 and 29.21 (F = 0.94, P>0.05) respectively, which indicates that QI and SNR did not change significantly. The distinction of ADC between TR 4 000 and 8 000 was significant (Tukey HSD, P<0.05) and that between TR 6 000 and 4 000 or 8 000 was not significant.

When the thickness was 2 or 5 mm and other parameters were the same, ADC values of hepatic parenchyma were 2.57±0.54 and 3.3±0.39 (t = -16.73, P<0.01) correspondingly, QI were 11.80 and 10.90 (t = 3.04, P<0.01) correspondingly and SNR were 28.65 and 71.56 (t = -17.86, P<0.01) correspondingly. The mean ADC value of the hepatic parenchyma and SNR of images were a great deal bigger, when the thickness was 5 mm than when the thickness was 2 mm, but QIs of images were smaller, when the thickness was 5 mm than when the thickness was 2 mm (Figure 3).

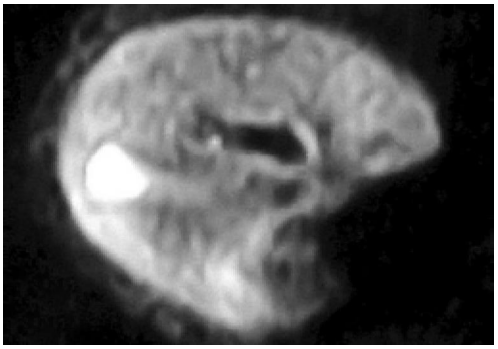

Figure 3 When *b* value was 100 and the thickness was 2 mm, SNR and the liver anatomy manifestation of the images were all good, while the artifact was low and the quality was high.

If rabbit liver was scanned with the cranium coil and the knee joint coil respectively while other parameters remained the same, QI of T1WI were 13.80 and 11.70 (t = 7.10, P<0.01) correspondingly and SNR of T1WI were 96.97 and 137.50 (t = -5.77, P<0.01) correspondingly while QI of T2WI were 11.23 and 9.71 (t = 3.97, P<0.01) correspondingly and SNR of T2WI were 36.41 and 43.63 (t = -4.02, P<0.01) correspondingly. SNR of the images was much bigger when the knee joint coil was used than when the cranium coil was used but QI of the images was smaller when the knee joint coil was used than when the cranium coil was used.

When FOV was 24 cm×24 cm, 20 cm×15 cm or 16 cm×12 cm while other parameters were the same, QI of T1WI were 12.87, 13.90 and 9.89 (F = 68.67, P<0.01) correspondingly and SNR of T1WI were 136.28, 96.97 and 52.03 (F = 85.81, P<0.01) respectively while QI of T2WI were 10.57, 11.23 and 7.45 (F = 69.46, P<0.01) correspondingly and SNR of T2WI were 47.86, 36.41 and 16.81 (F = 221.96, P<0.01) respectively. SNR of the images was the highest when FOV was 24 cm×24 cm and the smallest when FOV was 16 cm×12 cm and QI of the images was the highest when FOV was 20 cm×15 cm.

Based on 15 normal rabbit DWI with *b* value 100, TR 6 000 and thickness 2 mm, 13 images of the liver manifested average and high signals and the other two images of the liver did not manifest well due to the artifact. Eleven borders of the liver displayed well and the contrast between the liver and the neighboring organs was significant. The intrahepatic vessels of 10 cases manifested low signal and concentrated toward the first or the second porta hepatis. The intrahepatic bile ducts of four cases partly displayed high signal like the branches of a tree. All 15 cholecysts manifested high signal and part of them looked like "lamp bulbs". The VX-2 tumor manifested significantly high signal while surrounding hepatic parenchyma displayed low signal on DWI with a *b* value of 100, TR of 6 000 and a thickness of 2 mm. The distinction between VX-2 tumor and surrounding hepatic parenchyma was significant and the border of VX-2 tumor was clear (Figure 4).

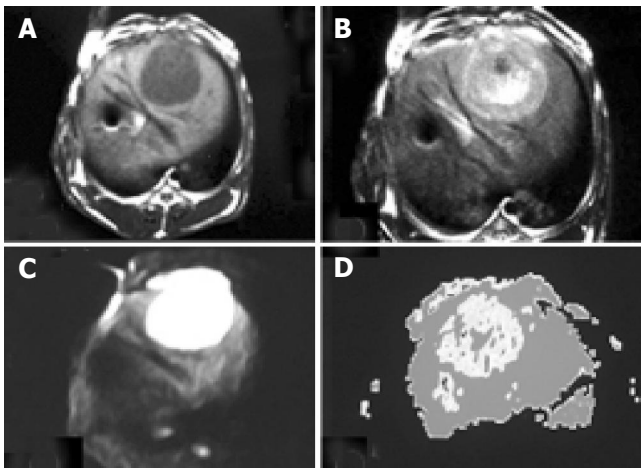

Figure 4 The VX-2 tumor manifests low signal on MR T1WI in image (A), while it displayed high signal on T2WI in image (B). The VX-2 tumor manifested significantly high signal while surrounding hepatic parenchyma displayed low signal on DWI in image (C) with b value 100, TR 6 000 and thickness 2 mm,the distinction between the VX-2 tumor and surrounding hepatic parenchyma was significant and the border of the VX-2 tumor was clear. The image (D) is the ADC map from VX-2 tumor DWI of the image (C).

DWI manifestation of rabbit liver

With *b* value, thickness, TR value, scanning coil and NEX were different, ADC value, the ability of liver anatomy manifestation or differentiation and SNR of rabbit liver on MR DWI were also different. In Figure 1, *b* values were respectively 10, 100, 300 and 800 s/mm^2 of the images (1), (2), (3) and (4). ADC value, SNR and the liver anatomy manifestation of the images became lower and lower with increasing *b* value. The distinction between *b* values 10 and 100 was insignificant and the diagnostic value of images at *b* value 800 was low. In Figure 2, *b* value, the thickness and the NEX of image (1) were 300, 2 mm and 8 respectively while those of image (2) were 100, 2 mm and 1 respectively. The quality and SNR of the images were poorer than that of Figure 3. In Figure 3, when *b* value was 100 and the thickness was 2 mm, SNR and the liver anatomy manifestation of the images were all good while the artifact was low and the quality was high. In Figure 4, the VX-2 tumor manifests low signal on MR T1WI in image (1), while it displayed high signal on T2WI in image (2). The VX-2 tumor manifested

significantly high signal while surrounding hepatic parenchyma displayed low signal on DWI in image (3) with *b* value 100, TR 6 000 and thickness 2 mm, the distinction between the VX-2 tumor and surrounding hepatic parenchyma was significant and the border of the VX-2 tumor was clear. The image (4) is the ADC map from VX-2 tumor DWI of the image (3).

DISCUSSION

Diffusion is caused by water molecular random motion, so-called "Brownian motion", and it is able to change the intensity of local magnetic field around hydrogen proton so that its phase position in the magnetic field is changed. When we added a powerful polar and quick switching gradient radiofrequent (RF) pulse besides routine RF pulse, we were able to amplify these phase changes so that we could detect water molecular diffusion motion, the so-called DWI. DWI was initially used to evaluate early ischemic stages of the brain and its value has been recognized in recent years. However, because of its poor image quality, DWI is rarely used in diagnosing and evaluating the lesions of the liver[24-28].

b value is the sensitivity of diffusion and it is the most important parameter of DWI scanning because changing it will directly lead to a change of the complemented gradient magnetic field and affect the ability of detecting water molecular diffusion. Ichikawa *et al*.[27,28], reported that high *b* value or *b* value deviation has an important influence on the quality of DWI and ADC value or DC value. When *b* value or its deviation is higher, ADC value would be stabler and could get closer to the DC value, which could better reflect water molecular diffusion motion, little affected by the microcirculation. When *b* value or its deviation is lower, ADC value will, to some degree, reflect the perfusion of the microcirculation while the ability of reflecting water molecular diffusion motion is worse than that of the former and the ADC value is also unstable. However, with increasing *b* value, gradient RF pulse will prolong, thus enlarging TE value, and the quality of images will be reduced[15,27,28]. Our results showed that ADC value, QI and SNR of the images would reduce with *b* value increase but, when *b* value was 100, QI of the images was basically the same as that when *b* value was 10 or 50 and SNR of the images was also better. Moreover, QI and SNR of the images were still high when *b* value was 300. Thus, we consider that at a *b* value of 100, QI and SNR of the images are good, together with a *b* value of 300, at which lesions are more sensitively detected as a good choice on DWI (Figures 1 and 3).

TR enlarging will raise the quality of the images because it prolongs the signal collecting time. But it leads to prolongation of the scanning time or reduction of the scanning coverage and it is not beneficial to control breathing. Our results indicated that the distinction of ADC between TR 4 000, 6 000 and 8 000 was significant ($P<0.01$) and that of QI or SNR was not significant. Because breathing has little influence on DWI after the rabbits are anesthetized generally and deeply, TR 6 000 is an appropriate choice and we may also choose a large NEX at the same time.

In our study, ADC value of hepatic parenchyma and SNR of images were significantly higher when the thickness was 5 mm than when it was 2 mm ($P<0.01$) and QI of the images were slightly higher when the thickness was 2 mm than when it was 5 mm ($P<0.01$). When the thickness is raised, SNR of images increases along with the increase of artifacts and decrease of the liver anatomy manifestations, which are not beneficial to the diagnosis of lesions. However, if we increase the collective information through enlarging NEX in order to compensate for the reduction due to the 2 mm thickness, we can obtain enough SNR and a good QI, especially for rabbit liver, which is small in volume andthe number of scans is limited and is not suitable for use in breath gating (Figures 2 and 3).

Both the knee joint coil and the cranium coil have applied reference in reported literature. Our results indicated that SNR of the knee joint coil group was higher than that of the cranium coil group ($P<0.01$), while QI of the knee joint coil group was lower than that of the cranium coil group ($P<0.01$). We found that the major reason for this was their clouding borders and artifacts because of small objective aperture of the knee joint coil, and effects of breathing movement. The cranium coil is a good choice for rabbit liver DWI because it is technically, the best.

As for FOV, it has a significant influence on the quality of DWI images. SNR of images increase with the increase in collective information as FOV enlarges, but QI do not increase continuously. This is because the liver anatomy manifestation decreases as the pixel enlarges and spatial resolution decreases due to the FOV increase. Small FOV (16 cm×12 cm) is not beneficial to diagnoses because of its small QI and SNR at the same time and we regard "20 cm×15 cm" as a more suitable FOV.

Due to the light weight, hair on body surface and quick breathing of rabbits, it was difficult to apply the technology of breath gating in rabbit liver DWI scanning. After rabbits were anesthetized by 3% soluble pentobarbitone injection into auricular vein, the breathing of rabbits was slow and stable; we acquired good images with SE-EPI series, the scan time was short, little affected by the respiratory movement. Our results indicated that the major reason for the artifact was the gas in the stomach and it was effective to use some precluding drug, fast the rabbits and use a stable and suitable posture to decrease the artifact.

In conclusion, the scanning techniques, including appropriate *b* value, thickness, coil, FOV, respiratory movement and control of stomach gas, are very important in DWI of rabbit liver and the overall quality of DWI with a *b* value (100 s/mm^2), thickness (2 mm), cranium coils and FOV (20 cm×15 cm) was considered the best in our study.

Abstract

AIM: To examine the effects of traditional Chinese medicine (TCM) on alcohol-induced fatty liver in rats. TCM consists of *Astragalus membranaceus*, *Morus alba*, *Crataegus pinnatifida*, *Alisma orientale*, *Salvia miltiorrhiza*, and *Pueraria lobata.*

METHODS: The rats were separated randomly into five groups. One (the CD group) was fed a control diet for 10 wk, another (the ED group) fed an ethanol-containing isocaloric liquid diet for 10 wk, and the last three (the TCM group) were fed an ethanol-containing isocaloric liquid diet for 10 wk and dosed orally with TCM (222 mg/kg·d, TCM222; 667 mg/kg·d, TCM667; and 2 000 mg/kg·d, TCM2000, respectively) weekly during the last 4 wk.

RESULTS: ED group developed fatty liver according to lipid profile and liver histological findings. Compared with the control group, liver/body weight, serum triglyceride (TG) and total cholesterol (TC), liver TG and TC, serum alanine aminotransferase (ALT) and aspartic aminotransferase (AST) significantly increased in the ED group. Whereas, in the rats administered with TCM, liver/body weight, serum TG and TC, liver TG and TC, serum ALT and AST were significantly decreased, and the degree of hepatic lipid droplets was markedly improved compared with those in the ED group.

CONCLUSION: TCM treatment causes significant reduction in alcohol-induced lipid hepatic accumulation, reversing fatty liver and liver damage, and can be used as a remedy for alcoholic fatty liver.

INTRODUCTION

Fatty liver is a common histological finding in human liver biopsies, it has been defined as both, more than 5% of cells containing fat droplets or total lipid exceeding 5% of liver weight[1,2]. In the majority of cases the accumulating lipid is predominantly TG. Fatty liver can occur in association in the majority of cases due to alcohol excess, and patients with it are susceptible to liver fibrosis and cirrhosis. Fatty liver is also associated with liver cancer[3-6]. Recovery from fatty liver seems to decrease susceptibility to liver fibrosis and cirrhosis, the more severe liver diseases in terms of liver function and treatment. However, there is as yet no clearly established therapy for reversing fatty liver. We screened a number of liver protective and anti-hepatic steatosis agents from natural products used for the treatment of liver diseases, and selected *Astragalus membranaceus*[7-9], *Morus alba* (Oh *et al*., 2002), *Crataegus pinnatifida*[10,11], *Alisma orientale*[12,13], *Salvia miltiorrhiza*[14,15] and *Pueraria lobata*[16-18]. All of these have been reported to effect liver protection; however, the question of whether a mixture of these continues to be effective is unknown. Thus, the current study investigates the effects of traditional Chinese medicine (TCM) on induced (by administration of alcohol) fatty liver in male Sprague-Dawley rats. Although the active ingredients of TCM is not completely known, any of their synergistic mixtures could play a role in resolving fatty liver, and the potential clinical therapeutic value for subjects with alcoholic fatty liver warrants further attention.

MATERIALS AND METHODS

Preparation of traditional Chinese medicine

TCM is a mixture of traditional medicine, consisting of *Astragalus membranaceus*, *Morus alba*, *Crataegus pinnatifida*, *Alisma orientale*, *Salvia miltiorrhiza*, and *Pueraria lobata* (2:2:2:2:1:1). The materials were obtained from Pharmaceutical Company in Korea, and cut into small pieces. After standing at room temperature for 30 min, the materials were extracted in 10 volumes of distilled water at 95-99 ℃, 0.5-0.6 kgf/cm^2, 3 h. The fluids were then filtered, and thickened under reduced pressure at 70-80 ℃. The extracts were spray dried to a dry powder, and maintained in humidity below 5%.

Animals and diets

Male Sprague-Dawley rats (Daehan Biolink, Chungbuk, Korea), weighing about 100 g, were purchased. All animals received humane care in compliance with the institution's guideline criteria for humane care, as outlined in the National Institute of Health Guidelines for the Care and

Use of Laboratory Animals[19]. The rats were acclimatized for at least 7 d after delivery and were given free access to standard rodent pellet food (Samtaco, Gyeonggi-do, Korea) and water during the adaptation period. The cages were placed in a room with controlled temperature (22±2 ℃), relative humidity (60±5%), and 12 h light/dark cycle (08:00 on-20:00 off). The body weight and general condition of the animals were monitored twice weekly and liquid diet intake was determined daily. The rats were randomly assigned to three groups: one (the CD group) fed a control diet for 10 wk and administered orally daily with saline on each of the last 4 wk, another (the ED group) fed an ethanol-containing isocaloric liquid diet for 10 wk and dosed orally with saline in each of the last 4 wk, and the last three (the TCM groups) were fed an ethanol-containing isocaloric liquid diet for 10 wk and dosed orally with TCM [0.222 g/(kg·d), TCM222; 0.667 g/(kg·d), TCM667; and 2.000 g/(kg·d), TCM2000, respectively] on each of the last 4 wk. Each group included 10 rats. The liquid diet (Table 1) was prepared according to the method described by Lieber-DeCarli[20] and provided 1 kcal/mL, containing 28% carbohydrate, 20% protein, 15% fat plus 37% ethanol (ED group) or isocaloric maltose dextrin as the control. Animals were started on the diet at a body weight of 125-140 g and ethanol was introduced progressively with 3% for the first 2 d (21% of total energy), 4% for the subsequent 2 d (28% of energy) followed by the final formula containing 5% (36% of energy) thereafter. Ethanol was incorporated into the diet just before the supply of the liquid diet to the rats. The diet was kept refrigerated in the dark and used within 1 wk of preparation.

Table 1 Composition of experimental diets (g/L)

Ingredients	Control	Ethanol
Casein	41.40	41.40
DL-Methionine	0.30	0.30
L-Cystine	0.50	0.50

Choline bitartrate	0.53	0.53
Xanthan gum	3.00	3.00
Ethanol	–	45.5

[1]AIN-76 mineral mix provided the following g/kg mix: calcium phosphate, dibasic, 500; sodium chloride, 74; potassium citrate • H_2O, 220; potassium sulfate, 52; magnesium oxide, 24; manganous carbonate, 3.5; ferric citrate, 6; zinc carbonate, 1.6; cupric carbonate, 0.3; potassium iodate, 0.01; sodium selenite, 0.01; chromium K sulfate.12H_2O, 0.55; sucrose, finely powdered, 118.03; Dyets, Bethlehem, PA, USA. [2]AIN-76A vitamin mix provided the following g/kg mix: thiamine HCl, 0.6; riboflavin, 0.6; pyridoxine HCl, 0.7; niacin, 3; calcium pantothenate, 1.6; folic acid, 0.2; biotin, 0.02; vitamin B12 (0.1%), 1; vitamin A palmitate (500 000 IU/g), 0.8; vitamin D3 (400 000 IU/g), 0.25; vitamin E acetate (500 IU/g), 10; menadione sodium bisulfite, 0.08; sucrose, finely powdered, 981.15; Dyets, Bethlehem, PA, USA.

Sampling procedures

On 0, 6, 8, and 10 wk of treatment, animals were killed and blood and tissue removed for analysis. The rats were anesthetized with ether and killed after 12 h of fasting. Blood samples were collected from hepatic portal vein into vacutainer (Becton Dickinson & Co., Rutherford, NJ, USA) for the separation of serum and centrifuged (3 000 r/min for 15 min at 4 ℃). The serum was frozen at -70 ℃ for biochemical analysis. The liver was removed and then weighed after being cleaned with ice-cold saline, and stored at -70 ℃ for the lipid analysis.

Biochemical analysis

Biochemical analysis was carried out using commercial kits. The analysis of serum TG, TC, and high-density lipoprotein cholesterol (HDL-C) concentration were done by automatic analyzer techniques (Asan Pharm. Co., Ltd, Korea). The concentrations were measured spectrophotometrically at a wavelength of 550, 500, and 500 nm respectively (Jasco V-530 UV/VIS, Japan). The low-density lipoprotein cholesterol (LDL-C) and very low-density lipoprotein cholesterol (VLDL-C) were estimated using the Friedewald formula as follows: LDL-C = TC-(VLDL-C+HDL-C) and VLDL-C = TG/5[21]. The activities of the serum aspartic aminotransferase (AST) and alanine aminotransferase (ALT) were measured using kits (Asan Pharm. Co., Ltd, Korea). To analyze hepatic lipid content, the lipids were extracted by homogenizing the liver with 2:1 chloroform-methanol (v/v) by the method devised by Folch *et al*.[22]. Then, TG and TC were measured using commercial kits (Asan Pharm. Co., Ltd, Korea).

Liver histology

A portion of the liver was fixed in 40 g/L formaldehyde and embedded in paraffin wax. Frozen liver sections from fixed tissues were cut into 10-μm pieces and mounted on the slide. The samples were stained for lipid with Oil Red O in propylene glycol with Mayer's hematoxylin as the counter stain, and it calculated the area by densitometer.

Statistical analysis

Statistical evaluation of data was performed by Duncan's multiple range tests to make comparisons among the groups. Values were given as the mean±SD. Differences of $P<0.05$ were considered statistically significant.

RESULTS

Effects on body weight and liver weight

Table 2 shows the body weight and liver weight (g/100 g body weight) in all rats during the 10 wk. At 10th wk, the body weight gain was significantly lower in the rats fed alcohol than in the rats fed without alcohol. However, a trend toward increased weights was seen in rats administrated TCM than those in the ED group. The liver weights tended to be higher in alcohol-fed rats than in the CD group. However, after the administration of TCM for 4 wk, the TCM groups showed significantly decreased liver weights above all, and TCM667 group was the lowest of all the TCM groups. It is considered that there is an inhibition of hepatic lipids accumulation in rats treated with TCM.

Effects on serum lipid profiles

Serum concentrations of TG and TC in rats administrated with alcohol increased to 3.8- and 1.5-fold higher levels respectively than those seen in rats given the control diet (Figure 1). Consumption of alcohol for 6 wk caused significant increases in TG and TC. At 10th wk, TG and TC were significantly reduced by consumption of TCM. TG concentration was reduced by 70%, and the TC concentration was significantly decreased to the level of control rats. Especially, a "middle dose" of TCM667 is more effective in decreasing serum TG than a high dose of TCM2000. In the current study, LDL-C and VLDL-C concentration in rats given alcohol significantly increased 5.8- and 3.8-fold higher levels than those seen in control diet-treated rats (Table 3). However, a trend toward decreased LDL and VLDL was seen after TCM administration; especially, TCM667 is more effective in this, than a high dose of TCM2000. On the other hand, HDL-C concentration in rats given alcohol declined significantly. However, the administration of TCM partially returned to normal.

Table 3 Effect of TCM on serum LDL-C, VLDL-C and HDL-C concentration of rats fed experimental diets for 10 wk and treated with TCM for the last 4 wk

[a]P<0.05, [c]P<0.05, [e]P<0.05, [g]P<0.05, *vs* others, [b]P<0.001, [d]P<0.001 *vs* control.

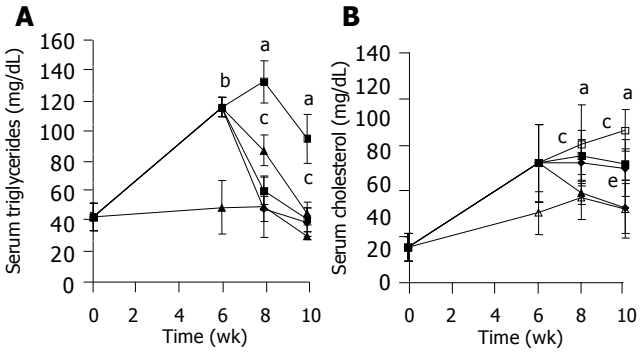

Figure 1 Effect of TCM on concentration of serum TGs (**A**) and TC (**B**) of rats fed experimental diet for 10 wk and treated with TCM for the last 4 wk. △, CD; □, ED; ▲, TCM2000; ●, TCM667; ■, TCM222. [a]P<0.05, [c]P<0.05, [e]P<0.05 *vs* others, [b]P<0.0001 *vs* control.

Effects on hepatic triglycerides and total cholesterol

In alcohol-fed rats, hepatic lipid content raised significantly compared to rats fed with an isocaloric diet without alcohol (Figure 2). Hepatic triglycerides (TGs) and total cholesterol (TC) concentration showed 2.3- and 2.7-fold increase, respectively, in rats fed an alcohol diet compared to those fed a control diet. Therefore, ingestion of alcohol containing diets for 6 wk causes the onset of fatty liver. At 10th wk, TG and TC were significantly reduced by consumption of TCM. Both the TG and TC concentration was significantly decreased to the level of control rats. Especially, TCM667 is more effective in decreasing serum TG than a high dose of TCM2000.

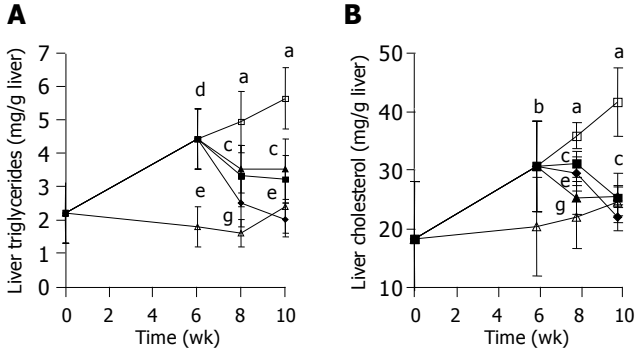

Figure 2 Effect of TCM on TGs and TC concentrations in liver of rats fed experimental diet for 10 wk and treated with TCM for the last 4 wk. △, CD; □, ED; ▲, TCM2000; ●, TCM667; ■, TCM222. [a]P<0.05, [c]P<0.05, [e]P<0.05, [g]P<0.05 *vs* others, [b]P<0.001, [d]P<0.0001 *vs* control.

Effects on hepatoprotective activities

The administration of alcohol to the rats significantly raised the activities of AST and ALT (Table 4). Supplementing with TCM reduced the activity of serum AST and ALT in rats with fatty liver. Moreover, TCM exhibited DPPH free radical scavenging effect (data not shown).

Hepatopathological manifestations

Histological examination of liver tissue (Figure 3) showed lipid accumulation greater in rats, which fed the ethanol-containing diets for 10 wk (Figure 3B), compared to control

diet-fed rats (Figure 3A). In contrast, in rats administrated with TCM for 4 wk, accumulation of lipid droplets was remarkably decreased (Figures 3C-E). Quantification of liver lipids was concordant with the histological findings (Figure 3F). Ethanol feeding increased the liver lipids content by threefold, these results are consistent with the rate of elevation of plasma and hepatic TG in the ethanol-fed rats. In striking contrast, when TCM was administered for the last 4 wk of the ethanol feeding, the lipids content was significantly decreased to the level of control rats.

DISCUSSION

Fatty liver is the most common pathological change induced by alcohol and is also one of the earliest pathological revelations of alcoholic liver disease. Autopsy studies in previously healthy adults, killed accidentally, have revealed an incidence of 1/3[1]. Potential pathophysiological mechanisms include: (1) increased uptake of fatty acids, (2) inhibition of fatty acid oxidation, (3) increased endogenous synthesis of fatty acids, and (4) decreased capacity of the liver to export TG in very-low density lipoprotein particles[23]. Fatty liver can lead to liver fibrosis and cirrhosis; therefore, it is important to treat the condition before it progresses into a more serious form. However, there is no established therapy for the recovery of fatty liver. In this regard, the present study aimed to evaluate the effects of TCM, which depletes levels of serum and hepatic lipid profiles on alcohol-induced fatty liver in rats.

The liquid diet containing alcohol resulted in the accumulation of liver lipids and thus provided a model for alcohol-induced lesions[20]. Despite strict isocaloric pair feeding, alcohol-fed rats did not gain as much weight as those in their pair fed control groups even though they received diets with the same energy content. The slower weight gain of the animals in this study compared to those reported by some authors may be due to the reduction of intake and absorption of nutrients[24,25]. The supplement of alcohol for 6 wk to the rats caused a significant increase in liver weight, and this accounted for by TG accumulation. However, body weight and liver weight of TCM groups were close to those of the control groups. Moreover, both serum and liver, lipid concentrations were significantly (P<0.0001) increased by alcohol feeding. In the present study, however, TCM administration decreased serum and hepatic lipids concentrations to levels lower than those seen before

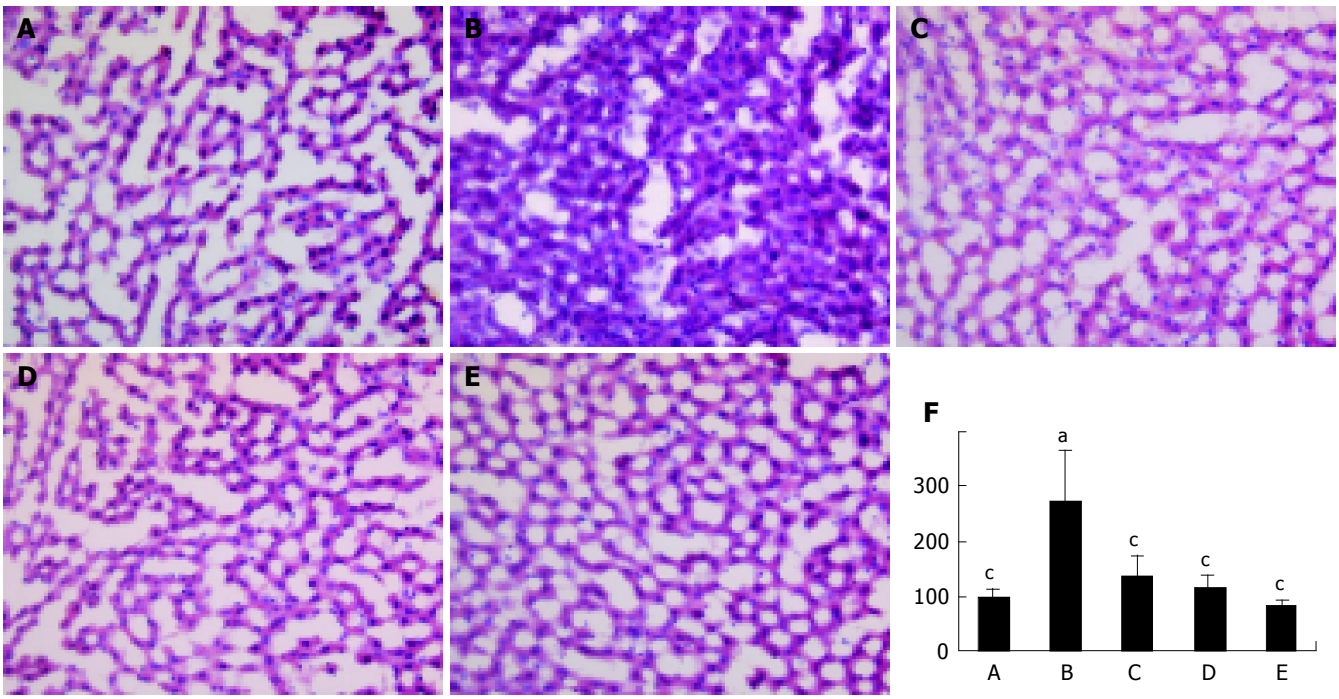

Figure 3 Liver histology in rats treated with alcohol or alcohol plus TCM. Frozen sections of liver (×40) taken from (**A**) CD+saline, (**B**) ED+saline, (**C**) ED+TCM2000, (**D**) ED+TCM667, (**E**) ED+TCM222-treated rats on 10 wk, (**F**) densitometer analysis: the representative experiment A–E were quantified and the integrated area were percentized in control rats (100%). In **A-E**, frozen sections were stained with Oil Red O and counterstained with Mayer's hematoxylin. Lipid droplets were stained red. [a]P<0.05, [c]P<0.05 *vs* others.

TCM administration or returned to normal range, even when rats consumed ethanol diets during the period of TCM administration.

Accordingly, we suggest that the treatment of rats with TCM for 4 wk reversed fatty liver to normal values, as appraised biochemically and histologically. In addition, VLDL was made up of TG-rich lipoproteins and transferred TG from the liver to peripheral tissues. Previous studies indicate that the impaired ability of hepatocytes to secrete lipid components as VLDL is likely to be one major mechanism linked to alcoholic fatty liver[4,26-28]. Accordingly, one important mechanism involved in TCM-induced recovery from an alcoholic fatty liver is decrease in serum LDL and VLDL concentrations. In the current study, the ED group showed increased VLDL and LDL, but the administration of TCM returned to normal. These findings suggest that TCM might enhance the secretion of VLDL from the liver and contribute to the improvement of alcoholic fatty liver. In addition, it seems remarkable that TCM administration increased serum HDL levels. HDL are cholesterol-rich lipoproteins and transferred cholesterol from peripheral tissues to the liver. Therefore, TCM might affect not only TG but also total lipid metabolism, including cholesterol metabolism. Additionally, the current study evaluated whether TCM could protect against liver damage, consequently, TCM takes effects to decrease AST and ALT.

In conclusion, administration of TCM diminishes the accumulation of lipids in the liver. These results suggested that intake of TCM (*Astragalus membranaceus*, *Morus alba*, *Crataegus pinnatifida*, *Alisma orientale*, *Salvia miltiorrhiza*, and *Pueraria lobata*) may be useful in preventing and improving fatty liver induced by alcohol. It is not certain by what mechanism this takes place from the current observation; therefore, follow-up investigations identifying the mechanism related to the reduction of lipids in liver are recommended.

Abstract

AIM: To determine the role of acupuncture therapy in treating experimental gastric ulcer in rats.

METHODS: Twenty-eight adult male Sprague-Dawley rats were randomly divided into four groups (pre-acupuncture group; acupuncture group; paradistance-acupuncture group; and control group), and pre-acupuncture, paradistance-acupuncture, and control groups received 5 μL acetic acid (200 mL/L HAc) injection after a same course of electroacupuncture (EA) treatment (4 Hz, 0.6 mA, 0.45 ms, 45 min for 4 d). The rats in these three groups recovered within 4 d. The acupuncture group received EA therapy for 4 d, after HAc injection. The stomach was dissected to compare the pathological structures of ulcer. Also c-Fos activation in the nuclei of solitary tract (NTS) was observed under microscope after regular immunohistochemistry staining of brain stem sections.

RESULTS: The number of ulcers was different among the four groups, especially between control group and paradistance-acupuncture group or pre-acupuncture group. In the latter group, the number of ulcers was much less. The gastric ulcer area was consistent with the histopathological results, indicating that pre-acupuncture had an obvious therapeutic effect on gastric ulcers. Acupuncture had a very modest effect and paradistance-acupuncture had no effect on gastric ulcers. No therapeutic effect was found in the control group. Fos-Li neurons in NTS induced by noxious gastric ulcer showed a significant difference between pre-acupuncture and control groups.

CONCLUSION: Acupuncture before ulceration can obviously alleviate ulcer. The production of c-Fos proves that the vagus nerve mediates the induction of c-Fos in nuclei of solitary tract following experimental ulceration, suggesting that parasympathetic afferents promote the process of noxious visceral stimulation.

INTRODUCTION

Acupuncture has been used for the treatment of a wide variety of conditions[1] including fever, inflammation and infection, especially stomach diseases. But the efficacy and mechanism of acupuncture in prevention of acid-induced ulcers are unknown. Here the previous animal ulceration model[2] by injection of acetic acid (HAc) was used to study the effectiveness of acupuncture. The zusanli (St36) acupuncture was chosen, because it may have therapeutic functions for stomach diseases and it may be related with the anti-inflammation effect of vagus nerve[3]. C-Fos has been used as a marker for activity in the central nervous system following noxious somatic and visceral stimulation. Experimental gastric ulcer could induce significant c-Fos activity in the nuclei of the solitary tract (NTS) and lumbosacral spinal cord, which receives more parasympathetic afferent inputs than sympathetic afferent inputs.

The study was carried out to examine the effect of electroacupuncture (EA) on attenuating the inflammation of animals subjected to acid-induced gastric ulcer. The acupuncture effect on gastric ulcer was compared among different groups and their relations with c-Fos-activated neurons in vagus-mediated nuclear NTS were analyzed.

MATERIALS AND METHODS

Animals

Twenty-eight adult male Sprague-Dawley rats weighing 150-250 g were included in this study. The rats were divided into four groups randomly and housed in a 12-h light and dark cycle with free access to food and water. They were deprived of food but not water 12 h prior to experiment. The experiment was approved by Chinese Animal Committee.

Animal models

Among several models[4,5], a previously established model to induce gastric ulcer in rats was used. The rats were anesthetized with 45-50 mg/kg pentobarbital intraperitoneally. A midline incision was made to expose the stomach, and 5 μL of 200 mL/L HAc in sterile saline was injected into the subserosal layer of the dorsal and ventral stomach wall and then the epigastric incision was closed. After a recovery period of 4 d, just before the repair time for ulcer[6,7], EA was performed for the acupuncture group. Then the animals were anesthetized, the stomach was opened along the greater curvature, and then pinned to a corkboard. Macroscopic mucosal damage and gastric ulcer were immediately evaluated and gastric ulcer tissues were stained with hematoxylin and eosin (HE). The rat body was perfused immediately after the stomach was removed.

Electroacupuncture

EA treatment (4 Hz, 0.6 mA, 0.45 ms) was carried out for 45 min/day for 4 consecutive d prior to acid injection. The rats were anesthetized, EA was applied with stainless steel needles inserted bilaterally into points corresponding to zusanli (St 36) in human beings. Since EA stimulation produced slight muscle twitch, and did not raise the blood pressure of the anaesthetized animals, it was mostly an innocuous stimulation.

Assessment of gastric mucosal damage

Gastric mucosal damage was quantitated by measuring the area and the number of mucosal lesions. The length and width of each gastric lesion were measured to assess the area of mucosal damage and then the total area of superficial ulceration was calculated. The area of aggregate lesions was expressed as square millimeters.

Histological processing for c-Fos protein

Under deep sodium pentobarbital anesthesia, the animals were perfused transcardially with 100 mL saline, followed by 500 mL fixative containing 40 g/L paraformaldehyde in 0.1 mol/L phosphate buffer (PB, pH 7.4). The brain tissue containing the medulla oblongata was removed and stored in 300 g/ L sucrose (4 ℃) until sedimentation of the blocks, and cut into serial 30 μm coronal sections on a cryostat. For anti-Fos immunostaining, the sections were treated with methanol, H_2O_2 and 3 g/L Triton X-100 for 30 min, then successively incubated with polyclonal primary rabbit anti-Fos antibody (1:10 000, Sigma) for 16 h, donkey anti-rabbit antibody (1:200, Vector) for 3 h, mixture complex liquid of avidin-biotin(1:100, Vector) for 1 h at room temperature. Then the sections were visualized by 0.5 g/L diaminobenzidine(DAB) and 0.3 g/L H_2O_2 (DAB kit, Dako) in distilled water, and rinsed in phosphate buffered saline (PBS) for 10 min thrice after each step. One set of sections were stained with Nissle to get the comparative nuclei in brain stem sections.

Statistical analysis

Results were expressed as mean±SD. The analysis of variance (ANOVA) was employed for statistical evaluations and comparisons of the data. The differences in mean values between two experimental g roups were evaluated by *t*-test. $P<0.05$ was considered statistically significant.

RESULTS

Significantly histological changes were observed after submucosal injection of HAc into the 4 groups. Microscopic examination showed that gastric ulcers induced by HAc-injection in acupuncture group had much more repairing area of submucosa than the untreated rats (Figure 1), and the whole area of gastric ulceration was found in the former group ($P<0.01$, Table 1). The ulceration area of paradistance acupuncture group increased obviously at the same time. The measured results were 5.6±0.5 mm^2 in early acupuncture prior to ulcer, 22.1±5.9 mm^2 in paradistance acupuncture group, and 16.9±0.8 mm^2 in acupuncture after ulceration. The submucosa of stomach in rats subjected to early stage acupuncture was well protected, but acupuncture therapy after HAc-injection failed to prevent mucosal ulcer injury ($P>0.1$, Figure 2). In comparison to the area of gastric ulceration, the acupuncture-dependent inhibition of ulceration could be observed (Figure 2).

Table 1 Area of gastric ulceration after acupuncture (mean±SD, mm^2, $n = 7$)

Group	Gastric ulcer area	*P*
Pre-acupuncture	5.6±0.5	$P<0.001^b$
Paradistance acupuncture	22.1±5.9	$P<0.05^a$
Acupuncture	16.9±0.8	$P>0.10^d$
Control(without acupuncture)	20.3±5.3	Control

$^aP<0.05$, $^bP<0.001$, $^dP>0.10$ *vs* control group.

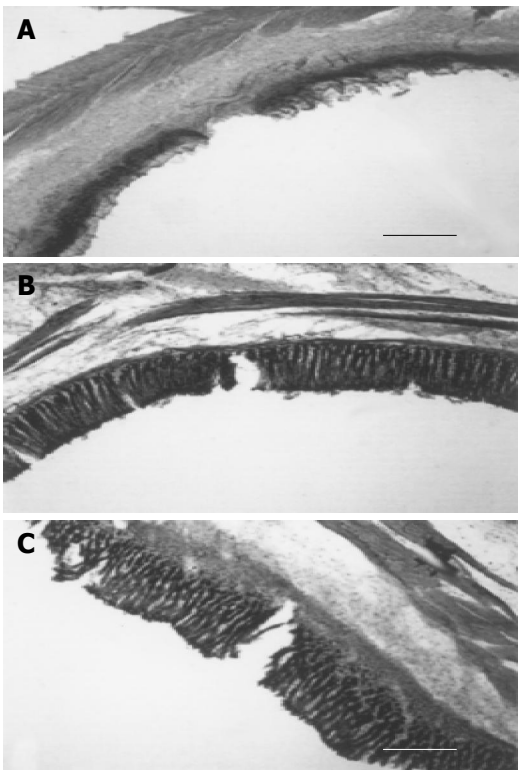

Figure 1 Histological change after submucosal injection of HAc. **A**: A repaired area of ulcer in submucosa of stomach; **B**: Ulcer-free areas after HAc-injection; **C**: Gastric ulcer in untreated rats.

Most Fos-Li neurons were distributed mainly around NTS (Figures 3: B, D, F). There were also some sparsely distributed Fos-Li neurons in surrounding area. At the lower (Figures 3: A, C) or higher magnification (Figures 3: B, D, E, F), the high density of Fos-Li neurons was obviously shown in non-acupuncture group (Figure 3D) and paradistance group (Figure 3F). The acupuncture therapy in early stage could prevent the production of c-Fos (Figure 3E). The number of c-Fos-stained nuclei was counted from NTS at three levels of brain stem in each group (seven rats) animals. For each section three fields were chosen to count the Fos-Li expressing neurons. In pre-acupuncture group the induced Fos-Li neurons were fewer (Figure 4, $P<0.05$). In both paradistance acupuncture group (Figure 4, $P<0.05$) and acupuncture group, the number of Fos-Li neurons significantly increased (Figure 4). In the control group the number of Fos-Li neurons was also higher (Figure 4).

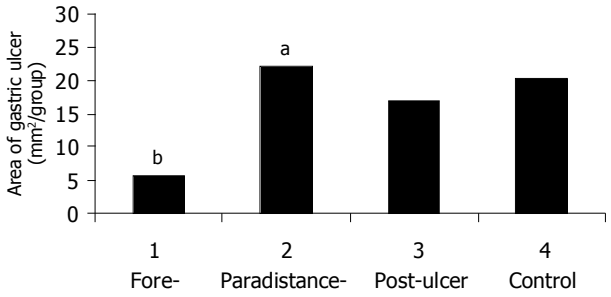

Figure 2 Effects of acupuncture on HAc-induced gastric ulcer in rats $^{a}P<0.05$, $^{b}P<0.01$ *vs* control group.

DISCUSSION

In our study, the acupuncture point was accurate and reasonable. When the rats were anesthetized, EA was applied with stainless steel needles inserted bilaterally into points corresponding to zusanli (St36) in human beings. EA stimulation produced slight muscle twitch, but did not raise the blood pressure in anaesthetized animals, indicating that it is an innocuous stimulation. Fos-Li cells induced by these factors should die after so long a repair time and also some of them might spread to other brain areas especially in the latter situation. It means that even if acupuncture and surgery could induce c-Fos protein expression, but it could be neglected over the long enough recovery time. The results are consistent with the hypotheses, otherwise sham group should have had fewer c-Fos-positive neurons than acupuncture group. But the opposite results we obtained indicate that the ulceration in control group can induce more noxious signals from ulcer inflammation than the acupuncture-treated animals.

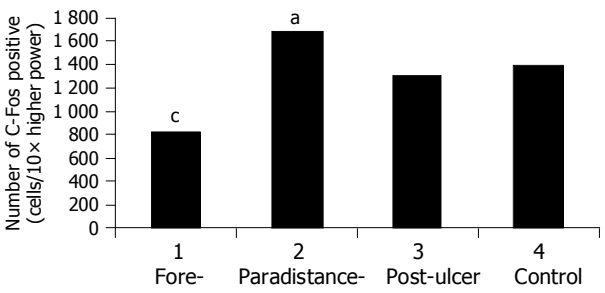

Figure 4 Total number of c-Fos positive cells in NTS $^{a}P<0.05$, $^{c}P<0.05$ *vs* control group.

HAc injected into the gastric wall induced significant inflammation and ulceration in rats. Four days were chosen for the ulceration time, because this is the most possible period for inducing ulceration[4,5]. Pathological examination showed that the acupuncture (St36) attenuated gastric ulcer in

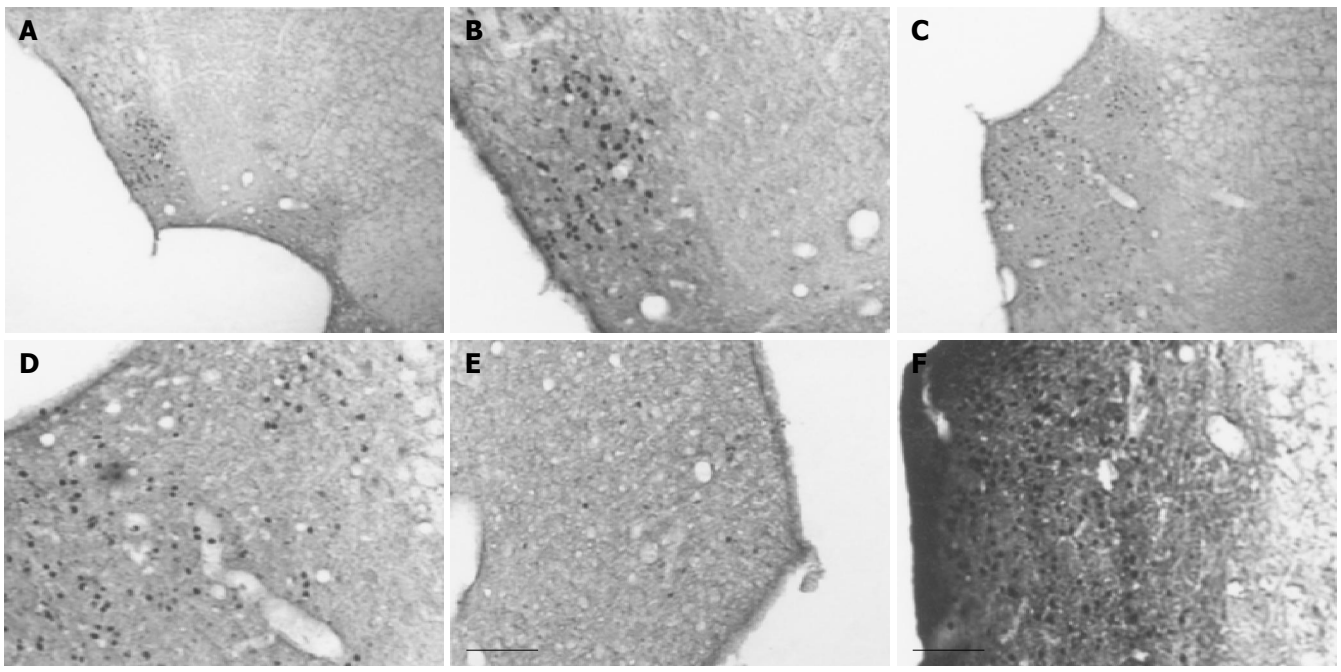

Figure 3 Fos-Li neurons within nuclei of solitary tract. **A**, **B**: Acupuncture after ulceration; **C**, **D**: No acupuncture after ulceration; **E**: Acupuncture prior to ulceration; **F**: Paradistance acupuncture prior to ulceration.

experimental rats. The repair in submucosa was more complete than that in non acupuncture group (Figures 1 and 3). The number and area of ulceration were different (Table 1).

Acupuncture has been used to treat gastrointestinal symptoms in China for more than 3 000 years. However, the mechanism of its beneficial effects remains unknown. It was reported that acupuncture at the right lower abdomen causes a transient relaxation of the stomach, and acupuncture-induced gastric relaxations can be abolished by guanethidine, propranolol, splanchnic ganglionectomy, spinal cord transection, and spinomedullary transection[8]. In contrast, N (G)-nitro-L-arginine, phentolamine, truncal vagotomy, and pontomedullary transection have no effect. Popova *et al*.[9], have proved the effect of acupuncture on activity of antioxidant system in rats with gastroduodenal ulcer. More recently the effect of acupuncture on young pigs with enteropathogenic *Escherichia coli* diarrhea has been evaluated by staining with hematoxylin and eosin[10]. All these results indicate that acupuncture treatment is effective in controlling some stomach diseases at their early stage.

Concerning both of these studies and our results, the number of c-Fos immunopositive cells at the NTS in medulla was changed because of prevailing acupuncture. NTS receives gastrointestinal mechno- and chemosensory information *via* the vagus nerve and vagal afferents may be involved in chemonoreception, which means that pain signals induced by gastric ulcer can be traced by the most related nucleus-NTS in medulla and this effect can be deduced by accurate acupuncture *via* vagus nerve, suggesting that acupuncture-induced gastric ulcer reduction is mediated *via* the somato-parasympathetic reflex system. But acupuncture afferent limb is composed of abdominal cutaneous and muscle afferent nerves. Though the direct or indirect efferent limb is questionable, our hypothesis is *via* the gastric parasympathetic nerve and the reflex center is within the medulla. NTS neurons may play an important role in mediating this reflex and are the 'brain of the gut' for autonomic control of digestion. Because 88-90% of axons in the vagus nerves are afferent nerve fibers that project to the nucleus tractus solitaries and area postrema[11,12], acupuncture prevents mainly brain structures from formation and increase of the products of Fos-Li neurons, suggesting that vagus nerve mediates induction of c-Fos in NTS following experimental ulceration, and that parasympathetic afferents promote noxious visceral stimulation. Results from this study are in agreement with some reports[13].

Although there is evidence that induction of Fos-Li neurons does not depend on the integrity of vagus nerves[8,14]. Tada *et al*.[8], suggested that acupuncture treatment of gastric ulcer can be mediated *via* the somatosympathetic reflex system. Its afferent limb is composed of abdominal cutaneous and muscle afferent nerves. Its efferent limb is the gastric sympathetic nerve and the reflex center is within the ventral lateral medulla. Our present study strongly supports that vagus nerve itself plays a very important role in peripheral gastric organ and central brain communication and cytokine-brain communication[15], because ulcer itself is a kind of cytokine-induced inflammation. The hypothesis that inflammation of gastric ulcer activates afferent vagal fibers that terminate in the nucleus tractus solitarius and may be adjusted by early stage acupuncture has been proved. Previous studies showed that vagal nerve may be a neural route and vagotomy blocks the afferent signaling to the central nerve system and the effects of peripheral cytokines. Peripheral cytokines induced by ulcer inflammation may influence the central nerve system by blood-borne routes of communication.

In conclusion, our study provides the possible neural mechanism of acupuncture underlying gastric ulcer formation. NTS neurons may play an important role in mediating gastric ulcer.

Abstract

AIM: To investigate if and to what extent antiviral therapy influenced a broad panel of quantitative testing of liver function (QTLF).

METHODS: Fifty patients with chronic hepatitis C were either treated with interferon (n = 8), interferon/ribavirin (n = 19) or peg-interferon/ribavirin (n = 23). Quantitative testing of liver function, including aminopyrine breath test (ABT), galactose elimination capacity (GEC), sorbitol clearance (SCl) and indocyanine green clearance (ICG) was performed before and 3 mo after initiation of antiviral therapy.

RESULTS: After 3 mo of antiviral treatment, 36 patients showed normal transaminases and were negative for HCV-RNA, 14 patients did not respond to therapy. ABT and GEC as parameters of microsomal and cytosolic liver function were reduced in all patients before therapy initiation and returned to normal values in the 36 therapy responders after 3 mo. Parameters of liver perfusion (SCl and ICG) were not affected by antiviral therapy. In the 14 non-responders, no changes in QTLF values were observed during the treatment period.

CONCLUSION: ICG and SCl remained unaffected in patients with chronic hepatitis C, while ABT and GEC were significantly compromised. ABT and GEC normalized in responders to antiviral therapy. Early determination of ABT and GEC may differentiate responders from non-responders to antiviral treatment in hepatitis C.

INTRODUCTION

Chronic infection with HCV is among the leading causes for impaired liver function and a major risk factor for developing liver cirrhosis and subsequently hepatocellular carcinoma[1,2]. Treatment of patients with chronic HCV infection has significantly improved, since the introduction of INF-based therapies[3-6]. Yet, more than 50% of patients infected with HCV genotype 1 and approximately 20% of patients with genotypes 2 and 3 do not achieve sustained virologic responses. Risk factors for non-response are HCV genotype, HCV RNA level and liver cirrhosis, which is usually accompanied by impaired liver function and blood flow[7]. Stage and prognosis of liver cirrhosis can be assessed by clinical examination, conventional blood tests and ultrasound or computed tomography. Yet, these conventional parameters (e.g., serum albumin, cholinesterase or coagulation factors) often lack sensitivity in early stages of liver diseases and are only changed in advanced stages. Therefore QTLF, which are based on the hepatic clearance or metabolism of test substances, have been successfully used to predict prognosis and outcome of a variety of different liver diseases[8-14].

So far, response to antiviral therapy is mainly based on HCV RNA levels and transaminases. Here, we investigated if and to what extent changes in either hepatic metabolic enzyme function and in liver perfusion can be achieved by different antiviral therapies, and if changes in QTLF may help to discriminate responders from non-responders to antiviral treatment strategies.

MATERIALS AND METHODS

Fifty consecutive patients (age 39±13 years) with chronic hepatitis C (HCV-RNA positive and raised transaminases, mild to moderate fibrosis, all with HCV genotype 1) were included in the study. Eight patients (16%) were treated with INF monotherapy, 19 patients (38%) with INF/RIB and 23 patients (46%) with peg-INF/RIB combination therapy. All patients underwent QTLF before and 3 mo after initiation of antiviral therapy. Drugs that could possibly interfere with QTLF were discontinued 120 h before testing. Twenty-five healthy adults with normal hepatic serum parameters served as controls[8].

HCV-RNA was assessed qualitatively and quantitatively using the HCV Monitor and the Cobas Amplicor systems,

respectively (both from Roche, Germany). Response to antiviral treatment was defined as being negative for qualitative HCV testing or less than two log steps drop in quantitative HCV-RNA levels.

The following tests were performed to quantitatively assess changes in liver function during antiviral therapy: aminopyrine breath test (ABT), galactose elimination capacity (GEC), sorbitol clearance (SCl) and indocyanine green clearance (ICG). ABT measures the metabolic capacity of hepatocytes by determining the activity of microsomal enzymes[15]. In detail, radioactively labeled ^{14}C-aminopyrine (1.5 μCr), applied intravenously, is demethylated by amino-N-demethylase, which reflects the activity of three different cytochrome P450-dependent microsomal enzymes, and further metabolized to $^{14}CO_2$ which is exhaled and measured with a β-counter.

GEC determines the cytosolic metabolic capacity of the liver[16]. The catabolic enzyme system is saturated by an intravenous bolus injection of galactose (45% galactose, 0.5 g/kg body weight). The cytoplasmic enzyme galactokinase phosphorylates galactose determines the elimination of this hexose, serving as a measure of functional liver cell mass. Serum concentrations of galactose are determined photometrically at 366 nm at 0 min and from 20 to 60 min p.i. in 5 min intervals.

SCl is regarded as a parameter of liver parenchymal perfusion (liver plasma flow). Sorbitol (500 g/L) is administered via a perfusor at 7.5 mL/h. The hepatic clearance corresponds to the measurement of the arteriovenous concentration difference[17]. Serum and urinary concentrations of sorbitol are determined photometrically at the beginning of the perfusion and after reaching steady-state conditions (150 min).

ICG is exclusively absorbed in the liver and quickly excreted in unmodified form (97%) in the bile and can therefore be used as a marker for liver perfusion and biliary secretion capacity after infusion of a bolus of 0.5 mg/kg body weight. Its serum concentration is measured photometrically at 800 nm in 3 min intervals until 21 min after ICG injection[18].

Transaminase levels (AST, ALT) were determined by routine methods in the Department of Medical Chemistry, University Erlangen.

Statistical analysis was performed using SPSS for Windows with $P<0.05$ regarded as significant. Spearman's correlation coefficient (r) was calculated with Microsoft Excel 2003 for Windows XP. The present study was performed in concordance with the ethical standards formulated in the version of 1964 Declaration of Helsinki. All patients gave their informed consent prior to inclusion in the study.

RESULTS

Of the 50 treated patients, 36 (72%) responded to the respective antiviral therapy, showing normal transaminases and negative HCV-RNA after 3 mo. Fourteen patients (28%) did not respond to the therapy regimens (Table 1). Transaminase levels correlated well with HCV-RNA copy numbers, with $r = 0.966$ and $r = 0.937$ for AST and ALT, respectively.

ABT (Figure 1A) and GEC (Figure 1B) were reduced in all patients before beginning the treatment (ABT: 0.65±0.24% dose-kg/mmol CO_2; GEC: 5.43±2.06 mg/min-kg; $P<0.05$ *vs* healthy controls). In patients responding to antiviral therapy, ABT and GEC returned to normal values after 3 mo (0.82±0.14% dose-kg/mmol CO_2 and 7.84±1.71 mg/min-kg.), showing a statistically significant change compared to the initial values ($P<0.05$). Non-responders still showed reduced parameters of microsomal and cytosolic liver function after the therapy interval (ABT: 0.68±0.19% dose-kg/mmol CO_2; GEC: 5.89±1.64 mg/min-kg). Paralleling transaminase levels, ABT and GEC showed a high correlation with HCV-RNA levels with $r = 0.974$ and $r = 0.99$, respectively.

In contrast to these metabolic liver function tests, no changes were observed in QTLF investigating parameters of liver perfusion. While SCl (Figure 1C) and ICG (Figure 1D) were lower in patients with hepatitis C compared to healthy controls (not significant, $P>0.05$), neither responders nor non-responders to antiviral therapies improved during the 3 mo treatment period. SCl was 12.86±2.58 mL/min-kg in healthy controls, 10.8±2.19 mL/min-kg in HCV patients before treatment and 11.3±2.13 and 10.72±2.37 mL/min-kg in responders and non-responders to antiviral therapy. ICG was determined as 0.21±0.11 L/min in controls, 0.17±0.07 L/min before treatment, 0.20±0.07 L/min in responders and 0.18±0.09 L/min in non-responding patients, respectively. Values for ICG and SCl did not correlate with HCV-RNA or transaminases. Although both parameters show slight differences in responders before and after antiviral therapy, these changes were statistically not significant.

Overall, antiviral therapy ameliorated QTLF of microsomal (ABT) and cytosolic (GEC) metabolic capacities, but did not influence parameters of liver perfusion (SCl) and secretion (ICG). Amelioration of ABT and GEC was independent of the applied antiviral regimen in the examined patient groups, but only dependent on overall response to treatment as evidenced by high correlation coefficients with serum transaminase levels.

DISCUSSION

We have shown previously that the application of a broad

Table 1 Transaminase levels and RNA copy numbers in HCV patients before and after 3 mo of antiviral therapy

	HCV patients ($n = 50$)	Responders ($n = 36$)	Non-responders ($n = 14$)	Controls ($n = 25$)
Age (yr)	39±13	41±12	37±11	39±10
Sex (m/f)	33/17	25/11	10/4	17/8
AST (U/L)	74±37	35±13	59±17	27±11
ALT (U/L)	97±45	30±11	63±21	23±13
RNA level (×1 000)	723±234	Neg/2 log drop	649±305	Negative

Transaminase levels and RNA copy numbers in HCV patients before and after 3 mo of antiviral therapy. Patients were divided in responders (negative or 2 log steps drop in HCV-RNA copy numbers) or non-responders according to RNA levels. HCV-RNA negative persons served as controls. Normal transaminase values: AST<31 U/L (male), <35 U/L (female); ALT <34 U/L (male), <45 U/L (female).

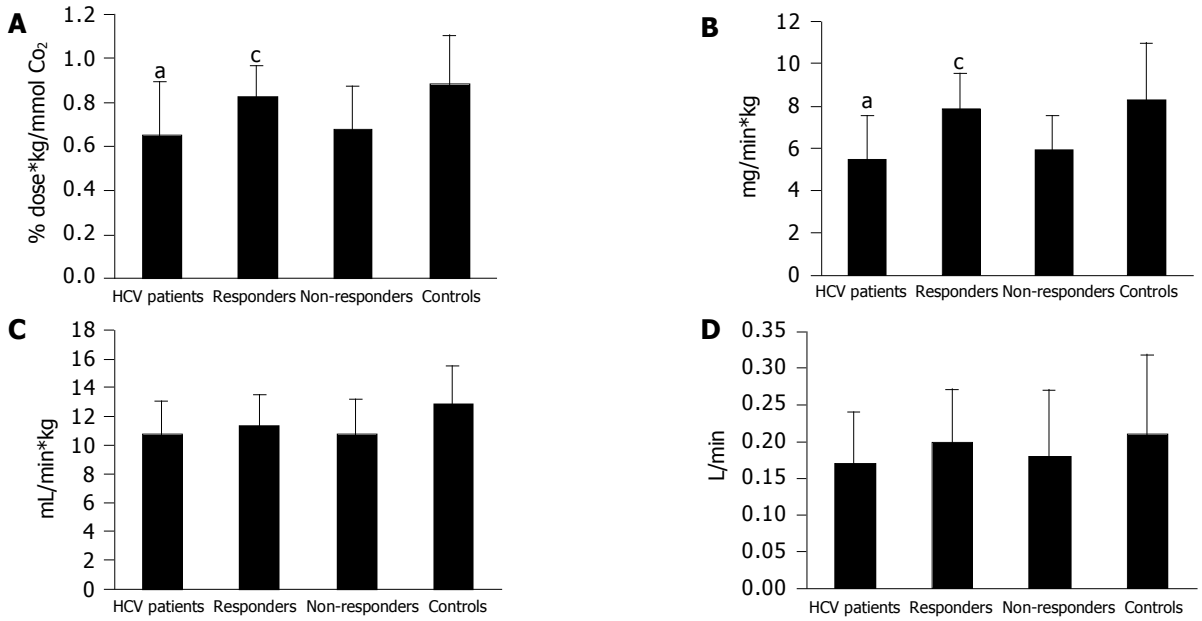

Figure 1 Quantitative testing of liver function in patients with hepatitis C. Shown are mean±SD of QTLF values in healthy controls (n = 25) and HCV patients (n = 50) before and 3 mo after antiviral therapy, divided into responders (n = 36) and non-responders (n = 14). [a]P<0.05 *vs* healthy controls; [c]P<0.05 *vs* pre-treatment values. **A:** Aminopyrine breath test. ABT (% dose-kg/mmol CO_2); **B:** Galactose elimination capacity. panel of QTLF is a useful diagnostic tool to assess prognosis and outcome in different liver diseases[8,13,14]. Although liver damage due to chronic viral hepatitis is considered more predictable than toxic injuries, so far only the application of a single QTLF has been described in small collectives[19,20] and we have shown recently that untreated viral hepatitis influences QTLF in a large cohort[12]. Additionally, we have shown previously that QTLF are inversely correlated with Child-Pugh grades in cirrhotic patients[8]. As there is no information available on the impact of antiviral therapies using INF, INF/RBV or PEG-INF/RBV, we applied a broad panel of QTLF to 50 consecutive patients with chronic HCV infection, 3 mo after beginning the antiviral therapy. At this time point, therapy response is usually re-evaluated to distinguish responders from non-responders to antiviral treatment. HCV has been shown to lead to parenchymal inflammation and to decrease microsomal as well as cytosolic hepatic enzyme capacities, which was independent of the etiology of hepatitis[12].

Compared to healthy controls, we found a significant reduction in metabolic liver function tests (ABT, GEC) in all HCV patients before the initiation of either antiviral therapy. ABT is mainly used to evaluate the prognosis of alcohol-induced hepatitis, paracetamol poisoning or cirrhosis[12,21-23]. ABT can be influenced by pharmacologic induction (e.g., barbiturates, phenytoine) or inhibition (e.g., contraceptives) of microsomal enzymes[14].

GEC was proposed as a prognostic parameter in chronic hepatitis as well as acute liver failure and has been demonstrated to be already reduced in patients with mild fibrosis or acute liver dysfunction[11,22,24].

In HCV patients, reduction of ABT and GEC can be explained by decreased enzymatic capacities caused by active viral replication and expression of viral proteins. Additionally, the total number of vital hepatocytes is decreased in chronic HCV due to ongoing parenchymal inflammation, tissue remodeling and scarring by advancing fibrosis/cirrhosis due to immunologic responses[25]. As responders to antiviral treatment, HCV-RNA was not detectable after 3 mo, independent of the therapy regimen and both metabolic parameters increased to the levels of healthy controls indicating that viral replication strongly influences both microsomal and cytosolic enzymes. HCV is a rapidly replicating virus whose genome is translated into a large polyprotein precursor which undergoes extensive post-translational modifications[26] by using different cellular enzyme systems which might explain lower metabolic QTLF values in HCV patients.

In contrast to the metabolic parameters, QTLF investigating hepatic perfusion (SCl and ICG) were not significantly reduced in the 50 patients with chronic HCV infection and remained unaffected by any response to antiviral therapies. This corroborates previous findings, where hepatic perfusion remained in the normal range even in patients with early fibrotic lesions and irrespective of inflammatory grade of size of the lesions[12]. ICG is considered to be insensitive to pharmacological influences, because its metabolism solely depends on hepatic transport and biliary secretion. Here, we found that 3 mo of different antiviral therapies did not influence ICG, as was shown previously for long-term treatment with beta-blockers, nitrates or antithyroid medications[9,27].

In summary, our results suggest that QTLF monitoring metabolic liver functions (ABT, GEC) may be a useful tool to discriminate responders from non-responders to antiviral therapy regimens in chronic HCV infection after a 3-mo treatment period. While liver perfusion is not altered by either HCV infection or antiviral treatment, ABT and GEC may help to optimize economic and medical treatment strategies in chronic viral hepatitis.

Abstract

AIM: To explore the feasibility of local interleukin 2 (IL-2) in patients with different forms of abdominal cancer. This required experimentation with the time interval between IL-2 applications and the methods of application.

METHODS: Sixteen patients with stages III and IV of gastrointestinal malignancies (primary or metastatic) who were admitted to our Department of Gastroenterology were treated with locoregionally applied IL-2 in low doses.

RESULTS: No major problems applying locoregional IL-2 were encountered. In 6 out of 16 patients, a modest but clinically worthwhile improvement was obtained. Adverse effects were minimal. The therapeutic scheme was well tolerated, even in patients in a poor condition.

CONCLUSION: This study demonstrates the feasibility of low dose locoregional IL-2 application in advanced abdominal cancer. Local IL-2 therapy gives only negligible adverse effects. The results suggest that it is important to apply intratumorally. Local IL-2 may be given adjunct to standard therapeutic regimes and does not imply complex surgical interventions. These initial results are encouraging.

INTRODUCTION

Treatment of cancer with intratumoral or peritumoral IL-2 application is very effective in mice with e.g. transplanted lymphoma[1] and colon carcinoma[2], and in guinea pigs with transplanted liver carcinoma[3]. In veterinary practice, it is also very effective in bovine ocular squamous cell carcinoma[4,5] and in equine sarcoids (fibro-epithelial tumors)[6]. Finally, it is effective in human patients with recurrent superficial bladder carcinoma following transurethral tumor resection[7,8], in patients with advanced nasopharyngeal carcinoma[9], and in patients with lung metastases of renal cell carcinoma[10]. Obviously, local IL-2 treatment does not cure all tumors. That is, in an experiment or a trial, usually only 50-70% of animals with large, metastasized tumors are cured or show complete tumor regression, whereas some tumors like EL4-lymphoma and MOT-carcinoma are not sensitive[11].

A well-known effect of IL-2 is vascular leakage. This side effect severely limits systemic application of IL-2. However, on a local level, this vascular leakage seems to be crucial for the therapeutic effect[2,12,13]. Locally applied IL-2 induces local vascular leakage and local edema, which results in massive tumor necrosis, a characteristic feature in most experimental animals after 5-20 d of local IL-2 treatment. Locally applied IL-2 also induces angiogenesis and attracts numerous macrophages and lymphocytes that invade the tumor debris and boost specific immunity against the tumor[2,14]. Animals that are cured from a transplanted tumor are immune to this tumor[1,3,15], suggesting that an immune response is essential for cure.

Recently we have successfully applied local IL-2 therapy to a patient with hepatocellular carcinoma[16] and to a patient with mesothelioma[17]. These results justified to proceed with local IL-2 therapy. In the present study, we have applied locoregional IL-2 therapy in 16 cancer patients with gastrointestinal malignancies (primary or metastatic) who were hospitalized in the University Gastroenterology Department in Sofia, Bulgaria. No alternative treatment was available for these patients. Our primary aim was to study the feasibility of locoregional IL-2 application in advanced abdominal cancer. Secondly, we wanted to establish, whether clinical improvement could be obtained with this treatment. We present the results of local IL-2 treatment of patients with a variety of advanced abdominal cancers.

MATERIALS AND METHODS

Patients

All the 16 patients were admitted to the Clinic of Gastroenterology for primary or metastatic gastrointestinal cancer. All patients who were admitted to this IL-2 trial were advanced cases with progressive disease (PD, stages III and IV), either inoperable or not fit for standard chemo- or

radiotherapy at the time of admission. Always a clinical oncologist was consulted to exclude that further radio- or chemotherapy was still a valid option. In all cases there was a histopathological diagnosis. Previous chemotherapy or radiotherapy was stopped at least 3 mo before IL-2 treatment. The patients were admitted to the trial, only if non-tumor-related serious conditions were absent such as heart, pulmonary, endocrine, or kidney disease. IL-2 was applied only following extensive information of the patients and with their full consent. All patients were treated in the period of 1999-2003. In Table 1 the characteristics of these patients are summarized.

Interleukin-2

Recombinant human IL-2 (rhIL-2; Proleukin; specific activity 18×10^6 IU/mg) from Chiron was used. RhIL-2 was dissolved according to the manufacturer's instructions and, if necessary, further diluted with 1% albumin and 0.9% NaCl.

Treatment

Our primary intention was to apply IL-2 as close as possible to the tumor (primary or metastatic) and at the site of the anti-tumor immune reaction. Direct intra-peritoneal IL-2 was applied in carcinosis of the peritoneum. In patients W5, W7, and W8, IL-2 could be instilled directly into the malignant ascites. In patients W1, W2, W3, and M3 'ascites' was artificially made by infusing between 500 and 2 000 mL 0.9% NaCl into the peritoneal cavity. Thereafter IL-2 was injected into this 'ascites', in order to ensure an intra-peritoneal spread of IL-2.

In hepatic tumors (primary or metastatic), IL-2 was injected directly into the tumor using a fine needle under ultrasound control or via the hepatic artery under X-ray control. In colon cancer patients with unresected primary tumor, IL-2 was endoscopically applied directly into the tumor. When it was possible, IL-2 was also directly injected into accessible peritoneal tumors.

We applied IL-2 weekly and monthly for 2 mo. In patients with weekly applications, IL-2 was injected every week in 7-d interval and in patients with monthly applications IL-2 was applied every month in 30-d intervals. This was followed by application of IL-2 at 3-mo intervals.

At the beginning of the treatment, when it was possible, we artificially induced necrosis in order to stimulate the immune reactivity[18,19]. For this purpose, 10 d before the start of IL-2 treatment, we applied single procedures of local ablation-percutaneous ethanol injection in five patients with liver tumors (primary or metastatic) and in one patient with unresected primary colorectal cancer-endoscopic ablation.

Ethical committee

The treatment protocol was accepted by the ethical committee of our hospital in Sofia.

Effect of treatment

(1) The effect of therapy was assessed as follows: complete response (CR: disappearance of all tumors and signs of disease); partial response (PR: reduction >50% in the sum of the products of perpendicular diameters of bidimensionally measurable disease or for unidimensionally measurable disease a reduction of ⩾50% in linear tumor measurement compared to those prior to treatment); stable disease (SD: <50% reduction, or an increase of <25% in the sum of the products of perpendicular diameters of bidimensionally measurable disease or in linear tumor measurement for

unidimensionally measurable disease compared to those prior to treatment with no new lesions for at least 4 wk); or PD (increase of ⩾25% in the sum of the products of perpendicular diameters of bidimensionally measurable disease or in linear tumor measurement for unidimensionally measurable disease compared to those prior to treatment/or the appearance of new lesions). Response to treatment was assessed with CT scan and ultrasound control; (2) IL-2 is thought to be effective in palliative therapy of neoplastic effusions[21]. For this reason in patients with malignant ascites we also assessed the effect of our treatment on fluid accumulation according to the following criteria: if there was a complete disappearance of ascites with no further reaccumulation of fluid for more than 30 d, it was defined as CR; if the ascites decreased but there was still minimal asymptomatic fluid, not requiring further drainage within 30 d, it was a PR; if there was further accumulation of fluid requiring paracenteses within 30 d, it was considered as a failure. The patients were assessed by ultrasound control and number of paracenteses. Our criteria for evaluation are similar to those reported by Lissoni *et al*.[20], but we did not drain the ascitic fluid before IL-2 applications in order to enable better spread of IL-2.

This assessment was performed 3 and 6 mo after the commencement of treatment. Separately we assessed the Karnofsky Index in patients in order to follow the changes in quality of life.

RESULTS

Feasibility

Application of IL-2 at the site of the tumor was feasible in all patients. No major obstacles were encountered. Locoregional IL-2 application in doses 1.5-9 MIU IL-2 did not cause undue discomfort, even in patients in poor general condition.

Therapeutic effect

The clinical effects of local IL-2 application are shown in Table 2. (1) After IL-2 treatment, most patients (12/16) had PD. One patient of the 'weekly' scheme (W4) and three patients of the "monthly" scheme (M2, M7, and M8) had SD. These four patients had PD at the start of therapy and stabilization of their disease is a success that was proved by their survival (Table 2). Patient W4 was cachectic at the first presentation. After IL-2 treatment, her condition improved (Karnofsky index of 50 became 80), she had SD for 7 mo. Thereafter liver metastases slowly progressed, liver function tests worsened, but the primary tumor in the colon did not progress. Her survival was 28 mo. Patient M2 showed SD for 8 mo. He was in a relatively good clinical condition and this remained so. Patient M7 had SD for more than 2 years (at the time of diagnosis of HCC he was decompensated, had cirrhosis Child C, and diabetes), and enjoyed an improved quality of life. This patient did not die from the tumor, but due to liver cirrhosis. Patient M8 had SD for 23 mo. At the time of writing this paper a progression of the tumor was registered, but she is still in good general condition. (2). Neoplastic ascites. All patients with malignant effusion were of the 'weekly' scheme. Two of them showed complete reduction of ascites (2/4) after IL-2 treatment, and the other two showed failure to IL-2 treatment. Responding patients were patients W5 and W8. In these two patients, IL-2 was initially applied directly into

Table 2 Therapeutic effect after 3rd mo and survival

A. Once weekly local IL-2 application

No.	Sex	Primary tumor	Clinical effect	Neoplastic effusion	Karnofsky before and after treatment (%)	*Survival mo
W1	M	Pancreatic Ca	PD	-	30-30	4
W2	F	Stomach Ca	PD	-	80-60	3
W3	F	Colorectal Ca	PD	-	80-60	L
W4	F	Colorectal Ca	SD	-	50-80	28
W5	M	Colorectal Ca	PD	Complete reduction	70-90	10
W6	F	Ovarian Ca	PD	Failure	60-50	2
W7	F	Mammary Ca	PD	Failure	60-40	1
W8	M	Hemangiosarcoma	PD	Complete reduction	50-80	12

B. Once monthly local IL-2 application

No.	Sex	Primary tumor	Clinical effect	Karnofsky before and after treatment (%)	*Survival mo
M1	M	HCC Liver cirrhosis	PD	70-70	4
M2	M	HCC Liver cirrhosis	SD	80-80	24A
M3	M	Abdominal mesothelioma	PD	80-50	6
M4	F	Colorectal Ca	PD	80-70	L
M5	F	Mammary Ca	PD	40-40	1
M6	F	Mammary Ca	PD	80-80	L
M7	M	HCC Liver cirrhosis	SD	90-90	27
M8	F	HCC Liver cirrhosis	SD	80-90	24A

I survival since the start of IL-2 therapy till death; W, weekly IL-2 application; M, monthly IL-2 application; A, alive; L, lost for follow-up; Ca, carcinoma; HCC, hepatocellular carcinoma; PD, progressive disease; SD, stable disease.

the neoplastic effusion, but with the reduction of the ascites, subsequent IL-2 applications were made into artificially made ascites. Patient W8 had complete reduction of ascites and significant reduction of the pleural effusion, though liver metastases progressed. The quality of life after IL-2 treatment had improved (Karnofsky index of 50% became 80%). Patient W5 had complete reduction of ascites and improved quality of life (Karnofsky of 70% became 90%) enabling him to resume his usual activities. (3) In conclusion, 6 out of 16 patients seemed to benefit more or less from IL-2 application at the site of the tumor. Three out of eight patients of the 'weekly' scheme improved -one had SD and two had reduction of ascites, and also 3/8 patients of the "monthly" scheme showed SD. Therapeutic results did not differ between the 'weekly' and the 'monthly' treatment schedule. Comparison with historical controls in our study was not possible due to the heterogeneity of our patients. In future larger prospective trial should be done.

Adverse effects

Adverse effects were minimal. The therapeutic scheme was well tolerated, even in patients in a poor condition. Often moderate fever was observed, though rarely above 38.2 ℃. A transient local skin rash was observed in one patient after intra-peritoneal IL-2 application.

DISCUSSION

This study shows that treatment of cancer, presented at a gastro-intestinal clinic, with locoregionally applied IL-2 in doses 1.5-9 MIU was feasible. No major problems arose. Locoregional IL-2 treatment induced a modest but worthwhile clinical gain: 6/16 patients benefited from this treatment. Four patients had SD for some time after IL-2 treatment and two had reduction of ascites. Four patients had an improved Karnofsky Index. Two patients lived considerably longer than was clinically expected (>24 and 27 mo).

Probably vascular leakage causing edema and subsequent tumor necrosis are indirect effects of local IL-2 application. IL-2 has pleiotropic immune effects *in vivo* and probably leads to macrophage reaction and homing of specific lymphocytes. Induction of tumor necrosis by irradiation[19] or Cisplatin[6,18] further enhances the therapeutic effect of following local IL-2 injections. Therefore, necrosis was induced in five of our patients. We applied only single procedure of local ablation, which cannot create significant necrosis, and therefore cannot lead to the therapeutic effect observed in our patients alone.

Whereas chemotherapy of cancer is usually connected with serious side effects such as extensive nausea and fatigue, leucopenia and related to this infections, such features were not observed in the patients treated with local IL-2 applications in these doses. Another advantage of this treatment is that IL-2 can usually be applied without complex surgical intervention. Further this treatment is cheap since only limited amounts of IL-2 are required.

Therapeutic gain might even be better if we can fine-tune our protocol. The results of this feasibility study thus warrant proceeding with a larger trial to further establish the effect of local IL-2 application in advanced gastro-intestinal cancer in combination with standard anti-cancer treatment.

In conclusion, this study demonstrates the feasibility of low dose locoregional IL-2 application in advanced abdominal cancer.

Local IL-2 application in patients with advanced GI malignancies led to modest but worthwhile clinical improvement in 6 out of 16 patients.

Important are the absence of adverse effects or serious discomfort, and the limited expenses.

Abstract

AIM: To investigate those associations using data of the population-based Study of Health in Pomerania.

METHODS: A study population of 3 749 residents aged 20-79 years without previously diagnosed thyroid disease was available for analyses. Serum TSH was used to assess thyroid function. Cholelithiasis was defined by either a prior history of cholecystectomy or the presence of gallstones on ultrasound. Logistic regression was performed to analyze independent associations between thyroid function and cholelithiasis.

RESULTS: There were 385 persons (10.3%) with low (<0.3 mIU/L), 3 321 persons (88.6%) with normal and 43 persons (1.2%) with high serum TSH levels (>3 mIU/L). The proportion of cholelithiasis among males and females was 14.4% and 25.3%, respectively. Among males, there was an independent relation between high serum TSH and cholelithiasis (OR 3.77; 95%-CI 1.06-13.41; $P<0.05$). Also among males, there was a tendency towards an elevated risk of cholelithiasis in persons with low serum TSH (OR 1.40; 95%-CI 0.96-2.02; $P = 0.07$). In the female population, no such relation was identified.

CONCLUSION: There is an association between thyroid and gallstone disease with a gender-specific relation between hypothyroidism and cholelithiasis.

INTRODUCTION

For decades, there has been a discussion, whether thyroid disorders could cause gallstone disease. Particularly, there are several explanations for a possible relation between hypothyroidism and gallstone disease. These explanations include the known link between thyroid failure and disturbances of lipid metabolism[1] that may consecutively lead to a change of the composition of the bile. Recent studies[2] also demonstrated low bile flow in hypothyroid subjects. Furthermore, the sphincter of Oddi expresses thyroid hormone receptors and thyroxine has a direct prorelaxing effect on the sphincter[3]. Both low bile flow and sphincter of Oddi dysfunction are regarded as important functional mechanisms that may promote gallstone formation[4].

In a series of 668 female patients who had undergone cholecystectomy for gallstone disease, the proportion of treated hypothyroidism was 2.4% compared to 0.8% in the 782 controls[5]. Other studies[6] found a proportion of previously diagnosed hypothyroidism of 8% and 6% in patients having common bile duct and gallbladder stones, respectively, compared to a proportion of only 1% in the controls. The usage of thyroxine was even suspected to dissolve gallstones[7]. However, a spontaneous passage of the stone to the duodenum could not be excluded in this case report[7]. In an animal model of rabbits in whom a fatty diet induced gallstone formation, administering thyroxine was associated with a low gallstone weight, but did not dissolve the gallstones[8].

Previous studies[5,6] that investigated the association between thyroid function and gallstone disease in human beings, were conducted in a series of patients with potential for selection bias that may have produced false positive results. Furthermore, the statistical analyses were only controlled for age, but not for further confounders in both studies[5,6]. To our knowledge, there is only one large case-control study[9] that was appropriately adjusted for other risk factors of gallstone disease. In this study[9], no independent relation between thyroid disorders and gallstone formation was found. Unfortunately, the exposure was only defined as previous history of thyroid disease, and assessments of the current thyroid function status were not included. Moreover, there are currently no investigations that also include ultrasound to evaluate asymptomatic gallstones in this context.

Therefore, the aim of our study is to analyze the association between thyroid function and the risk of cholelithiasis using the data on the population-based Study of Health in Pomerania (SHIP).

MATERIALS AND METHODS

The Study of Health in Pomerania (SHIP) is a cross-sectional

examination in West Pomerania, the north-eastern part of Germany[10]. The study region is a formerly iodine deficient area with a high prevalence of iodine deficiency-related disorders such as goiter, thyroid nodules and decreased serum TSH levels[11]. A stable and adequate iodine supply has been achieved in the study area for the past decade. A random sample from the population aged 20-79 years was drawn. The sample was selected using population registries. Only individuals with German citizenship and main residency in the study area were included. There were 7 008 subjects sampled, with 292 persons of each gender in each of the 12 five-year age strata. The net sample (without migrated or deceased persons) comprised 6 267 eligible subjects. Selected persons received a maximum of three written invitations. In case of no response, letters were followed by a phone call or by home visits, if contact by phone was not possible. The final SHIP sample comprised 4 310 participants (final response proportion 68.8%). All participants gave informed written consent. The study protocol is consistent with the principles of the Declaration of Helsinki and was approved by the Ethics Committee of the University of Greifswald.

All 423 persons with known thyroid disorders or current thyroid medication according to the anatomic, therapeutic and chemical (ATC) code H03 (iodine, thyroid hormone replacement, suppression therapy or thyrostatics), 44 more persons without data on serum TSH levels and 94 more persons with no liver ultrasound or uncertainty with regard to cholelithiasis were excluded. This resulted in a study population of 3 749 subjects who were available for the present analysis.

Sociodemographic characteristics and medical histories were assessed by computer-assisted personal interviews. Education was categorized into three levels [low (<10 years), medium (10 years), high (>10 years), categories based on the East German three-level school system]. Individuals who participated in physical training during summer or winter for at least 1 h a week were classified as being physically active. According to the smoking habits participants were categorized into current, former and non-smokers. Diabetes was defined as a self-reported physician's diagnosis of diabetes, or serum hemoglobin A1c >7%. Body height and weight were measured for the calculation of the body mass index (BMI = weight [kg]/ height^2 [m^2]). Blood samples were taken, and laboratory parameters were analyzed in a central laboratory. Serum low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol were precipitated and measured photometrically (Boehringer GmbH, Mannheim, Germany). Serum thyrotropin (TSH) was analyzed by immunochemiluminescent procedures (LIA-mat, Byk Sangtec Diagnostica GmbH, Frankfurt, Germany). All TSH measurements were performed in one central laboratory. The functional sensitivity of the TSH assay was 0.03 mIU/L. The reference range was 0.3-3 mIU/L.

The liver was examined using a 5 MHz transducer and a high-resolution instrument (Vingmed VST Gateway, Santa Clara, USA). The sonographers were unaware of the participant's clinical and laboratory characteristics. Gallstones were present if the gallbladder contained echoes that moved with gravity except when the stones were large, a septum existed in the gallbladder or there was an enclosed infundibulum[12]. Cholelithiasis was defined as previous history of cholecystectomy or current, sonographically diagnosed gallstones.

Statistical analyses

Data on quantitative characteristics are expressed as mean±SD. Data on qualitative characteristics are expressed as percentage values or absolute numbers as indicated. The study population was divided according to the TSH reference values that were provided by the manufacturer. The three groups consisted of persons with low (<0.3 mIU/L), normal (0.3-3 mIU/L) and high (>3 mIU/L) serum TSH levels. Comparisons between groups were made using χ^2-test (nominal data) and analysis of variance (ANOVA, continuous data). Sex-stratified logistic regression was performed in order to evaluate independent relationships between thyroid function and cholelithiasis. All analyses were adjusted for age and further potential confounders. Since missing values were present in some variables, data of 30 males (1.54%) and 21 females (1.17%) were lost for multivariable analyses. Serum lipids as mediators were not considered. The odds ratio (OR) was calculated, values being given as lower and upper 95%-confidence interval (CI). A value of $P<0.05$ was considered statistically significant. All statistical analyses were performed with SPSS software, version 11.0.5 (SPSS GmbH Software, Munich, Germany).

RESULTS

There were 385 persons (10.3%) with low, 3 321 persons (88.6%) with normal and 43 persons (1.1%) with high serum TSH levels. The three groups were compared with respect to baseline demographic and clinical characteristics (Table 1). Persons with low serum TSH levels were older, less educated, less physically active and had lower serum HDL cholesterol levels than persons with serum TSH levels within the reference range (Table 1). Compared to the latter persons, individuals with high serum TSH levels were more often of female gender and had higher serum total cholesterol concentrations (Table 1).

The proportion of persons with cholelithiasis among the total sample was 19.7% (Table 2). Women were affected nearly twice as often as men (OR females *vs* males 2.01; 95%CI 1.71-2.37). While gallstones were only slightly more often detected by ultrasound in women than in men (OR 1.54; 95%CI 1.24-1.92), females reported particularly more often a previous history of cholecystectomy compared to males (OR 2.63; 95%CI 2.09-3.30; Table 2). Given these gender-related differences, all multivariable analyses were performed separately among males and females. These analyses revealed an advanced age, high BMI and low serum HDL cholesterol levels as independent risk factors for cholelithiasis in males as well as in females (Table 3).

The prevalence proportions of cholelithiasis among males with low, normal and high serum TSH levels were 22.5%, 13.3% and 30.8%, respectively. Bivariate analyses revealed an increased proportion of cholelithiasis in male persons with low serum TSH levels. This association bordered statistical significance after adjustment for potential

HDL cholesterol; per 10 mg/dL	0.87 (0.78–0.97)	0.87 (0.78–0.97)

Logistic regression analysis, OR denotes odds ratio; 95%CI, confidence interval; LDL, low density lipoprotein; HDL, high density lipoprotein.

confounding variables (Table 4). The full model in the male study population further revealed an independent association between high serum TSH levels and cholelithiasis (Table 4). The prevalence proportions of cholelithiasis among females with low, normal and high serum TSH levels were 31.7%, 24.7% and 26.7%, respectively. The relation between low serum TSH levels and cholelithiasis that was found in bivariate analyses was not stable after appropriate adjustment for relevant confounders. Likewise, there was no independent association between high serum TSH levels and cholelithiasis in women (Table 4).

Further analyses were performed using ultrasound diagnosis of gallstones as the dependent variable. In the male population, multivariable analyses did not attain statistical significance for the association between low serum TSH levels and the endpoint (OR 1.25, 95%CI 0.78-2.02; P = 0.36). High serum TSH levels, however, were again detected as an independent risk factor for sonographically detected gallstones (OR 4.85, 95%CI 1.19-19.74; P<0.05). In the female population, no such association was present. Additional multivariable analyses that were run with previous history of cholecystectomy as the dependent variable also did not find an association between serum TSH levels and this endpoint in women. However, in the male population, the relation between low serum TSH levels and previous history of cholecystectomy bordered statistical significance (OR 1.55, 95%CI 0.94-2.56; P = 0.07), whereas no association between high serum TSH levels and this endpoint was observed (OR 1.91, 95%CI 0.22-16.59; P = 0.56).

Moreover, persons with a previous history of thyroid disease were compared to the study population with respect to their risk of cholelithiasis. Among both the sexes, persons with thyroid disease had cholelithiasis more often than persons without known thyroid disease (23.0% *vs* 14.5% in males and 38.4% *vs* 25.6% in females; P<0.05). After adjustment for the full model, however, there was no independent relation between thyroid and gallstone disease in males as well as females.

DISCUSSION

The present study investigated possible associations between serum TSH levels and gallstone disease. There was an independent relation of high serum TSH levels with cholelithiasis among males, predominantly among those who had sonographically detected gallstones. In the female population, no such associations were identified.

At least in the male population, the finding of high serum TSH levels as an independent risk factor for cholelithiasis confirm previous research[5,6]. An absence of such an association among females might be explained by two points. Firstly, the study population only comprised persons with as yet undiagnosed thyroid disorders. Females were more often excluded due to a known thyroid disorder than males. Thus, there might be earlier diagnosis and treatment of hypothyroidism in women compared to men, reflected by a longer and more intense exposure in males. Likewise, the higher proportion of cholelithiasis in women compared to men was mainly due to the higher proportion of previous history of cholecystectomy in females. Thus, in women,

gallstones may become symptomatic earlier than in men and the consecutive diagnostic procedures may further lead to an earlier detection and treatment of hypothyroidism. This assumption is supported by the fact that the association between high serum TSH levels and cholelithiasis was mainly found in males with sonographically detected gallstones. Secondly, there are also gender differences with respect to the type of gallstones. In one study[13], males had less often cholesterol stones than women. One may assume that, if hypothyroidism would indeed be a causal factor for gallstone disease, then this may lead to a specific type of stone other than cholesterol stones. In the same study[13], however, there was no association between thyroid function and the stone type.

In the male population, also an association between low serum TSH levels and cholelithiasis bordered statistical significance in the full model. This was not expected, because experimental evidence suggested a direct association between thyroid function and the bile flow to the duodenum. While the flow was reduced in hypothyroidism, it was enhanced in hyperthyroidism[14]. However, this study[14] was performed in rats without gall bladder. In hamsters, extremely high doses of thyroxine may induce the formation of gallbladder stones[15]. In the present study, particularly males with low serum TSH levels had a higher risk of previous cholecystectomy. Thus, a cholelithiasis may become symptomatic in an earlier state in hyperthyroid persons. In general, the role of hyperthyroidism with respect to gallstone formation in human beings is currently not well investigated and further research is needed.

The exclusion of patients with known thyroid disorders resulted in small numbers of individuals with hypothyroidism, limiting the power of the statistical analysis. We therefore repeated the analyses including these persons. The results confirmed an increased cholelithiasis prevalence in persons with previously diagnosed thyroid disease, however, there was no independent relation between these two parameters. In patients with known thyroid disease the thyroid function status may change dramatically over time mainly due to the effects of treatment. Further confounding variables in patients with known thyroid disease may include medical treatment, better health education and more frequent and intense contact with medical personnel.

Previous studies[16] that were conducted in a neighborhood region identified a high cholelithiasis prevalence proportion of greater than 30% and 55% in men and women who were ⩾65-years old, respectively. This high prevalence is in good agreement with the results of our study. Also in accordance with other studies[17], an advanced age, high BMI and serum lipids were identified as major independent risk factors for cholelithiasis. This argues for the good validity of the diagnostic method to define cholelithiasis used in the present study.

We conclude, that there is a gender-specific relation between hypothyroidism and cholelithiasis. Especially males with gallstones should be further examined for thyroid disorders. Further research is needed to explain the role of low serum TSH levels with respect to gallstone disease in men.

Abstract

AIM: To search the pathophysiological mechanism of diarrhea based on daily stool weights, fecal electrolytes, osmotic gap and pH.

METHODS: Seventy-six patients were included: 51 with microscopic colitis (MC) [40 with lymphocytic colitis (LC); 11 with collagenous colitis (CC)]; 7 with MC without diarrhea and 18 as a control group (CG). They collected stool for 3 d. Sodium and potassium concentration were determined by flame photometry and chloride concentration by titration method of Schales. Fecal osmotic gap was calculated from the difference of osmolarity of fecal fluid and double sum of sodium and potassium concentration.

RESULTS: Fecal fluid sodium concentration was significantly increased in LC 58.11±5.38 mmol/L (P<0.01) and CC 54.14±8.42 mmol/L (P<0.05) than in CG 34.28±2.98 mmol/L. Potassium concentration in LC 74.65±5.29 mmol/L (P<0.01) and CC 75.53±8.78 mmol/L (P<0.05) was significantly less compared to CG 92.67±2.99 mmol/L. Chloride concentration in CC 36.07±7.29 mmol/L was significantly higher than in CG 24.11±2.05 mmol/L (P<0.05). Forty-four (86.7%) patients had a secretory diarrhea compared to fecal osmotic gap. Seven (13.3%) patients had osmotic diarrhea.

CONCLUSION: Diarrhea in MC mostly belongs to the secretory type. The major pathophysiological mechanism in LC could be explained by a decrease of active sodium absorption. In CC, decreased Cl/HCO_3 exchange rate and increased chloride secretion are coexistent pathways.

INTRODUCTION

Microscopic colitis is a new form of idiopathic inflammatory bowel disease. First studies dealing with microscopic colitis appeared in the late seventies[1-3]. Clinical manifestations are substantially milder than other forms of idiopathic inflammatory bowel diseases. The main characteristics include chronic watery diarrhea and abdominal cramps. Endoscopic[4-8] and radiological examination of gastrointestinal tract are normal. The major criteria for diagnosis are set on the basis of histological findings of colonic mucosal biopsies[9] and stool examinations. There are two basic types of microscopic colitis: collagenous and lymphocytic colitis. They could be differentiated on the basis of pathohistological findings. Collagenous colitis is defined by the appearance of diffuse thickening of subepithelial collagenous band (>10 μm)[10], desquamation and degeneration of surface epithelium, increased number of intraepithelial lymphocytes and mild or moderate mononuclear infiltration of lamina propria[10,11-13]. Collagenous colitis shows striking predominance in women (F:M 7:1) in their fifth and sixth decades[4,10,14]. They are often associated with other autoimmune diseases: rheumatoid arthritis[15-17], systemic and discoid lupus erythematosus[18,19], juvenile scleroderma[20], CREST syndrome[21], abnormal function of thyroid gland[14]. Lymphocytic colitis is defined by increased number of intraepithelial lymphocyte of colonic mucosa (>20 IEL per 100 epithelial cells)[10]. Other histological features include flattened surface epithelium with mucine depletion, mononuclear infiltration of lamina propria, and minimal crypt distortion or cryptitis[10,11]. Lymphocytic colitis typically occurs in the sixth decade with roughly equivalent female to male ratio[10,14,19-21]. According to data from the literature there is an association between lymphocytic colitis and other

autoimmune diseases: sicca syndrome[15], celiac disease[24-26] idiopathic pulmonary fibrosis, uveitis, and idiopathic thrombocytopenic purpura[12]. Ethiopathogenesis of microscopic colitis still remains unclear. The long-term use of NSAID[27], and other medication (cyclo3fort[28], ranitidine[29], ticlodipin) could be important. A good number of authors[19,20,30] claim that autoimmune process is the cause of prime importance in ethiopathogenetic mechanism.

Intraepithelial lymphocytes in lymphocytic and collagenous colitis belong to T suppressor cells, CD_8 group[19]. Stimulated by some luminal antigen they can cause cross reaction with endogen antigen present in the epithelial cells, damage them or reveal direct toxic action on the enterocytes[31]. The hypothesis of the infective etiology of microscopic colitis is based on the results of success of antibiotic therapy[4]. Bile acids also may play a role as shown by malabsorption of bile acids and proper therapeutic response to the cholestiramine[32], which is also suggested by combined manifestation with primary ileal villous atrophy[33]. Deregulation of a collagen synthesis[19,33] has also been mentioned as a possible etiological factor. The precise pathophysiological mechanism of secretory diarrhea typical for microscopic colitis has not been clarified. Most of the authors[31,34,35] believe that the following processes prevail in the development of secretory diarrhea:

- Reduced active sodium absorption
- Inhibited chloride and bicarbonate exchange
- Increased electrogenic chloride secretion followed by passive sodium and water transport.
- Decreased passive permeability of colonic mucosa.

Evidence for each of these hypotheses is contained in a Bo-Linn perfusion study[34]. Results of net and unidirectional electrolyte fluxes and electrical potential difference suggested that colonic fluid absorption was abnormal. The main reasons for these are: reduced active and passive sodium and chloride absorption and reduced Cl/HCO_3 exchange. Zeroogian and Chopra thought that mediators secreted by inflammatory cells in lamina propria may play an important role in disturbances of absorptive colonic capacity and reducing passive transport[21]. Other authors consider that watery diarrhea is a consequence of increased active chloride intraluminal secretion and accompanying passive sodium and water transport[31,35]. Increased concentration of prostaglandin E2 secreted by pericryptal fibroblasts may stimulate active chloride secretion. Pericryptal fibroblasts compose pericryptal sheets which can cause functional abnormalities. In some cases an increased concentration of prostaglandin E2 is found in jejunal aspirate and feces[31]. The same group considers that injured surface epithelium and collagen deposit band of colonic mucosa may prevent absorption of luminal water and electrolytes. The most important pathophysiological role could be played by inflammatory cells infiltrated in the lamina propria, common characteristic for both lymphocytic and collagenous colitis. Precise mechanism of diarrhea remains unclear due to unknown etiological factors yet to be discovered. It is possible that different mechanisms cause diarrhea in the course of the disease, depending on whether pericryptal absorption site are blocked by the collagen deposit or inflammatory cells infiltrate.

MATERIALS AND METHODS

The study was performed in the Center for Gastroenterology and Hepatology (Zvezdara, University Clinical Center, Belgrade) between 1993 and 2004. Seventy-six people were included in the study (58 with diagnoses of microscopic colitis and 18 healthy people composing a control group).

The following diagnostic procedures were performed in both groups: routine biochemical examinations with electrolyte status, lactose tolerance test, thyroid status, presence of antinuclear antibody (ANA), antimitochondrial antibody (AMA) and antibodies to tyreoglobulin; standard and specific (*Yersinia enterocolitica* and *Campylobacter jejuni*) stool examinations for bacteria and parasites; duodenal tube with quantitative and qualitative bacterial culture of aspirate; small bowel barium enema, enteroscopy with small bowel biopsies; colonoscopy with terminal ileoscopy and serial biopsies of colonic and terminal ileum mucosa. Biopsy specimens were fixed with 40 g/L formaldehyde and embedded in paraffin. Five micrometer sections were stained with hematoxylin and eosin. Thickness of the subepithelial collagen layer was measured with light microscopy using screw micrometer by an experienced pathologist. Number of intraepithelial lymphocytes was determined with regard to 100 epithelial cells of colonic mucosa.

Functional examinations of stool

Stool samples All patients collected stool for 3 d (72 h) in preweight plastic bucket that held 3-5 L. Buckets with stools were kept cold under refrigeration (+4 ℃) during the collection period. During that time patients were on a diet with 70-100 g fats per day.

Determination of sodium, potassium and chloride concentration in fecal fluid Concentration of sodium and potassium were determined by flame photometry (Corning 480 Flame Photometer)[36,37] and chloride concentration by the titration method of Schales[38]. Data of sodium, potassium and chloride were multiplicities with water dilution factor. Daily losses of electrolytes by stool were calculated from the concentration of electrolytes in fecal fluid. Fecal osmotic gap was calculated from the difference of measured osmolality of fecal fluid and double sum of the sodium and potassium concentration [290-(Na+K)×2].

Estimation of pH of fecal fluid For estimating fecal pH we used balanced Beckman Expandomatic pH meter[37].

Determination of daily fecal fat The amount of fat in daily stool was quantified by titration method of Van de Kamer[39]. Normal values of fecal fat in our laboratory are less than 6 g/d. Normal values by the data of Fine are 6.4 g/d[40,43].

Statistical analysis

For all tested parameters we calculated mean and standard error (SE). For the statistical significant difference ($P<0.05$) among different group of patients, unpaired Student's *t*-test was used.

RESULTS

There were 51 patients with complete conditions for diagnosis

of microscopic colitis [40 patients with lymphocytic colitis (LC) and 11 patients with collagenous colitis (CC)]. Seven patients had histological diagnoses of MC (5 patients with LC and 2 with CC) without diarrhea at that moment. Control group consisted of 18 healthy persons.

Based upon the status of the collagen plate and the number of IEL of biopsy specimen of right colon, patients are classified as a group with LC or CC or CG (Table 1). In the group of patients with LC the median number of IEL/100 epithelial cells was (32±12) and the mean thickness of collagen plate was (8±2) μm with moderate inflammation of lamina propria. Patients with CC had average thickness of collagen band (25±9) μm and (14±4) IEL/100 epithelial cells with severe inflammation of lamina propria. Control group of patients had (4±1) IEL/100 epithelial cells and mean thickness of collagen plate (8±3) μm.

Physical examination, all biochemical tests, radiological and endoscopic findings were normal in all patients. Diagnoses of microscopic colitis was established based on the data of verified diarrhea [daily stool weight (DSW)> 200 g/24 h] and histopathology analysis of biopsy specimens of colonic mucosa. Mean values of DSW (mean±SE) in the group of patients with LC and CC were statistically significantly higher than in the other two groups: CG and group of 7 patients with histological signs of microscopic colitis without diarrhea ($P<0.01$, Table 2). The average values of sodium concentration in the patients with LC ($P<0.01$) and CC ($P<0.05$) were statistically significantly different than in the CG. Daily fecal loss of this electrolyte patient with LC and CC was statistically significantly different than among the healthy people ($P<0.05$, Figure 1) The mean values of potassium concentration in patients with LC ($P<0.01$) and CC ($P<0.05$) were statistically significantly different than CG. Daily fecal loss of potassium in patients with LC and CC was statistically significantly different with regard to CG ($P<0.05$). The average value of chloride concentration in patients with CC was statistically significantly different with regard to CG ($P<0.05$). Daily fecal loss of this electrolyte in patients with LC and CC was statistically significantly different than among the healthy people ($P<0.05$). We tried to clarify the mechanism of diarrhea by calculation of the fecal osmotic gap (FOG). Secretory diarrhea (FOG <50 memo/kg) was found in 44 (86.7%) of patients with microscopic colitis. Osmotic diarrhea was present in 7 (13.3%) of patients. The reason in determining the concentration of fecal fat in patients with LC and CC was to establish possible impact of some other disease (small bowel or pancreatic) on pathophysiological mechanism of diarrhea. Six (11.7%) patients with LC had slightly increased daily fecal fat (9-11 g/24 h). DSW in the group of patients [9 (17.46%)] with LC and accompanying disease (mean: 315.10 g/24 h) was not statistically significantly different than in the group of patients with LC (mean: 372.64 g/24 h). The average values of fecal pH in the patients with LC (6.31±0.14) and CC (6.36±0.11) were not statistically significantly different compared to CG.

Table 1 Mean±SD of number of IEL/100 EC and thickness of collagen plate in patients with LC and CC

	n	No. of IEL/100 EC (mean±SD)	Thickness of collagen band (mean±SD)	Inflammation of propria

Collagenous colitis	13	14±4	25±9	Severe
Control group	18	4±1	8±3	Mild/none

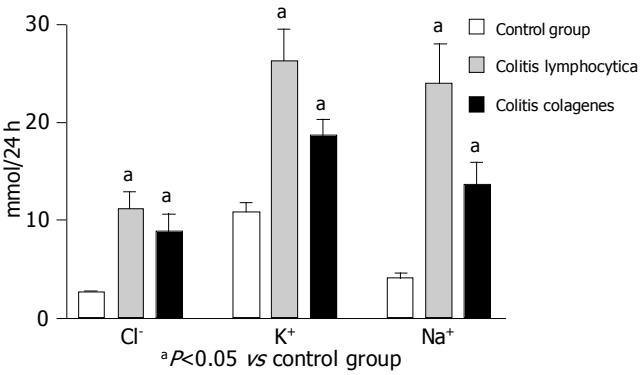

Figure 1 Average values of fecal daily loss of Na^+, K^+, Cl^- (mean±SE).

DISCUSSION

Precise mechanism of diarrhea in patients with microscopic colitis still remains unclear. Most of the authors[31,34,35] believe that dominant processes in the development of diarrhea are: 1. Reduced active sodium absorption 2. Inhibited chloride and bicarbonate exchange 3. Increased electrogenic chloride secretion followed by passive sodium and water transport. 4. Decreased passive permeability of colonic mucosa. First data about mechanism of secretory diarrhea were established by Bo-Linn perfusion study[34]. The average values of DSW in this and other similar studies[21,33,34] were higher than values from our study (LC: 200, 2-1 400 g/24 h; CC: 206-350 g/24 h). Using "steady-state" perfusion method, the authors have proved that electrolyte and fluid absorption in colon were seriously disturbed in patients with microscopic colitis. The reasons for reduced electrolyte and fluid absorption are microscopic changes of colonic mucosa. Degenerative injuries of surface epithelium, subepithelial

collagen deposit and persistence of inflammatory cells (prostaglandin E2)[31,34,35] infiltrate in lamina propria play the most important role in decreased absorption of luminal water and electrolyte. Pathohistological findings of colonic biopsy specimen in our patients are in accordance with the results of previous studies[8-10]. Decreased active sodium absorption is visible by a reduction of the flux lumen/plasma of sodium and chloride. Inhibited chloride and bicarbonate exchange is shown by the reduced bicarbonate secretion rate and lowered chloride absorption[34]. In our study, sodium concentration of the fecal fluid in patients with LC and CC was highly increased in relation to control group. These facts are in accordance with data of other authors. Potassium concentration in fecal fluid of patients with LC and CC was significantly less compared to CG. But the average values of potassium concentration were higher with regard to data from other studies. The mean values of chloride concentrations in patients with CC were statistically significantly higher with regard to CG. These results in our study were less than the data of other authors[34,35]. Daily fecal loss of electrolyte in patients with LC and CC were significantly higher compared to a group of healthy persons. These results were expected for sodium and chloride, due to great concentration of these electrolytes in fecal fluid. Despite smaller potassium fecal concentration, great potassium fecal loss appeared, due to daily stool weight. This fact could have clinical significance and could explain uncommon severe hypokalemia in some patients with microscopic colitis. Finally, our results of fecal electrolytes concentration and their daily fecal loss also confirm the hypothesis of disturbed active sodium absorption and absorption/secretion of chloride[31,34,35,41]. The dominant process in electrolyte malabsorption in patients with LC could be reduced by active sodium absorption. In the group of patients with CC prevailing mechanisms are decreasing the rate of Cl/HCO3 exchange and increased electrogenic Cl secretion, in addition to, reduced active sodium absorption. There were no significant differences between main values of fecal pH of examined patients with LC and CC with regard to healthy persons. Still it is interesting to note that all patients with proper therapeutic response to cholestyramine had slightly increased fecal pH (>6.8). This data could suggest possible co-factorial influence of bile acid malabsorption[17,33] on the mechanism of diarrhea in microscopic colitis. Only 6 (11.7%) patients had slightly increased daily fecal fat (9-11 g/24 h). All of them had lymphocytic colitis. In the group of patients with microscopic colitis and associated disease there were no differences in average values of daily stool weight compared to patients with microscopic colitis without accompanied disease. On the basis of our results it could be concluded that influence of accompanied disease on the mechanism of diarrhea is of secondary importance. Most of the authors[31,34,41-43,45] claim that secretory diarrhea is characteristic of microscopic colitis. By Erer's criteria, the border value of fecal osmotic gap (FOG) for distinction between secretory and osmotic diarrhea is 50 mOsmol/kg[43,44]. In our study 86.7% of patients had secretory diarrhea and 13.3% osmotic diarrhea. All patients with secretory diarrhea belong to the group of patients with lymphocytic colitis. There was a group of 7 patients with histological diagnosis of microscopic colitis and without approved diarrhea. All of them had intermittent diarrhea. We recommended them to collect stool during the period of diarrhea. The schedule for future examination of these patients remains imprecise.

In conclusion, on the basis of our results it could be stated that diarrhea in microscopic colitis (LC, CC) belongs to the secretory type. The major pathophysiological mechanism in patients with LC may be a decrease of active sodium absorption. In collagenous colitis decreased Cl/HCO_3 exchange rate and increased electrogenic chloride secretion is coexistent pathway in the genesis of diarrhea.

Abstract

AIM: To determine the tolerability and safety profile of a low-dose maintenance therapy with 6-TG in azathioprine (AZA) or 6-mercaptopurine (6-MP) intolerant inflammatory bowel disease (IBD) patients over a treatment period of at least 1 year.

METHODS: Database analysis.

RESULTS: Twenty out of ninety-five (21%) patients discontinued 6-TG (mean dose 24.6 mg; mean 6-TGN level 540 pmol/8×10^8 RBC) within 1 year. Reasons for discontinuation were GI complaints (31%), malaise (15%) and hepatotoxicity (15%). Hematological events occurred in three patients, one discontinued treatment. In the 6-TG-tolerant group, 9% (7/75) could be classified as hepatotoxicity. An abdominal ultrasound was performed in 54% of patients, one patient had splenomegaly.

CONCLUSION: The majority of AZA or 6-MP-intolerant IBD patients (79%) is able to tolerate maintenance treatment with 6-TG (dosages between 0.3 and 0.4 mg/kg per d). 6-TG may still be considered as an escape maintenance immunosuppressant in this difficult to treat group of patients, taking into account potential toxicity and efficacy of other alternatives. The recently reported hepatotoxicity is worrisome and 6-TG should therefore be administered only in prospective trials.

INTRODUCTION

Until now, no definite medical or surgical therapy is available for the treatment of inflammatory bowel disease (IBD) as the etiology remains essentially unknown. Therefore, the aims of medical therapy in IBD are relief of symptoms and to prevent long-term complications. Maintenance therapy should preferably be efficient, safe, and cost-effective. The immune modulating thiopurines 6-mercaptopurine (6-MP) and its pro-drug azathioprine (AZA) have proven efficacy in active IBD and in maintenance of an induced clinical remission[1]. These thiopurines are prescribed on a large scale in IBD and are considered as a mainstay treatment option. However, issues concerning delayed onset of activity, refractoriness, and toxicity have limited the general use of AZA and 6-MP. In previous reports, up to 20% of patients discontinued AZA or 6-MP prematurely due to adverse events[2]. The metabolism of thiopurines has been partly elucidated in recent years (Figure 1). The toxicity profile depends at least partly on the generated metabolites of AZA and 6-MP[3]. At first, AZA is converted to 6-MP by a non-enzymatic reaction, which is then

converted by a multi-step enzymatic pathway into a number of active, inactive, or toxic metabolites. The efficacy of AZA and 6-MP appears to be correlated with the formation of the 6-thioguanine nucleotides (6-TGNs). During this complex metabolization process, possible hepatotoxic metabolites are generated under the influence of the enzyme thiopurine methyltransferase (TPMT). The methylation products of 6-MP, 6-methylmercaptopurine (6-MMP) and their ribonucleotides, may be associated with hepatotoxicity[3]. Furthermore, flu-like symptoms, rashes, pancreatitis, and neutropenia induced by AZA or 6-MP have recently been related to mutations in the inosine triphosphate pyrophosphatase (ITPase) gene leading to accumulation of the proposed metabolite thio inosine triphosphate[4]. A possible strategy to avoid AZA or 6-MP-induced toxicity is the administration of a thiopurine, which is metabolically closer to the 6-TGNs. The thiopurine 6-thioguanine (6-TG) is an attractive candidate, which has the advantage of being directly converted to 6-TGNs[5]. Therefore, treatment and safety outcomes might be less sensitive for intra- and inter-individual metabolic variations. Furthermore, due to the relative simple metabolization, the number of possible toxic metabolites is strongly reduced. Several open label studies in patients with IBD have shown promising efficacy and acceptable short-term toxicity of 6-TG[6,7]. More recently, the use of 6-TG has been associated with the induction of nodular regenerative hyperplasia (NRH) of the liver. The aim of the present study was to determine the tolerability and safety profile of a low-dose maintenance therapy with 6-TG in AZA or 6-MP intolerant IBD patients over a treatment period of at least 1 year.

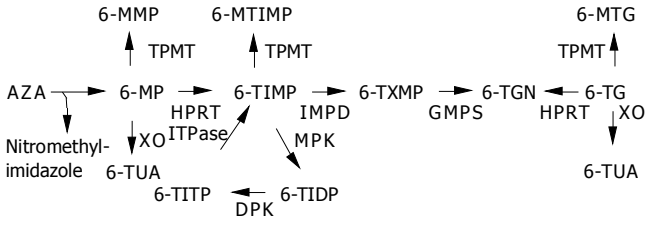

Figure 1 Metabolization process of thiopurines.

AZA is degraded to 6-MP and nitromethyl-imidazole, via a non-enzymatic step. Three competing enzymes metabolize 6-MP. Xanthine oxidase (XO) inactivates 6-MP to 6-thiouric acid (6-TUA). TPMT methylates 6-MP, the formed 6-MMP is associated with hepatotoxicity. By hypoxanthine guanine phosphoribosyl transferase (HPRT), 6-MP is catalyzed to 6-thioinosine monophosphate (6-TIMP), then via inosine monophosphate dehydrogenase to 6-thioxanthosine monophosphate, ultimately leading to the pharmacologically active 6-TGN via the enzyme guanosine monophosphate synthetase. 6-TIMP can also be methylated to 6-methyl-TIMP. In a normal useless cycle, 6-TIMP is phosphorylated by monophosphate kinase to 6-thioinosine diphosphate, subsequently by diphosphate kinase to 6-thioinosine triphosphate (6-TITP) and ultimately back to 6-TIMP due to the ITPase. When ITPase activity is impaired or lacking, 6-TITP accumulates. 6-TG is directly converted by HPRT to 6-TGN. XO and TPMT metabolize 6-TG to 6-methyl-TG and 6-TUA, respectively. ITPase has no known role in the metabolism of 6-TG.

MATERIALS AND METHODS

Patient selection

The study is a retrospective database analysis exploring the tolerability and safety of 6-TG over at least a 1-year treatment period in AZA or 6-MP-intolerant IBD patients, treated in participating university and district hospitals in the Netherlands. In each patient, the attending physician judged the indication for administration of 6-TG. Some patients have been described earlier in a short safety assessment of 6-TG[6]. Patients were eligible for the study, if they met the following in- and exclusion criteria. Inclusion criteria were: age between 18 and 75 years, presence of confirmed CD or UC with an indication for immunosuppressive therapy, but in whom standard AZA or 6-MP therapy failed, due to adverse events. Immunosuppression was indicated in case of chronic active disease, corticosteroid dependency or recurrent disease. Exclusion criteria were pregnancy, lactation, presence of active infection, history of tuberculosis, HIV, hepatitis B or C, history of severe pancreatitis (necrotizing pancreatitis or pancreatitis leading to multi-organ-failure), ongoing treatment with concomitant immunosuppressive drugs (e.g., cyclosporine, methotrexate (MTX), thalidomide or infliximab), impaired renal function (serum creatinine >2 times normal upper limit), impaired hepatic function (>2 times normal upper limit) and persistent bone marrow suppression.

Study design

In all patients, 6-TG (Lanvis®, tablet 40 mg, Glaxo Wellcome) was administered orally in a dose of 20-40 mg once daily based on the decision of the attending physician. The following data were collected: patient demographics, history of thiopurine exposure, type of thiopurine intolerance, the use of concomitant medication, blood cell counts, and liver enzymes were recorded. Dose of 6-TG, duration of 6-TG, occurrence of adverse events, blood cell counts, and liver enzymes were reviewed after a minimum of 12 mo after initiation of 6-TG treatment. During the described period, the genotyping of TPMT became available and in a subgroup of patients the TPMT status was determined. RBC 6-TGN levels were determined at least 4 wk after giving a stable dose in order to obtain steady-state levels of 6-TGN. Dose adjustments were left to the discretion of the attending physician, but when 6-TGN levels were above 1 000-1 500 pmol/8×10^8 RBC, dose reduction was contemplated. In case of a leukocyte count below 3.5×10^9/L, dose reduction was advocated and in case of severe leukopenia (below 1.0×10^9/L) 6-TG had to be discontinued. Additionally, in order to explore signs of hepatotoxicity, an abdominal ultrasonography was advised after at least 1-year 6-TG administration. Special attention was paid to splenomegaly, signs of portal hypertension, and hepatic changes.

Outcome measurements

Primary outcome measures were the ability to tolerate 6-TG and the occurrence of adverse events leading to discontinuation of 6-TG over the 1-year period. The relationship of any adverse event with the use of 6-TG was established by the following method: unrelated, no temporal relation and other etiology likely; possibly related, potential temporal relation and other etiologies possible; probably related, potential temporal relation and other etiologies unlikely; related, clear temporal relation not otherwise explained. Secondary outcome measures were the occurrence of hematological events (defined as leukocyte count $<4.0\times10^9$/L or platelet count $<100\times10^9$/L), the occurrence of hepatotoxicity (defined as a rise of at least two times the upper normal limit of a single liver enzyme level), pancreaticotoxicity (serum amylase >220 U/L) and signs of liver-related abnormalities on the abdominal ultrasound. The following data concerning disease activity were analyzed as well: ESR, C-reactive protein (CRP), serum albumin and a global physician assessment score (features were same, better or worse).

6-TG metabolite monitoring and genotyping of TPMT

Blood samples for 6-TGN measurements were obtained at least 4 wk after the onset of a stable 6-TG dose. The samples were centrifuged to isolate erythrocytes and after washing with PBS, erythrocyte counts were done. Samples were stored at -20 ℃ until required. RBC 6-TGN levels were measured in the laboratory of the Department of Clinical Pharmacy, Maasland Hospital Sittard, using a proprietary modified previously published assay[8]. The lower limit of quantification of the assay was 30 pmol/8×10^8 RBC for 6-TGN levels with a run-to-run coefficient of variation of 6.6%. Extra blood samples were drawn once during the 1-year period to assess TPMT (*G238C, G460A* and *A719G,* i.e., *TPMT*1, TPMT*2, TPMT*3A, TPMT*3B, TPMT*3C*) genotypes in a sub-group of patients, independent of the biochemical or clinical status. The genotyping was performed at the Department of Gastroenterology and Hepatology at the Academic Medical Centre in Amsterdam.

Statistical analysis

Data are expressed as mean±SD. Significance was evaluated by a *t* test for paired or independent data; *P* values of less than 0.05 were considered significant. Pearson's correlation was used to determine relationships between parameters. A χ^2 test was used to determine the significance between the TPMT genotype and 6-TG intolerance. SPSS for Windows version 11.0 was used for statistical analysis.

RESULTS

Patients

In 95 patients, treatment with 6-TG was initiated in the period from June 2001 to July 2003. Fifty-eight patients (61%) were female (mean age: 40 years, range: 20-74 years) and 37 (39%) were male (mean age: 47 years, range: 20-71 years). Forty-two (44%) patients were diagnosed with UC compared to 53 (56%) patients with CD. All patients were intolerant to AZA, 6-MP or both. The adverse events leading to discontinuation of AZA or 6-MP use were gastrointestinal complaints, general malaise, allergic reactions, hepatotoxicity or myelotoxicity. The patient's characteristics are given in detail in Table 1. The mean initial 6-TG dose was 24.6 mg (range 20-40 mg). The mean initial 6-TG dose adjusted to bodyweight was 0.37 mg/kg (SD 0.16 mg/kg).

Table 1 Patients' characteristics

	n = 95 patients
Female:male	58:37 patients
Age (yr)	43 years (range 20–74 yr)
UC:CD	42:53 patients
Duration of IBD at start 6-TG	10.4 yr (SD 9.4 yr)
AZA intolerance	78 patients (82%)
6-MP intolerance	4 patients (4%)
AZA and 6-MP intolerance	13 patients (14%)
AZA or 6-MP rechallenge	36 patients (38%)
Adverse events on AZA or 6MP:	30% gastrointestinal complaints
	20% general malaise
	14% allergic reactions
	10% pancreaticotoxicity
	6% hepatotoxicity
	5% myelotoxicity
	14% rest (e.g., myalgia or alopecia)
6-TG dosage at the start	24.6 mg (range 20-40 mg)

Primary outcome

Seventy-five (79%) of the ninety-five patients were able to tolerate 6-TG during 1-year use. In 20 (21%) patients, the administration was discontinued due to side effects. The 20 intolerant patients (9 females and 11 males) encountered 26 side effects. The data concerning the adverse events leading to withdrawal and the relationship with 6-TG use are summarized in Table 2. No mortality was reported. The mean 6-TG dosage was 0.30 mg/kg in the tolerant group compared to 0.34 mg/kg in the intolerant group (NS).

Table 2 Adverse events (*n* = 26) leading to discontinuation of 6-TG use in 20 patients (AE, adverse event; 6-TG, 6-thioguanine; GI complaints, gastrointestinal complaints)

AE on 6-TG	Frequency (%)	Mean time to AE (d)	Relationship with 6-TG
GI complaints	8/26 (31)	43	Probably 6/8 possibly 2/8
Hepatotoxicity	4/26 (15)	182	Probably 2/4 possibly ¼ unrelated 1/4
Myelodepression	1/26 (4)	50	Related
Pancreaticotoxicity	1/26 (4)	103	Possibly
General malaise	4/26 (15)	51	Probably 3/4 possibly ¼
Allergic reaction	1/26 (4)	1	Related
Other AE	7/26 (27)	39	Related 1/7 probably 2/7 possibly 4/7

Secondary outcomes

Hematological events Three patients had signs of myelosuppression. One patient had a leukocyte count of 3.2×10^9/L and a platelet count of 70×10^9/L after 50 d of 6-TG use (20 mg). Subsequently, 6-TG was discontinued.

The second patient had a leukopenia (leukocytes 3.5×10^9/L) and a third patient had a thrombocytopenia (platelets 87×10^9/L) at 1-year measurements, both did not discontinue 6-TG. All other patients, both tolerant and intolerant to 6-TG, had platelet and leukocyte counts above the set lower limits. However, the mean platelet count decreased significantly from baseline (309×10^9/L) to 1 year of 6-TG treatment (290×10^9/L, $P = 0.033$). The mean leukocyte count decreased as well (from 11.9 to 7.8×10^9/L) though not significantly. The 6-TGN level did not correlate with the decrease in both leukocytes or platelets counts. Hemoglobin levels remained unchanged in both patient groups.

Hepatotoxicity and pancreaticotoxicity In the 6-TG tolerant group the ASAT, ALAT, GGT, and AP levels were determined in 65%, 71%, 60%, and 68% of patients at 1-year 6-TG use, respectively. The mean levels of ASAT, ALAT, GGT, and AF were 24.7 U/L (range 6-118 U/L), 24.5 U/L (range 5-206 U/L), 48 U/L (range 6-535 U/L), and 84 U/L (range 42-322 U/L), respectively. A significant increase in liver enzymes during treatment in the tolerant group was not established. At 1-year use, in 9% of patients (7/75) hepatotoxicity occurrence on 6-TG treatment could be classified. Four patients (4/20) of the intolerant group discontinued 6-TG use due to hepatotoxicity. All had normal liver tests at entry and three of these patients encountered allergic reactions but no hepatotoxicity on the prior AZA therapy. Three patients had a serum amylase level above 220 U/L before the start of 6-TG that all became normal during treatment. One patient developed a transitory symptomatic pancreatitis with a serum amylase level of 430 U/L during 6-TG treatment and discontinued treatment.

Abdominal ultrasonography In 51 patients (54%), an abdominal ultrasonography was performed after at least 1 year 6-TG use. Five ultrasounds (10%) were considered as abnormal; three patients with steatosis, one patient had a choledocholithiasis and the last patient had a hydrops of the gallbladder and a splenomegaly (spleen size 13 cm). The latter two patients were classified as hepatotoxicity on 6-TG treatment.

Disease activity parameters No significant decrease in CRP (15-11 mg/L) or ESR level (15-14 mm) was established in the 6-TG tolerant group. The albumin level increased (37.6-40.1 g/L) significantly in the tolerant group ($P = 0.002$). A significant decrease of albumin level (38.5-36.6 g/L) was established in the intolerant group ($P = 0.03$). The global physician score was determined at 1-year 6-TG use in 85% (64/75) of the tolerant patients. Forty-seven patients (73%) were classified as better, 15 patients (23%) as the same and 4 patients (6%) as worse during 6-TG treatment.

6-TG metabolite monitoring and genotyping of TPMT The mean steady state 6-TGN level, determined in 63% (47/75) of the tolerant patients, was 540 pmol/8×10^8 RBC (SD 245, range 0-1 404). In the eight intolerant patients in whom metabolite levels were measured (40%), the 6-TGN level was 725 pmol/8×10^8 RBC (SD 422, range 229-1 563). The difference in 6-TGN levels between tolerant and intolerant patients was not significant. No statistical significant correlations were established between laboratory parameters (leukocytes, platelets, hemoglobin, AF, GGT, ASAT, and ALAT) and 6-TGN level. The TPMT genotyping was performed in 51 patients (54%). Two patients (3.9%) had one mutant non-functional allele (TPMT*3A and TPMT*3C) and both patients were intolerant for 6-TG (myelodepression and hepatotoxicity) (significant, $P = 0.003$). The 6-TGN level was not determined in both patients. Patients with two mutant non-functional alleles of TPMT (homozygous mutants) were not found in our population.

DISCUSSION

In this group of AZA or 6-MP-intolerant IBD patients, we demonstrated that 6-TG in dosages of 0.3-0.4 mg/kg daily was well tolerated over a period of 1 year as a maintenance immunosuppressant in 79% of the patients. This result suggests that during the metabolization process of AZA or 6-MP metabolites are generated that induce side effects, which at least in part are not generated during the 6-TG metabolism. No mortality was reported due to 6-TG use. When 6-TG was discontinued, the side effects leading to withdrawal resolved spontaneously. One patient developed a myelodepression that may be explained by the impaired TPMT activity, probably shunting 6-TG away from methylation by TPMT toward the formation of 6-TGNs, which have been associated with myelotoxicity. Unfortunately, no 6-TGN level was determined in this patient. The real incidence of 6-TG-related histological liver abnormalities like NRH or veno-occlusive disease (VOD) in the present study remains unknown, as liver biopsies were not performed. The incidence of 6-TG related increase in liver enzymes probably will be lower than 7 out of 75 patients, as 2 patients already had abnormal liver tests before the start of 6-TG and 1 patient had symptomatic choledocholithiasis.

In the present study, we found a mean 6-TGN level of 540 pmol/8×10^8 RBC in the tolerant group, which is above the proposed therapeutic threshold of 250 pmol/8×10^8 RBC and even higher than the proposed upper limit of efficacy (450 pmol/8×10^8 RBC) under AZA or 6-MP therapy[3,9]. This is consistent with previous observations[6,7]. It remains to be elucidated whether the same 6-TGN limits should be used when 6-TG is administered. In our study, 73% clinically benefited from 6-TG by using the global physician score and the mean albumin level increased significantly. However, due to the retrospective nature of the study, we must be reserved in drawing firm conclusions as no standard efficacy parameters as the Crohn's disease activity index or Truelove-Witts index were used. Despite the fact that we have not demonstrated a significant relationship between 6-TGN levels, laboratory results and adverse events, we believe that therapeutic drug monitoring may be a helpful tool in dosing 6-TG. Extremely high 6-TGN levels, which have been associated with an increased risk of developing myelotoxicity, can be prevented and compliance can be monitored.

The TPMT status has been associated with the ability to tolerate AZA or 6-MP. Patients with impaired TPMT activity are more prone to develop a myelodepression[10]. However, our study demonstrates that in AZA or 6-MP-intolerant patients only two patients (3.9%) had one mutant TPMT allele, which is even lower than the incidence in the normal Caucasian population[11]. Interestingly, both patients did not develop a myelodepression on AZA therapy. This

indicates that other metabolic pathways may lead to toxicity of AZA or 6-MP as was recently demonstrated for the ITPase routing (Zelinkova *et al*., submitted for publication). However, both patients with one mutant TPMT allele discontinued the use of 6-TG. Unfortunately, in these patients no 6-TGN concentrations were measured before discontinuation of 6-TG. Possibly, an impaired TPMT activity leads to more 6-TG being metabolized by the enzymes HGPRT or XO leading to higher 6-TGN and 6-TUA levels, respectively (Figure 1). The accumulation of these metabolites may lead to intolerance of 6-TG.

Recently, the use of 6-TG in IBD patients has been associated with the induction of NRH and VOD[12]. In the present study, we performed an abdominal ultrasonography after at least 1-year 6-TG use to screen for possible hepatotoxicity in 51 patients. Only one patient showed signs of portal hypertension indicated by an enlarged spleen. NRH has been associated with thrombocytopenia[16] and in our evaluation only two patients had platelets counts below 100 U/L. We are well aware of the fact that by using biochemistry and ultrasound outcomes, we probably underestimate the real incidence of 6-TG-induced NRH, as the golden standard is based on histology. Additionally, liver tests abnormalities were shown not to be indicative for NRH. Conversely, it should be taken into account that AZA and 6-MP can induce NRH or VOD as well, but performing liver biopsies during treatment with these compounds is not recommended in clinical practice.

Currently, the use of 6-TG in IBD patients is abandoned due to potential hepatotoxicity[12]. However, low-dose 6-TG may still be considered as an escape maintenance strategy in AZA- or 6-MP-intolerant IBD patients whom are refractory for alternative therapies. The number of proven effective medical maintenance options is scarce for these patients. MTX has a reasonable toxicity profile and seems effective in CD, comparable with AZA or 6-MP[13] but the potential use of MTX in UC patients has yet to be proven. In addition, long-term use of MTX may be limited[14]. Cyclosporine seems to have no role as a maintenance immunosuppressive alternative in IBD[15]. Infliximab can be administered as a maintenance option in CD with acceptable toxicity and may be effective in treating UC. However, concomitant immunosuppressive therapy with thiopurines or MTX next to infliximab therapy seems mandatory to reduce the immunogenic response[16].

Treatment with 6-TG is well tolerated in AZA and 6-MP-intolerant IBD patients and seems to be effective. We believe that low-dosed 6-TG (0.3-0.4 mg/kg per d) maintenance therapy may still be an escape option for this difficult to treat group of patients. The benefit of 6-TG use in this sub-group may balance its toxicity profile, especially taking into account the toxicity and efficacy of other therapeutic alternatives. Still, the reported hepatotoxicity is worrisome and 6-TG should therefore be administered only in prospective clinical trials.

Abstract

AIM: To evaluate the diagnostic accuracy and clinical utility of a new ELISA (URINELISA) test for detecting *Helicobacter pylori* (*H pylori*) antibody in the urine of Taiwanese population.

METHODS: In this prospective study, 317 consecutive dyspeptic patients (171 men, 146 women; mean age, 51.0 years) were included. They underwent gastroendoscopy for evaluation. Invasive tests, including culture, histology, and rapid urease test (RUT), and non-invasive ^{13}C-urea breath test were preformed. At the same time, urine specimens were collected for URINELISA. The status of *H pylori* infection was considered as positive when either culture was positive, or when two of the other, RUT, histology or 13C-UBT, were positive.

RESULTS: The sensitivity, specificity, positive predictive value, and negative predictive value of URINELISA are 91.7% (211/230), 90.8% (79/87), 96.3% (211/219), and 80.6% (79/98) respectively.

CONCLUSION: This URINELISA test is reliable, inexpensive and easy-to-use. The high diagnostic accuracy warrants the use of URINELISA as a first-line screening tool for diagnosis of *H pylori* infection in untreated patients.

INTRODUCTION

Since the discovery of *Helicobacter pylori* (*H pylori*) by Marshall and Warren in 1983[1], overwhelming evidence has confirmed that *H pylori* infection plays a significant role in the development of chronic active gastritis, peptic ulcer, and gastric adenocarcinoma[2]. *H pylori* infection is very common throughout the world, occurring in 40-50% of the population in developed countries, 80-90% of the population in developing regions[3], and about 54.4% of the population in Taiwan[4].

A large number of methods have been developed to diagnose *H pylori* infection, including invasive and non-invasive tests. The former requires endoscopy exam for gastric mucosal biopsy. Because of the patchy nature of the infection, biopsy-based tests may suffer sampling errors[5]. There is an increasing interest in non-invasive tests, as they are not influenced by sampling error and can profitably replace endoscopy making the diagnosis and determining the management of some types of patients[6]. The urea breath test (UBT) is based on the carbon dioxide labeled with carbon-13 or carbon-14 in expired air to detect *H pylori* urease activity[7]. Serological tests are based on the detection of a specific anti-*H pylori* immunological response, mostly by IgG antibodies in patient's serum. Same as serum antibody testing, an enzyme immunoassay method (URINELISA test, Otsuka Pharmaceutical Co., Ltd, Japan) for detecting *H pylori* antibody in the urine has been marketed in Japan, but at present, data on its clinical utility are limited[8,9]. It is possible that different genetic background of patients and *H pylori* strains could induce different antigen-antibody responses that would affect the results of URINELISA[10-14]. The aim of this study is to evaluate the usefulness of this new test in detecting *H pylori* antibody in the urine as a predictor of *H pylori* status in pretreatment settings in Taiwan.

MATERIALS AND METHODS

Patient selection and exclusion criteria

Three hundred and seventeen dyspeptic patients (171 men and 146 women; mean age, 51.0 years; range, 16-81 years) were recruited for this study. Exclusion criteria were as follows: antibiotic, bismuth salts, proton pump inhibitor therapy 2 mo before recruitment, previous anti-*H pylori*

treatment, chronic use of corticosteroids or immunosuppressant drugs, prior gastric surgery, presence of a bleeding peptic ulcer, severe concomitant disease, pregnancy, and lactation. Informed consent was obtained from each patient, and the study was performed in accordance with the Declaration of Helsinki.

Study design

All patients underwent gastroendoscopic examination, and gastric mucosal biopsies were performed. Non-invasive tests including URINELISA and ^{13}C-urea breath test (^{13}C-UBT) were also carried out. *H pylori* infection status was considered positive, when either culture was positive or when two of the following three tests, histology, rapid urease test (RUT), and ^{13}C-UBT, were positive. Urine samples were collected on the same day after endoscopic examination. The endoscopic biopsy protocol is shown in detail as follows: two specimens from the antrum and body for culture, five specimens from the angle and both greater and lesser curvatures of the antrum and body for histology and four specimens, excluding angle, for RUT.

Diagnostic tests for H pylori infection

Histology One set of specimens was fixed with formalin and embedded in paraffin. Sections were then stained with hematoxylin and eosin (H&E).

Rapid urease test CLO-test (Delta West, Bentley, Australia) was selected for determination of the presence of urease in the biopsied gastric mucosa. The results of the CLO-test were interpreted as positive if the color of the gel changed from yellow to pink or red within 6 h at room temperature.

Culture Culture of *H pylori* was made by rubbing the specimen on the surface of a Campy-BAP agar plate [Brucella agar (Difco)+IsoVitalex (Gibco)+10% whole sheep blood], and then incubating it at 35 ℃ under microaerobic conditions (5% O_2, 100 mL/L CO_2, and 85% N_2) for 4-5 d. The *H pylori* culture was considered positive if one or more colonies of gram-negative, oxidase (+), catalase (+), and urease (+) spiral or curved rods were present.

^{13}C-urea breath test (^{13}C-UBT) The ^{13}C-urea was 100 mg 99% ^{13}C-labeled urea produced by the Institute of Nuclear Energy Research (INER), Taiwan, and 100 mL of fresh milk was used as the test meal. This procedure has been modified since our previous study[15]. Patients were asked to fast at least 6 h beforehand, then a baseline sample was collected in duplicate by exhaling through a straw into a vacuum container tube 5 min after consuming the test meal. Five minutes later, the patients drank the urea solution prepared by dissolving 100 mg ^{13}C-urea in 50 mL of sterile water. Immediately after ^{13}C-urea consumption, subjects were asked to gargle rinsing the mouth to avoid detecting oral urease activity. The patient then rested on their sides for 15 min, changing sides every 5 min. Fifteen minutes after ^{13}C-urea was ingested, a breathing sample was collected in duplicate as the method of collecting baseline samples. All samples were sent to INER, where a continuous-flow isotope ratio mass spectrometer (CF-IRMS, Europa Scientific Ltd, Crewe, UK) was used for analysis. Based on findings from our previous study, the cut-off value was 4.2/mL at 15 min after ingesting ^{13}C -urea.

URINELISA *H pylori* antibody test All patients were asked to deliver a fresh urine specimen on the day of endoscopy. Urine samples were stored at 4 ℃ before analysis. Urinary antibodies to *H pylori* were determined by URINELISA *H pylori* antibody test (Otsuka Pharmaceutical Co., Ltd, Japan). This kit is an enzyme-linked immunosorbent assay (ELISA) kit using a 96-well microplate, and, as a solid phase of an antigen, a protein extracted from an *H pylori* strain isolated from a Japanese patient with gastritis is used. The assay procedure was performed according to the manufacturer's recommendations. To each well of the solid-phase microplate, 25 μL each of a buffer solution and 100 μL each of the urine specimen, the negative controls or positive controls were added in turn. After a reaction at 37 ℃ for 1 h, the plate was washed. One hundred microliters of an enzyme-labeled antibody solution was added to each of the wells subjected to the reaction at 37 ℃ for 1 h, and then washed. One hundred microliters of a substrate solution was then added. After the reaction was conducted for 15 min, 100 μL of a reaction stopping solution was added to each well. Absorbance was determined at a wavelength of 450 nm by an ELISA reader. Two positive controls and three negative controls were measured simultaneously. The cut-off value for urine-based ELISA was determined as the value calculated by the following formula: (mean absorbance of two positive controls)/8.5+ (mean absorbance of three negative controls). The equation employed was based on the results of numerous clinical studies[16]. Absorbance below the cut-off value was assessed as negative, and absorbance greater than the cut-off value was assessed as positive.

RESULTS

Of 317 patients, 230 (72.6%) were *H pylori*-infected and 87 (27.4%) were uninfected. Of the infected patients, 75 (23.7%) had non-ulcer dyspepsia, 224 (70.7%) had duodenal and gastric ulcers, and 18 (5.7%) had gastric adenocarcinoma. URINELISA was positive in 219 cases (8 of which were false positives) and negative in 98 (19 of which were false negatives). A summary of the diagnostic efficacy of individual tests is shown in Table 1. The urine test showed

Table 1 Summary of diagnostic efficacy of all tests used in this study

	URINELISA(%)	^{13}C-UBT (%)	RUT (%)	Culture (%)	Histology (%)
Sensitivity	91.7 (88.7–94.8)	96.7 (94.7–98.7)	94.4 (91.9–96.9)	55.6 (50.1–61.1)	86.7 (83–90.4)
Specificity	90.8 (87.6–94.0)	95.2 (92.8–97.6)	95.2 (92.8–97.6)	100 (100)	79.7 (75.3–84.1)
PPV	96.4 (94.3–98.5)	96.7 (94.7–98.7)	96.6 (94.6–98.6)	100 (100)	85.6 (81.7–89.5)
NPV	80.6 (76.2–85.0)	95.2 (92.8–97.6)	92.3 (89.4–95.2)	61.2 (55.8–66.6)	80.6 (76.2–85)

Results are expressed by percentages, with a 95%CI.

sensitivity of 91.7%, specificity of 80.8%, positive predictive value of 96.4% and negative predictive value of 80.6%. That is, the diagnostic efficacy of URINELISA was similar to ^{13}C-UBT and RUT.

DISCUSSION

Since the early 1980s, when *H pylori* was first discovered, significant progress has been made in identifying this infection, especially with respect to non-invasive techniques. The UBT, first described by Graham *et al*., in 1987[17], is presently considered as the most effective non-invasive test for *H pylori*[18]. Based on the direct identification of a bacterial enzyme activity (urease), the UBT detects an active, ongoing infection and is highly accurate even shortly after therapy[19]. However, the availability of ^{14}C-UBT is limited by the strict regulations governing the use, handling, and storage of radioactive isotopes, which in practice precludes use outside hospitals and the testing of children and women of childbearing age. ^{13}C on the other hand is a safe isotope that can be used for breath testing, but it is expensive ($ 250-350) when compared with other non-invasive tests ($ 20-100)[20], and does require the use of a CF-IRMS, thereby limiting widespread applicability. Furthermore, UBT for detection of *H pylori* is less effective in patients who have had a prior gastrectomy[21] and in those with severe atrophic gastritis[22]. In addition, equivocal or false-negative UBT results often occur in patients taking acid-suppression therapy[23-26]. Moreover, in most of the approved UBT protocols, demands are made on patients' time and cooperation (i.e., fasting before the test, the necessity of an office/laboratory visit, consumption of a test meal, and collection of a second breath sample after a time lag). Therefore, it is not easy to perform a UBT test on patients who cannot cooperate, such as children, psychological patients and unconscious patients.

Serology has clear advantages over breath tests, both in terms of cost and in being a non-invasive screening strategy, and it is the most important tool for epidemiological studies[27]. However, old-fashioned serological tests have suffered from cross-reactivity with *Campylobacter* species[28], resulting in a high rate of false positives. The reported sensitivity of serological tests is approximately 98-100%, but specificity varies from 26% to 96.4%[29]. Results of these assays may be due to the reference method used to confirm *H pylori* status, the source of the antigen on which the assay is based, and the reference population studies[29]. Furthermore, the specificity of most serologic tests decreases by approximately 10%, when sera from subjects more than 45 years are examined[30].

Recently, urine-based antibody tests have been developed for the screening of infectious diseases, including *H pylori*[31]. The benefits of using urine as the specimen are as follows: (1) Urine can be obtained easily, and its collection requires little skill. (2) Urine does not require centrifugation. (3) The cost of using urine as a sample is much lower than that of serum. (4) Urine tests can be simply formatted for use in doctors' offices or even for home testing. (5) Using urine provides a simpler alternative sample for epidemiological and screening studies. Laboratory-based urine testing using ELISA technology to detect IgG antibody is inexpensive (under $ 20), non-invasive, and well suited to primary care practice. Urine-based testing also combines the advantages of simplicity, cost-effectiveness and applicability under circumstances in which serological testing is largely impracticable. It has been reported that antibodies in urine are stable for 55 days at room temperature, and for one year at 2-8 ℃[32]. Katsuragi *et al*.[8], also confirmed that *H pylori* antibodies in urine were viable for at least 60 d at 4 ℃ and 25 ℃, and for at least 3 d at 37 ℃ and 45 ℃. In contrast, stool samples must be kept at 4 ℃ within 12 h after defecation, or diagnostic efficacy decreases.

Two studies have been performed in different populations with similar diagnostic efficacy with our results reported[33,34]. These studies show that URINELISA has a high degree of consistency in detecting *H pylori* infection in both Asian and European populations. Therefore, URINELISA is suitable for mass screening of *H pylori* infection. Such consistency has not been observed in stool antigen tests. In our own experience[35], and based on other reports made of an Asian population[34,36], the diagnostic efficacy of Premier Platinum HpSA® has been less consistent in an Asian population. However, there is a new stool antigen test, ImmunoCard HpSA STAT®, which seems to have higher diagnostic accuracy in Asian population[38]. In conclusion, URINELISA test is reliable, inexpensive and easy-to-use, and its high degree of diagnostic accuracy warrants its use as a first-line screening tool for the diagnosis of *H pylori* infection in untreated patients.

Abstract

AIM: To assess the effects of soy protein, isoflavone, and saponin on liver and blood lipid in rats that consumed high-cholesterol diets.

METHODS: High-cholesterol diets (1%) with or without soy material were fed to 6-wk-old male Sprague-Dawley rats for 8 wk. Blood lipids, liver lipids, glutamic oxaloacetic transaminase (GOT), and glutamic pyruvic transaminase (GPT) levels were measured. The *in vitro* bile acid-binding ability of soy materials was analyzed.

RESULTS: The results of *in vitro* studies showed that soy protein isolate had a significantly higher bile acid-binding ability (8.4±0.8%) than soy saponin (3.1±0.7%) and isoflavone (1.3±0.4%, $P<0.05$). On the other hand, at the end of the experimental period, rats that consumed soy protein diets had lower GOT and GPT levels than rats that consumed casein under high-cholesterol diets. Rats that consumed soy protein also had lower total cholesterol (TC) levels in the liver than those that consumed casein under high-cholesterol diets. Rats that consumed the soy protein diet containing both saponin and isoflavone had lower hepatic TC level than those that consumed the soy protein diet without isoflavone alone. The effect of different types of proteins on triglyceride was not significant.

CONCLUSION: Consumption of soy provided benefits to control lipid levels under high-cholesterol dieting conditions in this rat model of hypercholesterolemia. The major component that reduced hepatic TC was not saponin, but possibly isoflavone.

INTRODUCTION

Soybeans contain many ingredients that are considered to have health benefits. Among them, soy protein, soy saponin, and isoflavone are most commonly noted. All of them consist of aglycones and glycosides. Soy protein has been shown to have a cholesterol-lowering ability because some ingredients in soy protein bind with cholesterol so that the complex is absorbed[1]. Wang and Ng[2] also demonstrated that the alcohol-extractable materials in soy protein were effective in lowering cholesterol. Previous studies showed that soy protein loses its cholesterol-lowering effect if it is extracted with alcohol[3-5]. Saponin and isoflavone are alcohol-soluble components in soy beans. Unlike isoflavone, soy saponin is amphiphilic. Recent studies suggest that soy saponin is effective in lowering cholesterol[6] and inhibiting tumor because it binds with cholesterol[1,7]. Venter[8] indicated that soy protein decreases LDL cholesterol in people with elevated serum cholesterol[9]. The objective of this study was to identify the effect of individual components of the alcohol-soluble portion of soy protein on bile acid binding and lipid oxidation in order to delineate their potential role in the health benefits from soy consumption.

MATERIALS AND METHODS

Extraction of saponin

Soybeans were ground up in a blender for 2 min. The isoflavone/saponin mixture was then extracted from soy powder (1:20, soy powder:methanol) with 80% methanol at 40 ℃ for 2 h. After the methanol solution had been removed in a rotary evaporator, a certain amount of distilled water (e.g., 5 g of soy powder as starting material would need 10 mL of distilled water) was added to separate saponin from isoflavone. A quick test for saponin was performed by shaking the liquid sample for 1 min. Foaming for 10 min indicated a positive result of saponin. Saponin samples were analyzed for isoflavone residues with HPLC before further application. Commercial saponin was also purchased from Wako (Japan) for use as the HPLC standard.

In vitro bile acid binding of saponin

Ten grams of soy saponin was mixed with 5 mL of bile salt (10^{-4} mol)-containing buffer solution (0.1 mol/L of Tris-HCl and 0.1 mol/L NaN_3) at pH 4.0 and 37 ℃ for 2 h, followed

by dialysis (Spectra/POR, MW cut-off 6 000-8 000, Spectrum Medical, Los Angeles, CA, USA) for 4 d. The content of the bile salt was determined by enzymatic analysis as previously described[10].

Animals

Thirty-two 6-wk-old male Sprague-Dawley rats (Animal Center, National Scientific Council, Taipei, Taiwan) were randomly assigned to five groups according to the isoflavone and saponin contents in their diets: (1) soy protein (with isoflavone and saponin)+1% cholesterol (SP); (2) alcohol-washed soy protein (no isoflavone or saponin)+1% cholesterol (ASP); (3) alcohol-washed soy protein+soy saponin+1% cholesterol (SS); (4) casein+1% cholesterol (PC); and (5) casein (negative control, NC). The composition of each diet is shown in Table 1. Guidelines for the ethical care and treatment of animals from the Animal Care Committee at Taipei Medical University were strictly followed. Rats were individually housed and maintained in a temperature-controlled (23±2 ℃) room with a 12-h light/dark cycle. They were fed a chow diet for 1 wk before switching to the experimental diets. Five rats were randomly chosen and killed after completing the 1 wk of chow diet to acquire the baseline total cholesterol (TC) and triglyceride (TG) values of the liver. Water and food were available *ad libitum*. Two milliliters of blood samples were collected from the tail vein during wk 2, 4, and 6 after the start of the experimental diets. After wk 8, all rats were killed, and liver and blood samples were collected.

Table 1 Composition of the experimental diets

[1]Soy protein with isoflavone and saponin; [2]Alcohol-extracted soy protein; [3]NC, negative control (casein); PC, positive control (casein+1% cholesterol); SP, soy protein diet; ASP, alcohol-extracted soy protein diet; SS, soy saponin diet.

Blood lipid and liver function analyses

TC, TG, glutamic oxaloacetic transaminase (GOT), and glutamic pyruvic transaminase (GPT) were measured with commercial kits (Randox).

Statistical analysis

Data are presented as the mean±SD. One- and two-way ANOVA were performed using SAS® 8.1 software. Least significant difference test was performed to determine within-group differences.

RESULTS

Bile acid binding

The percentages of bile acid binding were as follows: soy saponin, 3.1±0.7%; soy isoflavone aglycones, 1.3±0.4%; and soy protein isolate, 8.4±0.8%. The differences in bile acid-binding percentages between each group were all significant ($P<0.05$).

In vivo studies

Table 2 shows the body weight changes of rats in each group during the feeding period. None of the mean body weights differed significantly among the groups. The effects of different diets on serum GOT, GPT, TG, and TC are shown in Table 3. In wk 0, the GOT and TC in five groups did not differ from each other. The GPT in the NC group was a bit, but significantly higher than that in the ASP group ($P<0.05$). The TG in the PC group was significantly higher (though the differences were not very big) than those in the ASP and SS groups ($P<0.05$). In wk 2, the GPT and TG levels did not differ among all groups, while the TC level in the SS group and the GOT level in the PC group were the highest ($P<0.05$). In wk 4, the PC group had higher GOT and GPT levels than the other groups ($P<0.05$), but the TC and TG levels still did not significantly differ among all groups. In wk 6, the PC group had higher GOT, GPT, and TG levels than the ASP, AS, and NC groups ($P<0.05$). The SS and NC groups also had higher TG levels than the SP and ASP groups ($P<0.05$). In wk 8, the PC group still had higher GPT levels than the other groups ($P<0.05$). The SS group had a lower TG level than the SP, NC, PC ($P<0.05$), and ASP ($P>0.05$) groups. The groups fed 1%-cholesterol diets had higher TC values than the NC group ($P<0.05$). Generally speaking, dietary consumption of soy protein either with or without alcohol extraction resulted in lower GOT and GPT levels than casein and showed a tendency to lower serum TG levels.

[1]ASP, alcohol-extracted soy protein; SS, alcohol-extracted soy protein plus saponin; NC, negative control (casein); PC, positive control (casein+1% cholesterol); SP, soy protein. [2]GOP and GPT, IU/dL; TG and TC, mg/dL. [a]$P<0.05$ within.

($P<0.05$). In the SP (intact soy protein) group, GOT, GPT, and TC levels had significantly increased ($P<0.05$) by the end of the experiment. Changes in the TG level did not show a clear trend. In the ASP (alcohol-washed soy protein) group, GOT and GPT levels did not change significantly during the experiment. The TC level significantly increased from wk 2 to 8 ($P<0.05$), while the TG level significantly decreased ($P<0.05$) during the experiment. In the SS group (ASP+saponin), the GOT level did not change throughout the experiment and the GPT level gradually increased toward the end of the experiment ($P<0.05$). By contrast, the TG level reached a maximum in wk 6 ($P<0.05$). In the PC group (high-cholesterol casein diet), the GOT, GPT, and the TC levels were elevated from wk 4 until the end of the feeding period ($P<0.05$).

Table 4 shows the hepatic TC and TG levels at baseline and at the end of the feeding period. The hepatic TG level in the SS group was the highest among the five groups in wk 8 ($P<0.05$), and was significantly higher than at baseline ($P<0.05$). TG levels in the other groups did not change significantly from baseline. Hepatic TC levels in all groups increased ($P<0.05$) compared to baseline. Rats that consumed soy protein (SP, SS, and ASP groups) had lower TC levels in the liver than those consumed casein (PC group) under high-cholesterol diets ($P\leqslant 0.05$). The SS and PC groups had higher hepatic TC levels than the other groups ($P<0.05$). Hepatic TC level in the SP and NC groups were significantly lower than those of the other groups ($P<0.05$). No significant differences were observed between the effects of casein and soy protein on hepatic TC and TG levels.

Table 4 TC and TG levels in the liver at the baseline and at the end of the feeding period

DISCUSSION

In this study, different types of dietary protein and the addition of saponin did not affect the growth of rats. We found that alcohol-extracted soy proteins (without isoflavone and saponin) with or without the addition of saponin had a protective effect on maintaining GOT and GPT under elevated cholesterol conditions. A diet high in cholesterol causes an increase in oxidative stress in the liver[11] and results in increases in GOT and GPT levels. In this study, the increasing levels of GOT and GPT in the rats fed casein with 1% cholesterol also produced elevated TC levels at the end of the feeding period compared to baseline.

The serum cholesterol content in the body is balanced by dietary cholesterol absorption, cholesterol synthesis in the body, and biliary cholesterol excretion. The cholesterol-lowering effect of saponin is due to the increase in bile acid excretion[12], which occurs through interference with the absorption of cholesterol[13]. Potter[14] also indicated that saponin might alter the absorption of cholesterol and bile acid. One of the possible mechanisms for this effect is that saponin forms micelles with bile acid[4]. Our *in vitro* data also suggested that soy protein and saponin bind a certain amount of bile acid, while the TC levels did not differ among

groups. Jimenez *et al*.[15], reported that soy saponin in the diet of rats did not have the same blood cholesterol-lowering effect of another amphiphilic compound, lecithin. This may have been due to soy saponin not being absorbed well in the small intestine through oral intake and reaching the colon directly[16]. Thus, the cholesterol-lowering effect of saponin appears to occur mainly through its bile acid- or cholesterol-binding ability in the digestive tract. In addition, the cholesterol-lowering effect may be changed if amino acids appear together[8]. Sautier *et al*.[17], also showed that the effect of soy saponin on lowering serum cholesterol might be greatly depressed if soy protein is added. In our experiments, soy saponin was added with soy protein and, therefore, no significant effect on TC was observed. Yamakoshi *et al*.[18], found that soy isoflavone had more significant cholesterol-lowering effects in plasma compared to saponin because saponin is not absorbed in the small intestine.

Soy isoflavone has been shown to have a cholesterol-lowering effect in the liver[19,20]. Soy protein also increases the activity of cholesterol receptors in the liver[21]. In our study, only the soy protein diet containing both isoflavone and saponin (SP group) lowered TC levels. Since we used healthy rats as the animal model, the liver cholesterol receptors should have been normal. This implies that the cholesterol-lowering effect in the liver in our study was from the effect of isoflavone rather than from saponin or soy protein. Sugano *et al*.[10], also suggested that the cholesterol-lowering effect of saponin might be reduced if it was ingested with soy protein.

In this study, we used SD rats as the animal model. It has been suggested that hypercholesterolemia is more easily induced in hamsters than in SD rats[22]. However, high cholesterol levels were observed in our SD rats fed high-cholesterol diets, which suggests that this animal model is also suitable for use in research. Since the hypercholesterolemic effect was not as apparent as that of hamsters; however, the results might have been affected. On the other hand, Gao *et al*.[22], suggested that SD rats might be a better animal model for investigating TG levels. In this study, the effect of different diets on blood TG levels of SD rats was highly significant.

In conclusion, this study found that soy protein was better than casein for liver protection in terms of GOT and GTP under high-cholesterol diet conditions. Soy protein and saponin showed some bile acid-binding abilities *in vitro*. However, the major component that reduced liver TC was isoflavone. The effects of various protein types on lowering TG still need further investigation. In addition, the SD rat is a useful animal model for studying hypercholesterolemia.

Abstract

AIM: To evaluate the hepatic dysfunction in leptospirosis is usually mild and resolved eventually. However, sequential follow-up of liver biochemical data remained lacking..

METHODS: The biochemistry data and clinical symptoms of 11 sporadic patients were collected and analyzed, focusing on the impacts of leptospirosis upon liver biochemistry tests.

RESULTS: The results disclosed that of the 11 cases, 5 or 45% died. The liver biochemistry data in the beginning of the disease course were only mildly elevated. Nevertheless, late exaggerated aspartate transaminase (AST) elevations were noted in three cases who finally died when compared with the typical course. Besides, significant higher AST/alanine transaminase (ALT) ratios (AARs) of the peak levels for transaminase were also noted in the cases who eventually succumbed. The mean±SD of AARs for the survival group and dead group were 5.65±2.27 (n = 5) and 1.86±0.64 (n = 6) respectively (P = 0.006). The ratios of the cases who finally died were all more than 3.0. Conversely, the survival group's ratios were less than 3.0.

CONCLUSION: Serial follow-up of transaminase might provide evidence to predict some rare evolutions in leptospirosis. If AST elevated progressively without a concomitant change of ALT, it might indicate an acute disease course with ensuing death. Additionally, AAR is another prognostic parameter for leptospirosis. Once the value was higher than 3.0, a grave prognosis is inevitable.

INTRODUCTION

Leptospirosis is caused by a variety of pathogenic spirochetes of the genus *Leptospira*[1], the human beings are generally the dead-end host after transmission from animal contact[2]. This disease is characterized by a broad spectrum of manifestations, which are usually subclinical[1,2]. Its diagnosis relies upon strong suspicions of this disease from some nonspecific clinical presentations[3]. Confirmation of this infection is usually established by serological studies[4] or PCR[5,6].

In terms of pathologic findings and biochemical manifestations, liver is not the main target of spirochete infection[2,3,7,8]. Hepatic dysfunction in leptospirosis was usually mild and resolved eventually. However, if jaundice occurs, serum bilirubin levels might be markedly elevated as compared with aspartate transaminase (AST) and alanine transaminase (ALT)[9]. Weil's disease, defined as severe icteric leptospirosis with renal failure, accounts for mortality associated with leptospirosis[1]. In some cases, aside from severe jaundice, the elevation of AST was so remarkable as acute viral hepatitis could be, which attracted our attention in the endemic area of the HBV. However, the data regarding sequential follow-up of liver biochemical data of leptospirosis remained lacking. Herein, our experiences of the sporadic leptospirosis are presented and the possible implication of exaggerated AST change in leptospirosis is discussed.

MATERIALS AND METHODS

During the period from May 1998 to January 2000, 11 patients with sporadic leptospirosis in intensive care unit, Chang Gung Memorial Hospital, Taiwan, were reviewed to evaluate the impact of severe leptospirosis on liver biochemistry tests. There were seven males and four females, and their age ranged from 30 to 78 years (mean: 57 years). None of the patients were alcoholics, nor suggestive of acute viral infection or chronic virus carrier by serological tests excluding the following: hepatitis A, B, and C, Epstein-Barr virus, cytomegalovirus and Hanta virus. Bacterial and fungal cultures were all sterile. There was no history of previous

liver disease in any of the patients. Leptospirosis was confirmed by either urine PCR tests or serum microscopic agglutinin test (single serum titer ≥100-fold or paired serum titers rise ≥4-fold).

The hepatic biochemistry parameters including AST (normal 0-34 U/L), ALT (normal 0-36 U/L), alkaline phosphatase (Alk-p, normal 28-94 U/L), γ-glutamyl transpeptidase (r-GT, normal <26 U/L), direct bilirubin (bili-D, normal 0-0.4 mg/dL), total bilirubin (bili-T, normal 0-1.3 mg/dL), creatine phosphokinase (CPK, normal 15-130 U/L) were chronologically collected and then analyzed. Student's *t*-test was used to compare the means. A probability value of less than 0.05 was considered statistically significant. Furthermore, the influence of leptospirosis on liver function tests was discussed.

RESULTS

The disease onset was severe and abrupt in all patients with fever and chills. The clinical manifestations included conjunctival suffusion in 9, jaundice in 9, abdominal pain in 7, myalgia in 7, consciousness disturbance in 4, hepatomegaly in 4, upper gastrointestinal bleeding 2, rhabdomyolysis in 2, and hemophagocytosis, hemolytic uremic syndrome each for one case. This disease progressed to acute renal failure in all and acute respiratory failure in six. All patients received parenteral penicillin and hemodialysis. Finally, five icteric cases died exclusively of multiple organ failure.

Table 1 illustrates the characteristics and liver biochemical data of the patients. Of the 11 patients, 5 (cases 1-5) or 45% contributes to the mortality rate. One of four (25%) younger than 50 years, and four out of seven (57%) older than 50 years expired. One hundred percent of the cases got abnormal liver biochemistry parameters in spite of various degrees. Alk-p and r-GT were only elevated mildly during the entire course and never exceeded 4-folds of the normal limit. Upon admission, eight had hyperbilirubinemia; however, in the 3rd wk of the disease, one of the patients who originally had normal bilirubin levels became icteric. Therefore, there were nine cases of Weil's disease by the definition mentioned before. The highest bilirubin level attained 35.1 mg%. CPK ranged from 178 to 2 889 U/L.

The most evident difference of liver biochemistry parameters between the dead and survival group was bilirubin levels (Table 1). The mean±SD of Bili (D) of the peak level for the former are significantly higher than the latter ($P = 0.03$). All those who died had jaundice; however, four cases with jaundice recovered.

Upon admission, both AST and ALT levels of all the patients elevated modestly with an average of 117.27 and 70.63 U/L respectively. However, three patients (cases 1, 3, and 5) with Weil's disease had unusually exaggerated AST elevation more than 2-3 wk after the onset of disease (Table 1, the peak AST level for case 1, 3, and 5 were 901, 1 216 and 580 U/L respectively). A representative case (case 1) showed disproportional progressive elevations of AST levels since the first admission day, which was the 12th d since the disease onset (Figure 1). Although ALT peaked at 144 U/L, it did not increase in proportion with AST, which peaked at 901 U/L. Meanwhile, CPK was 628 U/L. Due to pancytopenia, a bone marrow biopsy was performed for this patient and revealed hemophagocytosis. Case 3 displayed peak AST and ALT levels (1 216 and 308 U/L) (Table 1) after an episode of septic shock. However, they returned to normal 4 d later. Case 5 obtained peak levels of AST (580 U/L) and ALT (139 U/L) 18 d after the onset of disease. CPK was only 99 U/L then. A peripheral blood smear for pancytopenia demonstrated burr cells and toxic granules in WBCs. A disseminated intravascular coagulopathy (DIC) profile revealed positive finding, while both direct and indirect Coomb's tests yielded negative findings. All three patients eventually died of multiple organ failure.

In addition to exaggerated transaminase elevations of the late stage in the three cases mentioned above, significant higher AST/ALT ratios (AARs) of the peak levels for transaminase were also noted in the cases who eventually succumbed (Table 1 and Figure 2). The mean±SD of the AAR for the survival group and dead group were 5.65±2.27

(n = 5) and 1.86±0.64 (n = 6) respectively (P = 0.006). The ratios of the cases who finally died were all higher than 3.0. Conversely, the survival group's ratios were lower than 3.0 (Figure 2).

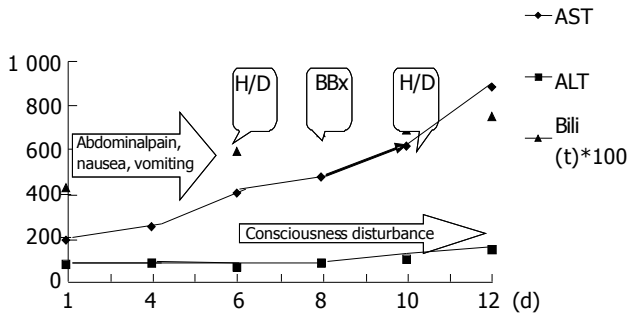

Figure 1 Clinical manifestations and biochemical changes in the whole course of case 1. Unit: AST (U/L), ALT (U/L), Bili(T) (mg/dL), H/D: hemodialysis, BBx: bone marrow biopsy.

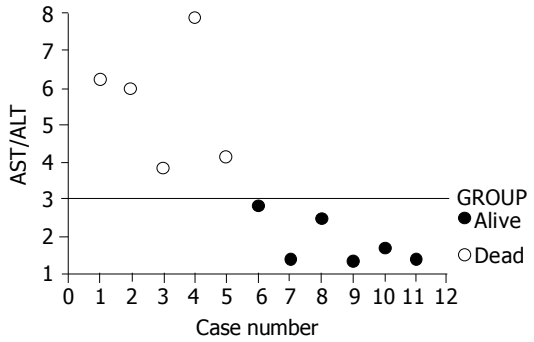

Figure 2 Scattered figure of AST/ALT (AAR) values. All the dead cases are shown as AAR >3.0. On the contrary, the ratios of all the survival cases were <3.0.

DISCUSSION

Age is reported as the most significant host factor related to mortality of leptospirosis. The mortality rate rose from 10% (in patients less than 50 years) to 56% (in those over 51 years)[1]. As the average age (57 years) of our cases was much higher than those of teenagers and young adults, who were considered as the major victims of leptospirosis, they were rarely admitted to hospital on account of their subclinical symptoms[1,3,6]. Furthermore, all the cases were enrolled from the intensive care unit, it is reasonable why the overall mortality (45%) of this hospitalized series was much higher than other published reports (5-16%)[1,2].

On hospitalization, the liver biochemistry tests disclosed only modest elevations in AST, ALT, Alk-p, and r-GT. However, total bilirubin ranged from normal limits to as high as 28.2 mg/dL. Such a pattern was compatible with the fact that the liver dysfunction in leptospirosis is typically mild, resolved finally and serum bilirubin can be markedly elevated as compared with other liver enzymes[1,2,3,9]. Hyperbilirubinemia is not only related to hepatocellular dysfunction but also magnified by impairing bilirubin excretion from renal failure, and bilirubin overproduction from tissue hemorrhage and intravascular hemolysis[8]. Five Weil's disease accounted for the mortality (Table 1, cases 1-5), it was also consistent with that leptospirosis is never fatal without jaundice[1,8]. It is because the pathogenesis in jaundice resulted from leptospirosis is as complex as mentioned above[8].

Nevertheless, among the five cases dying of Weil's disease, three (cases 1, 3, and 5) had exaggerated AST elevation 2-3 wk after the onset of disease. In contrast, among the four Weil's disease of the survival group (cases 6, 7, 9, and 10), none had been found with exaggerated AST elevation through the whole disease course. All the cases 1, 3, and 5 developed progressive AST elevation without concomitant ALT change. Therefore, the extrahepatic origin of AST should be considered. Myositis is a common presentation in leptospirosis and usually abated by the 2nd wk[10,11]. If the extrahepatic AST had come from muscle, AST would return to normal within 2 wk rather than being progressively elevated as seen in the two cases. Moreover, it has been reported that for severe myositis in leptospirosis, CPK elevation up to 8 880 U/L only correlated with AST elevation as high as 440 U/L[12]. Myositis alone could not contribute to AST elevation in the two cases, as their AST elevations (901 and 580 U/L) were not in proportion to CPK (628 and 99 U/L) elevations in terms of myositis. Therefore, the muscle origin of AST could not simply explain this phenomenon, and the exaggerated AST elevation must have had another source.

The pathogenesis of the systemic lesions in leptospirosis was ascribed to directly damaging the parenchymal cellular membranes. It may initially cause functional disorder of these membranes, and only later lead to necrosis[13]. Nevertheless, complete cell necrosis is not prominent in leptospirosis, which is in accordance with the low level of serum transaminase in this disease[7]. Notably, hemophagocytosis and DIC were proved in the two cases (cases 1 and 5) respectively. Both are rare presentations in human leptospirosis[13,14], and they indicated a severe form of infections and disease progression. Besides, clinical presentations (respiratory failure, renal failure, consciousness disturbance, *etc*.,), they indicated grave multiple organ failure. It was suggested that, in rare and deteriorated situations, the systemic parenchymal cellular dysfunction in leptospirosis could evolve into extensive cellular necrosis. Namely, severe and extensive destruction of cells in various organs -not only muscle and liver -might lead to the unusual AST elevations. It had been documented that, in acute and/or fatal leptospirosis, the pathogenesis of the pathologic features are related to the presence of the organisms in the tissues, and was usually multi-system involvement[15,16].

All the five fatal cases displayed multiple organ failure (Table 1). The major difference between those who with (cases 1, 3, and 5) and without (cases 2 and 4) exaggerated AST elevation was the natural course of disease. The duration from disease onset to death appeared much shorter in the former (12-19 d) as compared to the latter (47-78 d). The clinical course of leptospirosis can be divided into two stages, a 3-7-d septic stage followed by an immune stage lasting for 4-30 d[2]. All the exaggerated AST occurred in the immune stage of leptospirosis. The balance between

the host and parasite determines, whether the infection runs an acute or a protracted course[17]. In acute leptospirosis, the main pathogenesis was probably due to the direct toxic damage of spirochetes[13,18,19]. However, an immune complex-mediated mechanism was suggested when the course was protracted[18]. Because the infections ran acute courses in cases 1, 3, and 5, it might indicate that although the exaggerated AST elevations occurred in the immune stages (after 1 wk of disease onset), the hosts could not clear the spirochetes then from the blood by immune reactions efficiently. The spirochetes were consistently virulent to the systemic parenchymal cells. Finally unavoidable deaths with fulminant courses of the hosts ensued.

Aside from AST, AAR of peak levels for transaminase might predict the outcome of leptospirosis. AAR was significantly higher in the fatal cases. The ratios were higher than 3.0 (Table 1 and Figure 2) in all of the deaths. In contrast, all the cases who finally recovered had the ratios of less than 3.0. The ratios seemed to stop at 3. Both multiple major organ failure and systemic parenchymal cells necrosis might contribute to the higher ratios in the fatal cases.

In endemic areas of hepatitis B infection such as Taiwan, viral hepatitis was the first consideration for icteric patients with abrupt disease onset associated with transaminase elevation. Such impression might delay the appropriate management of the true culprit-leptospirosis. Typically acute viral hepatitis presented as exaggerated transaminase elevations initially and recovered thereafter regardless of the existence of jaundice. Besides, the ALT elevation usually sustains longer than that of AST. On the contrary, leptospirosis showed as initial modest transaminase elevations accompanied with extremely high CPK levels[1,2,8]. The initial amplitude of transaminase could be a clue to differentiate viral hepatitis and leptospirosis. However, in a chronic HBV carrier, the delayed transaminase elevation would confuse the physician, if the elevation is due to acute exacerbation of chronic HBV infection. We were convinced that delayed and disproportional AST elevation is in favor of nonhepatic origin. In leptospirosis, it might hint a fulminant disease course with high mortality.

Conclusively, in addition to clinical symptoms, serial follow-up of transaminase could provide some evidence to predict the rare evolution in leptospirosis. Late disproportional AST elevation indicates an ominous sign, mortality that typically ensues from a fulminant disease course. AAR is a parameter responsive to the prognosis of leptospirosis, the ratio >3.0 means a grave prognosis. Furthermore, in endemic areas of viral hepatitis, Weil's disease still should be considered in icteric cases of unknown origin regardless of AST level, since exaggerated AST might herald the unusual fulminant mortality.

Abstract

AIM: To analyze systematically our experience over 22 years with symptomatic acquired diverticular disease of the jejunum and ileum, exploring the clinical manifestations and diagnosis of this rare but life-threatening disease.

METHODS: The medical records of patients with surgically confirmed symptomatic jejunoileal diverticular disease were retrospectively reviewed. Data collected included demographic data, laboratory results, clinical course (acute or chronic), preoperative diagnosis, and operative findings. Inclusion criteria were as follows: (1) surgical confirmation of jejunoileal diverticular disease and (2) exclusion of congenital diverticula (e.g. Meckel's diverticulum).

RESULTS: From January 1982 to July 2004, 28 patients with a total of 29 operations met the study criteria. The male:female ratio was 14:14, and the mean age was 62.6±3.5 years. The most common manifestation was abdominal pain. In nearly half of the patients, the symptoms were chronic. Two patients died after surgery. Only four cases were correctly diagnosed prior to surgery, three by small bowel series.

CONCLUSION: Symptomatic acquired small bowel diverticular disease is difficult to diagnose. It should be considered in older patients with unexplained chronic abdominal symptoms. A small bowel series may be helpful in diagnosing this potentially life-threatening disease.

INTRODUCTION

According to the literature review by Longo and Vernava[1], the first report of jejunal diverticulosis was published by Sir Astley Cooper in 1807, and the first operation for small bowel diverticula was performed by Gordinier and Sampson in 1906. The small bowel is the least common site for diverticula in the entire GI tract. According to the literature, the duodenum is the most common location for a small bowel diverticulum[2,3]. After excluding Meckel's diverticulum, less than 30% of reported diverticula occurred in the jejunum and ileum. The reported incidence of jejunoileal diverticula on small bowel studies by enteroclysis is 2-2.3%[4,5], comparable to autopsy data demonstrating an incidence of 1.3-4.6% for acquired diverticula of the jejunum and ileum[6,7].

Most small bowel diverticula, whether duodenal or jejunoileal, are asymptomatic[1,8] and are simply incidental findings. Complicated acquired diverticular disease of the jejunum and ileum is, on the other hand, a diagnostic dilemma. The exact prevalence of complicated small bowel diverticula is difficult to ascertain, estimates in the literature range from less than 10% to nearly 40%[9,10]. In a series of 47 patients, operative intervention was required because of complications in 7 (15%) patients[11]. We conducted a retrospective review of our experience with this rare entity, with a view to expanding the cumulative information in the literature.

MATERIALS AND METHODS

General data

The chart and operative records of Mackay Memorial Hospital from January 1982 to July 2004 were reviewed for cases of surgically proven jejunoileal diverticula. During this period, 28 patients with symptomatic, acquired jejunoileal diverticular disease were managed. We retrospectively reviewed their age, sex, admission data, and outcome. We reviewed the major symptoms and recorded whether they were acute or chronic. The definition of chronic symptoms was vague complaints with no other identifiable cause persisting for at least 1 mo[7]. The preoperative laboratory data was also recorded and compared according to gender and whether the disease was acute or chronic. The preoperative diagnosis and surgical findings were recorded, including the location, number, and size of diverticula and the operative method.

Statistical analysis

Data were expressed as percentages or the mean±SD. Sigma Stat software (version 2.03, SPSS Inc., Chicago, IL) was used to perform a Student's *t*-test to compare the difference between groups of patients. Differences were considered significant at a *P* value of less than 0.05.

RESULTS

The records of 28 patients with surgically proven jejunoileal diverticula were retrieved for this study. The male:female ratio was 14:14. One woman with multiple jejunal diverticula had two episodes requiring surgery, once at age 66 and again at 77. Therefore, a total of 29 operations were reviewed. The mean age was 62.6±3.5 years (ranging from 22 to 93 years). Symptoms were acute in 15 episodes and chronic in 14. Two patients died, for a mortality of 7% (2 of 29). The length of hospital stay was 23.2±3.7 d, and the length of time between admission and surgery was 5.0±2.7 d. Six patients (21%) had colonic diverticular disease, with one tentatively diagnosed with colonic diverticulitis before surgery.

Some patients had multiple presenting symptoms. The most common was abdominal pain (25 of 29 episodes, 86%). Four patients had GI bleeding on arrival and six were febrile. One patient had a palpable left lower quadrant mass and was found to have diverticulitis of the terminal ileum with rupture. Other manifestations included nausea or vomiting in nine patients, abdominal fullness in seven, constipation in two, shock in two, and others in five.

Table 1 shows the surgical findings noted in the records. In the 29 episodes where the information was available, the diverticula were located in the jejunum in 16, the ileum in 11, and both jejunum and ileum in 2. In the 27 records where the number of diverticula was stated, 19 patients had multiple diverticula. The majority (12 of 21) of diverticula in cases where the size was recorded were greater than 3 cm. More than three quarters (22 of 29) of surgeries involved segmental resection of the intestine, and three patients had resection of the diverticula only. Additional procedures, such as enteroclysis and drainage, were done in four cases. Diverticulitis with or without perforation was the most common final surgical diagnosis (17 of 29).

Table 1 Surgical findings in 29 episodes of acquired symptomatic jejunoileal diverticular disease

Surgical findings	*n*	%
Location (*n* = 29)		
Jejunal:ileal:both	16:11:2	55:38:7
Number of diverticula (*n* = 27)		
Single:multiple	8:19	30:70
Size of diverticula (*n* = 21)		
Less than 1 cm:1–3 cm:over 3 cm	2:7:12	10:33:57
Operative method (*n* = 29)		
Segmental resection of intestine	22	76
Resection of diverticulum only	3	10
Others	4	14
Postoperation finding (*n* = 29)		
Diverticulitis with/without perforation	17	58
Hemorrhage	4	14
Intestinal obstruction	8	28

Table 2 shows the preoperative diagnoses, with acute appendicitis being the most common (6 of 29). Five patients were thought to have ileus, one of whom had an enterolith. Only four patients had a correct diagnosis before surgery, three of which were suggested by a small bowel series. The other patient had an upper GI series that disclosed a proximal jejunal diverticulum.

Table 2 Preoperative diagnoses in 29 episodes of acquired jejunoileal diverticular disease

Preoperative diagnosis	
Acute appendicitis	6
Ileus	5
Small bowel diverticula	4
GI tract bleeding	4
Perforated peptic ulcer	3
Intussusceptions	2
Colonic diverticulitis	1
Intra-abdominal tumor	1
Volvulus	1
Others	2

Table 3 lists the laboratory data. The mean blood sugar, leukocyte count and amylase were slightly elevated, while the mean albumin, calcium were mildly decreased. When we compared the data between patients with acute or chronic symptoms and between males and females, we found no significant statistical differences.

Table 3 Laboratory data in 29 episodes of acquired symptomatic jejunoileal diverticular disease

Laboratory data	mean±SD	Normal range
Hemoglobin	11.6±3.0	11.0-16.0 g/dL
Leukocyte count	11 540±4 656	4.0-10.0×10^3/μL
Platelet count	237 541±99 860	140-450×10^3/μL
Blood sugar	133.6±47.0	70-120 mg/dL
Blood urea nitrogen	16.9±12.6	7-24 mg/dL
Creatinine	1.1±0.4	0.5-1.2 mg/dL
Albumin	3.0±0.6	3.4-4.8 g/L
Calcium	7.8±0.7	8.4-10.0 g/L
Aspartate aminotransferase	26.9±18.7	5-35 IU/L
Bilirubin	0.80±0.5	0.2-1.3 mg/dL
Amylase	129.2±165.4	25-125 U/L

DISCUSSION

Our study confirms the rarity of symptomatic acquired jejunoileal diverticular disease, with only 28 patients seen with this disorder in our hospital in the past 22 years. It is more common in older patients, with a mean age in our series being 62.6±3.5 years. This is in general agreement with the findings of previous studies, with few young patients reported[1,7,12]. Although other investigators have reported a male predominance[1,2], this was not the case in our series. Because of the small number of patients in any one of the series, it is difficult to collect enough data to determine a clear pattern of gender distribution.

Most acquired jejunoileal diverticula are false diverticula,

occurring along the mesenteric border of the small bowel[1,10]. The incidence decreases distally progressively from the ligament of Treitz. The pathogenesis of jejunoileal diverticula has been ascribed to a pulsion phenomenon with local increases in intraluminal pressure. The mucosa and submucosa are forced through vascular channels in the muscle layer[13-15]. It is also possible that smooth muscle abnormalities create localized weakness in the wall. Diverticula are thought to occur more frequently in the proximal jejunum because of the larger size of the vasa recta at this area[7]. Another theory is that abnormalities of the myenteric plexus may result in uncoordinated smooth muscle activity, producing high pressure in localized area[1,2]. In our series, the distribution of diverticula was similar to the findings of others, with 55% in the jejunum, 38% in the ileum, and 7% in both.

Of patients with jejunoileal diverticula reported in the literature, more than 60% have been asymptomatic, another 30% minimally symptomatic, and only 10% have developed serious complications[13]. The rarity of symptomatic acquired jejunoileal diverticula often results in missed or delayed diagnosis. de Bree *et al*., advocated earlier diagnosis and timely treatment to reduce the morbidity and mortality[16]. Only four patients in our series (14%) were correctly diagnosed before surgery. Geroulakos reported an even worse record, with none of their patients being correctly diagnosed preoperatively. Three of the thirteen patients in their series were once labeled as psychoneurotic because diagnostic studies failed to demonstrate obvious pathology. The correct diagnosis was made only at emergency laparotomy[17]. This demonstrates the importance of remembering that there are such uncommon entities that are difficult to diagnose but which, if unrecognized, may result in serious complications.

Acute complications of diverticula include diverticulitis with or without perforation, hemorrhage, and intestinal obstruction[18-21]. In a patient with diverticular bleeding, endoscopy is unlikely to reveal the source, although it is of benefit in excluding other source of bleeding. Mesenteric angiography or Tc^{99m} RBC scan can be more helpful in such cases[22]. The differential diagnosis of intestinal obstruction includes volvulus, adhesions, intussusception, compression by a large diverticulum, or enterolith[1,7,23]. Small bowel dyskinesia, caused by bacterial overgrowth, visceral myopathy, or neuropathy may induce pseudo-obstruction[15]. Pseudo-obstruction is in fact a more common complication than mechanical obstruction and has been reported in 10-25% of cases[24]. Most of the patients in our study (58%) had diverticulitis with or without perforation. Hemorrhage and intestinal obstruction were only minor findings in our series, with only four patients presenting with GI bleeding. One of eight patients had an enterolith in his diverticulum that resulted in obstruction.

Chronic symptoms included intermittent abdominal fullness, vague abdominal discomfort or pain, passage of oily stool, weight loss, and weakness, which resolve after treatment. These might have been caused by pseudo-obstruction or bacterial overgrowth[1,7]. In one report, 14 of 27 patients had chronic refractory symptoms[15]. In our series the result was comparable (14/29). Small bowel diverticula should be considered in patients presenting with such unexplained chronic symptoms.

Nobles described a radiographic finding suggestive of jejunoileal diverticulum, namely a segmental dilatation of the small bowel in the epigastrium or left upper quadrant. He also suggested that the diagnosis be considered whenever the triad of obscure abdominal pain, anemia, and dilated small bowel loops on abdominal radiographs is encountered[7,25]. An upper GI series with small bowel follow through is a simple method for identifying a diverticulum. Three of the four correct preoperative diagnoses in our series were made by this method. However, diverticula may protrude into the leaves of mesentery and be hidden by the mesenteric fat. They also often communicate with bowel lumen through a wide opening. These factors may prevent the lesion being seen on routine barium follow through[26]. Enteroclysis (i.e., a double contrast of small bowel series) is more reliable for detecting these lesions, because the barium is able to flow out of a wide-mouthed diverticulum after air insufflation[4,5,16]. A meticulous search of the mesenteric portion of the small bowel as well as air insufflation with a small gauge needle into isolated segments of the bowel have been used to demonstrate obscure diverticula during operation[7,14,18].

Asymptomatic non-Meckelian diverticula as an incidental finding on radiographic studies or at laparotomy usually do not need resection[20]. However, if a dilated, hypertrophied segment of bowel with large diverticula is found, it may indicate a progressive form of the disease, in which case resection of the diverticular segment found incidentally at laparotomy is recommended[1,9]. Although some patients with chronic symptoms can be treated conservatively, when symptoms are persistent or refractory to treatment, resection may be beneficial[1].

In conclusion, symptomatic acquired diverticular disease of the jejunum and ileum is an uncommon disorder. Diagnosis is often difficult and delayed, resulting in unnecessary morbidity and mortality[16]. All published studies are limited by being retrospective analyses of small numbers of cases. There has thus been an inherent bias in patient selection. Preoperative diagnosis is difficult, and the paucity of studies makes it difficult to define the optimal diagnostic method. Certainly a high index of suspicion for this often obscure disease is necessary.

ACKNOWLEDGMENT

The authors wish to thank Dr. Mary Jeanne Buttrey for critical reading and correction of the manuscript.

Abstract

AIM: To investigate the interaction between heat shock protein 70 (HSP70) and α-fetoprotein (AFP) in human hepatocellular carcinoma (HCC) cell line BEL-7402.

METHODS: The expression and localization of HSP70 and AFP in human HCC cell line BEL-7402 were determined by immunocytochemistry and indirect immunofluorescence cytochemical staining. The interaction between HSP70 and AFP in HCC cells was analyzed by immunoprecipitation and Western blot.

RESULTS: Immunocytochemical staining detection showed that HCC cell BEL-7402 expressed a high level of HSP70 and AFP synchronously. Both were stained in cell plasma. AFP existed in the immunoprecipitate of anti-HSP70 mAb, while there was HSP70 in the immunoprecipitate of anti-AFP mAb.

CONCLUSION: HSP70 chaperones AFP in human HCC cell BEL-7402. The interaction between HSP70 and AFP in human HCC cell can be a new route to study the pathogenesis and immunotherapy of HCC.

INTRODUCTION

Alpha-fetoprotein (AFP) is a major serum protein synthesized by fetal liver cells, yolk sac cells, and in trace amounts by the fetal gastrointestinal tract[1]. AFP appears to function as an osmotic and carrier protein in the fetus and to regulate the immune system by immunosuppressive functions, such as preventing immunological attacks to the embryo by the maternal immune system[1]. Reappearance of AFP in adult serum often signals pathological conditions, particularly the presence of hepatocellular carcinoma (HCC) and germ cell tumors containing yolk sac cell elements[2]. Now AFP has been successfully used as a diagnostic and prognostic tool for HCC. Although many investigations for the function of AFP had been carried out, the biological role of AFP is still a riddle so far.

Heat shock proteins (HSPs) are molecular chaperones which are emerging as biochemical regulators of cell growth, apoptosis, protein homeostasis and cellular targets of peptides[3-5]. Up regulated expression of HSPs during the growth of cancer cells has a close relationship with cell proliferation[6-8]. It is interesting to note that several studies have shown that AFP plays some roles during cell survival and proliferation of HCC cells[9-11]. Previous studies have confirmed overexpression of HSP70 in HCC[12]. So there may be a possible correlation between the expression of HSP70 and AFP during the growth and differentiation of HCC cells. In this study, by immunocytochemistry and immunoprecipitation, we observed that HSP70 chaperoned AFP in HCC cell cytoplasm. The interaction between HSP70 and AFP in human HCC cells will provide a new route for studying the pathogenesis and immunotherapy of HCC.

MATERIALS AND METHODS

Reagents

Rabbit anti-human HSP70 antibody, mouse anti-human AFP monoclonal antibody, TRITC labeled goat anti-rabbit antibody and FITC labeled goat anti-mouse antibody were purchased from Santa Cruz Company. EnVisionTM kits were purchased from Dako Biological Technology Company. ProteinA/G-agarose beads were purchased from Gene Company.

Cell line and cell culture

Human HCC cell line BEL-7402 was provided by the Institute of Oncology, Chinese Academy of Medical Sciences, Beijing, China. The derived cell lines were grown in RPMI 1 640 medium supplemented with 100 mL/L heat-inactivated fetal calf serum, 50 000 U/L penicillin and 0.05 g/L streptomycin. The cells were maintained at 37 ℃ in a humidified atmosphere

containing 50 mL/L CO_2. Viability of the cells used in these experiments was consistently more than 95% when evaluated by the trypan blue exclusion method. Cells at a density of 2.5×10^5/mL were seeded into six-well plates for 24 h, washed with PBS, fixed by adding 2 mL of cold 500 mL/L methanol-acetone and stored at 4 ℃ for 20 min, then washed with PBS, and dried at room temperature.

Immunocytochemistry

All cells in six-well plates were hydrated with graded alcohol. Endogenous peroxidase was then blocked with 3 mL/L H_2O_2 diluted in methanol for 30 min at room temperature. Antigen retrieval was performed by treating the slides in citrate buffer in a microwave for 10 min. The cells were incubated in a moist chamber with HSP70 rabbit antibody (1∶100) or AFP mouse monoclonal antibody (1∶100) at 4 ℃ overnight, respectively. After a complete wash in PBS, the cells were treated with HRP labeled goat anti-rabbit and goat anti-mouse antibody (1∶100) for 45 min at 37 ℃. After a complete wash in PBS, all cells were developed in 0.5 g/L freshly prepared diaminobenzidine solution (DAB, Sigma Co.) for 8 min, and then counterstained with hematoxylin, dehydrated, air dried, and mounted. Anti-HSA was used to substitute for the primary antibody as a negative control.

Indirect double-immunofluorescence cytochemistry

All cells in six-well plates were hydrated with graded alcohol. The cells were blocked in 10 mL/L bovine serum albumin (BSA) for 30 min at room temperature, and then incubated with HSP70 rabbit antibody (1∶100) or AFP mouse monoclonal antibody (1∶100) at 4 ℃ overnight, respectively. After a complete wash in PBS, the cells were treated with TRITC labeled goat anti-rabbit antibody or FITC labeled goat anti-mouse antibody (1∶20) for 40 min at room temperature. After extensive washing, the stained cells were observed under an immunofluorescence microscope. Anti-HSA was used to substitute for the primary antibody as a negative control.

Immunoprecipitation and Western blot

Cells at a density of 2.5×10^5/mL were seeded into six-well plates for 24 h. Then cells were treated with 0.5 g/L trypsin and 0.2 g/L EDTA. After washing with cold PBS, the cells were centrifuged and harvested. They were then lysed with 500 μL of lysis buffer (10 mmol/L Tris-HCl, pH 7.4, 150 mmol/L NaCl, 1 mL/L Triton X-100, 10 g/L sodium deoxycholate) containing 1 μg/mL pepstatin and 1 mmol/L phenyl-methylsulfonyl fluoride (PMSF). Also, five units of apyrase (Sigma, Co.) were added to the lysate to deplete endogenous ATP. The cell lysates were sonicated and clarified by centrifugation. The supernatants were preabsorbed with 20 μL protein A/G-agarose beads at 4 ℃ for 4 h. After centrifugation, the supernatants were incubated with 100 μL HSP70 rabbit antibody (1∶100) or 100 μL AFP mouse monoclonal antibody (1∶100), respectively at 4 ℃ for 60 min. Then 50 μL protein A/G-agarose beads were added and incubated for 60 min at 4 ℃. The immunoprecipitates were collected by centrifugation and washed five times with PBS. The precipitated protein complexes were released from the immunopellet with SDS-sample buffer (62.5 mmol/L Tris-HCl, pH 6.8, 25 g/L SDS, 50 mL/L β-mercaptoethanol, 100 mL/L glycerol) at 100 ℃ for 5 min. The immunoprecipitates were then analyzed by 90 g/L SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Proteins were transferred to nitrocellulose (NC) membrane (BioRad) and detected by immunoblotting with anti-AFP monoclonal antibody or anti-HSP70 antibody (1∶100) at 4 ℃ overnight, respectively. After a complete wash in PBS, the membranes were treated with HRP labeled goat anti-rabbit and goat anti-mouse antibody (1∶100) for 45 min at 37 ℃. After a complete wash in PBS, the membranes were developed in 0.5 g/L freshly prepared diaminobenzidine solution (DAB, Sigma Co.) for 8 min. Anti-HSA was used to substitute for the primary antibody as a negative control.

Statistical analysis

HSP70, AFP expression differences between HCC cell BEL-7402 and control group were analyzed statistically using χ^2-test. $P<0.05$ was considered statistically significant.

RESULTS

Expression of HSP70 and AFP in HCC cell line BEL-7402

Positive expression of HSP70 and AFP showed brown staining in the nuclei or cytoplasm, more than 500 cells calculated in different microscopic fields of each well, and the percentage of positive cells were evaluated.

Immunocytochemical staining showed that the positive rate of HSP70 was 96.0% (480/500), and AFP was 100.0% (500/500), while control group was 5.0% (25/500). There was a significant difference between experimental group and control group ($P<0.01$). HSP70 and AFP were mainly stained in cell cytoplasm (Figure 1).

Interaction between HSP70 and AFP in HCC cell line BEL-7402

Immunoprecipitate and Western blot showed that there were

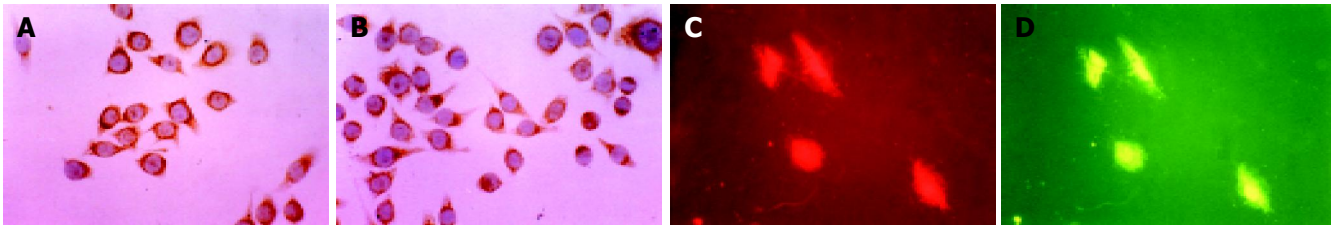

Figure 1 Expressions of HSP70 and AFP in HCC cell line BEL-7402 by immunocytochemistry and immunofluorescence cytochemistry, ×400. **A:** HSP70 positive expression in cytoplasm; **B:** AFP immunostaining in cytoplasm; **C:** HSP70 immunostaining in cytoplasm; **D:** AFP green immunofluorescence in cytoplasm.

two clear protein bands in the transferred NC membrane. Under-precipitated with anti-HSP70 antibody, there appeared a M_r 68 000 clear AFP band (lane 1) and under-precipitated with anti-AFP mAb, there existed a M_r 72 000 clear HSP70 band (lane 2), demonstrating that AFP existed in the immunoprecipitate of anti-HSP70 antibody and HSP70 existed in that of anti-AFP mAb. The results indicated that HSP70 interacted with AFP in HCC cell line BEL-7402 (Figure 2).

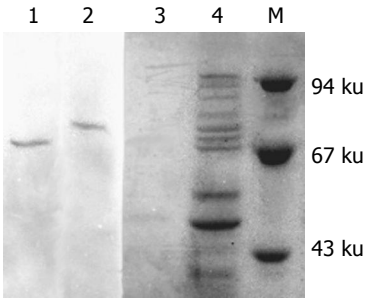

Figure 2 Analysis of immunoprecipitate of anti-HSP70 antibody and anti-AFP mAb by SDS-PAGE and Western blot (lane 1: precipitated with anti-HSP70 antibody; lane 2: precipitated with anti-AFP mAb; lane 3: precipitated with anti-HSA antibody; lane 4: cell lysates supernatants; M: molecular mass markers).

DISCUSSION

In this study we examined the expressions of HSP70 and AFP in HCC cell line BEL-7402 by immunocytochemistry, immunofluorescence cytochemistry and immunoprecipitate analysis. The results showed that almost all HCC cells detected expressed a high level of HSP70 and AFP, which had a significant difference compared with control group. HSP70 chaperoned AFP that mainly localized in cell cytoplasm.

AFP always accompanies the growth of liver cells, and it is possible that AFP may be related to the proliferation of tumor or fetal cells[8-10]. The mechanism for growth-promoting activity of AFP is still unclear. Escaping from the surveillance of immune system is the primary cause for malignant growth of HCC cells[12,13]. Several investigations have shown that AFP could be individually synergistic with other growth factors to promote the growth of many tumor cells[14,15]. AFP receptors have been found anchoring on the membrane of various tumor cells[16-17]. The receptor may mediate intercellular signal transduction which influences the expression of genes related to proliferation[16,17]. AFP can stimulate the expression of some oncogenes which controls cell cycle, and then enhance the proliferation of human HCC[19,20]. When BEL-7402 cell line were treated with AFP, oncogene protein, such as c-fos, c-jun, n-ras and mutative p53 and $p21^{ras}$ increased rapidly, which have an important function in modulating growth and differentiation of the cells.

Heat shock protein (HSP) is a group of highly conserved proteins synthesized after heat induction[3-5]. In normal cells, HSP70 is constitutively expressed at low levels but the expression was dramatically enhanced by stressful conditions[3]. HSPs are thought to act as molecular chaperone, helping in transporting, folding and processing of their target proteins. Although the cellular implication of the increased production of these proteins is unknown, it may be expected that each response would enhance the capacity of the pathway(s) in which these proteins function and perhaps protect the associated cellular compartments from damage via abnormal protein interactions. Enhanced expression of HSPs during the growth of cancer cells implies its close relationship with cell growth[6-8]. It is interesting to note that AFP plays some roles during tumor cell survival and proliferation[9-11]. These studies have suggested a possible correlation between the overexpression of HSP70 and AFP during the growth and differentiation of tumor cells. Continuous expression of HSP70 in tumor cells is required to serve as molecular chaperones in regulating and stabilizing tumor growth process. Some studies have suggested that high level expression of HSP70 could contribute to tumorigenecity of certain tumors[7,8], but its role in tumorigenecity is not clear. So, it is reasonable to propose that HSP70 and AFP up-expression in these tumor cells is closely related with the tumor cell survival and proliferation. Up-regulated expression of HSP70 in tumor cells may be required to serve as molecular chaperones in regulating and stabilizing oncofetal protein and mutant oncogene products during the tumor growth process[21,22]. Therefore, HSP70 could assist to stabilize AFP in cell cytoplasm, transport it to cell membrane and release its monomer to the serum, which indirectly prompts and protects AFP function. Conversely, AFP itself stimulates HCC cell proliferation through membrane receptor mediating cellular signal transduction pathways. This indicates that the proliferating HCC cells need much more HSP70 to maintain the formation of AFP activities. Our results showed that, in human HCC BEL-7402 cell line, there exists a high level of expression of HSP70 and AFP. It indicates that co-expression of HSP70 and AFP is likely to have some relationship with proliferation, development and poor prognosis of human HCC. The observed fact is that HSP70 chaperoned AFP may be useful to study the pathogenesis and immunity of human HCC.

Recent studies on the immunodominant epitopes of AFP have provided a solution to the obstacle of HCC immunotherapy. AFP is produced at low serum levels after birth throughout life[1]. The majority of human HCC overexpress the oncofetal antigen AFP, M_r 64 000-72 000 glycoprotein[2]. Despite being exposed to high plasma levels of this oncofetal protein during embryonic development, the body has a low immunity to it[3-5]. Butterfield *et al*.[23], recently found that four peptides of human AFP processed and presented in the context of HLA-A0201, could be recognized by the human T cell repertoire, and could be used to generate AFP-specific CTL in human T cell cultures. It was also found that murine immune system could generate T-cell responses to this oncofetal antigen[24]. Therefore, it may be a better target for immunotherapy. But AFP immunization alone still results in lower levels of specific response and poorly reproducible protective immunity[24,25].

How to enhance the host's active immunity to AFP may be an interesting strategy for HCC therapy. In our previous study, tumor rejection assay demonstrated that recombinant DNA vaccine AFP/HSP70 elicited strong specific antitumor

immunity against AFP-producing SP2/0 cells than AFP DNA vaccine. Results indicated that AFP immunogenicity can be improved greatly by HSP70 molecular and vaccination with DNA encoding HSP70 could increase both humoral and T-cell proliferation responses to AFP. We attributed the successful AFP specific T-cell responses in mice to the HSP70 molecule by mediating APCs for efficient uptake and process of AFP. Numerous investigations have been verified that HSP70 is a better molecular chaperone and adjuvant which can process and present weak tumor antigen to MHC-I of host APCs, eliciting specific T-cell response and CTL reaction[26,27]. HSP70-associated peptides can also anchor antigen on the cell membrane and directly present it to nature killer cells or γδ T cells as superantigen without being dependent on the stimulation of MHC-I molecules[28,29]. The observed fact is that HSP70 chaperoned AFP in HCC, may be useful to study tumor pathogenesis or design effective vaccine against liver cancers.

Abstract

AIM: To investigate the presence of HBsAg, HBcAg, and HBV DNA in ovarian tissues from patients with HBV infection.

METHODS: HBsAg and HBcAg were examined in ovarian biopsy tissues from 26 patients with HBV infection by immunocytochemistry, and HBV DNA was detected in ovarian tissues by PCR.

RESULTS: HBsAg and HBcAg were present with the same positive rate of 34.6% (9/26). The total positive rate was 46.2% (12/26). HBsAg and HBcAg were positive in 6 (23.1%) of the 26 patients. Brown positive particles were diffusely distributed in ovarian cells. The positive rate of HBV DNA was 58.3% (7/12).

CONCLUSION: HBsAg, HBcAg, and HBV DNA can be detected in ovarian tissues from patients with HBV infection. The presence of HBsAg and HBcAg in ovarian tissues does not correlate with the HBV markers in serum.

INTRODUCTION

The prevalence of hepatitis B is high in China. The overall positive rate of serum HBsAg is about 10%. Hepatitis B virus (HBV) infection can cause acute hepatitis, chronic hepatitis, hepatocirrhosis and hepatocellular carcinoma[1,2]. HBV is not a kind of virus that locates strictly in the liver cells. HBV infection may cause either pathological hepatic lesion or extra-hepatic lesion. It has been well documented that the extra-hepatic lesion due to acute hepatitis is temporary, and that due to chronic hepatitis is associated with persistent HBV infection and draws more attention of researchers. Animal experiments have confirmed that HBV can exist and replicate in various organs and tissues[3,4]. With the development of molecular biology, HBV can be detected in patients with HBV infection outside the liver, such as in peripheral blood mononuclear cells, tissues or cells of pancreas, spleen, skin, kidney, etc.[5]. Moreover, it has been shown to be present in blood, saliva, semen, vagina secretion, sweat, breast milk, tear, and urine[6].

Although some studies on the infection and location of HBV in extra-hepatic tissues have been carried out and a few papers have been published at home or abroad[3-5], whether HBV replicates outside the liver after its infection is still controversial. The location and distribution of HBV in extra-hepatic tissues or cells are not consistent, and the pathologic lesions caused by the extra-hepatic infection of HBV and their pathogenesis are not fully understood. Whether HBV exists in ovarian tissues is unknown. If we can demonstrate this, then it is reasonable to assume that vertical transmission may be due to HBV transmitting from ovary to ovum and fetus. In this study, we investigated the presence of HBsAg, HBcAg, and HBV DNA in 26 ovarian biopsy specimens using immunocytochemistry and PCR in order to analyze and interpret the mechanism and significance of HBV infection in ovarian tissues.

MATERIALS AND METHODS

Subjects

We reviewed the medical history at the Department of Pathology, Xiangya Hospital, Central South University and found 170 patients who had ovarian biopsy from June 2002 to June 2003. Among them, 26 patients had positive serum HBV markers. Seven out of the twenty-six patients were positive for HBsAg, and the other 19 patients had two or more HBV markers in serum. Paraffin-embedded ovarian tissues from these 26 patients were enrolled for further analysis. The age of the 26 patients ranged from 2 mo to 71 years, with an average of 40 years. Five patients were diagnosed as ovarian cyst, and 21 patients as ovarian cancer.

Detection of HBsAg and HBcAg by immunocytochemistry

The presence of HBsAg and HBcAg was examined in ovarian biopsy tissues from the 26 patients by immunocytochemistry (streptavidin-peroxidase-biotin) according to the manufacturer's instructions. The main steps were as

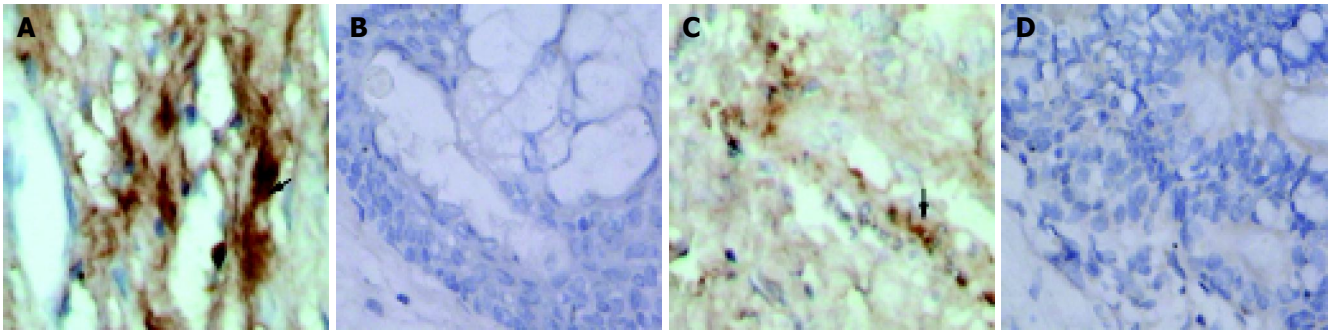

Figure 1 Positive HBsAg (**A**) expression and positive HBcAg (**B**) expression in ovarian tissue and negative control (**C** and **D**).

follows. Cover slips were dewaxed with xylene, and dehydrated in alcohol, washed thrice with PBS for 5 min each time. Endogenous peroxidase activity was quenched by incubating cover slips with 50 μL peroxide for 10 min, and washed with PBS. Samples were blocked by incubating cover slips with 50 μL goat serum for 30 min, washed with PBS and incubated with primary antibody for 60 min at room temperature, then washed with PBS and incubated with biotin-conjugated secondary antibody for 10 min at room temperature, washed again with PBS and incubated with streptavidin-peroxidase for 10 min at room temperature, washed with PBS and incubated with DAB for 5 min, counterstained with hematoxylin, dehydrated in alcohol and xylene. The coverslips were permanently mounted and observed under light microscope. Brown signals were considered as positive result.

When primary antibody was replaced by PBS, the result was negative.

Ovarian tissues from patients without HBV infection were used as negative control.

Liver tissues from patients with hepatitis B were used as positive control.

Mouse anti-HBsAg, mouse anti-HBcAg, and SP kit were purchased from Zhongshan Biological Technology Limited Company, Beijing.

Detection of HBV DNA by PCR

Paraffin-embedded ovarian tissues were digested with proteinase K, and HBV DNA was isolated using phenol and chloroform. Primer sequences were designed by us using Primer 3 software: forward primer, 5'-TCGGAAATACACCTCCTTTCCATGG-3' (HBV genome 1 353-1 377); reverse primer, 5'-GCCTCAA GGTCGGT-CGTTGACA-3' (HBV genome 1 702-1 681). The length of PCR product was 350 bp. Liver tissue DNA from patients with hepatitis B and ovarian tissue DNA from patients without HBV infection were used as positive control and negative control respectively. Thirty cycles of DNA amplification were performed in 50 μL PCR reaction mixture. The condition of each cycle was denaturation at 94 ℃ for 30 s, primer annealing at 55 ℃ for 30 s, and elongation at 72 ℃ for 30 s, followed by a final 10-min elongation at 72 ℃. DNA marker, proteinase K, Taq DNA polymerase and dNTP were purchased from TaKaRa Company, Dalian. Primer was synthesized by BioAsia Company, Shanghai.

RESULTS

The results of immunocytochemistry indicated that HBsAg and HBcAg were present in ovarian tissues (Figures 1). The positive rate of HBsAg and HBcAg in ovarian tissue was 34.6% (9/26), respectively. The total positive rate was 46.2% (12/26). HBsAg and HBcAg were positive in 6 (23.1%) of the 26 cases. Brown positive particles were predominantly within the ovarian cells, depositing linearly or in clusters. According to HBV markers in serum, the 26 patients were divided into two groups: patients with one indicator positive and patients with two or more positive indicators. The positive rate of HBsAg and HBcAg in ovarian tissues of these two groups showed no statistical difference ($P>0.05$) as listed in Table 1.

HBV DNA was examined in ovarian tissues from the 12 patients with positive immunocytochemical results. The positive rate of HBV DNA was 58.3% (7/12), as shown in Figure 2.

Table 1 HBsAg and HBcAg in ovarian tissues from 26 patients with HBV infection

	HBsAg in ovarian tissue[1]		HBcAg in ovarian tissue[2]	
	Positive	Negative	Positive	Negative
Patients with one HBV marker	2	5	1	6
Patients with two or more HBV markers	7	12	8	11

[1]P = 1.000 (Fisher's exact test), [2]P = 0.357 (Fisher's exact test).

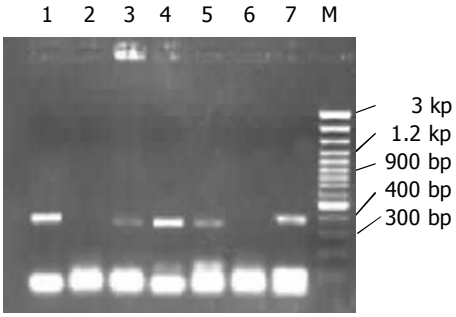

Figure 2 Detection of HBV DNA in ovarian tissue by PCR. M: DNA marker; lanes 1, 3, 4 and 5: positive samples; lane 6: negative control; lane 7: positive control.

DISCUSSION

Whether HBV can locate and replicate in ovarian tissue is not clear. This is the first report to detect HBsAg, HBcAg, and HBV DNA in ovarian tissues by immunocytochemistry and PCR. Our data indicate the positive rate of HBsAg and HBcAg was 34.6% (9/26) respectively, and the presence of HBsAg and HBcAg in ovarian tissues does not correlate with the HBV markers in serum.

PCR is a technique for quickly cloning a particular piece of DNA *in vitro*. The essential steps include thermal denaturation of the double-stranded molecules, the primers binding to their complementary template, and extension of the primers by enzymatic synthesis with DNA polymerase. The reaction is efficient, specific, and extremely sensitive[7-9]. Using PCR to assay clinical specimens has become a common method in the diagnosis of infectious diseases. HBV DNA is present in ovarian tissues with a positive rate of 58.3%. Our data provide evidence for extra-hepatic infection of HBV.

It is not clear what pathologic changes might be induced in ovary by HBV infection. An early study[10] reported that HBV can induce immune damage, even cell carcinogenesis through antigen expression in cells or integration to cell genome. In our research, all the samples were collected from patients with ovarian tumor. Whether HBV infection in ovary relates to ovarian tumor needs further study. HBV extra-hepatic infection plays a role in the preservation of the virus, but extra-hepatic tissues and cells with HBV infection often escape immune damage without obvious pathologic changes because of the small amount of viruses and the incomplete protein expression in extra-hepatic infection.

Extra-hepatic HBV infection should be targeted as liver pathologic changes in the treatment of hepatitis B. Since our study indicated the presence of HBV in ovary, and HBV might be possible to replicate in ovary, it is reasonable to assume that vertical transmission is due to HBV transmitting from ovary to ovum and fetus. There are three classical mechanisms underlying HBV transmission from mother to child[11,12]. (1) HBV transmit to the fetus through placenta, namely intrauterine infection, which has been confirmed by studies based on newborn, abortus and germ cells. (2) If there is a small cut in the skin of the fetus, and the cut is contaminated by the mother's blood or vaginal secretion in the process of childbearing, HBV infection may occur. This is the main type of vertical transmission. (3) Mother to child horizontal transmission is the main transmission route via breast milk feeding. Further studies should be focused on the transmission routes of HBV in order to control and prevent hepatitis B.

Abstract

Acute esophageal necrosis (AEN) is extremely rare and the pathogenesis of this is still unknown. We report a case of AEN caused by alcohol abuse. In our case, the main pathogenesis could be accounted for low systemic perfusion caused by severe alcoholic lactic acidosis. After the healing of AEN, balloon dilatation was effective to manage the stricture.

INTRODUCTION

Acute esophageal necrosis (AEN) in the absence of ingestion of a caustic or corrosive agent has been reported to be extremely rare. AEN is defined as a dark pigmentation of the esophagus associated with histologic mucosal necrosis. The exact pathogenesis is still unknown, but several etiologies have been suggested including ischemia[1,2], gastric outlet obstruction[3], hypersensitivity to antibiotics[4], gastric volvulus[5], and viral infection[6]. We reported a case of AEN caused by alcohol abuse.

CASE REPORT

A 41-year-old man visited the emergency room with a 12-h history of epigastric pain, violent vomiting, and coffee-ground emesis. His past medical history included alcoholic liver injury. He had felt nausea and appetite loss for a week. The previous day, he had consumed 1.8 L of shochu, distilled spirits containing 25% alcohol. He denied the ingestion of any caustic agents, antibiotics, and NSAIDs. He was afebrile with a regular pulse of 110 bpm, a blood pressure of 74/40 mmHg, a respiratory rate of 26 breaths/min and a core temperature of 37.0 ℃. Physical examination revealed a mild distended abdomen and epigastric tenderness. The liver edge was measured at 4 cm below the right costal margin. A Foley catheter was inserted into the bladder, but no urine was returned. Arterial blood gas measurements using with O_2 flow at 3 L/min was: pH 6.981, $PaCO_2$ 16.4 mmHg, PaO_2 156.4 mmHg, AG 55.7 mmol/L, HCO^{3-} 3.9 mmol/L, lactate 26.4 mmol/L. Laboratory data were: WBC 32 430/mm^3, hemoglobin 149 g/L, platelets 194 K/mm^3, TP 55 g/L (normal 67-83 g/L), SGOT 169 U/L (8-38 U/L), SGPT 47 U/L (4-44 U/L), T. chol 2 670 mg/L (1 270-2 380 mg/L), TG 20 370 mg/L (430-1 610 mg/L), BUN 320 mg/L (80-200 mg/L), creatinine 33 mg/L (6-10 mg/L), Na 129 mmol/L (138-149 mmol/L), K 5.4 mmol/L (3.5-5.0 mmol/L), Cl 71 mmol/L (99-110 mmol/L), Ca 65 mg/L (82-102 mg/L), amylase 484 U/L (43-116 U/L). Abdominal CT demonstrated a grossly dilated stomach, a few linear strands in peripancreatic fat suggesting inflammation, a small amount of fluid in the anterior pararenal space, a thickened distal esophagus with evidence of transmural inflammation, but no free air. A naso-gastric tube was placed and 800 mL of brown liquid was removed. The patient was admitted and received intravenous fluids with 80 mL of 7% sodium bicarbonate. He was rapidly rehydrated and urinalysis did not reveal ketones. Arterial blood gas, 5 h after his admission, showed pH 7.505, lactate 4.1 mmol/L.

Esophago-gastro-duodenoscopy (EGD), on the next day, demonstrated black and friable mucosa from 3 to 4 cm below the cricopharyngeus to the cardia (Figure 1A). Biopsies of the esophagus were not taken at this time due to concern over possible perforation. The stomach had a few linear ulcers and the mucosa was edematous. A barium swallow revealed thickened esophagus and decreased esophageal motility, but no evidence of perforation.

Platelets count was rapidly decreased (d 3: 74 K/mm^3) and we considered disseminated intravascular coagulation. Treatment was conservative management with oral intake restriction, intermittent naso-gastric tube suction, total parental nutrition, intravenous famotidine, antibiotics, and nafamostat mesilate. Laboratory data, including thrombocytopenia, were gradually recovered.

Ten days after admission, EGD revealed the presence of a thick, white exudate on the pink esophageal mucosa. Oral feeding was started on d 13. However, he sometimes complained about chest oppression after meal. Both an EGD

on d 24 (Figure 1B) and a barium swallow on d 27 (Figure 2A) demonstrated stricture of the middle esophagus. On d 39, we performed balloon dilatation to the stricture. With the assistance of esophagoscope and a guidewire, a 20-mm balloon dilator was inserted to the stricture. The balloon dilator was inflated to a pressure of 2 atm for 5 min. Balloon dilatation was accomplished without any complication. Two days after, the barium swallow demonstrated improvement of the stricture (Figure 2B). The patient was discharged without complaints on d 46 taking 20 mg of omeprazole once a day. His alcoholic hepatitis was reversible and laboratory data has been normal since discharge.

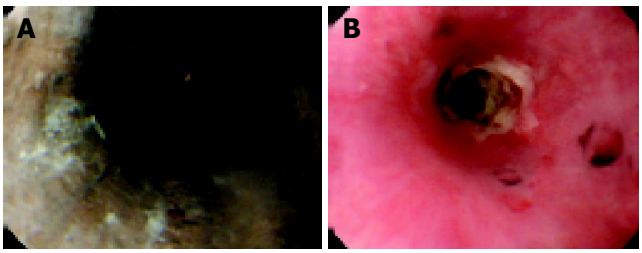

Figure 1 **A:** Endoscopy on d 2 shows that esophagus is circumferentially black and friable. **B:** Endoscopy on d 24 shows stricture formation at the middle esophagus. The mucosa is covered by white exudate.

Figure 2 Barium swallow study. **A:** Stricture formation at middle esophagus on d 27. The diameter of the lumen was 6 mm; **B:** On d 41, improvement of the stricture was seen after balloon dilatation.

DISCUSSION

AEN or Black esophagus was first described in 1990 by Goldenberg *et al*.[1], although two post-mortem cases had previously been reported[7,8]. The precise incidence and prevalence of this disease are unknown. Autopsy studies have estimated its prevalence at 0.1-0.2%[9,10]. Moreto *et al*.[11], have identified 10 cases of AEN in a review of more than 80 000 upper endoscopies, an incidence rate of only 0.0125%. Among variety of mechanisms for the development of this condition including direct toxic effect[12,13] or indirect acidic effect[14,15], low systemic perfusion seems to play the dominant role. The main complications are esophageal stenosis and stricture formation[3].

Lactic acidosis is the cause of sudden death in alcoholics[16]. It is caused by an elevation of the NADH/NAD+ ratio with increased formation of lactate from pyruvate, diminished gluconeogenesis and decreased lactate uptake into the liver[17,18]. Thiamine deficiency due to malnutrition and the direct action of alcohol are responsible for the occurrence of lactic acidosis[19,20]. Five typical symptoms of alcoholic lactic acidosis are vomiting, nausea, abdominal pain, tachycardia and the Kussmaul form of respiration. In this case, we suspect that his acidosis appeared at least a week before his admission because his nausea and appetite loss had started. Lactic acidosis might have been worsened by his malnutrition and alcohol abuse.

The fall in blood pH had profound effects on circulation systems. Intrinsic cardiac contractility may be depressed, but inotropic function can be normal because of catecholamine release. Both peripheral arterial vasodilatation and central venoconstruction can be present. Several reports described cases of stroke[21], intestinal necrosis[22], heart failure, and pancreatitis[23] in severe metabolic acidosis and those may be associated with physiologic response to hypovolemia and subsequent poor organ perfusion caused by severe acidosis. Low esophageal perfusion pressure, a presumed cause of our case, was suggested by his original hypotension. In addition, coagulation abnormality by acute pancreatitis can aggravate esophageal mucosal perfusion. Severe peripheral circulatory failure also makes massive gastric distension and renal insufficiency. Moreover, alcohol overindulgence induces irritation of the gastric mucosa and the accumulation of large volume of gastric secretions. This can overwhelm the normal defense of the esophagus, and could be another cause of our case.

In conclusion, we reported a case of AEN caused by alcohol abuse. The main pathogenesis can be accounted for low systemic perfusion caused by severe lactic acidosis. The stricture area of middle esophagus was managed with balloon dilatation.

Abstract

We report a case of a 77-year-old female with a local recurrence of cancer after right hemicolectomy which infiltrated the pancreatic head affording pancreatoduodenectomy, who developed 3 years later recurrent tumor masses localized in the mesentery of the jejunum and in the lower pole of the left kidney. Partial nephrectomy and a segment resection of the small bowel were performed. Histological examination of both specimens revealed a necrotic metastasis of the primary carcinoma of the colon. Although intraluminal implantation of colon cancer cells in the renal pelvic mucosa from ureteric metastasis has been described, metastasis of a colorectal cancer in the kidney parenchyma is extremely rare and can be treated in an organ preserving manner. A complex pattern of colon cancer recurrence with unusual and rare sites of metastasis is reported.

INTRODUCTION

Adequate resection of colon and mesentery including standardized lymphadenectomy remains the cornerstone of treatment for colorectal cancer[1-3]. Although most patients can be treated surgically with a chance of cure, colorectal neoplasms are still the second leading cause of cancer-related death because 25-50% of the patients suffer from local recurrences or metastasis after complete resection[1,4]. Without adjacent organ invasion and limited nodal disease, local recurrence should be rare depending on technical aspects and quality of the performed operation[5,6]. Among patients with recurrences, the most frequent sites are the liver and the lungs, local and/or regional retroperitoneal and peripheral lymph nodes[7]. Metastases of colorectal cancer in the kidney are considered to be extremely rare. Lee did not identify renal metastasis when analyzing colorectal tumor manifestations in the genitourinary tract[8].

CASE REPORT

In July 1998, 6 mo after laparoscopic cholecystectomy, a 77-year-old female presented herself having a palpable mass in the right upper abdomen with a heavy loss of weight. CT scan showed a tumor involving the right colonic flexure. Colonoscopy revealed an adenocarcinoma, which was intraoperatively found to be perforated locally. Right hemicolectomy and resection of the anterior wall of the duodenum were performed and a highly differentiated adenocarcinoma without lymph node involvement was found histologically. Due to the negative lymph node status, no adjuvant therapy was initiated.

Again 6 mo later a local recurrence at the anastomosis was diagnosed with infiltration of the head of the pancreas. This situation afforded re-resection including a pylorus-preserving pancreatoduodenectomy. No lymph node involvement was found and the TNM tumor stage was rpT3, G2, N0 and M0. CEA levels were normal postoperatively, adjuvant therapy was started with standard intravenous administration of 5-FU/FA for 6 mo.

In October 2001, two tumor sites were found in a MRI localized in the mesentery of the jejunum and in the lower pole of the left kidney. Partial nephrectomy and a segment of the small bowel were done. Histological examination of the kidney specimen as well as of the mesentery of the jejunum showed necrotic metastasis of the colon carcinoma in the kidney with a size of 2.5 cm in diameter. The patient refused any further adjuvant chemotherapy.

In January 2003, multiple jejunal tumors were found in a CT scan, one of them causing complete small bowel obstruction. Because of endoscopic inaccessibility, an open segment resection was needed and performed. Palliative chemotherapy with oral anti-tumor drug administration was started. It was consented not to perform any further surgery. No hepatic or pulmonary metastasis could be found during any hospital stay.

DISCUSSION

In the present case, colon cancer of the right flexure was

not diagnosed during laparoscopic surgery. The rate of missed colonic neoplasms during laparoscopic cholecystectomy is reported to be as low as 0.24-0.4%. Because of this low incidence, most surgeons do not screen patients prior to cholecystectomy for colorectal cancer routinely, although careful attention to preoperative physical findings and laboratory data as well as meticulous techniques during laparoscopic cholecystectomy is regarded to be essential to identify patients with concomitant malignant disease[9,10]. If cancer of the colon is overseen during an initial operation, 46% of the patients are readmitted during the first, and another 30% during the second year postoperatively[11]. In these advanced cases, extended surgical procedures such as hemicolectomy with duodenal or pancreatic resection have been shown to be adequate, since they can be performed safely with an increased survival time[12]. In the present case, local tumor growth could not be controlled by the surgical procedure, thus a local recurrence infiltrating the anastomosis was seen 6 mo after primary resection of the tumor.

Isolated anastomotic recurrence is rare after resection of colonic lesions, but more common for rectal cancer, whereas the average time for anastomotic recurrence is about 16 mo[13]. In the case of local or distant recurrent disease, 20% of the patients can be reoperated upon with curative intent, a solitary lesion being a favorable prognostic factor[14,15]. The purpose of postoperative follow-up after curative resection is to identify recurrences at an early and localized stage, because surgical excision remains the only effective treatment, although a substantial impact of any tumor follow-up has been questioned. Nevertheless, using computed tomography and frequent measurements of serum CEA or both, an absolute reduction in mortality of 9-13% can be achieved[16,17].

Localizations of distant colon cancer recurrences are most likely the liver and the lungs, but also metastasis to other organs, such as the thyroid gland or the spleen, has been described[18,19]. In combination with metastasis to the ureter, intraluminal implantation of colon cancer cells in the renal pelvic mucosa has been discovered[20]. Only one case of an intraluminal renal metastasis of a carcinoma of the rectum has been described before[21].

Abstract

Neurofibromas of the large bowel are very rare and usually are part of the colonic involvement in neurofibromatosis type 1 (Nf1, von Recklinghausen's disease). Solitary neurofibromas of the colon are extremely rare. We describe a case of an isolated neurofibroma that was found in the large bowel of a patient who suffered from segmental colitis and presented with bloody diarrhea. A review of the literature is also included, concerning the disclosure of isolated neurofibromas in the gut and other body parts and the type of gastrointestinal involvement in von Recklinghausen's disease.

INTRODUCTION

Neurofibromas exist rarely in the colon as isolated neoplasms outside the classical clinical picture of von Recklinghausen's disease (neurofibromatosis type 1, Nf1)[1]. Intestinal neurofibromatosis characterized by multiple neurofibromas usually in the small intestine and stomach may rarely present as a sporadic case in a patient without features of the generalized neurofibromatosis. Isolated colonic neurofibromatosis is even more unusually described in the literature[2]. Here we describe a rare case of a solitary colonic neurofibroma in a patient without features of Nf1 or isolated colonic neurofibromatosis.

CASE REPORT

A 65-year-old Caucasian female came to the emergency department of our hospital complaining of bloody diarrhea. Twelve hours before admission the patient experienced a dull abdominal pain of sudden onset, located at the hypogastrium, and her temperature rose to 37.8 ℃. She reported 10 bowel movements, which were diarrheal at first and became hemorrhagic later. Physical examination revealed moderate tenderness on palpation of the hypogastrium and increased bowel sounds on auscultation. Inspection of the skin revealed two firm, subcutaneous masses with ill-defined borders, each one located at the apex of the scapula with a diameter of 2 cm. Physical examination of the lungs, heart, skin, and other body systems revealed no abnormal features. It was the first episode of bloody diarrhea experienced by the patient. Her past medical history included essential hypertension, hyperlipidemia, and an acute coronary syndrome and she was receiving an angiotensin-converting enzyme inhibitor, enteric-coated aspirin and a statin. Furthermore, she had atopy to grass, tree pollens and fungal spores, manifested by bronchoconstriction. There was no family history of intestinal diseases.

Laboratory investigation including complete blood count, biochemical examination, tumor markers (CEA, CA 19-9, aFP, CA125, CA 15-3), coagulation tests, microbiological cultures for bacterial and parasites in feces and cultures of the urine were normal except for a slightly elevated blood glucose level (120 mg%) and CRP (12, normal <4). Chest x-ray and ECG had no abnormal features. An abdominal plain radiograph showed only an air-filled large bowel.

Colonoscopy was performed after cessation of the hemorrhage. The endoscope reached the hepatic flexure and revealed a segmental colitis. At the splenic flexure and proximal portion of the descending colon there were erythema and edema of the mucosa with hemorrhagic petechiae. A sessile polyp 1 cm in diameter was detected at the descending colon, near the site of inflammation and was endoscopically removed. The transverse colon and the rectum were macroscopically normal. At the sigmoid colon a few, small diverticulae were noticed, without inflammation. Ultrasonography of the abdomen revealed no pathological findings.

Pathology findings

Microscopically, the biopsy from the polyp showed fragments of mucosa of the large bowel lined by normal epithelium. In the lamina propria there was a nodule, with ill-defined borders, which was composed of longitudinal cells with elongated, pointed nucleus. These cells were

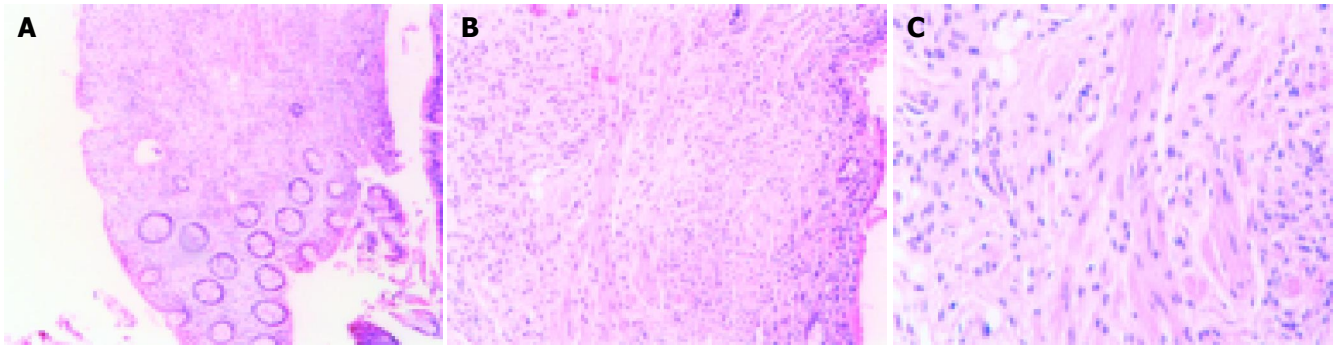

Figure 1 **A**: Neurofibroma, hematoxylin-eosin (H-E) ×100; **B**: Neurofibroma, H-E ×250; **C**: Neurofibroma, H-E ×400.

deposited in interlaced bundles and in near proximity with collagen fibers. There were no signs of atypia, nor significant mitotic activity. Immunohistochemical stains were positive for vimentin and S-100 protein but negative for desmin, smooth muscle actin, c-kit and CD34. The above morphological and immunohistochemical characteristics were consistent with the diagnosis of neurofibroma (Figures 1A-C). Biopsy samples from the site of colitis showed focal erosions of the surface mucosal epithelium and focal decrease in mucus production. The architecture of the glands was intact. There was edema and dense infiltrate of inflammatory cells (lymphocytes, polymorphonuclear and plasma cells) in the lamina propria. There was an increased number of eosinophils in the same area. Crypt abscesses were rarely encountered. Granulomas were not recognized microscopically. These findings could not support a definite diagnosis of idiopathic inflammatory bowel disease and were classified as nonspecific colitis (Figures 2A-C).

Clinically the patient had no café-au-lait spots on her skin, axillary freckling or peripheral neurofibromas. Also there were no pigmented hamartomas of the iris and no family history of neurofibromatosis. The patient received crystalloid solutions, antibiotics and mesalazine, had an uneventful recovery and was discharged 5 d later. Two months later in a follow-up examination, the patient had no symptoms from the intestine and her physical examination was unremarkable. Colonoscopy was again performed and the colon was examined to the hepatic flexure. The previous findings were absent and the mucosal surface was normal. The patient was advised to have a barium enema done for the visualization of the remaining large bowel which showed only diverticula of the right colon and sigmoid. Due to the polypoid neurofibroma the patient underwent spiral CT of the brain, thorax and abdomen for pathological features associated with neurofibromatosis. No abnormalities were found. Biopsy samples, taken from one of the subcutaneous masses located at the back of the patient showed a lipoma with fibrous components and S-100 negative immunoreactivity. New serum laboratory tests were normal except glucose, which was 142 mg%. Gastroscopy revealed erosive duodenitis and no other suspicious pathologic lesion.

DISCUSSION

Neurofibromas are usually manifestations of the von Recklinghausen's disease. They are benign neoplasms consisting of neural and connective tissue components like Schwann and perineural cells and myofibroblasts. They are usually multiple on presentation and are part of a hereditary disorder with two clinical forms: Nf1 (or von Recklinghausen's neurofibromatosis or peripheral neurofibromatosis, Nf1) and neurofibromatosis type 2 (or central neurofibromatosis or bilateral acoustic neurofibromatosis). These disease entities have variable clinical expressions with manifestations involving the skin, nervous system, eyes, bones, gastrointestinal tract, and other body parts. Cardiovascular disease manifested as hypertension, myocardial infarction, hemorrhage, or cerebral ischemia, are the most frequent causes of death in Nf1 patients[3]. Survival is lesser than expected in the normal population as much as 15 years. There is also a disease type called segmental neurofibromatosis, which involves a specific

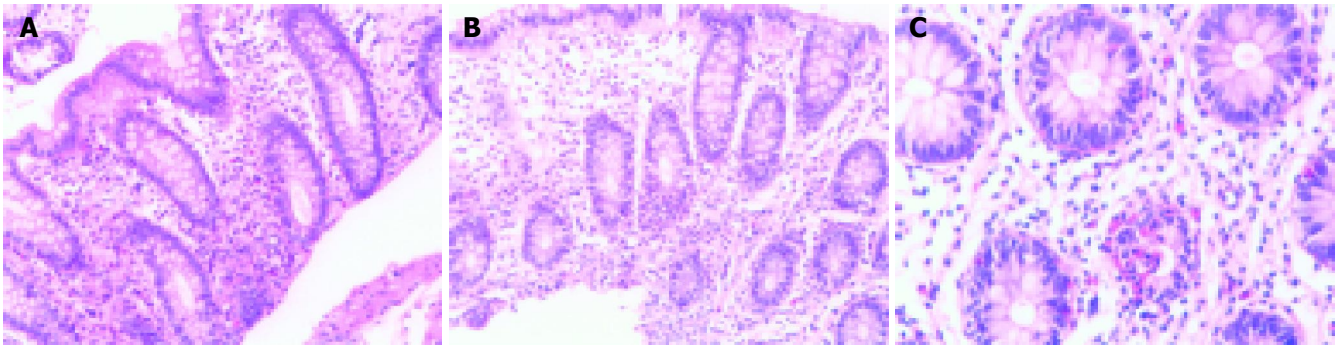

Figure 2 **A**: Nonspecific colitis, H–E ×250; **B**: Nonspecific colitis, H-E ×250; **C**: Nonspecific colitis, crypt abscess, H-E ×400.

body organ without the variety of multiple pathologic expressions of the generalized form.

Neurofibromas of the digestive system are usually found as part of the Nf1. This is a relative common inherited disorder based on genetic transmission of the autosomal dominant type. The incidence of the disease is 1:3 000 births and the population prevalence is 1:5 000[1,4]. The diagnostic criteria for Nf1 include the following: (1) the so-called "café-au-lait" spots (at least six spots, size $\geqslant$1.5 cm in postpubertal patients), (2) the characteristic neurofibromas (at least two or one plexiform), (3) axillary or groin freckling, (4) pigmented hamartomas of the iris, the so-called Lisch nodules (at least two), (5) an osseous lesion which may include thinning of the long bone cortex or sphenoid wing dysplasia, (6) first degree relative with Nf1, (7) optic glioma. The patient should have at least two of the previous criteria to be considered as Nf1. The penetrance of the disease is 100% until age 5[5]. The majority of patients have café-au-lait spots (95%), neurofibromas (95%), Lisch nodules (95%) and axillary freckling (70%). Optic gliomas affect 15% of the patients[1]. Café-au-lait spots most commonly present before 2 years of age[6].

Neurofibromas may be cutaneous, nodular derived from peripheral nerves or plexiform with aggressive, infiltrative growth that extends outside the nerve sheath to the surrounding tissue. Although benign, neurofibromas of the nodular and particular the plexiform type may demonstrate a malignant transformation in 2-16% of affected individuals[1,2,7]. About 50% of the cases of Nf1 are not familial but sporadic as a result of germ-cell mutations. Segmental Nf seems to involve a group of somatic cells that have exclusively acquired the specific neurofibromatosis mutations presenting a mosaicism[4]. The Nf1 gene has been located on chromosome 17q11.2 and produces a peptide of 2 818 aminoacids, called neurofibromin, which works as a tumor suppressor[1,3]. Neurofibromin seems to interact with the RAS/GTP membrane-signaling pathway in cells by activating the GTPase that converts GTP to inactive GDP and therefore shutting down the RAS effector system which is involved in cell growth and differentiation. Mutations of the Nf1 gene result in deficient neurofibromin, which in turn seems unable to control responses to proliferation signaling thus giving birth to neoplastic growth.

Participation of the gastrointestinal tract has been documented in 25% of patients with Nf1. Ganglioneuromatosis and neurofibromatosis are the pathologic forms of gastrointestinal involvement[8]. Ganglioneuromatosis refers to extended hyperplasia and hypertrophy of the nerve plexuses and ganglion cells in the mucosa or throughout the intestinal wall. Characteristic neurofibromas have been found in the digestive tract in 11% of patients with Nf1[5].

Intestinal neurofibromatosis exists, in the majority of cases, in association with Nf1 and only rarely presents outside this disease as a separate pathologic entity (familial or sporadic)[2]. Multiple neurofibromas are discovered in the gut, more often located in the jejunum, stomach, ileum, duodenum, and colon according to the frequency of their appearance[1,5]. Neurofibromas are usually originating from either the plexus of Meissner in the submucosa or the plexus of Auerbach's in the muscularis propria or even from the serosa[2,9]. The lesions are often sessile and wide based but also pedunculated polyps have been observed[2]. These lesions most often are discovered in the 4th-6th decade of life[8-10]. It is common to remain clinically silent and rarely cause symptoms before puberty. Nf1 is also associated with the occurrence of other neoplasms that involve the gastrointestinal tract. These include carcinoids and somatostatinomas that are located mainly in the duodenum and ampulla of Vater, stromal tumors mainly leiomyomas and sarcomas and pancreatic adenocarcinomas[5,8,10]. The clinical picture includes abdominal pain, palpable masses, hemorrhage due to necrosis or ulceration of the mucosa, obstruction due to intussusception or extraluminar pressure, perforation, megacolon, peptic ulcer disease, diarrhea, steatorrhea, obstructive jaundice and obstruction of the pancreatic tract. Iron deficiency anemia has also been reported and caused by occult blood loss[2,5,11].

Neurofibromatosis of the colon as part of the Nf1 is rare[7,9,12–14]. Isolated colonic neurofibromatosis without other features suggestive of Nf1 has been very rarely encountered in the clinical practice. Only 13 such cases of isolated colonic neurofibromatosis with no evidence of Nf1 have been documented in the literature[2,15]. Isolated neurofibromas of the colon are even rarer and only two such cases have been published[11]. In the first case an asymptomatic polyp was discovered to represent a neurofibroma while in the second case the neurofibroma presented as a large polypoid mass in the transverse colon. The mass had intussuscepted into the rectum causing massive bleeding of the gastrointestinal tract. There are also other parts of the digestive tract in which solitary neurofibromas have been detected. There have been 8 cases of solitary mesentery neurofibroma (7 ileal, 1 gastrocolic)[6], 1 case of ileal isolated neurofibroma[16], 3 cases of the anal canal[17], 1 case of the esophagus[18], 1 case of the soft palate[19], 7 cases of the gallbladder[20], and 1 case of the common bile duct[21].

Isolated neurofibromas in other body organs are also very rare. Very few cases have been reported so far, namely to the kidney[22], spermatic cord[23], nasal cavity[24], palatine tonsil[25], parapharyngeal space[26], larynx[27], humerus[28], submandibular salivary gland[29], conjuctiva[30], retroperitoneal space[31], cranial ventricles[32], and chest wall[33].

In our case a solitary neurofibroma was discovered in the descending colon in the form of a sessile polyp. The patient has no associated features of von Recklinghausen's disease. The patient presented with lower gastrointestinal bleeding. In colonoscopy a segmental colitis was revealed, involving the splenic flexure and associated proximal part of the descending colon. Although a definite diagnosis of ischemic colitis cannot be made, there are many clues that support this explanation. The medical history of atherosclerotic disease including hypertension, ischemic heart attack, diabetes and hyperlipidemia (syndrome X), which justify the presence of predisposing factors for the development of vascular blood flow defects as a pathogenetic mechanism for ischemic attacks. The age of the patient is compatible with ischemia. The symptoms and physical findings are among those found in ischemic, perfusion-compromised bowel: sudden onset of pain in the lower

abdomen, passage of red blood with stools within 24 h and abdominal tenderness. The endoscopic findings of transient, segmental colitis located around the splenic flexure are a characteristic pattern in 11% of colonic ischemia. The histologic evaluation of the biopsy specimens revealed a nonspecific inflammatory process, which is mostly encountered in mild cases of ischemic colitis. The clinical course with remission of symptoms within 72 h and the reversal of mucosal damage after 8 wk correlates with the usual prognosis of mild ischemic colitis. In less than 10% of patients with colonic ischemia, there is a potentially obstructing lesion located distally to the ischemic segment with normal intervening mucosa between them. In our case the polypoid neurofibroma and the diverticula of the sigmoid appear at a site distal to the colitis.

Aspirin, which is a drug implicated in the induction of inflammatory colitis, might have attributed to the patient's symptoms. In a recent review, 5 cases of inflammatory colitis have been attributed to hypersensitivity reactions caused by salicylates[34]. The clinical presentation in these cases has included, among others, abdominal pain, distention, and pyrexia. Endoscopy has revealed erythema, friability and ulcers and the histologic examination included an eosinophilic infiltration and crypt abscesses. Many of the above symptoms and signs also exist in our case and therefore aspirin colitis may also be an explanation for our findings.

Abstract

A 62-year-old male was referred to our hospital because of liver dysfunction, diffuse pancreatic swelling, and trachelophyma. At admission, the patient was free of pain. Physical examination showed enlarged and palpable bilateral submandibular masses, but no palpable mass or organomegaly in the abdomen. Laboratory findings were as follows: total protein 90 g/L with γ-globulin of 37.3% (33 g/L), total bilirubin 4 mg/L, aspartate aminotransferase 39 IU/L, alanine aminotransferase 67 IU/L, γ-glutamyl transpeptidase 1 647 IU/L, and amylase 135 IU/L. Autoantibodies were negative, and tumor markers were within the normal range. Serum IgG4 level was markedly elevated (18 900 mg/L). Computed tomography (CT) showed diffuse swelling of the pancreas and dilatation of both common and intra-hepatic bile ducts. Endoscopic retrograde pancreatography (ERP) revealed diffuse irregular and narrow main pancreatic duct and stenosis of the lower common bile duct. Biopsy specimens from the pancreas, salivary gland and liver showed marked periductal IgG4-positive plasma cell infiltration with fibrosis. We considered this patient to be autoimmune pancreatitis (AIP) with fibrosclerosis of the salivary gland and biliary tract, prescribed prednisolone at an initial dose of 40 mg/d. Three months later, the laboratory data improved almost to normal. Abdominal CT reflected prominent improvement in the pancreatic lesion. Swelling of the salivary gland also improved. At present, the patient is on 10 mg/d of prednisolone without recurrence of the pancreatitis. We present here a case of AIP with fibrosclerosis of salivary gland and biliary tract.

CASE REPORT

A 62-year-old Japanese male was referred to our hospital because of liver dysfunction, common and intra-hepatic bile duct dilatation, diffuse pancreatic swelling, and trachelophyma. He had complained about fatigability and appetite loss without abdominal pain and noticed enlarged bilateral submandibular masses. There was no past history of pancreatitis, biliary tract disease or collagen disease. He was not a habitual drinker, and his family history was not contributory.

On admission, the patient was free of pain. Physical examination showed enlarged and palpable bilateral submandibular masses, but no palpable mass or organomegaly in the abdomen. Laboratory tests showed elevation of hepatobiliary enzyme levels without hyperbilirubinemia: total-bilirubin 7 mg/L, aspartate aminotransferase 39 IU/L, alanine aminotransferase 67 IU/L, alkaline phosphatase 1 293 IU/L, γ-glutamyl transpeptidase 1 647 IU/L. BUN and creatinine (Cre) levels were also elevated; BUN 230 mg/L, Cre 17 mg/L. Serum IgG level was elevated to 33 680 mg/L, serum IgG4, a subclass of IgG, was especially elevated to 1 890 mg/mL, although autoantibodies such as anti-nuclear antibodies (ANA), rheumatoid factor (RF), SS-A and SS-B antibody were negative. Pancreatic enzyme levels were elevated except for amylase (Amy); Amy 135 IU/L, lipase 95 IU/L, trypsin 584 ng/mL, elastase I 5 200 ng/L, and pancreatic exocrine function determined by the urinary para-aminobutyric acid excretion rate (BT-PABA test) was 27.5%. Tumor markers were also elevated: CA19-9 125 U/mL, DUPAN-2 330 U/mL, and SPAN-1 97 U/mL. The 75 g oral glucose tolerance test showed a diabetic pattern. The glucagon-loading test revealed impaired insulin secretory function.

Contrast-enhanced abdominal CT demonstrated diffuse enlargement of the pancreas, wall thickness of the dilated common bile duct, and heterogeneous enhancement of both kidneys (Figures 1A and B). Endoscopic retrograde pancreatography (ERP) revealed an irregular narrowing of the entire main pancreatic duct (Figure 2A). Drip infusion cholangiography-CT (DIC-CT) showed a smooth stenosis

Figures 1 Abdominal CT scans on admission. Note the diffuse enlargement of the pancreas and wall thickness of the enlarged common bile duct (CBD) (white circle) (**A**, **B**). Abdominal CT scans taken at 3 mo after treatment. Note the improvement in pancreatic swelling and CBD (**C**, **D**).

of the lower common bile duct with upstream dilatation (Figure 2B). Ultrasonography (US) of the neck showed diffuse swelling of bilateral salivary glands and Ga scintigraphy revealed abnormal uptake in the salivary glands (Figures 3A and B).

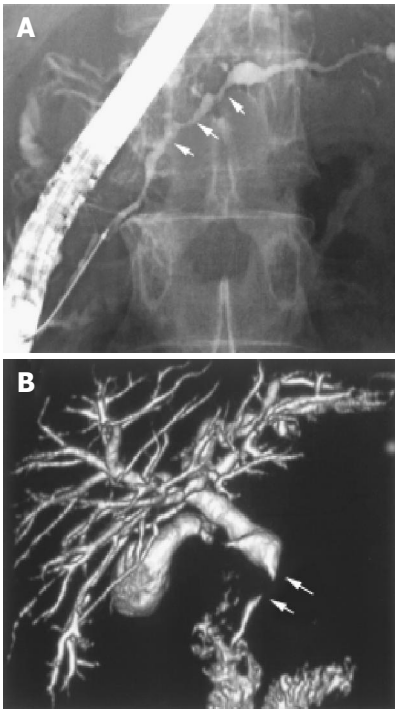

Figure 2 ERP (**A**) and DIC-CT (**B**) on admission. **A**: Note the diffuse irregular narrowing of the main pancreatic duct (arrow); **B**: Note the smooth stenosis of the common bile duct (arrow) and dilatation of the distal portion of the biliary tract.

Pancreatic tissue samples obtained by needle biopsy under US showed periductal lymphoplasmacytic infiltration and marked interstitial fibrosis with acinar atrophy (Figures 4A and B). Immunohistochemically, diffuse infiltrates in the pancreas consisted predominantly of CD4- or CD8-positive T lymphocytes, and IgG4-positive plasma cells rather than CD20-positive B lymphocytes (Figures 4C-F). Liver and salivary gland tissue samples by

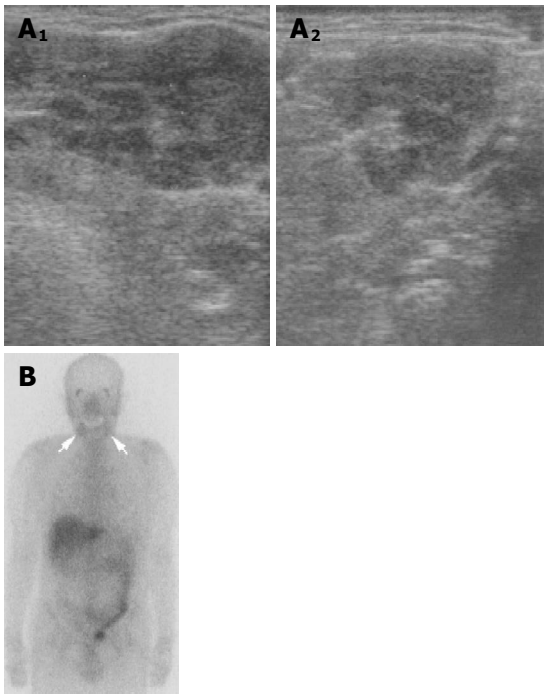

Figure 3 Neck US (**A**) and Ga scintigraphy (**B**) on admission. Note the diffuse swelling (**A**) and abnormal uptake (**B**: arrow) in the bilateral salivary glands.

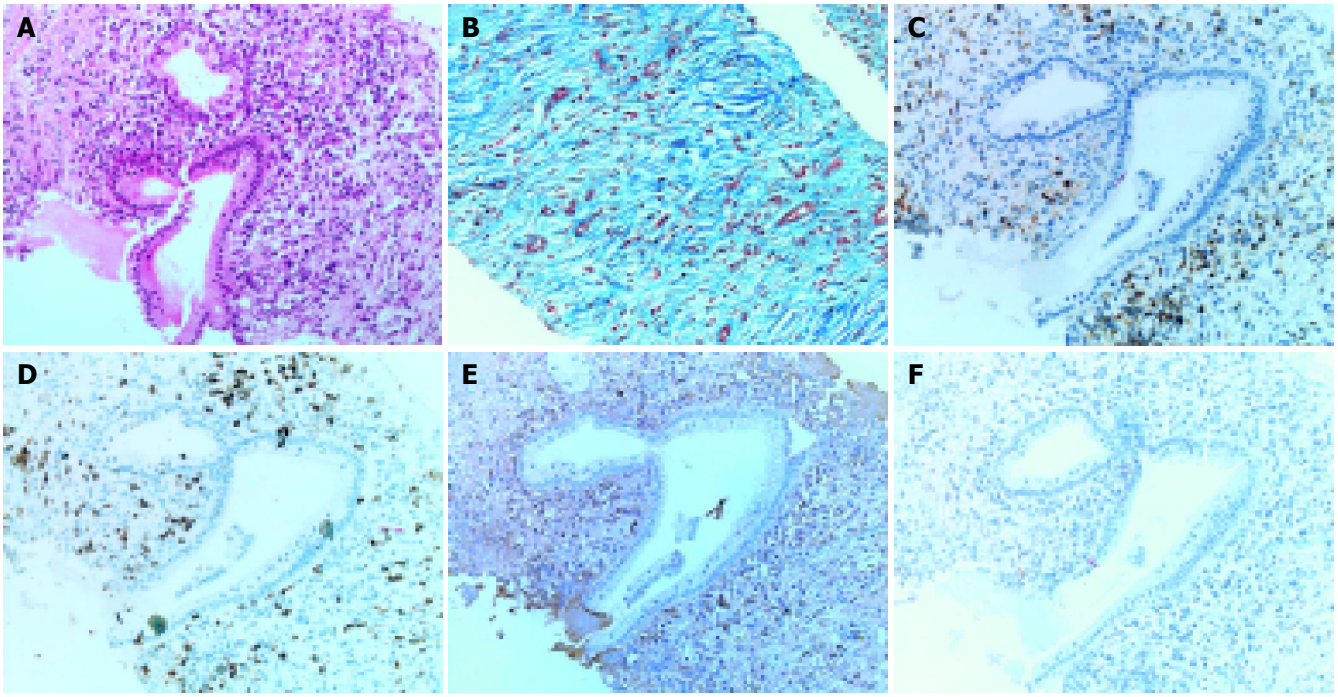

Figure 4 Histological examination of pancreatic specimen obtained by needle biopsy. Note the extensive fibrosis, acinar atrophy, infiltration of lymphocytes and plasma cells were seen. The infiltrates were observed predominantly around the pancreatic duct (**A**: hematoxylin and eosin staining; **B**: Masson staining). These infiltrates consisted mainly of CD4- or CD8-positive T lymphocytes, and CD20-negative and IgG4-positive plasma cells (**C**-**F**: immunostaining of CD4, 8, IgG4, and CD20 respectively).

needle biopsy also showed the periductal IgG4-positive plasma cell infiltration with interstitial fibrosis (Figures 5A-D).

Oral administration of prednisolone at an initial dose of 40 mg/d, following a diagnosis of autoimmune pancreatitis (AIP), led to an immediate improvement in all blood chemistries including tumor markers and serum γ-globulin concentration. In addition, the endocrine function improved from HbA1c 6.6% to 5.7%, the exocrine function determined by BT-PABA test also improved from 27.5% to 52.9% and renal function determined by serum Cre improved from 17 to 11 mg/L after steroid therapy. Subsequent follow-up CT showed improvement in pancreatic swelling, stenosis of lower common bile duct with upstream dilatation and wall thickness of the bile ducts and heterogeneous enhancement of both kidneys (Figures 1C and D). Moreover, the salivary glands swelling also improved. Prednisolone was gradually reduced to 10 mg/d over the course of 9 wk without any exacerbation.

DISCUSSION

AIP is a recently noted clinical entity and a rare group of pancreatitis in which autoimmunity is a suspected pathogenic mechanism. The diagnostic criteria for AIP according to the Japan Pancreas Society (2002) are as follows: (1) Diffuse or segmental narrowing of the main pancreatic duct with irregular wall (more than 1/3 length of the entire pancreas) and diffuse or localized enlargement of the pancreas by imaging studies, such as US, CT and magnetic resonance imaging. (2) High serum γ-globulin and/or IgG, or the presence of autoantibodies, such as ANA and RF. (3) Marked inter-lobular fibrosis and prominent infiltration of lymphocytes and plasma cells in the periductal area occasionally with lymphoid follicles in the pancreas. Diagnosis of AIP is established when criterion 1, together with criteria 2 and/or 3, are fulfilled[1-3]. We diagnosed our patient as AIP by these criteria.

Recent studies have revealed extrapancreatic involvements in AIP, such as sclerosing cholangitis, retroperitoneal fibrosis, and salivary gland swelling[4,5]. In AIP patients, the high serum levels of IgG4, subclass of IgG, and IgG4-positive lymphoplasmacytic infiltration are observed not only in the pancreas, but also in extra-pancreatic organs, such as the biliary duct, salivary gland and lymph nodes. These observations suggest a common pathogenesis related to the IgG4 subclass of immune complexes[6,7]. In our case, immunohistochemical examination of biopsied specimens showed infiltration of IgG4-positive plasma cells in the periductal area of the salivary gland (Figure 5D) and the portal area of the liver (Figure 5B), as well as in the pancreas (Figure 4E).

Nishimori *et al*.[8], found jaundice in 30% of AIP patients and stenosis of the lower common bile duct in 68% of 64 AIP patients. Two possible mechanisms of stenosis were hypothesized: one is the direct effect of the swollen pancreas on the bile duct, the other is wall inflammatory swelling of the bile duct wall, independent of the pancreas. In our case, smooth stenosis of the lower common bile duct was accompanied by wall thickening of bile duct (Figure 1A), which improved completely after steroid therapy (Figure 1C). These results support the latter hypothesis. It is reported that the histological features of bile duct lesions are similar to those typically seen in the pancreas[9]. Moreover, the liver biopsy specimen showed IgG4-positive cell infiltration

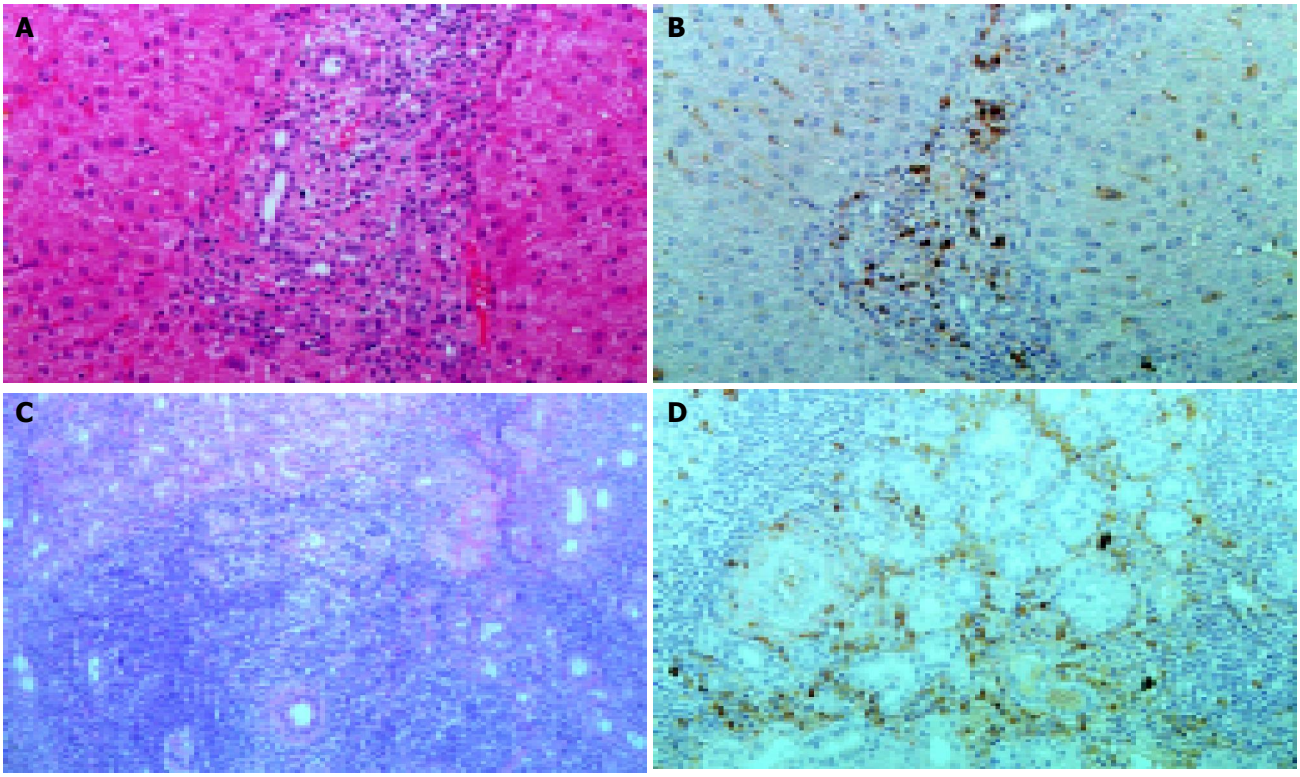

Figure 5 Histopathological examination of the liver (**A** and **B**) and salivary gland (**C** and **D**) specimens obtained by needle biopsy. Note the infiltrated lymphocytes and IgG4-positive plasma cells in the portal area, around the ducts of the salivary gland (**A** and **C**: hematoxylin and eosin staining, **B** and **D**: immunostaining of IgG4).

around the small bile duct in the portal area (Figure 5B). In fact, the focus of the bile duct, one of the extrapancreatic lesion of AIP, is diffuse from the common to intrahepatic bile ducts. Stenosis of the upper common bile was seen in 53% of AIP patients[8].

Pancreatic islets as well as acinar cells are involved in the same inflammatory process in AIP[10]. Kamisawa *et al*.[11], reported that 42% and 88% of AIP showed pancreatic endocrine and exocrine dysfunction, respectively. The endocrine and exocrine function improved in 60% and 50% of these patients after steroid therapy, respectively. Although we were unable to demonstrate extensive islet destruction in the pancreas due to lack of islets in the biopsy specimen, HbA1c, a marker of glycemic control, improved without anti-diabetic treatment and the exocrine function evaluated by BT-PABA test also improved after steroid therapy.

Salivary gland function, which is known to be frequently impaired in patient with AIP, even when clinical symptoms are not obvious as determined by β_2-microglobulin level in the saliva and parotid gland scintigraphy improves after steroid therapy in almost all AIP patients[11,12]. In our case, the patient noticed swelling of the salivary glands and abundant infiltration of IgG4-positive plasma cells, which has not been detected in Sjögren's syndrome[7]. In addition, specific marker of Sjögren's syndrome, anti SS-A and SS-B antibodies were negative. Swelling of the salivary glands disappeared after steroid therapy. These results suggest that the salivary swelling was due to extrapancreatic lesion of AIP rather than due to Sjögren's syndrome. Ductal system of salivary gland and pancreas are similar in histological structure, so common autoantigen might be involved in the pathogenesis of these organs.

On admission, mild renal dysfunction was seen and contrast-enhanced CT demonstrated heterogeneous enhancement of both kidneys (Figure 1B). Treatment with steroid improved CT findings (Figure 1D) and renal function. Renal dysfunction in AIP is reported to be due to retroperitoneal fibrosis[13] and/or IgG4-associated tubulointerstitial nephritis[14,15]. Although we could not prove histologically, renal dysfunction in the present case was probably due to tubulointerstitial nephritis, one of the extrapancreatic involvements in AIP.

Following steroid therapy, most of all clinical symptoms and laboratory data improved and the pancreas became small and atrophic (Figure 1C). Takayama *et al*.[16], reported pancreatic stones in 20% of AIP patients during observation for 4.5 years. This suggests that AIP is a progressive disease and a possibility of an early stage of idiopathic chronic pancreatitis. We continued maintenance steroid therapy at 10 mg/d, but prognosis with AIP is also unknown at this stage.

In conclusion, we presented here a case of AIP with IgG4-associated fibrosclerosis of the salivary gland and biliary tract. AIP may be one lesion of systemic multifocal fibrosclerosis in some cases.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG,* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published jointly by
The WJG Press and Elsevier Inc.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the Editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Elsevier Inc., and may not be reproduced by any means, in whole or in part without the written permission of both the Authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com for assistance. If you submit manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

World Journal of Gastroenterology
Apartment 1066 Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors originating from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be involved. Titles should be concise and informative (removing all unnecessary words), emphasize what is NEW, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initials and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or Figures and Tables, not both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should add into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) and not RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by Freehand and Illustrator, or TIFF from Photoshop. EPS files must be accompanied by a version in native file format for editing purposes. Scans of existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size at which they will appear when printed, not smaller. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...;C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be involved under the tables. This part should add into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data which is not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used; Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^1F, ^2F, ^3F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

References

Cited references should mainly be drawn from journals covered in the Science Citation Index (http://www.isinet.com) and/or Index Medicus (http://www.ncbi.nlm.nih.gov/PubMed) databases. Mention all references in the text, tables and figure legends, and set off by consecutive, superscripted Arabic numerals. References should be numbered consecutively in the order in which they appear in the text. Abbreviate journal title names according to the Index Medicus style (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=journals). Unpublished observations and personal communications are not listed as references. The style and punctuation of the references conform to ISO standard and the Vancouver style (5th edition); see examples below. Reference lists not conforming to this style could lead to delayed or even rejected publication status. Examples:

PMID requirement

From the full reference list, please submit a separate list of those references embodied in PubMed, keeping the same order as in the full reference list, with the following information only: (1) abbreviated journal name and citation (e.g. *World J Gastroenterol* 2003;9(11): 2400-2403; (2) article title (e.g. Epidemiology of gastroenterologic cancer in Henan Province, China; (3) full author list (e.g. Lu JB, Sun XB, Dai DX, Zhu SK, Chang QL, Liu SZ, Duan WJ; (4) PMID (e.g. 14606064). Provide the full abstracts of these references, as quoted from PubMed on a 3.5 inch disk or CD-ROM in Microsoft Word format and send by post to The *WJG* Press. For those references taken from journals not indexed by *Index Medicus*, a printed copy of the first page of the full reference should be submitted. Attach these references to the end of the manuscript in their order of appearance in the text.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean±SD and mean±SE.

Statistical expression

Express *t* test as *t*(in italics), *F* test as *F*(in italics), chi square test as χ^2 (in Greek), related coefficient as *r*(in italics), degree of freedom as γ(in Greek), sample number as *n*(in italics), and probability as *P*(in italics).

Units

Use SI units. For example: body mass, m(B) = 78 kg; blood pressure, p (B)=16.2/12.3 kPa; incubation time, t(incubation)=96 h, blood glucose concentration, c(glucose) 6.4±2.1 mmol/L; blood CEA mass concentration, p(CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23,243,641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italicization

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *Helicobacter pylori, H pylori, E coli, etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the WJG Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of WJG to acquire copyright in all contributions. Papers accepted for publication become the copyright of WJG and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

Abstract

The surgical outcome of most early gastric cancer (EGC) is usually satisfactory. Some cases show bone metastasis even though the depth of cancer invasion is confined to the mucosa. The most frequent site for recurrence of EGC is the liver. Cases of EGC with bone metastasis are reviewed to clarify the clinicopathological characteristics of EGC giving rise to bone metastasis. Possible mechanisms and risk factors underlying this rare condition are proposed. Forty-six cases of bone metastasis from EGC are reviewed from published reports and meeting proceedings in Japan. This investigation suggests that risk factors for bone metastasis from EGC include depressed-type signet-ring cell carcinoma, poorly differentiated carcinoma, and/or the likely involvement of lymph node metastasis, even though the cancer is confined to the gastric mucosa. The risk factors do not include recurrence of EGC in the liver. We speculate that the mechanism of bone metastasis from EGC is via lymphatic channels and systemic circulation. Post-operative follow-up of cases should consider the development of bone metastasis from EGC. We propose the use of elevated alkaline phosphatase levels for the detection of bone metastasis and recommend bone scintigraphy in positive cases.

INTRODUCTION

Early gastric cancer (EGC) is defined as a cancer confined to the mucosa or submucosa regardless of lymph node metastasis and/or distant metastasis. Although the 5-year survival rate for EGC is 90% or greater[1], EGC can recur. Most of the recurrences from EGC are hematogenous metastasis of the liver. Bone metastasis is a common event in advanced cancers of the breast, lung and prostate, but not in gastric cancer (GC). We have previously reported a rare case of mucosal EGC giving rise to multiple bone metastases[2].

In this article, we reviewed bone metastasis from EGC through a literature search of published reports and meeting proceedings in Japan. We have discussed the possible mechanisms and risk factors underlying this rare condition.

RECURRENCE OF EGC

Ichiyoshi *et al*., reviewed 503 consecutive cases of curative resection for EGC at a single institution from 1965 to 1988[3]. Seventeen patients (3.4%) died from a recurrence of GC. Of these 17 cases, 9 with submucosal invasion developed hematogenous metastasis in the liver, lung or bone. These cases showed that high-risk factors for hematogenous recurrence included submucosal cancers with a macroscopically elevated lesion, lymph node metastasis, and vessel invasion[4].

Sano *et al*., investigated the follow-up records of 1 475 EGC cases treated at the National Cancer Center Hospital Tokyo[4]. Twenty patients (1.4%) developed a recurrence of GC, including 14 (70%) with the lymph node metastases and 13 (65%) with blood-borne metastases. The incidence of recurrence of GC was shown to be significantly higher in submucosal, node-positive, and histologically differentiated carcinomas than in mucosal, node-negative, and undifferentiated groups. Hematogenous metastasis was thought to be the most common mode of recurrence and the investigation by Sano *et al*., showed that hematogenous recurrence of EGC accounted for 68% of 91 histologically differentiated tumors and 34% of 32 undifferentiated tumors[4]. This review also showed that lymph node metastasis at the time of surgery was not related to the mode of recurrence.

Lee *et al*., investigated 1 452 EGC patients with curative resection at Seoul National University Hospital in Korea from 1986 to 1995[5]. Twenty-one patients (1.4%) showing recurrence of GC included four cases with locoregional disease, two with peritoneal disease, nine with distant recurrence, and six with a mixed pattern of recurrence. Using multivariate analysis Lee *et al*., concluded that EGC with lymph node metastasis carries a high risk of recurrence.

Guadagni *et al*.[6], investigated 172 EGC patients who underwent gastrectomy at seven institutes in Italy. Twelve patients (7.0%) developed a recurrence of GC after surgery. Of these, three had liver metastasis, two had lymph node

recurrence, four had peritoneal disease and five had recurrence of GC in the gastric stump. The two cases with lymph node metastasis also had peritoneal dissemination. The most frequent site of recurrence was the gastric stump and Guadagni *et al*., concluded that recurrence in this location may be related to inadequate histological examination of resection margins. They suggested that submucosal and intestinal type cancers were a high risk factor for recurrence of GC.

Kodama *et al*., investigated 167 EGC cases and proposed growth patterns for EGC[7]. They classified a carcinoma growing expansively with complete destruction of the muscularis mucosae as Pen A-type. The characteristics of Pen A-type carcinoma were elevated lesions (87.5%), histological differentiation (81.3%), a high incidence of lymphatic metastasis and frequent hematogenous metastasis. The most common site of recurrence for this type of cancer was liver metastasis within 3 years[7].

According to the reports discussed above, the recurrence of EGC occurs in 1.4-3.4% of surgically resected cases. Macroscopically elevated, submucosal, lymph node positive, and histologically differentiated cancer types show a higher incidence of recurrence than their counterparts. The most common mode of recurrence is hematogenous metastasis of the liver. Bone metastasis is rare, even in cases with hematogenous recurrence of GC.

LYMPH NODE METASTASIS IN EGC

The most important prognostic factor for patients with EGC is the presence of lymph node metastasis. Lymph node metastasis of EGC is found in 5.4-24.0% of cases. Sano *et al*., investigated the clinicopathological features of 748 solitary EGC cases and found that only depth of invasion (submucosal invasion) and tumor size (more than 2 cm) significantly correlated with lymph node metastasis[8]. Maehara *et al*., analyzed 396 EGC cases and found that lymphatic involvement, in addition to depth of invasion and tumor size, were independent risk factors for the occurrence of lymph node metastasis[9]. Lehnert *et al*., reported that the rate of lymph node metastasis of mucosal and submucosal EGC is 4.2% (of a total of 1 447 cases) and 16.8% (of a total of 1 509 cases), respectively[10]. Gotoda *et al*., reported that the rate of lymph node metastasis from intramucosal cancer was 2.2%[11] and for differentiated and undifferentiated mucosal carcinoma was 0.4% and 4.2%, respectively. They showed that lymph node metastases from differentiated and undifferentiated submucosal cancer were 17.0% and 15.1%, respectively[11].

Although metastases occurs most commonly in peri-gastric nodes, Kawata *et al*., identified 16 EGC cases, until 1991 in Japan, with distant lymph node metastasis. Most of these cases showed submucosal invasion, only two had mucosal EGC, one case had bilateral inguinal lymph node metastasis, and one had paraaortic lymph node metastasis[12].

BONE METASTASIS IN GC

Bone metastasis is a rare condition in GC and is clinically underestimated. Mori *et al*., investigated 719 cases of malignant tumors among 2 240 consecutive autopsies[13] in Tokyo Medical and Dental University. These included 176 cases of GC of which 28 cases (15.9%) exhibited metastasis in bone, the third-most common site of GC metastases. The metastatic rate in the liver and lungs was 34.7% and 31.3%, respectively. Consistent with these findings, Yoshikawa and Kitaoka and Yamamura *et al*., showed that the metastatic rate in bone from curatively resected GC cases was high among autopsy cases, but was comparatively low in clinical practice at a rate of 1.2-1.4%[14,15]. Also in support of these findings, Maeyama *et al*., reported the rate of bone metastasis in clinical practice and autopsy as 0.7% and 17.6%, respectively.

Choi *et al*., evaluated bone metastasis from GC by bone scintigraphy[16]. They investigated 234 bone scans from a total of 17 176 GC patients. The 234 patients were classified according to their original clinical stage rather than by standard stage and were identified as having advanced stage disease. Of these cases, 106 (45.3%) had metastatic bone lesions.

The findings discussed above suggest that asymptomatic bone metastasis is underestimated as examination by bone scintigraphy is not a routine clinical practice. It is also possible that peritoneal dissemination or liver metastasis masks the clinical manifestation of bone metastasis. For these reasons, the rate of bone metastasis in clinical cases may be higher than expected.

OTHER DETECTION METHODS FOR BONE METASTASIS FROM GC

Maehara *et al*., investigated bone micrometastasis using a monoclonal anti-cytokeratin antibody[17]. They found that 9 (20%) of 45 EGC cases examined had cytokeratin-positive cells in the bone marrow at the time of primary surgery. Microvessel density in the primary tumor was significantly higher in cytokeratin-positive than in cytokeratin-negative patients. These findings suggested that the presence of micrometastatic cells in the bone marrow was closely related to angiogenesis in the primary tumor.

Immunocytochemistry was performed by Macadam *et al*., to investigate recurrence of GC[18]. In this study, the monoclonal antibody Ber-EP4 that recognizes 34 and 39 ku glycopeptides present in human epithelium, was used to detect cells derived from squamous and columnar epithelial tumors. Of 74 patients with esophago-gastric cancer, 27 (36.5%) had Ber-EP4 positive cells in their bone marrow at the time of operation. Fourteen patients with benign gastrointestinal disease were used as a control group. There were no patients with clinical evidence of overt bone metastases, pathological fractures or signs of bone marrow fracture. Multivariate analysis of risk factors revealed that bone marrow cytology was a significant factor for recurrence and death.

While investigations on bone marrow micrometastasis by immunocytochemistry may play a role in predicting disease recurrence, at present it cannot be clinically applied to detect bone metastasis.

REVIEW OF EGC CASES GIVING RISE TO BONE METASTASIS IN THE JAPANESE LITERATURE

Cases of EGC giving rise to bone metastasis in Japan were

reviewed from literature and meeting proceedings in English or Japanese. Kodama *et al*., reported 13 cases of GC recurrence out of 167 EGC cases of which 5 had liver metastasis and 1 had bone metastasis[7]. The case of bone metastasis was classified as 'small mucosal type', defined as a carcinoma lesser than 4.0 cm in diameter with mucosal invasion or slight submucosal invasion. This case was thought to be a premature type of carcinoma that had invaded the submucosa in a wide-penetrating fashion[7]. Most 'small mucosal type' carcinomas are depressed lesions (73.8%) unlike the Pen A-type, which possess the potential for liver metastasis[7].

In a previous report we, reviewed 46 bone metastasis cases arising from EGC in Japan to the end of 2003[2]. These cases were used to clarify the clinicopathological characteristics of EGC leading to bone metastasis. It is possible that in some cases, metastatic bone cancer is not recognized as a recurrence of EGC. Table 1 summarizes the clinicopa-thological data from this study. Although more than half of the patients were females, the male to female ratio for ECG is 2:1. The incidence of mucosal and submucosal cancer was almost identical. Macroscopically, 34 out of 36 lesions were depressed or flat type. Histological characteristics were described for 48 lesions in the 44 cases. Twenty-three lesions were classified as signet-ring cell carcinoma, 14 as poorly differentiated adenocarcinoma and 2 as undifferentiated carcinoma. These characteristics differed from the histological type of EGC overall[4,5]. The macroscopic features (poor histological differentiation and depressed shape) of lesions of EGC cases with bone metastasis were clearly different from those exhibiting liver metastasis[3,4,19]. A description of lymph node status was available for 29 cases. The rate of lymph node metastasis was 55.2% (16 cases) and represented a higher rate of lymph node involvement compared with EGC as a whole[8,9,11,20].

The time interval between diagnosis of EGC and bone metastasis was described for 40 cases out of 46 cases. Fourteen cases had bone metastasis at the time of diagnosis for EGC. In 26 cases, bone metastasis was diagnosed metachronously. The mean time interval to the development of metachronous bone metastasis after surgery was 46.9 mo, classified as a late recurrence of EGC. There were seven cases in which bone metastasis was diagnosed more than 5 years after surgery and two cases that presented with bone metastasis 96 mo after surgery (one from a meeting proceeding in Japan and the other a case report written in Japanese).

Concomitant metastasis, other than lymph node metastasis, was described in 16 out of the 46 cases and are summarized in Table 2. Lung metastasis was present in 11 cases (68.8%) and liver metastasis was observed only in 4 cases (25.0%). These findings are consistent with the finding by Seto *et al*., that 60% of cases with bone metastasis cases arising from GC did not have liver metastasis[21]. Similarly, a lack of liver metastasis is characteristic of cases of EGC with bone metastasis. It appears that liver metastasis has a different pathogenesis from bone metastasis arising from EGC.

POSSIBLE MECHANISMS RESPONSIBLE FOR BONE METASTASIS

Lehnert *et al*., used light and transmission electron microscopy to investigate lymph and blood capillaries of human gastric mucosa and found that the upper and middle levels of the lamina propria of the gastric mucosa contained no lymph capillaries[10]. The mucosa has a rich supply of blood capillaries, many of which are adjacent to the basal lamina of gastric glands and surface epithelium[6]. Lehnert *et al*., suggests that the low incidence of lymph node metastases in the early mucosal GC might be explained by the rarity of lymph vessels in the mucosa, and that blood-borne metastases in

recurrent EGC might be related to the rich vascularity of the gastric mucosa[10].

As there are no lymphatic vessels in the bone marrow, bone metastasis is usually regarded as a hematogenous spread[22]. Rino *et al*., reported five EGC cases without vascular invasion (v_0) resulting in bone metastasis[23] and concluded that high risk factors for bone metastasis were accompanying ulceration, lymph node metastasis, and distant metastasis to other organs[23].

Our review of the literature found that EGC resulting in bone metastasis had different macroscopic and histological types, suggesting that the mechanisms responsible for bone metastasis might not be through regular hematogenous routes via the portal vein as in liver metastasis. This is supported by the fact that concomitant metastasis was much more frequent in the lung than in the liver. We speculated that GC might metastasize to the bones through the vertebral vein system as suggested by Batson[24]. Yamamura *et al*., reported that GC with bone metastasis resulted in the invasion of the lymphatic vessels more frequently than invasion of venules[15]. They also speculated that GC might metastasize to the bone through the thoracic duct.

For EGC, cancer cells may invade the capillary network or postcapillary venules in the gastric mucosa as mentioned in the investigation of Lehnert *et al*.[10]. Alternatively, they may metastasize to regional lymph nodes following cancer cell invasion into the venules of lymph nodes as reported by Rino *et al*.[23]. The latter is supported by the higher rate of lymph node metastasis in those cases with bone metastasis compared to that for EGC as a whole. For advanced cancer that has invaded adjacent organs, cancer cells may invade a fairly large vein, such as those found in the vertebral vein system outlined by Seto *et al*.[21].

The possible mechanisms of hematogenous metastasis of GC are: (1) through the portal vein, (2) through the venous system, other than the portal vein, and (3) through lymphatic channels into the systemic circulation. Most cases of bone metastasis do not show liver metastasis, most venous drainage from the stomach is via the portal vein, and many cases of bone metastasis are associated with lymph node metastasis, suggesting that the mechanisms underlying bone metastasis involves lymphatic channel into the systemic circulation.

CLINICAL FEATURES AND TREATMENTS OF BONE METASTASIS

Ell reviewed skeletal imaging of metastatic diseases and identified MRI as sensitive in detecting bone marrow involvement[25]. Despite this finding, bone scintigraphy continues to be the modality of choice in view of its simplicity, low cost, and ability to screen the entire body[25]. Choi *et al*., evaluated bone metastasis from GC by Tc-99m MDP imaging[16]. They investigated 234 bone scans of GC patients. One hundred and six patients (45.3%) had bone scan abnormalities that qualified as metastatic bone lesions. The most frequent metastatic sites were the spine (66%), the ribs (59%), pelvis (43%), femur (30%), and skull (22%)[16]. The least frequent metastatic sites were the shoulder girdle (17%), such as the scapula and clavicle, sacroiliac joint (7.2%), humerus (6.0%), sternum (4.2%), and tibia (3.0%)[16]. On the other hand, roentgenographic evaluation of bone metastases has limited value because symptoms caused by bone metastases frequently occur before abnormal imaging. Bone metastases were diagnosed by bone scintigraphy in 13 out of 24 cases described in our review.

Laboratory data may be helpful in the diagnosis of bone metastasis. Although tumor markers do not play an important role, many cases with bone metastasis show elevated serum alkaline phosphatase (ALP). In the study by Choi *et al*., ALP was elevated in 64% of 106 patients with bone metastasis[16]. Seto *et al*., also found that ALP was significantly elevated in GC cases with bone metastasis compared to those without[21].

Once cancer disseminates to the bone marrow, disseminated intravascular coagulation (DIC) may occur. Clinically, patients show a tendency to bleed that is confirmed on a combination of laboratory data for platelet count and fibrin degradation products. Several chemotherapy regimens for bone metastasis of GC have been reported as case reports. Kobayashi *et al*., and Hironaka *et al*., demonstrated that sequential methotrexate and 5-fluorouracil chemotherapy resulted in a high rate of alleviation (80% and 89%, respectively) of DIC caused by bone metastasis from GC[26,27].

CONCLUSION

The incidence of bone metastasis from GC may be underestimated, and may occur after surgical resection in EGC. The mechanisms underlying bone metastasis arising from EGC most likely involve the lymphatic channels. Some cases give rise to late bone metastasis after surgery. As only 46 cases of bone metastasis arising from EGC are reported in Japan up to 2003, the exact incident rate cannot be estimated accurately. It can be considered that bone metastasis arising from EGC is a rare condition and as a result adjuvant chemotherapy is not recommended. In the post-operative follow-up of EGC cases that are histologically less differentiated and display involvement of lymph nodes, recurrences as bone metastasis should be considered. Elevation of ALP can be used to detect bone metastasis and bone scintigraphy is recommended for its diagnosis.

ACKNOWLEDGMENTS

We would like to thank Dr. Alan GK Li, Aberdeen Royal Infirmary, for his valuable advice.

Abstract

AIM: To investigate DNA ploidy and expression of MMP-9, TIMP-2, and E-cadherin in gastric carcinoma and to explore the mechanism of invasion and metastasis of gastric carcinoma.

METHODS: Immunohistochemical methods were used to detect the expressions of MMP-9, TIMP-2, and E-cadherin in 156 cases, including 99 cases of gastric carcinoma, 16 cases of adjacent noncancerous mucosa, 16 cases of distant metastases and 25 cases of metastatic lymph node (LN) from gastric carcinoma. Flow cytometry DNA ploidy and S-phase fraction (SPF) analysis were performed on 57 cases, including 47 cases of gastric cancer, 6 cases of adjacent noncancerous mucosa, and 4 cases of distant metastatic cancer.

RESULTS: The expression of MMP-9 was significantly correlated with Lauren's classification, Borrmann's classification, LN metastasis, tumor metastasis, and TNM stage, as well as depth of invasion (all $P<0.05$). The positive rate was lower in noncarcinoma than in carcinoma (31.3% *vs* 66.7%, $P<0.01$). The expression of TIMP-2 was significantly correlated with Borrmann's classification, LN metastasis, and the depth of invasion (all $P<0.05$). The expression of E-cadherin was significantly correlated with differentiation, Lauren's classification, Borrmann's classification, and LN metastasis, as well as the depth of invasion ($P<0.01$ or $P<0.05$). E-cadherin was less expressed in carcinoma than in noncarcinoma (42.4% *vs* 87.5%, $P<0.01$). There was a positive correlation between MMP-9 and TIMP-2 and a negative correlation between MMP-9 and E-cadherin, but no correlation between TIMP-2 and E-cadherin. Also there was a positive correlation between DNA aneuploid rate and differentiation and LN metastasis. SPF that was higher than 15% was positively correlated with tumor size, differentiation and LN metastasis. And there was a significant difference between carcinoma and noncarcinoma in DNA aneuploid rate and SPF.

CONCLUSION: With tumor progression and development of heterogeneity, the abnormal expressions of MMP-9, TIMP-2, and E-cadherin or DNA aneuploid rate or high SPF gradually increases, suggesting that they play a crucial role in gastric carcinoma progression.

INTRODUCTION

Gastric cancer is the second most common malignancy worldwide. Although the achievement in early diagnosis and treatment of gastric cancer has improved the patients' outcome, it is still among the leading causes of mortality in countries such as China and Japan; even in the developed Western countries the 5-year survival rate for gastric cancer is only 10-19%[1]. The mechanisms of its development, progression, and metastasis are under investigation[2].

Breakdown of cell-cell adhesion and degradation of extracellular matrix (ECM) represent an essential step for tumor metastasis and invasion. The cadherin superfamily is a major class of adhesion molecules that play an important role in homotypic cell-cell interactions and hence cancer cell metastasis and invasion[3]. E-cadherin is a member of the cadherin family that is expressed in all epithelial cells. It is a calcium-dependent cell adhesion molecule and has been recognized as an important suppressor gene. A variety of human cancers exhibit altered expression of E-cadherin, which correlates with high grade and advanced stage of tumor.

Matrix metalloproteinases (MMPs) are a large family

of zinc-dependent proteolytic enzymes, which are believed to play a pivotal role in malignant behavior of cancer cells such as rapid growth, invasion, and metastasis by degrading ECM[4,5]. Increased expression of MMPs has been found in various carcinomas. The family of human MMPs comprises mainly four classes according to their structure and *in vitro* substrate specificity: collagenases, gelatinases, stromelysins, and membrane-type MMPs. MMP-9 belongs to gelatinases and most investigations supported that there was a positive correlation between MMP-9 and tumor progression[9]. Tissue inhibitors of matrix metalloproteinases (TIMPs) are the major natural inhibitors of MMPs. To date, four types of TIMPs have been recognized[6]. TIMPs are secreted proteins that are complex MMPs and are involved in the inhibition of individual MMPs and regulation of their activity. Indeed, it is thought that the balance between activated MMPs and TIMPs determines the overall MMP activity and proteolysis *in vivo*. However, recent experimental data suggest that TIMPs not only have MMP inhibitory functions, but also are multifunctional molecules, with apparent paradoxical effects on tumor progression. Recently some studies suggest a positive correlation between TIMP-2 level and poor outcome in certain types of tumors[7,8].

In this study, we detected the expression of MMP-9, TIMP-2, and E-cadherin proteins in gastric cancer, its adjacent noncancerous mucosa, metastatic lymph nodes (LNs), and metastatic cancer by using immunohistochemical staining. Moreover we detected DNA ploidy and S-phase fraction (SPF) in gastric cancer by flow cytometry to explore the molecular and cellular mechanisms of tumor progression so as to develop novel therapies and provide scientific basis for prognostic evaluation of gastric carcinoma.

MATERIALS AND METHODS

Patients and specimens

One hundred and fifty-six surgically removed specimens from the year 2000-2003 were collected from the Department of Pathology, Affiliated Hospital of Medical College, Qingdao University, including 99 cases of gastric carcinoma, 16 cases of adjacent noncancerous mucosa, 25 cases of metastatic LNs, and 16 cases of metastatic carcinoma from gastric cancer. Patients consisted of 87 male and 28 female with a mean age of 58.2 years (range 32-82 years) and were untreated before surgery. Sections from the surgical specimens were fixed in 4% formaldehyde solution for 24-48 h, and embedded in paraffin. A 4-μm section from each specimen block was stained with H&E for histological evaluation, and representative blocks were chosen for immunohistochemical study. In addition, normal gastric epithelium, colon adenocarcinoma, and breast carcinoma were used as positive controls for E-cadherin, TIMP-2, and MMP-9, respectively. For negative controls, sections were incubated with PBS (0.01 mol/L, pH 7.4) instead of the primary antibodies.

For flow cytometry, 57 specimens were selected from immunohistochemical study cases, including 47 cases of gastric carcinoma, 6 cases of adjacent noncancerous mucosa, and 4 cases of metastatic carcinoma from gastric cancer. For each case, we selected the most representative area of the specimen for flow cytometry analysis with H&E section. Five 50-μm sections from each specimen block and one 50-μm section from normal LN block, which was fixed and embedded with the same method and used for internal standard were cut for preparation of single cell suspensions.

Antibodies and other chemicals

The goat anti-human polyclonal antibody against TIMP-2, rabbit anti-human monoclonal antibodies against MMP-9 and E-cadherin were from Santa Cruz (CA, USA); Histostain^{TM}-Plus kit was from Zymed (CA, USA); Coulter DNA-Prep Reagent kit was from Beckman Coulter (Miami, USA).

Immunohistochemical staining

Immunohistochemical staining was performed with SP method, according to instruction of the kit and antibodies against MMP-9, TIMP-2, and E-cadherin were used at a concentration of 1:60, 1:30, and 1:120, respectively.

Sample preparation for flow cytometry analysis

Modified Hedley protocol was a workable method for making nuclear suspensions from paraffin blocks. Sections were deparaffinized and rehydrated through changes of xylene and graded alcohol, then immersed in water, and converted to a nuclear suspension by digestion in 0.5% pepsin (pH 1.5). The dispersive nuclear suspension was pelleted by centrifugation (1 500 r/min, 5 min) and filtered through a nylon filter, and then incubated with DNA-prep reagents kit for 30 min for DNA quantitation. The exciting spectrum was 488 nm and about 20 000 signals were collected per specimen with a coefficient of variation (CV) of 2% or less. Data collection was performed on a flow cytometer (FCM, Beckman Coulter EPICS XL).

Evaluation of immunostaining

Clear brown staining was restricted to cytoplasm, and was considered as positive for MMP-9 and TIMP-2. Slides were scored semi-quantitatively based on staining intensity and distribution. Two investigators without knowledge of the clinical data independently performed analysis of immunohistochemical staining. Staining was graded based on the method by Massi *et al*.[9], as follows: negative (-): no positive cells were found; focal (+): positive tumor cells accounted for <20% of the total; moderate (++): 21-50% of tumor cells were positive; diffuse (+++): >50% tumor cells were positive. The positive staining of E-cadherin appeared pale brown and was located in the cell membrane. Staining was scored according to the method described by Li *et al*.[10]: 0 score: no expression; 1 score: expression in cytoplasm; 2 scores: decreased expression; 3 scores: expression in cell membrane, namely normal expression. A score of 0-2 was considered as negative expression.

Evaluation of flow cytometry

FCM-derived parameters were DNA ploidy and SPF. According to DNA index (DI), aneuploid and diploid tumors were evaluated[11].

Statistical analysis

Statistical analysis was performed using the χ^2 test. A P value lesser than 0.05 was considered as statistically significant.

All statistical analyses were performed using the SPSS 11.0 statistical software.

RESULTS

Immunohistochemical staining of MMP-9

Immunoreactivity for MMP-9 was present in the cytoplasm of neoplastic and non-neoplastic mucosa cells. MMP-9 expression showed moderate or diffuse distribution in neoplastic cells (Figure 1A), but was single or focal in noncancerous mucosa cells (Figure 1B). In the invasion front, MP-9 showed strong positive staining (Figure 1C) and positive staining was also noted in vascular endothelial cells and inflammatory cells (Figure 1D). The expression of MMP-9 was significantly correlated with Lauren's classification (in intestinal and diffuse types, the positive rate was 58.2% and 90.9%, respectively, $\chi^2 = 8.025$, $P<0.05$), Borrmann's classification (in Borrmann's types I-II, III, and IV, the positive rate was 33.3%, 65.7%, and 85.0% respectively, $\chi^2 = 7.554$, $P<0.05$), LN metastasis (in negative and positive cases, the positive rate was 54.3% and 79.2% respectively, $\chi^2 = 6.986$, $P<0.05$), metastasis (in primary gastric carcinoma, metastatic LN, and metastatic carcinoma, the positive rate was 66.7%, 92.0%, and 81.7%, respectively, $\chi^2 = 7.121$, $P<0.05$) and TNM stage (in stages II, III, and IV, the positive rate was 37.5%, 50.0%, and 73.3%, respectively, $\chi^2 = 6.647$, $P<0.05$, Tables 1 and 2). A significant association between the depth of invasion and expression of MMP-9 (in submucosa, superficial muscular layer, and deep muscular layer or serosa, the positive rate was 28.6%, 59.3%, and 73.8% respectively, $\chi^2 = 6.743$, $P<0.05$) was detected. The positive rate was lower in noncarcinoma than in carcinoma (31.3% *vs* 66.7%, $\chi^2 = 7.314$, $P<0.01$).

Immunohistochemical staining of TIMP-2

Immunoreactivity for TIMP-2 was also present in the cytoplasm of neoplastic and non-neoplastic mucosa cells. TIMP-2 expression showed moderate or diffuse distribution in neoplastic cells (Figure 2A), but focal or moderate distribution in noncancerous mucosa cells (Figure 2B). The expression of TIMP-2 was significantly correlated with Borrmann's classification (in Borrmann's types I-II, III, and IV, the positive rate was 66.7%, 47.1%. and 20.0% respectively, $\chi^2 = 6.839$, $P<0.05$) and LN metastasis (in negative and positive cases, the positive rate was 56.5% and 32.1% respectively, $\chi^2 = 5.992$, $P<0.05$). A significant association between the depth of invasion and expression of TIMP-2 (in submucosa, superficial muscular layer, and deep muscular layer or serosa, the positive rate was 71.4%, 59.3%, and 33.8% respectively, $\chi^2 = 7.417$, $P<0.05$) was also revealed (Tables 1 and 2).

Immunohistochemical staining of E-cadherin

Immunoreactivity for E-cadherin was present in the membrane of neoplastic and non-neoplastic mucosa cells. In noncancerous mucosa epithelia, E-cadherin expression showed strong membranous staining, especially at the intercellular border (Figure 3A), but abnormal expression was observed in neoplastic tissues with reduction or loss of membranous expression and cytoplasmic or nuclear staining (Figures 3B-D). The expression of E-cadherin was significantly correlated with differentiation (in well-, moderately-, and poorly-differentiated, and signet ring cell carcinoma, the positive rate was 75.0%, 61.1%, 30.6%, and 27.6% respectively, $\chi^2 = 14.215$, $P<0.01$), Lauren's classification (in intestinal and diffuse type, positive rate was 53.7% and 13.6% respectively, $\chi^2 = 11.603$, $P<0.05$), Borrmann's classification (in Borrmann's

types I-II , III, and IV, the positive rate was 66.7%, 44.3%, and 25.0% respectively, $\chi^2 = 7.097$, $P<0.05$) and LN metastasis (in negative and positive cases, the positive rate was 54.3% and 32.1% respectively, $\chi^2 = 5.012$, $P<0.05$). A significant association between the depth of invasion and expression of E-cadherin (in submucosa, superficial muscular layer, and deep muscular layer or serosa, the positive rate was 85.7%, 48.1%, and 35.4% respectively, $\chi^2 = 7.051$, $P<0.05$) was observed. E-cadherin was less expressed in carcinoma than in noncarcinoma (42.4% *vs* 87.5%, $\chi^2 = 11.223$, $P<0.001$, Tables 1 and 2).

Correlation between MMP-9 and TIMP-2

The expression of MMP-9 was significantly and positively correlated with expression of TIMP-2 (Table 3). Positive rate of TIMP-2 in cases with MMP-9 positive was higher than those with MMP-9 negative, and the coefficient of correlation was 0.22.

Table 3 Correlations between MMP-9 and TIMP-2 expression

	TIMP-2	
MMP-9	-	+
+	32	34

FCM results

Typical DNA histogram of non-neoplastic mucosa showed a large diploid peak and a smaller tetraploid peak, and SPF was less than 15% (Figure 4A), but the histogram from gastric carcinoma showed a definitely abnormal (aneuploid or hyperdiploid) peak (Figure 4B) or/and increased SPF (Figure 4C). Aneuploid rate was significantly correlated with differentiation (in well- or moderately- and poorly-differentiated or signet ring cell carcinomas, the aneuploid rates were 42.1% and 75.0%, respectively, $\chi^2 = 5.183$, $P<0.05$) and LN metastasis (in negative and positive cases, the aneuploid rates were 80.0% and 29.4% respectively, $\chi^2 = 11.752$,

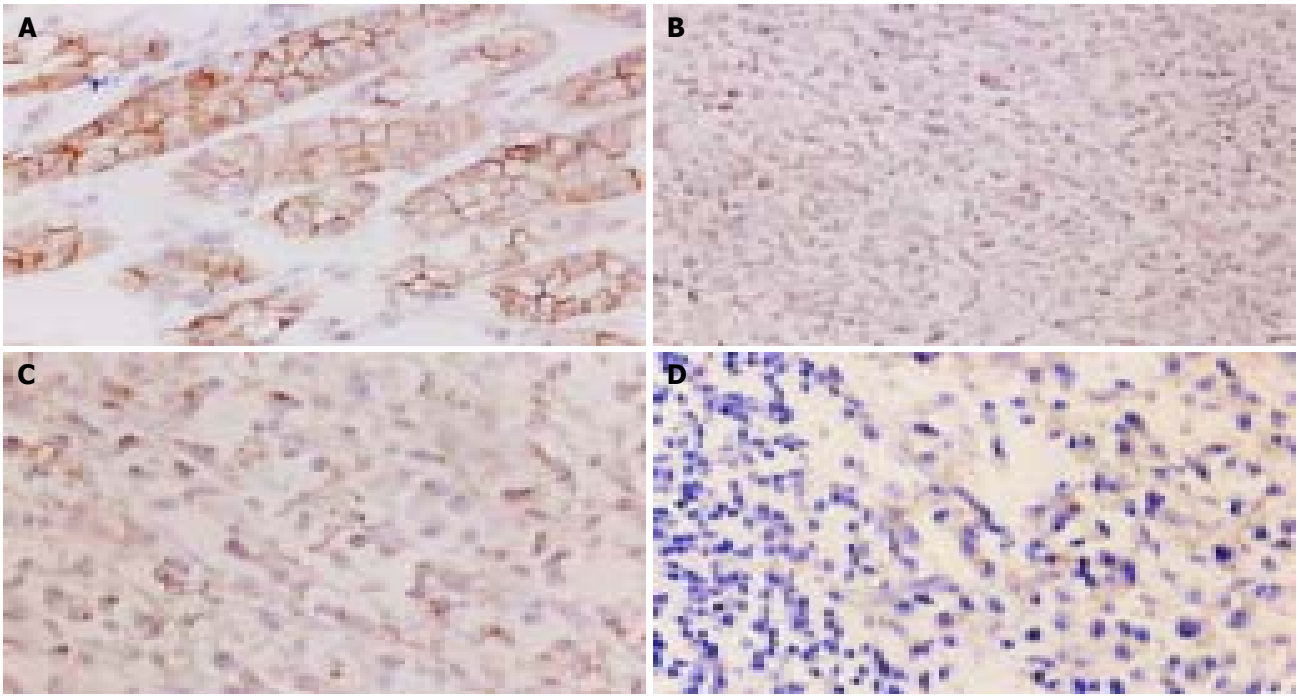

Figure 3 E-cadherin expression in gastric carcinoma. **A:** E-cadherin expression showed strong membranous staining in noncancerous mucosa cells, especially at the intercellular border (×400); **B-D:** abnormal expression was observed in neoplastic tissues which showed reduction or loss of membranous expression and showed cytoplasmic or nuclear staining (**B** and **D**, ×200; **C**, ×400).

$P<0.001$, Table 6). It was significantly different between carcinoma and noncarcinoma (aneuploid rate were 61.7% and 16.7%, respectively, $\chi^2 = 4.393$, $P<0.05$). SPF was significantly correlated with tumor size (the number of cases with SPF>15% and tumor size <5 cm was 9 and it was 23 in tumors with SPF>15% and tumor size >5 cm, $\chi^2 = 4.931$, $P<0.05$), differentiation (the number of cases with SPF>15% and well- or moderately-differentiated carcinoma was 8 and it was 21 in poorly-differentiated or signet ring carcinoma, $\chi^2 = 6.299$, $P<0.05$) and LN metastasis (the number of cases with SPF>15% and negative LN metastasis was 24 and it was 8 in cases with SPF>15% and positive LN metastasis, $\chi^2 = 5.419$, $P<0.05$). And the number of cases with SPF higher than 15% was significantly different between carcinoma and noncarcinoma (32 *vs* 1, $\chi^2 = 5.987$, $P<0.05$).

DISCUSSION

One of the typical characteristics of malignant tumor is invasion and metastasis, which is the main cause for their lethality. Tumor progression is considered to be a dynamic, complex, and a multi-step process, but the essential steps are the breakdown of cell-cell adhesion and degradation of basement membrane (BM) and ECM.

In the present study, immunohistochemical analysis revealed a progressive increase in expression of MMP-9 with increasing severity of lesions of carcinoma (Figure 1A). And in tumor invasion front or the surrounding of tumor nests, MMP-9 showed a strong staining (Figure 1C), while in non-neoplastic tissues it was weakly positive (Figure 1B). Although the antibodies do not distinguish between proenzyme and active forms of MMP-9, an increase in intensity of immunohistochemical reactions of MMPs may play a crucial role in the progression of carcinoma. MMP-9 upregulation will confer on tumor cells the ability to degrade BM and ECM and lead to tumor progression. MMP-9 immunoreactivity in vascular endothelial cells and inflammatory cells was also noted (Figure 1D), suggesting that those cells might secrete MMP-9 induced by malignant cells, the so-called host reaction[12]. As reported, MMP-9 promoted inflammatory reaction by upregulation of cytokines such as IL-1β[13], and this then stimulated host reaction, thus forming a pernicious cycle. Therefore, in view of MMP-9, it is not a good phenomenon that tumor cells can induce inflammatory reaction. MMP-9 participates in the whole process of carcinogenesis and development of gastric carcinoma and even in intramucosal gastric carcinomas MMP-9 showed strong staining and promoted LN metastasis[14,15], suggesting an early tumor progression. Our result demonstrated that MMP-9 activity increased as the depth of invasion extended,

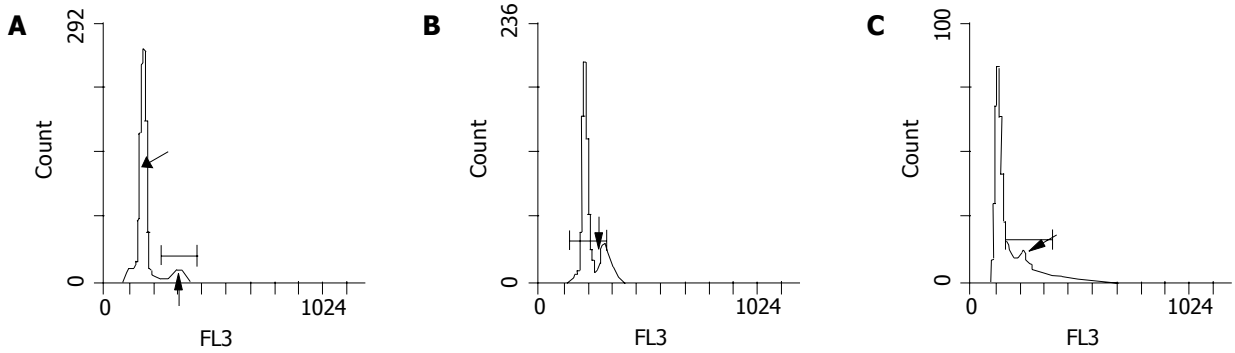

Figure 4 Histograms from FCM. **A:** A large diploid peak and a smaller tetraploid peak; **B:** an aneuploid peak (see arrow); **C:** higher SPF (see arrow).

Table 6 Correlation between DNA ploidy or SPF and histopathological or clinical features in gastric carcinoma

	n	Aneuploid rate (%)	*P*	*n* (SPF>15%)	*P*
Tumor size					
⩾5 cm	29	65.5	>0.05	23	>0.05
<5 cm	18	55.6		9	
Differentiation					
Well or moderate	19	42.1	<0.05	9	<0.05
Poor or signet ring cell type	28	75.0		23	
Depth of invasion					
Submucosa	7	28.6	>0.05	3	>0.05
Muscular layer or serosa	40	67.5		29	
LN metastasis					
Negative	30	80.0	<0.001	24	<0.05
Positive	17	29.4		8	
Metastasis					
Primary carcinoma	47	61.7	>0.05	32	>0.05
Metastatic carcinoma	4	100		3	
Carcinoma and noncarcinoma					
Gastric carcinoma	47	61.7	<0.05	32	<0.05
Noncarcinoma gastric mucosa	6	16.7		1	

indicating that MMP-9 participated in tumor invasion. It was also revealed that MMP-9 activity increased as LN metastasis progressed, indicating that MMP-9 participated in tumor metastasis. Expression rate of MMP-9 was significantly different between carcinoma and noncarcinoma (66.7% and 31.3% respectively), implying that MMP-9 may be related to carcinogenesis. Recent findings support the view that MMPs are not only responsible for the proteolytic degradation of BM as an important step in metastasis, but also essentially regulate the growth of tumor by maintaining its access to growth factors from ECM and regulation of angiogenesis[16]. Single MMP strong expression does not necessarily suggest invasion or metastasis, because its activity is influenced by its inhibitors such as RECK and TIMPs[17]. TIMPs are endogenous specific inhibitors of MMPs. They have such abilities to form tight binding, non-covalent inhibitory complexes with multiple members of the MMP family that they inhibit ECM degradation by MMPs and have anti-metastasis function[18]. TIMP-2 inhibits active and proenzyme forms of MMPs. It was reported that transfection of TIMP-2 gene into human gastric cancer cell line SGC-7901 by lipofection technology reduced their invasion potential *in vivo* and *in vitro*[19]. The expression of type IV collagenase in the untransfected group was higher than in the transfected group. The high expression of TIMP-2 may represent a mechanism by which tumor cells control the proteolysis and remodeling of ECM that occurs during invasion and progression of tumors. Another report suggested that transfection of TIMP-2 into the liver tissue could treat colorectal cancer liver metastasis[20]. However, some studies suggested that high expression level of TIMP-2 related to poor prognosis. It showed that high level of TIMP-2 mRNA correlated with the development of distant metastasis[21]. A study on gastric cancer showed that TIMP-1 and TIMP-2 were identified in 41% and 57% of tumors, respectively, whereas normal gastric mucosa was negative. No correlation was observed between the presence of TIMP-2 and tumor stage, histological type, LN status or survival[22]. However, our results demonstrated that there was correlation between the presence of TIMP-2 and depth of invasion and LN metastasis and different from MMP-9; there was no correlation between TIMP-2 and other clinical or histopathological features. Our results also suggested that as MMP-9 activity increased during tumor progression a corresponding increase in TIMP-2 level also occurred. Therefore, it appears that the expression of MMPs and TIMPs during tumor progression is coordinately regulated. Imbalance between MMP-9 and TIMP-2 could be an essential factor in tumor progression and may be more important than the concentrations of single components of MMPs and TIMPs[23,24]. The increased ratios could be interpreted as a sign of proteolytic inequilibrium in the early stage of carcinogenesis and in the advanced stage of tumor progression. We believed that the high expression of MMP-9 was the basis of tumor invasion and metastasis and that relatively high level of TIMP-2 was induced by MMP-9. Our results are contradictory to previous reports. It might be due to different study methods and antibodies used, and double effects of TIMP-2. TIMP-2 not only inhibits MMPs activities but also takes part in other activities such as cell growth and survival that cannot always be clearly reconciled with their abilities to abrogate MMP activity[25,26]. Therefore, further investigations are required to explore this controversy.

E-cadherin plays a critical role in the establishment and maintenance of intercellular adhesion, cell polarity, and tissue architecture. Abnormalities of E-cadherin adhesive system have been detected in a number of cancers. Loss of E-cadherin adhesive function has been found in premalignant conditions such as colorectal adenoma, Barrett's esophagus, and gastric dysplasia[27] and in tumors such as ductal carcinoma *in situ* of the breast, prostate carcinoma, and gastric carcinoma. In gastric carcinoma, the overall expression of E-cadherin ranges from 20% up to 90% due to different score systems and different antibodies used. The present study showed that the expression rates of E-cadherin in carcinoma and noncarcinoma were 42.4% and 87.5% respectively, suggesting that E-cadherin played a role in carcinogenesis and tumor progression. The downregulation of expression of E-cadherin may contribute to disruption of normal cell-cell adhesion in malignantly transformed cells, which may associate with tumor cells' enhanced migration and proliferation, leading to invasion and metastasis. It was also revealed that the expression of E-cadherin was significantly correlated with tumor differentiation and Lauren's classification. That is, abnormal expression rate was significantly higher in poorly differentiated (or diffuse-type) adenocarcinomas than in well-differentiated (or intestinal-type) ones, in another word, strong E-cadherin staining correlated with well-differentiated cancers and tumor cell cohesiveness, while loss of staining or changes in localization were associated with poorly differentiated, discohesive and highly invasive tumors. Multiple *in vitro* and *in vivo* studies demonstrated that a loss of E-cadherin expression correlated with the development of metastasis[28]. We proved that abnormal expression rate of E-cadherin was higher in LN metastasis positive cases than in negative ones. E-cadherin participates in the whole process from early stage to advanced stage of tumor development and in addition to its interaction with β-catenin, experimental work has also indicated that E-cadherin is involved in inducing cell-cycle arrest, at least partially, through upregulation of the cyclin-dependent kinase inhibitor, p27[29]. These interactions provide a direct link between the proliferative phenotype, presumed to be a precursor of neoplasia, and E-cadherin. It was reported[30] that the presence of paranuclear E-cadherin in cancer-associated benign epithelium suggested that alteration in E-cadherin molecule responsible for the paranuclear distribution might be an early change in gastric adenocarcinoma progression. Our result also showed the presence of paranuclear E-cadherin in cancer, especially in low-differentiated tumors (Figures 3B-D). E-cadherin has been associated with dedifferentiation, loss of adhesion and invasion in tumor cells, suggesting a role for loss of E-cadherin expression in the acquisition of potentially invasive and metastatic phenotype. Despite some contrary results, the bulk of evidence from clinical studies suggests that loss of E-cadherin is linked to prognosis and has been found to be an independent predictor in patients with various cancers[31]. Level of serum soluble E-cadherin is a potentially valid prognostic marker for gastric cancer and high concentration predicts advanced stage and indicates palliative/conservative treatment[32]. However, the reasons that E-cadherin showed strong expression in

inflammatory breast cancer are still under investigation[33].

Correlation between E-cadherin and MMP-9

It was reported that MMP-9 degraded membranous E-cadherin and caused an increase of serum soluble E-cadherin fragment which could upregulate the level of MMPs, forming a vicious cycle[34]. The present study showed that expression of E-cadherin and MMP-9 was reversely or negatively correlated, supporting previous findings. MMP-9 and E-cadherin interact and accelerate tumor progression. Llorens[35] investigated the correlation between MMP-9 and E-cadherin from another perspective, and detected that the activity of enhancer for MMP-9 was upregulated in rat skin carcinoma HaCa[Ecad(-)] cell line, accompanied with upregulation of the expression of MMP-9 mRNA and MMP-9 protein, but was downregulated in HaCa[Ecad(+)] cell line. The expression of MMP-9 protein and its activity were upregulated while signal transmission was blocked by cDNA for anti-E-cadherin monoclonal antibody. E-cadherin regulates MMP-9 at transcriptional level, which aggravates tumor invasion and metastasis. From this point of view, E-cadherin seems to be an initiating factor and more important than MMP-9. The reason may lie in Snail or SIP1, because during HCC progression, Snail/SIP1 directly represses E-cadherin gene transcription and activates cancer invasion via upregulation of MMP gene family[36].

In brief, E-cadherin and MMP-9 form a malignant cycle and detecting the levels of those two molecules simultaneously would have important significance for predicting prognosis[37]. However, some scholars reported that E-cadherin down-regulated MMPs in high-invasive bronchogenic carcinoma cell line[38], which is controversial to our report.

Correlation between E-cadherin and TIMP-2

According to our investigation, a positive correlation existed between MMP-9 and TIMP-2 and negative correlation between MMP-9 and E-cadherin, thus there is supposed to be a negative correlation between E-cadherin and TIMP-2. E-cadherin and TIMP-2 genes both belong to tumor suppressor gene (TSG)[39], however we did not find any association between them. It may be limited by our experimental method and further investigation is required.

DNA ploidy analysis

Normal human cells undergo a series of sequential changes culminating in mitotic division. These complex changes can be roughly identified using DNA measurements in which the cell population can be divided into three basic cell-cycle compartments: G_1, S, and G_2+M. Figure 4A shows typical DNA distribution of normal cells. The first peak on the left represents the G_0/G_1 population and the smaller peak to the right represents the G_2+M populations. The S phase cells are residing in between these two peaks. In contrast to normal tissues, neoplastic lesions often undergo chromosomal aberrations resulting in the appearance of nondiploid (aneuploid) clones within the tumor population and/or an increase in the proportion of S-phase cells. Numerous investigations suggested that slight changes of DNA content would lead to malignant tumors. Therefore, detecting DNA ploidy and content would be of great value for diagnosis of malignant tumors. Recent studies showed that DNA content of carcinoma cells is an independent prognostic factor[40-42]. According to our investigation result that since SPF was significantly correlated with tumor size, differentiation, LN metastasis, and depth of invasion, we conclude that percentage of cells synthesizing DNA (S phase cells) is an indirect reflection of tumor proliferation, hence aggressive behavior. However, some scholars reported that SPF was not correlated with tumor differentiation. Normal or near-normal DNA modes often correlate with a high degree of histological differentiation and abnormal DNA modes with low degree of histological differentiation. In carcinoma aneuploid rate was 61.7%, much higher than in noncarcinoma (16.7%). These results indicate that the DNA pattern is a valuable predictor of early stage of cancer and prognosis.

In summary, with tumor progression and development of heterogeneity, the abnormal expressions of MMP-9, TIMP-2 or E-cadherin or the rate of DNA aneuploidy or high SPF gradually increase correspondingly, suggesting that they play a crucial role in gastric carcinoma progression and can be objective markers for biological behaviors of gastric carcinoma. Furthermore, these factors correlate with one another, accelerating the process of tumor progression. In early stage of cancer or precancerous lesion, we may detect those factors to prevent tumor development and improve prognosis.

Abstract

AIM: To clarify the importance of complete treatment by PEIT.

METHODS: A total of 140 previously untreated cases of HCC were enrolled in this study from 1988 to 2002. The inclusion criteria were: a solitary tumor less than 4 cm in diameter or multiple tumors, fewer than four in number and less than 3 cm in diameter, without extrahepatic metastasis or vessel invasion. As general principles for the treatment of HCC, the patients underwent transcatheter arterial chemoembolization (TACE) prior to PEIT. After the initial treatment of the patients, ultrasonography and computed tomography were performed, and measurement of serum levels of α-fetoprotein (AFP) was determined. When tumor recurrences were detected, PEIT and/or TACE were repeated whenever the hepatic functional reserve of the patient permitted. We then analyzed the variables that could influence prognosis, including tumor size and number, the serum levels of AFP, the parameters of hepatic function (albumin, bilirubin, ALT, hepaplastin test, platelet number, and indocyanine green retention at 15 min [ICG-R15]), combined therapy with TACE, distant recurrence, and local recurrence.

RESULTS: Univariate analysis identified the ICG test, serum levels of AFP and albumin, tumor size and number, and local recurrence, but not distant recurrence, as significant prognostic variables. In multivariate analysis using those five parameters, the ICG test, tumor size, tumor number, and local recurrence were identified as significant prognostic factors. In both univariate and multivariate analyses, the relative risk for the ICG test was the highest, followed by local recurrence.

CONCLUSION: We found that local recurrence is an independent prognostic factor of HCC, indicating that achieving complete treatment for HCC on first treatment is important for improving the prognosis of patients with HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a highly malignant tumor with a high morbidity and mortality rate, carrying a poor prognosis[1]. Improvement of imaging techniques has enabled the diagnosis of HCC at an early stage, making it possible to treat tumors locally. The first local treatment for HCC consisted of percutaneous ethanol injection therapy (PEIT), which was reported by Livraghi *et al*., in 1986[2]. Although PEIT has been limited to small-sized HCC and liver resection remains a good treatment for HCC[3], the long-term prognosis due to recurrence or survival after treatment is close to that for hepatic resection[4-6]. Furthermore, PEIT can be used for HCC patients with reduced hepatic functional reserve attributable to pre-existing liver cirrhosis[7]. In 1996, however, Ishii *et al*., pointed out that a significant number of patients experienced local recurrence after PEIT[8]. This local recurrence is caused predominantly by intra-tumor septa, which may inhibit the infiltration of the injected ethanol into the entire tumor.

When the technique of percutaneous microwave coagulation therapy (PMCT) was established, it was expected that the rate of local recurrence would decrease because thermal coagulation should be achieved regardless of intra-tumor septa[9]. Contrary to that expectation, however, the effect of PMCT was limited to tumors of 15 mm or less in diameter. Radio frequency ablation (RFA) was later developed, which can achieve thermal necrosis throughout a mass of 35 mm in diameter[10,11]. Although the development of techniques for local treatment of HCC was aimed at decreasing the rate of local recurrence, it has remained unclear whether local recurrence does indeed worsen the prognosis

of patients with HCC[12], and whether an additional treatment for local recurrence can overcome the failure of initial treatment. Several studies have attempted to identify the significant prognostic factors for HCC[13-17]; however, to our knowledge, none of those studies considered local recurrence as a prognostic factor[18,19].

In this study, we aimed to clarify how local recurrence after initial treatment influences the prognosis of HCC patients. If the survival rate of patients with local recurrence is the same as that of those without local recurrence, the advantage of PMCT or RFA over PEIT would be diminished greatly, since PMCT and RFA were developed to reduce local recurrence.

MATERIALS AND METHODS

Patients

The inclusion criteria were as follows: (1) the patients not diagnosed with HCC previously; (2) a solitary HCC less than 4 cm in diameter, or fewer than four tumors with diameter less than 3 cm; and (3) patients without extrahepatic metastasis or vessel invasion. Of the 452 consecutive patients who were diagnosed with HCC in Kyushu University Hospital between January 1988 and December 2002, a series of 140 consecutive HCC patients meeting the inclusion criteria were enrolled. The enrolled patients included 95 males and 45 females, ranging in age from 35 to 83 years (mean 63.2 years, Table 1). Computed tomography (CT) and ultrasonography (US) were performed on all of the patients. To confirm the findings obtained by CT and US, angiography was also performed on patients, who gave consent for angiography examination. The diagnosis of HCC was finally confirmed histologically by aspiration tumor biopsy using a 21 G needle prior to the PEIT procedure.

Table 1 Characteristics of 140 patients at base line (means±SD)

		(Range)
Age (yr)	63.3±8.54	(35-83)
Male/female	95/45	
Child (A/B/C)	77/48/15	
Albumin (g/dL)	3.56±0.43	(2.5-4.5)

Platelet (10^4/L)	9.74±6.0	(0.8-69.9)
ALT (U/L)	84.58±47.04	(14-266)
HPT (%)	60.98±17.14	(25-116)
ICG-R15 (%)	28.13±15.29	(3.5-76.5)
AFP (ng/mL)	155.37±565.3	(2-5 653)
Tumor size (mm)	20.51±8.26	
Tumor number	1.51±0.79	

In accordance with general principles for the treatment of HCC, the patients underwent transcatheter arterial chemoembolization (TACE) prior to local treatment to enhance the effects of PEIT. In total, TACE was carried out on 81 patients 7 to 14 d before local treatment. With a therapeutic goal of complete necrosis of HCC, PEIT was carried out on all tumors for each patient. Ethanol (4-8 mL) was injected into each tumor during one session of PEIT. The total number of PEIT sessions was decided based on achieving a total amount of injected ethanol for each HCC that was more than two times the mass volume and all tumors consequently received more than two sessions of PEIT. CT was performed to evaluate treatment after finishing all sessions of PEIT. Successful treatment with PEIT was confirmed by CT and demonstrated that the tumor was completely covered by at least a 5 mm region (i.e., the ethanol-injected region) that was non-enhanced with contrast medium. When evidence of treatment success was not obtained, additional PEIT was performed until success was achieved, as assessed by CT. Major complications, such as intraperitoneal bleeding, hemobilia or liver abscesses were not observed in any case after PEIT.

After the initial treatment of the patients, US and measurement of serum α-fetoprotein (AFP) levels were carried out on an outpatient basis. The patients were also observed regularly by CT at 1, 3, 6, and 12 mo after the initial treatment, and every 6 mo after the first year of the treatment. Whenever changes were observed on US or CT imaging, or in the serum AFP levels, CT and/or angiography were carried out to confirm the recurrence, which was verified by enhanced uptake of contrast medium. Among the cases of recurrence, we defined "local recurrence" as those cases in which tumors occurred within or in contact with the treated lesion as determined by CT findings (Tables 2 and 3). The number and size (diameter) of locally and/or distantly recurrent tumors were also determined by CT examination (Table 3). Where recurrences were detected, PEIT and/or TACE were repeated whenever the hepatic functional reserve of the patient permitted. Among the local recurrence group, four patients suffered rapid and diffuse tumor growth involving the portal and hepatic veins. Two of them had been treated only with PEIT and the other two patients had undergone both PEIT and TACE at first treatment. In the local recurrence-free group, on the other hand, venous invasion was not seen. Although PEIT and/or TACE were available for all patients in the local recurrence-free group, four patients in the local recurrence group could not be given further treatment because of their decreased hepatic functional reserve.

recurrence-free group; these included tumor size and number, serum AFP levels, the parameters of hepatic function (albumin, bilirubin, ALT, hepaplastin test, platelet number, and ICG-R15), and combination with TACE.

Statistical analysis

Baseline data were presented as mean±SD for quantitative variables. Differences in baseline characteristics between the local recurrence group and local recurrence-free group were analyzed using the Wilcoxon rank sum test and the Fisher's exact test for qualitative variables.

The prognostic values of baseline characteristics, local and distant recurrence after initial treatment were assessed using the univariate and multivariate Cox proportional hazards regression models. Variables that met the selected cut-off value ($P<0.05$) in the univariate comparison were entered into the multivariate analysis. Both univariate and multivariate results were presented as relative risks with corresponding 95%CIs and *P* values from the Wald test. All significant tests were two-sided and differences with a $P<0.05$ were considered statistically significant.

RESULTS

Among the 140 patients enrolled, 44 (31.4%) suffered from local recurrence. Of the remaining 96 patients, non-local recurrence was found in 80, and only 16 patients (11.4%) remained free of recurrence throughout the period of observation.

For comparison of baseline characteristics, we divided the patients with recurrence into two groups, the local recurrence group and local recurrence-free group. There was no significant difference between these two groups with respect to the hepatic functional reserve (Table 2). The proportion of patients in the local recurrence group who underwent TACE was higher than that in the local recurrence-free group (50% *vs* 39%), but the difference was not significant. On the other hand, the differences in tumor size and numbers were significant between these two groups (Table 2). The local recurrence group had significantly larger average tumor size and greater tumor numbers compared to the local recurrence-free group (tumor size: 24.00±9.48 mm *vs* 18.92±7.15 mm, $P<0.001$; tumor number 1.77±0.94 *vs* 1.3±0.69, $P<0.01$). Combination with TACE did not affect the rate of local recurrence.

We then compared the features of recurrence after initial treatment between these two groups. At the time of recurrence, the tumor number in the local recurrence group was 3.6±0.6 and the largest tumor size among them was 33.0±22.0 mm in diameter, whereas the tumor number in the local recurrence-free group was 2.3±1.9 and the largest size was 19.4±8.8 mm in diameter (both $P<0.001$, Table 3). All cases of the local recurrence group ($n = 44$) showed

	(-)	59			

solitary local recurrence, but 31 cases also showed distant recurrence, in addition to local recurrence, when the recurrence was confirmed. In all cases of local recurrence combined with distant recurrence, the tumor size of local recurrence was larger than that of distant recurrence. Therefore, the recurrent tumor size (33.0±22.0 mm) in the local recurrence group was derived from the locally recurrent tumor (Table 3). The period from the initial treatment to the detection of recurrence (recurrence-free period) was 325.6±216.8 d in the local recurrence group, which was significantly shorter than that in the local recurrence-free group (710.5±813.3 d, $P<0.01$, Table 3). There was no significant difference between the two groups in the method of treatment after recurrence (Table 3).

Using univariate analysis, we identified the ICG test, serum levels of AFP and albumin, tumor size and number, and local recurrence, but not distant recurrence, as significant prognostic variables (Table 4). Additionally, in multivariate analysis using those five parameters, the ICG test, tumor size and number, and local recurrence were identified as significant prognostic factors (Table 5). In both univariate and multivariate analyses, the relative risk for the ICG test was the highest, followed by local recurrence.

Local recurrence	0.0081	2.362	1.250-4.462

DISCUSSION

Multivariate analysis showed that the ICG test, tumor size, tumor number, and local recurrence after initial treatment were significant prognostic factors. Those factors could be classified into three categories: the hepatic functional reserve, the progression of HCC, and local recurrence. In this study, "local recurrence" was defined as those cases in which tumor (s) occurred within or in contact with the treated lesion as detected by CT. It is impossible to determine whether local recurrence was attributable to residual HCC that had not been detected after initial evaluation or to newly developed HCC. We believe that local recurrence reflected failure (residual HCC) not recognized initially after treatment, since it seemed to be rare to newly develop within or in contact with the treated lesion, and because the recurrence-free period in the local recurrence group was significantly shorter compared to the local recurrence-free group. In earlier reports investigating the prognostic factors of HCC, tumor size and hepatic functional reserve were commonly identified as significant factors[15-19]. Those results, however, depended on the hypothesis that the treatment for HCC was performed completely. On the other hand, it has been reported repeatedly that a significant number of patients experience local recurrence after non-surgical treatment, which indicates that it cannot be expected that all treatments are performed completely. Therefore, multivariate analysis of HCC prognosis should be performed, and it should include factors relating to the completeness of the treatment, which is directly referable to local recurrence. Local treatments, including PEIT, require technical skill in both US and puncture, and it is well known that considerable variation in the PEIT technique occurs among different surgeons. In our univariate and multivariate analyses, the relative risk of local recurrence was the greatest, next to the ICG-R15 value, indicating that cautious PEIT technique is required when treating new cases of HCC.

In the treatment of HCC using PEIT, there are three difficulties that prevent the achievement of complete tumor necrosis. The first is the existence of septa in the tumor which partitions it into several closed spaces. The existence of septa is very common when the diameter of the tumor is larger than 20 mm. When a tumor has septa, injected ethanol is not able to spread across the tumor and it is necessary to repeat the puncture, aiming at each separate partition[20,21]. Such a tedious procedure would risk that viable HCC cells may remain. The second problem relates to the location of the tumor. Because PEIT is performed under the guidance of US, it is sometimes difficult to image tumors located close to the diaphragm. Poor imaging of the tumor leads inevitably to insufficient injection of ethanol. Tumors on the surface of the liver also are difficult to puncture because a direct puncture of the projecting area should be avoided to prevent bleeding from the needle track. Furthermore, the tumors located near the portal vein or gall bladder are not easy to be treated completely without the possibility of viable HCC cells remaining. In such situations, surgeons tend to hesitate to inject a sufficient volume of ethanol (more than twice the mass volume)[22,23], fearing the possibility of causing inflammation in the wall of the intrahepatic vessel or gall bladder. The third problem is that the injected ethanol does not always spread fully into the target space. When the tumor includes a relatively large vein, injected ethanol leaks out through the vessels before it can infiltrate the tumor. Taking into account the aforementioned difficulties, multiple sessions are required to decrease the local recurrence after PEIT.

When we compared the local recurrence group and the local recurrence-free group, the latter had smaller diameter and fewer numbers of tumors; whereas there were no significant differences in the variables indicating their hepatic functional reserve (Table 2). Considering the difficulties in the PEIT procedure mentioned above, our results are clinically acceptable. As the number of tumors increases, the probability of tumor occurrence in the areas difficult to puncture also increases. Similarly, larger HCCs contain more septa and are more likely to involve vessels as compared with smaller HCCs. Furthermore, as the number of tumors to be treated increases, it becomes more difficult for the surgeon to maintain concentration.

There are several possible explanations for the poor prognosis of patients with local recurrence. The first possible explanation is that the residual part of the tumor might change to a poor differentiation after treatment. It is well known that there are cases in which rapid sarcomatous change

developed from residual HCC after TACE[24]. Recently, similar results also have been reported after RFA[12,25]. These phenomena are considered to be the result of the hypoxemia caused by TACE. HCC cells basically require a rich blood supply. Therefore, artificial hypoxic pressure could result in undifferentiation of malignant cells. In our study, it should be emphasized that the recurrences in the local recurrence group were more likely to be multiple and emerged more rapidly than that in the local recurrence-free group, indicating that the character of the residual tumor cells had changed to a more malignant one. On the other hand, it is well known that locally recurrent HCC often occurs with an extrahepatic arterial supply. Such vessel reconstruction is observed after treatments that could damage the original feeding artery. In short, all TACE, PEIT, PMCT and RFA procedures could be a cause of revascularization. Once the residual tumor is supplied by blood flowing from the extrahepatic artery, it is very difficult to perform complete treatment following chemoembolization.

Combined TACE and PEI is a therapeutic option that has been proposed to overcome the weakness of each of the two procedures in the treatment of HCC[21,26-30]. The rationale for a combination of these two treatments relies on the fact that tumor consistency is markedly decreased and intratumoral septa are usually disrupted after TACE. Consequently, these changes make subsequent treatment with PEIT easier, as they provide enhanced ethanol diffusion within the tumor and higher doses of ethanol than those used in conventional PEIT. In our general principles for the treatment of HCC, the patients underwent TACE prior to local treatment to enhance the effects of PEIT, however, combining with TACE did not affect the rate of local recurrence or the prognosis in our study. Koda *et al*.[21], reported that in patients with HCC less than 2 cm in diameter, combination with TACE showed lesser rate of local and distant recurrence and better prognosis than PETI alone. Further study will be needed including more number of cases and/or longer observation.

In conclusion, we showed that, in addition to factors such as the hepatic functional reserve and tumor size, it is important to achieve complete necrosis upon initial treatment in order to improve the prognosis of HCC patients. This result warrants the surgeons to be more cautious when performing the first treatment. New RFA devices that cover a greater volume might contribute to this goal, and further study of local recurrence after RFA is critical for improving the local treatment of HCC.

AIM: To investigate the usefulness of 1.5 Harmonic Imaging Sonography with the use of the contrast agent Levovist for the diagnosis of hepatocellular carcinoma (HCC) and for the evaluation of therapeutic response.

METHODS: Phantom experiments were performed to compare the contrast effects of 2nd harmonic imaging and 1.5 Harmonic Imaging Sonography. 1.5 Harmonic Imaging Sonography was employed to examine 36 patients with HCC (42 nodules) before and after the treatment and to compare against the findings obtained using other diagnostic imaging modalities.

RESULTS: In 1.5 Harmonic Imaging Sonography, the tumor vessels of HCCs were clearly identified during the early phase, and late-phase images clearly demonstrated the differences in contrast enhancement between the tumor and surrounding hepatic parenchyma. Blood flow within the tumor was detected in 36 nodules (85.7%) during the early phase and in all 42 nodules (100%) during the late phase using 1.5 Harmonic Imaging Sonography, in 38 nodules (90.5%) using contrast-enhanced CT, in 34 nodules (81.0%) using digital subtraction angiography (DSA), and in 42 nodules (100%) using US CO_2 angiography. Following transcatheter arterial embolization, 1.5 Harmonic Imaging Sonography detected blood flow and contrast enhancement within the tumors that were judged to contain viable tissue in 20 of 42 nodules (47.6%). However, 6 of these 20 cases were not judged in contrast-enhanced CT. 1.5 Harmonic Imaging Sonography was compared with the US CO_2 angiography findings as the gold standard, and the sensitivity and specificity of these images for discerning viable and nonviable HCC after transcatheter arterial embolization were 100% and 100%, respectively.

CONCLUSION: 1.5 Harmonic Imaging Sonography permits the vascular structures of HCCs to be identified and blood flow within the tumor to be clearly demonstrated. Furthermore, 1.5 Harmonic Imaging Sonography is potentially useful for evaluating the therapeutic effects of transcatheter arterial embolization on HCC.

Key words: 1.5 Harmonic imaging sonography; Hepatocellular carcinoma; Microbubble

Yamamoto K, Shiraki K, Nakanishi S, Fuke H, Nakano T, Hashimoto A, Shimizu A, Hamataki T. 1.5 Harmonic Imaging Sonography with microbubble contrast agent improves characterization of hepatocellular carcinoma. *World J Gastroenterol* 2005; 11(36): 5607-5613
http://www.wjgnet.com/1007-9327/11/5607.asp

The usefulness of the peripheral ultrasound contrast agent Levovist was originally thought to be limited to signal enhancement in color/power Doppler ultrasonography[1,2]. Levovist is now employed for the diagnosis of hepatic tumors, in which it has been found to enhance blood flow signals and thus improve the visualization of hepatic tumor vessels[3-5]. However, recent advances in ultrasonographic technologies have led to the development of new imaging techniques collectively referred to as "harmonic imaging", in which images are obtained using the 2nd harmonic components of the ultrasound signal. Among these new techniques, flash echo imaging (FEI) employs intermittent transmission at high acoustic power to permit the microbubbles to enter the scanning plane and thus to obtain echoes with high sensitivity. In other words, FEI makes it possible to acquire detailed images with high spatial resolution in which only blood flow information is extracted, making it easier to visualize tumor vessels. In contrast ultrasonographic examination of hepatocellular carcinoma (HCC), the microbubbles in Levovist cause higher frequency signals to be generated by the tumor than by normal hepatic parenchyma. Consequently, the contrast resolution of the tumor and normal parenchyma is further improved and minute blood vessels within the tumor can be visualized[6-11]. One technique is digital subtraction imaging,

which permits the contrast effect to be clearly identified and is therefore employed for the diagnosis of hepatic tumors[12-15]. In 2nd harmonic imaging, however, the presence of tissue harmonic components may lead to poorer contrast enhancement in some cases. In another method, Doppler technology is used to eliminate tissue echoes and to visualize the nonlinear behavior of the microbubbles[16-18], but this method is susceptible to motion artifacts near the heart. A new technology known as 1.5 Harmonic Imaging Sonography has been developed to overcome these problems. In this method, images are obtained using a band that is intermediate between the fundamental and the 2nd harmonic components (Figure 1). In the 1.5 Harmonic Imaging technique, a frequency band whose center frequency is higher than the fundamental by a factor of 3/2 is extracted and visualized. This frequency band is intermediate between the fundamental and the second harmonic. It includes only bubble echoes and is free of tissue echoes. This imaging technique reduces tissue echoes without generating motion artifacts such as those that are seen in the pseudo-Doppler imaging technique. Contrast between tissues and bubbles is improved by 20 dB or more compared with the 2nd harmonic imaging technique. 1.5 Harmonic Imaging Sonography involves the use of a transmission waveform in which the bandwidth is limited and the leakage of fundamental components is therefore reduced. The fundamental components of tissue echoes are effectively separated from the 2nd harmonic components, permitting images to be obtained in an intermediate band that is almost completely free from tissue echoes. When images are obtained in this intermediate band, higher contrast can be achieved between contrast agent and tissue echoes than in conventional 2nd harmonic imaging. The echo from the tissue has only fundamental and 2nd harmonic component. In the intermediate band, there exists no tissue echo with the dedicated transmission where the fundamental band width and leakage are well controlled. On the other hand, bubble echo has broadband harmonics in high mechanical index (MI) contrast imaging. So high bubble/tissue signal ratio is achieved in image with the component of that intermediate band. Nevertheless, to our knowledge, there have been no studies on the clinical application of 1.5 Harmonic Imaging Sonography for the evaluation of hepatic tumors and the assessment of therapeutic effects. The present study was therefore conducted to investigate the clinical usefulness of the ultrasound contrast agent Levovist for the examination of HCCs and for the assessment of therapeutic effects.

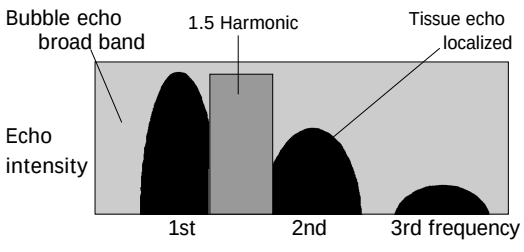

Figure 1 Basic concept of 1.5 Harmonic Imaging Sonography. A high microbubble/tissue ratio is obtained in the intermediate domain.

Patients

This study was performed with approval from the institutional review board, and informed consent was obtained from each patient before undergoing this procedure.

From September 2002 and November 2003, we enrolled in this study 36 patients with unresectable HCC, who had a total of 42 hypervascular HCC nodules. The subjects in the present study were 36 patients with 42 nodules that were diagnosed as HCC based on histopathological examination (n = 18) and diagnostic imaging findings (n = 24). The study group comprised 36 patients with type C cirrhosis: 24 men and 12 women ranging in age from 41 to 78 years and with a mean age of 62 years. The minimum tumor diameter was 10 mm, the maximum tumor diameter was 73 mm, and the mean tumor diameter was 25.8±15.1 mm (±SD). All those HCC nodules have been diagnosed by the sonography. Before therapy, serum α-fetoprotein levels (normal, <7 ng/mL) ranged from 4.7 to 928.6 ng/mL (mean, 186.1 ng/mL). 12/36(33.3%) case showed normal α-fetoprotein level.

Methods

Contrast-enhanced sonography examination

Ultrasound images were acquired using a diagnostic ultrasound system (SSA-770A, Aplio, Toshiba) with phased-array transducers operating at frequencies of approximately 2.5 and 3.0 MHz (PST-25AT and PST-30AT sector transducers, Toshiba). The MI was set to 1.6, and the transmission/reception frequencies were 1.4 MHz/3.0 MHz for 2nd harmonic imaging and 2.3 MHz/3.3 MHz in phantom experiments and 1.7 MHz/2.5 MHz in clinical study for 1.5 Harmonic Imaging Sonography. Contrast images were acquired using FEI.

Phantom experiments were conducted to compare images obtained by 2nd harmonic imaging and 1.5 Harmonic Imaging Sonography (i.e., to compare tissue and microbubble echo contrast between 2nd harmonic imaging and 1.5 Harmonic Imaging Sonography). The phantom consisted of agar mixed with powdered graphite to simulate attenuation in the living body (Nihonkai Medical; 0.6, 0.9 dB/cm/MHz). The tube in this phantom was filled with the ultrasound contrast agent Levovist, which contains particles composed of a mixture of galactose and palmitic acid (SHU 508A, Levovist, Schering, Berlin, Germany; concentration 300 mg/mL). Images of this phantom were acquired using FEI.

In the clinical study, a total of 7 mL of Levovist at a concentration of 300 mg/mL was injected as a single bolus via a peripheral vein at a rate of 1 mL/s. Images were acquired using FEI at intervals of 0.2 s. The early phase was specified as the period of up to 60 s after the injection of contrast agent, and the tumor vessels were observed with the focal point set at the bottom of the tumor. Then, after an interval of 4 min, the late phase was specified as the period beginning at the 5-min time point, and ultrasound transmission was performed once manually to observe vascular enhancement (staining) of the tumor tissues. Images

were recorded on S-VHS videotape immediately after the injection of contrast agent. The patient was instructed to hold his or her breath for 10-50 s after the injection of Levovist in order to maintain a constant respiratory phase, and early-phase images were obtained continuously. Subsequently, the system was temporarily set to freeze mode and the images stored in cine loop memory were recorded onto the system hard disk. Five minutes after the injection, late-phase images were observed for several seconds during breath-holding and recorded onto the system hard disk.

Contrast-enhanced CT Contrast-enhanced CT was performed in all patients before treatment. Contiguous 5-mm-thick axial CT scans were obtained with a HiSpeed Advantage RP scanner (Lemage Supreme, General Electric Yokogawa Medical Systems, Tokyo, Japan). A nonionic contrast material, 100 mL of iopamidol (Iopamiron, Nippon Schering, Osaka, Japan), was administered at a rate of 3 mL/s, and CT scans of the entire liver were obtained twice: first at 20-40 s (arterial phase) after IV injection of contrast material and then at 90 s (portal phase). Lesions were considered to be hypervascular if they appeared denser than the surrounding liver during the arterial phase.

Digital subtraction angiography Digital subtraction angiography (DSA) images were obtained using a DSA system (Infinix NB, Toshiba). The contrast agent was injected via a catheter placed in the hepatic artery. The presence or absence of tumor vessels was assessed. When tumor vessels were identified, the tumor was considered to be hypervascular. We performed transcatheter arterial chemoembolization in all patients by selectively introducing a coaxial microcatheter into a segmental branch or a subsegmental branch of the hepatic artery and injecting a mixture of iodized oil (Lipiodol, Guerbet, Aulnay-sous-Bois, France; 3.0-10.0 mL/body) or epirubicin hydrochloride (Farmorubicin, Pharmacia and Upjohn, Tokyo, Japan: 30-60 mg per body weight). We then preformed embolization using 0.5 mm×0.5 mm×0.5 mm gelatin sponge (Spongel, Yamamouchi Pharmaceuticals) in all patients. These embolic materials were injected until the feeding arteries were completely obliterated. If the blood supply was from two different subsegmental arteries, both were embolized. The effectiveness of transcatheter arterial chemoembolization was evaluated by 1.5 Harmonic Imaging Sonography and contrast-enhanced CT at 7 d after treatment.

US CO_2 angiography In ultrasound angiography, after the tumor was identified in a cross-sectional ultrasound image, CO_2 microbubbles were injected at a constant rate during breath-holding via a catheter placed in the hepatic artery. The CO_2 microbubbles were prepared by adding 5 mL of autologous blood to 10 mL of CO_2, connecting the container to a three-way stopcock, and transferring the mixture repeatedly approximately 30 times with a pump. Ultrasound images were acquired using a diagnostic ultrasound system (SSA-250A, Toshiba) with a 3.75-MHz convex transducer. Images were simultaneously recorded on videotape and magneto-optical disk from the time immediately before the injection of CO_2 microbubbles until the time when tumor enhancement was observed. When the tumor showed stronger enhancement than the surrounding hepatic parenchyma, it was considered to be hypervascular.

CT during arterial portography CT during arterial portography (CTAP) was performed using a CT scanner (Asteion, Toshiba, Tokyo Japan). For CTAP, 100 mL of Iopamidol contrast medium (Iopamiron 150; Nihon Schering, Osaka, Japan) was administered via a catheter in the superior mesenteric artery at an estimated rate of 2.0 mL/s during sequential helical scanning of the liver. For CT arteriography, 30-50 mL of contract medium (Iopamiron 150) was administered via a catheter in the proper hepatic, left, or right hepatic artery at an estimated rate of 1.5-2.5 mL/s during sequential helical scanning of the liver. Tumors that did not contain portal blood flow were identified as low-absorption areas in the hepatic parenchyma (portal perfusion defects).

Imaging analysis All the sonographic data were recorded on videotape from the beginning of B-mode scanning. The still images were stored on the hard disk of the unit by reviewing the cine loop memory. The images obtained using the above modalities were interpreted by three specialists in diagnostic imaging. When a discrepancy occurred among the interpreters, re-evaluation and discussion were done for agreement. On contrast-enhanced imaging with 1.5 Harmonic Imaging Sonography, the presence of the intratumoral blood flow signals on either the vessel image or on the tumor parenchymal stain image was considered as hypervascular or residual tumor due to inadequate treatment. In contrast, the absence of the intratumoral blood flow signals was evaluated as hypovascular or complete response to the treatment. The contrast enhancement on CT was reviewed by three radiologists without knowledge of the 1.5 Harmonic Imaging Sonography results.

The sensitivity and specificity of 1.5 Harmonic Imaging Sonography in detecting intratumoral blood flow signals on the vessel tumor were determined using US CO_2 angiography as a gold standard[21,22]. The detectability of residual tumor using contrast-enhanced 1.5 Harmonic Imaging Sonography was compared with that of the tumors using contrast-enhanced CT.

The data were analyzed with the χ^2 test. A P value less than 0.05 was considered significant.

In vitro study

In the phantom experiments, the area occupied by the contrast agent was shown as a gleaming white zone, with the surrounding area corresponding to a tissue-equivalent phantom composed of agar mixed with powdered graphite. In oblique images, the echoes from the microbubbles appeared as an oblique bright zone, and the surrounding dark area corresponded to echoes from the agar phantom. The images clearly demonstrated the improvement in tissue-microbubble contrast in 1.5 Harmonic Imaging Sonography as compared with 2nd harmonic imaging. In 1.5 Harmonic Imaging Sonography, the contrast between tissues and microbubbles was found to be clearly superior to that in 2nd harmonic imaging (Figure 2).

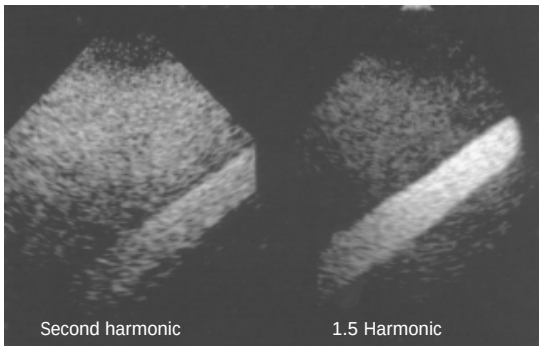

Figure 2 Comparison of contrast images obtained by 1.5 Harmonic Imaging Sonography and 2nd harmonic imaging.

Clinical study

Blood vessels in all HCCs were more clearly depicted by 1.5 Harmonic Imaging Sonography than by 2nd harmonic imaging (Figures 3A and C). Moreover, during the late phase, 1.5 Harmonic Imaging Sonography demonstrated the surrounding hepatic parenchyma with higher contrast enhancement than 2nd harmonic imaging, clearly depicting the area of the tumor (Figures 3B and D).

In hypervascular HCCs, the blood vessels within the tumor were clearly demonstrated during the early phase (Figures 4B-D and 5A). In addition, late-phase images revealed partial residual enhancement in all tumors, but with less enhancement than the surrounding hepatic parenchyma (Figures 3B and 5B).

With regard to the detection of blood flow signals within the tumor in the 42 nodules, early-phase 1.5 Harmonic Imaging Sonography revealed the tumor vessels in 36 nodules (85.7%). Late-phase images demonstrated significantly lower enhancement of the tumor than the surrounding hepatic parenchyma in all 42 nodules (100%). Early-phase 1.5 Harmonic Imaging Sonography did not show hypervascular enhancement in six nodules (14.3%), and late-phase images confirmed that these six nodules were not enhanced ($P>0.05$). As for the findings of other imaging modalities, blood flow signals were detected within the tumor in 39 nodules (92.9%) by contrast-enhanced CT, in 34 nodules (81.0%) by DSA, and in 42 nodules (100%) by US CO_2 angiography. CTAP showed a perfusion defect image in all 42 nodules (100%, Table 1).

Contrast-enhanced CT did not show hypervascular enhancement in three nodules (one small HCC nodule measuring 10 mm in diameter and two nodule near the heart), but 1.5 Harmonic Imaging Sonography was able to

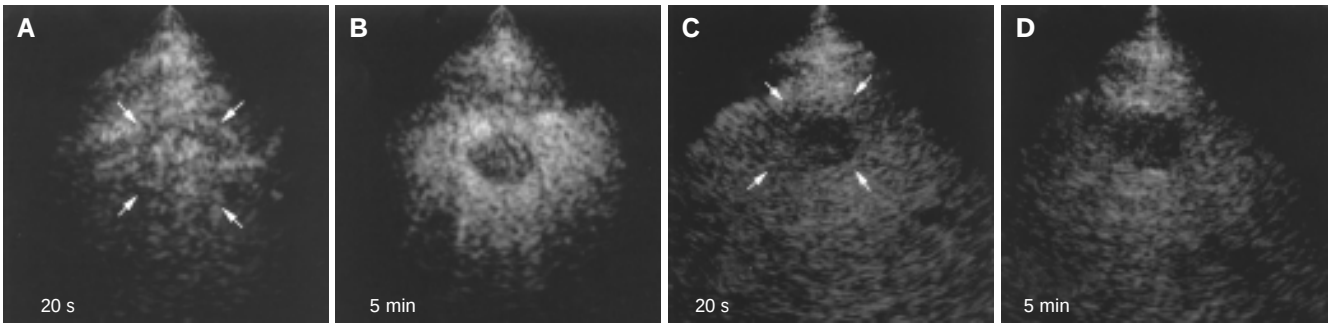

Figure 3 A 74-year-old man with C-type cirrhosis and HCC (15.4 mm in diameter) in the right liver. Comparison of contrast images obtained by 1.5 Harmonic Imaging Sonography and 2nd harmonic imaging. A: 1.5 Harmonic Imaging Sonography image obtained by real-time continuous sonography in the early phase (20 s after injection). Abundant tumor vessels (arrows) with peripheral branching are seen; B: 1.5 Harmonic Imaging Sonography image obtained by real-time continuous sonography in the late phase (5 min after injection). Residual enhancement of some tumor vessels is seen, but the boundary between the tumor and the hepatic parenchyma is clearly demonstrated; C: 2nd harmonic imaging obtained by real-time continuous sonography in the early phase (20 s after injection). The abundant and peripherally branching tumor vessels (arrows) cannot be clearly depicted; D: 2nd harmonic imaging obtained by real-time continuous sonography in the late phase (5 min after injection). The boundary between the tumor and the hepatic parenchyma is somewhat obscure.

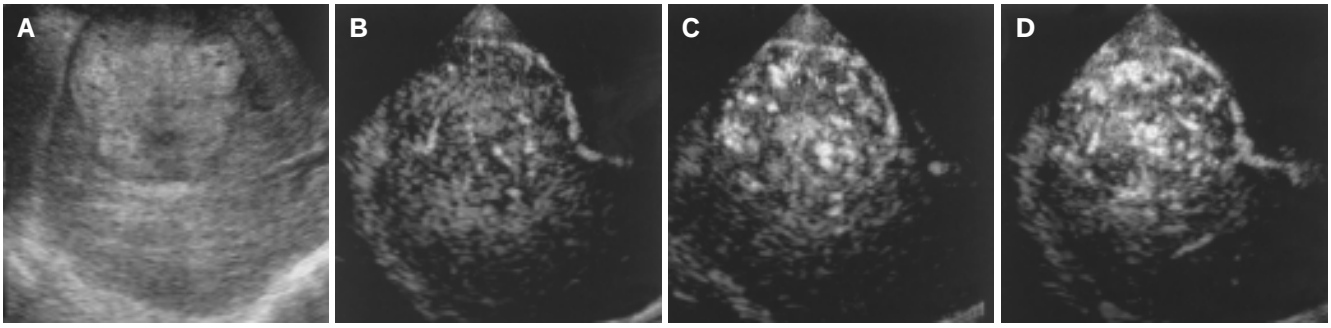

Figure 4 A 78-year-old man with C-type cirrhosis and HCC (73.3 mm in diameter) in the right liver. A: Right oblique conventional sonography image of the liver shows a mixed-pattern nodule 73.3 mm in diameter in segment 6 that exhibits the typical characteristics of HCC; B: 1.5 Harmonic Imaging Sonography image obtained by real-time continuous sonography in the early phase (20 s after injection) shows the tumor vessels; C and D: 1.5 Harmonic Imaging Sonography images obtained by real-time continuous sonography in the early phase, 28 s (C) and 32 s (D) after injection, show abundant tumor vessels with peripheral branching.

demonstrate the tumor vessels even in these three nodules. Furthermore, DSA failed to demonstrate tumor vessels in eight nodules, while these vessels were successfully visualized by 1.5 Harmonic Imaging Sonography. 1.5 Harmonic Imaging Sonography were compared with the US CO_2 angiography findings as the gold standard, and the sensitivity and specificity of these images for discerning viable and nonviable HCC after transcatheter arterial embolization were 100% and 100%, respectively.

With regard to treatment, 1.5 Harmonic Imaging Sonography revealed residual blood flow signals within the tumor in 20 (47.6%) of the 42 nodules that had been treated by transcatheter arterial embolization. MRI, US CO_2 angiography also revealed residual blood flow signals within the tumor, but contrast-enhanced CT demonstrated residual blood flow signals in only 14 nodules (33.3%). In the remaining 22 nodules (52.4%), no blood flow signal was observed within the tumor by 1.5 Harmonic Imaging Sonography or contrast-enhanced CT (Table 2, Figures 6 and 7).

In the present study, phantom experiments were conducted to investigate the usefulness of 1.5 Harmonic Imaging Sonography. In 1.5 Harmonic Imaging Sonography, unlike 2nd harmonic imaging, images are obtained using a frequency band that is lower than that of the 2nd harmonics, resulting in a significant improvement of the contrast enhancement non-uniformity that is frequently observed when a sector transducer is used. In 1.5 Harmonic Imaging Sonography,

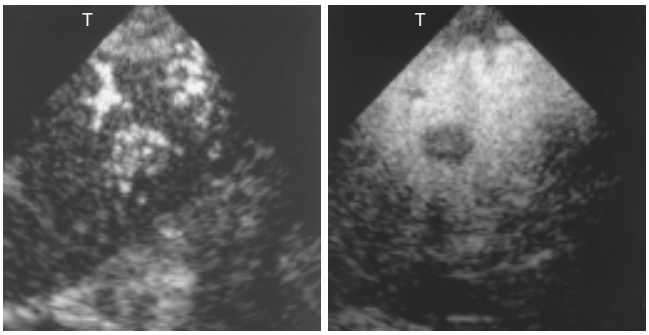

Figure 5 A 62-year-old man with C-type cirrhosis and HCC (18.9 mm in diameter) in segment 4 of the liver. A: 1.5 Harmonic Imaging Sonography image obtained by real-time continuous sonography in the early phase (28 s after injection) shows abundant tumor vessels with peripheral branching; B: 1.5 Harmonic Imaging Sonography image obtained by real-time continuous sonography in the late phase (5 min after injection) shows residual enhancement of some tumor vessels, but the boundary between the tumor and the hepatic parenchyma is clearly depicted.

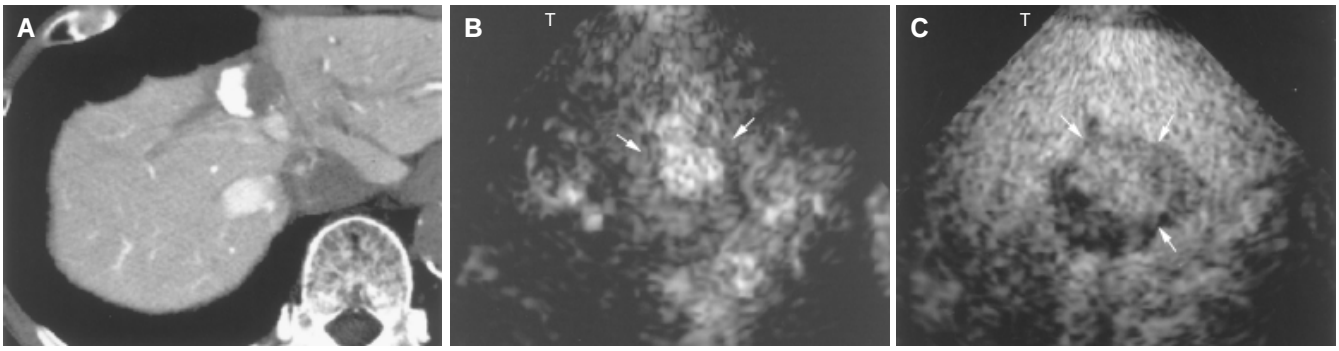

Figure 6 A 73-year-old man with C-type cirrhosis and HCC (16.5 mm in diameter) in the right liver who had undergone transcatheter arterial chemoembolization therapy with iodized oil and an anticancer drug. A: Transverse CT image with iodized oil obtained 7 d after treatment shows incomplete retention of iodized oil within the nodule; B and C: 1.5 Harmonic Imaging Sonography images obtained 35 s (B) and 5 min (C) after injection show partial enhancement. Right oblique 1.5 Harmonic Imaging Sonography image depicts residual tumor vessels within the tumor and subcapsular area (arrows), which is suggestive of possible future recurrence in this region.

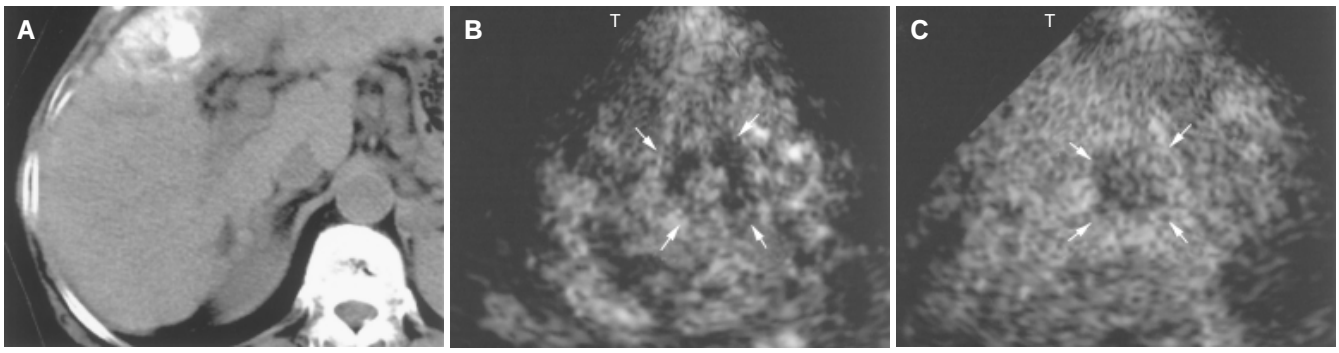

Figure 7 A 59-year-old woman with C-type cirrhosis and HCC (17.7 mm in diameter) in the right liver who had undergone transcatheter arterial chemoembolization therapy with iodized oil and an anticancer drug. A: Transverse CT scan with iodized oil obtained 7 d after treatment shows incomplete retention of iodized oil within the nodule; B and C: 1.5 Harmonic Imaging Sonography images obtained 34 s (B) and 5 min (C) after injection show partial enhancement. Right oblique 1.5 Harmonic Imaging Sonography image depicts residual tumor vessels within the tumor and subcapsular area (arrows), which is suggestive of possible recurrence in this region.

Table 1 Detection of HCC tumors with different imaging modalities (n = 42)

	1.5 Harmonic (early phase) enhancement	Imaging sonography (late phase) no enhancement	CTAP	US CO_2 angiography	DSA	CECT
Positive cases	36	42	42	42	34	39
(%)	(85.7)	(100)	(100)	(100)	(81.0)	(92.9)

Table 2 Evaluation of TAE response in HCCs by using 1.5 Harmonic Imaging Sonography compared with contrast-enhanced CT

Findings at contrast-enhanced CT	Vascular findings at 1.5 enhancement	Harmonic imaging sonography no enhancement
Incomplete (n = 14)	14	0
Complete (n = 28)	6	22

on the other hand, since there are almost no tissue echoes, the gain can be increased. As a result, enhancement is significantly improved in deep regions from which only weak echoes are received. In addition, images are generated using the B-mode processing system, resulting in good spatial resolution and minimal motion artifacts and blooming, which are often a problem in the pseudo-Doppler method. Furthermore, the combined use of flash echo mode and monitor mode ensures that slices can be maintained or adjusted in real time even though images are acquired at high acoustic power and the microbubbles are destroyed. Therefore, the enhanced slice can easily be adjusted during the continuous injection of contrast agent. When a frequency near the mean value is used, adequate contrast enhancement is obtained in all areas, from the near field to the far field, in 1.5 Harmonic Imaging Sonography. Furthermore, this method avoids the problems associated with the Doppler method and provides extremely clear contrast-enhanced images[19,20].

The results of the present clinical study have clearly demonstrated that the use of 1.5 Harmonic Imaging Sonography is effective for evaluating the vascularity of HCCs, including the assessment of tumor vessels during continuous early-phase arterial imaging as well as the assessment of late-phase enhancement (staining) due to blood flow signals in the tumor tissues. In early-phase real-time continuous imaging, the movement of microbubbles provides the signals used to obtain enhancement. In other words, the image can depict the flow of the microbubbles in the tumor vessels. The results of our study have also shown that 1.5 Harmonic Imaging Sonography can clearly depict the hypervascular tumor vessels of HCCs. The findings obtained by late-phase imaging show partial residual enhancement of the tumor tissues, but with less enhancement than the surrounding hepatic parenchyma. It is thought that the microbubbles flow from the tumor into the hepatic parenchyma over time, resulting in lower enhancement. Residual enhancement in the area of the tumor during the late phase is believed to reflect the enhancement (staining) due to the microbubbles that are trapped in the very small, tortuous blood vessels that are characteristically found in HCCs. In the present study, however, there were six nodules (14.3%) in which the tumor vessels were identified by US CO_2 angiography but not by 1.5 Harmonic Imaging Sonography. In principle, 1.5 Harmonic Imaging Sonography selectively eliminates the fundamental components in order to generate images, thus reducing the quality of B-mode images and the degree of visualization of the tumor area. In addition, the use of a sector transducer makes it difficult to assess deep regions. Generally, line density of sector scan is lower than that of convex in the deep region. Furthermore, lateral resolution of sector image is inferior to that of convex image. For these reasons, it was expected that the tumor vessels associated with small tumors in deep regions would not be detectable during the early phase. But, due to the reduction in motion artifacts, 1.5 Harmonic Imaging Sonography has significant advantages in the detection of nodules near the heart, which are difficult to detect by contrast-enhanced CT.

In the present study, the usefulness of 1.5 Harmonic Imaging Sonography and contrast-enhanced CT for evaluating treatment effects following transcatheter arterial chemoembolization of HCCs were compared, and the results showed that areas of insufficient treatment could be clearly identified by 1.5 Harmonic Imaging Sonography. Early-phase images clearly showed microbubbles flowing into the residual tumor vessels in insufficiently treated areas. Such areas were identified particularly well in late-phase images, and the information provided by such images was found to be useful for planning additional treatment. When percutaneous ethanol injection therapy and radiofrequency thermal ablation are performed under ultrasonographic guidance, 1.5 Harmonic Imaging Sonography permits viable areas within the tumor to be accurately identified during treatment and is therefore expected to improve treatment accuracy. Furthermore, 1.5 Harmonic Imaging Sonography has the advantage of being unaffected by lipiodol accumulation in the area of the tumor, which is associated with an increased risk of false-negative findings. In the present study, contrast-enhanced CT was found not to be useful for the evaluation of six nodules following transcatheter arterial chemoembolization with lipiodol.

With regard to the detection of early-stage tumor vessels, the results obtained by 1.5 Harmonic Imaging Sonography were comparable to those obtained by Sonography angiographic evaluation of blood flow signals within the tumor, except for six nodules measuring approximately 10 mm in diameter that were located 80 mm or more from the body surface. However, evaluation of all cases is difficult because of a sector probe, and an ultrasound image quality needs to be improved. The reasons for the difficulty in evaluating tumors in deep regions are thought to be (1) the use of 2.5- and 3.0-MHz sector transducers; (2) the attenuation of ultrasound signals in deep regions due to the elimination of the fundamental components, which is characteristic of 1.5 Harmonic Imaging Sonography; and (3) MI values insufficient to destroy the microbubbles.

These problems may be overcome in future when 1.5 Harmonic Imaging Sonography with the use of a convex transducer becomes available.

The next step will involve the use of a next-generation contrast agent with fluorocarbon-containing gas, which has already been employed clinically in Europe and USA. The main advantage of this contrast agent is that real-time contrast images can be obtained at low acoustic power without the need to destroy the microbubbles, and imaging techniques employing this contrast agent are therefore expected to be comparable or superior to US CO_2 angiography in terms of diagnostic capabilities.

In conclusion, 1.5 Harmonic Imaging Sonography is therefore considered to be an extremely useful diagnostic imaging modality for the assessment of patients with HCC.

Abstract

AIM: To investigate the anti-tumor effect of dendritic cells (DCs) pulsed with hsp70-peptide complexes derived from human hepatocellular carcinoma (HCC) cells on human T cells.

METHODS: Hsp70-peptide complexes were purified from human HCC cells with column chromatography using ADP-agarose and DEAE-Sepharose. DCs were derived from peripheral blood mononuclear cells of healthy donors in the presence of human GM-CSF and IL-4. The anti-tumor effect of DCs pulsed with hsp70-peptide complexes on human T-cell was assayed by CTL and enzyme-linked immunospot (ELISPOT) tests.

RESULTS: Hsp70-peptide complexes derived from human HCC cells activated phenotypic and functional maturation of DCs. The matured DCs stimulated a high level of autologous T-cell proliferation and type I cytokine secretion, and induced HCC-specific cytotoxic T lymphocytes (CTLs), which specifically killed HCC cells by a MHC class I restricted mechanism.

CONCLUSION: Hsp70-peptide complexes derived from human HCC cells can serve as a potent tumor antigen source for pulsing DCs, the pulsed DCs are very effective in activating specific T-cell responses against HCC cells.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies in the world, especially in sub-Saharan Africa and Southeast Asia, and it rarely responds to conventional treatment, such as surgery, radiation, or chemotherapy[1,2]. The ability of tumors to escape from immune surveillance contributes to their uncontrolled growth, recurrence, and metastasis[3]. Finding an efficient therapeutic method for HCC has become the focus of researchers around the world. An ideal cancer therapy should have the potency to eradicate systemic tumors in multiple sites in the body and the specificity to discriminate between neoplastic and non-neoplastic cells. In these respects, immunotherapy that stimulates tumor-specific immune responses has become an attractive approach.

Dendritic cells (DCs) are professional antigen presenting cells (APCs), which direct the cellular immune response through antigen presentation in the presence of appropriate costimulation. These cells reside in an immature state in non-lymphoid tissues, where they can efficiently capture invading pathogens. After antigen uptake, they rapidly migrate to the draining secondary lymphoid tissues and convert into mature DCs with decreased antigen processing ability, enhanced expression of MHC and costimulatory molecules, and increased capacity of priming naïve T cells and initiating an adaptive immune response[4]. The extraordinary functional profile of DCs suggests that they may represent an ideal vector in the immunotherapy of cancer and infectious diseases[4]. Studies have shown that DC-based vaccines can induce potent anti-tumor immunity. Various strategies have been developed to introduce tumor-specific antigens into DCs and thereby to generate cytotoxic T lymphocyte (CTL) responses against malignant cells.

Heat shock proteins (HSPs) are important molecular chaperones that play essential roles in the regulation of protein synthesis and folding, and vesicular trafficking[5-7]. They are ubiquitously expressed at a basal level but are specifically induced in response to various stress conditions such as heat, anoxia, and metabolic stress[3]. The observation that preparations of HSPs from various tumors can elicit specific anti-tumor immune responses suggests their immunotherapeutic activity[8]. The observed immunogenicity of HSP preparations is derived from the antigenic peptides

they chaperone[9]. Studies concerning the mechanisms of HSP preparations' immunogenicity have shown that HSPs transfer antigenic peptides to professional APCs, such as DCs, and channel them into the class I antigen presenting pathway through receptors[10-14]. HSPs can also elicit cytokine production by, and adhesion molecule expression of, a range of cell types, and they can deliver maturation signals to APCs through receptor-mediated interactions[5,11,15].

In the current study, we used DCs pulsed with hsp70-peptide complexes derived from human HCC cell line SMMC-7721 to activate autologous T cells. We found that the pulsed DCs stimulated a high level of T-cell proliferation and type I cytokine secretion, and induced HCC-specific CTLs which specifically killed HCC cells by a MHC class I restricted mechanism. Also the hsp70-peptide complexes induced the maturation of DCs by enhanced expression of HLA class II, CD86, and CD83. Our findings provide a new approach for pulsing DCs as tumor vaccines and a rationale for HSP-based vaccination against human HCC.

MATERIALS AND METHODS

Culture of cell lines

Human HCC cell line SMMC-7721, human NK cell sensitive cell line K562 and human cervix cell line Hela (American Type Culture Collection) were cultured in RPMI 1640 medium (GIBCO, Invitrogen Corporation, CA, USA) supplemented with 10% heat-inactivated fetal calf serum (FCS) (HyClone, UT, USA), 2 mol/L L-glutamine (GIBCO, Invitrogen Corporation), 100 U/mL penicillin G, 100 μg/mL streptomycin and 250 ng/mL amphotericin B (GIBCO^{TM}, Invitrogen Corporation). Cultures were incubated at 37 ℃ in humidified air with 50 mL/L CO_2.

Preparation of DCs and T cells

DCs were generated as described with some modifications[16]. Briefly, peripheral blood mononuclear cells (PBMCs) were isolated from healthy donors (Beijing Red Cross Blood Center, China) by Ficoll-Hypaque (1.077 g, Shang Hai Heng Xin Co., China) density gradient centrifugation and cultured in RPMI 1640 medium containing 10% FCS for 2 h. The non-adherent cells were removed for isolation of T cells and the adherent cells were cultured for 6 d in RPMI 1640 medium containing 10% FCS, 1 000 U/mL human GM-CSF (Biosea Biotechnology Co., Beijing, China) and 500 U/mL human IL-4 (Peprotech Inc., NJ, USA). Culture medium and cytokines were refreshed every other day. DCs were harvested from the non-adherent and loosely adherent cells.

T cells were purified by nylon wool column (Polysciences Inc., Warrington, USA) from non-adherent cells according to manufacturer's instructions. Briefly, non-adherent cells were resuspended in RPMI 1640 medium containing 10% FCS and added to the prepared nylon wool column. After incubating for 1 h at 37 ℃, the non-adherent cells, which contained mainly T cells, were collected by washing with RPMI 1640 medium containing 10% FCS.

Purification of hsp70-peptide complexes

The method for hsp70-peptide complex purification was as described with minor modifications[17]. In brief, SMMC-7721 tumor cells were harvested by culturing tumor cells in roller bottles and then 10 g tumor cells were suspended in 40 mL (4 volumes) of 30 mmol/L sodium bicarbonate (pH 7.0) and lysed by Dounce homogenization. The homogenate was centrifuged at 100 000 *g* for 90 min at 4 ℃ and the supernatant obtained. The sample was subjected to column chromatography using Sephadex G25 (Amersham Pharmacia Biotech, NJ, USA) for buffer exchange, affinity chromatography ADP-agarose (Sigma Chemical Co., St. Louis, Missouri, MO, USA), Sephadex G25 for buffer exchange, and ion-exchange chromatography with DEAE-Sepharose (Amersham Pharmacia Biotech, NJ, USA). The eluted proteins were identified by 12% reducing SDS-PAGE followed by silver staining and Western blot with an anti-hsp70 antibody (PharMingen, San Diego, CA, USA). Fractions containing more than 50% hsp70 were stored at -20 ℃ and used for additional experiments. Protein concentration was determined by Bio-Rad protein assay (Bio-Rad Laboratories, Inc., CA, USA). Endotoxin level in the preparations was determined by Limulus amebocyte lysate (LAL) assay (Ocean Biologicals Co., China).

T-cell proliferation assay

DCs were pulsed with hsp70-peptide complexes purified from SMMC-7721 cells at 37 ℃ for 4 h and then harvested followed by washing with PBS. Autologous T cells isolated by nylon wool column were cocultured with the pulsed DCs in a 96-well flat bottomed culture plate (NUNC, Roskilde, Denmark). Proliferation was determined after 5 d by uptake of tritiated thymidine (Amersham Pharmacia Biotech, Buckinghamshire, UK) measured at 18 h after a pulse of 1 μCi/well.

In vitro cytotoxicity test

DCs were pulsed with hsp70-peptide complexes purified from SMMC-7721 cells at 37 ℃ for 4 h. After washing with PBS, DCs were then cocultured with autologous T cells isolated by nylon wool column for 7-10 d in the presence of 20 U/mL human IL-2 (Kexing Co., China) in 24-well culture plate (NUNC, Roskilde, Denmark). The stimulated T cells were harvested with Ficoll-Hypaque density gradient centrifugation and used as effector cells in the CTL assay using LDH cytotoxicity detection kit (Roche, Indianapolis, USA). SMMC-7721, K562, Hela and autologous DCs pulsed with or without hsp70-peptide complexes were used as target cells in the assay. Briefly, target cells and effector cells were resuspended in assay medium (RPMI 1640 with 1% BSA), and then target cells (1×10^4 cells/well) were cocultured with effector cells at different ratios in a 96-well round bottomed culture plate (NUNC, Roskilde, Denmark) at 37 ℃. In the indicated experiment, target cells were preincubated with anti-MHC class I antibody (W6/32, PharMingen, San Diego, CA, USA) for 30 min at 37 ℃ before being cocultured with effector cells to test if the cytotoxicity was MHC class I restricted. After 5 h of incubation, the culture plate was centrifuged and the supernatant (100 μL/well) was transferred to another ELISA plate (NUNC, Roskilde, Denmark). LDH detection mixture (100 μL/well) was then added and incubated in the dark for 30 min at room temperature. After adding 50 μL stop

solution per well, the absorbance of the samples was measured by ELISA reader (Bio-Rad Laboratories, Inc., CA, USA) at 490 nm with 630 nm as reference wavelength. The spontaneous release of LDH by target cells or effector cells was assessed by incubation of target cells in the absence of effector cells and vice versa. The maximum release of LDH was determined by incubation of target cells in 1% Triton X-100 in assay medium. The percentage of specific cell-mediated cytotoxicity was determined by the following equation: cytotoxicity (%) = [(effector and target mixture-effector spontaneous-target spontaneous)/(maximum-target spontaneous)]×100.

Enzyme-linked immunospot (ELISPOT) assay

ELISPOT assay was performed to assess the IFN-γ production of T cells using IFN-γ ELISPOT kit (U-CyTech BV, Utrecht, Netherlands). DCs were pulsed with hsp70-peptide complexes purified from SMMC-7721 cells at 37 ℃ for 4 h. After washing with PBS, DCs were then cocultured with autologous T cells isolated with nylon wool column in the presence of 20 U/mL human IL-2 for 7-10 d. The stimulated T cells (1×10^4/well) as effector cells and irradiated SMMC-7721 cells (5×10^3/well) as target cells were transferred to ELISPOT plate and incubated for 18 h at 37 ℃. The IFN-γ secreting spots were developed as described in the IFN-γ ELISPOT kit manual and evaluated in a blind fashion by Dakewe Biotech Co., China, with an automated ELISPOT reader system (Biosys Co. Ltd, Germany).

Flow cytometry DCs were pulsed with hsp70-peptide complexes at 37 ℃ for 4 h and then cultured for another 48 h. The DCs unpulsed or pulsed with hsp70-peptide complex were washed with cold PBS and incubated with murine antibodies directed against human HLA-DR, CD86, CD83 (all from PharMingen, San Diego, USA), for 1 h in ice. After washing with cold PBS, the cells were incubated with FITC conjugated with goat anti-mouse IgG (Zymed Laboratories, Inc., South San Francisco, USA) for 30 min in ice. The cells were then washed with cold PBS and fixed with 2% paraformaldehyde (Sigma). The fluorescence intensity was analyzed by FACS Calibur and the CellQuest software (Becton Dickinson, NJ, USA).

RESULTS

Purification of hsp70-peptide complexes

As described in Materials and methods, the hsp70-peptide complexes were purified from HCC SMMC-7721 cells and identified by reduced SDS-PAGE stained with silver and Western blot using an hsp70-specific antibody. The result showed that the purified protein was approximately 72 ku (Figure 1A) and could hybridize with the hsp70-specific antibody (Figure 1B), demonstrating that the obtained protein was hsp70. The purity of the protein preparations was estimated to be >99% by silver-stained SDS-PAGE. The endotoxin level in the preparations was lower than 0.03 EU/μg of hsp70-peptide complexes, as determined by LAL assay.

Stimulation of autologous T cells by DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells

To determine if DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells are effective in stimulating autologous T cells, the pulsed DCs were cocultured with autologous T cells. As a control, the T cells were used alone or cocultured with unpulsed DCs. After a 5-d coculture, the T-cell proliferation was tested by uptake of tritiated thymidine. As shown in Figure 2A, DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells stimulated autologous T cells to proliferate significantly stronger than did T cells cultured by themselves or cocultured with unpulsed DCs. By contrast, unpulsed DCs exhibited little capacity to stimulate autologous T cells. To further assess the selectivity of this stimulation response, we changed the ratio of DCs:T cells in coculture (Figure 2B). The result showed that the proliferation of T cells cocultured with DCs pulsed with hsp70-peptide complexes was enhanced rapidly by increasing the ratio of DCs:T cells. Contrarily, T-cells coculture with unpulsed DCs proliferated at almost the same level despite an increase in the ratio of DCs:T cells. These results demonstrate that DCs pulsed with hsp70-peptide complexes are capable of specifically stimulating T-cell responses.

Induction of specific CTLs and type I cytokine secretion against SMMC-7721 by DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells

Cell-mediated immunity, which is particularly important in suppressing tumors, is characterized by induction of CTLs and production of type I cytokines. To explore whether DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells are capable of generating SMMC-7721-specific CTLs and inducing type I cytokine secretion, we examined cytotoxic activities and IFN-γ production of autologous T cells cocultured with DCs. DCs pulsed with

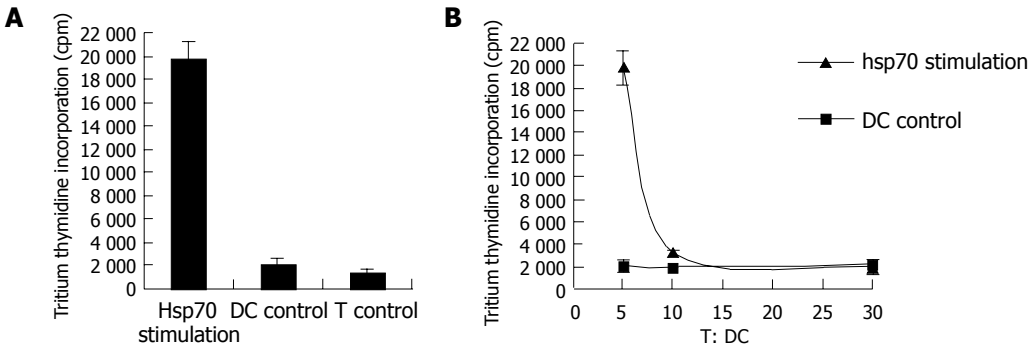

Figure 2 Stimulation of T cells by autologous DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells. DCs were incubated with 20 μg/mL hsp70-peptide complexes derived from SMMC-7721 for 4 h at 37 ℃ and cocultured with autologous T cells at different ratios for 5 d, and then tritiated thymidine was added and its incorporation was measured 18 h later. (**A**) 1×10^5 T cells were cocultured with 2×10^4 autologous DCs, pulsed with hsp70-peptide complexes (indicated as hsp70 stimulation) or unpulsed (indicated as DC control), or by themselves (indicated as T control) per well; (**B**) 1×10^5 autologous T cells were cocultured with 2×10^4, 1×10^4, or 3.3×10^3 DCs pulsed with hsp70-peptide complexes (indicated as hsp70 stimulation) or unpulsed (indicated as DC control) per well separately. The results are expressed as mean±SD and each value represents the mean of three replicates.

hsp70-peptide complexes were cocultured with autologous T cells for 7-10 d in the presence of 20 U/mL human IL-2 and then the T cells were isolated by density gradient centrifugation for cytotoxicity testing and type I cytokine secretion assessing. As a control, the T cells were used alone or cocultured with unpulsed DCs.

The result of cytotoxicity testing showed that T cells cocultured with unpulsed DCs or by themselves failed to exhibit evident cytotoxicity against SMMC-7721 cells, but significantly, T cells cocultured with DCs pulsed with hsp70-peptide complexes were capable of killing SMMC-7721 cells at high levels (Figure 3A). To test if the lysis

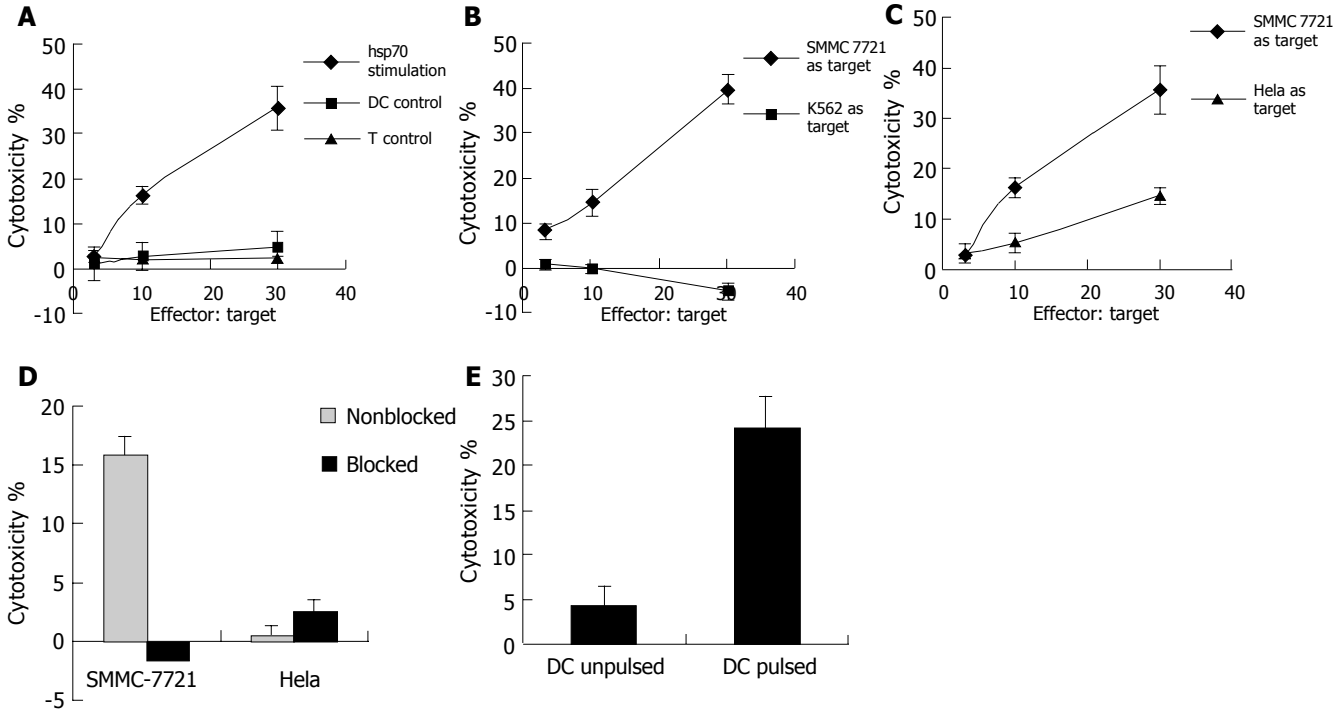

Figure 3 Generation of specific CTLs against SMMC-7721 by DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells. 1×10^5 DCs were incubated with 20 μg/mL hsp70-peptide complexes derived from SMMC-7721 for 4 h at 37 ℃ and then cocultured with 1×10^6 autologous T cells in each well of 24-well culture plate for 7-10 d in the presence of 20 U/mL human IL-2. The stimulated T cells were harvested by density gradient centrifugation and the cytotoxicity was determined by testing LDH release. As a control, T cells cocultured with unpulsed DCs or by themselves were also used as effectors. (**A**) T cells were cocultured with autologous DCs pulsed with hsp70-peptide complexes (indicated as hsp70 stimulation) or unpulsed (indicated as DC control), or by themselves (indicated as T control), and SMMC-7721 cells were used as target cells; (**B**) T cells were cocultured with autologous DCs pulsed with hsp70-peptide complexes, and SMMC-7721 cells (indicated as SMMC-7721 as target) or NK-sensitive cell line K562 cells (indicated as K562 as target) were used as target cells; (**C**) T cells were cocultured with autologous DCs pulsed with hsp70-peptide complexes and SMMC-7721 cells (indicated as SMMC-7721 as target) or Hela cells (indicated as Hela as target) were used as target cells; (**D**) T cells cocultured with autologous DCs pulsed with hsp70-peptide complexes were used as effector cells and SMMC-7721 cells or Hela cells were used as target cells. The ratio of effector cells:target cells was 10:1. The target cells were preincubated with an anti-MHC class I antibody (W6/32; 1:50 dilution) or not, indicated as blocked and nonblocked separately. (**E**) T cells cocultured with autologous DCs pulsed with hsp70-peptide complexes were used as effector cells and autologous DCs pulsed with hsp70-peptide complexes or unpulsed were used as target cells (indicated as DC pulsed or DC unpulsed separately). The ratio of effector cells:target cells was 10:1. The results are expressed as mean±SD and each value represents the mean of three replicates.

against SMMC-7721 was due to the presence of NK cells, the NK cell-sensitive cell line K562 was used as target cell in the cytotoxicity assay (Figure 3B). The result showed that the cytotoxicity against K562 cells was very little, much lower than that against SMMC-7721 cells, indicating that it was not NK cells but rather CTLs that killed SMMC-7721 cells.

To further prove that CTLs killed the SMMC-7721 cells and to define the specificity of the CTLs generated by the coculture of T cells with autologous DCs pulsed with hsp70-peptide complexes, we compared the cytotoxicity of the T-cell against SMMC-7721 cells and another human cervix cell line Hela cells (Figure 3C), and assessed if the cytotoxicity was MHC class I restricted (Figure 3D). As shown in Figure 3C, T cells stimulated by DCs pulsed with hsp70-peptide complexes showed significant cytotoxicity against SMMC-7721 cells, whereas they exhibited little lysis against Hela cells. As shown in Figure 3D, preincubation of SMMC-7721 cells with anti-MHC class I antibody resulted in abrogation of tumor cell lysis; however, the anti-MHC class I antibody had little if any effect on lysis of Hela cells, demonstrating that the cytotoxicity against SMMC-7721 cells was MHC class I restricted and therefore due to $CD8^+$ T cells which directed against tumor-specific antigens. The quite weak lysis against Hela cells may result from non-specific killing activity. These results demonstrated that CTLs induced by autologous DCs pulsed with hsp70-peptide complexes were specific to SMMC-7721 cells from which hsp70-peptide complexes were derived.

To exclude the possibility that the SMMC-7721 specific cytotoxicity was due to allogeneic response, autologous DCs pulsed or unpulsed with hsp70-peptide complexes were used as target cells in CTL assay. As shown in Figure 3E, the CTLs induced by DCs pulsed with hsp70-peptide complexes exhibited significant cytotoxicity against DCs pulsed with hsp70-peptide complexes which expressed tumor antigens on their surface, whereas little cytotoxicity was exhibited against unpulsed DCs which did not express tumor antigens. The result confirmed that the cytotoxicity against SMMC-7721 was a tumor-specific response rather than an allogeneic response.

In addition to the cytotoxicity test, we also examined if DCs pulsed with hsp70-peptide complexes could induce autologous T cells to secret IFN-γ. As shown in Figure 4, T cells cocultured with DCs pulsed with hsp70-peptide complexes secreted a high level of IFN-γ against SMMC-7721; however, T cells cocultured with unpulsed DCs or by themselves secreted very little IFN-γ. Consistent with the CTL testing result, this finding suggested that DCs pulsed with hsp70-peptide complexes efficiently induce SMMC-7721 specific CTLs, which secrete type I cytokines at a high level.

These findings illuminate that DCs pulsed with hsp70-peptide complexes are very effective in inducing functional CTLs which direct to tumor cells from which hsp70-peptide complexes are isolated and secrete type I cytokine at high levels.

Maturation of human DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells

To examine the effect of hsp70-peptide complexes derived from SMMC-7721 cells on DCs, immature DCs generated by culturing human PBMCs in the presence of human GM-CSF and IL-4 for 6 d, were incubated with hsp70-peptide complexes for 4 h at 37 ℃ and then cultured for 48 h. The expression level of HLA-DR, CD86, and CD83 was determined by flow cytometry. The result showed that hsp70-peptide complexes promoted upregulation of HLA-DR, co-stimulation molecule CD86 and maturation marker CD83 (Figure 5), indicating that hsp70-peptide complexes induced maturation of DCs. This maturation effect of hsp70-peptide complexes on DCs suggests that they can activate DCs effectively.

DISCUSSION

Cancer, which is difficult to cure completely using conventional treatment such as surgery, radiation or chemotherapy, has become one of the most common causes

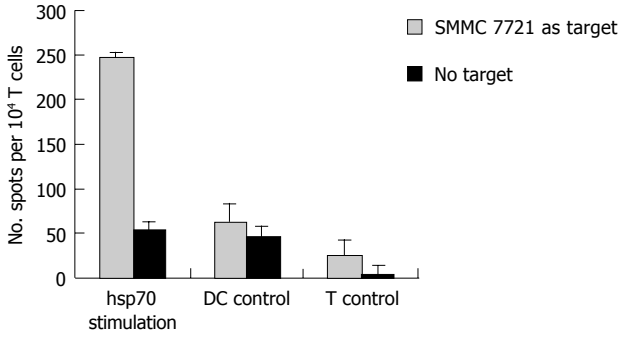

Figure 4 Secretion of IFN-γ by T cells induced with autologous DCs pulsed with hsp70-peptide complexes derived from SMMC-7721 cells. 1×10^5 DCs were incubated with 20 μg/mL hsp70-peptide complexes derived from SMMC-7721 for 4 h at 37 ℃ and then cocultured with 1×10^6 autologous T cells in each well of 24-well culture plate for 7–10 d in the presence of 20 U/mL human IL-2. The stimulated T cells were harvested by density gradient centrifugation and their IFN-γ production was determined by ELISPOT assay (indicated as hsp70 stimulation). As a control, T cells cocultured with unpulsed DCs (indicated as DC control) or by themselves (indicated as T control) were also used as effectors. The results are expressed as mean±SD and each value represents the mean of three replicates.

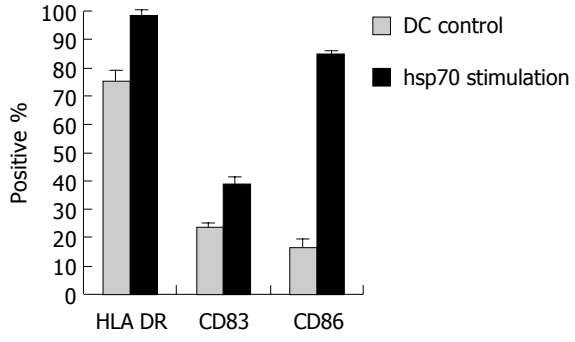

Figure 5 Maturation of human DCs by hsp70-peptide complexes derived from SMMC-7721 cells. DCs were incubated with 20 μg/mL hsp70-peptide complexes derived from SMMC-7721 cells for 4 h at 37 ℃, and cultured for 48 h. The DCs were then harvested and analyzed for expression of the indicated surface molecules using FACS analysis. The percentages shown were positive for the indicated surface markers. The results are expressed as mean±SD and each value represents the mean of three replicates.

of death in industrialized societies[3]. Immunotherapy, which utilizes the immune response in combating cancer, seems to be a potentially effective approach for treatment of cancer. Numerous vaccination approaches have been explored and developing more effective anti-tumor vaccines has become one of the major goals in tumor immunotherapy.

It is commonly accepted that tumor rejection is mediated by lymphocytes, and most notably by CTLs. Therefore, activating tumor-specific CTLs to kill tumor cells is considered to be one of the most important events in tumor immunotherapy[18]. T-cell activation requires two signals. Signal one is generated when TCR interacts with the MHC-peptide complex and signal two is provided by costimulatory molecules expressed by professional APCs. Most tumors do not express costimulatory molecules and thus fail to activate tumor-specific T lymphocytes[19]. The HCC cell line SMMC-7721 expresses MHC class I molecules, but does not express costimulatory molecules, such as CD80 or CD86 (data not shown). So to generate tumor-specific CTLs, it is essential to find a good tumor antigen source and then present them in the context of costimulatory molecules.

The features of HSPs suggest that they are very potent tumor antigen sources for pulsing DCs to stimulate anti-tumor response. Three features characterize HSPs as a tumor antigen source: first, they can induce multiple anti-tumor immune responses without prior identification of tumor antigens; second, they can chaperone tumor antigens associated with them and present them with high efficiency through specific receptors on DCs; third, they can induce phenotypical and functional maturation of DCs. In the present study, we used hsp70-peptide complexes derived from HCC cell line SMMC-7721 as the tumor antigen source to pulse DCs, which are known to be critical activators of T-cell responses. Various studies suggest that hsp70 has immunotherapeutic potential as hsp70 purified from malignant and virally infected cells can transfer and deliver antigenic peptides to APCs to elicit peptide-specific immunity[20]. We demonstrated that DCs pulsed with hsp70-peptide complexes derived from human HCC cell line SMMC-7721 stimulated significant autologous T-cell proliferation and that unpulsed DCs had little stimulatory effect (Figure 2). More importantly, we proved that DCs pulsed with hsp70-peptide complexes were able to induce tumor cell-specific CTLs with high efficiency and specificity (Figure 3) and the generated CTLs could secrete a high level of type I cytokine (Figure 4). Our results demonstrated that the cytotoxicity against SMMC-7721 cells was due to the presence of CTLs but not NK cells because NK cell-sensitive cell line K562 could not be killed (Figure 3B). In addition, we tested the phenotype of the cytotoxic cells using T-cell lineage marker CD3, NK cell lineage marker CD56 and NK-T-cell lineage marker CD56+CD3 by flow cytometry (data not shown). The result showed that most of the cytotoxic cells were T cells and there were very few NK cells or NK-T cells. Also we demonstrated that the generated CTLs exhibited specific cytotoxicity against SMMC-7721 cells (Figure 3C) and the cytotoxicity was MHC class I restricted (Figure 3D). Furthermore we excluded the possibility that the induced anti-tumor response was an allogeneic response (Figure 3E). The result indicated that the generated CTLs exhibited significant cytotoxicity against autologous DCs pulsed with hsp70-peptide complexes, but little lysis against unpulsed DCs, demonstrating that the CTLs were directed against tumor-specific antigens expressed on DCs rather than allo-antigens. This result also implied that DCs took up hsp70-peptide complexes, and then processed and presented tumor-specific antigens in the MHC class I pathway, making them available for CTL recognition. Our findings indicated that the SMMC-7721 specific antigens chaperoned by hsp70 had been functionally presented to T cells through the active interaction of hsp70 and DCs. The implication of the original studies was that immunization of HSPs was able to generate anti-tumor CTLs via cross-priming by transferring the antigenic peptides with which they were associated into the MHC class I antigen presenting pathway within APCs, a pathway usually restricted to antigens derived from the cytoplasm of the APCs[21]. The mechanism of receptor-mediated endocytosis contributes to the high efficiency of antigen transfer[10,22]. More recently, different receptors involved in the capacity of hsp70 to induce peptide-specific immunity have been identified[11,23]. Consistent with these observations, our results indicated that hsp70 was a potent adjuvant for presenting tumor-associated antigens and then inducing specific anti-tumor immune responses.

Activation of DCs is a key step in the stimulation of tumor-specific CTLs. As professional APCs, with a potent capacity to present antigens and activate naive T cells, DCs can both initiate and modulate immune responses[24]. In the present study, we showed that hsp70-peptide complexes derived from HCC cell line SMMC-7721 induced maturation of allogeneic DCs by enhancing the expression of HLA class II, costimulatory molecule CD86, and maturation maker CD83. The matured DCs were able to stimulate high levels of autologous T-cell proliferation and type I cytokine secretion, and to induce tumor-specific CTLs with high efficiency. The results indicate that hsp70-peptide complexes derived from HCC cell line SMMC-7721 have the capacity to induce human DCs maturation phenotypically and functionally. The phenotypical and functional maturation is critical for DCs to efficiently activate immune responses[25].

Consistent with previous reports[26], MHC matching between the SMMC-7721 cells used as source of hsp70-peptide complexes and the responding T cells was not required, suggesting that the peptides complexed by hsp70 were not restricted to the MHC haplotype of the donor cells and hsp70-peptide complexes were able to induce tumor-specific CTLs across MHC barriers by active interaction with DCs.

In conclusion, our present study demonstrated varied attributes of hsp70 which included chaperoning a broad array of antigenic peptides, delivering them into MHC class I antigen presentation pathway within DCs via cross-priming through receptor-mediated interaction, and activating DCs phenotypically and functionally. These properties of hsp70 suggest that hsp70-peptide complexes are appealing antigen sources for immunization against tumors and infectious diseases. In this study, we combined the characteristics of DCs and hsp70 for stimulating anti-tumor

immune responses and offered a new kind of anti-tumor immunotherapeutic strategy against human HCC. Our results suggest that DCs pulsed with hsp70-peptide complexes derived from human HCC cells can be used as potential vaccines in anti-tumor immunotherapy, as these pulsed DCs are capable of inducing multiple CTLs efficiently without the need for identifying tumor-specific antigens. In the present study, we used allogeneic rather than autologous HCC cells to isolate hsp70-peptide complexes for pulsing DCs derived from healthy donors. We hope to apply this approach to HCC patients in future clinical research.

Abstract

AIM: To investigate the effect of bromocriptine (BCT) and tumor necrosis factor-α (TNF-α) on hepatocellular carcinoma (HCC) multidrug resistance (MDR) in nude mouse MDR model of liver neoplasm.

METHODS: Human hepatocarcinoma cell line $HepG_2$, drug resistant hepatocarcinoma cell line $HepG_2$/adriamycin (ADM) and hepatocarcinoma cell line transfected with TNF-α gene $HepG_2$/ADM/TNF were injected into the liver of nude mice via orthotopic implantation and MDR model of liver neoplasm *in vivo* was established ($HepG_2$, ADM, TNF, BCT groups). Among these groups, BCT group and TNF group were treated with BCT through gastric canal. Each group was divided into control group and chemotherapy group. Size and weight of the tumor were measured. Furthermore, tumor histological character and growth of the nude mice were observed and their chemosensitivity was tested. MDR-associated genes and proteins (MRP, LRP) of implanted tumors were detected by immunohistochemistry, reverse transcriptase polymerase chain reaction, and apoptosis rate of hepatocarcinoma cells was detected by TUNEL assay.

RESULTS: The nude mouse model of each cell line was inoculated successfully. The tumor growth rate and weight were significantly different among groups. After chemotherapy, abdominal cavity tumor growth inhibition rate was higher in BCT group (67%) compared to ADM and TNF groups, and similar to $HepG_2$ group (54%). MDR1 and LRPmRNA could be detected in all groups, but TNF-α was detected only in TNF and BCT groups. Furthermore, MDR1 and LRP protein expression of tumors in TNF and BCT groups was low similar to $HepG_2$ group. The apoptosis rate of hepatocarcinoma cells was much higher in BCT group than in other groups with TUNEL assay.

CONCLUSION: BCT and TNF-α can reverse HCC MDR in nude mouse MDR1 model of liver neoplasm.

INTRODUCTION

The development of multidrug resistance (MDR) in human tumors may be a major obstacle to successful cancer chemotherapy[1]. MDR is often associated with increased expression of the MDR1 (also known as P-glycoprotein) gene, encoding P-glycoprotein (Pgp)[2]. Since the MDR1 gene appears to represent a major cause of MDR in tumor cells, MDR1 messenger RNA (mRNA) and Pgp may be important targets in MDR reversal strategies. But almost all MDR reverse studies are only performed *in vitro*[3-5], and few are performed *in vivo*. A study[6] indicates that overexpression of Pgp, a product of MDR1, is intimately associated with liver cancer development and therefore inhibitors of Pgp should inhibit the development of liver cancer. Accordingly, we determined the effect of bromocriptine (BCT), a potent inhibitor of Pgp[7,8], and tumor necrosis factor-a (TNF-α)[9-11] which could downregulate expression of the MDR-associated genes LRP and MRP in multidrug resistant model of nude mice via orthotopic implantation of multidrug resistant human hepatocellular carcinoma (HCC) cells $HepG_2$/adriamycin (ADM).

TNF is a cytokine playing an important role in immunoregulation and antitumor mechanisms, and has been extensively tested in *in vitro* and *in vivo* investigations as well as in clinical trials for immunotherapy of malignant diseases[12,13]. More recently, it has been demonstrated that TNF can modulate

MDR1 expression and enhance cytotoxicity of certain MDR-related drugs to various cell lines[10,14]. The ability of cytokines to influence MDR phenotype is strongly supported by a previous study[15].

BCT, as a D_2 dopaminergic receptor agonist, has been reported to inhibit activity of ATPase and function of Pgp[7]. Moreover, because of its slight side-effects and the MDR-reversing effect[8], we chose BCT and TNF-α to detect their synergistic antitumor effects.

MATERIALS AND METHODS

Reagents

1640 medium, fetal bovine serum (FBS), lipofectamine 2000, and G418 were purchased from Invitrogen Inc., USA. Upstream and downstream primers were produced by Shanghai Boya Biosynthesis Co., Shanghai, China. dNTPs, RNasin, AMV reverse transcriptase, Taq and DNA enzymes were purchased from Sigma Company, USA. TRIzol reagent was purchased from Gibco Company, USA. BCT mesilate was purchased from Novartis, Italy; 5-fluorouracil (5-FU), ADM, mitomycin (MMC) were from Pharmacia & Upjohn, Italy; and S-P immune test kit was from Beijing Zhongshan Company, Beijing, China. LRP mouse antibody, P170 mouse antibody and Pan actin antibody-5 were purchased from Neomarker Inc., Germany.

Cell lines and cell culture

Human HCC cell line, $HepG_2$ (GDC024), was purchased from the China Center for Type Culture Collection (Wuhan University, Hubei). $HepG_2$ was induced to form a multidrug resistant cell line ($HepG_2$/ADM) by exposure to gradually increased concentration of ADM. Firstly, eukaryotic expression vector pBK-TNF-α was constructed by recombinant DNA technique, and transfected into multidrug resistant cell line ($HepG_2$/ADM) to obtain cell line $HepG_2$/ADM/TNF and cultured in the presence of 800 mg/mL G418. All cells were maintained in 1640 medium containing 10% heat-inactivated FBS at 37 ℃ in a humid atmosphere of 50 mL/L CO_2.

Multidrug resistant model establishment and grouping

BALB/c, nu/nu, nude mice, male and female from Centers for Disease Control and Prevention of Hubei province, age ranging 4-5 wk, weighing 12.1-15.0 g, bred in specific pathogen-free condition, were used in this study. Firstly, a left subcostal incision was made under anesthesia with 20% urethane, then left lobe of the liver was exposed, and each kind of cells was injected into mice liver and an orthotopic MDR1 hepatoma was obtained successfully ($HepG_2$, ADM, TNF, BCT groups respectively). Each group contained 16 nude mice inoculated with each kind of cell lines, and was divided into control group and experiment group, 8 in each group. Chemotherapy was performed when tumor diameter was 1.5 cm. Among these groups, BCT group and TNF group were treated with BCT (6.25 mg/kg·d) through gastric canal. Association of 5-FU (0.15 g/kg·d)+MMC (1.5 mg/kg·d) +ADM (10 mg/kg·d) were administered through intraperitoneal injection in experiment groups, but 0.9% NS 15 μL/g was given to control groups for 3 d. Nude mice were weighed and the size of tumors was measured every week by B-ultrasound after orthotopic implantation, when the mice were killed 14 d after chemotherapy. Furthermore, some specimens were fixed in 40 g/L formaldehyde and embedded with paraffin for immunohistochemistry (IHC), and other markers were detected by molecular biological techniques.

Evaluation of growth and sensitivity of chemotherapy

The living condition, diet and reaction with stimuli from environment were observed everyday from the first day of chemotherapy. The size of tumors was measured every week by B-ultrasound after chemotherapy using the formula $V = a \times b^2/2$ (V: volume; a: long diameter; b: short diameter). Meanwhile xenograft tumors were observed and weighed until the mice were killed. Lastly, the inhibition rate of volume and weight was calculated by the formula (inhibition rate of volume or weight = [1-volume or weight of chemotherapy group/volume or weight of control group]×100%).

HE staining and immunohistochemistry (IHC) for detection of MDR1 expression

Firstly, each kind of orthotopic tumor tissues was stained with HE, and fixed in formalin and embedded in paraffin. The expression of Pgp protein was studied using mouse anti-human MDR1 C219 and sections of 5 μm from the tumor tissues were implanted in each kind of cell lines and MDR1 expression was assayed by immunoperoxidase staining with the SP method (SP kit, Zhongshan Biocompany). IHC process was strictly done as the indication of SP kit. In summary, endogenous peroxidase was blocked with H_2O_2 and non-specific antigens were blocked with normal serum. The primary antibodies were diluted to 1∶100 for Pgp, then incubated at 4 ℃ overnight, washed thrice with PBS. The secondary antibody (1∶500) was incubated for 15 min at 37 ℃, sections were stained with diaminobenzidine tetrahydrochloride (DAB) and restained with hematoxylin for visualization of nuclei. For negative controls, primary antibodies were substituted by PBS instead of Pgp antibodies. The Pgp protein expression intensity was observed through ocular lens and the positive cells per square millimeter were calculated and expressed as mean±SD.

Expressions of TNFmRNA, MDR1 mRNA and LRP mRNA

Total RNA was respectively extracted from tumors in nude mice with TRIzol according to the manufacturer's instructions. Reverse transcription (RT) was performed with random primers by a complementary DNA (cDNA) synthesis kit (Promega). RT-reaction reagents (25 μL) were added as follows: 0.1 μg OligdT (100 g/L), 25 U rRNasin, 1.25 μL dNTP (10 mmol/L), 5 μL M-MLV 5×buffer, 200 U M-MLVRT. After all the components were mixed, the mixture was incubated at 42 ℃ for 1 h in a DNA thermal cycler (PTC-100, MJ Research Inc., Watertown, MA, USA), and the reverse transcriptase was inactivated by heating the reaction mixture to 95 ℃ for 5 min. Then each tube was kept at -20 ℃ until PCR was performed. The primers of the target genes MDR1, LRP, and the endogenous reference β-actin were designed using the Primer Express Software (Applied Biosystems) (Table 1). The final volume of the reaction (25 μL) of PCR included: 25 μL transcription solution containing 15 pmol upstream and downstream respectively, 2.5 μL 10×buffer, 2 μL cDNA, 0.5 μL dNTP (10 mmol/L),

Table 1 MDR1, LRP primers

Gene	Quantification method	Sequence (5′-3′)	Size (bp)
MDR1	Forward primer	CATTGGTGTGGTGAGTCAGG	176
	Reverse primer	CTCTCTCTCCAACCAGGGTG	
LRP	Forward primer	TAAGGGCTTCCAGCACCAAC	237
	Reverse primer	GGAGTTCTCGCTTCTCGTCC	
TNF-α	Forward primer	GC*GGATT*CATGAGCACTGAAAGCATGATCC	725
	Reverse primer	CCC*AAGCTT*TCACAGGGCAATGATCCCAAAG	
β-actin	Forward primer	GTGCGTGACATTAAGGAG	530
	Reverse primer	CTAAGTCATAGTCCGCCT	

2 μL $MgCl_2$ (25 mmol/L), 1 μL Taq polymerase (10×10^6 U/L), ddH_2O to a final volume of 25 μL. Thirty-five PCR cycles were performed, for each cycle, the sample was denatured at 94 ℃ for 1 min, annealed at 55 ℃ for 1 min, extended at 72 ℃ for 1 min, and finally extended at 72 ℃ for 10 min.

TUNEL assay for apoptosis detection

The paraffin-embedded specimens were cut into 5-μm-thick sections, rehydrated and then incubated with protease K solution for 30 min at room temperature. After being washed twice with PBS, the sections were incubated with TUNEL reaction solution at 37 ℃ for 60 min. The transforming solution (POD) was added and incubated at 37 ℃ for 30 min. The sections were stained with DAB for 10 min. Then counterstained with hematoxylin for 10 min, dehydrated in graded alcohol and covered with resin. The criterion of positive staining was that the nuclei were stained pale brown.

Statistical analysis

Data were presented as mean±SD, significance of statistical difference was assessed by Student's *t*-test and analyzed with SPSS11.0. $P<0.05$ was considered statistically significant.

RESULTS

TNF-α mRNA expression in orthotopic tumor tissues

TNF-α mRNA could be amplificated only from the tumors of TNF and BCT groups in the orthotopic tumor tissues injected into three kinds of cell lines, and no positive band could be seen from the other two groups. Electrophoresis showed that there was a positive band at 725 bp in the tissues injected into multidrug resistant cells transfected with TNF-α gene (Figure 1) and no band was found, indicating TNF-α mRNA was integrated into the nude mice implanted with multidrug resistant cells transfected with TNF-α gene. Thus, the model of implanted orthotopic tumor was successfully established.

Evaluation of growth and sensitivity of chemotherapy

No death occurred. The successful rate of tumor implantation was 100%, and tumor could be seen via B ultrasound after 10 d. The rate of tumor growth in the group transfected with TNF-α was lower compared to other groups ($P<0.05$). Low appetite and emotion occurred in the mice receiving chemotherapy, especially in BCT group. The tumor volume and weight of BCT group decreased compared to the other group ($P<0.01$), and tumor growth inhibition rate in $HepG_2$ group was similar to TNF group ($P>0.05$), but lower than that in BCT group ($P<0.05$, Table 2, Figures 2 and 3).

[a]$P>0.05$ *vs* $HepG_2$ group, $\chi^2=4.32$; [b]$P<0.01$ *vs* ADM group, $t=2.38$; [c]$P<0.05$ *vs* $HepG_2$ group, $\chi^2=2.49$.

Histologic characteristics and Pgp protein expression in orthotopic tumor tissues

Histological characteristics of the tumor model in different groups were similar (Figure 4). Pgp protein expression was low. Pgp protein expression was lower in $HepG_2$ group, but high in ADM group, and lower in groups TNF and BCT than in ADM group. There was a significant difference between the groups ($P<0.01$), but no difference among $HepG_2$, BCT and TNF groups ($P>0.05$, Figure 5)

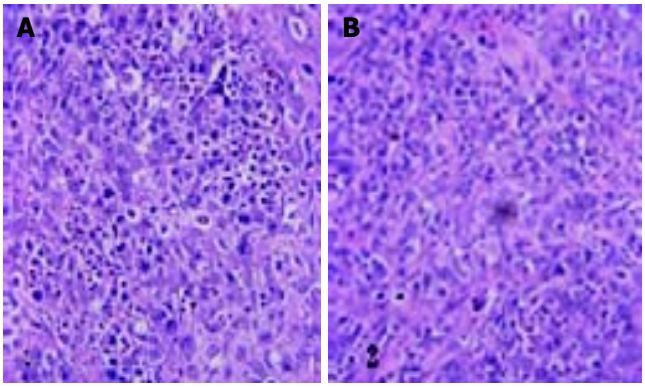

Figure 4 Histological characteristics of tumor in $HepG_2$ group (**A**) and BCT group (**B**).

Downregulation of MDR1mRNA expression in orthotopic tumor tissues transfected with TNF-α

Electrophoresis in each group showed 176, 237, and 530 bp bands, which were coincident with the amplification fragments of designed MDR1mRNA, LRPmRNA and β-actin genes. The relative quantity of MDR1mRNA in groups of BCT, TNF, $HepG_2$ was 0.21±0.02, 0.15±0.03, 0.13±0.02 respectively. The relative quantity of LRPmRNA in groups BCT, TNF, $HepG_2$ was 0.17±0.04, 0.15±0.01, 0.11±0.01. There was no difference among these groups ($P>0.05$), but the relative quantity of MDR1mRNA, LRPmRNA was significantly lower in groups of BCT, TNF, and $HepG_2$ than in ADM group ($P<0.05$, Figure 6, Table 3).

Apoptosis of tumor cells

After intra-abdominal chemotherapy with ADM, 5-FU, and mitomycin, the apoptotic rate of tumor cells expressing TNF-α was significantly higher compared to those not expressing TNF-α. The average of apoptotic cells in TNF-α and BCT group was (21.9±2.1) and (30.5±4.2) per field of high-power microscope respectively. There was a difference between the groups ($P<0.05$). TNF-α could reduce the tolerance of hepatoma cells to chemotherapy and increase apoptosis of tumor cells. BCT and TNF-α could induce apoptosis of HCC (Figure 7, Table 4).

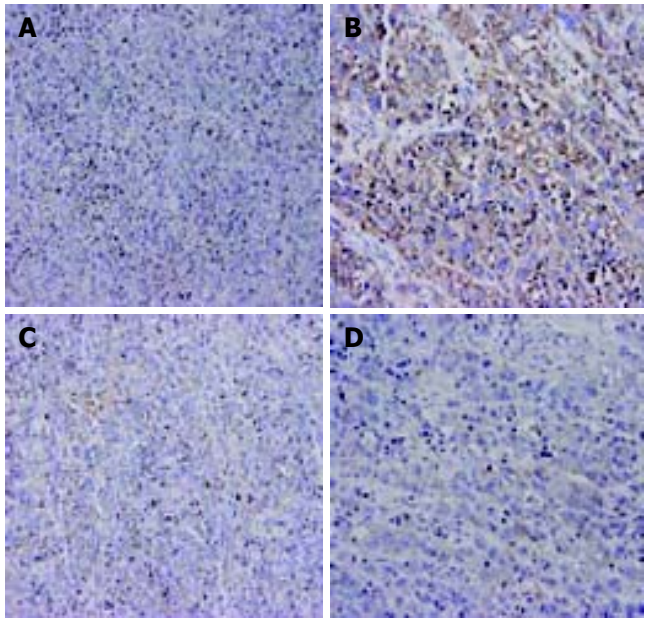

Figure 5 Pgp protein expression in groups of $HepG_2$ (**A**), ADM (**B**), BCT (**C**), and TNF (**D**).

DISCUSSION

Since MDR is the leading cause of failure of comprehensive therapy for HCC, investigations aimed at circumvention of intrinsic tumor-mediated drug resistance are warranted. But the efficacy of some drugs used to reverse MDR is limited due to their side-effects[16-18]. BCT has been used to treat hyperprolactinemia for more than two decades because of its slight side-effects[19,20]. It was reported that BCT can

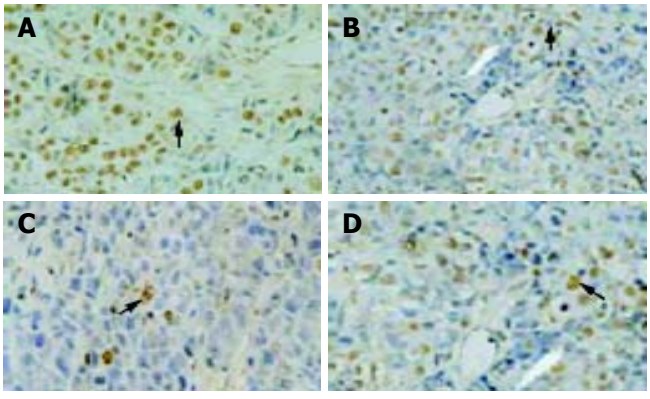

Figure 7 HHC cell apoptosis in groups of BCT (**A**), TNF (**B**), ADM (**C**), and $HepG_2$ (**D**).

be used as a chemosensitizer against MDR tumor cells[7,8] and a current study showed that TNF-α may play a role in MDR[21].

In this study, we first demonstrated that TNF-α was expressed in the orthotopic tumor tissues injected into $HepG_2$/ADM cells transfected with TNF-α. Moreover, tumor inhibition rate after treatment with 5-FU, ADM, MMC through intraperitoneal injection was higher in BCT group (67%, P<0.05) than in TNF group (57%) and ADM group (18%), and similar to $HepG_2$ group (54%). As the data shows, the drug-resistant hepatocarcinoma cell line $HepG_2$/ADM transfected with TNF-α could excrete cytokine TNF-α which could induce cancer cell apoptosis and inhibit the growth of tumor[22,23]. The result is in coincidence with Stein *et al*.[24]. Furthermore, TNF-α gene in combination with BCT could reverse HCC MDR. Moreover, IHC and reverse transcriptase polymerase chain reaction (RT-PCR) showed that transduction and expression of human TNF-α in drug-resistant HCC cell line $HepG_2$/ADM could reverse expression of MDR1mRNA, LRPmRNA, and Pgp, but had no synergistic effect compared to BCT, suggesting that TNF-α can downregulate the expression of MDR-associated genes and proteins[25], and BCT may act on for its potential interaction and transport by Pgp[26-31], but has no effect on MDR-associated genes. Additionally, an interesting discovery indicate that the rate of apoptosis after chemotherapy in BCT group is the highest in all experiment groups, and BCT and TNF-α can reverse HCC MDR in nude mice MDR1 model of liver neoplasm.

Abstract

AIM: To study the changes of human telomerase reverse transcriptase (hTERT) mRNA expression in human hepatocarcinoma cell lines (HepG2) and cholangiocarcinoma cell lines (QBC939) after HBx gene transfection and to illustrate the significance of transcriptional regulation of hTERT gene by HBx gene in the carcinogenesis.

METHODS: HepG2 and QBC939 cell lines were cultured and co-transfected with eukaryotic expression vector containing the HBx coding region and cloning vector containing enhanced green fluorescent protein (EGFP) coding sequence using lipid-mediated gene transduction technique. Thirty-six hours after transfection, EGFP expression in cells was used as the indicator of successful transfection. Flow cytometry was performed to determine the transfection efficiency. Cells were harvested and total RNA was extracted using TRIzol® reagent. The expression of hTERT mRNA in HepG2 and QBC939 cell lines was assayed by reverse transcription-polymerase chain reaction. The expression of HBx protein in both cell lines was detected by immunocytochemical staining and Western blotting.

RESULTS: Flow cytometry showed that the transfection efficiency was 46.4% in HepG2 cells and 29.6% in QBC939 cells for both HBx gene expression vector and blank vector. The expression of hTERT mRNA was meaningfully increased in HepG2 and QBC939 cell lines when transfected with HBx gene expression vector compared to those transfected with OPTI-MEM medium and blank vector. Immunocytochemical staining and Western blotting revealed HBx protein expression in HepG2 and QBC939 cells only when transfected with HBx gene.

CONCLUSION: HBx gene transfection can upregulate the transcriptional expression of hTERT mRNA. The transactivation of hTERT gene by HBx gene is a newfound mechanism for pathogenesis of hepatocarcinomas and cholangiocarcinomas after HBV infection.

INTRODUCTION

As an oncogenic DNA virus, HBV has been ascertained as the major causative factor for hepatocarcinogenesis[1]. Our recent study has also shown that HBV infection may be associated with biliary tract carcinogenesis[2]. The X gene of HBV (HBx gene) encodes a viral protein (HBx protein), which performs an essential function in the development of human hepatocarcinoma[3] and cholangiocarcinoma[4]. The finding that HBx gene can upregulate telomerase activation, when transferred into hepatocarcinoma cells reveals a new mechanism for HBx gene in carcinogenesis[5]. Human telomerase reverse transcriptase (hTERT) is the rate-limiting determinant for telomerase activity and its expression parallels frequently to telomerase activity[6,7]. Our previous findings that HBx gene can upregulate hTERT mRNA expression, when transferred into normal human cholangiocytes and cholangiocarcinoma cells[8], ascertain the regulation of hTERT gene by HBx gene. To learn more about the mechanism in carcinogenesis, we transferred the eukaryotic expression vector encompassing the entire HBx coding region into both hepatocarcinoma cell line (HepG2) and cholangiocarcinoma cell line (QBC939). By assaying the expression of hTERT mRNA, we attempted to elucidate the significance of transcriptional regulation of hTERT gene by HBx gene in the carcinogenesis.

MATERIALS AND METHODS

Cell and culture

HepG2 cell line was purchased from Foundation Institute, Chinese Academy of Medical Sciences. QBC939 cell lines

were obtained from Dr. Shuguang Wang (Southwest Hospital, the Third Military Medical University, Chongqing). Cells were maintained in Dulbecco's modified Eagle's medium containing 100 mL/L fetal bovine serum (FBS), 100 U/mL penicillin and 100 μg/mL streptomycin, and propagated at 37 ℃ in a humidified atmosphere of 50 mL/L CO_2 in air. Cells in monolayer culture passaged approximately thrice a week by incubation with 2.5 g/L trypsin/1 mmol/L versene at 37 ℃ for approximately 5 min until the cells were shrunken. Trypsin activity was quenched by the addition of fresh medium containing FBS and cells were seeded at 1/4 split ratio.

Plasmids and transfection

The empty vector pcDNA3 is eukaryotic expression vector used as a negative control. pCMV-X is constructed by inserting the entire HBx coding region (HBV nucleotides 1 372-1 833, 465 bp) into the *Eco*RI/*Eco*RV sites of the pcDNA3 vector. Cloning vector pEGFP carries an enhanced green fluorescent protein (EGFP) gene, which was cloned between the two MCS of the pPD16.43. EGFP encoded by pEGFP can emit bright green fluorescence in eukaryotic cells. All the plasmids contain ampicillin resistance genes for propagation and selection in *E. coli*.

Transient transfection of plasmids into both HepG2 and QBC939 was performed using LipofectAMINE PLUS™ reagent (Gibco BRL®) according to the manufacturer's instructions. The day before transfection, cells were trypsinized and seeded in six-well plates. At the day of transfection, cells reached over 80% confluence, and then 2.9 μg pcDNA3 or pCMV-X DNA and 0.1 μg pEGFP DNA were diluted into OPTI-MEM medium (Invitrogen) and mixed with Lipofect-AMINE PLUS™ reagent. After the cells were washed once by OPTI-MEM medium, a total of 1 mL transfection medium was added to the cells. The cells were incubated at 37 ℃ for 3 h in a humidified atmosphere containing 50 mL/L CO_2. After 3 h of incubation, the transfection medium was replaced with fresh complete medium containing serum and the cells were further incubated for 36 h. Then the cells were harvested, and the expression of hTERT mRNA was assayed. The cells transfected with OPTI-MEM medium were used as blank control (group A) and that transfected with pcDNA3 vector were used as negative control (group C), while that transfected with pCMV-X were defined as experimental group (group B). Co-transfection of pEGFP was used to evaluate the successful transfection.

Detection of transfection efficiency by flow cytometry

Cells were trypsinized, washed with PBS for twice, followed by dilution at 1×10^6 cells/mL. Transfection efficiency was detected using flow cytometry by following the manufacturer's instructions.

Extraction of total cellular RNA and RT-PCR analysis for hTERT mRNA

Total cellular RNAs were extracted from cells of different groups by TRIzol® reagent (Gibco BRL®) according to the manufacturer's instructions. Two micrograms of extracted RNA was reverse transcribed into cDNA first-strand using 200 U of Moloney Murine Leukemia Virus Reverse Transcriptase (Promega, Madison, USA) and 1 μg of oligo $(dT)_{15}$ primer (Promega) in a final volume of 25 μL of enzyme buffer (Promega) for 60 min at 42 ℃. hTERT cDNA analysis was performed by PCR amplification of a fragment of 145 bp using primer pairs: 5'-CGGAAGAGTGTCTGG-AGCAA-3' (sense) and 5'-GGATGAAGCGGAGTCTGGA-3' (antisense). A 320-bp fragment of GAPDH gene was amplified as an internal control. The primers for GAPDH are 5'-GGAAGCTTGTCATCAATGG-3' (sense) and 5'-CTGTGGTCATGAGTCCTTC-3' (antisense). PCR was performed with 5 μL of cDNA first-strand in a 50 μL reaction volume containing 2 mmol/L $MgCl_2$, 1 mmol/L dNTPs, 0.4 μmol/L of each primer, and 2.5 U of Taq DNA polymerase (Promega). The reaction mixture was heated at 94 ℃ for 5 min, followed by amplification through 33 cycles. Each cycle included denaturation at 94 ℃ for 40 s, annealing at 60 ℃ for 40 s and extension at 72 ℃ for 90 s. Then 10 μL of the PCR product was electrophoresed on a 15 g/L agarose gel containing ethidium bromide (0.5 μg/mL), and visualized under ultraviolet light. The quantitative difference of bands between groups was analyzed by NIH Image software. The reverse transcription-polymerase chain reaction (RT-PCR) was repeated in triplicate and quantitative data were expressed as mean±SD.

Detection of HBx protein by Western blotting

Total cellular protein was extracted by cell lysis (20 mmol/L Tris-HCl [pH 7.5], 1 mmol/L EDTA, 1 mmol/L EGTA, 150 mmol/L NaCl, 2.5 mmol/L sodium pyrophosphate, 1 mmol/L β-glycerolphosphate, 1 μg/mL leupeptin, 1 mol/L PMSF) and quantitated by BCA™ protein assay kit (Pierce Biotech). An equal amount of protein sample was separated on SDS-polyacrylamide gel electrophoresis and transferred onto nitrocellulose membrane. The membrane was incubated in a blocking buffer (1 g/L Tween-20, 50 g/L non-fat dry milk in TBS) for 3 h. Rabbit anti-human HBx polyclonal antibody was diluted by primary antibody dilution buffer (1 g/L Tween-20, 50 g/L BSA in TBS) at 1∶800. The membrane was then incubated with HBx antibody overnight at 4 ℃. The expression of HBx protein was detected using Phototope®-HRP Western Blot Detection Kit (Cell Signaling Technology).

Detection of HBx protein in transferred cells by immunocytochemistry

The cells in different groups were cultured on cover slips and fixed with fixative (acetone and methanol). Detection of HBx protein expression in the transfected cells was performed by UltraSensitive™ Immunochemistry kit according to the manufacturer's instructions. A rabbit anti-human HBx polyclonal antibody was used at dilution of 1∶800.

Statistical analysis

Comparison between means was tested by Student's *t*-test and *P* value lesser than 0.05 was considered statistically significant.

RESULTS

Transfection efficiency

Under fluorescence microscope, EGFP expression could only be observed in the cells of groups B and C (Figure 1). There

was no such green fluorescence could be seen in group A. Transfection efficiency was 46.4% for HepG2 and 29.6% for QBC939 when detected by flow cytometry (Figure 2).

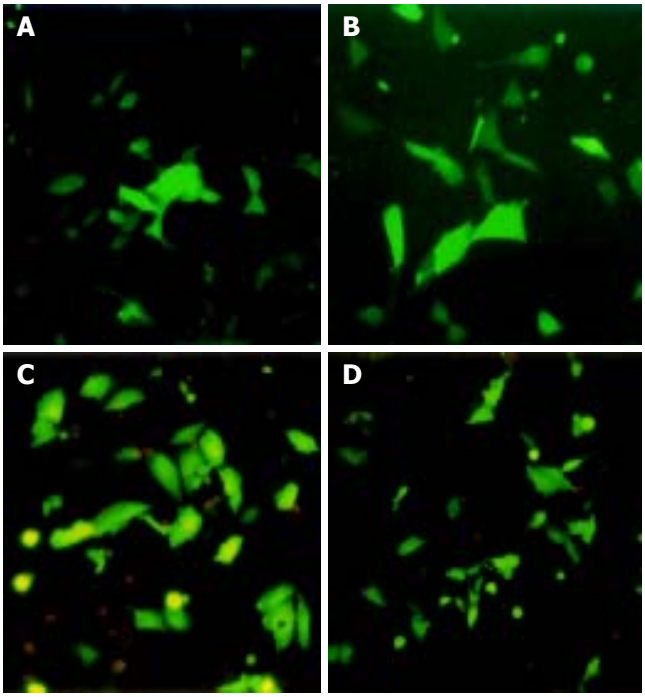

Figure 1 EGFP expressions in HepG2 (**A** and **B**) and QBC939 (**C** and **D**) cell lines under fluorescence microscope. After 36 h of transfection, EGFP-expressing cells were visible in group B (**A** and **C**) and group C (**B** and **D**), but not in group A.

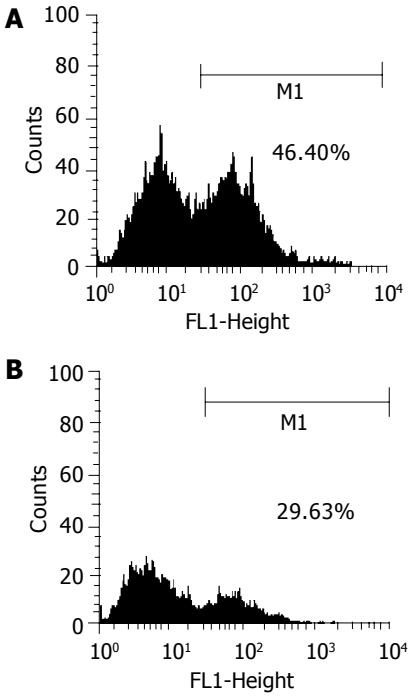

Figure 2 Transfection efficiency evaluated by flow cytometry. The transfection efficiencies were about 46.4% for HepG2 (**A**) and 29.6% for QBC939 (**B**).

hTERT mRNA expression

To examine the effects of HBx gene on hTERT transcription, pCMV-X expression vector was co-transfected with pEGFP into HepG2 and QBC939 cell lines. Thirty-six hours after transfection, the total cellular RNA was extracted and hTERT transcript was assayed using RT-PCR. The result showed that hTERT transcript was expressed in all groups (Figure 3). Expression of the human GAPDH gene was monitored for quantitation of the amount of RNA in all of the samples as an internal control. Relative expression of hTERT mRNA was determined by measuring band intensities of both hTERT transcript and GAPDH transcript and calculating the ratio of hTERT to GAPDH. After being analyzed by NIH Image software, hTERT mRNA expression was more distinct in group B than that in other two groups (Figure 4).

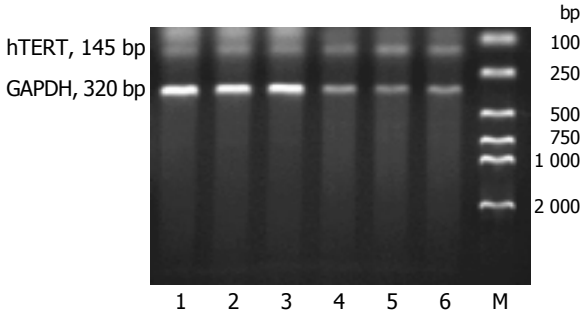

Figure 3 Analysis of hTERT mRNA expression by RT-PCR. RT-PCR was performed on total RNA extracted from both HepG2 (lanes 1-3) and QBC939 (lanes 4-6) cell lines transfected with OPTI-MEM medium (lanes 1 and 4), pCMV-X (lanes 2 and 5) and pcDNA3 (lanes 3 and 6) respectively. M: DL 2000 marker.

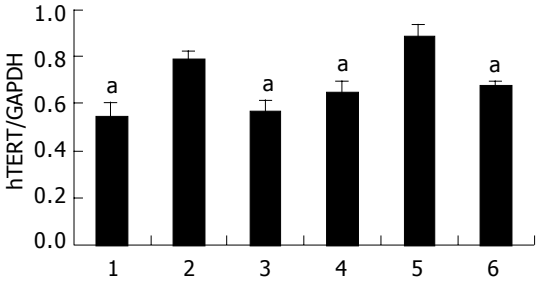

Figure 4 Relative quantitative changes of hTERT mRNA in HepG2 (lanes 1-3) and QBC939 (lanes 4-6) cell lines. A significant higher expression of hTERT mRNA was observed in both HepG2 and QBC939 cells after being transfected with pCMV-X vector (lanes 2 and 5) compared to those transfected with OPTI-MEM medium (lanes 1 and 4) and pcDNA3 (lanes 3 and 6). $^{a}P<0.05$ *vs* others.

Western blotting analysis

The result of Western blot analysis showed that the expression of HBx protein could only be detected in HepG2 and QBC939 cells when transfected with HBx gene, but undetected in those when transfected with OPTI-MEM medium and blank vector (Figure 5).

Immunocytochemical staining

A sensitive immunocytochemical staining was performed to identify whether there was HBx protein expression in transfected HepG2 and QBC939 cell lines. The results showed positive signals observed in cytoplasm of HepG2

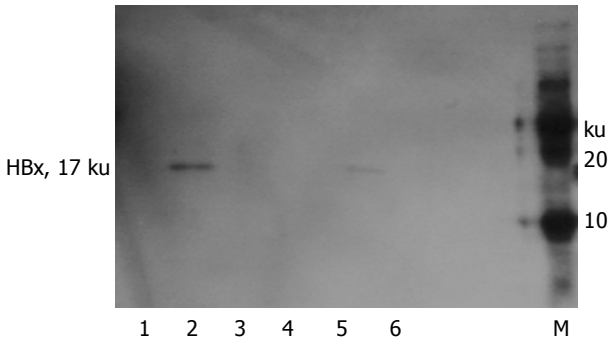

Figure 5 Western blot analysis of HBx protein expression in transfected HepG2 (lanes 1-3) and QBC939 (lanes 4-6) cell lines. A marked expression of HBx protein was observed in HepG2 and QBC939 cells when transfected with pCMV-X vector (lanes 2 and 5), but there were no such protein expression in those when transfected with OPTI-MEM medium (lanes 1 and 4) and blank vector (lanes 3 and 6). M: Protein marker.

(Figure 6) and QBC939 cells (Figure 7) in group B, while no such positive signals could be observed in HepG2 and QBC939 cells in groups A and C.

DISCUSSION

Telomerase/hTERT mechanisms have long been investigated for their potential role in cancer. Activation of telomerase is considered as the major episode for carcinogenesis[9] and over 85% of tumorigenic tissues and malignant cells express telomerase activity. hTERT is the rate-limiting determinant for regulating telomerase activity and also highly expressed in neoplastic tissues and tumor cells[10]. Most studies have shown that hTERT expression is usually correlated with telomerase activity and upregulation of hTERT expression is considered as the major step in carcinogenesis[11]. Multiple transcriptional factor binding sites are well identified in hTERT core promoter region and these regulatory factors make up a complex system of hTERT regulation[12]. The findings that HBV genome integration into upstream of hTERT core promoter region[13] and the *cis*-activation of hTERT gene transcription by HBV enhancer first elucidate a new mechanism for HBV in oncogenesis are the possible transcriptional regulation of hTERT gene[14].

HBV has been illustrated as the major causative factor for hepatocarcinogenesis[15]. Recent researches have also revealed that HBV infection might be associated with the development of cholangiocarcinoma. HBx protein, which is encoded by HBx gene, is considered as an essential oncogenic factor in oncogenesis of both human hepatocarcinomas and cholangiocarcinomas. HBx protein is a multifunctional viral oncoprotein and functions mainly as a transcriptional co-

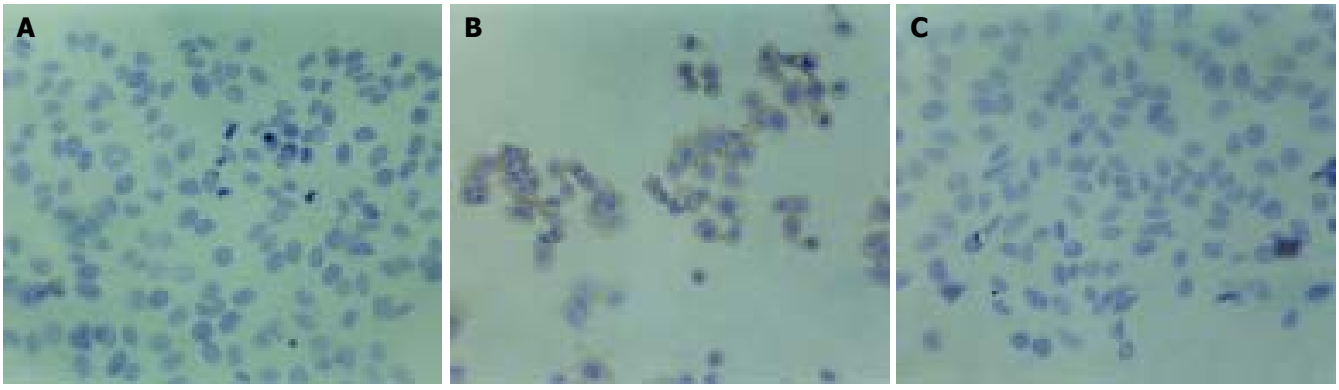

Figure 6 HBx protein expression in transfected HepG2 cells as assayed by UltraSensitive™ immunocytochemistry (SP×200). The cells transfected with OPTI-MEM medium (**A**) and blank vector (**C**) showed no expression of HBx protein, while some cells transfected with pCMV-X vector (**B**) showed visible brown positive signals.

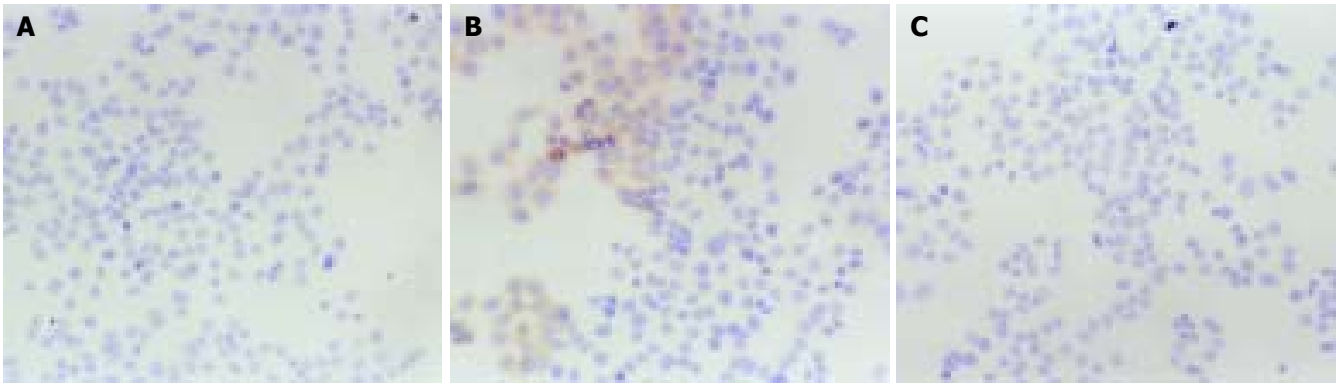

Figure 7 HBx protein expression in transfected QBC939 cells as detected by UltraSensitive™ immunocytochemistry (SP×200). The cells transfected with OPTI-MEM medium (**A**) and blank vector (**C**) showed no expression of HBx protein, but some cells transfected with pCMV-X vector (**B**) showed brown positive signals.

activator involving in multiple gene regulation and signaling pathways[16]. The integration of HBV genome into the hTERT promoter region[17] and upregulation of telomerase expression by HBx gene transfection[5] imply the possibility that HBx gene and protein may regulate hTERT gene transcription. In order to validate this surmise, we cultured HepG2 and QBC939 cells *in vitro* and transferred transiently the HBx gene into both the cell lines through lipid-mediated gene transduction technique. By observing the changes of hTERT mRNA expression, we attempted to elucidate the transcriptional regulation of hTERT gene by HBx gene. We observed that both HepG2 and QBC939 cell lines, when transfected with OPTI-MEM medium, could express hTERT mRNA quantitatively. Though there was no increase for hTERT mRNA expression in both cells when transfected with blank vector, a dramatic higher expression of hTERT mRNA was observed in both HepG2 and QBC939 cells when transfected with HBx gene. The results showed that HBx gene transfection could upregulate transcriptional expression of hTERT gene in both hepatocarcinomas and cholangiocarcinoma cells.

It is well known that some viruses contribute to carcinogenesis in two ways. One way is to transcriptionally activate proto-oncogenes of host cells by the integration of viral genome into the cellular genome and activation of the regulatory sequences (i.e., promoter or enhancer) of the viral genome[18]. This viral *cis*-activation mechanism can target the hTERT gene transcription[19]. Previous studies have found that HBV genome integrated in the hTERT promoter region and HBV enhancer could *cis*-activate the transcription of hTERT gene. Taken together with our present results, it is revealed that activation of telomerase by integration of HBV genome into telomerase gene is a new mechanism for oncogenic virus, HBV, in carcinogenesis. Another way is that some virus-encoded proteins contribute to cell transformation and carcinogenesis by modulating cellular signaling pathways that regulate cell-cycle progression, cell proliferation and differentiation, and cell apoptosis[20]. Recent evidence suggests that the activation of telomerase through transcriptional activation of the hTERT gene is another way in which human tumor-associated viruses can work[21]. Human papilloma viruses, especially its oncoproteins E6 and E7[22], which can abrogate the tumor suppressive function of p53 and Rb signaling pathways[23] and upregulate the hTERT promoter activity[24,25], play an important role in the development of cancers. The E-box elements within the hTERT promoter seem to be the target motifs responsible for the E6 activation of the hTERT transcription[26]. It is most likely that the aforementioned two ways are responsible for the upregulation of hTERT gene expression after HBx gene transfection into HepG2 and QBC939 cells. Although no direct evidence shows the existence of the integrated sites for HBx gene and the binding sites for HBx protein in hTERT promoter region, further investigations will identify these functional sites and validate the regulatory mechanisms eventually. HBx protein is a potential oncogenic factor and functions mainly as a transcriptional co-activator[16] involved in multiple gene regulation[27] and signaling pathway[28]. We suppose that upregulation of hTERT mRNA expression by HBx gene transfection is the result of the regulatory functions of binding motifs within the hTERT promoter for HBx protein or HBx-containing transcriptional complexes. But the exact mechanisms of these regulatory functions need to be elucidated through the study of transcription regulation for hTERT gene. Using immunocytochemical staining and Western blotting, we observed HBx protein expression only in HepG2 and QBC939 cells transfected with HBx gene. The expression of HBx protein in transfected cells indicates the achievement of transcription and duplication for HBx gene in some of these cells and meanwhile, demonstrates a key factor in regulating hTERT gene expression.

In conclusion, activation of telomerase and transcriptional regulation of hTERT gene involve in the development of carcinomas and act as the major targets for some tumor-associated viruses[19]. The transactivation of hTERT mRNA expression by HBx gene is a newfound mechanism for HBV in oncogenesis of hepatocarcinomas and cholangiocarcinomas. The elucidation of this mechanism may contribute to the deep understanding of the pathogenesis of HBV infection and subsequent formation of cancers.

ACKNOWLEDGMENTS

We thank Dr. Shu-Guang Wang for kindly providing us cholangiocarcinoma cell lines (QBC939) and Professor Xiao-Dong Zhang for providing us plasmids and technical assistance.

AIM: To investigate the effect of all-trans-retinoic acid (ATRA) on arsenic trioxide (As_2O_3)-induced apoptosis of human hepatoma, breast cancer, and lung cancer cells in an attempt to find a better combination therapy for solid tumors.

METHODS: Human hepatoma cell lines HepG2, Hep3B, human breast cancer cell line MCF-7, and human lung adenocarcinoma cell line AGZY-83-a were treated with As_2O_3 together with ATRA. Cell survival fraction was determined by MTT assay, cell viability and apoptosis were measured by annexin V-fluorescein isothiocyanate (FITC) and PI staining, and intracellular glutathione (GSH) and glutathione-S-transferase (GST) activities were determined using commercial kits.

RESULTS: Cytotoxicity of ATRA was low. ATRA (0.1, 1, and 10 μmol/L) could synergistically potentiate As_2O_3 to exert a dose-dependent inhibition of growth and to induce apoptosis in each of the cell lines. HepG2 and Hep3B with low intracellular GSH or GST activities were remarkably sensitive to As_2O_3 or As_2O_3+ATRA, while AGZY-83-a with higher GSH or GST activities was less sensitive to As_2O_3 or As_2O_3+ATRA. Treatment with 2 μmol/L As_2O_3 for 72 h significantly decreased intracellular GSH and GST levels in each of the cell lines, and 1 μmol/L ATRA alone reduced minimal intracellular GSH and GST levels. ATRA potentiated the effect of As_2O_3 on intracellular GSH levels, but intracellular GST levels were not significantly affected by the combination of As_2O_3 and ATRA for 72 h as compared to As_2O_3 alone.

CONCLUSION: ATRA can strongly potentiate As_2O_3-induced growth-inhibition and apoptosis in each of the cell lines, and two drugs can produce a significant synergic effect. The sensitivity to As_2O_3 or As_2O_3+ATRA is inversely proportional to intracellular GSH or GST levels in each of the cell lines. The GSH redox system may be the possible mechanism by which ATRA synergistically potentiates As_2O_3 to exert a dose-dependent inhibition of growth and to induce apoptosis.

Liver, breast, and lung cancers are the most common malignant diseases in the human race. Surgical resection or radiation therapy is potentially curative for localized diseases. Advanced liver, breast, and lung cancers are associated with a poor prognosis, and conventional chemotherapies and radiation therapy are still of limited effectiveness. Innovative approaches for advanced disease are necessary.

During the last decade, investigators using As_2O_3 alone or the combination of all-trans-retinoic acid (ATRA) and As_2O_3 for patients with acute promyelocytic leukemia (APL), have achieved great success[1-3]. Because of the many pathways involved in mediating the effects of arsenic, the potential exists for synergism with other agents to provide enhanced therapeutic benefits. Retinoic acid and arsenic synergize to eradicate leukemic cells in a mouse model of APL[4,5].

Other studies have also shown that As_2O_3 or ATRA alone has antiproliferative and apoptotic activities in some solid tumors, including human hepatoma and breast cancer[6-8]. Because of the drug resistance of solid tumors to As_2O_3, it has not been widely used in the treatment of solid tumors. Therefore, this study was to investigate the effect of ATRA on As_2O_3-induced cell apoptosis in human

hepatoma, breast cancer, and lung cancer in an attempt to find a better combination therapy for solid tumors. To our knowledge, this is the first report on the effects of the combination of As_2O_3 and ATRA for solid tumors.

The glutathione (GSH) redox system is known to modulate the growth-inhibitory and apoptotic effect of As_2O_3. Different kinds of malignant cells have different GSH levels. It was reported that the GSH redox system is relative to sensitivity of malignant cells to As_2O_3[9]. Elevated GSH levels are associated with the chemoresistance of malignant cells. Optimal therapies for chemoresistant malignant cells should overcome or bypass the increased intracellular GSH levels. Glutathione-S-transferase (GST), an enzyme involved in metabolic detoxification of a variety of xenobiotics, is increased in an arsenic-resistant CHO cell line[10,11]. Therefore, we also measured intracellular GSH and GST levels in malignant cells, when they were treated in the absence or presence of As_2O_3, ATRA, or As_2O_3+ATRA.

Materials

Human hepatoma cell lines HepG2, Hep3B, human breast cancer cell line MCF-7 (American Type Culture Collection, Rockville, MD, USA) and human lung adenocarcinoma cell line AGZY-83-a (Harbin Medical University) were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 100 U/mL penicillin, 100 μg/mL streptomycin, 1 mmol/L L-glutamine, and 10% heat-inactivated fetal bovine serum in a humidified atmosphere of 50 mL/L CO_2 at 37 ¡æ Cells in logarithmic growth were seeded at 1×10^5 cells/mL for studies performed in duplicate and repeated at least thrice. As_2O_3 solution (0.1%) was purchased from Harbin Medical University (Harbin, China). ATRA, MTT, and dimethyl sulfoxide (DMSO) were purchased from Sigma Chemical Co. (St. Louis, MO, USA).

Cell proliferation and cell survival rate tested with MTT

Cell proliferation was measured by a MTT assay. For proliferation assays, cells were plated onto 96-well plates (2×10^3 cells/well, 200 μL cell suspension per well) and cultured overnight to allow for cell attachment. Cells were then treated with drugs of different concentrations in the absence (control) or presence of As_2O_3 (0.5, 1, 1.5, and 2 μmol/L), ATRA (0.1, 1, and 10 μmol/L), or As_2O_3+ATRA. All groups had concentrations of four compound wells. After incubation for 72 h, 20 μL of 0.5% MTT was added to each well and incubated for another 4 h. The supernatant was discarded and 150 μL of DMSO was added. When the stain was dissolved, the optical density ABS (absorbance) value of each well was read on Minireader II at 490 nm. Cell survival rate was calculated with the following equation: average *A* value of experimental group/ average *A* value of control group×100%. Each experiment was repeated at least thrice.

Quantitation of cell viability and apoptotic cells

Cell viability and apoptosis were measured by annexin V-fluorescein isothiocyanate (FITC) (Becton Dickinson) and PI staining. Cells were plated onto six-well dishes (1×10^5 cells/dish) and grown overnight to allow for cell attachment. They were then treated in the absence (control) or presence of As_2O_3 (2 μmol/L), ATRA (1 and 10 μmol/L), or As_2O_3+ATRA (1 and 10 μmol/L) for 72 h. After the indicated time, cells were harvested, washed once in PBS and stained with annexin V-FITC (Biovision) and PI (2 mg/mL) according to manufacturer's instructions. Samples were acquired on a FACScan flow cytometer (Becton Dickinson, San Jose, CA, USA) and analyzed with CellQuest software (Becton Dickinson).

Intracellular glutathione measurements

Intracellular GSH levels were determined in all cell lines. Cells were plated onto six-well dishes (1×10^5 cells/dish) and grown overnight to allow for cell attachment. They were then treated in the absence (control) or presence of As_2O_3 (2 μmol/L), ATRA (1 μmol/L), or As_2O_3+ATRA for 72 h. After the indicated time, cells were harvested, and intracellular GSH was measured using the GSH assay kit (Calbiochem, San Diego, CA, USA). Briefly, cells were pelleted, resuspended in 500 μL ice-cold 5% metaphosphoric acid, and homogenized with a Teflon pestle and an overhead stirrer. After centrifugation at 3 000 r/min for 10 min at 4 ¡æ, 60 μL supernatant, 60 μL solution R1, 2 μL solution R2, and 1 mL solution R3 were combined according to the manufacturer's instructions. Samples were incubated at room temperature for 5 min in the dark, and the final absorbance was measured at 412 nm and compared to a GSH standard curve. To quantitate the total protein, the pellet from the above centrifugation was resuspended in 1 mol/L NaOH, and the protein concentration was measured using the Bio-Rad DC protein assay (Bio-Rad, Hercules, CA, USA). Intracellular GSH was normalized to total protein content.

Measurement of intracellular GST

GST activity was determined using commercial kits (Calbiochem, San Diego, CA, USA). GST activity was measured using 1-chloro-2,4-dinitrobenzene (CDNB) and GSH as substrates. Cells were plated onto six-well dishes (1×10^5 cells/dish) and grown overnight to allow for cell attachment. They were then treated in the absence (control) or presence of As_2O_3 (2 μmol/L), ATRA (1 μmol/L), or As_2O_3+ATRA for 72 h. After the indicated time, cells were harvested. The cell pellets were resuspended in 300 μL of 100 mmol/L potassium phosphate buffer, pH 6.8, sonicated for 10 s at 4 ¡æ and centrifuged at 14 000 *g* for 30 min. Supernatant was used for GST measurement according to the manufacturer's instructions. The absorbance at 412 nm was continuously recorded for 2 min. The pellet was dissolved in 1 mol/L NaOH and analyzed for protein by Bio-Rad protein assay (Bio-Rad Laboratories, Hercules, CA, USA). The GST content was expressed as nanomoles per milligram protein per minute.

Statistical analysis

Data were presented graphically as mean±SD. Treatment groups were compared by independent *t*-test or paired *t* test as appropriate, with *P* reported in each figure legend. Statistical analyses were performed using SPSS 10.1 software.

Effects of ATRA and As_2O_3 on growth inhibition in each cell line

To examine the possible relationship between serum concentration and growth-inhibitory effects of the two drugs, cells were treated with drugs of different concentrations in the absence (control) or presence of As_2O_3 (0.5, 1, 1.5, and 2 μmol/L), ATRA (0.1, 1, and 10 μmol/L), or As_2O_3+ATRA for 72 h, and then cell growth was measured by MTT assays.

The ATRA alone at 0.1, 1, and 10 μmol/L could only moderately inhibit cell growth in each of the cell lines. As_2O_3 exerted a dose-dependent growth inhibition of the HepG2, Hep3B, MCF-7, AGZY-83-a cells (Figures 1A-D).

Interestingly, the combination of ATRA (0.1, 1, and 10 μmol/L) and As_2O_3 had at least an additive effect on growth inhibition in each of the cell lines. ATRA (0.1, 1, and 10 μmol/L) could synergistically potentiate As_2O_3 to exert a dose-dependent growth inhibition in each of the cell lines. High concentration of ATRA (10 μmol/L) exerted greater synergistic effects on growth inhibition than low concentration (0.1 μmol/L, Figures 1A-D).

Effects of two drugs on apoptosis in each cell line

Cytotoxicity of ATRA was low. The apoptotic rate of 1 or 10 μmol/L of ATRA approached to that of control in each of the cell lines, and the difference was not significant

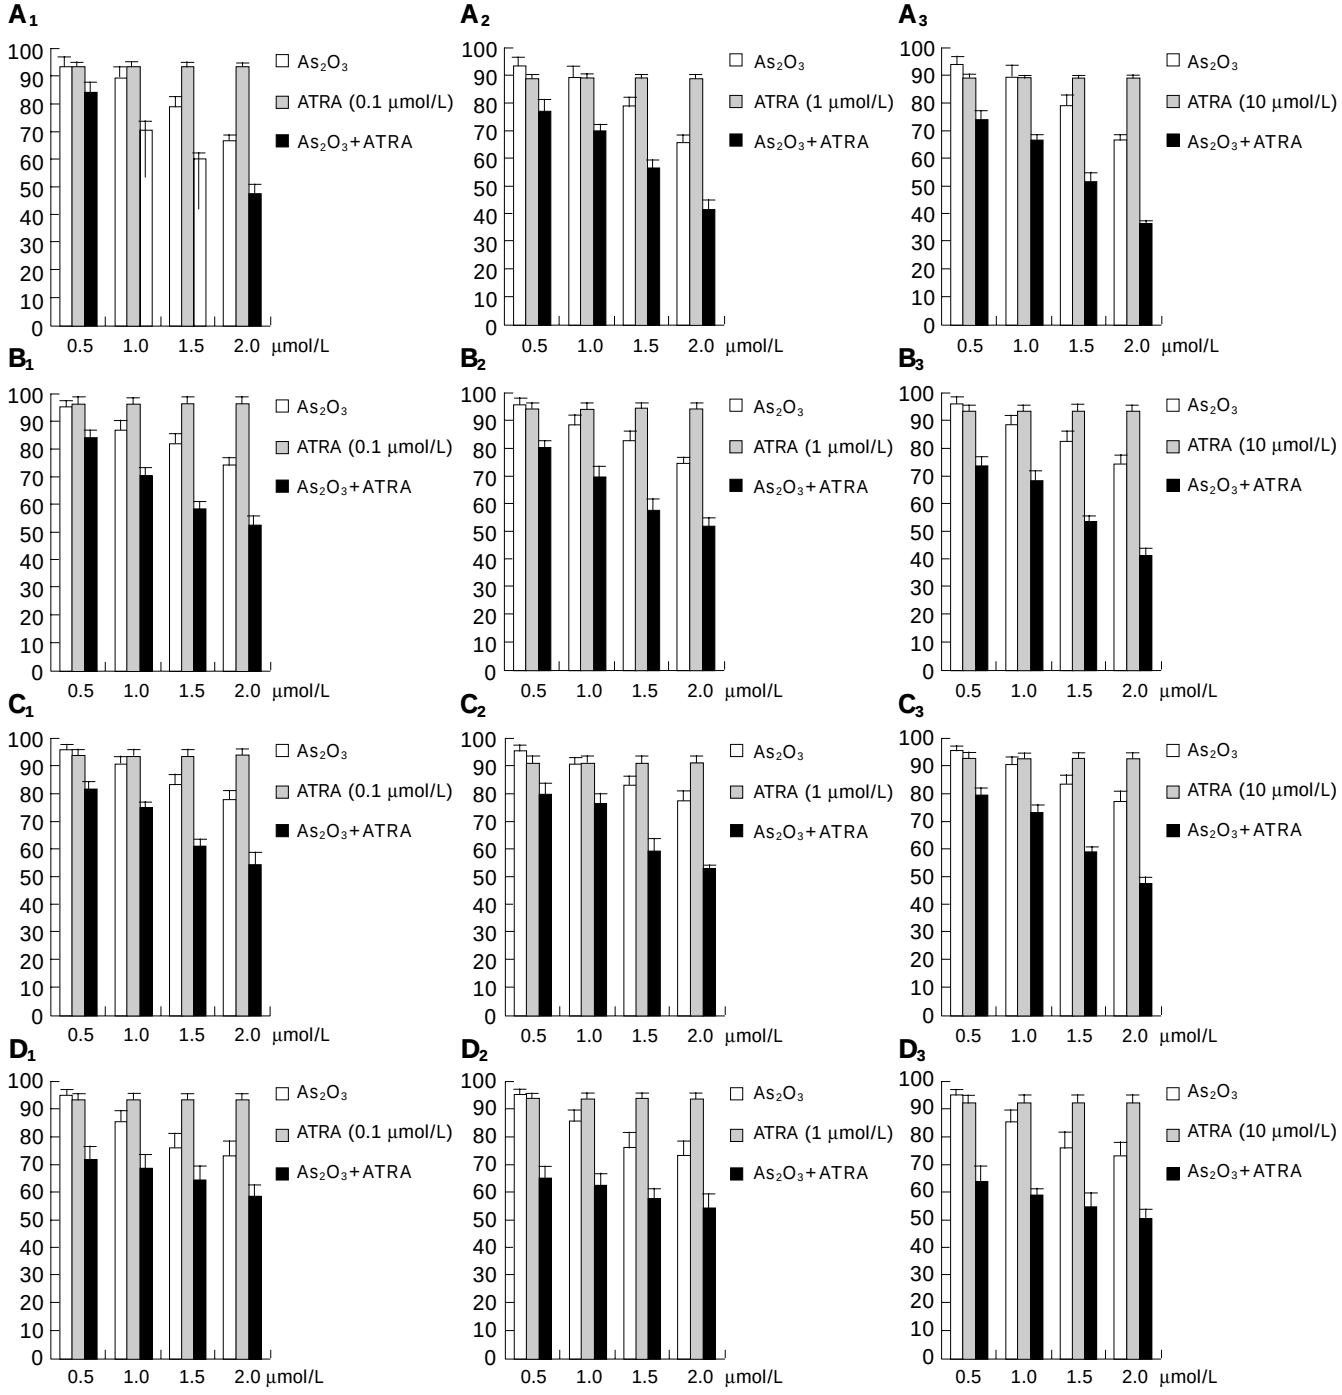

Figure 1 Effects of ATRA and As_2O_3 on growth inhibition in cancer cell lines HepG2 (A), Hep3B (B), MCF-7 (C), and AGZY-83-a (D).

Table 1 Basal activities of GSH or GST and As_2O_3+ ATRA or As_2O_3-induced apoptosis in different cell lines (mean±SD)

Cell lines	GSH	GST	As_2O_3	Apoptosis (%)	
				As_2O_3+ATRA (10 μmol/L)	As_2O_3+ ATRA (1 μmol/L)
HepG2	60.7±7.1	22.3±1.4	29.3±3.2	61.1±5.6	48.4±4. 1
Hep3B	62.4±5.4	21.4±2.8	27.3±6.5	57.1±4.9	49.3±4.2
MCF-7	76.0±5.1	31.0±2.6	22.6±3.3	45.5±3.0	40.2±3.3
AGZY-83-a	104.8±8.1	50.6±4.5	19.0±3.8	40.8±5.6	32.9±3.0

(P>0.05). ATRA greatly potentiated the apoptosis induced by As_2O_3. Exposure of the cells to the combination of As_2O_3 (2 μmol/L) and ATRA (10 μmol/L) for 72 h synergistically induced apoptosis in HepG2 (61.1±5.6%), Hep3B (57.1±4.9%), MCF-7 (45.5±3.0%), AGZY-83-a (40.8±5.6%) respectively, as measured by annexin V-FITC and PI staining as compared to exposure of the cells to either agent alone (Figure 2A). A similar, dramatic effect was observed, when they were treated in the absence (control) or presence of As_2O_3 (2 μmol/L), ATRA (1 μmol/L), or As_2O_3+ATRA for 72 h, with HepG2 being 48.4±4.1%, Hep3B being 49.3±4.2%, MCF-7 being 40.2±3.3%, AGZY-83-a being 32.9±3.0% respectively (Figure 2B). All these findings indicated that ATRA could synergistically potentiate As_2O_3 to induce apoptosis in each of the cell lines.

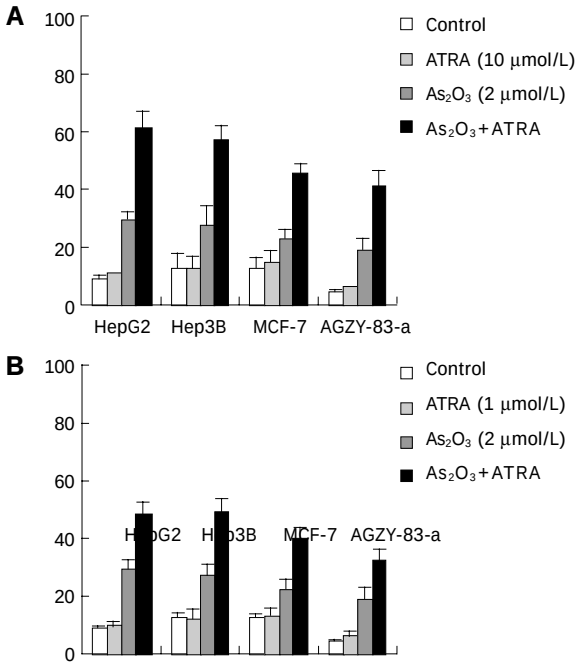

Figure 2 Effects of combined ATRA (10 mol/L: A, 1 mol/L: B) and As_2O_3, and either agent alone on apoptosis in cancer cell lines.

Changes of intracellular GSH and GST

HepG2 and Hep3B with low intracellular GSH or GST activities, were remarkably sensitive to 2 μmol/L As_2O_3 or As_2O_3 (2 μmol/L)+ATRA (10 μmol/L), the apoptotic rate was 29.3±3.2% and 61.1±5.6%, respectively. AGZY-83-a with higher GSH or GST activities was less sensitive to As_2O_3 or As_2O_3+ATRA, the apoptotic rate was 19.0±3.8% and 40.8±5.6%, respectively (Table 1). The sensitivity to As_2O_3 or As_2O_3+ATRA was inversely proportional to intracellular GSH or GST levels in each of the cell lines. A similar, dramatic effect was observed when they were treated in the presence of As_2O_3 (2 μmol/L), or As_2O_3 (2 μmol/L)+ATRA (1 μmol/L) for 72 h (Table 1).

Dramatic changes of intracellular GSH or GST activities were observed when the cell lines were treated in the absence (control) or presence of As_2O_3 (2 μmol/L), ATRA (1 μmol/L), or As_2O_3+ATRA for 72 h. Treatment with 2 μmol/L As_2O_3 for 72 h significantly decreased the intracelluar GSH and GST levels in each of the cell lines, and 1 μmol/L ATRA alone reduced minimal intracellular GSH and GST levels. ATRA potentiated the effect of As_2O_3 on intracellular GSH levels, but intracellular GST levels were not significantly affected by the combination of As_2O_3 (2 μmol/L) and ATRA (1 μmol/L) for 72 h as compared to As_2O_3 alone (Tables 2 and 3).

Table 2 Effect of As_2O_3 on intracellular GSH levels (mean±SD)

Cell lines	Control	ATRA[a]	As_2O_3[c]	As_2O_3+ATRA[e]

Our *in vitro* studies showed that the combination of As_2O_3 and ATRA was statistically superior to either As_2O_3 or ATRA alone in the treatment of the three cell lines. Furthermore, ATRA (0.1, 1, and 10 μmol/L) could synergistically potentiate As_2O_3 to exert a dose-dependent growth inhibition in each of the cell lines. Cell survival rate could be reduced from 89.5±3.9% to 70.5±3.3% in HepG2 cells exposed to 1 μmol/L As_2O_3 or the combination of 1 μmol/L As_2O_3 and 0.1 μmol/L ATRA for 72 h.

Apoptosis is important for the development and

homeostasis of multicellular organisms. Specific therapies have been designed to enhance the susceptibility of human cancers to apoptosis. We showed that the combination of As_2O_3 and ATRA dramatically and significantly increased the number of apoptotic cells in each of the cell lines, especially the human hepatoma cell lines HepG2 and Hep3B.

Drug resistance of cancer cells and toxicity of cell apoptotic agents are the major factors contributing to the failure of chemotherapy. At least four distinct mechanisms contribute to the chemoresistance. Cellular response to steroids typically depends on the expression of the glucocorticoid receptor, and resistance to steroid therapies is classically associated with downregulation or loss of glucocorticoid receptor expression in some malignant cells[12,13]. The overexpression of drug efflux pumps, such as *mdr* gene product P-glycoprotein (PgP), is also a common trait of chemoresistant malignant cells[14,15]. In addition, it was reported that the expression of the antiapoptotic protein Bcl-xL is higher in some chemoresistant malignant cells[16]. Furthermore, increased expression or activity of GSH and GSH-related enzymes confers resistance to antineoplastic agents[17,18]. GSH is the major auto-oxidant of the cells, and functions to scavenge free radicals and to detoxify toxins and chemotherapeutic agents. GSH can bind to arsenic by the formation of a transient $As(GS)_3$ complex[19].

The GSH redox system is known to modulate the growth-inhibitory and apoptotic effect of As_2O_3. Different kinds of malignant cells have different GSH levels. It was reported that the GSH redox system is relative to sensitivity of malignant cells to As_2O_3[9]. Elevated GSH levels are associated with the chemoresistance of malignant cells. Optimal therapies for chemoresistant malignant cells should overcome or bypass the increased intracellular GSH levels. It is known that GST, an enzyme involved in metabolic detoxification of a variety of xenobiotics, is increased in an arsenic-resistant CHO cell line[10]. Our study showed that HepG2 and Hep3B with low intracellular GSH or GST activities were remarkably sensitive to As_2O_3 or As_2O_3+ATRA, while AGZY-83-a with higher GSH or GST activities was less sensitive to As_2O_3 or As_2O_3+ATRA. The sensitivity to As_2O_3 or As_2O_3+ATRA was inversely proportional to GSH or GST levels in each of the cell lines.

Arsenite can decrease GSH levels which can result in DNA damage as a result of increased intracellular reactive oxygen molecules. Our intracellular GSH and GST assays showed that treatment with 2 μmol/L As_2O_3 for 72 h significantly decreased intracellular GSH and GST levels in each of the cell lines, and 1 μmol/L ATRA alone reduced minimal intracellular GSH and GST levels (Tables 2 and 3). ATRA potentiated the effect of As_2O_3 on intracellular GSH levels, but intracellular GST levels were not significantly affected by the combination of As_2O_3 (2 μmol/L) and ATRA (1 μmol/L) for 72 h as compared to As_2O_3 alone. These findings indicate that GSH redox system may be the possible mechanism by which ATRA synergistically potentiates As_2O_3 to induce apoptosis or to exert a dose-dependent inhibition of growth. Either As_2O_3 alone or in combination with ATRA may become a useful adjuvant therapy for liver, breast, and lung cancers.

Abstract

AIM: To examine whether lysophosphatidic acid (LPA) induces phosphorylation of c-Met and epidermal growth factor receptor (EGFR), both of which have been proposed as prognostic markers of colorectal cancer, and whether LPA induces cyclooxygenase-2 (COX-2) expression in human colon cancer cells.

METHODS: Using a human colon cancer cell line, LoVo cells, we performed immunoprecipitation analysis, followed by Western blot analysis. We also examined whether LPA induced COX-2 expression, by Western blot analysis.

RESULTS: Immunoprecipitation analysis revealed that 10 μmol/L LPA induced tyrosine phosphorylation of c-Met and EGFR in LoVo cells within a few minutes. We found that c-Met tyrosine phosphorylation induced by LPA was not attenuated by pertussis toxin or a matrix metalloproteinase inhibitor, in marked contrast to the results for EGFR. In addition, 0.2-40 μmol/L LPA induced COX-2 expression in a dose-dependent manner.

CONCLUSION: Our results suggest that LPA acts upstream of various receptor tyrosine kinases (RTKs) and COX-2, and thus may act as a potent stimulator of colorectal cancer.

INTRODUCTION

Although the incidence of colorectal cancer was substantially lower in Asia than that in the USA in the mid-twentieth century, the incidence in Japan and China has been rapidly increasing[1,2]. Thus, colorectal cancer is now a major cause of cancer death worldwide. Surgery is the main modality of treatment for colorectal cancer, other modalities like chemotherapy being adjuvant in nature. Whereas fluorouracil has been reported to be the only effective systemic therapeutic agent for colorectal cancer until recently, considerable improvement has been achieved in the last decade with the development of newer chemotherapeutic agents, such as irinotecan and oxaliplatin. In addition to these conventional cytotoxic agents, growing interest and significant advances have been made in the use of targeted therapy for colorectal cancer during the last few years. Bevacizumab, a mAb against vascular endothelial growth factor (VEGF), and cetuximab, a chimeric mAb directed against epidermal growth factor receptor (EGFR), were shown to improve the survival of patients with metastatic colorectal cancer in large randomized clinical trials[3-5]. Now that molecular target therapy for colorectal cancer has started in clinical settings, new and more effective molecular targets are eagerly being investigated.

From this standpoint, we have focused on lysophosphatidic acid (LPA, 1- or 2-acyl-sn-glycero-3-phosphate). LPA, the simplest glycerophospholipid, has been shown to interact with at least three G protein-coupled receptors (GPCRs), such as LPA1/Edg-2, LPA2/Edg-4, and LPA3/Edg-7[6,7]. Through these receptors, LPA mediates a broad range of cellular responses, including smooth muscle cell contraction, platelet aggregation, neurite retraction/cell rounding, regulation of cell proliferation, protection from apoptosis, modulation of chemotaxis and transcellular migration[8-10]. Some of these cellular responses implicate LPA as a mediator of tumor progression[11]. We have previously reported several experimental studies using cell lines and surgically resected specimens. Using various human colon cancer cells, we revealed that LPA stimulated migration, adhesion, proliferation, and secretion of angiogenic factors *in vitro*, although the responses induced showed some differences among cells, which seemed to be based on their expression pattern of LPA receptors[12]. We also revealed aberrant

expression of LPA receptors in human colorectal cancer tissues; i.e., overexpression of LPA2 and underexpression of LPA1 in colorectal cancer compared with normal mucosa[13]. Thus, LPA and its receptors play crucial roles in the development and progression of colorectal cancer.

As for colorectal cancer, it is well known that the use of nonsteroidal anti-inflammatory drugs (NSAIDs) has been linked to a 40-50% reduction in relative risk for cancer development[14]. The molecular basis for this striking chemopreventive effect has been attributed to inhibition of cyclooxygenases (COX)[14]. Consistent with this, approximately 80% of colorectal cancers show increased levels of COX-2[14,15]. COX-2 is responsible for the synthesis of prostaglandin E_2 (PGE_2), a bioactive lipid molecule with diverse biological activities, including growth-promoting actions on the gastrointestinal mucosa. Although the precise mechanism of these trophic actions of PGs had remained unclear for a long time, it was recently demonstrated that PGE_2 could phosphorylate EGFR and trigger the extracellular signal-regulated kinase 2 (ERK2)-mitogenic signaling pathway, which reveals a previously unknown mechanism by which PGE_2 mediates a trophic action resulting in the growth of colonic polyps and cancers[16].

Thus, tyrosine phosphorylation of various receptor tyrosine kinases (RTKs) in response to activation of many GPCRs, which was designated as "transactivation", has been shown to have important physiological consequences and has received considerable attention in recent years. In addition to EGFR, PGE_2 was also shown to transactivate c-Met, the receptor for hepatocyte growth factor (HGF) resulting in increased invasiveness of colon cancer cells[16,17]. In colorectal cancer, c-Met expression level has been shown to be a predictor of tumor invasion and lymph node metastasis, suggesting that c-Met signals contribute to colorectal cancer progression[18,19].

LPA has been reported to transactivate EGFR in several cell types, and, in some epithelial cells, LPA has also been reported to induce COX-2 gene expression[13,20-24]. However, to the authors' knowledge, LPA signaling pathways in colon cancer cells have not been fully understood as yet. In the present study, using colon cancer LoVo cells which are known to express abundant c-Met at both mRNA and protein levels[25], we investigated whether LPA induces phosphorylation of c-Met as well as EGFR, and whether LPA induces COX-2 expression.

MATERIALS AND METHODS

Materials

A selective inhibitor of COX-2, NS-398, was purchased from Cayman Chemicals (Ann Arbor, MI, USA), and 1-oleoyl-LPA was purchased from Sigma Chemical Co. (St. Louis, MO). Recombinant human HGF was purchased from R&D Systems, Inc. (Minneapolis, MN, USA) and recombinant human EGF was purchased from PeproTechEC Ltd. (London, UK). Rabbit polyclonal anti-human c-Met antibody (C-28), rabbit polyclonal anti-human EGFR antibody, and mouse monoclonal anti-human phosphotyrosine antibody (PY20) were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). Mouse monoclonal anti-human COX-2 antibody was purchased from Exalpha Biologicals, Inc. (Boston, MA, USA). Pertussis toxin (PTX) and the broad-spectrum matrix metalloproteinase (MMP) inhibitor GM6001 were purchased from Calbiochem (La Jolla, CA, USA).

Cell culture

The human colon cancer cell line, LoVo cells, were obtained from American Type Culture Collection (Manassas, VA, USA) and maintained in Dulbecco modified Eagle medium (DMEM) supplemented with 100 mL/L fetal calf serum (Sigma, St. Louis, MO, USA), 100 U/mL penicillin, and 100 μg/mL streptomycin (Gibco BRL Co., Grand Island, NY, USA).

Immunoprecipitation and Western blot analysis of RTK transactivation

Immunoprecipitation and Western blot analysis were performed as described previously[13,26,27]. In brief, LoVo cells were starved in serum-free medium for 24 h and then LPA was added to the culture. After incubation of starved LoVo cells with 10 μmol/L LPA for various times, cellular protein lysates were obtained and then proteins were incubated with antibodies against two RTKs, c-Met and EGFR. Immunoprecipitates were collected with protein A-agarose. Immunoprecipitated proteins were electrophoresed on sodium dodecyl sulfate (SDS)-75 g/L polyacrylamide gel for 35 min at 200 V. Then, the protein was transferred onto an Immobilon transfer membrane (Millipore Co., Bedford, MA, USA) for sequential incubation with 50 g/L reconstituted non-fat milk powder to block nonspecific sites, dilutions of rabbit polyclonal anti-phosphotyrosine antibody, and then horseradish peroxidase-labeled donkey anti-rabbit IgG, prior to the development with a standard ECL kit (Amersham, Inc., Buckinghamshire, UK). Some cells were pretreated with 100 ng/mL PTX for 24 h before stimulation, and other cells were pretreated with 5-50 μmol/L GM6001 for 30 min before stimulation. All membranes were stripped and immunoblotted with antibodies against RTKs as a control.

Western blot analysis of cyclooxygenase-2

LoVo cells were starved in serum-free medium overnight and then various concentrations of LPA were added to the culture. After incubation of starved LoVo cells with LPA for 24 h, cellular protein lysates were obtained. Then, cell proteins (15 μg per lane) were electrophoresed on SDS-150 g/L polyacrylamide gel for 45 min at 200 V. Then, the protein was transferred onto an Immobilon transfer membrane (Millipore Co.) for sequential incubation with 50 g/L reconstituted non-fat milk powder to block nonspecific sites, dilutions of mouse monoclonal anti-human COX-2 antibody, and then horseradish peroxidase-labeled donkey anti-rabbit IgG, prior to the development with a standard ECL kit (Amersham, Inc.). The same membrane was stripped and immunoblotted with antibodies against β-actin as a control.

Proliferation assay

LoVo cells (5×10^3 cells in 100 μL solution per well), which were pretreated with DMSO or 100 μmol/L NS-398, were seeded in a 96-well plate in DMEM containing 1 g/L fatty acid-free BSA with various concentrations of LPA, which

was added every 24 h. After incubation at 37 ℃ in 50 mL/L CO_2 for 120 h, the number of living cells was measured using an MTS assay (Promega Co., Madison, WI, USA) according to the manufacturer's instructions. Briefly, MTS solution was added to each well and the cells were further incubated for 3 h. The number of living cells was determined by measuring optical density at 490 nm.

RESULTS

LPA-induced tyrosine phosphorylation of c-Met in colon cancer cells

In order to investigate whether tyrosine phosphorylation of c-Met was induced by LPA, LoVo cells were incubated with 10 μmol/L LPA for 2-60 min. As shown in Figure 1, LPA induced a significant level of tyrosine phosphorylation of c-Met in LoVo cells. Time course experiments revealed that phosphorylation was maximal after 2 min of stimulation and declined thereafter, suggesting that LPA-induced rapid and transient tyrosine phosphorylation of c-Met. After stripping, c-Met in LoVo cells was detected by anti-human c-Met antibody at 190 ku. The amount of c-Met immunoprecipitation was not different with or without LPA (Figure 1). In reverse experiments, phosphotyrosine immunoprecipitation and anti-c-Met immunoblotting revealed the same results (Figure 1). Tyrosine phosphorylation of c-Met induced by 10 μmol/L LPA was as strong as that induced by 10 ng/mL HGF (Figure 2).

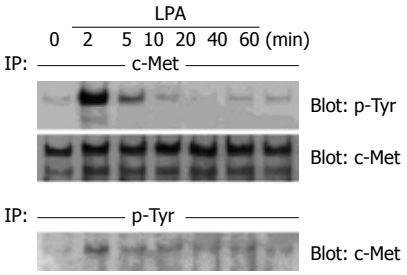

Figure 1 Rapid tyrosine phosphorylation of c-Met in response to LPA in human colon cancer cells. (**A**) Human colon cancer LoVo cells were serum-starved for 24 h and then incubated with 10 μmol/L LPA for 2-60 min. After cell lysis, c-Met was immunoprecipitated (IP) using polyclonal anti-c-Met antibody, and immunoprecipitates were immunoblotted with monoclonal anti-phosphotyrosine antibody. Then the membrane was stripped and immunoblotted with anti-c-Met as a control. (**B**) Human colon cancer LoVo cells were serum-starved for 24 h and then incubated with 10 μmol/L LPA for 2-60 min. These cell lysates were IP with anti-phosphotyrosine, and the immunoprecipitates were immunoblotted with anti-c-Met.

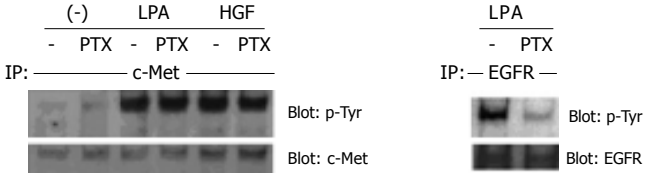

Figure 2 Effect of PTX, a Gi inhibitor, on LPA-stimulated c-Met transactivation in colon cancer cells. Human colon cancer LoVo cells were serum-starved for 24 h with or without 100 ng/mL PTX and then stimulated with 10 μmol/L LPA or 10 ng/mL HGF for 2 min. Cell lysates were IP with anti-c-Met. Immunoprecipitates were immunoblotted with anti-phosphotyrosine. Then the membrane was stripped and immunoblotted with anti-c-Met as a control. The same experiments were performed using anti-EGFR as a control for the inhibitory effect of PTX.

Tyrosine phosphorylation of c-Met induced by LPA was not inhibited by pertussis toxin

As shown in Figure 2, pretreatment with PTX partly decreased the LPA-induced phosphorylation of EGFR in LoVo cells. This is compatible with previous reports that LPA-induced EGFR transactivation in Cos-7 cells, and head and neck squamous cell carcinoma cells (HNSCC) was PTX sensitive, suggesting the involvement of Gi protein in this signaling pathway[28,29]. To address the question of whether a Gi-dependent mechanism is also involved in LPA-induced c-Met transactivation in colon cancer cells, we examined the effect of PTX in our system. In contrast to EGFR transactivation, PTX did not significantly inhibit tyrosine phosphorylation of c-Met in response to LPA in any experimental condition (24-48 h pretreatment with 100-200 ng/mL PTX) (Figure 2). Thus, LPA-induced c-Met transactivation in colon cancer cells seems to be Gi-independent.

Tyrosine phosphorylation of c-Met induced by LPA was not dependent on MMP activation

Previous reports have shown that GPCR-induced EGFR transactivation requires MMP activation and cleavage of the membrane-anchored growth factor precursor pro-HB-EGF in COS-7 cells, HEK-293 cells and HNSCC[20,30]. As shown in Figure 3, pretreatment with an MMP inhibitor, GM6001, decreased the phosphorylation of EGFR by LPA in LoVo cells in a dose-dependent manner, which is compatible with previous reports. In contrast to EGFR transactivation, GM6001 did not significantly inhibit LPA-induced tyrosine phosphorylation of c-Met at any concentration (Figure 3). Thus, LPA-induced c-Met transactivation in colon cancer cells does not require MMP activation.

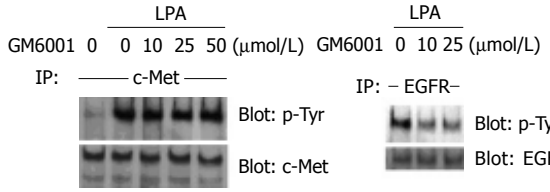

Figure 3 Effect of GM6001, an MMP inhibitor, on LPA-stimulated c-Met transactivation in colon cancer cells. Human colon cancer LoVo cells were serum-starved for 24 h and pre-incubated with the indicated concentrations of GM6001 for 30 min. After incubation with 10 μmol/L LPA for 2 min, cell lysates were obtained and IP with anti-c-Met. Immunoprecipitates were immunoblotted with anti-phosphotyrosine. Then the membrane was stripped and immunoblotted with anti-c-Met as a control. The same experiments were performed using anti-EGFR as a control for the inhibitory effect of GM6001.

LPA induced COX-2 expression in colon cancer cells

LPA has been shown to induce COX-2 expression in some epithelial cells[13,20,21]. However, as for cancer cells, to our knowledge, there is no report of LPA-induced COX-2 expression. Hence, we examined whether LPA induces COX-2 expression in LoVo cells. When LoVo cells were stimulated with various concentrations of LPA for 24 h, the 72-ku COX-2 protein was increased in a concentration-dependent manner (Figure 4). This effect was maximal at an LPA concentration of 40 μmol/L.

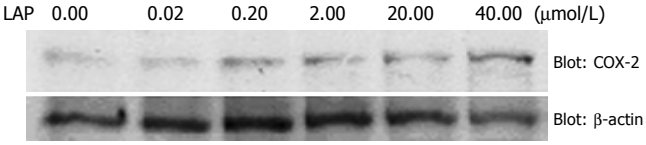

Figure 4 Effect of LPA on COX-2 expression in colon cancer cells. Human colon cancer LoVo cells were serum-starved for 24 h, and then treated with 0.02-40 μmol/L LPA for 24 h. After cell lysis, the expression level of COX-2 protein was examined by Western blotting using anti-COX-2 antibody. Then the membrane was stripped and immunoblotted with anti-β-actin as a control.

COX-2 inhibitor reduced LPA-induced proliferation in colon cancer cells

LPA has been shown to be a potent mitogen for various cell types. In order to investigate the role of LPA-induced COX-2 expression, we performed a proliferation assay using NS398, a selective COX-2 inhibitor, with the measurement by MTS assay. LPA itself induced a dose-dependent increase in proliferation, showing significant growth stimulation at 0.2 μmol/L and a stronger effect at 20 μmol/L (5.2±0.6 -fold increase compared with control) (Figure 5). NS398 alone did not show a significant effect in control conditions without LPA; however, NS398 markedly inhibited LPA-induced proliferation at 20 μmol/L LPA (51±6% inhibition) (Figure 5). Thus, NS398 significantly inhibited LPA-induced LoVo cell proliferation.

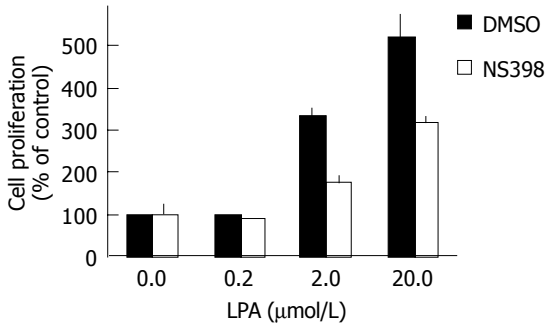

Figure 5 Inhibition of LPA-induced proliferation of LoVo cells by NS398, a COX-2 inhibitor. Human colon cancer LoVo cells, after being pretreated with DMSO or NS398, were seeded with the indicated concentrations of LPA. After incubation for 120 h, the cell proliferation was measured using MTS assay. Data are expressed as a percentage of control, where control indicates cell proliferation in the absence of LPA without NS398 pretreatment (100%).

DISCUSSION

In this study, using LoVo cells, we revealed LPA induced transactivation of c-Met as well as EGFR. Since both c-Met and EGFR serve as prognostic markers in human colorectal cancer, LPA may be a potent stimulator of colorectal cancer progression that acts upstream of these RTK signaling pathways (Figure 5)[18,31]. We also revealed that LPA induced COX-2 expression. Interestingly, PGE_2, which is synthesized by COX-2, is known to transactivate both c-Met and EGFR[16,17]. Taking these results together, LPA may act upstream of these RTK signaling pathways in a dual manner; one is a direct effect and the other an indirect effect accomplished via COX-2 upregulation (Figure 6).

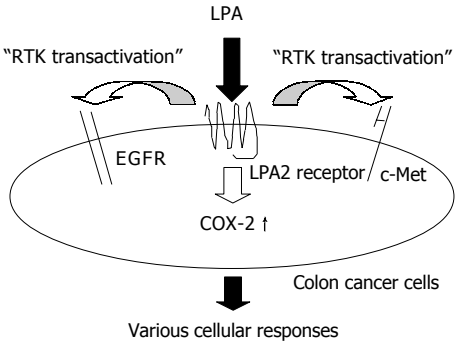

Figure 6 Mechanism of the effects of LPA on human colon cancer cells.

EGFR is well-known to not only transduce EGF signals, but also integrate diverse stimuli, such as LPA, bombesin, thrombin, and S1P[28,30,32-34]. This transactivation of EGFR represents a paradigm for cross-talk between GPCRs and RTK signaling pathways. From this knowledge, a novel picture of EGFR as a central cellular network element has been established in recent years, which broadens both its physiological as well as pathological significance[35-37]. In addition to EGFR transactivation, Pai *et al*.[17], recently reported c-Met transactivation which was induced by PGE_2 in colon cancer cells. They also showed that, whereas HGF induces autophosphorylation of tyrosine residues in c-Met and can enhance invasion into the extracellular matrix, ligand-independent activation of the c-Met signaling pathway could cause similar changes and increase colon cancer cell invasion[17]. Thus, c-Met signals, which were activated by various stimuli, also seem to play an important role in colorectal cancer progression. In this study, we revealed that tyrosine phosphorylation of c-Met induced by LPA was rapid and transient, which is exactly the same pattern as that of EGFR. Thus, LPA utilizes EGFR and c-Met as a downstream signaling partner in colon cancer cells.

Previous studies indicated that LPA-stimulated transactivation of EGFR in COS-7 cells and HNSCC was mediated partly via Gi protein and required MMP activation[28-30]. In our study of colon cancer cells, we also confirmed that LPA-induced transactivation of EGFR was mediated partly via Gi protein and required MMP activation. In contrast, LPA-induced transactivation of c-Met did not show significant inhibition by either PTX or GM6001. These data indicated that c-Met transactivation by LPA does not require Gi proteins and MMP activation, in marked contrast to EGFR transactivation induced by LPA. Since Gq is known to be coupled with LPA receptors and plays a role in EGFR transactivation, this Gq or other G proteins could be involved in the transactivation of c-Met. The contribution of MMP activation in EGFR transactivation has been shown to induce proteolytic cleavage of transmembrane precursors, such as pro-HB-EGF, which subsequently activates the EGFR family[20,30]. Our results, however, suggested that HGF or other c-Met ligands do not exist as a membrane-bound form, such as HB-EGF.

Accumulating evidence indicates that COX-2 plays key roles in intestinal tumorigenesis. In addition, COX-2 overexpression in colon cancer cells was shown to promote

cell motility and stimulate the production of angiogenic factors[38]. Thus, the expression level of COX-2 may determine, at least in part, the aggressiveness of cancer. In this study, we demonstrated LPA induced COX-2 expression in a dose-dependent manner. We also revealed that a COX-2 inhibitor significantly reduced LPA-induced proliferation of LoVo cells. These results suggest that LPA uses COX-2 as a downstream signaling partner, which results in making cancer cells aggressive.

We have previously demonstrated that LoVo cells exclusively expressed LPA2 among the three LPA receptors, by both Northern blot analysis and real-time RT-PCR method[12,13]. Therefore, LPA-induced transactivation of c-Met and EGFR in LoVo cells, as well as LPA-induced COX-2 expression, might be presumably mediated by the LPA2 receptor. We have previously demonstrated that, in colorectal cancer tissue, the LPA2 receptor is markedly overexpressed as compared with normal mucosa[12,13]. Moreover, overexpression of the LPA2 receptor was also shown in ovarian cancer, thyroid cancer, and breast cancer as compared to normal tissue[39-42]. Since, in general, the targets of newly developed drugs are mostly GPCRs, the LPA2 receptor, a member of GPCR, could be a novel molecular target for cancer therapy.

In summary, this study demonstrates that LPA, at a physiological concentration, induces transactivation of c-Met as well as EGFR, and induces COX-2 expression. Colorectal cancers are often associated with local bleeding and thus, at the tumor site, platelets are activated and secrete lysophospholipids such as lysophosphatidylcholine (LPC), lysophosphatidylethanolamine (LPE), and lysophosphatidylserine (LPS). These lysophospholipids are subsequently converted to LPA by lysophospholipase D[43]. Therefore, a significant amount of extracellular LPA is thought to be present in colorectal cancer tissue, and is able to induce various important biological responses in cancer tissues. Our findings indicate that the development of an antagonist for LPA or the appropriate spectrum of LPA receptors may be a new and effective therapy for colon cancer.

Abstract

AIM: To clarify the expression patterns and prognostic implications of the mitotic regulator Polo-like kinase 1 (PLK1) in colon cancer.

METHODS: Expression of PLK1 was investigated by immunohistochemistry (158 cases) and immunoblotting in tissue of colon adenomas and adenocarcinomas. PLK1 expression patterns were correlated with clinicopathological parameters and patient prognosis. In addition, expression of PLK1 was evaluated by immunoblot and PCR in colon carcinoma cell lines, and coexpression of PLK1 with the proliferation marker Ki-67 was investigated.

RESULTS: Weak PLK1 expression was observed in normal colon mucosa and adenomas. In contrast, 66.7% of carcinomas showed strong expression of PLK1. Overexpression of PLK1 correlated positively with Dukes stage ($P<0.001$), tumor stage ($P = 0.001$) and nodal status ($P<0.05$). Additionally, PLK1 expression was a prognostic marker in univariate survival analysis ($P<0.01$) and had independent prognostic significance (RR = 3.3, $P = 0.02$) in patients with locoregional disease. Expression of PLK1 mRNA and protein was detected in all cell lines investigated. Coexpression of PLK1 and Ki-67 was observed in the majority of colon cancer cells, but a considerable proportion of cells showed PLK1 positivity without Ki-67 expression.

CONCLUSION: PLK1 is a new prognostic marker for colon carcinoma patients and may be involved in tumorigenesis and progression of colon cancer. Strategies focusing on PLK1 inhibition *in vivo* might therefore represent a promising new therapeutic approach for this tumor entity.

INTRODUCTION

Colorectal cancer ranks third in cancer deaths for both sexes in the Western world, with 146 940 estimated new cases and 56 730 estimated deaths in USA in 2004[1]. Incidence and mortality of colon cancer have decreased only slightly over the last 20 years. Though surgery is potentially curative, the risk of recurrence is high. Apart from surgical resection, treatment strategies for high risk patients are still mainly based on adjuvant/neoadjuvant use of 5-fluorouracil and leukovorin as chemotherapeutic agents alone or in combination with radiotherapy. Unfortunately, use of the standard therapeutic protocols results only in a moderate decline in mortality and the risk to sustain a recurrence of disease remains high[2]. Furthermore, it is still uncertain which of the patients should be treated, as prediction of the prognosis for an individual patient remains problematic[3]. With increasing knowledge about molecular changes in the malignant phenotype, therapeutic strategies focusing on targeted modulation of signal transduction pathways, which are imperative to malignant cells, are becoming increasingly important. Genetic alterations, typically associated with a malignant cell phenotype, affect genes involved in DNA repair and apoptosis, cell adhesion and invasion, angiogenesis and finally cell proliferation and cell cycle control[4].

After its discovery in Drosophila 16 years ago by Sunkel and Glover[5] *polo* has become the founding member of a whole family of protein kinases centrally involved in the mitotic regulation of both normal and malignant transformed cells. Since then, polo homologs have been discovered in a broad variety of species, including certain bacteria, yeast, mice, and men[6,7]. Till date, there are four known polo homologs in human beings with Polo-like kinase 1 (PLK1) being the best characterized protein of this family[8].

There is convincing evidence that PLK1 plays a central role in the G_2/M transition by exerting an important control function in several steps of mitosis[7]. Additionally, PLK1 plays an important role in the regulation of microtubule dynamics and in the maturation of centrosomes[9].

Expression of PLK1 has been described in a variety of

human malignancies[10-21]. We and others have reported that PLK1 overexpression had a significant impact on patient prognosis in some of these tumor entities[0,13,15,17,20]. For colon cancer, the prognostic impact of PLK1 has not been investigated so far.

The central aim of this study was to evaluate the status of PLK1 expression in a cohort of 158 benign and malignant colon tumors and in colon cancer cell lines by immunohistochemistry and immunoblotting, and to investigate the association of PLK1 expression with clinicopathological parameters and patient survival.

MATERIALS AND METHODS

Patients

A total of 153 patients (age: 31-86 years, median 65.45 years) who were diagnosed for colon cancer at the Institute of Pathology, Charité University Hospital between 1996 and 1999, were included in this study. Only patients with primary colon adenocarcinomas and no other known malignancies were included. None of the patients received radiotherapy or chemotherapy prior to diagnosis. All patients were residents of the city of Berlin. The majority of patients represented consecutive cases of colon cancer in our institute. Based on tissue availability in our archive, a small number of cases (7.8%, 12 cases) had to be excluded from this study. Histologic diagnosis was established on standard H&E stained sections according to the guidelines of the World Health Organization. The details on the distribution of clinicopathological factors in the study cohort are listed in Table 1. Clinical follow-up data were available for all patients. The median follow-up time of survivors was 47 mo. Forty-one patients (27%) died after a median time of 60 mo of follow-up. As a control for non-malignant colon tumors, five adenomas of the colon were included in the study as well.

Cell lines

The human colon carcinoma cell lines RKO and HT29 were obtained from ATCC. CX2 and HRT18 were from the German Cancer Research Center (Heidelberg, Germany). Cells were cultured in either DMEM (RKO) or RPMI (CX2, HRT18, HT29) supplemented with 10% fetal bovine serum.

Polymerase chain reaction

Subconfluent colon carcinoma cells were harvested and total RNA was prepared with RNAeasy kit (Qiagen, Hilden, Germany) and reverse transcribed. PCR cycling conditions for PLK1 were 30 cycles of denaturation, annealing and extension at 95 ℃ for 60 s, at 54 ℃ for 60 s, and at 72 ℃ for 120 s. The primers used were human PLK1 sense 5'-AGTGCTGCAGTGACTGCA-3' and antisense 5'-GGAGGCCTTGAGACGGTT-3' (generating a 1 807-bp band). As control GAPDH sense 5'-ACCACAGTCC-ATGCCATCAC-3' and antisense 5'-TCCACCACCCTG-TTGCTGTA-3' (generating a 452-bp band) primers were used.

Immunoblotting

Tissues from colon carcinomas and normal colon mucosa were dissected by a senior pathologist in the operation theater from surgical specimens sent for frozen section analysis and were immediately frozen in liquid nitrogen and stored at -80 ℃ until analysis.

Subconfluent colon carcinoma cells were harvested and 100 μg protein/sample was loaded on a 10% polyacrylamide gel. Western blots were performed as previously described[22], using a mouse monoclonal anti-PLK1 antibody (BD Transduction, San Diego, CA, USA) diluted 1:500 and an anti-β-actin antibody (Chemicon, Temecula, CA, USA) diluted 1:3 000.

Immunohistochemistry on tissue slides

For immunohistochemical detection of PLK1 on tissue samples and cells, a monoclonal mouse antibody (BD Transduction) directed against human PLK1 protein was used on 5-μm paraffin sections. Antibody specificity has been ascertained by Western blot and immunohistochemistry in preceding expression studies[14,23]. For immunolabeling of Ki-67, a polyclonal rabbit antibody (Dako, Glostrup, Denmark) directed against human Ki-67 protein was used. As negative controls, slides were processed without primary antibody. For antigen retrieval, the deparaffinized slides were placed in 0.01 mol/L sodium citrate buffer, pH 6.0 and boiled for 5 min in a pressure cooker. Then slides were allowed to cool down for additional 5 min in the same buffer. After several rinses in TBS and pre-treatment with blocking reagent (Dako, Glostrup, Denmark) for 5 min, slides were incubated with primary antibody diluted 1:500 (PLK1) and 1:50 (Ki-67) in antibody diluent solution (Zymed, San Francisco, CA, USA) for 20 min at room temperature and then at 4 ℃ overnight. After the slides were washed in TBS, bound antibody was detected by applying a streptavidin-biotin system (BioGenex, San Ramon, CA, USA) following the standard protocol with standard antibody dilutions as supplied by the manufacturers. For color development, a fast red system (Sigma, Deisenhofen, Germany) was used. The slides were mounted using Aquatex (Merck, Gernsheim, Germany).

Double-immunostaining of cells

RKO cells were grown on Labtek chamber slides. Subconfluent cells were fixed in 100% methanol for 20 min at -20 ℃. For immunolabeling of PLK1, slides were processed as described above but without applying the pressure cooker. After the color developed, slides were washed in PBS and subsequently incubated with a 1:50 dilution of primary antibody directed against Ki-67 for 20 min at room temperature and subsequently at 4 ℃ overnight. After the slides were washed in TBS, bound antibody was detected by the peroxidase anti-peroxidase method following the standard protocol with standard antibody dilutions as supplied by the manufacturers (Dako). Color development was performed using a DAB+system (Dako). Finally, slides were mounted using Aquatex.

Evaluation of tissue staining

Staining intensity of tissue slides was evaluated independently by two pathologists who were blinded towards patients' characteristics and survival. Cases with disagreement were discussed using a multi-headed microscope until agreement

was achieved. To assess differences in staining intensity, an immunoreactivity scoring system (IRS) was applied. Intensity of staining was designated as negative (0), weak (1), moderate (2) or strong (3). Additionally, the percentage of positive cells was evaluated and scored as either no cells (0), less then 10% of cells (1), 10-50% of cells (2), 51-80% of cells (3) or over 80% of cells stained (4). By multiplication of these two parameters, the IRS for each case was calculated. Finally, cases were grouped as PLK negative (IRS 0-6) or PLK positive (IRS 7-12) for statistical analysis.

Statistical analysis

Statistical correlation between clinicopathological factors and expression of PLK1 was assessed by applying either Fisher's exact test, Spearman's rank order correlation or χ^2 test for trends. The probability of differences in overall survival as a function of time was determined by Kaplan-Meier analysis and log-rank test. Multivariate probing for significance was performed applying the Cox proportional hazard model. Generally $P<0.05$ was considered statistically significant. For all statistical procedures, SPSS v10.0 software was used.

RESULTS

PLK1 expression in colon tissue and cell lines

Normal colon mucosa from both the vicinity of benign and malignant tumors as well as from more distant sites showed a weak cytoplasmic staining of the epithelium at the basis of colon crypts (Figure 1). Staining was lost in the epithelium of apical parts of the crypts. A comparable staining in the epithelium was observed on serial sections for the proliferation marker Ki-67 (data not shown).

Occasionally, lymphocytes resident in normal colon mucosa showed moderate staining for PLK1 in the cytoplasm. Moderate PLK1 positivity was observed in autonomous neural plexus cells in the submucosa and muscularis propria of the colon. This staining served as an internal positive control.

None of the five adenomas of colon mucosa showed sufficient staining of PLK1 to be designated as PLK1 positive, although a weak patchy staining in the epithelium was observed in all cases (Figure 1).

Among the 153 colon cancers investigated, 102 (66.7%) were PLK1 positive in the neoplastic epithelium (Figure 1 and Table 1). Staining was inhomogeneous in a considerable number of cases with pronounced PLK1 positivity at the leading edge of tumor invasion. However, cases scored as PLK1 negative consistently showed a weak irregular staining for PLK1 in the cytoplasm as well (Figure 1). The tumor-associated inflammatory infiltrate occasionally expressed moderate amounts of PLK1, while all other stromal cells were PLK1 negative in all cases.

Overexpression of PLK1 in colon carcinoma compared to normal colon mucosa could be confirmed by immunoblotting in three of four matched samples of normal colon mucosa and colon carcinoma (Figure 2). In one case the tumor tissue showed a loss of expression in comparison to the normal colon mucosa.

In addition to the investigation of primary colon carcinoma tissue, we also tested four colon carcinoma cell lines for expression of PLK1 mRNA and protein. As shown in Figure 2, all cell lines expressed PLK1 mRNA measured by RT-PCR with a 1 807-bp band. On the protein level, PLK1 expression with an estimated size of 68 ku was

A considerable number of cells were PLK1 positive, but remained Ki-67 negative (arrowheads). Note cells in M-phase (small arrows) strongly expressing both proteins. Original magnifications **D**: ×200, **E**: ×500.

detected in all cell lines by immunoblot.

PLK1 and Ki-67 coexpression in primary colon carcinomas and RKO cell line

Since PLK1 plays a pivotal role in cell cycle control, we investigated the coexpression of Ki-67 and PLK1 in the colon cancer cell line RKO by immunolabeling both proteins consecutively on the same slide. As illustrated in Figure 2, simultaneous expression of PLK1 in cytoplasm and Ki-67 in nuclei was evident in the majority of cells. However, while almost all cells expressed PLK1, there was a considerable fraction of cells without simultaneous Ki-67 expression. Similar results were observed in serial sections of primary colon carcinoma tissue. Staining of serial sections of colon carcinomas with PLK1 and Ki-67 revealed no strict overlap between the expressions of both proteins though highly proliferating tumors (strong Ki-67 positivity) were more prone to overexpress PLK1.

Correlation of PLK1 expression with clinicopathological data

A highly significant positive correlation of PLK1 expression with either Dukes stage ($P<0.001$, χ^2 test for trends) and WHO tumor stage ($P = 0.001$, χ^2 test for trends) could be observed. More advanced tumors expressed significantly higher amounts of PLK1 than locally restricted carcinomas (Table 1). Additionally, a significant positive correlation of PLK1 expression with nodal status could be demonstrated ($P = 0.049$, χ^2 test for trends). This observation was further confirmed by a significant positive correlation ($P = 0.044$, $r = 0.163$, Spearman's rank order correlation) of the number of positive lymph nodes with ungrouped PLK1 score. We did not observe a correlation of PLK1 expression in colon cancer with patients' age, status of distant metastasis and tumor grade (Table 1)

Correlation of PLK1 expression with patient prognosis

Known prognostic parameters in colon cancer, as patients' age, Dukes stage, WHO tumor stage, lymph node status, status of distant metastasis and tumor grade were confirmed to have a significant impact on patient prognosis in this study (Table 2).

Additionally, PLK1 expression had a significant impact on patient prognosis both in the whole study cohort ($n = 153$, $P = 0.006$) and in the subgroup of patients without distant metastasis at the time of diagnosis ($n = 140$, $P = 0.012$). The mean survival time of patients in the PLK1 negative groups was 74.13 mo (whole group) and 76.36 mo (subgroup without distant metastasis), while the survival time was reduced to a mean of 63.75 mo (whole group) and 67.77 mo

In the whole study population, PLK1 expression failed to be a significant independent predictor of prognosis ($P = 0.091$, RR = 2.1). Independent prognostic predictors were patients' age, nodal status, state of distant metastasis and tumor grade (Table 3). In contrast, in the subgroup of patients without distant metastasis, PLK1 expression had a significant impact on patient prognosis in multivariate survival analysis. Patients with PLK1 positive tumors were approximately thrice (RR = 3.3, $P = 0.019$) more likely to die in the given time interval compared to their PLK1 negative counterparts. Again, patients' age, nodal status and tumor grade remained independent significant predictors of prognosis (Table 4).

DISCUSSION

To our knowledge, this is the first study showing an adverse effect of PLK1 overexpression on the prognosis of patients with colon cancer. This effect remains independently significant in the clinically important subgroup of patients without known distant metastasis.

In the present study, PLK1 was overexpressed in 66.7% of colon cancers and overexpression was positively linked to tumor stage and lymph node status, two parameters

that determine the extent of tumor burden. This is in line with the results of Takahashi *et al*.[21]. In another study by Macmillan *et al*.[24], increased PLK1 transcription levels were observed in colon carcinoma.

PLK1 overexpression in malignancies seems to be a common event, since it has been observed in a variety of different neoplasms, including cancer of stomach[10], esophagus[10], breast[11], endometrium[12], ovary[13], brain[14], head and neck[15], skin[16], lung[17], prostate[18], thyroid[19], liver[20], and colon[21]. Effects of PLK expression on patient prognosis have already been reported in a variety of other tumor entities, including esophageal carcinoma[10], ovarian carcinoma[13], carcinoma of head and neck[15], non-small cell lung carcinomas[17], and hepatoblastoma[20].

Among the possible functions of PLK1 overexpression in tumor biology, the most important factor might be the central role of PLK1 in mitotic regulation. PLK1 initiates mitosis by the activation of cdc25 and cyclin B1 via direct phosphorylation. Both events lead to an accumulation of cdc2/cyclin B1 complex in the nuclei, a precondition known to be crucial for the onset of mitosis[25,26]. Later in mitosis, PLK1 triggers the dissociation of cohesins from their chromosomal binding sites[27] and activates the anaphase-promoting complex[28]. The central involvement of PLK1 in mitosis of malignant cells is supported bys findings in several tumor entities including colon cancer[21], showing that PLK1 expression correlated positively with markers of cell proliferation.

Nevertheless, there are several arguments supporting the theory that additional functions of PLK1 must exist. First, only a part of the variety of PLK1 expression can be explained by mitotic activity. Second, we observed expression of PLK1 in irreversibly postmitotic cells such as neuronal ganglion cells. Third, PLK1 expression is unlikely to reflect cell proliferation exclusively, since we observed cases with strong PLK1 expression in almost 100% of tumor cells (Figure 1), a number that by far exceeds the rate of cells that can be expected to be in G_2/M phase. Finally, we could show that PLK1 expression is not strictly confined to cycling cells by double staining of colon cancer cells. Additional functions of PLK1 in tumor biology may have something to do with its ability to control microtubule dynamics[9], which is not only essential in mitosis but also important in golgi protein transport and cytoskeletal formation and rearrangement. These possible additional roles of PLK1 overexpression in tumor biology should be subjected to further functional studies.

Another explanation for the cause of PLK1 deregulation might be that either enhanced transcription by altered intracellular signal transduction or chromosomal over-representation of the respective gene locus leads to high cellular protein levels, which in turn enhance mitotic activity. In fact, chromosomal amplifications of 16p12, the gene locus of PLK1 has been described in human colorectal carcinomas[29].

Most recently, several groups found that inhibition of PLK1 expression in cancer cells of various tumor entities leads to a dramatic decline in cell proliferation[23,30] and to an induction of apoptosis[31]. These results suggest that PLK1 is an attractive target for novel chemotherapeutic approaches. Expression studies, like ours, may thus provide the translational basis for such new therapeutical approaches.

In summary, PLK1 is overexpressed in 66.7% of colon cancers, overexpression of PLK1 is linked to advanced tumor stages in this disease and can be considered as a new independent prognostic marker for colon cancer patients with locoregional disease.

Abstract

AIM: To study the effect of *SNC19/ST14* gene overexpression on invasion *in vitro* of colorectal cancer cells.

METHODS: The adhesion of *SNC19/ST14* gene-transfected cells to ECM was measured by MTT assay. The cell movement was evaluated by wound healing assay. Cell invasion and migration were determined by invasion assay *in vitro*.

RESULTS: *SNC19/ST14* gene overexpression could enhance invasion of colorectal cancer cells *in vitro* significantly and influence early cell adherence to ECM, but could not change cell movement significantly.

CONCLUSION: *SNC19/ST14* gene overexpression increases the local invasion of colorectal cancer cells *in vitro*.

INTRODUCTION

SNC19/ST14 is recently found to be a new member of the serine protease family[1]. *SNC19* gene has been isolated from a subtractive cDNA library of colorectal cancer by Cancer Institute of Zhejiang University, and is uploaded in the GenBank in 1995[2-4], and designated as *ST14* (suppression of tumorigenicity 14) by Gene Nomenclature Committee in 1998[5]. From then on, homologous products of *SNC19/ST14* have been found in many types of tissue cells, cell lines, and milk. SNC19/ST14 protein is designated as ST14/MT-SP1/matriptase/TADG-15, EC 3.4.21. SNC19/ST14 could convert hepatocyte growth factor (HGF)/scattering factor to its active form, and activate c-Met tyrosine phosphorylation[5]. Further, protease-activated receptor 2 (PAR2) and single-chain urokinase plasminogen activator (sc-uPA) have been identified as substrates of *SNC19/ST14/MT-SP1/matriptase/TADG-15*[6].

The uPA and HGF/SF are closely correlated with ECM degradation, growth, movement, and metastasis of cancer cells[7]. The SNC19/ST14 protein could also directly degrade ECM[8,9]. Studies suggest that *SNC19/ST14* is highly expressed in prostate, breast, and cervical cancer tissue[10-12]. The results suggest that *SNC19/ST14* and its human ortholog may play an important role in cell migration, cancer invasion, and metastasis. To know the detailed information on how the *SNC19/ST14* takes part in tumor invasion and metastasis, we compared the change of adhesion, movement, migration, and invasion of the stable *ST14*-transfected colorectal cancer cell clones to vector alone-transfected clones.

MATERIALS AND METHODS

Cell culture

RKO, a colorectal cancer cell line, *SNC19/ST14*-transfected (RKO-ST14-1) and vector alone-transfected colorectal cancer cell clones (RKO-pSecTag) were grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum (Gibcol Inc.), penicillin (50 U/mL), streptomycin (50 g/mL), glucose (4 500 mg/L), L-glutamine (2 mmol/L) and Zeocin™ (600 mg/mL), then incubated at 37 ℃ in a humidified 95% air, 50 mL/L CO_2. Culture medium was changed on alternate days to avoid nutrient depletion.

Cell adhesion assay

Polystyrene 96-well plates (Costar) were coated with 50 μL/well of 8 μg/mL ECM (Sigma, USA), and left uncovered in a laminar flow hood overnight to allow evaporation. The plates were then rinsed with PBS and used for the attachment assays. Cells were washed thrice with PBS, trypsinized and seeded into 200 μL cells at a density of 2×10^5/mL on ECM. After 1, 2, 6, and 12 h of incubation at 37 ℃, the wells were gently rinsed thrice with PBS to remove unattached cells. The remaining cells in 96-well plates were reacted with

MTT for 4 h at 37 ℃, then solved with DMSO. The absorbance of each well was measured at 570 nm. Results were expressed as the percentage of total cells assuming that the adhesion of cells in control was 100%. The percentage of adhesion was determined using the formula: (A570 nm after being rinsed with PBS/A570 nm no rinse)×100%. The experiments were performed in triplicate.

Wound healing assays

Confluent monoplayers were serum starved for 24 h and washed with PBS, and wounds were made with a pipette tip. After cell debris were removed, the cultures were incubated in DMEM alone or containing fetal calf serum. After 24 and 48 h, healing was evaluated under a phase contrast microscope and photographed at 200×magnification under a Zeiss microscope (Germany). The movement distance of the wounded cells was measured by ImageJ software.

ECM invasion assay

Invasion assays were carried out, following the manufacturer's instructions of cell invasion assay kit (Chemicon International Inc., catalog: ECM550). For the invasion assay, we used a modified Boyden chamber. The chamber has two compartments divided by a polycarbonate filter (8 μm pore size) coated by a reconstituted basement membrane (ECMatrix™ solution). RKO, pSecTag vector controls (RKO-pSecTag), ST14-transfected cell clones (RKO-ST14-1) were grown in DMEM and harvested in PBS. After centrifugation the cell pellets were suspended in serum-free DMEM and 1.5×10^5 cells were placed into the upper chamber and 500 μL DMEM containing 10% fetal calf serum was added into the bottom chamber. Cells were incubated for 48 h at 37 ℃ in 50 mL/L CO_2. The non-invading cells and the ECMatrix gel were gently removed from the upper chamber with cotton-tipper swabs, and the filters were stained in the staining solution for 20 min and rinsed several times in water and air dried. Three filters were used for each cell type. The number of invading cells was counted in 10 random high-powered (HP) fields per filter under a Zeiss microscope.

Statistical analysis

The data were expressed as mean±SD and compared by ANOVA and Student's *t*-test. $P<0.05$ was considered statistically significant.

RESULTS

SNC19/ST14 transfectants adhesion to ECM in vitro

After 1 and 2 h, the percentage of ST14 transfectant (RKO-ST14-1) adhesion to ECM was about 5.1% and 32.3%, respectively, and significantly decreased compared to the wild type (RKO) and vector-transfected control (RKO-pSecTag) ($P<0.05$). But after 6 and 12 h, their difference in cell adhesion to ECM was not significant ($P>0.05$, Figure 1, and Table 1).

Table 1 Percentage of cell adhesion to ECM (mean±SD)

Cell type	1 h	2 h	6 h	12 h
RKO	12.0±1.8	52.7±6.5	59.7±2.9	98.5±0.6
RKO-pSecTag	7.6±1.8	42.8±1.6	56.5±3.4	93.4±0.6
RKO-ST14-1	5.1±1.9[a]	32.3±0.8[a]	55.6±5.7	88.5±2.0

[a]$P<0.05$ *vs* RKO and RKO-pSecTag.

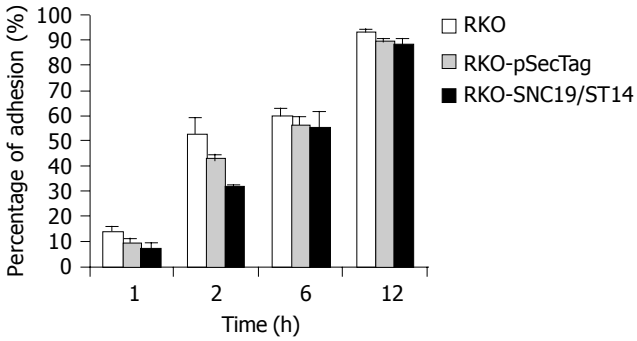

Figure 1 Percentage of cell adhesion to ECM.

SNC19/ST14 transfectants did not increase cell movement in vitro

There was no significant difference in movement distance between RKO-ST14-1 and vector-transfected cells (RKO-pSecTag) ($P>0.05$), but the movement distance of RKO-ST14-1 cells had a tendency to increase (Figure 2 and Table 2).

Table 2 *In vitro* cell movement assay (cm, mean±SD)

Cell	24 h	48 h	*P*
R-P-media	0.56±0.24	0.44±0.08	0.22
R-S-media	0.73±0.56	0.72±0.45	0.15
R-P-serum	0.97±0.07	1.01±0.27	0.37
R-S-serum	1.15±0.46	1.11±0.6	0.70

SNC19/ST14 transfectants increased cell invasion in vitro

The number of invasive cells per HP field of *SNC19/ST14* transfected clones (RKO-ST14-1), vector-transfected cells (RKO-pSecTag) and wild type cells (RKO) were 64.5±7.3, 44.9±7.0, and 32.6±4.1, respectively. RKO-ST14-1 cells show a significantly increased the cell invasion as compared to wild type cells (RKO) and vector-transfected control (RKO-pSecTag) (Figure 3 and Table 3), suggesting that the ST14 protein might promote invasion of colorectal cancer cells.

Table 3 *In vitro* cell invasion assay (n = 30, mean±SD)

Cell line	Cell number/HP	*P*
RKO	32.6±4.1	0.000018
RKO-pSecTag	44.9±7.0	0.00009
RKO-ST14-1	64.5±7.3	

DISCUSSION

Tumor progression and metastasis can be considered as a cascade of events and a continuous selection process, which includes ECM recognition, matrix degradation, migration,

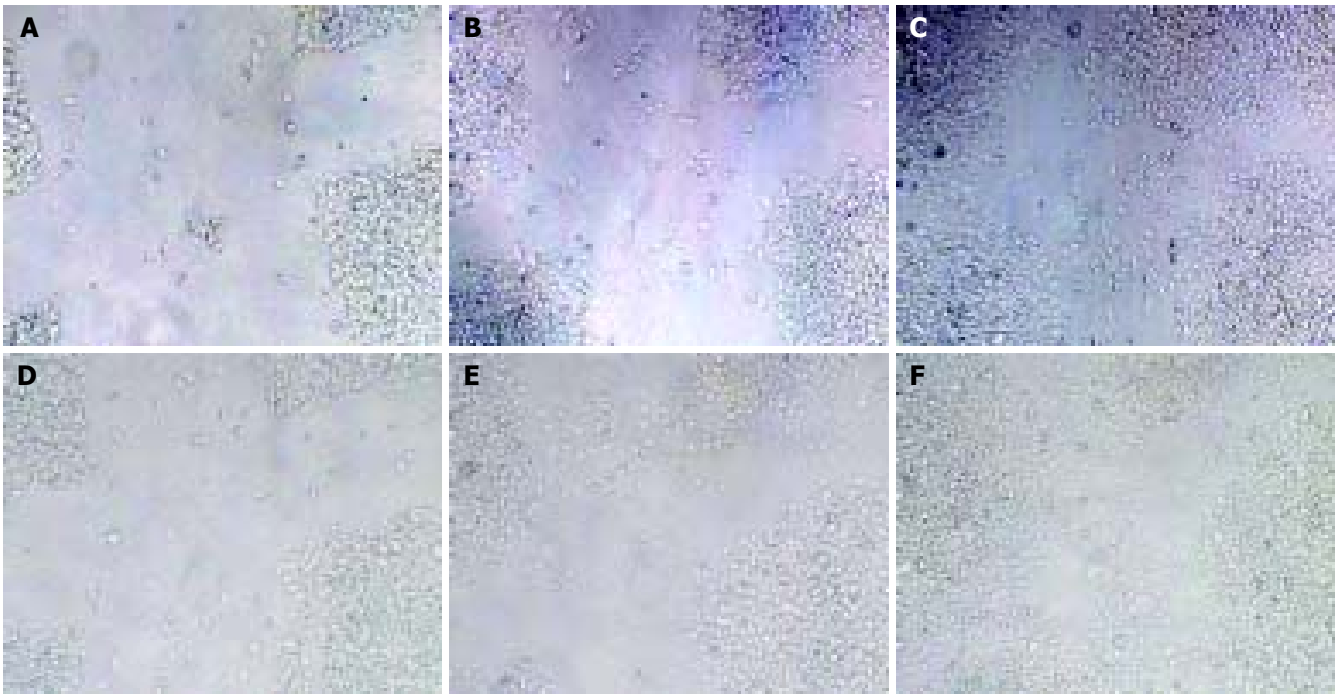

Figure 2 Wounding healing assay in wounds of RKO-ST14-1 (**A**), RKO-pSecTag (**D**), RKO-ST14-1 and RKO-pSecTag after 24 h (**B** and **E**) and 48 h (**C** and **F**).

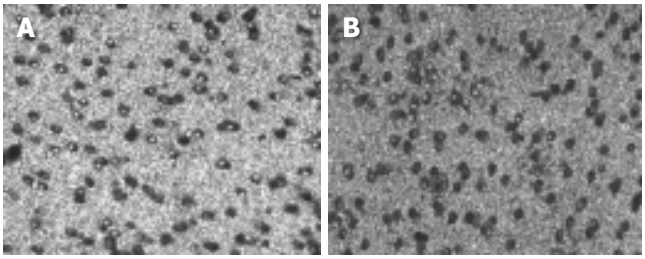

Figure 3 Cell invasion assay (200×). RKO-pSecTag (**A**) and RKO-ST14-1 (**B**).

hematogenous dissemination and organ selection metastasis[13]. It is accepted that malignant cell-ECM interaction must be considered as the key feature of malignancy. Malignant cells must recognize and degradate ECM before invasion and metastasis. Therefore, it is important to study matrix degrading enzymes for understanding and controlling the metastasis. The serine protease is a member of these ECM-degrading enzymes family. SNC19/ST14 protein has been recently found to be a new member of type II transmembrane serine protease (TTSPs)[1].

In our experiments, the SNC19/ST14 protein could enhance cell invasion *in vitro* when it was overexpressed in colorectal cancer cells. The final results of cell adhesion, degradation, and movement were evaluated by ECM invasion assay *in vitro*. In this study, although SNC19/ST14 overexpression could decrease cell adhesion to ECM in a short time, after 6 h this change was not observed. Besides, *SNC19/ST14* overexpression could not increase cell movement. Since *SNC19/ST14* overexpression could not induce cell cycle, apoptosis and proliferation, we believe that SNC19/ST14 enhancing cancer cell invasion results from increased ECM degradation.

There are several reasons to explain why *SNC19/ST14* overexpression could increase ECM degradation. Firstly, *SNC19/ST14* protein has extracellular matrix-degrading activity[8,9]. Secondly, SNC19/ST14 protein can activate HGF and uPA *in vitro*[6]. HGF and uPA have been implicated in cancer invasion and metastasis due to their cellular motility, extracellular matrix degradation, and tumor vascularization[14,15]. As a protease, uPA is best known to convert zymogen plasminogen into active plasmin. Plasmin promotes degradation of diverse ECM substrates such as fibrin, fibronectin, and laminin[16], activates certain matrix metalloproteases (MMPs) to allow further degradation of ECM, especially interstitial and type IV collagen. Therefore, uPA can promote metastasis by degrading ECM and permitting local invasion. Besides, HGF increases the expression of uPA and its receptor (uPAR)[18], and HGF precursor (pro-HGF) can be activated by uPA[19].

In conclusion, SNC19/ST14 can directly degrade ECM and activate uPA and HGF/SF to enhance ECM degradation, which might be one of the reasons why *SNC19/ST14* overexpression enhances local invasion and tumor metastasis.

Abstract

AIM: To observe the status of tumor-associated B_7 molecule mRNA expression in human colorectal cancer tissue by *in situ* hybridization.

METHODS: The mRNA expression patterns of cancer-associated $B_{7\text{-}1}$,B_7H_1,B_7H_2,ICOS in 22 specimens of human colorectal cancer tissue were monitored by *in situ* hybridization (ISH) with digoxin-labeled oligonucleotide probes.

RESULTS: $B_{7\text{-}1}$,B_7H_1,B_7H_2,ICOS mRNA were detected in both cancer cells and tumor infiltrating lymphocytes (TIL). The mRNA expression level of these molecules in tumor cells was higher than that in TIL (0.76±0.54-1.62±0.82 *vs* 0.38±0.19-0.65±0.33, $P<0.001$). There was no relationship between expression level of tested B_7 family molecules and patients' sex, age, differentiation status of cancer and regional lymph node metastasis.

CONCLUSION: Th2 cytokine predominant in tumor microenvironment might be related to the expression of B_7H_1,B_7H_2 co-signal molecules in tumor cells and TIL.

INTRODUCTION

Although it has been well accepted that human tumor is immunogenic, most patients suffering from cancer are destined to die due to tumor progress. Establishment of the bisignal model for T-cell activation leads people to think that inactivation of infiltrating immune potential cells in tumor tissue might be immune anergic owing to the deficiency of co-stimulatory molecules. Tumor cells modified with B_7 co-stimulatory molecule gene could be rejected by tumor bearing host[1,2], but most human cancer tissues express co-stimulators[3,4], suggesting that co-stimulatory molecules might not be the only mechanism of immune evasion. The tumor-associated B_7H_1 and B_7H_2, new members of B_7 family can preferentially stimulate the production of IL-10, promote activated T cell apoptosis[5].

In the present study, the status of tumor-associated B_7 molecule mRNA expression in human colorectal cancer tissue was observed using B_7H_1, B_7H_2 and ICOS cDNA probe, *in situ* hybridization. The results showed that $B_{7\text{-}1}$, B_7H_1, B_7H_2, ICOS mRNA were expressed in both cancer cells and tumor infiltrating lymphocytes (TIL), indicating that Th2 cytokine predominant in tumor microenvironment might be related to the expression of B_7H_1, B_7H_2 co-signal molecules in tumor cells and TIL. Elucidation of tumor-associated B_7 molecules may contribute to the design of T cell-based cancer immunotherapy.

MATERIALS AND METHODS

Samples

Tissue samples were obtained from 22 patients with colorectal cancer. The specimen were fixed in 4 g/L formaldehyde in phosphate-buffered saline (PBS) immediately and embedded in paraffin. Serial sections (5 μm in thickness) were cut for *in situ* hybridization or histological evaluation, and mounted on slides covered with APES, dried overnight at 65 ℃, stored at -70 ℃ until use. The diagnosis of colorectal carcinoma was histopathologically verified in all cases. None of the patients had previously received radio-, chemo-, or immunotherapy.

Preparation of oligonuleotide probes

Primer 3 software was used to design oligonuleotide probes complementary to the mRNA of all kinds of target sequences including $B_{7\text{-}1}$, B_7H_1, B_7H_2, ICOS mRNA. The specificity of all oligonucleotide probes was analyzed by BLAST software (www.ncbi.nih.gov). The probes were labeled by tailing the oligonucleotides with digoxigenin-11-dUTP kit (Boehringer Mannheim, German). A labeling activity of 1.56 nmol/L was obtained (Primer3 http://www.genome.wi.mit.edu/cgi-bin/primer/Primer3;BLAST http://www.ncbi.nlm.gov/cgi-bin/BLAST). Sequence of oligonuleotide probes of co-stimulatory molecules was tested ($B_{7\text{-}1}$: 5'-CAT GAA GCT GTG GTT GGT TG -3'; B_7H_1:

5'-TGC TTG TCC AGA TGA CTT CG -3'; B_7H_2: 5'-CCA TCG CTC TGA CTT CCT TC -3'; ICOS: 5'-TTC AGC TGG CAA CAA AGT TG-3').

In situ hybridization (ISH)

Diethyl pyrocarbonate (DEPC) water was used for all solutions necessary for ISH. The sections were deparaffinized in xylene and rehydrated in descending ethanol, followed by digestion with 1 g/L proteinase K at 37 ℃ for 30 min and terminated with 20 g/L glycine in PBS for 5 min. Then, the sections were refixed in 40 g/L polyformaldehyde for 20 min, washed with PBS for 10 min, treated with 0.2 mol/L HCI for 10 min and washed with DEPC water for 3 min. The sections were dehydrated in ascending gradient ethanol, air-dried and followed by prehybridization at 42 ℃ for 2 h. Hybridization reaction was carried out at 42 ℃ for 22 h. Then the sections were washed with gradient SSC thoroughly and followed by treatment with digoxin antibody at 37 ℃ for 2 h. The color was developed in NBT-BCIP substrate, then counterstained with 10 g/L methyl green in distilled water, dehydrated and mounted with neutral gum.

For negative controls, probes and antibodies were replaced by PBS or the slides were treated with RNase A (20 mg/L) at 37 ℃ for 30 min. $B_{7\text{-}1}$ mRNA expression in mononuclear leucocytes was used as positive control.

Evaluation of results

Purple blue precipitation in cytoplasm under light microscope was considered as positive signal, and 5 high power fields were randomly chosen from each slide, The percentage of positive cells and the positive cell index (total positive granule number/positive cell number) were calculated. Intensity of the color reaction was classified into 4 grades: strongly positive (+++), positive (++), weakly positive (+) and negative (-) and scored as 3, 2, 1 and 0, respectively. The Accumulation index was determined as percentage of positive cells multiply intensity score.

Statistics analysis

All datas were expressed as mean±SD. Analysis was performed by using chi-square test and Spearman correlation analysis with SPSS 11.0 software. $P<0.05$ was considered statistically significant.

RESULTS

Expression of $B_{7\text{-}1}$, B_7H_1, B_7H_2, ICOS mRNA was detected in both cancer cells and tumor infiltrating lymphocytes (Figure 1). The mRNA expression level of these molecules in tumor cells was higher than that in TIL (0.76±0.54-1.62±0.82 *vs* 0.38±0.19-0.65±0.33, $P = 0.000$). However, when the expression of B_7 family mRNA was analyzed with respect to the tested members, there was a significant difference in B_7H_1 and ICOS expression between TIL and cancer cells ($P<0.05$). The expression of B_7H_1 and ICOS mRNA was higher in tumor cells and TIL. The expression of B_7 family molecules either in tumor cells or in TIL was not correlated with patients' sex, age, differentiation status of cancer and regional lymph node metastasis. B_7H_1 expression in TIL and tumor invasiveness was significantly associated with the intensity and the depth of tumor invasion ($P = 0.050$, Tables 1-3).

DISCUSSION

It has been accepted that the efficacy of antitumor immunity is mainly affected by three factors, namely status of tumor immunogenecity, expression of co-stimulatory molecules and type of cytokines. Lack of co-stimulatory molecules in tumor cells might be a reasonable explanation of the tumor immune evasion, but the fact that most human cancer tissues express co-stimulators makes it contradictory. Si *et al.*[3], reported that $B_{7\text{-}1}$ molecule expresses at least in more than half of human solid tumors. MHC-I, II molecules are detectable in human cervical cancer and tumor-associated dendritic cell (DC)[4]. Analysis of tumor microenvironment has demonstrated that type II cytokines are predominant in non-small cell lung cancer and gastric carcinoma[5,6]. Interestingly there is a dynamic change with the progress of tumor, i.e. the expression of IFN-γ and IL-2 decreases, whereas the expression of Th2 cytokines such as IL-4, IL-10 and TNF-β increases significantly.

There is evidence that co-stimulators play a very important role in antigen-specific T cell activation. *In vitro* and *in vivo* experiments have shown that T cell interaction via T-cell receptor (TCR) with MHC/antigen complexes in the absence of co-stimulation may lead to induction of anergy rather than activation. $B_{7\text{-}1}$ gene-modified tumor cells can elicit tumor rejection response in xenograft tumor models. All these suggest that deficiency of co-stimulators is the key factor for immune evasion. However, Dong *et al.*[7], found that CD_{28} by its natural legend $B_{7\text{-}1}$ or $B_{7\text{-}2}$ triggers Th1 cytokine secretion including IFN-γ and IL-2, while IL-10 production is increased considerably after stimulation with immobilized B_7H_1Ig and antibody against CD_3. Dynamic observation has demonstrated that the production of IL-2 peaks 24 h after B_7H_1 co-stimulation, whereas IL-10 secretion starts to increase after 48 and 72 h. Additionally, monoclonal antibody against IL-2 could inhibit IL-10 secretion from T cells co-stimulated with B_7H_1Ig. ICOS, one of the B_7 legends, plays a critical and non-dispensable role in T cell activation and proliferation *in vitro*, especially in regulating Th2 differentiation. In addition, it is critical for efficient T-cell priming and production of Th2 cytokines *in vivo*, in particular IL-4 and IL-10. Results obtained from some experiments demonstrated that Ag stimulation of naive $CD4^+$ T cells in the absence of ICOS signal results in impaired Th2 development[8]. At the molecular level, ICOS is involved in upregulating the expression of CD40L as well as promoting the secretion of IL-4 and IL-13. ICOS is a co-stimulatory receptor essential for T-cell activation and function and also plays an important role in acquired immunity[9,10]. This could well elucidate our previous findings, i.e. although expression of $B_{7\text{-}1}$ by human tumor cells can activate T cells and enhance the secretion of Th1 cytokines such as IL-2 and IFN-γ, Th2 cytokine predominates ultimately since co-stimulators such as B_7H_1, B_7H_2 and ICOS act dominantly.

In the present study, we observed that $B_{7\text{-}1}$ co-stimulatory molecule mRNA was expressed in tumor cells and tumor infiltrating lymphocytes (TIL) of human colorectal carcinoma by *in situ* hybridization, which is consistent with many experiments of B_7-gene transfection vaccine[11,12]. However, the other members of B_7 family such as B_7H_1, and ICOS can also be detected. In our study, the expression of B_7 molecules in tumor cells was higher than that in TIL (P<0.005), and B_7H_1 and ICOS mRNA expression in tumor cells was even higher than that of $B_{7\text{-}1}$, suggesting that B_7 family plays a role in tumor immunity. In addition, the expression of B_7H_1 and ICOS mRNA is related with the invasion depth of tumor, the mRNA expression of B_7H_1 and ICOS in both tumor cells and TIL is associated with the metastasis of colorectal carcinoma. A recent study on B_7 family molecules in tumor biological behavior demonstrated that aberrant expression of B_7H_1 in renal cell carcinoma apparently impairs T cell function and survival[13]. Our results and these data provide the morphological and clinical support to elucidate the role of B_7 co-stimulatory molecules in tumor immune evasion.

The present findings indicate that new members of B7 family such as B_7H_1, B_7H_2 and ICOS are involved in promoting TH2-based responses preferentially. More interestingly, it has been reported that tumor-associated B_7H_1 can promote apoptosis of antigen-specific human T-cell clones *in vitro*[14,15], and mouse P815 tumor -expressed B_7H_1 increases apoptosis of activated tumor-reactive T- cells and promotes the growth of highly immunogenic $B_{7\text{-}1}^+$ tumor *in vivo*[10]. These results suggest that induction of apoptosis of tumor-infiltrating lymphocytes by B_7H_1 molecules overexpressed in human colorectal carcinoma may be a potentially active escape strategy of various tumors from immune attack as is shown by Wintterle *et al.*[16].

Tumor escape is attributed to a variety of immune evasion strategies, including downregulation of MHC-I class molecules, regulatory T cells, Th2 cytokines, secretion of immunosuppressive factors from tumor cells or TIL, and lack of T-cell co-stimulation. Tumor local microenvironment plays an essential role in determining the final destiny of antitumor immunity[17].

The discovery of new members of B_7 family presenting different co-stimulatory effects indicates that different co-signaling molecules lead to different results, such as enhancement of T-cell Receptor (TCR)-mediated immune responses or inhibition of TCR-mediated immune responses. Tumor-associated B_7H_1 might produce tumor immune escape by promoting apoptosis of tumor-reactive T-cells and type II cytokine secretion through PD-1 ligand[18,19]. Hirano *et al.*[20], reported that B_7H_1/PD-1 forms a molecular shield to prevent destruction by CTL, suggesting that to block B_7H_1 or PD-1 by specific monoclonal antibodies could reverse this resistance and profoundly enhance therapeutic efficacy. Strome *et al.*[21], have shown the

feasibility of the new immunotherapy. With the suggestion of the concept of co-inhibitors[22], investigation of the functional characteristics of tumor-associated signal molecules may contribute to exploitation of T cell-based tumor immunotherapy.

Key words: Hepatitis C virus; F protein; Yeast two-hybrid system

Huang YP, Cheng J, Zhang SL, Wang L, Guo J, Liu Y, Yang Y, Zhang LY, Bai GQ, Gao XS, Ji D, Lin SM, Shao Q. Screening of hepatocyte proteins binding to F protein of hepatitis C virus by yeast two-hybrid system. *World J Gastroenterol* 2005; 11(36): 5659-5665
http://www.wjgnet.com/1007-9327/11/5659.asp

AIM: To investigate the biological function of F protein by yeast two-hybrid system.

METHODS: We constructed F protein bait plasmid by cloning the gene of F protein into pGBKT7, then recombinant plasmid DNA was transformed into yeast AH109 (a type). The transformed yeast AH109 was mated with yeast Y187 (α type) containing liver cDNA library plasmid in 2×YPDA medium. Diploid yeast was plated on synthetic dropout nutrient medium (SD/-Trp-Leu-His-Ade) containing X-α-gal for selection and screening. After extracting and sequencing plasmids from positive (blue) colonies, we underwent sequence analysis by bioinformatics.

RESULTS: Thirty-six colonies were selected and sequenced. Among them, 11 colonies were zymogen granule protein, 5 colonies were zinc finger protein, 4 colonies were zinc-α-2-glycoprotein, 1 colony was sialyltransferase, 1 colony was complement control protein factor I, 1 colony was vitronectin, and 2 colonies were new genes with unknown function.

CONCLUSION: The yeast two-hybrid system is an effective method for identifying hepatocyte proteins interacting with F protein of hepatitis C virus. F protein may bind to different proteins.

Hepatitis C virus (HCV) is the major etiologic agent of parenterally transmitted non-A, non-B hepatitis worldwide[1-3]. Most infected individuals are unable to eliminate the virus, resulting in a persistent infection in about 80% of cases. Chronically infected patients often develop progressive liver disease, cirrhosis, hepatic failure, and hepatocellular carcinoma (HCC)[4,5]. Because development of a robust cell culture system for HCV infection has remained elusive, little is known about HCV-host cell interactions and how they influence cell physiology or viral replication. There is no vaccine against HCV.

HCV, discovered by cDNA cloning in 1989, is a member of the Hepacivirus genus within the Flaviviridae family, and a 9.6-kb positive single-stranded RNA virus. The HCV genome carries a single open reading frame (ORF) flanked by nontranslated regions and encodes a single polyprotein of about 3 010-3 033 amino acids. HCV polyprotein is cleaved by both host cell and viral proteases into at least 10 distinct structural and nonstructural protein products. The major structural proteins are a core (C) protein and two envelope proteins called E1, E2 and a short hydrophobic peptide p7. Four major nonstructural proteins called NS2, NS3, NS4, and NS5 are also generated, two of which, NS4 and NS5 are further processed into smaller polypeptides called NS4A, NS4B, NS5A, and NS5B. Most nonstructural proteins have enzymatic activities critical for viral replication. An additional HCV protein, F (for "frameshift protein") or ARFP (for "alternate reading frame protein"), encoded by the ORF that overlaps the core gene in the +1 frame (core+1 ORF), is synthesized *in vitro* from the initiator codon of the polyprotein sequence followed by a +1 ribosomal frameshift operating in the region of core codons 8-14[6-9]. Antibodies to F protein have been detected in HCV patients, indicating the production of F protein during natural HCV infection[10,11]. The function of F protein in the life cycle of HCV remains unknown. To investigate the biological

importance of F protein, we screened and identified the proteins interacting with HCV F protein by yeast two-hybrid system. One of the positive interacting proteins, named HCV F-interacting protein (HCV FBP2), was without known function.

Bacterial yeast strains and plasmids

All yeast strains and plasmids for yeast two-hybrid experiments were obtained from Clontech Co. (Palo Alto, CA, USA) as components of the MATCHMAKER two-hybrid system 3. Yeast strain AH109 (MATa, *trp1-901*, *leu2-3*, *112*, *ura3-52*, *his3-200*, *gal4*△, *gal80*△, *LYS2*:*GAL1*$_{UAS}$-*GAL1*$_{TATA}$-*HIS3*, *GAL2*$_{UAS}$-*GAL2*$_{TATA}$-*ADE2*, *URA3*:*MEL1*$_{UAS}$-*MEL*$_{1TATA}$-*LacZ*) containing pGBKT7-53, coding for DNA-BD/mouse p53 fusing protein was used for cloning of bait plasmid. Yeast strain Y187 (MATa *ura3-52*, *his3-200*, *Ade2-101*, *trp1-901*, *leu2-3*, *112*, *gal4*△, *gal80*△, *met-*, *URA3*:*GAL1*$_{UAS}$-*GAL1*$_{TATA}$-*lacZ MEL1*) containing pTD1-1 in which pACT2 coding for AD/SV40 large T antigen fusing protein was used for cloning of library plasmids. Pretransformed human cDNA liver cell library Y187 and bacterial strain DH5a were used for cloning of each shuttle plasmid. Yeast-*Escherichia coli* shuttle plasmids pGBKT7 DNA-BD, pGADT7 AD, pGBKT7-53, pGADT7, pGBKT7-Lam, pCL1 were from Clontech Co. (K1612-1). pGEM T vector was from Promega Co., USA.

Chemical agents and culture media

Taq DNA polymerase was purchased from MBI Co. T4 DNA ligase, *Eco*RI, and *Bam*HI restriction endonuclease were from Takara Co. c-myc mAb secreted by 1-9E10.2 hybridoma (ATCC), goat anti-mouse IgG conjugated with horseradish peroxidase were from Zhongshan Co., China. Lithium acetate, semi-sulfate adenine, acrylamide and *N*, *N*'-bis-acrylamide were from Sigma Co., TEMED was from Boehringer Mannheim Co. Tryptone and yeast extracts were from OXOID Co. X-α-gal and cultural media YPDA, SD/-*Trp* SD/-*Leu*, SD/-*Trp*/-*Leu*, SD/-*Trp*/-*Leu*/-*His*, SD/-*Trp*/-*Leu*/-*His*/-*Ade* were from Clontech Co. Protein-G agarose was from Roche Co. pGEM-T vector was from Promega Co.

RT-PCR kit and TNT® coupled reticulocyte lysate systems were from Promega Co. [^{35}S]-methionine (1 000 Ci/mmoL, 10 mCi/mL) was from Isotope Company of China. Amplification fluorographic reagent (#NAMP100) was from Amersham Life Sciences Co. Others were from Sigma Co.

Construction of "bait" plasmid and expression of HCV F protein

HCV-F sequences were generated by PCR amplification of HCV plasmid (HCV strain 1b) containing coding sequences for all the structural and nonstructural proteins. The sequences of the primers, containing the *Eco*RI and *Bam*HI restriction enzyme sites, are sense primer: 5'-GAA TTC ATG GCA CGA ATC CTA AAC C-3', and antisense primer: 5'-GGA TCC CTA CGC CGT CTT CCA GAA C-3'. The PCR conditions were at 94 ℃ for 30 s, at 60 ℃ for 30 s, at 72 ℃ for 30 s. Ten nanograms of PCR product was cloned with pGEM-T vector. The primary structure of insert was confirmed by direct sequencing. The fragment of encoding F was released from pGEM-T-F by digestion with *Eco*RI and *Bam*HI, and ligated to pGBKT7. Vector pGBKT7 expressing proteins were fused with amino acids 1-147 of the GAL4 DNA binding domain (DNA-BD), pGADT7 expressing proteins were fused with amino acids 768-881 of the GAL4 activation domain (AD). Plasmid pGBKT7-F (Figure 1) containing full-length HCV F gene could directly express DNA binding domain, c-myc and F fusion protein. The plasmid was transformed into yeast strain AH109 by lithium acetate method[12]. Western blotting was performed to confirm the expression of the fusion protein using c-myc monoclonal antibody. Transformed AH109 (bait) was cultured on quadruple dropout media to exclude the auto-activation activity.

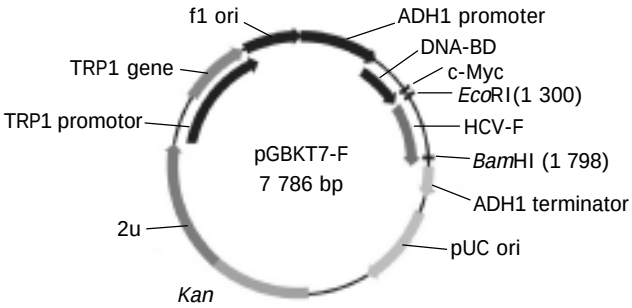

Figure 1 Map of "bait" plasmid pGBKT7-F.

Yeast two-hybrid library screening using yeast mating

One large (2-3 mm) fresh (<2 mo old) colony of AH109 [bait] was inoculated into 50 mL of SD/-*Trp* and incubated at 30 ℃ overnight (16-24 h) with shaking at 250-270 r/min. Then the cells were spun down by centrifuging the entire 50 mL culture at 1 000 r/min for 5 min. After the supernatant was decanted, the cell pellet was resuspended in the residual liquid by vortexing. A human liver cDNA library was cloned into pACT2 and yeast reporter strain Y187 (Clontech Co., USA). The entire AH109 [bait] culture and 1 mL human liver cDNA library (1×10^6 cfu/mL) were combined and cultured in a 2-L sterile flask and 45 mL of 2×YPDA/Kan was added and swirled gently. After 20 h of mating, the cells were spun down and resuspended, and then spread on 50 large (150-mm) plates containing 100 mL of SD/-*Ade*/-*His*/-*Leu*/-*Trp* (QDO). After growth for 6-15 d, the yeast colonies were transferred onto the plates containing X-α-gal to check for expression of the MEL1 reporter gene (blue colonies).

Plasmid isolation from yeast and transformation of E.coli with yeast plasmid

Approximately 1×10^6 colonies were screened and positive clones were identified. Yeast plasmid was isolated from positive yeast colonies by the lyticase method (Clontech Co.), and transformed into super-competence *E.coli* DH5α by chemical method. Transformants were plated on ampicillin SOB selection media and grown under selection. Subsequently, pACT2-cDNA constructs were re-isolated, and analyzed by

restriction digests and sequencing.

Bioinformatic analysis

After the positive colonies were sequenced, the sequences were blasted with GenBank to analyze the function of the genes (http://www.ncbi.nlm.nih.gov.blast).

Cell culture and new gene cloning

The hepatoblastoma cell line HepG2 was propagated in DMEM supplemented with 10% FBS, 200 μmol/L L-glutamine, penicillin, and streptomycin. HepG2 cells were plated at a density of 1×10^6/well in 35-mm dishes. Total cellular RNA was isolated using TRIzol (Invitrogen Co., USA) according to the manufacturer's instructions. cDNAs were reverse-transcribed from total RNA.

On the basis of liver cDNA library of genes of proteins interacting with HCV-F protein, the coding sequence of a new gene with unknown function, named HCV FBP2, was obtained by bioinformatics methods. The sequence of HCV FBP2 was deposited into GenBank, and the accession number was AY553876. The standard PCR cloning technique was used to amplify HCV FBP2 gene. Cytoplasmic RNA was isolated from HepG2 cells. RNA was used for RT-PCR. The primers were sense: 5'-GGA TTC ATG CCA TAT ATT CCT CTCA-3', and antisense: 5'-GGA TCC CTA ATA CAA ATG TAT GTG G-3' (HepG2 cDNA). The PCR conditions were at 94 ℃ for 60 s, at 58 ℃ for 60 s, at 72 ℃ for 60 s, for 30 cycles. The PCR product was cloned with pGEM-T vector (Promega Co.). The primary structure of insert was confirmed by direct sequencing. The gene was ligated into yeast plasmids pGBKT7 and pGADT7.

Confirmation of true interaction in yeast

To confirm the true protein-protein interaction and exclude false positives, the plasmids of positive colonies were transformed into yeast strain Y187, then mating experiments were carried out by mating with yeast strain AH109 containing pGBKT7-F or pGBKT7-Lam. After mating, the diploid yeast was plated on SD/-*Ade*-*His*-*Leu*-*Trp* (QDO) covered by X-α-gal to test the specificity of interactions.

In vitro translation

Twenty-five microliters of mixture of TNT® reticulocytes, 2 μL TNT® reaction buffer, 1 μL T7 TNT® RNA polymerase, 1 μL amino acid mixture (minus methionine, 1 mmol/L), 2 μL [^{35}S]-methionine, 1 μL RNasin RNase inhibitor (40 U/mL), 2 μL DNA template (pGBKT7-F or pGADT7-library gene) (0.5 μg/mL), 16 μL ddH_2O, were incubated at 30 ℃ for 90 min.

Co-immunoprecipitation

Following reactants were combined in a 1.5-mL microcentrifuge tube on ice: 5 μL *in vitro* translated bait protein, 5 μL *in vitro* translated library protein. Only 10 μL pGBKT7-F plasmid was added into the control. The mixtures were incubated at 30 ℃ for 1 h. Then, the following reagents were added into the reaction tubes: 470 μL co-immunoprecipitation buffer (20 mmol/L Tris-HCl [pH 7.5], 150 mmol/L NaCl, 1 mmol/L DTT, 5 μg/mL aprotinin, 0.5 mmol/L PMSF, 0.1% Tween 20), 10 μL protein-G agarose beads, 10 μL c-myc mAb, and incubated at 4 ℃ for 2 h with continuous shaking. The tubes were centrifuged at 14 000 *g* for 1-2 min. The supernatants were removed, 0.5 mL TBST was added to the tubes. Rinse was repeated thrice, 15 μL SDS-loading buffer was added. The samples were heated at 80 ℃ for 5 min. The tubes were placed on ice, and briefly centrifuged, and 10 μL was loaded onto an SDS-PAGE mini-gel for electrophoresis. After electrophoresis, the gel was transferred onto a tray containing gel fixation solution, and placed on a rotary shaker for 10 min at room temperature. The gel was rinsed with H_2O, then amplification fluorographic reagent was added and shook for 20 min at room temperature, then dried at 80 ℃ under constant vacuum. The gel was exposed to X-ray film overnight at room temperature. The film was developed by standard techniques.

Identification of recombinant plasmid

The full-length sequences of HCV F were generated by PCR amplification of HCV plasmid (HCV strain 1b), and a 840-bp fragment of HCV FBP2 was amplified by RT-PCR after total RNA was isolated from HepG2 cells, sequenced and analyzed by comparing to Vector NTI 6 and BLAST database homology search (http://www.ncbi.nlm.nih.gov/blast). After being cut by *Eco*RI/*Bam*HI, the fragments were in-frame ligated respectively into pGBKT7 and pGADT7 *Eco*RI/*Bam*HI sites. Restriction enzyme analysis of pGBKT7-F, pGBKT7-FBP2, and pGADT7-FBP2 plasmids with *Eco*RI/*Bam*HI yielded two bands respectively: 7 300 bp empty pGBKT7 and 486 bp HCV F, 7 300 bp empty pGBKT7 and 840 bp HCV FBP2, 7 900 bp empty pGADT7 and 840 bp HCV FBP2. The products of plasmid were amplified by PCR. Analysis of the PCR products by agarose gel electrophoresis showed the clear bands with the expected size (486 bp of F, 840 bp of FBP2). Sequences of the PCR products were correct (Figures 2A-D).

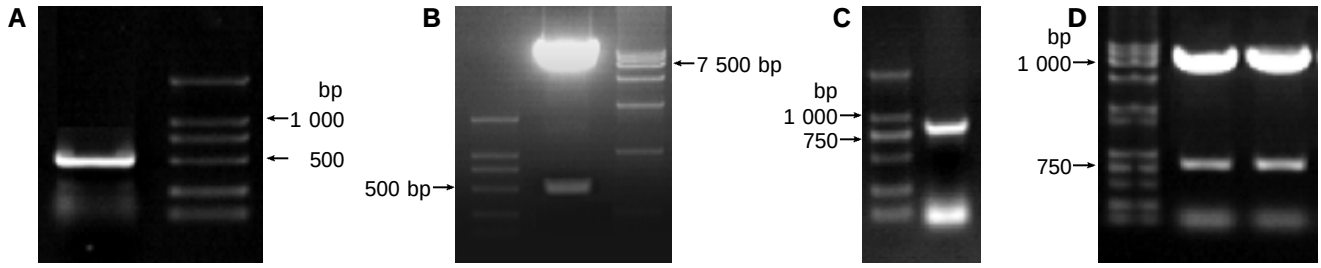

Figure 2 Sequences of PCR products A: a 486-bp fragment-F amplified by RT-PCR; B: pGBKT7-F cut by *Eco*RI/*Bam*HI; C: a 840-bp fragment-FBP2 amplified by RT-PCR; D1: pGBKT7-FBP2; D2: pGADT7-FBP2 cut by *Eco*RI/*Bam*HI.

Expression of "bait" fusion protein

Yeast strain AH109 transformed with pGBKT7-F and pGBKT7-FBP2 stably expressed the fusion protein at high level (Figure 3) and only grew on SD/-*Trp* medium but not on QDO medium. Thus, the transformed yeast could be used for yeast hybrid analysis.

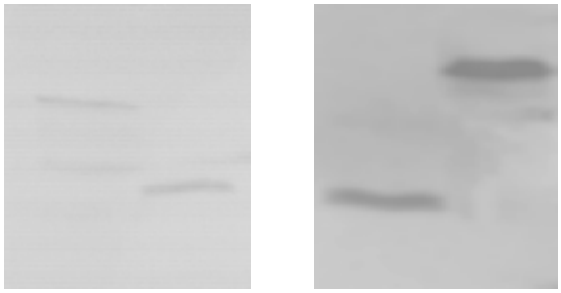

Figure 3 Expression of HCV F and HCV FBP2 proteins in yeast . Lane 1: HCV F protein; lane 2: positive control; lane 3: HCV FBP2 protein.

Screening of liver cell cDNA library

We isolated plasmids from the blue colonies containing only pGBKT7-F and one library plasmid other than other plasmids. Because plasmid pACT2- cDNA contains two restriction endonuclease sites of *Bgl*II, the gene fragments of the liver cell cDNA library (pACT2- cDNA) were released by *Bgl*II digestion (Figure 4). The gene fragments with different lengths proved that these screened clones were positive colonies but not false positive colonies growing on SD/-*Trp*/-*Leu*/-*His*/-*Ade* culture medium after mating .

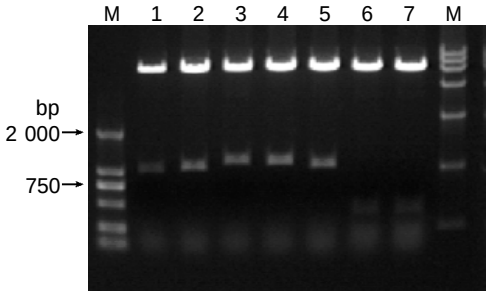

Figure 4 Identification of different colonies by *Bgl*II digestion.

Analysis of cDNA sequence and homology

A total of 36 positive colonies were grown on the selective SD/-*trp*-*leu*-*his*-*ade*/X-α-gal medium. These colonies were prescreened by *Bgl*II digesting to make sure that only colonies with different inserts were subjected to sequencing. Thirty-six colonies from cDNA library were sequenced. Using the BLAST program from the National Center for Biotechnology Information, two of the sequences were unknown genes and one of them was named as HCV FBP2. The full-length sequences accepted by GenBank were obtained by bioinformatics method. The other 34 sequences had a high similarity to known genes. The data are presented in Table 1.

Table 1 Comparison between positive clones and similar sequences in GenBank

High similarity to known genes	Similar number	Homolog (%)
Homo sapiens zymogen granule protein 16	11	99
Homo sapiens zinc-alpha-2-glycoprotein	4	99
Highly similar to *Homo sapiens* SL15 protein	5	100
Homo sapiens RAB14, member RAS oncogene family	1	98
Human mRNA for complement control protein factor I	1	98
Homo sapiens angiotensinogen (serine or cysteine) proteinase inhibitor, clade A (alpha-1 antiproteinase, antitrypsin), member 8)	1	97–99
Homo sapiens sialyltransferase 1	1	97
Similar to *Homo sapiens* zinc finger protein 83	5	100
Homo sapiens mRNA for peroxisomal ion protease	2	100
Homo sapiens cathepsin B mRNA	1	99
Homo sapiens vitronectin (serum spreading factor, somatomedin B, complement S-protein)	1	100
Homo sapiens serine (or cysteine) proteinase inhibitor, clade G (C1 inhibitor), member1	1	99
Homo sapiens genes of unknown functions	2	

Back-across testing

We confirmed the protein-protein interaction between HCV F and a new gene named as HCV FBP2 by back-across in yeast. Expressive vector pGADT7-HCV FBP2 was constructed and transformed into yeast Y187. This Y187 containing pGADT7-HCV FBP2 was mated with the yeast AH109 containing pGBKT7-F. The mated yeast was plated on the dropout medium. The positive colonies emerged and became blue.

In vitro co-immunoprecipitation

HCV F protein containing 161 aa, M_r = 17 710, being smaller than FBP2 containing 280 aa, M_r = 30 800 is shown in Figure 5.

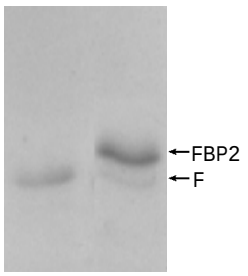

Figure 5 Interaction between HCV F protein and FBP2 protein identified by co-immunoprecipitation. Lane 1: HCV F protein; lane 2: interaction between HCV F and FBP_2 proteins.

The core protein of HCV is a multifunctional protein[13-15]. There is evidence that this protein can directly modulate intracellular signal transduction, gene transcription, cell proliferation, and cell death, interfere with lipid metabolism

and suppress host immune responses[16-19]. HCV F protein is a newly discovered HCV gene product encoded by the ORF that overlaps the core gene in the +1 frame[6-8]. F protein might have previously escaped attention because it possesses the immunodominant epitopes located in the N-terminus, in common with the core protein. A F protein analog synthesized *in vitro* reacts with the sera of HCV patients but not with the sera of hepatitis B patients, indicating that F protein is expressed during natural HCV infection. F protein is a very unstable protein with a half-life of <10 min in Huh7 hepatoma cells and *in vitro*, and is mediated by the proteasome pathway[20,21]. Immunofluorescence staining and subcellular fractionation experiments indicate that the subcellular localization of F protein is in the endoplasmic reticulum, and is similar to those of HCV core and NS5A proteins, suggesting that F protein may participate in HCV morphogenesis or replication. F protein shows more sequence diversity than the core protein[22-25]. Mutations of the core protein help virus to escape host immunologic reaction and may trigger cellular malignancy conversion. F protein might regulate cellular functions that are important for the viral life cycle or might play a role in viral morphogenesis or viral entry.

Because proteins often assemble into large complexes to perform different activities, characterization of the interaction pattern of a protein could contribute to the elucidation of the functions of protein[26]. Interaction between viral and hepatocellular proteins plays an important role in the pathogenesis of the virus and may mediate virus to enter hepatocytes. Their network interaction can change normal biological functions of proteins, influence self-replication of virus, prolong infection and develop diseases. Yeast two-hybrid 3 is an effective gene analysis method which can analyze interactions between protein and protein, protein and DNA, protein and RNA in eukaryotic cells, as well as a new genetics technique for studying interactions of proteins in physiologic condition *in vivo*.

Yeast two-hybrid system 3 based on the system originally designed by Fields and Song[27] takes the advantage of the properties of GAL4 protein of the yeast *Saccharomyces cerevisiae*. GAL4-yeast two-hybrid assay uses two expression vectors, one uses GAL4-DNA-binding domain (DBD) and the other uses GAL4-activation domain (AD). The GAL4-DBD is fused to protein 'X' and GAL4-AD is fused to protein 'Y' to form the bait and the target of the interaction trap, respectively. A selection of host cells with different reporter genes and different growth selection markers can detect and confirm protein-protein interactions and has fewer false positives[27-30].

In this study, the "bait" plasmid pGBKT7-F was transformed into yeast strain AH109. HCV F gene was expressed in yeast cells. After the "bait" plasmid pGBKT7-F yeast strain AH109 was mated with liver cDNA library yeast strain Y187, the diploid yeast cells were plated on QDO media containing X-α-gal, 36 true positives were obtained. By sequencing analysis of isolated library plasmids, we got the sequences of 34 genes with known functions and the sequences of two genes with unknown function, one of them was named as HCV FBP2. In order to further confirm the interaction between expressed protein and HCV F protein, we performed the experiment of co-immunoprecipitation of both proteins. A strong interaction between HCV F protein and HCV FBP2 protein *in vitro* was observed.

We screened *Homo sapiens* zymogen granule (ZG) protein 16 (ZG16p) interacting with F protein from liver cDNA library. ZG protein is highly expressed in the pancreas cells and regulates ATP-sensitive K(+) conductance of ZGs. ZG16p is one of the linker proteins with a submembranous protein matrix on the inner surface of ZG. The submembranous matrix composed of sulfated proteoglycans, glycoproteins and lectin ZG16p is essential for the binding and sorting of aggregated zymogens during granule formation. ZG16p is associated with lipid microdomains ('rafts') and affects the protein synthesis and intracellular transport of secretory proteins and maturation of zymogens in ZGs[31-34]. HCV infection and chronic hepatopathy caused by HCV are significantly associated with diabetes, and reduction of glucose tolerance is related to the severity of chronic hepatitis C[35,36]. The result of our experiment showed that interaction occurred between HCV F and ZG16p, thus providing a new clue for revealing the function of HCV F protein and relationship between pathogenesis of HCV and diabetes mellitus.

Another important protein interacting with F protein from liver cDNA library is the *Homo sapiens* zinc-alpha 2-glycoprotein (Zn-α2-GP). It is present at a high concentration in the seminal plasma and in other human body fluids. Hepatocytes are a source of protein in blood plasma and epithelia. Zn-α2-GP is present at carcinoma of prostate, breast cancer and hydroadenoma. Zn-α2-GP production is associated with tumor differentiation, decreased or absent Zn-α2-GP production is found in poorly differentiated (high Gleason grade) tumors. Zn-α2-GP production in tumors can elevate the systemic ZAG concentration and induce lipolysis leading to cachexia. Zn-α2-GP is a potential serum marker of prostate cancer that may elevate early in tumor development. Whether tumors can induce secretion of endogenous Zn-α2-GP by normal prostatic or other secretory ZAG expression can predict the risk of a progressive disease needs further study[37].

Vitronectin, also known as a serum spreading factor, is a glycoprotein present in both human plasma and serum. It is also present in different loose connective tissues, often in co-localization of elastic fibrils. Vitronectin binds to cells through interaction of the Arg-Gly-Asp (RGD) sequence in its cell-binding domain with vitronectin-specific cell surface receptors and may modulate blood coagulation and complement-induced cytolysis. Matrix-bound vitronectin plays a role in regulating pericellular proteolysis by binding to plasminogen activator inhibitor type I. Vitronectin may promote cell attachment, spreading, proliferation, and differentiation of normal and neoplastic cells[38,39].

C1 inhibitor (C1 INH) is a highly glucosylated protein. The content of glucose is up to 35-49%. It has 30% homology of amino acids of serine proteinase inhibitor superfamily members including α1 anti-trypsin, α1 anti-chymotrypsin and anti-thrombin III. C1 INH combines activated C1r or C1s to form a stable complex, leading to inactivation of serine proteinase C1. C1 INH may prevent auto-activation of C1. Because C1 INH still inhibits factors XIIa, XIa,

kallikrein and fibrinolysin, it plays an important role in regulation of blood coagulation, kinin, and fibrinolytic system[40,41].

Sialyltransferase is a member of glycosyltransferase family and presents at Golgi apparatus. Sialyltransferase possesses the functions of catalyzing cellular adhesive molecule-ganglioside polysialic acidification. Ganglioside, a kind of glycosphingolipid containing sialic acid, is an important factor for cellular adhesion and malignancy cell growth *in vitro* culture.

HCV F protein also interacts with complement control protein factor I, peroxisomal ion protease, cathepsin B, RAS oncogene. These interacting proteins are closely correlated with carbohydrate metabolism, immunoregulation, occurrence and development of tumor. How interactions between HCV F protein and interacting proteins affect the occurrence and development of chronic hepatitis C, hepatic fibrosis and hepatocarcinoma, needs to be further elucidated.

Abstract

AIM: To elucidate the biological function of HBV core antigen (HBcAg) on pathogenesis of hepatitis B, a novel gene C12 coding for protein with unknown function interacting with HBcAg in hepatocytes was identified and characterized.

METHODS: HBcAg bait plasmid pGBKT7-HBcAg was constructed and transformed into yeast AH109, then the transformed yeast was mated with yeast Y187 containing liver complementary DNA (cDNA) library plasmid in 2×YPDA medium. Diploid yeast was plated on synthetic dropout nutrient medium (SD/-Trp-Leu-His-Ade) and synthetic dropout nutrient medium (SD/-Trp-Leu-His-Ade) containing X-α-gal for screening twice. After extracting and sequencing of plasmid from blue colonies, we isolated a cDNA clone encoding a novel protein designated as C12 that directly interacted with HBcAg. The interaction between HBcAg and C12 was verified again by re-mating. pEGFP-N1-C12 fluorescent protein fusion gene was transfected in 293 and L02 cell, and observed by fluorescent microscope. MTT reduction assay was used to study the action of C12 protein effect on metabolism of mammal cell. Yeast two-hybrid and cDNA microarray were performed to search binding protein and differential expression genes regulated by C12 protein.

RESULTS: C12 gene was screened and identified by yeast two-hybrid system 3. The interaction between HBcAg and the novel protein coded by the new gene C12 was further confirmed by re-mating. After 48 h, fluorescence of fusion protein could be observed steadily in the 293 and L02 cell plasma. Under MTT assay, we found that the expression of C12 did not influence the growth of liver cells. Seventeen differential expression genes in HepG2 cells transfected with C12 protein expression plasmid by cDNA microarray, of which 16 genes were upregulated and 1 gene was downregulated by C12 protein. Twenty-one colonies containing 16 different genes coding for C12 protein binding proteins were isolated by yeast two-hybrid, there were 2 new genes with unknown function.

CONCLUSION: The novel protein C12 is located in cell plasma, and its overexpression has no significant effect on the metabolism of liver cell. It interacts with many proteins in hepatocytes and may be involved in many processes of gene expression.

INTRODUCTION

There are more than 400 million carriers of HBV worldwide who are at high risk for the development of chronic liver diseases, but the precise mechanism of virus involvement remains elusive[1,2]. Identification of cellular HBV core antigen (HBcAg) interaction protein would provide insights into the mechanism of HBV cellular effects[3-5]. Based on the yeast two-hybrid screening and bio-information assay, we found a novel gene named C12 coding for protein binding with HBcAg, and located in cell plasma. After the finishing of human genome project, we obtained mass information of chromosome DNA including many sequences of coding gene with unknown functions. While DNA constitutes the information archive of the genome, it is the proteins that actually serve as the functional effectors of cellular processes. How to elucidate the structure, biological function and medical significance of protein coding by novel genes, are the most difficult and complex work in future. By means of MTT reduction assay, complementary DNA (cDNA) microarray and yeast two-hybrid technique, the potential biological function of C12 protein was initially investigated in the context of effect on cell metabolism and gene expression, the binding protein in hepatocytes. We expected the results would bring us some valuable information and pave the way for further study.

MATERIALS AND METHODS

Plasmid construction

The HBcAg gene from a known HBV DNA sequence

(subtype ayw) was amplified by PCR (P1 3'-GAA TTC ATG GAC ATC GAC CCT TAT AA-5', P2 3'-CTG CAG AAC ATT GAG ATT CCC GAG AT-5') and cloned into the DNA-binding domain vector pGBKT7 (Clontech, Palo Alto, CA, USA). This plasmid contains TRP1 gene, permitting it to grow in trp medium. A normal human adult liver cDNA stretch library was cloned into the activation domain vector pACT2 and transformed into yeast strain Y187 to build pretransformed cDNA liver cell library (Clontech Co., USA); pACT2 plasmid contain Leu2 gene (Clontech Co., USA), permitting it to grow in leu-medium[6-9].

Western blotting

The plasmid pGBKT7-HBcAg containing full length of HBcAg gene was constructed by insertion of HBcAg gene in-frame into *Eco*RI/*Bam*HI site, and could directly express DNA binding domain, *c-myc* and core fusion protein was transformed into yeast strain AH109 by using lithium acetate method. Yeast protein of AH109 was extracted and Western blotting was performed to confirm the expression of the fusion protein by using *c-myc* mAb. Transformed AH109 was cultured on quadrupole dropout media to exclude the auto-activity.

Two-hybrid library screen and cDNA isolation

One large (2-3 mm), fresh (<2 mo old) colony of AH109 containing bait plasmid was inoculated into 50 mL of SD/-Trp and incubated at 30 ℃ overnight (16-24 h) with shaking at 250-270 r/min. Then the cells were spun down by centrifuging the entire 50-mL culture at 1 000 r/min for 5 min and supernatant was decanted, the cell pellet was resuspended in the residual liquid by vortexing. The entire AH109 (bait) culture and the 1-mL library were combined and cultured in a 2-L sterile flask and 45 mL of 2× YPDA/Kan was added and swirled gently. After 20-h mating, the cells were spun down, resuspended and then spread on 50 large (150-mm) plates, containing 200 mL of SD/-Ade/-His/-Leu/-Trp. After 6-18 d of growth, the yeast colonies were transferred onto the plates containing X-α-gal to check for expression of the MEL1 reporter gene (blue colonies). Blue colonies were considered to be true positives and were discarded. Yeast plasmid DNA was isolated with lyticase method (Clontech), and transformed into *E. coli* by using electroporation; transformants were plated on ampicillin LB selection media and analyzed by DNA sequencing.

DNA sequencing and computation

cDNA inserts were sequenced with the Sequenase version 2.0 sequencing kit (Boya Biochemical Corp, China) based on the dideoxy method. Homology searches for the DNA sequences thus determined and their deduced amino acid sequences were performed at the National Center for Biotechnology Information with the BLAST network service.

RT-PCR and re-mating

Based on the information of GenBank, PCR primers of the novel gene C12 were designed (P3 5'-GAA TTC ATG ATA AGT GAA GGC GGA TG-3', P4 5'-GGA TCC CTA TTG TTA ACA GAG GAC T-3'), and the full-length gene of C12 was amplified by using reverse transcription polymerase chain reaction (RT-PCR) by using genomic DNA from HepG2 cell line as the template. C12 gene was inserted into yeast expression vector pGADT7 and transformed into yeast strain Y187, then re-mated with AH109 containing pGBKT7-HBcAg. After mating, the diploid yeasts were plated on QDO covered with X-α-gal for further verification[10].

Sub-cellular localization

Full-length C12 gene was amplified by PCR with primers (P5 5'-GAA TTC ATG ATA AGT GAA GGC GGA TG-3', P6 5'-GGA TCC TTG TTA ACA GAG GAC TTT T-3') and inserted into green fluorescent protein (GFP) expression vector pEGFP-N1 (Promega Co., USA). The human liver cell line L02 and African green monkey renal cell line 293 was incubated in DMEM medium with 10% fetal bovine serum (FBS), 200 μmol/L L-glutamine, penicillin, streptomycin, and plated at a density of 1×10^4/well in 35-mm dishes. Purified plasmid pEGFP-N1-C12 was transfected into 293 and L02 cell by using Lipofectamine PLUS (Gibco Co., USA) and observed under fluorescent microscope after 48-h incubation.

MTT reduction assay

L02 and Bel7402 cells were respectively divided into four groups; they were empty cell group, liposomes group, pEGFP-N1 group, and pEGFP-N1-C12 group. Each group included six wells and each well was incubated with 1×10^4 cells. Deionized water, liposomes, pEGFP-N1, and pEGFP-N1-C12 were transfected into corresponding groups and incubated for 18 h in DMEM medium with 10% FBS at 37 ℃ (Roche Co., USA). Cells were incubated for next 4 h with DMEM without FBS, and 750 μL DMSO was added in each well followed by discarding the medium and washing with 1× PBS. After mixing steadily, the absorbance of samples was measured (detection wavelength 550 nm, reference wavelength 650 nm) to quantify cell number.

Screening of binding protein

pGBKT7-C12 bait plasmid was constructed by inserting C12 full-length gene into yeast expression vector pGBKT7 and transfected into AH109 cell. Positive AH109 cell mated with pretransformed cDNA liver cell library Y187 cell for screening twice. Blue colonies were discarded and analyzed by DNA sequencing and bioinformatic assay.

cDNA microarray assay

HepG2 cell line transfected with pcDNA3.1(-)-C12 and pcDNA3.1(-) were incubated at DMEM medium for 48 h. mRNA from these cells were extracted by using Quick Prep micro mRNA Purification Kit (Amersham Pharmacia Co., USA). Cy3-dUTP was labeled into cDNA of pcDNA3.1(-) group and Cy5-dUTP was labeled into cDNA of pcDNA3.1(-)-C12 group during the RT-PCR procedure. These cDNA was hybridized with cDNA chip containing 1 152 cDNA and amplified by PCR with common primer. After dotting, hydrating, dehydrating, ultraviolet joining, and washing with SDS, water and sodium borocaptate solution, samples were degenerated in water at 95 ℃ for 5 min and hybridized

with mixed probe for 15-17 h. Followed by washing, drying at room temperature, specimens were analyzed by ScanArray 3000 (General Scanning, positive standard: Cy5/Cy3>2.0, negative standard: Cy5/Cy3<0.5).

RESULTS

Expression of the "bait" fusion protein

Yeast strain AH109 transformed with pGBKT7-HBcAg could stably express the fusion protein at high level (Figure 1). The transformed AH109 could only grow on SD/-Trp medium but not on QDO medium. Thus, the transformed yeast could be used for yeast hybrid analysis.

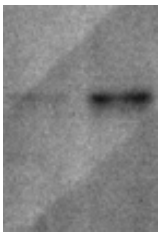

Figure 1 Western blotting showed the expression of HBV core protein in yeast. Lane 1: 5-μL sample; lane 2: 10-μL sample.

Two-hybrid library screen and re-mating

In order to unravel the molecular mechanisms of HBcAg, we adopted the yeast two-hybrid system to identify and characterize cellular targets of HBcAg. An adult human liver cDNA library containing cDNAs fused to the GAL4 activation domain in yeast vector pCAT2 was used to screen for clones interacting with HBcAg. Plasmid pACT2-cDNA was recovered from the true positive clone and was sequenced. The result of our screening led to the identification of a clone containing gene without homologs in GenBank. This cDNA was 591 bases long (Figure 3), which contained an open reading frame (ORF) able to encode a protein of 197 amino acids. The protein was named C12. Sequence homology searches in GenBank revealed that it was a novel gene. The entire ORF coding for C12 was obtained from HepG2 cells and subcloned into yeast plasmid pGADT7 to be expressed as a fusion protein with DNA activation domain of GAL4. pGADT7-C12 was transfected into Y187 and re-mated with AH109 transfected with pGBKT7-HBcAg to verify the reliability of the interaction between them.

Figure 3 Nucleic and amino acid sequences of C12 cDNA.

Sub-cellular localization

After the full-length gene of C12 was cloned into pEGFP-N1 (Figure 2), the fluorescent protein expression plasmid pEGFP-N1-C12 was transfected into 293 and L02 cells and incubated for 48 h. When we observed under the fluorescent microscope, the steady, powerful green fluorescent signal could be observed in most cells (Figures 4A and B). The result indicated that the C12 protein could be expressed in these cells and mainly localized in the cell plasma.

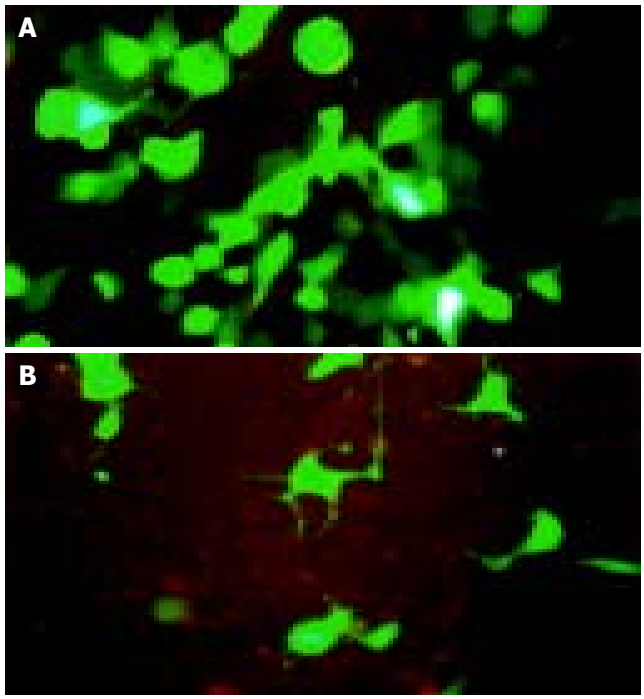

Figure 4 A pEGFP-N1-C12 expression in 293 cell line; **B**: pEGFP-N1-C12 expression in L02 cell line.

MTT reduction assay

MTT reduction assay was performed in Bel7402 and L02 cell line transfected with deionized water, liposomes, pEGFP-N1 and pEGFP-N1-C12 respectively. The results showed that the optical density in Bel7402 cell line

groups were 0.547±0.076, 0.575±0.122, 0.470±0.124, 0.503±0.093, while the optical density in L02 cell line groups were 0.216±0.028, 0.201±0.01, 0.197±0.011, 0.205±0.024. It revealed that the expression of C12 gene in both cells did not have inhibitory or promotional effect on the growth of these cells, compared with deionized water, liposomes and empty vector (P>0.01).

Screening of binding protein

Yeast strain AH109 transformed with pGBKT7-C12 could grow on SD/-Trp medium and could not grow on QDO medium, the result showed that C12 protein have no autoactivation in yeast cell and could be used for yeast two-hybrid screening. After being mated with pretransformed cDNA library strain Y187 and screened on QOD, 21 blue clones were obtained. Plasmid in these clones were cloned into *Escherichia coli* and analyzed by DNA sequencing. After comparing these sequences in GenBank, 16 different genes were screened. Fourteen genes were homolog of known genes, two genes did not find homolog in GenBank (Table 1)[11].

Table 1 Binding protein of C12 protein screened by yeast two-hybrid

Homeobox gene	Homogeneity %	Clones
Cathepsin B	99	1
Apolipoprotein M	98	1
Cytochrome C oxidase II	97–99	3
Receptor JAK (EPHB4) variation factor	99	1

cDNA microarray assay

Eight paddy genes from 1 152 cDNA on the chip that served as negative control showed very weak hybrid signal, which confirmed the reliability of the experiment. Total mRNA of HepG2 cells transfected with pcDNA3.1(-) and pcDNA3.1(-)-C12 were purified, respectively, then labeled with Cy3-dUTP and Cy5-dUTP during RT-PCR procedure. Cy5 fluorescein showed red fluorescence and Cy3 fluorescein showed green fluorescence. The difference of color showed the difference of gene expression level, such as yellow showed that there was no difference between the two groups. Based on the criteria, 16 differential expression genes upregulated by C12 and 1 gene downregulated by C12 were screened (Table 2). These genes were involved in cell signal conduction, cell proliferation, differentiation, and generation of carcinoma[12].

Table 2 Differential expression genes upregulated by C12 gene

GenBank number	Homeobox gene
000208	Insulin receptor (INSR),
005500	SUMO-1 activating enzyme subunit 1 (SAE1),
006292	Tumor susceptibility gene 101 (TSG101),
012248	Selenophosphate synthetase 2 (SPS2),
006217	Serine (or cysteine) proteinase inhibitor, clade I (neuroserpin), member 2 (SERPINI2),
016614	TRAF and TNF receptor-associated protein (TTRAP),
006437	ADP-ribosyltransferase-like 1 (ADPRTL1)

004127	G protein pathway suppressor 1 (GPS1),
014887	Hypothetical protein from BCRA2 region
000660	Transforming growth factor, beta 1 (TGF-β1),

DISCUSSION

The HBV infection is a public health problem worldwide, particularly in East Asia. The current therapy of HBV infection is mostly based on chemical agents and cytokines that have been shown to provide limited efficacy are also toxic to the human body[13-15]. Elucidating the interaction between hepatocytes and HBV was essential for finding new methods to inhibit the replication of HBV. The HBV nucleocapsid or core antigen (HBcAg) is extremely immunogenic during infection and after immunization. HBcAg has a unique three-dimensional folding that interacts with immunoglobulins outside the classical antibody-binding site, has the $CD4^+$ T cell epitopes and the encapsidated nucleic acids that can efficiently interact and activate antigen presenting cells, especially naive B cells. HBcAg also performs pivotal functions by mediating release of (sub) viral particles, regulation of supercoiled DNA amplification, and transcriptional transactivation[16-19]. To assess its multiple functions and host-protein assistance involved, we initiated a two-hybrid screen using the HBcAg domain as bait and had identified a novel gene named C12 with unknown function. To study the biological function of C12 gene and its role in the HBV infection, we performed the following researches and hoped to get some valuable clues for the further investigation.

First of all, the full-length gene of C12 was amplified from HepG2 cell and verified by DNA sequencing. Gene of C12 was cloned into GFP expression vector pEGFP-N1 and transfected into 293 and L02 cell line. After incubating for 48 h, cells were observed under the fluorescent microscope. We found that these cells were stained with steady, strong green fluorescence in the whole cell, the result indicated that C12 protein mainly expressed in cell plasma. Eighteen hours after incubation with medium, cell number, as measured by absorbance (A), was quantified by using colorimetric MTT assay. The result showed that the optical

density in Bel7402 and L02 cell line groups transfected with deionized water, liposomes, pEGFP-N1 and pEGFP-N1-C12 have no significant difference. This result could be explained as follows: C12 protein was a normal protein present in cells and may have the promotive or inhibitive effect on cell growth. It did not show significant effect because of the interference of network regulation of other proteins. The main expression of C12 protein does not intervene the growth and reproduction of normal cells.

Screening binding protein in hepatocytes, identification of interaction protein in the protein network, may provide valuable clues for the further research[20-23]. Based on the modified yeast two-hybrid technique, the "bait" plasmid pGBKT7-C12 was transformed into yeast strain AH109. After mating with liver cDNA library yeast strain Y187, the diploid yeast cells were plated on QDO media containing X-α-gal, 21 true positives were obtained. Sequencing analysis of isolated library plasmids, 16 different genes were found. Among them, cytochrome C oxidase, ornithine decarboxylase, and acetolactate synthase related to energy metabolism. C12 bind with these proteins indicating that C12 may participate in mitochondrion energy metabolism. KSRP was a factor that regulated the shearing process of enhancer exon[24,25]. Calpain, phosphatidylinositol deacylase poly-glucose Q transcriptional variation factor and receptor JAK (EPHB4) variation factor were important members involved in cellular signal transduction and cell cycle regulation. The interaction between C12 and these proteins suggest that C12 may serve in the above procedure. Ferritin related to hepatocellular damage and HCC[26]. Interaction between C12 and ferritin may play the bridge role in hepatocellular damage and HCC. C12 also take part in blood coagulation procedure for binding with coagulation factor IX. All of the above suggest that proteins found to binding C12 in the yeast two-hybrid system 3 appeared to reveal some probable functions of C12.

The cDNA microarray is a genomic technology, which is widely used in both basic and applied research. Recent advances in cDNA microarray technology have great impact on many areas of biomedical research and pharmacogenomics: discovering novel targets and genes, elucidating signatures of complex diseases, transcriptional profiling of models for diseases, and the development of individually optimized drugs based on differential gene expression patterns[17-29]. The commercial availability of several different precoated arrays and the ease of handling supported the broad distribution of this new technique. The basic protocol in this article involves the hybridization of complementary strands of fluorescent (Cy3 and Cy5) labeled cDNA from HepG2 cells transfected with expression plasmid pcDNA3.1(-)-C12 and empty vector pcDNA3.1(-) spotted onto a solid support and then detected by fluorescence scanning. Sixteen differential expression genes upregulated by C12 and 1 gene downregulated by C12 were screened (Table 2). These genes were involved in cell signal conduction, cell proliferation and differentiation, generation of carcinoma.

The preliminary data from the context studies suggest that the novel protein C12 is located in cell plasma, and its overexpression has no significant effect on the metabolism of liver cells; it interacted with many proteins in hepatocytes and may be involved in many processes of gene expression. These results stride the first step for the functional study of C12 gene and pave the way for the new gene biology research. We will further refine our understanding of currently known results as well as identify novel pathways and methods to elucidate the integral biological functions.

Abstract

AIM: Prior *Helicobacter pylori* (*H pylori*) infection has often been underestimated. These underestimations have misled physicians attempting to determine the significance between *H pylori* and certain gastrointestinal lesions such as intestinal metaplasia, atrophic gastritis, and gastric cancer. Our study endeavored to detect past *H pylori* infections accurately, easily, and rapidly with the newly developed immunoblot kit, Helico Blot 2.1.

METHODS: Thirty-three patients, including 25 *H pylori* infected and 8 uninfected cases, were enrolled in our study. All patients received consecutive gastroendoscopic examinations and ^{13}C-urea breath test (UBT) tests at 6- or 12-mo intervals for up to 4 years. Serum samples were obtained from each patient at the same time. Intragastric *H pylori* infection was confirmed in accordance with the gold standard. Twenty-five *H pylori*-infected patients received triple therapies after initial bacterial confirmation, and were successful in eradicating their infections. Serially obtained sera were tested by means of Helico Blot 2.1.

RESULTS: Current infection marker detected by Helico Blot 2.1 was unreliable for representing ongoing *H pylori* infection. Only 35 and 37 ku antibodies of *H pylori* had significant seroconversion rates 1 year after having been cured. The seropositive rates of 116 ku (cytotoxin-associated antigen [CagA]) and Helico Blot 2.1 were nearly 100% during 4-year follow-up period. Both CagA antigen and Helico blot 2.1 could serve as indicators of long-term *H pylori* infection.

CONCLUSION: Helico Blot 2.1 can detect past *H pylori* infections for up to 4 years, and is the best method to date for detecting previous long-term *H pylori* infection.

INTRODUCTION

Since Warren and Marshall reported *Helicobacter pylori* (*H pylori*) in 1983[1], this gram negative, spiral-shaped bacterium has been designated as a causative agent in many benign and malignant gastrointestinal diseases, such as peptic ulcer[2,3] and gastric cancer[4-7]. However, low intragastric *H pylori* infection rates have been reported in connection with certain precancerous lesions, such as intestinal metaplasia[8] and atrophic gastritis[9,10]. This has been attributed to inappropriate use of medications or intragastric environmental changes. Recent meta-analysis reports[11-13] about serology studies have even argued that the association between *H pylori* and gastric cancer is relatively weak. Therefore, accurate detection of past *H pylori* infection is important in deciding the real prevalence rates of many gastrointestinal diseases.

Conventional ELISA serology study was previously known as the best method of determining past *H pylori* infection, because the IgG antibody decreases slowly and may remain detectable for months after bacterial cure[14-17]. The delay in fall in serum anti-*H pylori* IgG antibody following eradication therapy inspired the idea that serum antibodies to specific *H pylori* immunoreactive antigens could serve as tools in detecting past *H pylori* infections. The *H pylori* cytotoxin-associated antigen (CagA) is known to be more virulent[18-21], have a stronger immunoreactivity[22,23], and persist longer after *H pylori* eradication[24]. The other low molecular weight antigens of *H pylori* have also been helpful in detecting *H pylori* infection[25-27].

The primary goal of our study was to determine the feasibility and accuracy of a newly developed immunoblot

device in the detection of past *H pylori* infections.

MATERIALS AND METHODS

A total of 33 patients were enrolled in this study. Of these, 25 (19 men, 6 women, mean age 57.5±14.3 years) were the *H pylori* positive study group, and 8 (2 men, 6 women, mean age 63.8±15.8 years) made up the *H pylori* negative control group. The 25 *H pylori* positive patients included 23 cases of peptic ulcers and 2 cases of early gastric cancers. There were eight *H pylori* negative patients as a control group, including four cases with peptic ulcers, two cases with gastro-esophageal regurgitation diseases, one case with gastritis, and one case with early gastric cancer. The *H pylori* positive study group was followed up for 18-45 mo, on an average of 30.0±8.9 mo. The negative control group was followed up for 26-48 mo, on an average of 34.6±7.1 mo. During the follow-up periods, all of the patients received gastroendoscopic examinations and biopsy-based *H pylori* studies at 6-mo or 1-year intervals. ^{13}C-urea breath test (UBT) tests and sera collection for the diagnosis of *H pylori* infection were conducted at the same time. Exclusion criteria were the following: use of antibiotics or bismuth salts, or proton pump inhibitors therapy within the last 2 mo, previous anti-*H pylori* treatment, chronic use of corticosteroids or immunosuppressant drugs, prior gastric surgery, presence of a bleeding peptic ulcer, severe concomitant disease, and pregnancy or lactation.

The gold standard of identifying a *H pylori* infected patient is determined by positive culture results, or positive results in any two of the following: histology (hematoxylin and eosin, H&E stain), rapid urease test and ^{13}C-UBT test. The negative *H pylori*-infected patient was identified by a negative culture result and at least two negative results in the following: histology, rapid urease test, and ^{13}C-UBT test. All of the *H pylori* infected patients received *H pylori* eradication therapy with standard full-dose triple therapy regimen (omeprazole 20 mg, amoxicillin 500 mg, and clarithromycin 500 mg twice a day for 7 d).

The Helico Blot 2.1 kit (Genelabs Diagnostics, Singapore) was used to detect IgG antibodies to specific antigens of *H pylori* in accordance with manufacturer's instructions. Helico Blot 2.1 kit is a qualitative serologic test using a Western blot made from bacterial lysate, and including a recombinant antigen of *H pylori* with a predictive value for indicating current *H pylori* infection. The corresponding bands to these specific antigens of *H pylori* are 116 ku (CagA), 89 ku (vacuolating-associated antigen [VacA]), 37, 35, 30 ku (Urease A), and 19.5 ku (Figure 1). The determinations of *H pylori* seropositivity on Helico Blot 2.1 and corresponding specific antigens were in accordance with the manufacturer's criteria. The recommended criteria for determining a sample as *H pylori* seropositive on Helico Blot 2.1 kit is any one of the following conditions: (1) 116 ku (CagA) positive, where CagA has to be present with one or more of the following bands: 89 ku (VacA), 37, 35, 30 ku (Urease A), and 19.5 ku together, or with a current infection marker (CIM). (2) Presence of any one band at 89, 37 or 35 ku, with or without a CIM. (3) Presence of both 30 and 19.5 ku with or without a CIM. Each patient's serum samples were analyzed at the same time to avoid interassay variation. Furthermore, three specialists who did not know about the study's objectives were invited to examine and interpret the nitrocellulose strips to decrease the individual subjective bias (Figure 1).

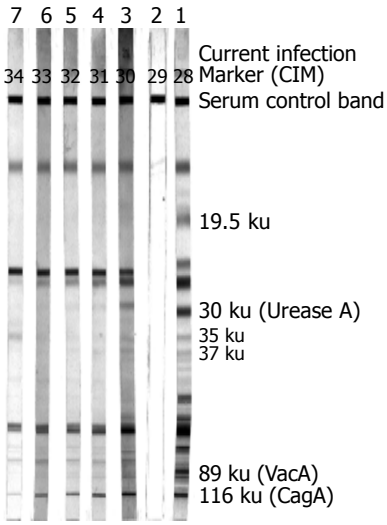

Figure 1 The nitrocellulose strips of Helico Blot 2.1 representative of immunoblot results: lane 1, positive control; lane 2, negative control; lanes 3-7, serial serum samples of a patient showing positive results.

Statistics

Due to the repeated measurements to determine antibody positive or negative status, the generalized estimating equation (GEE) was applied to statistically analyze intra- and inter-individual changes in specific antigens of *H pylori* during the follow-up periods (every 6 mo).

RESULTS

All 25 *H pylori* positive patients underwent successful bacterial eradication with triple therapy, as confirmed by gastroendoscopic biopsy-based studies and ^{13}C-UBT tests. A total of 112 sera samples obtained from the 25 patients in our study group were checked with Helico Blot 2.1. The test results are recorded in Tables 1 and 2, and depicted in Figure 2.

Except for 37 and 35 ku, other *H pylori* specific antibodies (19.5, 30, 89, 116 ku, and even CIM) showed as seropositive for over half of the serum samples tested with Helico Blot 2.1 test during a 4-year follow-up period (Figure 2). Both Helico Blot 2.1 and 116 ku (CagA) antibody seropositive rates were nearly 100% (98% and 99% respectively, as shown in Table 1). Also, at least 79% of *H pylori* 30 ku antibody can be detected positively before the end of a 3-year follow-up. The 89 ku (VacA) was also at least 67% positive during the 4-year follow-up (Table 2 and Figure 2).

The seropositive rate of 19.5 ku antibody decreased significantly, but wide fluctuation decreased its reliability (Figure 2). The seroconversion rates of 35 and 37 ku antibodies were significant (GEE testing significance, *P* values as 0.008 and 0.001 respectively) till 1 year after bacterial cure, in spite of initial lower seropositive rates (35 ku, 44% down to 29% and 37 ku, 68% down to 36%, Table 2 and Figure 2). The positive rate of CIM decreased significantly between

the 3rd and 4th years, but the small number of cases studied has influenced reliability (Figure 2).

The *H pylori* statuses in the negative control group were still negative as determined by the gold standard and Helico Blot 2.1 tests after a follow-up period similar to the study groups. Because of this, the data is not shown in tables or figures.

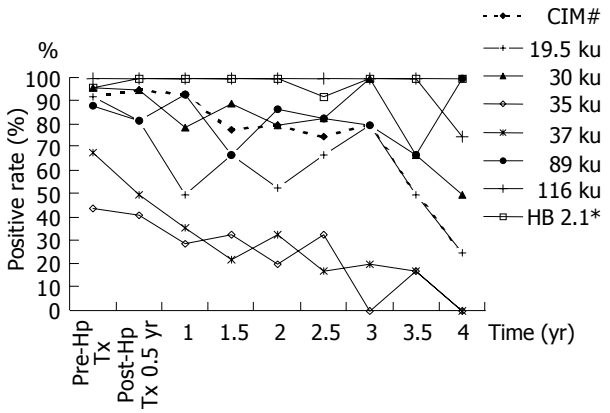

Figure 2 Fluctuating positive rates of various *H pylori*-specific antigens and Helico Blot 2.1 in 25 *H pylori*-infected patients were charted at half-year intervals during a 4-year follow-up period. The CIM was unreliable, because it maintained high positive rates for at least 3 years after *H pylori* eradication. Thirty-five and thirty-seven kilounits antibodies of *H pylori* showed significant seroconversion changes at 1 year after bacterial cure. The seropositive rates of 116 ku (CagA) and Helico Blot 2.1 were nearly 100% during the 4-year follow-up period.

DISCUSSION

Although *H pylori* was designated as a human class I carcinogen already in 1994[28], the exact nature and strength of the association with gastric cancer has remained debatable[11-13]. Because *H pylori* infection are primarily acquired in childhood[29,30], older subjects have had more time to develop mucosal atrophy and to loose their infection than younger subj-ects[9,10]. Also, decades may pass between initiation and detection of gastric cancers. *H pylori* may disappear spontaneously with progressing precancerous intragastric environmental change and invalidate various studies of its association with gastric cancer. The significance of detecting the past *H pylori* infection is to re-estimate the strength of the *H pylori*-gastric cancer relationship.

The CIM of Helico Blot 2.1 was developed and claimed to be able to detect ongoing *H pylori* infection. However, our study showed that the CIM band was oversensitive and unreliable, because it remained at a 75-80% positive rate for 3 years after *H pylori* eradication (Table 2). Our results differ from the conclusions of Oleastro's *et al*., study of pediatric patients[31]. There were two reasons for these discrepancies with our report. First were the different age groups of the studies. It is known that *H pylori* infection occurs beginning in childhood, and gradually accumulates as the patients get older[29,30]. Consequently, pediatric studies will have more true negative cases when compared with adult groups. Our adult patients may have had immunological memory due to past *H pylori* infection, and were mistaken for currently infected by the oversensitive CIM band. Second, these two studies had different designs. Oleastro's study[31] was a cross-sectional design, not a long term follow-up study like ours. Their study checked serum *H pylori* antibody at only one time point, and the serial seroconversion changes could not be detected in cross-sectional study designs.

The seropositive rate of 116 ku (CagA) was the highest (up to 100% before the end of a 3.5-year follow-up period) among various antibodies to *H pylori*-specific antigens and nearly parallel to Helico Blot 2.1 (Table 2 and Figure 2). This phenomenon explains why the CagA antibody was the

[1]HB2.1: Helico Blot 2.1; [2]CIM: current infection marker; Pre-Hp Tx: before *H pylori* eradication therapy; Post-Hp Tx: after *H pylori* eradication therapy.

last antibody to disappear after *H pylori* eradication, and may serve as a single predictor in *H pylori* long-term infection. Our results showed that CagA antigen had the strongest immunoreactivity among various *H pylori* antigens, and was in agreement with numerous previous reports[22,24,32,33].

The roles of various low molecular weight antibodies of *H pylori* were ambiguous. The heat shock protein of *H pylori* was related to chronic gastric inflammation[34,35]. Mucosa-associated lymphoid lymphoma (MALToma) patients had higher prevalence rates of 19.5 and 30 ku antibodies of *H pylori*. After *H pylori* eradication, MALToma patients had significant negative seroconversion of 19.5, 30, and 35 ku antibodies[36]. The 35 ku antibody of *H pylori* also plays a role in peptic ulcers[37]. The immunoreaction with 30 ku (Urease A) of *H pylori* could provide a serological assessment of not only *H pylori* infection[25-27], but also of eradication[27]. In our study, the seroconversion of 35 and 37 ku was significant for up to 1 year after *H pylori* eradication.

According to our previous study[14], IgG seroconversion rates by conventional ELISA method were 42% and 94% at 6 and 12 mo after *H pylori* eradication, respectively. Although some papers[15,38] have proposed latent IgG seroconversion, many confounding factors, including small case numbers, different antigenic preparations, and variable cut-off values, made this conflict. Moreover, the follow-up periods of most studies were less than 2 years, which would mean that whether or not *H pylori* could be detected beyond 2 years after bacterial cure would be difficult to determine, and has rarely been addressed by the conventional ELISA method. Our study test kits can detect past intragastric *H pylori* infections for at least 3, or even 4 years after eradication.

The positive or negative results of Helico Blot 2.1 are given as the presence or absence of immunodetection of certain specific antigen bands, 116 ku (CagA), 89 ku (VacA), 37, 35, 30 ku (Urease A) and 19.5 ku, by the patient's serum (Figure 1). Even the decay or disappearance of serum CagA antibody, the positive result of Helico Blot 2.1 could still be achieved by other recommended criteria (criteria 2 or 3). There is one serum sample in our 4th-year study shows negative CagA antibody and positive Helico Blot 2.1 results (Table 2). Besides, Helico Blot 2.1 can differentiate various *H pylori* strains according to the presence of corresponding specific immunoreactive bands. So, Helico Blot 2.1 has more advantages over CagA only in detecting the past *H pylori* infection.

We expected that Helico Blot 2.1 will improve the detection of *H pylori* infection in many GI and non-GI diseases, such as ischemic heart disease and chronic urticaria. The present role of *H pylori* in these non-GI diseases is debatable[39,40], and improvements in detecting past *H pylori* infections would further clarify the correlations between these diseases and *H pylori*.

In summary, Helico Blot 2.1 is the best method thus far of detecting past intragastric *H pylori* infections for up to 4 years after treatment. This newly developed device with Western blot method improves the detection of *H pylori* and further clarifies its role in many *H pylori*-related diseases.

Abstract

AIM: To evaluate the role of nitric oxide (NO) in the motor disorders of the dilated uninflamed mid-colon (DUMC) from trinitrobenzene sulfonic acid (TNBS)-induced acute distal colitis in rats.

METHODS: Colitis was induced in male Sprague-Dawley rats by a single intracolonic administration of TNBS. Control rats received an enema of 0.9% saline. The rats were killed 48 h after TNBS or saline administration. Macroscopic and histologic lesions of the colon were evaluated. Myeloperoxidase (MPO) and nitric oxide synthase (NOS) activity were measured on the colonic tissue. In TNBS rats, we evaluated spontaneous and evoked contractile activity in circular muscle strips derived from DUMC in comparison to the same colonic segment of control rats, both in the presence and in the absence of a non-selective NOS isoforms inhibitor *N*-nitro-L-arginine (L-NNA). Pharmacological characterization of electric field stimulation (EFS)-evoked contractile responses was also performed.

RESULTS: In TNBS rats, the distal colon showed severe histological lesions and a high MPO activity, while the DUMC exhibited normal histology and MPO activity. Constitutive NOS activity was similar in TNBS and control rats, whereas inducible NOS activity was significantly increased only in the injured distal colon of TNBS rats. Isometrically recorded mechanical activity of circular muscle strips from DUMC of TNBS rats showed a marked reduction of the force and frequency of spontaneous contractions compared to controls, as well as of the contractile responses to a contracting stimulus. In the presence of L-NNA, the contractile activity and responses displayed a significantly greater enhancement compared to controls. The pharmacological characterization of EFS contractile responses showed that a cooperative-like interaction between cholinergic muscarinic and tachykinergic neurokinin 1 and 2 receptors mediated transmission in DUMC of TNBS rats *vs* a simple additive interaction in controls.

CONCLUSION: The results of this study show that, during TNBS-induced acute distal colitis, circular muscle intrinsic contractile mechanisms and possible enteric neural excitatory activity are inhibited in the distended uninflamed mid-colon. Suppression of NO synthesis markedly improves spontaneous and evokes muscle contractions, in spite of any evident change in local NO activity.

INTRODUCTION

Changes in motility patterns have been described in the gastrointestinal tract in association with inflammatory conditions, independent of the etiologic origin[1,2]. Indeed, ulcerative colitis (UC), an idiopathic inflammatory disease of the colon, is associated with impaired intestinal motility such as defective colonic contractility[3-5] sometimes leading to dramatic colonic dilatation (toxic megacolon, TMC)[1]. Data derived from human colitis and from animal models of colitis suggest a clear relationship between the impaired colonic motility and the abnormal local production or release of inflammatory mediators and neuropeptides[6,7].

However, changes in motility patterns are not related only to the inflamed site of the colon[8-10]. In fact, in UC, concomitant distension of the small bowel and, less frequently, of the stomach has been reported[11,12]. Small

bowel distension may even precede colonic dilation, and this has been termed as impending megacolon. This condition characterizes a subgroup of UC patients with a poor response to medical treatment and an increased risk for TMC, a need for surgery and mortality[11-14]. Furthermore, experimental colitis leads to changes in myenteric nerve function at inflamed and uninflamed gastrointestinal sites in the rat[15,16]. Several mechanisms have been hypothesized to explain motility disorders of an inflamed colonic segment[12,17,18].

In the last few years, growing evidence appears to suggest that nitric oxide (NO), synthesized by constitutive NO synthase (cNOS) expressed by certain descending interneurons in the myenteric plexus and by almost all enteric inhibitory non-adrenergic non-cholinergic motorneurons (iNANC), play a major role in the neuronal inhibitory control of intestinal mechanical activity in physiological conditions[19-21]. NO exerts its action both through direct inhibition of smooth muscle contractility and negative modulation in myenteric excitatory motorneurons activity, mainly releasing acetylcholine and tachykinins[22]. Furthermore, in human beings and experimental severe colitis, there is evidence that a burst of NO production by inducible NO synthase (iNOS) in inflammatory and smooth muscle cells is responsible for severe motility disorders of the inflamed colon[23,24]. In fact, several studies have suggested that NO may be involved in the pathogenesis of acute colonic distension in severe UC and in animal model of acute colitis[25,26]. Nevertheless, little is known about the role of NO on motility disorders in intestinal tracts far from the inflamed segment[16].

Aim of the present study was to establish whether, in trinitrobenzene sulfonic acid (TNBS)-induced acute distal colitis in rats, abnormal NO activity was also responsible for the colonic motor disorders of the dilated mid-colonic segment apparently devoid of inflammatory alterations. In TNBS distal colitis, we, therefore, evaluated spontaneous and evoked contractions in circular muscle strips derived from the dilated uninflamed mid-colon (DUMC) and compared findings with those in the same colonic segment of control rats, both in the presence and absence of *N*-nitro-L-arginine (L-NNA), a non-selective nitric oxide synthase (NOS) isoforms inhibitor. Furthermore, NOS activity was also evaluated on samples of tissues adjacent to those used for the evaluation of mechanical activity.

MATERIALS AND METHODS

Animals

Adult male Sprague-Dawley rats (250-300 g) were kept in a restricted access room at a constant temperature of 21-23 ℃ with light/dark cycles of 12 h. The animals were housed in rack-mounted wire cages and fed with standard chow pellets and water *ad libitum*.

Induction of colitis

Adhering to the Italian National Research Council criteria for the care and use of laboratory animals, colitis was induced as originally described by Morris[27]. Briefly, colitis was induced in 10 rats under light ether anesthesia by a single intracolonic administration of 0.25 mL of 50% ethanol containing 30 mg of TNBS. The solution was introduced via a catheter placed 8 cm from the anal verge. Ten rats in the control group were given an enema of the same volume of 0.9% saline instead of TNBS. The rats were anesthetized and then killed by decapitation 48 h after TNBS or saline administration.

Sample recovery and preparation

Laparotomy was performed under ether anesthesia, the colon was visualized, and the perimeter of the mid-colon was measured. Under anesthesia the entire colon was then rapidly excised and placed in a Petri capsule containing Tyrode solution (6.9 g/L NaCl, 0.35 g/L KCl, 0.16 g/L KH_2PO_4, 0.29 g/L $MgSO_4$, 1 g/L glucose, 0.28 g/L $CaCl_2$, 2.1 g/L $NaHCO_3$) continuously oxygenated with a mixture of 95% O_2 and 5% CO_2 and maintained at a temperature of 37 ℃. The colon was carefully opened along the mesenteric side and the luminal surface was flushed with pre-warmed Tyrode solution through a fine needle syringe to remove the feces. If perforation of the organ was observed, the rat was excluded from the study. Fragments from the mid-colon (corresponding to the dilated non-inflamed region of the colon in TNBS rats) and the distal colon in both treated and control rats were processed for structural and enzymatic activity (myeloperoxidase (MPO), NOS). The mid-colon, from TNBS and control rats, was used for motility studies.

Assessment of colonic damage and inflammation

All tissue fragments were immediately and rapidly examined under a stereomicroscope by a blinded expert observer, and any visible damage was scored according to the following scale: 0 = no damage, 1 = localized hyperemia without ulcers, 2 = linear ulcers without inflammation, 3 = linear ulcers plus inflammation, 4 = two or more sites of ulceration and/or inflammation, 5 = ulceration >1 cm extension.

Samples from the DUMC and from the inflamed distal colon of TNBS rats and from mid- and distal colon of control rats were taken for conventional histology and for MPO activity evaluation.

For histology, tissue specimens were fixed in formalin and embedded in paraffin. Coded sections were then stained with hematoxylin and eosin, and examined at light microscopy, by a blinded observer.

For the measurement of MPO activity, full-thickness tissue, obtained from the sites adjacent to the tissue retrieved for histological studies, was snap frozen in liquid nitrogen and stored at -80 ℃. The MPO activity was measured according to the protocol of Wallace[28]. One unit of MPO activity was defined as the quantity of enzyme needed to convert 1 mol of hydrogen peroxide to water in 1 min, at room temperature, and was expressed in units per milligram of tissue.

Assessment of NOS activity

Full thickness samples, obtained from DUMC and inflamed distal colon of TNBS rats and from mid- and distal colon of control rats, were used for the assessment of NOS activity.

NOS activity was determined by measuring the conversion of [3H]-L-arginine to [3H]-L-citrulline. Tissue samples were homogenized by sonication in homogenization ice-cold buffer (25 mmol/L Tris-HCl, pH 7.4, 1 mmol/L ethylenediaminetetraacetic acid (EDTA), 1 mmol/L ethylene glycol-bis (β-aminoethyl ether)-*N*,*N*,*N*',*N*'-tetraacetic acid containing protease inhibitors (0.2 mmol/L phenylmethanesulfonyl fluoride, 10 g/mL aprotinin, 10 g/mL pepstatin A, 10 g/mL leupeptin). The homogenates were centrifuged at 4 ℃ for 20 min at 15 000 *g*. The supernatants were passed through AG50WX-8 Dowex resin (Bio-Rad Laboratories, Melville, NY, USA) to remove endogenous arginine. The protein content was determined by the bicinchoninic acid procedure (Pierce) using BSA as standard. Enzymatic reactions were conducted at 37 ℃ for 30 min in 50 mmol/L Tris-HCl, pH 7.4, containing 1 mmol/L $CaCl_2$, 1 mmol/L $MgCl_2$, 6 mol/L tetrahydrobiopterin (BH4), 2 mol/L flavin adenine dinucleotide, 2 mol/L flavin adenine mononucleotide, 1 mmol/L L-citrulline (to inhibit the catabolism of [3H]-L-citrulline), 60 mmol/L L-valine, 60 mmol/L L-ornithine, 60 mmol/L L-lysine (to inhibit nonspecific arginase activity) and 10 Ci/mL of [3H]-L-arginine (specific activity 66 Ci/mmol/L (Amersham, Buckinghamshire, UK). When indicated, $CaCl_2$ (0.6 mmol/L) and calmodulin (CAM, 0.1 mol/L) were added to the assay system. This reaction was stopped by the addition of 0.4 mL of stop buffer (50 mmol/L Hepes, pH 5.5, 5 mmol/L EDTA). Citrulline was determined by introducing the samples into columns containing 0.1 mL of Dowex AG50WX-8, equilibrated resin to Na+ form, to bind all the unreacted radio-labeled L-arginine. The columns were vortexed and centrifuged (15 000 *g* for 30 s). Therefore, 100 μL of the eluate were counted by liquid scintillation to quantitate the formation of [3H]-L-citrulline. This assay measures both the calcium-dependent (constitutive) and the calcium-independent (inducible) isoenzymes. Any activity detected in the absence of Ca/CAM represented the iNOS activity. Quantitative results for citrulline-production are expressed as picomoles of citrulline per milligram proteins per minute (citrulline pmol/mg protein/min).

Evaluation of circular muscle contractile activity

Tissue preparation Full wall thickness strips containing the mucosa (1.5 mm×10 mm) were derived both from the DUMC of the TNBS rats and the corresponding mid-colon of the control rats. Strips were oriented in the axis of the circular muscle and were attached to an isometric force transducer (Model Gemini Basile, Varese, Italy) and placed in an organ bath containing 20 mL of Tyrode solution which was continuously oxygenated with a mixture of 95% O_2 and 5% CO_2 and maintained at a temperature of 37 ℃. Muscle strips were allowed to stabilize for 2 h before they were stretched by 2-mm increments to the optimal length for contraction (L_o). The force of muscle contraction was normalized for cross-sectional area obtained by the following equation: $XS = M/L_o \times d$[29,30], where XS (cm^2)=cross-sectional area of muscle, M (g) = mass of circular muscle layer (after removal of the mucosa and submucosa), L_o (cm)=optimal length for muscle contraction, d (g/mL) = density of colonic muscle in bath numerically equal to specific gravity of colonic muscle in Tyrode solution. The muscle strips from TNBS rats which were devoid of spontaneous activity were, nevertheless, used to study the effects of NOS inhibitor (L-NNA) when basal activity was absent. These muscle strips, after 2 h of equilibration, were stretched to 1.25× resting length. In this way, each muscle strip was stretched to a similar length.

Spontaneous contractile activity The parameters considered were the frequency and force of contraction. In a preliminary set of experiments, in order to evaluate the nature of the phasic contractions, i.e. myogenic or neurogenic, the preparations were treated with tetrodotoxin (TTX, 1 μmol/L), a sodium channel blocking agent, commonly used to block inhibitory and excitatory motorneurons activity.

Muscle stimulation High potassium (high $[K+]_o$, 80 mmol/L) was used as a mainly direct smooth muscle depolarizing and contracting agent without the need for receptor activation to assess whether the observed decrease in basal contractile efficacy of the circular muscle strips derived from the TNBS rats was due to a post-receptor event, i.e. intrinsic smooth muscle properties. In a set of experiments, TTX was added to the buffer in order to evaluate the potential neuro-mediated effects of high $[K+]_o$.

Electric field stimulation (EFS) was obtained through two platin electrodes placed in parallel with respect to the circular muscle strip. The electrodes were connected to a stimulator (Mod. 1193 Tuniati, Pavia Italy) and 4 Hz stimuli were applied (25; 60 V; 0.3 ms impulses) for a total duration of 5 s. This stimulus induced a submaximal contractile response evaluated in the context of a range of stimuli applied from 1 to 15 Hz. EFS were applied every 5 min. The EFS-induced responses were neuromediated in that no effect was observed when the stimulation was performed in the presence of TTX 1 μmol/L.

Effect of L-NNA To evaluate the role of NO on basal and evoked contractile activity, the experiments were performed both in the absence and in the presence of a non-selective NOS inhibitor, L-NNA (100 μmol/L)[31]. The full effect of the compound was obtained after 10 min of incubation.

Pharmacological characterization of EFS-evoked contractile response This study was performed only in the presence of L-NNA which made responses of circular muscle strips more stable[32] and excluded the inhibitory action of NO on neuromuscular function. The major putative excitatory neurotransmitters responsible for intestinal muscle contraction after EFS are considered to be acetylcholine and tachykinins (substance P and neurokinin A)[33]. The cholinergic component of EFS contractions was determined by adding atropine (1 mol/L) to the bath. The tachykinergic component of EFS evoked contractions was established by adding neurokinin 1 (NK_1) plus neurokinin 2 (NK_2) receptor antagonists (0.3 μmol/L) and SR48968 (0.3 mol/L), respectively, to the bath[34,35]. SR140333 and SR48968 are selective non-peptide tachykinin NK_1 and NK_2 receptor antagonists, respectively[34,35]. The concentrations of these antagonists used in our study have previously been demonstrated to be effective and receptor-selective in the mammalian intestinal preparations[34,35]. The antagonists were

left for at least 20 min before EFS. The antagonist concentration and time incubation were established following the demonstration of their ability to block the contractile effect of submaximal concentration of NK_1 and NK_2 receptor agonists, substance P methyl ester and [ALA]8-NKA[4-10] respectively, on circular muscle strips derived from controls. Atropine and NK_1 plus NK_2 receptor antagonists were, sequentially, added to the bath.

Drugs and solutions

The following drugs were obtained from Sigma Chemicals (Milan, Italy): atropine sulfate, TTX, L-NNA, substance P methylester and [ALA]8-NKA[4-10]. SR140333 and SR48968 were obtained by the courtesy of Dr. X. Edmond-Alt (Sanofi Research, Montpellier, France).

Substance P methylester, [ALA]8-NKA[4-10], SR140333 and SR48968 were dissolved in dimethyl sulfoxide (final solution 0.1%) and diluted in distilled water.

Statistical analysis

Statistical analysis was performed in a double-blind fashion using a suitable computer program (SAS/STAT software). Results were expressed as means±SD. Comparison of results between groups was made using the unpaired *t* test, Kruskal-Wallis test, Wilcoxon rank sum test, Mann-Whitney *U* test, Duncan's multiple range test, and ANOVA, when appropriate. All statistical tests were two sided. A value of $P<0.05$ was considered significant.

RESULTS

Course of colitis

All rats presented bloody diarrhea within 12 h of intracolonic administration of TNBS. All ($n = 10$) had lost 14±4 g body weight, while control rats ($n = 10$) gained 12±4 g, $P<0.01$. No animal died within 48 h of colitis induction.

Colonic lesions and inflammation

After laparotomy and upon visualization of the colon, TNBS rats presented a severely dilated mid-colon proximal to the grossly impaired distal colon. The *ex vivo* mean perimeter of the mid-colon in TNBS rats ($n = 10$) was 21±6 mm compared to 12±5 mm of the mid-colon in controls ($n = 10$) ($P<0.01$).

In TNBS rats, a dischromic, opaque, but not perforated, serosa was observed, nearly 8 cm from the anal verge, corresponding to the contact area of the instilled TNBS solution, the lumen of the colon was entirely filled with liquid feces, while in control rats the serosa appeared normal and well-formed fecal pellets, mainly at the distal colon, were observed.

In TNBS rats, the macroscopic damage score (0-5), at the macroscopically inflamed distal colon, was 4.1±0.2 while, at the DUMC the score was 0.3±0.1 ($P<0.01$).

In TNBS rats, the histological evaluation showed no lesions or inflammatory infiltrate at the mid-colon, which represents the area of interest for mechanical activity studies. The distal segment was grossly ulcerated and necrotic up to the smooth muscle layers appeared to be slightly damaged. The inflammatory infiltrate was composed mainly by neutrophils and, to a lesser extent, by monocytes. The entire colon of the control rats was devoid of any significant lesions.

MPO activity, in the TNBS inflamed distal colon (dilated and macroscopically and histologically inflamed segment), was significantly higher than that in the distal colon of control rats (Figure 1). Whereas, in the TNBS uninflamed mid-colon (dilated but macroscopically and histological normal), MPO activity was similar to that of the corresponding mid-colon of control rats.

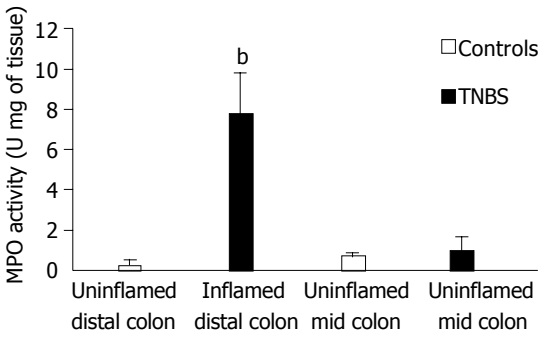

Figure 1 Colonic MPO activity in TNBS and control rats. $^bP<0.01$ *vs* controls distal colon.

NOS activity

In TNBS rats, NOS activity of the inflamed distal colon was significantly increased ($P<0.01$) compared to that of DUMC of TNBS and of controls (Figure 2). iNOS activity was observed only in the inflamed distal colon of TNBS rats where it was responsible for the marked increase of the overall NOS activity observed at this level. In the inflamed distal colon of TNBS rats, cNOS activity was not, in fact, significantly different from that in the controls and TNBS uninflamed mid-colon.

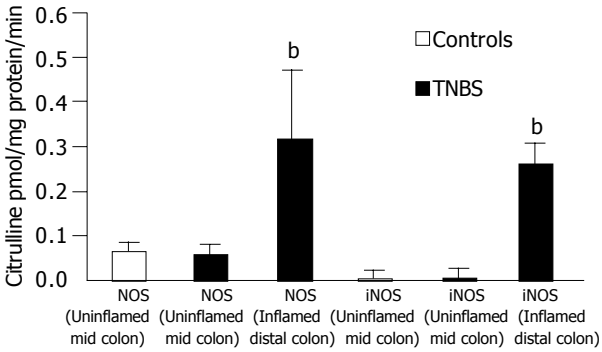

Figure 2 NOS activity in different colon segments in TNBS and control rats. $^bP<0.01$ *vs* uninflamed mid-colon.

Circular muscle contractile activity

Spontaneous contractile activity In controls, two types of spontaneous mechanical contractions were identified, i. e., low- and high-frequency spontaneous contractions. High-frequency contractions are intermittent and produce

summation contractions which are not constantly present and, therefore, these were not considered, in detail, in the present study.

Spontaneous activity was absent in 28% of the TNBS rat DUMC preparations or they showed a significant reduction of frequency and force compared to controls (Figures 3 and 4). In both groups, the spontaneous phasic activity was significantly increased both in frequency and force by TTX (1 μmol/L), the effects being significantly greater and long lasting in the strips from the DUMC of TNBS rats than in the controls. In the former, the increase in frequency and force was 40±9% and 22±7%, respectively, $P<0.01$; in the latter, the increase was 22±8% and 14±7%, respectively, $P<0.01$. Furthermore, TTX evoked spontaneous contractions in 80% of specimens which, in basal conditions, appeared to be inactive. Taken together, these data highlight the greater sensitivity to neuronal inhibitory input of DUMC of TNBS *vs* controls.

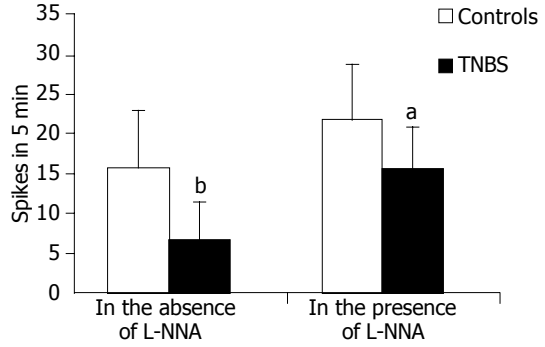

Figure 3 Frequency of phasic contractions of mid-colon circular muscle in controls compared to DUMC of TNBS rats. [a]$P<0.05$ *vs* controls, [b]$P<0.01$ *vs* controls.

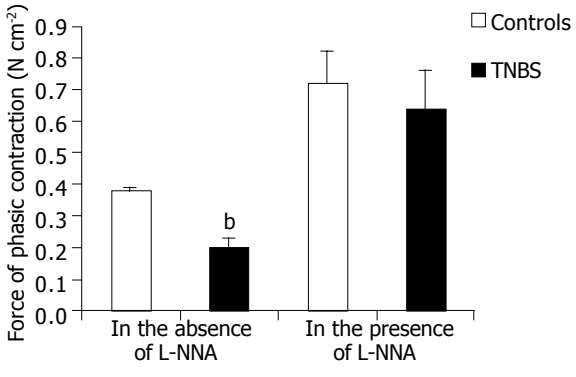

Figure 4 Force of phasic contractions of mid-colon circular muscle in controls compared to DUMC of TNBS rats. [b]$P<0.01$ *vs* controls.

L-NNA (100 μmol/L) induced a slow onset enhancing the effect of the frequency and force of spontaneous contractile activity which peaked after 5-7 min and remained unchanged for about 40 min in circular muscle strips from both animal groups, the effect being more pronounced in TNBS rats (Figures 3 and 4). In the presence of TTX, L-NNA induced, in both groups and to the same extent, a further slight increase (10%) in the force of muscle contraction suggesting a very small additional non-neuronal location of NO biosynthesis. L-NNA did not affect the frequency of contractions in the presence of TTX. Furthermore, L-NNA evoked phasic activity in almost all the strips (90%) from the DUMC of TNBS rats which had not originally shown any spontaneous contractions.

Overall, these findings suggest that endogenous NO negatively modulates the frequency and force of spontaneous phasic activity, and these effects were relatively more marked in tissues derived from TNBS rats than from controls.

Muscle stimulation High $[K+]_o$ (80 mmol/L)-induced contractile response was quantitatively and qualitatively different in circular muscle strips from DUMC of TNBS rats compared to those from controls. In the former, the force of contraction was markedly lower (Figure 5), and its time course to peak was longer. Furthermore, in control strips, high $[K+]_o$ induced a rapid onset inhibitory response followed by contraction. In the presence of TTX, the inhibitory response was abolished indicating its neuromediated nature. The inhibitory effect to high $[K+]_o$ was seldom observed in tissues from TNBS rats probably due to their lower basal tone. In both groups, in DUMC of TNBS and controls, the contractile responses to potassium were not significantly affected by TTX, indicating that this component of potassium responses was due to a mainly direct, non-neuromediated, circular muscle activation.

In the presence of L-NNA (100 μmol/L), high $[K+]_o$ contraction was enhanced by 112±22% in TNBS rats and by 28±2% in control animals ($P<0.001$) (Figure 5). However, the contractile response obtained in TNBS rats remained lower [by 23.5±1.8% ($P<0.01$)] than in controls without L-NNA.

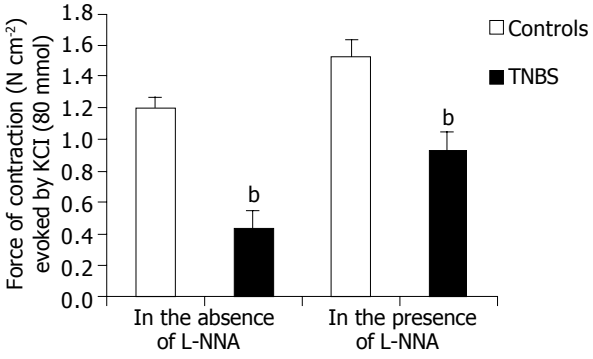

Figure 5 High $[K^+]_o$ induced contractile response of mid-colon circular muscle in controls compared to DUMC of TNBS rats. [b]$P<0.001$ *vs* controls.

EFS (1-15 Hz) evoked frequency-dependent contractile responses both in TNBS rat colonic muscle and in that of control rats (data not shown). In this study, a submaximal frequency of stimulus of 4 Hz was used. In controls, an initial inhibitory response precedes the contraction. The force of contractions was markedly smaller in TNBS rats (Figure 6) and tended to progressively fade after further stimulations until it became stable after the third stimulus. The value of the stabilized contraction has been assumed as EFS response. EFS induced contractions, in control rats, were stable and reproducible for at least 60 min. The EFS effects were abolished by TTX thus indicating the

neuromediated nature of the mechanical events (data not shown). In the presence of L-NNA, the force of contraction induced by EFS was enhanced by 121±19% in TNBS rats and by 27.4±1.9% in control rats ($P<0.001$) (Figure 6). However, the response obtained in TNBS rats remained lower [by 17.6±1.5% ($P<0.05$)] than in controls without L-NNA.

In the presence of L-NNA, the inhibitory response to potassium and EFS, observed in the controls, was not significantly lesser in amplitude than in the absence of NO synthesis inhibition, indicating the relative role of NO in inducing neuromediated relaxation in these colonic preparations.

Effects of cholinergic muscarinic and NK_1 plus NK_2 tachykinin receptor blockade on EFS evoked circular muscle contractile response In the presence of L-NNA, in control preparations, the sequential administration of atropine (1 μmol/L) and non-peptide tachykinin NK_1 and NK_2 receptor antagonists SR140333 (0.3 μmol/L) plus SR48968 (0.3 μmol/L) induced an apparent additional inhibitory effect of the EFS induced contraction leaving a non-cholinergic non-tachykinergic contractile component which was completely abolished by TTX. In TNBS rats, atropine alone induced a dramatic inhibition of contraction and the residual response was abolished by the sequential administration of SR140333 plus SR48968 (Figure 7). These results indicate the appearance of a cooperative-like interaction between the neuromuscular excitatory transmissions subserving EFS contraction in TNBS rats.

DISCUSSION

The present study focused on changes in colonic motility of the uninflamed regions of the colon observed in the course of severe human and experimental focal colitis. In rats with TNBS-induced acute distal colitis, we evaluated the spontaneous and evoked contractile activity of circular muscle strips from a region of the mid-colon, which was dilated but showed a normal appearance at light microscopy and normal MPO activity.

Low-frequency spontaneous contractile activity was always present in controls, but conversely, was absent in 28.5% of specimens from the DUMC of TNBS rats, and, if present, showed a significant reduction both in frequency and force of contraction, with respect to that in controls. Removal of the overall neural control, on smooth muscle activity, by TTX, induced an increase in the frequency and force of contractions which were significantly greater in tissues from TNBS rats and this contractile activity became present in almost all specimens. These findings confirm previous evidence that the spontaneous contractions in rat circular muscle strips, as, in general, in the mammalian colon, are myogenic in nature and under tonic neuronal inhibition[4,21]. Thus, the impairment of spontaneous activity in tissues from TNBS rats may be due to a disorder of the intrinsic muscle contractile machinery and/or due to an inappropriate neural inhibitory control.

Evoked contractions were induced by a mainly direct smooth muscle plasma membrane depolarization by high $[K+]_o$ in the buffer, and by indirect neuronal- and receptor-mediated activation of circular muscle strips by EFS, the former being largely resistant to TTX and the latter abolished by it. In the controls, both stimulatory procedures, in addition to contraction, induced a rapid onset and transient relaxation due to the release of inhibitory neurotransmitters in that it was abolished by TTX and slightly reduced by L-NNA. In the DUMC of TNBS rats, the relaxing effects were not usually observed, probably because of the lower basal tone of the circular muscle and, moreover, the high $[K+]_o$ contractions appeared markedly impaired in amplitude and slower in the time course compared to controls. Likewise, the EFS contractile responses, in TNBS rats, were smaller in force than those in controls and tended to fade at subsequent stimulations until a stable response was reached after the third stimulation.

Impairment of evoked contractions in TNBS rats may still suggest a defect of contractile machinery (as suggested by the high $[K+]_o$ response). However, a simultaneous defect in the excitatory neurotransmission (neurotransmitter release and/or receptor–postreceptor functions) in the EFS response could not be ruled out.

On the base of increasing evidence that NO plays an important role in inhibiting colonic tone and motility of the inflamed region in human and experimental animal colitis[12,17,25,26], we evaluated the potential role of NO in the impairment of muscle contractility also in the dilated uninflamed region of the TNBS rat. NO is the most important inhibitory transmitter of enteric neurons in the mammalian gut[20-22] and, in human colitis, iNANC activity has been shown to be increased[36]. Furthermore, extraneuronal NO production, by iNOS, localized in

immune cells and enteric myocytes has recently been detected in inflamed colonic mucosa from patients with UC compared to controls, with significantly higher levels in TMC than in uncomplicated colitis[23-25]. Similarly, in TNBS-induced colitis, associated with colonic dilation, a striking increase in iNOS expression was found, whereas inhibition of NOS activity, by L-NNA, prevented colonic dilation[26]. The observation that interleukin 1 (IL-1), tumor necrosis factor-α (TNFα), and interferon-γ (INFγ), which are of prime importance in the inflammatory process of severe colitis, as well as free radicals and lipopolysaccharides, are able to induce iNOS expression in human colonic smooth muscle strips, further supports the role of iNOS in the genesis of TMC[25,26,37,38].

In this study, the role of NO on the contractility of circular muscle from DUMC of TNBS rats has been evaluated using L-NNA, a non selective NOS isoforms inhibitor. Previously, an analogous compound of L-NNA, the *N*-monomethyl-L-arginine, has been reported to increase spontaneous contractions of rat distal colon circular muscle strips, indicating that this colonic preparation is under tonic neural inhibition by NO biosynthesis[29]. L-NNA, added to the organ bath, induced both a relatively greater increase in the frequency and force of circular muscle phasic contractions in DUMC of TNBS than in controls and, indeed, their appearance, when absent, in the former. Furthermore, L-NNA induced a considerably greater increase of high $[K+]_o$ contractile responses in DUMC of TNBS compared to controls with a reduction in the time course. Likewise, in the presence of L-NNA, the contraction induced by EFS was enhanced in both groups, the effect being relatively more marked in strips from TNBS rats.

Studies on the pharmacological characterization of contractions induced by EFS were performed only in the presence of L-NNA in order to obtain more stable responses as already observed in rat duodenal preparations[32], and to better define potential dysfunctions in the excitatory neuromuscular transmissions and responses, i.e., independently of the NO-mediated inhibitory action, both on excitatory neurotransmitters release and muscular contractile response. The nature of the contractile responses induced by EFS were analyzed using atropine and SR140333 plus SR48968 as selective antagonists of cholinergic muscarinic and NK_1 and NK_2 tachykinin receptors, respectively. In controls, a simple additional interaction was observed between the cholinergic and tachykinergic transmission in inducing contractions and the sequential blockade of the respective receptors left a non-cholinergic-non-tachykinergic contractile component which was abolished by TTX. In TNBS rats, a cooperative-like interaction between cholinergic and tachykinergic excitatory transmissions appeared to be present. The existence of a non-simple additional interaction in the latter was suggested by the evidence that the blockade of only one of the neuronal transmissions (i.e., muscarinic transmission) induced a dramatic inhibitory effect on EFS responses, and the residual contraction was completely abolished after sequential tachykinergic transmission blockade, indicating that the contribution of both the excitatory transmissions was mandatory to induce contractile responses.

The biochemical studies performed to define the activity of NOS isoforms in the DUMC tissues of TNBS showed that only cNOS was present and its activity was not different from that in control rats. In the injured distal colonic segments of TNBS rats, cNOS activity was similar to that in controls, whereas iNOS activity was markedly present, confirming previous observations[26]. These findings indicate that enhancement of spontaneous and evoked muscle contractility, in the presence of blockade of NOS activity, is due to the inhibition of the cNOS in the two groups studied. The set-up used did not allow us to characterize the cellular source and isoform of cNOS (neural or endothelial/muscular) in the colonic preparations. However, the observation that L-NNA induced a slight but not a significant increase in the amplitude of spontaneous contractions in the presence of TTX may suggest a scanty role of non-neural cNOS in the overall enzyme activity in both groups of rats. The lack of appreciable quantitative differences, in the presence and activity of cNOS, between the two groups did not allow us to give a simple interpretation for the considerably greater enhancing effect, induced by L-NNA, on the spontaneous and evoked contractions of circular muscle strips from DUMC of TNBS compared to those from controls. However, it is tempting to hypothesize that a relatively greater inhibitory effect is exerted by NO on the functionally impaired myogenic and possibly excitatory neurogenic mechanisms subserving contractions in TNBS rats. The observation that also TTX induced a considerably greater enhancing effect on spontaneous and high potassium ($High[K+]_o$)-evoked contractions in DUMC of TNBS compared to controls may suggest that circular muscle strips from DUMC of TNBS present an abnormally high sensitivity to inhibitory neurotransmitters. On the other hand, it is unlikely that the increase in mechanical activity of the circular muscle induced by L-NNA in DUMC, is not due to the suppression of NO synthesis, but rather due to the inhibition of the production of peroxynitrite (ONOO-) in as much as the production of the latter requires the presence of the superoxide radical ($\cdot O_2$), (i.e. $NO+\cdot O_2 \rightarrow$ONOO-). The generation of $\cdot O_2$ requires the presence of local inflammation which was absent in the intestinal preparations in which mechanical activity was evaluated.

The importance of the neurogenic mechanisms in the distension and hypocontractility of uninflamed gastrointestinal segments in TNBS-induced intestinal inflammation in rats has recently been reported[18,39].

As far as concerning the potential mechanisms involved in the impairment of intrinsic muscle contractile machinery, in the rat model of acute TNBS colitis, a decrease in the activity of smooth muscle L-type Ca++ channels has been demonstrated. Ca++ mobilization, via the L-type Ca++ channel, is the primary mechanism for excitation-contraction coupling in gastrointestinal smooth muscle. The dysfunction of the L-type Ca++ channels appears to be mediated by the activation of the NF-kB-dependent pathway leading to a marked alteration in the assessment of cytokines, as observed in acute TNBS colitis. Theoretically, the hematogenic diffusion of cytokines from the inflammatory to the non-inflammatory region of the colon may also result in the inhibition of TNBS DUMC muscle contractility as observed in the present study.

In conclusion, results emerging from the present study show that impairment of spontaneous and evoked circular muscle contraction of the DUMC in TNBS-induced distal colitis, in rats, is mainly due to a disorder of the intrinsic muscle contractile machinery. Failure of enteric neural excitatory input to the smooth muscle cannot be ruled out. Local suppression of NO synthesis markedly improves both the spontaneous and evoked muscle contractions, in spite of any evident abnormal local NO activity. New therapeutic approaches aimed at inhibition of NO synthesis or effects may improve muscle contractility, not only in the inflamed, but also in the distended uninflamed intestinal regions in the course of acute severe inflammatory bowel disease.

Abstract

AIM: To evaluate the efficacy of combination chemotherapy with interferon-α (IFNα) and 5-fluorouracil (5-FU) in patients with advanced hepatocellular carcinoma (HCC).

METHODS: Twenty-eight HCC patients in advanced stage were enrolled in the study. They were treated with IFNα/5-FU combination chemotherapy. One cycle of therapy lasted for 4 wk. IFNα (3×10^6 units) was subcutaneously injected thrice weekly on days 1, 3, and 5 for 3 wk, and 5-FU (500 mg/d) was administered via the proper hepatic artery for 5 consecutive days per week for 3 wk. No drugs were administered during the 4th wk. The effect of combination chemotherapy was evaluated in each patient after every cycle based on the reduction of tumor volume.

RESULTS: After the 1st cycle of therapy, 16 patients showed a partial response (PR, 57.1%) but none showed a complete response (CR, 0%). At the end of therapy, the number of patients who showed a CR, PR, or no response (NR) was 1, 10, and 17, respectively. The response rate for therapy (CR+PR) was 21.5%. Biochemical tests before therapy were compared between responsive (CR+PR) and non-responsive (NR) patients, but no significant differences were found for any of the parameters examined, indicating that no reasonable predictors could be identified in our analysis.

CONCLUSION: Attempts should be made to discriminate between responders and non-responders by evaluating tumor size after the first cycle of IFNα/5-FU combination chemotherapy. For non-responders, therapy should not proceed to the next cycle, and instead, different combination of anticancer drugs should be explored.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common tumors worldwide. Therapies for HCC have been developed, such as percutaneous ethanol injection therapy (PEIT), microwave coagulation therapy (MC), and radiofrequency ablation (RFA). For patients in whom these localized therapies cannot be used, transarterial chemoembolization (TACE) and liver transplantation may be selected. However, in cases with repeated recurrence, vascular invasion or distant metastasis were used; these methods often become ineffective or impossible, and the last treatment option is chemotherapy. Although it is thought that HCCs are generally resistant to anticancer drugs, combination chemotherapy has been used to increase the responsiveness of cancer cells.

Combination therapy with interferon-α (IFNα) and 5-fluorouracil (5-FU) was first reported for the treatment of patients with colorectal cancer[1]. Recent studies indicated that the combined chemotherapy involving arterial injection of 5-FU and subcutaneous injection of IFNα was also markedly effective in some patients with advanced HCC. In these studies, the response rates to therapy were 62.5%[2] and 53.1%[3]. In the present study, we describe the use of this combination therapy in HCC patients for whom there were no other treatment options.

MATERIALS AND METHODS

Between 2003 and 2004, 28 patients with unresectable HCC associated with multiple intrahepatic tumors and/or portal vein tumor thrombi received IFNα/5-FU combination therapy at the Third Department of Internal Medicine, Kyushu University Hospital. The treatment regimen is shown in Figure 1. IFNα (3×10^6 units) was subcutaneously injected thrice per week on d 1, 3, and 5 for 3 wk. 5-FU (500 mg/d) was given over 2 h through a catheter introduced

into the proper hepatic artery for 5 consecutive days per week for 3 wk. No drugs were administered during the 4th wk. One cycle of the therapy lasted for 4 wk and patients received 1-4 cycles. The effect of combination chemotherapy was evaluated in each patient after every cycle based on the reduction of tumor volume. The degree of the response was categorized as follows: (1) complete response (CR); depletion of all the tumors on computed tomography (CT); (2) partial response (PR); over 15% reduction of the total diameters of all detectable tumors on CT; and (3) no response (NR); those that did not show a CR or PR. Combination chemotherapy was stopped after the fourth cycle was completed, or when there was no reduction in the tumor volume after any cycle. At that time, final evaluations were performed.

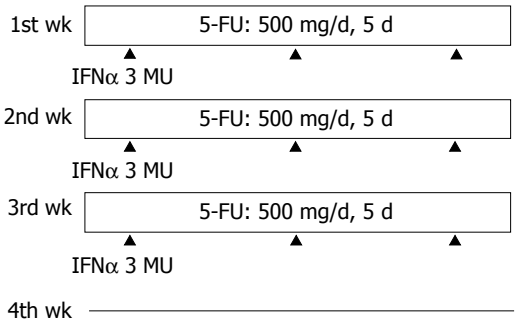

Figure 1 Regimen for IFNα plus 5-FU combination therapy (one cycle).

RESULTS

The baseline characteristics of the patients who received IFNα/5-FU combination chemotherapy are shown in Table 1. Because of the advanced stage of HCC in these patients, no other therapeutic options were available. Seven of the patients were being treated for HCC for the first time. Other therapies, such as surgical resection, PEIT, MC, RFA, and TACE, had been repeated at least twice in the other patients. Portal thrombi existed in Vp3-4 in seven patients. The combination chemotherapy was performed on these patients (see Patients and methods).

The response to chemotherapy is shown in Table 2. In these patients, chemotherapy was not stopped by adverse effects, such as thrombocytopenia and leukocytopenia. After the first cycle of therapy, 16 patients showed a PR (57.1%) but none showed a CR. In all the patients with PR, levels of the tumor marker α-fetoprotein (AFP) decreased (-2.6-91.2%, mean: -55.6%). When the therapy was completed, 1 of these 16 PR patients achieved a CR, and 10 of them showed a NR. The overall response rate for chemotherapy (CR+PR) was 21.5% (6/28). CT of a patient who achieved a CR is shown in Figure 2. After three cycles of therapy, the enhanced area of the HCC observed before chemotherapy disappeared and elevated levels of AFP decreased to the normal range (from 761.0 to 8.9 ng/mL). The backgrounds of the patients, including their laboratory test profiles before chemotherapy, were compared between responders (CR+PR) and non-responders; however, no significant differences were found for any of the parameters examined.

Table 1 Baseline characteristics of the patients

Patient (*n*)	28
Male/female	21/7
Portal thrombi (+/–)	7/21
TNM classification (II/III/IV)	5/11/12
Albumin	3.4±0.1 (g/dL)
Total bilirubin	1.3±0.2 (mg/dL)
ALT	48.2±6.4 (IU/L)
Platelet	11.3±1.7 (×10⁴/mL)
PT	70.9±2.8 (%)
AFP	7 105±2 756 (ng/mL)

ALT, alanine aminotransferase; PT, prothrombin time; AFP, alpha-fetoprotein.

Table 2 Evaluation of IFNα/5-FU combination therapy

	Evaluation after 1st cycle patient *n* (%)	Final results patient *n* (%)
CR		1 (3.6)
PR	16 (57.1)	5 (17.9)
NR	12 (42.9)	22 (78.6)

IFN, interferon; FU, fluorouracil; CR, complete response; PR, partial response; NR, no response.

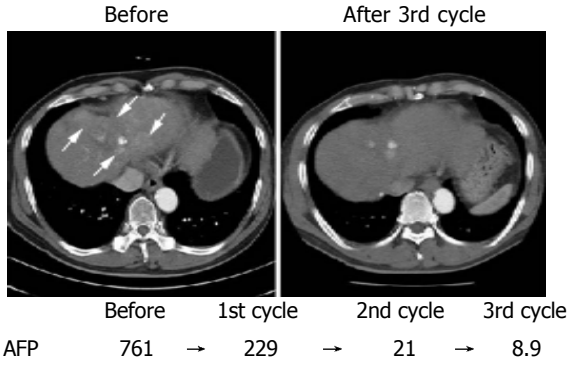

Figure 2 CT of a patient who showed a complete response. Enhanced lesions of HCC (arrows) disappeared after three cycles of combination therapy with IFNα and 5-FU. The serum levels of AFP are also presented.

DISCUSSION

The mechanism underlying the ability of IFNα to strengthen the anti-cancer effect of 5-FU has been studied previously. IFNα enhances the conversion of 5-FU to an active metabolite, fluorodeoxyuridine monophosphate (FdUMP), through an increase of thymidine phosphorylase and a suppression of dihydropyrimidine dehydrogenase[4,5]. FdUMP induces DNA damage and the expression of death receptors (tumor necrosis factor-related apoptosis-inducing ligand [TRAIL] receptors) on cancer cells, resulting in cell death[6]. IFNα reduces tumor cell proliferation through cell cycle elongation[7] and induces p53, which contributes to tumor suppression[8]. IFNα also exerts immunomodulatory effects by stimulating T cells, NK cells, and monocytes[9,10], and enhances production of TRAIL by immune cells[11-13].

Several studies have attempted to distinguish between responders and non-responders to 5-FU/IFNα combination chemotherapy. Low levels (<50 ng/mL) of serum AFP were reported as a predictor[14], but conflicting results have

also been reported[15]. A relationship between the expression levels of the IFN receptor on HCC cells and sensitivity to 5-FU/IFN therapy was reported previously[7], but another study group indicated that the expression levels of the type I IFN receptor were similar between responders and non-responders[3]. Yamamoto *et al*., reported that, among HCC patients who received 5-FU/IFNα combination chemotherapy, the expression of TRAIL mRNA in peripheral blood mononuclear cells (PBMC) was significantly higher in clinical responders than in non-responders[6]. It was suggested that upregulation of TRAIL mRNA in PBMC may be a predictor of the clinical response to combination therapy. In our patients, no predictors were found among the biochemical tests that were analyzed. We advocate that, in practice, responders and non-responders should be discriminated after the first cycle of the therapy by evaluating tumor size and the levels of tumor markers. For non-responders, therapy should not proceed to the next cycle and instead a different therapeutic option should be explored.

Some groups have reported much better results from combination chemotherapy than those observed in our study[2,3]. Apart from the dose of IFNα used, their regimens were nearly identical to ours. Those studies used 5×10^6 units of IFNα per treatment. We previously tested the effect of IFNα at doses of 3×10^6 and 6×10^6 units, and found no significant difference (data not shown). We therefore used the lower dose of 3×10^6 units to decrease the incidence of adverse effects. Since other types of therapies have been repeated in many of our patients, the HCCs in these patients may have existed in polyclonal nodules. In fact, in some patients, some HCC nodules were reduced in size, and others were enlarged during the chemotherapy. It is possible that the polyclonality weakened the clinical effects of therapy. In our patients, a relatively high response rate, 57.1%, was observed after the first cycle, but resulted in a rate of 21.5% at the end of the last cycle. Many of the patients who initially showed a PR after the first stage ended up having NR at the end of therapy. These findings suggest that the original clones with resistance against anticancer drugs and some cancer cells that acquire resistance during therapy can proliferate, and their rate of growth increases synergistically whenever a cycle is repeated.

What can be done to make combination chemotherapy more effective? A better regimen for IFNα/5-FU combination chemotherapy could be developed. Which is better, IFNα or IFNβ? IFN can be administered intravenously or intra-arterially. How many times should IFN be administered? What should be the dose of 5-FU at a time? What will be the best duration for 5-FU injection? It is also a problem whether the couple of 5-FU and IFNα is the best combination as chemotherapy for HCC. Many anticancer drugs can be selectable such as CDDP, MTX, LCV, and Gemcitabine. We should develop better regimen and combination for HCC.

Abstract

AIM: As intraductal papillary mucinous neoplasm (IPMN) has a favorable prognosis, associated malignancies have potential significance in these patients. We examined the incidence and characteristics of pre-existing, coexisting and subsequent malignancies in patients with IPMN.

METHODS: Seventy-nine cases of IPMN were diagnosed by detection of mucous in the pancreatic duct during endoscopic retrograde pancreatography. Histological diagnosis was confirmed in 30 cases (adenoma (n = 19) and adenocarcinoma (n = 11). Other primary malignancies associated with IPMN, occurring in the prediagnostic or postdiagnostic period, were investigated. Postdiagnostic follow-up period was 3.3±0.5 years (range, 0.2-20 years).

RESULTS: Other 40 malignancies occurred in 28 patients (35%). They were found before (n = 15), at (n = 19) and after (n = 6) the diagnosis of IPMT. Major associated malignancies were gastric cancer (n = 12), colonic cancer (n = 7), esophageal cancer (n = 4), pulmonary cancer (n = 4), and independent pancreatic cancer (n = 3). Pancreatic cancer was synchronous with IPMN in two patients and metachronous in one (3 years after diagnosis of IPMN). Thirty-one lesions were treated surgically or endoscopically. Fourteen patients died of associated cancers. Development of other malignancies was related to age (71.9±8.2 *vs* 66.8±9.3, P<0.05), but not to gender or site of the tumor.

CONCLUSION: IPMN is associated with a high incidence of other malignancies, particularly gastric and colonic cancers. Common genetic mechanisms between IPMN and other associated malignancies might be present. Clinicians should pay attention to the possibility of associated malignancies in preoperative screening and follow-up of patients with IPMN.

INTRODUCTION

Intraductal papillary mucinous neoplasm (IPMN) of the pancreas is a distinct entity characterized by intraductal papillary growth and thick mucous secretion. Copious mucous fills the main and branch pancreatic ducts and causes ductal dilatation. IPMN histologically shows a broad spectrum ranging from adenoma to invasive carcinoma. IPMN is classified into two subtypes of main duct type and branch duct type based on the site of tumor involvement. IPMN is a slow-growing tumor and many cases of branch duct type IPMN have been followed. IPMN, even when malignant, is often resectable, and has a favorable prognosis, compared with that of pancreatic ductal adenocarcinoma[1-3]. Prolonged postoperative survival can be anticipated in many IPMN cases. There are few papers reporting that IPMN is sometimes accompanied by malignant diseases of the other organs or pancreatic adenocarcinoma[4,5]. This report thus evaluates the incidence and features of associated malignancies in patients with IPMN.

MATERIALS AND METHODS

Between 1980 and 2004, 79 patients with IPMN were treated in Tokyo Metropolitan Komagome Hospital. They were diagnosed by detection of mucous in the pancreatic duct during endoscopic retrograde pancreatography. These patients comprised 54 males and 25 females, with an age of 68.5±9.2 (mean±SD) years. Twenty-three patients underwent surgical resection. Thirteen patients became unclear during follow up (1-5 years). Histological examination of the surgical (n = 23), biopsied (n = 2), and autopsied (n = 5) specimens revealed adenoma in 19 patients, non-invasive adenocarcinoma in 6, and invasive adenocarcinoma in 5. They were classified into main duct type (n = 30) and branch duct type (n = 49) based on the site of tumor involvement. Postdiagnostic follow-up period was 3.3±0.5 years (range, 0.2-20 years).

The inpatient records of these 79 patients were reviewed mainly for previous and coexisting nonpancreatic and

independent pancreatic neoplasms found at the time of diagnosis of IPMN. Furthermore, postdiagnostic follow-up data were obtained from outpatient charts.

Statistical analysis was performed using Student's *t*-test and Fisher's exact probability test. Differences were considered significant at $P<0.05$.

RESULTS

Other 40 malignancies were diagnosed in 28 (35%) of 79 patients with IPMN. They were found before ($n = 15$), at ($n = 19$) and after ($n = 6$) the diagnosis of IPMN. Major associated malignancies were gastric cancer ($n = 12$), colonic cancer ($n = 7$), esophageal cancer ($n = 4$), pulmonary cancer ($n = 4$), and independent pancreatic cancer ($n = 3$) (Table 1). Three other organs were involved in three patients, and two organs in four patients (Table 2). Double gastric cancers occurred in two patients. All of 15 other malignancies occurring 1-10 years (3.7±3.6 years) before the diagnosis of IPMN were resected surgically or endoscopically. Fifteen of nineteen other malignancies diagnosed simultaneously with IPMN were resected surgically or endoscopically. Only one other malignancy diagnosed after IPMN was surgically resected. Fourteen patients died of associated malignancies. Age at IPMN diagnosis in patients with other malignancies was significantly older than that in those without other malignancies ($P<0.05$). However, gender, follow-up period, site of IPMN, and resection of IPMN did not differ significantly between the two groups (Table 3).

Three patients had both IPMN and independent pancreatic cancer. Two patients had the two lesions synchronously, and pancreatic cancer occurred 3 years after the diagnosis of IPMN in one patient. All the three IPMNs were of branch type located in the pancreatic head and ranged from 1.5 to 3 cm. The lesion of IPMN was proximal to pancreatic cancer in two patients and distal in the other. Independence of IPMN and pancreatic cancer of two patients was proved histologically in the resected and autopsied pancreas, respectively. Two lesions were radiologically far from each other in the other patient (Figure 1). Although prognosis was poor in two patients in whom the presence of pancreatic cancer led to the diagnosis of IPMN, one patient with pancreatic cancer discovered during the follow-up of IPMN is doing well without any signs of recurrence, 36 mo after the operation (Table 4).

DISCUSSION

The incidence of occurrence of multiple primary malignant neoplasms occurring in different tissues has been reported

Table 1 Other malignacies in patients with IPMN

Syn: synchronous, Met: metachronous, PD: pancreatoduodenectomy, DP: distal pancreatectomy. [1]: This case is the same as case 7 in Table 2.

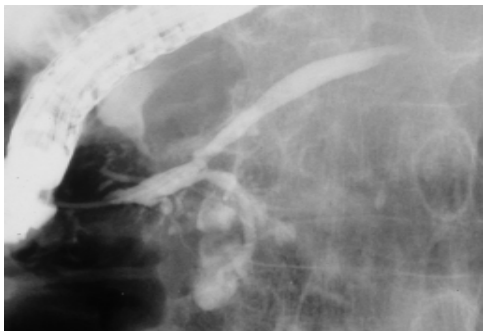

Figure 1 Endoscopic retrograde pancreatography showing branch-type intraductal papillary mucinous tumor of the pancreatic head and tapering obstruction of the main pancreatic duct involved with the concomitant pancreatic cancer of the body.

as 5.1%[6]. The incidence of other malignant neoplasms preceding, following or occurring simultaneously with the diagnosis of pancreatic cancer was reported to be 7%[4]. The present study revealed a high incidence of other malignancies (35%) in patients with IPMN. Other 40 malignancies were found before (n = 15), at (n = 19) and after (n = 6) the diagnosis of IPMN. Major associated malignancies were gastric cancer (n = 12) and colonic cancer (n = 7). Sugiyama and Atomi[4] reported that 15 (32%) of 42 patients with IPMN had nonpancreatic malignancies, including colonic cancer (n = 5) and gastric cancer (n = 4). Yamaguchi *et al*.[5], also reported that 13 (27%) of 48 patients with IPMN had malignant diseases, including gastric cancer (n = 5) and colonic cancer (n = 2). Incidence and associated other malignancies were similar to our results. In the present series, 14 patients died of associated malignancies. As IPMN is a slow-growing tumor with a relatively favorable prognosis, associated malignancies have potential prognostic significance. Systemic surveillance at the diagnosis of IPMN and careful follow-up is necessary for early detection of associated malignancies in patients with IPMN.

Interestingly, three patients with IPMN had also independent pancreatic cancer. All these IPMNs were of branch type located in the pancreatic head. The lesion of IPMN was proximal to pancreatic cancer in two patients and distal in the other. Pancreatic cancer occurred during the follow-up of IPMN could be diagnosed in relatively early stage. There is only one report describing the relationship between IPMN and pancreatic cancer[7]. In this report, independent pancreatic cancer was detected in 7 (10%) of 69 patients with IPMN, suggesting that the entire ductal epithelium of the pancreas with IPMN might already be in the premalignant condition.

The cause of frequent development of other malignancies in patients with IPMN is unknown. In the present study, age at IPMN diagnosis in patients with other malignancies was significantly older than the age in those without other malignancies. As elderly patients are more susceptible to neoplasms in most organs than younger patients and IPMN mainly affects elderly men, patients with IPMN have increased risk for other malignancies due to their age. Furthermore, oncogenetic changes of various organs of patients with IPMN might induce frequent development of other malignancies. Recent study has suggested that IPMN might form part of the spectrum of lesions encountered in attenuated familial adenomatous polyposis[8]. Common underlying genetic etiology might be present between IPMN and other associated malignancies. Further investigations focusing on this field are necessary in future.

In conclusion, IPMN is associated with a high incidence of other malignancies including pancreatic cancer. As IPMN has a relatively favorable prognosis, associated malignancies have potential prognostic significance. Clinicians should pay attention to the other associated malignancies in patients with IPMN.

AIM: While hepatocellular adenomas (HAs) have often been studied as a unique entity, we aimed to better define current management of the various forms of HAs.

METHODS: Twenty-five consecutive patients operated for solitary-uncomplicated (9), multiple (6), and ruptured (10) HAs were reviewed according to management strategies and outcomes.

RESULTS: All solitary-uncomplicated HAs (ranged 2.2-14 cm in size) were removed. Out of 25 HAs, 2 (8%) included foci of carcinoma. In the multiple HA group, previously undiagnosed tumors were identified during surgery in 5/6 cases. In three cases with multiple spread HA, several lesions had to be left unresected. They remained unmodified after 4-, 6-, and 6-year radiological follow-up. Patients with ruptured HA (ranged 1.7-10 cm in size) were initially managed with hemodynamic support and angiography, allowing the embolization of actively bleeding tumors in two patients. All ruptured tumors were subsequently removed 5.5 d (range 4-70 d) after admission.

CONCLUSION: Tumors suspected of HA, regardless of the size, should be resected, because of high chances of rupture causing bleeding, and/or containing malignant foci. Although it is desirable to remove all lesions of multiple HA, this may not be possible in some patients, for whom long-term radiological follow-up is advised. Ruptured HA can be managed by hemodynamic support and angiography, allowing scheduled surgery.

Toso C, Majno P, Andres A, Rubbia-Brandt L, Berney T, Buhler L, Morel P, Mentha G. Management of hepatocellular adenoma: Solitary-uncomplicated, multiple and ruptured tumors. *World J Gastroenterol* 2005; 11(36): 5691-5695
http://www.wjgnet.com/1007-9327/11/5691.asp

Hepatocellular adenomas (HAs) are generally considered as a single clinical entity, because they share a common histological appearance. However, HA can present as single or multiple tumors to be investigated in an elective setting (usually after the discovery of a silent hepatic lesion), or acutely as ruptured tumors causing right upper quadrant pain and/or intra-abdominal bleeding. Although the characteristics of HA have been described by several studies, still some controversy remains on its management. The aim of the present study is to offer a practical approach to the treatment of HA based on the various presentation forms of the disease, i.e., solitary-uncomplicated, multiple, or ruptured tumors.

From February 1980 to March 2003, 667 adults over 16-year underwent liver resection at our institution. Among them, 25 patients (3.7%) with HA represented the study population. All patients with a liver tumor compatible with a HA were operated in our hospital. No extra patient was found in the records of pathology, hepatology, and radiology.

For the purpose of the study, the patients were classified as cases with solitary-uncomplicated, multiple, and ruptured HA on the basis of clinical presentations and radiological evidences. The solitary-uncomplicated and multiple HA groups included patients with HA, but without a clinical bleeding episode. Patients with ruptured HA had clinical evidence of bleeding.

Data related to clinical picture, radiology, surgery and pathology were collected and compared between each group. Follow-up was performed in the outpatient clinic.

Over a 23-year period, 25 patients with HA were identified and included in the study. All patients were operated upon for a total of 58 HAs. Nine patients had solitary-uncomplicated (36%), 6 multiple (24%) and 10 ruptured HAs (40%). There were 23 females and 2 males, with a median age of 38 years (range, 19-55 years).

Clinical presentation

Signs and symptoms are summarized in Table 1. In the

Table 1 Clinical presentation of different forms of HA

	Solitary-uncomplicated HA	Multiple HA	Ruptured HA	Total
Cases (*n*)	9	6	10	25
No. of HA[1]	9	>39[2]	10	>58
Symptoms (no. of cases)				
None	3	3	0	6
Pain	6	3	10	19
Nausea / vomiting	3	0	5	8
Diarrhea	0	0	2	2
Asthenia	1	1	0	2
Median duration of symptoms (wk)[3]	8 (1-24)	5 (2-16)	1 (0.5-2)	2
Signs (no. of cases)				
None	6	5	0	11
Tenderness	3	1	10	14
Fever	2	0	4	6
Hepatomegaly	0	1	0	1

[1]Hepatocellular adenoma; [2]two patients presented more than 10 HA (adenomatosis); [3]median duration of symptoms up to diagnosis, excluding asymptomatic patients (three solitary-uncomplicated and three multiple HA).

solitary-uncomplicated and multiple HA groups, six patients (3/9 and 3/6, respectively) had no symptoms. Tumors were discovered because of increased liver function tests (LFT) in two, hepatomegaly in one, during laparotomy in one or at ultrasonography done for other reasons in two patients.

Twenty-two of the twenty-five patients (88%) were or had been taking exogenous sex hormones for a median duration of 9.25 years (range, 3 mo-22 years). They were equally distributed between all groups.

Laboratory findings

Seventy-two percent (18/25) of the patients had at least one increased LFT. Anemia and increased transaminases were more often associated to ruptured HA, while increased alkaline phosphatase and γ-glutamyl transpeptidase to solitary-uncomplicated and multiple HA (Table 2). Prothrombin time, albumin, and bilirubin were normal in all patients. α-Fetoprotein was normal in all nine patients in whom this marker was tested, including the two cases of HA with foci of hepatocellular carcinoma.

Table 2 Results of laboratory tests

Laboratory test (range)	Solitary-uncomplicated HA (9 cases)	Multiple HA (6 cases)	Ruptured HA (10 cases)
Anemia (Hb<12 g / dL)	4	2	7
Bilirubin (>25 μmol / L)	0	0	1
ALP (>125 μmol / L)	4	4	1
AST (>42 U / L)	0	0	4
ALT (>42 U / L)	0	0	4
γ-GT (>35 U / L)	5	3	4

ALP: alkaline phosphatase; AST: aspartate aminotransferase; AST: alanine aminotransferase; γ-GT: γ-glutamyl transpeptidase.

Radiological investigations

Ultrasonography was performed in 23 cases. Abnormal findings (a focal lesion or a hematoma) were detected in all cases, but a diagnosis of HA could never be established by ultrasonography alone. Computer tomography (CT), angiography, and magnetic resonance imaging (MRI) demonstrated possible images of HA in 3/25, 2/18, and 3/9 patients, respectively. Needle biopsy gave the correct diagnosis in five of eight cases who underwent this procedure.

Among the 10 patients with ruptured HA, no clear tumor could be identified by preoperative imaging in 7 cases, and the diagnosis of HA remained presumptive until gross examination of the resection specimen.

In patients with solitary-uncomplicated or multiple tumors (i.e., excluding patients with ruptured tumors), a correct pre-operative diagnosis could be made with radiology or liver biopsy in 9/15 cases.

Clinical management

The indication for surgery was either the presence of a possibly malignant tumor, or the preoperative diagnosis of HA. Liver resections were performed according to the principles of segmental surgery, with Kellyclasy or the ultrasonic dissector[1]. Intra-operative ultrasound was routinely performed to clarify the anatomical relationship of the known lesions and to guide the resection when the tumor could not be identified with certainty on preoperative imaging.

Patients with solitary-uncomplicated HA All the nine patients with solitary-uncomplicated HA required less extensive resections as compared to the patients of other groups (Table 3). Two HA patients (6.4 and 11.2 cm in tumor size) with tumor appearing heterogeneous on gross inspection demonstrated foci of hepatocellular carcinoma on frozen sections. In one of these patients, a local excision was extended for right hepatectomy after the results of the frozen sections. Both results on frozen section were further confirmed on paraffin-embedded sections.

Patients with multiple adenomas In these six patients, no clear diagnosis could be made before surgery, and intra-operative ultrasonography and frozen sections were performed in order to resect the largest lesions or the one most likely to be malignant. In five cases, previously unidentified tumors were discovered during the operation. In these patients, resections were extensive, involving three segments or more in four cases. A vascular exclusion maneuver was required more often in multiple HA group compared to the other groups (four hepatic inflow occlusion and one total vascular exclusion). In three cases with multiple

[1]Seven enucleations performed in the same patient; [2]performed in the same patient; [3]performed in an elective setting.

HA, several lesions were left unresected, and they were subsequently followed-up by yearly CT or MRI.

Patients with ruptured HA None of the 10 patients with ruptured HA was in hypovolemic shock on admission. The early management included hemodynamic monitoring and in two cases, transfusion of packed RBCs (two units in each patient). An angiography was performed in all cases of ruptured HA and in two, a vessel bleeding actively within liver parenchyma was identified and embolized. In all cases of ruptured HA, resection was delayed for a median of 5.5 d (range, 4-70 d) after presentation. In all cases, a hematoma was present in the tumor (two cases), in the liver parenchyma (six cases) or intraperitoneally (two cases). The risk of rupture was not associated with the size of the HA, and the ruptured HA ranged between 1.7 and 10 cm in size. The mean number of packed RBCs required during the operation was higher in the ruptured HA group compared to the others (Table 3).

Follow-up

The length of hospital stay was similar in all groups. There was no peri-operative death. The overall peri-operative complications rate was 28% (7/25), including three lung infections, two bile leakage (one in multiple HA and one in ruptured HA), one pulmonary embolism and one transitory coma of unknown origin, possibly due to a gas embolism on withdrawal of a central line. Both patients with foci of hepatocellular carcinoma were followed-up with a yearly CT during first 2 years and every second year thereafter, and were found to be disease-free for 2 and 11 years after surgery and without adjuvant treatment. In the three patients with multiple HA left unresected, no growth of lesion or new tumor appeared after 4, 6, and 6 years of follow-up, respectively. All other patients did not demonstrate any tumor recurrence.

The present study describes the management of the three modes of presentations of HA, such as solitary-uncomplicated, multiple, and ruptured tumors, in a series of 25 consecutive patients operated for 58 HAs.

HAs are rare tumors, representing 3.7% of all liver resections performed during the same period in our center and 10-25% of all operated benign tumors in other studies[2-4]. The various forms of presentation are often studied together according to the common pathological appearance rather than as separated clinical entities with specific presentations and deserving specific management. In addition to the solitary-uncomplicated cases, 12-42% of HA present acutely as ruptured tumors[3-5] and 8-36% are multiple tumors often requiring complex surgical decisions and procedures[3,6-10].

Management of solitary-uncomplicated HA

We defined solitary-uncomplicated HA as single adenomas without clinical or pathological evidence of bleeding on gross examination of the cut surface. In this group, the clinical challenge is the appropriate management of a solitary liver nodule and its differential diagnosis with other tumors, such as hemangioma and focal nodular hyperplasia, which, in contrary to HA, do not require surgical removal. Symptoms are non-specific, including pain that is rarely acute[2,7,10-12]. In one-third of the cases, the tumor is silent and discovered incidentally[2,11]. While LFTs are increased in many patients in the present study, they are most often normal, and do not help to identify the tumor[2,7,12,13].

Radiological investigations play a key role in detection of HA. Due to the wider use of ultrasonography to investigate a variety of abdominal conditions from uncomplicated pregnancy to non-specific abdominal pain, an increasing number of focal liver tumors are discovered accidentally. Diagnosis of HA remains difficult, with accurate tumor characterization in only 50-70% for CT, angiography, and scintigraphy[4,13,14]. These results can be explained by the highly variable radiological behaviors of HA according to the presence of steatosis, necrosis, bleeding, or malignant transformation, as well as by the similarities to some cases of focal nodular hyperplasia and fibrolamellar hepatocarcinoma. MRI appears to be more effective, and identifies HA in 75% of cases[8,12,13,15]. In the present study, the low preoperative diagnostic accuracy is explained by the long study period and the use of radiological examinations with low accuracy

for the initial patients.

In our institution, all patients suspected of having HA were operated and the outcome of conservative management could not be assessed. This is an important issue, as some studies advise resection of HA only, when they are larger than 5 cm, because of the tendency of regression of smaller HA[4,10,16,17]. However, only half of these tumors were found to regress on long-term follow-up[4], and we believe, together with others, that adenomas should be removed with an open[2,7,18,19] or laparoscopic approach[20,21], regardless of size. HA generally occur in young patients without hepatocellular dysfunction, and a resection, even major, has a mortality rate lower than 1%[2,4,6,9]. On the contrary, after rupture, resection is more complex, transfusion requirements increase and overall mortality figures up to 10% have been quoted[22-24]. Furthermore, foci of hepatocellular carcinoma have been identified within HA of any size with a prevalence of 4-16% of the cases[3,10,18,25], probably a conservative estimate, as later stages of malignant transformation can no longer be recognized as originating from HA and are diagnosed as *de novo* carcinomas. The follow-up of HA is also difficult because malignant transformation can appear without increase in size, and the tumor marker α-fetoprotein has low sensitivity[4,10,12,18,25]. Finally, the occurrence of rupture is not related to the size of HA, and can happen, as shown in our series, in HA as small as 1.7 cm.

Management of multiple HA

Multiple HAs pose a diagnostic and therapeutic challenge. A malignant lesion is difficult to be ruled out, excluding the possibility of conservative management, and in some cases, the totality of the lesions cannot be removed. Two options remain open: liver transplantation or surgical exploration with resection of the largest lesion. Transplantation is required in some symptomatic patients[9], in cases of massive or multifocal lesions, especially with an underlying metabolic disease[2,5,6,26-28]. In the other cases, such as the patients of this study, surgical exploration should be preferred, because of its lower morbidity[5,6,27]. The direct examination of liver and intra-operative ultrasonography often discover new tumors (5/6 cases in this study)[2-12]. Frozen section should be performed because of its superiority over fine needle biopsies in diagnosing the type of tumor, and its high consistency, as seen in our study, with the paraffin-embedded histological results. After identification of all tumors, if removal of all lesions is not possible, we advise surgical resection of the largest and most heterogeneous ones, and yearly radiological follow-up of the remaining lesions. In this study, three patients with unresected lesions were symptom-free without increase in tumor size after a follow-up of 4, 6, and 6 years, respectively. In cases of symptomatic patients or of tumor relapse, a further resection or transplantation should be considered.

Management of ruptured HA

Patients with ruptured HA do not represent a diagnostic challenge, because the association of acute abdominal pain (all patients in this group), increased LFTs and radiological evidence of intrahepatic or intraperitoneal bleeding often point to the diagnosis of a ruptured hepatic tumor. The differential diagnosis between a bleeding HA and hepatocellular carcinoma remains difficult in some cases, but hepatocellular carcinoma is rare in young women without underlying liver disease. The early management of all spontaneous hemorrhages, regardless of tumor origin, is the same with hemodynamic monitoring and support. Most patients are stable on admission and require only intravenous fluids and occasionally blood transfusions[22,24,29]. Rarely, patients in shock may require emergency laparotomy[29]. Angiography should be performed as soon as possible: it allows the control of a possible actively bleeding vessel (two patients in our series), and a better identification of the lesion and its blood supply, which can be helpful to establish the surgical strategy. Resection can be postponed to later in the hospital stay, when the patient has fully recovered from the bleeding episode, to minimize the surgical morbidity and to allow the contralateral part of the liver to increase size, if embolization has been performed[22,24,29,30].

In summary, the present study describes the specific presentations and managements of the different types of HA. Tumors diagnosed as or suspected of being HA should be resected, regardless of their size. Multiple tumors should be explored surgically by performing intra-operative ultrasonography and frozen sections, which are mandatory to solve the differential diagnosis of hepatocellular carcinoma and other malignant tumors. Ruptured HA are managed primarily with hemodynamic support and angiography, followed by scheduled resection.

AIM: Esophageal squamous cell carcinoma is generally sensitive to chemoradiotherapy (CRT), but some cases are not. Using a retrospective analysis, we aimed to identify the predictors of the response by esophageal squamous cell carcinoma to definitive CRT.

METHODS: The intensities of expression of *p*53, Ki67, Bcl-2, Bax, cyclin D1, VEGF, CDC25B, and metallothionein (MT) were evaluated immunohistochemically in the biopsy specimens obtained before CRT, and the intensities of their expression were tested for correlations with the clinical effects of CRT.

RESULTS: The esophageal squamous cell carcinomas with negative *p*53, positive CDC25B, and negative MT expression were found to be significantly more sensitive to CRT. In addition, p53 positivity and CDC25B positivity respond well to CRT.

CONCLUSION: Esophageal squamous cell carcinomas with negative *p*53,positive CDC25B, and negative MT expressions respond well to CRT. Even with p53 positivity, if with CDC25B positivity, CRT can be expected.

Sunada F, Itabashi M, Ohkura H, Okumura T. *p*53 negativity, CDC25B positivity, and metallothionein negativity are predictors of a response of esophageal squamous cell carcinoma to chemoradiotherapy. *World J Gastroenterol* 2005; 11(36): 5696-5700

http://www.wjgnet.com/1007-9327/11/5696.asp

Chemoradiotherapy (CRT) is one of the most commonly used modalities of treatment for squamous cell carcinoma of the esophagus. Although the response rate to CRT with 5-fluorouracil and cisplatin is high (64%), there is no survival benefit for non-responders[1]. Hence, it would be useful to be able to predict the response to CRT so that the non-responders could avoid the side-effects of CRT. This has not been possible, however, on the basis of the clinicopathological factors that are routinely examined. Recent advances in tumor biology, especially in relation to apoptosis, offer a possible solution to this problem. Apoptosis induced by CRT involves various biological phenomena, such as DNA repair, altered drug metabolism, inflammation, molecular chaperoning and changes to the cell cycle, and a variety of biological markers, including *p*53, Ki67, Bcl-2, Bax, VEGF, cyclin D1, metallothionein (MT), and CDC25B have been investigated for an association with response to CRT[2-5]. *p*53 is a tumor suppressor gene that contributes to the preservation of genetic stability by facilitating both G_1 arrest and apoptosis in response to DNA damage[6,7]. The Bcl-2 family of proteins includes molecules with both the anti-apoptotic effects (e.g., Bcl-2 and Bcl-XL) and pro-apoptotic effects (e.g., Bax and Bak), and cell susceptibility to apoptosis has been found to be determined by competing dimerization of different members of the Bcl-2 family[8,9]. Previous studies have revealed that CDC25B, which activates CDC2 and the G_2-M progression, is significantly associated with radiation sensitivity among various molecules regulating the G_2-M checkpoint[10]. MT is an intracellular metal-binding protein involved in zinc homeostasis and the detoxification of heavy metals[11]. A study has shown that MT affects cisplatin-induced apoptosis[12]. Moreover, another recent study has reported that essential cytotoxic targets of both oxidants and heavy metals exist in the cytoplasm and establish the importance of nucleocytoplasmic partitioning for the function of MT[13], and a positive association has also been found between MT expression and resistance to CRT[14]. Thus, the purpose of our study was to identify the predictors of the response to definitive CRT with a retrospective analysis. Therefore, we have investigated a variety of biological markers, including *p*53, Ki67, Bcl-2, Bax, VEGF, cyclin D1, MT, and CDC25B.

Thirty-six patients with advanced squamous cell carcinoma of the esophagus, who refused surgery and gave informed consent to CRT at Ibaraki Prefectural Central between 1996 and 2001, were included in this study (Table 1). The diagnosis of squamous cell carcinoma was confirmed by histological examination of biopsy specimens obtained before starting CRT (the clinicopathological data are summarized in Table 1). Response to CRT was evaluated clinically after two courses and the evaluation included a barium esophagogram, esophagoscopy, and computed tomography (CT) of the chest and abdomen. A complete response was defined as no visible tumor by esophagoscopy, biopsy specimens free of tumor tissue, and normal CT findings; a partial response as >50% tumor regression as evaluated by CT, and >50% reduction of intraesophageal tumor extension assessed by barium swallow and esophagoscopy; no change as <50% regression of tumor extension, and no evidence of tumor progression; and progressive disease as increasing tumor growth indicated by barium swallow or esophagoscopy and increasing tumor diameter assessed by CT.

Chemoradiotherapy

Chemotherapy consisted of protracted infusion of 5-FU at a dose of 400 mg/m^2 per d on d 1-5 and 8-12, combined with a 2-h infusion of CDDP at 40 mg/m^2 per d on d 1 and 8, repeated twice every 5 wk. Concurrent radiotherapy was started on d 1 at 2 Gy/d for 5 d/wk. The total radiation dose was 60 Gy, with a 2-wk break after a dose of 30 Gy. The patients were followed up every 3 mo for the first 3 years after the end of treatment, and afterward every 6 mo thereafter. New chemotherapy agent (e.g., docetaxel) was applied for the patient with non-effective CRT.

Immunohistological staining and its evaluation

Immunostainings for *p*53, Ki67, Bcl-2, Bax, cyclin D1, VEGF, MT, and CDC25B were performed using streptavidin-peroxidase complex methods with an EnVision+™ peroxidase kit (Dako, Glostrup, Denmark) on a TeckMate Horizon automated staining system (Dako, Glostrup, Denmark). Primary antibodies were incubated overnight at 4 ℃ with E9 (dilution 1:50; Dako, Kyoto, Japan) for MT, and for 1 h at room temperature with DO-7 (dilution 1:50; Novocastra Laboratories, Newcastle upon Tyne, UK) for *p*53, with Ki-S5 (dilution 1:50; Dako, Kyoto, Japan) for Ki-67, with 124 (dilution 1:50; Dako, Kyoto, Japan) for Bcl-2, with A3533 (dilution 1:50; Dako, Kyoto, Japan) for Bax, with DSC-6 (dilution 1:200; Novocastra) for cyclin D1, with JH 121 (dilution 1:50; Upstate, Lake Placid, NY, USA) for VEGF, and with C45820 (5 μg/mL; Transduction Laboratories, Lexington, KY, USA) for CDC25B. The expressions of *p*53, Bcl-2, Bax, VEGF, cyclin D1, MT, and CDC25B were investigated in consecutive histological sections prepared from the biopsy specimens. After being pretreated thrice, each for 5 min, in a citrate buffer (pH 6.0) at 750 W, the slides were separately incubated overnight at 4 ℃ with the mAbs, and the expressions of *p*53, Ki-67, Bcl-2, Bax, VEGF, cyclin D1, MT, and CDC25B were assessed under light microscope by one observer (Itabashi), who was unknown about the clinical outcome. The percentages of positive tumor cells were determined semiquantitatively, and each sample was assigned to one of the following categories: negative (0-10%) and positive (11-100%). In addition, the intensities of immunostaining of antigens localized in the cytoplasm (Bcl-2, Bax, cyclin D1, VEGF, MT, and CDC25B) were classified as negative or positive. Staining intensity was not determined for *p*53 (nuclear immunostaining), because no significant differences in staining intensity were observed in the *p*53-positive cases.

Statistical analysis

Associations between two parameters were analyzed by the Spearman's rank correlation test. For continuous parameters, the difference between the two groups was analyzed by Student's *t*-test. Determination of the distribution of immunohistochemical staining between groups was analyzed using χ^2 analysis. Cumulative survival of the patients was calculated on July 31, 2002, by the Kaplan-Meier method and the statistical significance was analyzed by the log-rank test. $P<0.05$ was considered statistically significant in all analyses. All statistical analyses were performed using the StatView version 5.0 software package (Abacus Concepts, Berkeley, CA, USA).

The overall proportions of the cells positive for expression of *p*53, Bcl-2, Bax, Ki67, cyclin D1, VEGF, MT, and CDC25B were 58.3%, 27.8%, 30.6%, 86.1%, 41.7%, 58.3%, 27.8%, and 13.9%, respectively (Tables 2 and 3). Not MT negativity, but CDC25B positivity with p53 positivity is a predictor of a response to CRT (respectively p=0.39, 0.027).The median survival time of the *p*53-negative and *p*53-positive patients were 588 and 415 d, respectively ($P<0.001$, Student's *t*-test), but no significant difference was found between the survival curves of the *p*53-negative and *p*53-positive patients and esophageal cancer staging (Figures 1 and 2). However, there was a significant association between *p*53-negative and MT-negative patients and effect of CRT (Table 4). At the end of the follow-up period on July 31, 2002, 25% patients (9/36) were still alive. The follow-up time for all 36 patients ranged from 26.7 to 81 mo (median, 59.5±18.1 mo). In the group treated by CRT, there was a marked difference in mean survival time between the patients with *p*53-negative tumors (19.6±10.3 mo) and with *p*53-postive tumors (13.8±8. 6 mo). Esophageal squamous cell carcinomas relapsed in

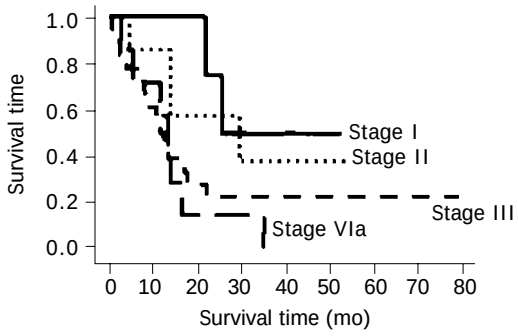

Figure 2 Relation between survival rates of 36 patients and staging of esophageal cancer. No significant difference was seen between survival curves of the *p*53-negative and *p*53-positive patients and esophageal cancer staging.

Esophageal cancer is a relatively uncommon but aggressive disease. Surgical resection has been widely accepted as the standard treatment for esophageal cancer, and techniques have improved during the past decades. However, long-term survival after resection of carcinoma of the thoracic esophagus is generally poor, with rates of only 20-42.4%[15-18]. Some reports on CRT have indicated that it offers various advantages in managing esophageal cancer[19]. Oncologists have advocated a non-surgical approach with definitive CRT as the standard treatment for this disease[20-23]. The value of CRT for the treatment of unresectable esophageal squamous cell carcinoma remains a matter of controversy. Only a few clinical studies have been published since the 1980s, and most patients in those studies had local-regional disease (UICC stage I or II). Several investigators have reported successful results with these modalities, either with or without surgery, against local-regional carcinoma[24-26]. The combination of 5-FU and CDDP has become the standard regimen, not only because of the clinical outcome but also because of the synergism between the two agents and their radiosensitizing effects[27,28]. Recently published results on CRT have indicated that it offers various advantages for the treatment of carcinoma of the esophagus[29,30]. A multicenter study on the indications for CRT as curative therapy for patients with locally advanced disease has suggested that concurrent CRT is potentially curative, even in cases of locally advanced carcinoma of the esophagus (i.e., T4 and/or M1 lymph node metastasis disease)[31]. Some studies have implicated various molecules, including *p*53, CDC25B, and MT, as candidates for biological markers for the response of human esophageal cancer to CRT[10,14]. We evaluated the role of cell-cycle-regulating molecules in the sensitivity of human squamous cell carcinoma of the esophagus to CRT by immunohistochemical methods and found *p*53, MT, and CDC25B to be significant independent markers for predicting sensitivity to CRT. Our results showed that negative

immunostaining for *p*53 in pre-CRT biopsy specimens predicted a good response. In addition to being the only established biological marker for response to CRT in clinical studies, *p*53 is the best characterized and most powerful marker[32,33], and it is commonly acknowledged to be a definite indicator of radiation sensitivity in various cancers[34,35]. The *p*53 immunoreactivity is generally thought to be attributable to the accumulation of abnormal *p*53 protein[36]. In our results, even the tumors with *p*53 positivity were sensitive to the CRT. In most of the esophageal squamous cell carcinoma, p53 are positive immunohistologically. Even with p53 positivity, CDC25B positivity respond well to CRT. So, we think that another pathway independent of *p*53 that regulate CRT sensitivity is sure to exist. G_2-M checkpoint, in which CDC25B is involved, is a candidate for this *p*53-independent pathway. Among the various molecules that regulate G_2-M arrest, overexpression of CDC25B has frequently been observed in human cancer[37,38], and also found to be related with response to CRT[10]. In our cases, no significant difference was observed between the survival curves of the *p*53-negative and *p*53-positive patients. It might be because a new chemotherapeutic agent (e.g., docetaxel) was applied for the patients with non-effective CRT. Docetaxel is an active drug for treating squamous cell carcinoma of head and neck. For the patients with recurrent or metastatic disease of squamous cell carcinoma, docetaxel could be used as a second line chemotherapy[39]. From a clinical standpoint, it is very important that a prospective study based on this result should be done. There are only retrospective studies that have been reported up to now. Standard therapy may be developed from the results of a prospective study based on the immunohistochemical characteristics of the tumor biopsy.

AIM: Although most patients with achalasia respond to pneumatic dilation, one-third experienced recurrence, and prolonged follow-up studies on parameters associated with various outcomes are scanty. In this retrospective study, we reported a 15-years' experience with pneumatic dilation treatment in patients with primary achalasia, and determined whether previously described predictors of outcome remain significant after endoscopic dilation.

METHODS: Between September 1989 and September 2004, 39 consecutive patients with primary symptomatic achalasia (diagnosed by clinical presentation, esophagoscopy, barium esophagogram, and manometry) who received balloon dilation were followed up at regular intervals in person or by phone interview. Remission was assessed by a structured interview and a previous symptoms score. The median dysphagia-free duration was calculated by Kaplan-Meier analysis.

RESULTS: Symptoms were dysphagia (n = 39, 100%), regurgitation (n = 23, 58.7%), chest pain (n = 4, 10.2%), and weight loss (n = 26, 66.6%). A total of 74 dilations were performed in 39 patients; 13 patients (28%) underwent a single dilation, 17 patients (48.7%) required a second procedure within a median of 26.7 mo (range 5-97 mo), and 9 patients (23.3%) underwent a third procedure within a median of 47.8 mo (range 37-120 mo). Post-dilation lower esophageal sphincter (LES) pressure, assessed in 35 patients, has decreased from a baseline of 35.8±10.4-10.0±7.1 mmHg after the procedure. The median follow-up period was 9.3 years (range 0.5-15 years). The dysphagia-free duration by Kaplan-Meier analysis was 78%, 61% and 58.3% after 5, 10 and 15 years respectively.

CONCLUSION: Balloon dilation is a safe and effective treatment for primary achalasia. Post-dilation LES pressure estimation may be useful in assessing response.

Achalasia is a disorder of the esophagus characterized by increased lower esophageal sphincter (LES) tone, lack of LES relaxation with swallowing and aperistalsis of the body of the esophagus. The etiology and pathogenesis of idiopathic achalasia are still unclear, although a viral cause, genetic influences (associations with HLA loci) and autoimmune processes have been postulated. Degeneration and significant loss of nerve fibers, associated with an inflammatory infiltration of the myenteric plexus in idiopathic achalasia, provide evidence of an immune-mediated destruction of the myenteric plexus, possibly through apoptotic process[1,2].

Current therapy is aimed at reducing the pressure gradient across the LES to allow passage of food. Therapeutic options for achalasia include pharmacologic therapy, surgical myotomy, mechanical rupture of LES smooth muscle by endoscopic balloon dilation, metal or plastic autoexpandable stent placement, and relaxation of the hypertonic muscles by injection of botulinum toxin, an inhibitor of acetylcholine release from nerve endings[3-6]. Drugs, including calcium-channel blockers, may be tried in mild cases, but their efficacy is modest and their side effects can be bothersome[3]. Besides, surgery has proved to be effective, although invasive[7]. In most cases therefore, gastroenterologists prefer pneumatic dilation as the first therapeutic step, due to its low cost[8] and high success rates, ranging from 70% to 90%. However, there is little information with regard to the patients' long-term course following a single pneumatic dilation or after repeated therapies[3].

In 1993, we reported our experience of 31 patients with achalasia, treated with pneumatic dilation[9]. Since then, the same patient cohort was regularly reassessed at 2-year intervals and eight patients were added until September 2004, thereby obtaining a median follow-up time of 9.3 years

(range 0.5-15 years).

The aim of the present study was to evaluate the long-term results of endoscopic balloon dilation treatment for achalasia, over a prolonged observation period.

Using records from a therapeutic endoscopy registry that has been kept in our department for a 15-year period, consecutive patients, who had undergone pneumatic dilation for achalasia from September 1989 to September 2004, were reviewed retrospectively. The diagnosis was based on clinical presentation, barium swallow contrast studies, endoscopic criteria and manometry studies. Exclusion criteria included pseudoachalasia, prior endoscopic or surgical therapy, and those with inadequate records. Patients under 14 years were also not included and they were referred to the pediatric gastrointestinal unit.

Evaluation of symptoms

Symptoms of dysphagia, retrosternal (chest) pain, regurgitation, and weight loss were evaluated at the first visit and during subsequent follow-up in the outpatient clinic of our department or by phone interview. The frequency of the symptoms was graded as following: grade 0, none; grade 1, less than once weekly; grade 2, two to three times weekly; grade 3, once daily; grade 4, more than once daily. Moreover, relative data on the effectiveness of treatment were classified as follows: (a) excellent, restoration to complete health (free of symptoms); (b) good, dysphagia or pain of short duration, defined as retrosternal hesitation of food lasting about 3 min and disappearing after drinking fluids, less than once weekly; (c) moderate, dysphagia lasting about 3 min without weight loss, more than once weekly; (d) poor, dysphagia lasting more than 3 min, accompanied by regurgitation or weight loss, more than once weekly. Clinical remission was considered as symptomatic scores of (a) and (b). Clinical recurrence in less than 3 mo following the second or subsequent dilations was considered as an indication for surgical myotomy.

Esophageal manometry

Esophageal manometry was performed in all patients after overnight fasting using a low compliance, pneumohydraulic, water infusion system (Arndofer, Medical Specialties, Milwaukee, WI, USA) and an eight lumen, manometric catheter. The catheter had four ports radially oriented (90°) near the tip and four more centrally positioned, 5 cm apart (5, 10, 15, and 20 cm from the tip). The recording sites were connected to an eight-channel polygraph (Synetics Medical AB, Stockholm, Sweden). The manometric catheter assembly was passed transnasally without any sedation into the stomach. The LES pressure was determined using the station pull through technique and recorded as the mean of four measurements at mid-respiration. Completeness of LES relaxation (normal >85%) was assessed as percent decrease from resting LES pressure to gastric baseline following wet swallows. Esophageal body motility was recorded at 3, 8, 13, and 18 cm above the LES in response to 5 mL swallows of water at 30-s intervals. LES pressures and peristalsis were determined at the time of diagnosis, and 1 mo after the dilation.

The diagnostic criteria for primary achalasia were incomplete LES relaxation and aperistalsis of the esophageal body. Once the diagnosis was confirmed, the patients were asked to choose between pneumatic dilation or Heller myotomy as treatment options and gave informed consent for the procedures; they were informed that pneumatic dilation carries a 5% perforation rate with an 80% success rate, whereas Heller myotomy generally requires 1 wk of hospitalization with 3-4 wk needed for recovery and has a 90% success rate and a 10% chance of postoperative gastroesophageal reflux. All patients chose balloon distension as an initial therapeutic procedure.

Pneumatic dilation

All dilations were performed with a Rigiflex (Microvasive, Boston Scientific Corporation, Boston, MA, USA) achalasia balloon dilator by two experienced gastroenterologists. After a liquid diet for 48 h and an overnight fast, sedation for upper gastrointestinal endoscopy was administered using intravenous pethidine (25-50 mg), diazepam (5-10 mg) and recently midazolam (2-5 mg), as required. Following complete upper gastrointestinal endoscopy to exclude malignancy or peptic strictures, a stiff guidewire was placed into the stomach through the endoscope. The balloon dilator was passed over the guidewire under endoscopic guidance and positioned at the esophagogastric junction under fluoroscopic control and partly inflated with dilute water-soluble contrast medium. The position of the catheter was adjusted so that the waist of the partly inflated balloon caused by the LES lay at the midpoint of the balloon. Maintaining the balloon catheter into position by fixation against the bite guard, the balloon was fully inflated with dilute water-soluble contrast. Full inflation was confirmed visually by the loss of the waist at the midpoint of the balloon and inflation was maintained for 1-3 min.

Because there is currently no consensus regarding the size of balloon that should be used for the dilation, the choice was solely based on the individual endoscopist's preference. A water-soluble contrast examination immediately after the dilation to look for perforation was ordered only if there was clinical suspicion of perforation.

Statistical analysis

All data were expressed as the mean±SD, and the paired *t*-test was used for statistical comparisons before and after dilation. The median dysphagia-free duration following balloon dilation was calculated by Kaplan-Meier analysis.

A total of 39 patients (17 men, 22 women) who underwent pneumatic balloon dilation for achalasia during the 15-year study period were included in the analysis. Age ranged from 27 to 87 years, with a mean age of 56±11 years. Symptoms at presentation were dysphagia (n = 39, 100%), regurgitation (n = 23, 58.7%), weight loss (n = 26, 66.6%), and chest pain (n = 4, 10.2%). The mean duration of symptoms prior to treatment was 32.1±56.2 mo (Table 1). Three patients with retrosternal pain were diagnosed as a vigorous achalasia by esophageal manometry. Thirteen patients underwent a single dilation, and 17 and 9 patients underwent 2 and 3 procedures respectively (Table 1).

Table 1 Demographic data, presenting symptoms, number of procedures and follow-up of the patients

Age (yr) [median (range)]	56 (27-87)
Gender (M/F)	17/22
Dysphagia	39 (100%)
Regurgitation	23 (58.7%)
Chest pain	4 (10.2%)
Weight loss	26 (66.6%)
Mean duration of symptoms (mo)	32.1±56.2
No of procedures	74
No of patients undergoing	
1 procedure	13
2 procedures	17
3 procedures	9
Median follow-up (yr) (range)	9.3 (0.5-15)

The choice of the balloon size was at the discretion of individual endoscopist; a 30-mm balloon-dilator was utilized in 26 of 74 procedures (35.1%), a 35-mm balloon in 39 procedures (52.8%), and a 40-mm balloon in 9 procedures (12.1%). The balloon was inflated once per procedure in 21 of 74 (28.3%) dilations and twice per procedure in 53 of 74 (72.7%). The duration of the inflation ranged from 30 s to 2 min (median 93 s) and in each procedure obliteration of the balloon "waist" was fluoroscopically noted. Upon withdrawal, traces of blood were noted on the balloon in 21 of 74 procedures (81.1%), by using 30- and 35-mm balloon dilators in 11 and 10 procedures, respectively. Four patients (5.4%) presented post-dilation esophageal perforation (Table 2), which occurred during the initial dilation with a 30-mm balloon dilator. The esophageal perforations were successfully managed with surgical intervention. In one (1.3%) patient tachycardia (120/min) and hypotension (70/40 mmHg) were developed 5 h after the procedure by using a 35-mm balloon dilator, followed by hematemesis and a drop of the Ht from 44% to 30%. After administration of crystalloids solutions and 4 units of blood, an emergency endoscopy disclosed a mucosal tear (Mallory-Weiss) 0.7 cm in length, with an overlying clot on the anterior wall of the esophagogastric junction. Bleeding stopped spontaneously and the patient's course was uneventful. The median hospital stay was 1.9 d (range 1-21 d); all four patients who underwent operation for post-dilation esophageal perforation required parenteral nutrition for 7-11 d and no mortality was recorded.

Table 2 Post-dilation complications

Perforation	4 (5.4%)
Bleeding	1 (1.3%)

A significant improvement in symptom score and LES pressure was noted 1 mo post-treatment (Table 3). The median follow-up period was 9.3 years (range 0.5-15 years) (Table 1).

The overall cumulative success rates at 5, 10, and 15 years after balloon dilation for achalasia were 78%, 61%, and 58.3% respectively (Figure 1). At their last attendance for follow-up, 20 of 29 patients (68%) complained for mild intermittent dysphagia, and 9 of 29 (32%) for moderate intermittent dysphagia.

Table 3 Symptom score and LES pressure at baseline and 1 mo after dilation

	Baseline	After 1 mo	*P*
Dysphagia	2.8±1.3	0.8±0.4	<0.01
Regurgitation	2.1±0.7	1.1±0.5	<0.01
Chest pain	1.8±1.2	1.4±0.9	<0.05
Weight loss	8.3±2.2	0.3±0.1	<0.01
LES pressure	35.8±10.4 (15-63)	10.0±7.1 (0-13)	<0.01

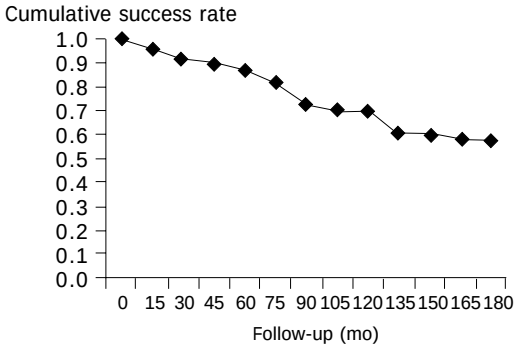

Figure 1 Cumulative success rate with pneumatic balloon dilation during the 15-yr study period.

Within the 15-year follow-up period, balloon dilation was considered to have failed in one patient, three patients died from unrelated causes and six young patients (2 men, 4 women) with a median age of 32 years (range 19-46 years) decided to undergo Heller myotomy after a median follow-up period of 34 mo (range 14-93), and could not be further contacted.

Physiologic studies have established the occurrence of denervation of the smooth muscle segment of the esophagus in patients with achalasia. A loss of ganglion cells (possibly through an apoptotic attack of T lymphocytes against nerve fibers and ganglia) in the region of the LES, particularly if the loss is predominantly of inhibitory neurons, would lead to an increased basal pressure and poor relaxation[2]. In particular, electron microscopic examination of the esophageal vagal branches reveals degeneration of myelin sheaths and disruption of axonal membranes, the valerian degenerative changes characteristic of experimental nerve transaction. Degenerative changes, including fragmentation and dissolution of nuclear material, have also been reported in ganglia of the vagal dorsal motor nucleus during the apoptotic process[10-12]. Ganglion cells degeneration in the esophageal body itself would ultimately result in permanent aperistalsis and allow for dilation of the esophagus. The damage in the LES might be the earliest event, and the aperistalsis of some early nondilated cases might be related to the obstruction of the esophagus at the level of the sphincter. After reduction in LES pressure by pneumatic dilation or myotomy in these patients, occasional peristalsis may be observed[13].

In this regard, pneumatic dilation has been the first-line therapeutic option for achalasia. The reported success rate varies widely, with figures ranging from 59% to 93% in a

review by Vaezi and Richter[14]; the differences may result from variations in the definition of success used, and in the techniques applied. The Rigiflex balloon dilator has been used in our department for the last 15 years, and data from the group of patients studied in this report compare favorably with data of previous studies, with an initial success rate of more than 80% in the 1st year and a overall cumulative success rates at 5, 10, and 15 years of 78%, 61%, and 58.3% respectively. A standardized protocol for the size of the Rigiflex dilator was not used.

The most extensive experience with objective evaluations of treatment responses after pneumatic dilation relates to determination of LES pressures[15-24]. In nine of these investigations, improvement in symptoms correlated significantly with decrease in LES pressure, and optimal response was found in patients exhibiting a post-dilation sphincter pressure of less than 10 mmHg, or of >50% reduction from baseline. With a post-dilation LES pressure of 10±7.1 mmHg achieved in our patients, the current study extends these observations by showing that post-dilation LES pressure appears to be helpful in assessing the long-term clinical response.

Apart from a significant fall in LES pressure, several authors have tried to determine other factors that predict clinical outcome following pneumatic dilation. In these studies, advanced age, a moderately dilated esophagus and a long history of symptoms prior to diagnosis were all found to predict a favorable treatment result[14,25-27], whereas male gender was found to predict a poor outcome[15]. However, the most significant factor predicting response to treatment appears to be the age at diagnosis. The results of our study with patients' advanced age (70% of cases), confirm and strengthen this observation. Although the reason for these differences in treatment remains unknown, it has been speculated that a general difference in muscle strength across the age groups may account for this observation[28].

The perforation rate with the Rigiflex balloon dilator ranges from 0% to 6.6%[29], and graded balloon dilation starting with a 30-mm balloon dilator and progressing to 35 and 40 mm if necessary appears to be the safest approach[30]. In the present series, 5.4% of dilations were complicated by perforation. Despite the common belief that dilation with a larger balloon (35 or 40 mm) increases the chance of perforation, all perforations observed in the present series occurred during the initial dilation with a 30-mm balloon dilator. In our study, gastrografin swallowing was performed following dilation only when there was clinical suspicion of perforation, despite the fact that the use of immediate contrast studies to exclude perforation had become routine in the late 1970s and that this approach is recommended in several studies and textbooks. It must be emphasized that an immediate contrast study may not always exclude a perforation that may become clinically evident several hours later[30].

Less common complications including intramural hematoma, diverticula of the gastric cardia, mucosal tears, reflux esophagitis, prolonged post-procedure chest pain, fever, hematemesis with or without changes in hematocrit, and angina may occur after pneumatic dilation[30]. In our series, a patient developed hematemesis due to a Mallory-Weiss lesion, which is an uncommon complication.

Eckardt *et al*.[16], reported that the size of the balloon dilator can predict a favorable outcome after a single dilation. In contrast, the present study suggests that the use of both 30- and 35-mm balloons exerts a similar good outcome.

Finally, there is no consensus as to whether repeated pneumatic dilations are associated with longer remission or not[31,32]. A number of studies have shown that the additional sessions of pneumatic dilations are followed by a longer duration of remission, while others believe that subsequent pneumatic dilations after the second or third dilation are less likely to result in a sustained remission, and surgical intervention should be considered for patients who have had two or three unsuccessful sessions of pneumatic dilations[15,16,24,33]. According to our clinical experience, better long-term results of pneumatic dilation can be achieved with repeated procedures, because additional procedures improve the initial success and are followed by progressively longer duration of remission.

In conclusion, this study shows that pneumatic dilation is a safe and effective treatment for achalasia, with a long duration of efficacy; once, twice and rarely thrice pneumatic dilation appears to provide good results in the majority of patients.

Abstract

AIM: To evaluate the serum concentration of antimitochondrial antibodies (AMAs) as a prognostic indicator of progressive primary biliary cirrhosis (pPBC).

METHODS: Serum concentrations of AMA subtypes (anti-M2, anti-M4, and anti-M9), biochemical indices of liver function and Mayo risk factor (MRF) were determined in 30 women with diagnosed primary biliary cirrhosis (PBC) selected among 348 females with elevated alkaline phosphatase but without signs of hepatic decompensation. They were followed up for 5 years for possible development of hepatic decompensation.

RESULTS: Anti-M2 concentration was significantly correlated with bilirubin and albumin levels as well as MRF, whereas anti-M4 was significantly correlated with albumin level, prothrombin time and MRF. During the 5-year follow-up, progressive PBC (pPBC) was diagnosed in 3 among 23 patients available for evaluation. These 3 patients were positive for both anti-M2 and anti-M4. Anti-M2 serum concentration exceeded 1 300 RU/mL in patients with pPBC and only in 1 among 20 non-progressive PBC persons (5%). Anti-M4 serum concentration exceeded 400 RU/mL in 2 of the progressive patients and none in the non-progressive group. In contrast, anti-M9 serum concentration was below 100 RU/mL in all patients with pPBC, and higher than 100 RU/mL in 11 women (55%) among the non-progressive group.

CONCLUSION: Females with elevated alkaline phosphatase and high anti-M2 and anti-M4 concentrations are at a high risk for developing pPBC. Quantitative AMA detection should be considered as a method for early diagnosis of pPBC.

INTRODUCTION

Primary biliary cirrhosis (PBC) is an autoimmune disease of unknown etiology leading to progressive destruction of small intrahepatic bile ducts and liver cirrhosis. It is characterized by female predominance (90%) with most cases observed between the ages of 40 and 60[1,2]. PBC incidence in different parts of the world is estimated to be 4-58 cases/million per year that can be affected by diagnostic efficacy[3-7]. Antimitochondrial antibodies (AMAs) are highly specific hallmarks for PBC diagnosis, but their prevalence in the general population and its relationship to the development of PBC are not well known[8]. Nine different types of AMAs have been described in non-hepatic and hepatic disorders. Among them only anti-M2, anti-M4, anti-M8, and anti-M9 are considered specific for PBC[9]. Retrospective studies have reported that subtypes of AMAs can discriminate between a benign and a progressive course of the disease[9,10]. However, it was recently reported that profiles can predict PBC prognosis[11]. All these studies focused on qualitative evaluation of AMA subtypes whereas quantitative measurement was not investigated for PBC management.

This study was to evaluate the serum concentration of different types of AMAs as a prognostic indicator of progressive PBC (pPBC).

MATERIALS AND METHODS

Patients

Thirty women aged between 30 and 65 years with diagnosed PBC were selected among 348 females with elevated alkaline phosphatase (ALP) activities at admission to the Liver Unit of the Department of Infectious Diseases, Medical University of Bialystok in 1999. PBC diagnosis was established according to American Association for the Study of Liver Disease (AASLD) Practice Guidelines and the presence of AMAs, elevated ALP and normal bile ducts on ultrasound[12]. All 30 patients demonstrated normal activities of serum alanine transaminase and no clinical signs of liver disease decompensation (jaundice, pruritus, ascites, encephalopathy, and shank edema). Further evaluations performed in PBC patients included quantitative measurement of serum concentration of AMA subtypes (anti-M2, anti-M4,

and anti-M9). Mayo risk factor (MRF) usually applied for estimation of PBC patient survival probability was also determined. Among these 30 patients, only 23 became available for evaluation during the 5-year follow-up. Patients who demonstrated clinical signs of hepatic decompensation were identified as having pPBC. In contrast, patients without any signs of decompensation during the follow-up were diagnosed as non-progressive PBC (nPBC). Baseline results were analyzed for the diagnosis of pPBC or nPBC within the follow-up period. Ethical approval for the study was obtained from the Bioethical Committee of the Medical University of Bialystok.

AMA measurement

Serum concentration of AMA subtypes was determined by ELISA (Euroimmun, Lubeck, Germany) for human autoantibodies of the IgG class against the mitochondrial antigens M2 (pyruvate dehydrogenase complex), M4 (sulfite oxidase) and M9 (glycogen phosphorylase). For qualitative evaluation, serum samples with extinction values exceeding the recommended cut-off level (20 RU/mL) for at least one subtype of AMAs were considered positive. Quantitative determination of AMA subtype serum concentration was performed using calibration sera provided by the manufacturer.

Liver function tests

Bilirubin and albumin concentrations were determined using a Cobas Mira instrument (Roche) and the prothrombin time (PT) was detected using Kselmed K-3002 (Poland). MRF was calculated according to the formula of Dickson *et al*.[13], based on the following variables: age, bilirubin and albumin concentration, PT, presence of peripheral edema and diuretic treatment.

Statistical analysis

Values were expressed as mean±SE. The significance of difference was calculated by two-tailed Student's *t*-test. For correlation analysis, the Pearson product moment correlation was performed. $P<0.05$ was considered to be statistically significant.

RESULTS

Among the screened 348 women, quantitative evaluation of AMA demonstrated positive results in 30 (8.6%). Anti-M2 was demonstrated in 13 (3.7%), including 5 (1.4%) with accompanying anti-M4. The remaining 8 women (2.3%) were positive only for anti-M2. In the other 5 (1.4%) women, the only anti-M9 was demonstrated. Anti-M4 without any other AMA was present in sera of 12 women (3.4%, Table 1). Quantitative evaluation demonstrated significantly higher concentrations of all three types of AMAs in persons with at least one type of AMAs present in qualitative evaluation (Table 2). As demonstrated in Table 3, anti-M2 concentration was significantly correlated with bilirubin and albumin levels as well as MRF, whereas anti-M4 was significantly correlated with albumin level, PT, and MRF. Anti-M9 was not correlated to any of these parameters.

During the 5-year follow-up, clinical signs of hepatic decompensation were demonstrated in 3 among 23 patients available for evaluation, and they were recognized as having pPBC. The remaining 20 patients were diagnosed as nPBC. All three women were positive for both anti-M2 and anti-M4. Anti-M2 serum concentration exceeded 1 300 RU/mL in all pPBC women and only in 1 among 20 nPBC patients (5%). Anti-M4 serum concentration exceeded 400 RU/mL in 2 pPBC patients and in none of the nPBC patients. Anti-M9 serum concentration was below 100 RU/mL in all pPBC patients, and was higher than 100 RU/ml in 11 nPBC patients (55%). As demonstrated in Table 4, the mean concentrations of anti-M2 and anti-M4 were about five times higher in pPBC patients than in nPBC patients, however statistical significance was shown only with respect to anti-M2. The mean concentration of anti-M9 was two-fold higher in nPBC patients (Table 4). As demonstrated in Table 5, the difference found in both groups in relation to biochemical indices of liver injury and MRF was not statistically significant.

Table 1 Profiles of AMAs in 348 screened women

	n	%
Anti-M2	8	2.3
Anti-M4	12	3.4
Anti-M9	5	1.4
Anti-M2+Anti-M4	5	1.4
Any AMA	30	8.6

Table 2 Serum concentrations of different types of AMAs in women with positive (at least one type of AMAs present) or negative AMAs (mean±SE)

	Qualitative AMAs		*P*
	Positive	Negative	
Anti-M2 (RU/mL)	378.1±96.8	6.1±1.3	3×10^{-15}
Anti-M4 (RU/mL)	140.5±27.7	18.1±1.9	2×10^{-17}
Anti-M9 (RU/mL)	112.5±25.9	35.8±3.8	2×10^{-7}

DISCUSSION

According to AASLD Practice Guidelines, the diagnosis of PBC can be made in AMA positive patients with biochemical evidence of cholestasis, and normal biliary system in ultrasound examination. In these patients, a liver biopsy is not essential to make the PBC diagnosis[12].

The prevalence of AMAs in the general population is usually estimated below 1%. According to recent studies AMAs are detected in 0.64% Japanese and 0.16% Chinese workers who have an annual health check[8]. Sakugawa *et al*.[14], demonstrated that 6 AMA among 122 women with elevated γ-glutamyl transpeptidase levels (4.9%) are positive for AMAs. The prevalence of AMAs in our study, that varied from 3.7% (anti-M2 positive) to 8.6% (any positive AMA subtype), was due to inclusion of Caucasian women aged 30-65 years with elevated ALP[3-6]. However, the purpose of this study was not to demonstrate AMA prevalence, but to capture as many asymptomatic AMA positive women as possible.

Progressive PBC can be predicted even at its early stages when antibodies against M2 and M4 are present in patient sera[9]. In our study the three patients with PBC progression during follow-up, were positive for both anti-M2 and anti-M4, suggesting that the presence of anti-M2 plus anti-M4 profile in asymptomatic persons can predict pPBC. Concentrations of these antibodies were significantly higher in pPBC than in nPBC. However, this profile demonstrated that in PBC patients, it is not possible to predict fatal prognosis, and the proportion of patients, who died of liver disease or transplantation does not differ among the AMA profiles[11].

Anti-M2 serum levels in PBC patients are closely associated with the degree of liver insufficiency[15]. There is a significant correlation between Child-Pugh and Mayo scores and both are useful for the estimation of survival probabilities[16]. Our study also confirmed this observation with respect to asymptomatic AMA positive women, because there was a significant correlation between serum concentrations of anti-M2 or anti-M4 and bilirubin, albumin or PT values. Moreover, in this association we also demonstrated regarding the MRF. Prince *et al*.[17], have shown that patient age, alkaline phosphatase, albumin, and bilirubin as well as Mayo prognostic score at diagnosis can independently predict survival. However, according to Krzeski *et al*.[18], the Mayo model overestimates death risk in PBC patients, and serum bilirubin concentration appears to be the only variable of prognostic importance. Corpechot *et al*.[19], demonstrated that elevated bilirubin and decreased albumin are predictive factors for cirrhosis development under ursodeoxycholic acid treatment. We demonstrated a significant difference only regarding albumin among possible biochemical and clinical predictive factors. However, the most important factor for pPBC development is the high level of anti-M2 and anti-M4 antibodies in sera of asymptomatic persons. Similar results but without quantitative AMA evaluation are demonstrated by Kisand *et al*.[20]. According to our results, serum concentration of anti-M2 exceeding 1 300 RU/mL and anti-M4 exceeding 400 RU/mL are critical for detection of pPBC. However, border-line levels need to be validated in a larger number of patients.

In conclusion, persons with elevated ALP and high concentrations of anti-M2 and anti-M4 are at a high risk of developing pPBC. Quantitative detection of these antibodies should be considered as a method for early diagnosis of pPBC.

Abstract

AIM: To test the hypothesis that the variant UDP-glucuronosyltransferase *1A1* (*UGT1A1*) gene, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and thalassemia influence bilirubin metabolism and play a role in the development of cholelithiasis.

METHODS: A total of 372 Taiwan Chinese with cholelithiasis who had undergone cholecystectomy and 293 healthy individuals were divided into case and control groups, respectively. PCR and restriction fragment length polymorphism were used to analyze the promoter area and nucleotides 211, 686, 1 091, and 1 456 of the *UGT1A1* gene for all subjects and the gene variants for thalassemia and G6PD deficiency.

RESULTS: Variation frequencies for the cholelithiasis patients were 16.1%, 25.8%, 5.4%, and 4.3% for $A(TA)_6$ TAA/$A(TA)_7$TAA (6/7), heterozygosity within the coding region, compound heterozygosity, and homozygosity of the *UGT1A1* gene, respectively. Comparing the case and control groups, a statistically significant difference in frequency was demonstrated for the homozygous variation of the *UGT1A1* gene ($P = 0.012$, χ^2 test), but not for the other variations. Further, no difference was demonstrated in a between-group comparison of the incidence of G6PD deficiency and thalassemia (2.7% *vs* 2.4% and 5.1% *vs* 5.1%, respectively). The bilirubin levels for the cholelithiasis patients with the homozygous variant-*UGT1A1* gene were significantly different from the control analog (18.0±6.5 and 12.7±2.9 μmol/L, respectively; $P<0.001$, Student's *t* test).

CONCLUSION: Our results show that the homozygous variation in the *UGT1A1* gene is a risk factor for the development of cholelithiasis in Taiwan Chinese.

INTRODUCTION

The life span of erythrocytes in individuals with chronic hemolytic disease is short relative to normal subjects. The accelerated red-cell turnover produces more bilirubin and is probably a risk factor for the development of gallstones. Cholelithiasis has been detected in 38% of subjects with chronic hemolytic anemia due to glucose-6-phosphate dehydrogenase (G6PD) deficiency[1]. It has been demonstrated that G6PD-deficient subjects without chronic hemolytic anemia also have a higher frequency of cholelithiasis development than normal individuals[1]. Because the enzyme UDP-glucuronosyltransferase 1A1 (UGT1A1) catalyzes unconjugated bilirubin into the diglucuronidated and conjugated forms, UGT1A1 defects decrease the elimination of bilirubin[2]. Genetic variation in the *UGT1A1* gene promoter, $A(TA)_7$TAA, instead of $A(TA)_6$TAA influences bilirubin levels causing hyperbilirubinemia, which is associated with Gilbert's syndrome in Caucasians[2]. Further, it has been determined that *UGT1A1* gene expression is a major modifying factor for bilirubin levels in heterozygous β-thalassemia[3] and that cholelithiasis is one of the manifestations of thalassemia[4].

In a previous study of the *UGT1A1* gene in Taiwan Chinese[5], we found that occurrence of the $A(TA)_7$TAA allele in the promoter area was relatively rare (14.3% *vs* 40%) and that the variation rate within the coding region was much higher (29.3% *vs* 0.1%) relative to Caucasians[2], respectively. The aim of this study was to analyze variations in the promoter area and coding region in the *UGT1A1* gene in Taiwan Chinese patients with cholelithiasis. The incidence and genetic expression of G6PD deficiency in

these subjects was also investigated. Additionally, we studied the genetic alteration of thalassemia. Variations in the *UGT1A1*, *G6PD* and thalassemia genes were compared with those of normal subjects. To our knowledge, this is the first report elucidating the relationship between these three genes and cholelithiasis.

MATERIALS AND METHODS

Study subjects, healthy controls, and laboratory tests

The study subjects (157 males and 215 females) were selected from Taiwan Chinese adults who had undergone cholecystectomy for symptomatic gallstone. Healthy controls (135 males and 158 females) were selected from adults who had undergone physical examination at Cathay General Hospital as previously described[5]. The control subjects were investigated for cholelithiasis by abdominal ultrasonography (model SSD-1700, Aloka Co., Tokyo, Japan) and no change in abdomen was determined with respect to gallstones. Blood samples were collected from all subjects in the morning after 10-12 h of fasting. An automatic cell-counter (NE 9000, Sysmex Co., Kobe, Japan) was used for hematology testing, and erythrocyte G6PD activity was quantitatively measured using the enzyme-coupled method[6]. G6PD deficiency was confirmed by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP)[7]. The 15 single-nucleotide mutations, restriction enzymes, and restriction-fragment results are listed in Table 1, with priority arranged in descending order of mutation frequency of our Taiwan Chinese sample population[7]. The promoter area and nucleotides 211, 686, 1 091, and 1 456 of the *UGT1A1* gene were amplified by PCR and analyzed using RFLP[8]. The restriction enzymes and restriction-fragment results are listed in Table 2. Mean corpuscular volume $\leqslant$80 fL, the gene variants for α- and β-thalassemia were identified using PCR-RFLP[9,10].

Comparison of bilirubin values

Serum bilirubin levels were measured using an autoanalyzer (model 747, Hitachi Co., Tokyo, Japan). The bilirubin values in cholelithiasis patients with statistically significant differences in gene frequency relative to controls were obtained from the records made 2-3 mo after cholecystectomy and compared with that in the control group.

Statistical analysis

The χ^2 test, with or without Yate's correction, and Student's *t* test were used to analyze the data as appropriate. A *P* value less than 0.05 was defined as statistically significant.

RESULTS

G6PD deficiency was confirmed for 4 of the 157 males (2.5%) and 6 of the 215 females (2.8%) cholelithiasis patients, with respective gender distribution as follows: hemizygous 493, 871, 1 024, and 1 388 (n = 1 each), and heterozygous 1 376 (n = 5) and heterozygous 1 388 (n = 1) (data not shown in Tables). There was no significant between-gender difference in incidence of G6PD deficiency. Analysis of pooled data showed an overall incidence of G6PD deficiency of 2.7% (10/372) for the cholelithiasis group. The frequencies of the *UGT1A1* genotypes are presented in Table 3. Less than half (48.4%) of the cholelithiasis patients carried the wild genotype. The variation frequencies for A(TA)$_6$TAA/A(TA)$_7$TAA (6/7), heterozygosity within the coding region, compound heterozygosity, and homozygosity were 16.1%, 25.8%, 5.4%, and 4.3%, respectively. The incidence of thalassemia in the cholelithiasis patients was 5.1% (19/372) [heterozygous α-thalassemia 2.7% (n = 10); heterozygous β-thalassemia 1.6% (n = 6); homozygous β-thalassemia 0.53% (n = 2); and heterozygous α-thalassemia plus heterozygous β-thalassemia 0.27% (n = 1)] (detailed data not shown in Tables). Analysis for the combination of G6PD deficiency, homozygous variation in the *UGT1A1* gene, and presence of thalassemia revealed that two cholelithiasis patients carried the 211 G→A/211 G→A *UGT1A1* and the heterozygous α-thalassemia genes (data not shown in Tables).

Clinical data for the cholelithiasis patients and healthy controls are compared in Table 3. There was no difference in gender distribution, neither in the mean of age, comparing the two groups. A significant difference was demonstrated comparing the frequency of homozygous variation (7/7, 211 G→A/211 G→A, and 686 C→A plus 7/7) of the *UGT1A1* gene for the case and control groups (P = 0.012, χ^2 test), while those for the other three variation types were not statistically meaningful. There was no significant between-group difference in the incidence of G6PD deficiency and thalassemia (2.7% *vs* 2.4% and 5.1% *vs* 5.1%, respectively). Nine (56.3%) of the 16 cholelithiasis patients

with the homozygous variant-*UGT1A1* gene had bilirubin levels ⩾17.1 μmol/L (upper limit of normal reference value) with significant difference between means in comparing the 16 patients with the controls [18.0±6.5 μmol/L (range 6.8-32.5 μmol/L) and 12.7±2.9 μmol/L (range 6.8-17.1 μmol/L), respectively; P<0.001, Student's t test] (data not shown in Tables).

DISCUSSION

No gender difference has been demonstrated in the incidence of variant *UGT1A1* gene and thalassemia, while G6PD deficiency is X-linkage transmitted[11]. In this study, as the male/female ratio was approximately equal for the case and control groups, the genders were pooled for analysis. More than 50% of the members of both groups had at least one heterozygous variation in the *UGT1A1* gene, while the frequency of homozygous variation differed between groups. The 686 C→A variation was associated with the 6/7 or 7/7 variation for both study subjects and the controls, as observed in our previous studies[5,7,8,12,13]. In the present investigation, however, the 7/7 and 686 C→A plus 7/7 variations were found only in the case group (Table 3). Since bilirubin may be affected by cholelithiasis status, bilirubin values were obtained for cholelithiasis patients with the homozygous variant-*UGT1A1* gene from the records which were made 2-3 mo post cholecystectomy. UGT1A1 enzyme activity was found to be 18-33% of normal in individuals with the 7/7 variation of the *UGT1A1* gene[2]. In another *in vitro* gene-expression study[14], subjects bearing the homozygous 211 G→A variant-*UGT1A1* gene were demonstrated to have 32.2% of the UGT1A1 enzyme activity of normal analogs. Moreover, coinheritance of heterozygous α-thalassemia gene was observed in two of our four cholelithiasis patients who carried the homozygous 211 G→A variation. These findings may account for the significant difference in serum bilirubin levels in cholelithiasis patients with the homozygous variant-*UGT1A1* gene (7/7, 211 G→A/211 G→A, and 686 C→A plus 7/7) related to controls.

Although it has been determined that G6PD deficiency and thalassemia are risk factors for cholelithiasis development in Caucasians[1,4], these associations were not observed in our sample, with no between-group difference in incidences of these two factors were noted. This discrepancy may be due to the ethnic differences between the sample populations. Co-inheritance of the homozygous variant-*UGT1A1* gene and G6PD deficiency may lead to pronounced hyperbilirubinemia in adults[13], and co-inheritance of Gilbert's syndrome and hereditary spherocytosis may increase the risk for developing gallstones[15]. However, these co-inheritances were not noted in this study. Structural analysis of gallstones from a sample of Taiwan Chinese patients revealed that a relatively small proportion of the gallstones were composed of bilirubin (pure cholesterol 35%, combination 12%, mixed 17%, black 25%, calcium bilirubinate 8%, and unclassified 3%)[16]. It is not surprising, therefore, that only 4.3% of our cholelithiasis patients carried the homozygous variant-*UGT1A1* gene, which leads to the bilirubin accumulation and is a risk factor for cholelithiasis. We suggest that investigation of cholelithiasis status and carriage of variant *UGT1A1* gene for specific subpopulations, such as G6PD-deficient or thalassemic Taiwan Chinese, is a superior alternative in genetic research for gallstones. A research program of this type is ongoing at the Cathay General Hospital.

Abstract

AIM: To identify the decreasing effect of xenotransplantion in combination with privileged sites on rejection and death of biological semipermeable membrane-(BSM) encapsulated implanted islets.

METHODS: After the BSM experiment *in vitro*, BSM-encapsulated SD rat's islet-like cell clusters (ICCs) were xenotransplanted into normal dog's brain. Morphological changes were observed under light and transmission electron microscope. The islets and apoptosis of implanted B cells were identified by insulin-TUNEL double staining.

RESULTS: The BSM used in our study had a favorable permeability, some degree of rigidity, lighter foreign body reaction and toxicity. The grafts consisted of epithelioid cells and loose connective tissue. Severe infiltration of inflammatory cells was not observed. The implanted ICCs were identified 2 mo later and showed typical apoptosis.

CONCLUSION: BSM xenotransplantation in combination with the privileged site can inhibit the rejection of implanted heterogeneous ICCs, and death of implanted heterogeneous B cells is associated with apoptosis.

INTRODUCTION

Studies have shown that porcine ICCs xenotransplanted into rat's brain could survive for only eighteen days[1,2], suggesting that the immuno-privileged function of brain cannot ensure the long-time survival of heterogeneous islets. Immunity-isolation is an effective way to lessen the immunological rejection damage[3,4]. Better effect can be achieved through the combination of different immunity-isolation techniques[5]. Rat's pancreatic islet is easy to be separated, transgenic rats are also developed, and the cell line secreting insulin has been established[6]. However, the exact effects of apoptosis on the death of xenotransplanted islets cannot be shown[7-9]. In this study, BSM-encapsuled SD rat's ICCs were xenotransplanted into a normal dog's brain to identify their decreasing effect on rejection and death of implanted islets.

MATERIALS AND METHODS

Separation, purification and culture of rat ICCs[6]

SD rats, weighing 50-200 g were used in this study. Pancreas and its amiculas and vessels were washed twice in Hank's solution and then minced. The fragments were digested with collagenase V (1 g/L, Sigma) at 37 ℃ for 15-20 min, ground and filtrated through an 80-mesh steal net to remove connective tissue, washed in cold Hank's solution to stop the activity of collagenase. Then the filtrates were filtrated with a 400-mesh steal net to remove the small exocrine cells, red and white blood cells with the bigger ICCs kept on the net. The cell clusters on the net were collected and put into the Ficoll fluid (Euro-Collin) at the concentrations of 25 g/L, 23 g/L, 20 g/L and 11 g/L. The mixed liquors were centrifuged at 3 500 r/min at 4 ℃ for 15 min. ICCs were washed three times. The purity of ICCs obtained in this way was (88.2±7.6) %. These ICCs were cultured in non-insulin DMEM supplemented with 10% fetal bovine serum, 2 mmol/L glutamine, 10 mmol/L nicotinamide, 5 mmol/L hydroxyethyl methylmethane sulfonic acid, 100 000 U/L penicillin and 1 g/L streptomycin, and maintained at 37 ℃ in a high-humidity incubator with 50 mL/L CO_2. A total of 400-1 000 purified ICCs were obtained from each rat. These ICCs were stained with trypan blue and the activity was 90%.

Lymphocytes diffusion

Five semipermeable membrane encysts were filled with 1 mL of fresh blood plasma, put into 200 mL of blood and maintained at 37 ℃ in a high-humidity incubator with 50 mL/L CO_2 and kept agitated with magnetic force. Fluid

in encysts was suctioned respectively 5 h later, then smeared and observed under a light microscope by Wright's staining.

Glucose diffusion

Eight semipermeable membrane encysts were filled with 1 mL of isotonic sodium chloride, put into 400 mL of isotonic sodium chloride containing 29.1 mmol/L glucose and kept agitated with magnetic force. The encysts were taken out at 1, 4, 8, 12, 16, 20, 24 and 28 min, respectively, and washed with isotonic sodium chloride. The fluid in the encysts was obtained and the concentration of glucose was detected.

In vitro culture of BSM-encapsulated ICCs

About twelve thousands separated ICCs were divided into ten parts, five were encapsulated by BSM, five were routinely cultured. The culture medium was changed every three days. The concentration of insulin in the medium was detected on d 3, 6, and 15 respectively when the medium was changed.

Transplantation of BSM-encapsulted SD rat ICCs into dog's brain

After ICCs were cultured for 72 h, they were encapsulated by aseptic BSM. The volume of encysts was 1.5 cm×1.5 cm×1.5 cm. Each of them contained 6 000 to 10 000 ICCs.

The recipients were normal male local hybrid dogs weighing 7-14 kg. The dogs were intravenously anesthetized and their hair was shaved. The straight nick was made at frontal-occipital middle line perpendicular to the zygomatic arch. The temporalis muscles were pulled back to expose the skull, a hole was burred to enlarge the skull window to 3 cm×3 cm, and the dura mater was cut open. The pallium was exposed to make a nick under the cerebral lateral fissure, and a fistula was made into ventricle between the rectal fissure and rectal lateral fissure to form a 2 cm×2 cm×1.5 cm tunnel. The brain tissue was wet compressed with 0.5 g/L orthophosphoric acid dexamethasone for 15 min[7], then encysts were transplanted into the tunnel. The dura mater was relocated and compressed with gelatin sponges from the outside. Scalp and muscles were then sutured. Dogs were allowed to take food when consciousness was regained after anesthesia. Penicillin and streptomycin were used 30 min before and 1-3 d after operation.

The dogs were divided into control group (n = 2) and experimental group(n = 4). In control group, a fistula was made, the stoma at the ventricle side was covered with gelatin sponges. Then the encysts were cut open to let the contents efflux into the brain tissue and the stoma at cortex side was covered with gelatin sponges. In experimental group, brain tissue was obtained 1 mo and 2 mo after encapsulated ICCs were transplanted.

Observation of morphological changes after surgery

According to the schedule, the brain was perfused with 4 g/L paraformaldehyde phosphate buffer through the ambi-common carotid artery. The grafts' shape, color, location and changes of surrounding brain tissue were observed. Then part of the grafts and surrounding brain tissue were paraffin embedded, sectioned and stained with HE. Morphological changes of grafts and brain tissue were observed under a light microscope. Some grafts were divided into 1 mm×1 mm×1 mm piecers. These pieces were fixed with 25 g/L glutaraldehyde, dehydrated, embedded and then cut into ultrathin sections. The ultramicro-changes of the grafts were observed under a transmission electron microscope (JEM2000).

Identification of islets and apoptosis of implant ICCs

The first antibody was replced by normal mouse serum in the negative control group. Paraffin-embedded sections were used. The first antibody was mouse anti-human insulin used at 1:100 dilution and stained according to the avidin-biotin compound method (ABC), and then counterstained with hematoxylin to identify B cells in the grafts. The DNA fragmentation of transplanted B cells was identified by insulin-TUNEL double staining .

RESULTS

In vitro experiments of BSM

The BSM was not damaged during the whole process of the experiment *in vitro*. In lymphocyte-diffusion experiment, lymphocytes and any other blood cells were not immersed into the semipermeable membrane capsule, but glucose could rapidly diffuse into the capsule. The concentration of glucose in the capsule was 14.3 mmol/L after 8 min, which was 50% of the concentration out of the capsule. After 28 min. The concentration of glucose in the capsule reached the same environmental level. The concentration of insulin on d 3, 6 and 15 was (139.0±3.4) mU/L, (78.7±3.9) mU/L and (66.2±2.9) mU/L, respectively in the experimental group , and (145.4±4.2) mU/L, (79.4±2.1) mU/L and (48.2±4.1) mU/L, respectively in the control group. There was no conspicuous variability (P>0.05) between the two groups at various time points. Insulin secreted from pancreatic islet cells could diffuse rapidly out of the capsule.

ICCs xenotransplanted into dog's brain

The dogs of both groups had no conspicuous behavior disorder. No dog in the experimental group was infected. The graft was deep gray and homogenous in the experimental group. It was connected with the ventricle at the inner side and adhered to the thickening dura mater at the lateral side as well as in contact with the cerebral parenchyma. The boundary was clear. Brain tissue around the graft had no obvious hemorrhage, necrosis and inflammatory abscess. Only residual semipermeable membrane was observed in the control dogs.

Under light microscope, the graft was consisted of epithelial cells and loose connective tissue, including epithelial cells, fibroblasts, collagen fiber, and small vessels. In the middle of them, there were lymphocytes and other kinds of white blood cells. Epithelial cells mostly adhered to the fibroblasts, collagen fiber or small vessels, and were arranged loosely in the connective tissue along the collagen fibers. The structure of small vessels was normal, while that of some parts of the semipermeable membrane was different, but there was no clump-like infiltration of lymphocytes.

Slight hyperplasia and hydropsia of glial cells were observed in the brain tissue around the graft, but severe infiltration of inflammatory cells was not observed.

Under electron microscope, secreting granulae were observed in the endochylema. The granulae were not only different in size but also diferent from those of pancreatic islet cells. Intact and contracted caryons, aggregated chromosome and typical apoptotic bodies were found in some cells (Figure1).

No xenotransplanted cell disappeared in the control group.

Cytoplasms of many epithelial cells in the grafts of EG were stained yellow, indicating that they were islet B cells (Figure2). The implanted B cells showed typical apoptosis by insulin-TUNEL double staining.

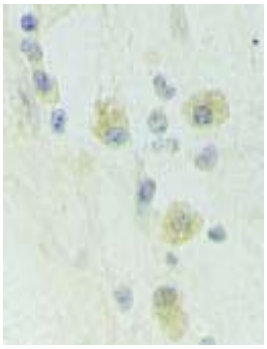

Figure 1 Typical morphology of apoptotic cells 1 mo after transplantation (×6 000). ↑ collagen fiber, ↑ WBC, ▲ apoptosis body.

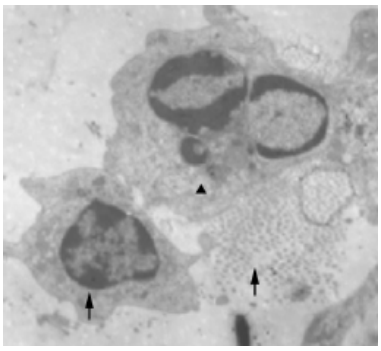

Figure 2 Yellow staining of cytoplasma of some graft cells 1 mo after transplantation (×6 000).

DISCUSSION

Studies have shown that porcine ICCs xenotransplanted into a rat's brain can survive for only 18 d[1,2], and fetal porcine ICCs transplanted into cynomolgus monkey's kidney encysts are completely rejected on d 6[5,8]. In the present study, no infiltration of clump-like polymorphic nuclear cells and lymphocytes was found, suggesting that rejection occurs in xenotransplanted ICCs. Immunohistochemical staining showed that pancreatic islet B cells still existed in the grafts after 2 mo. The dogs had no conspicuous behavior disorder after transplantation. Slight hyperplasia and hydropsia of glial cells were observed in the brain tissue around the graft. These facts suggest that ing Xenotransplantation of BSM in combination with the privileged site can inhibit the rejection of implanted heterogeneous ICCs.

In the present study, cells displayed different morphological features in different environments to adapt themselves to the microenvironment. The culture medium was gradually absorbed after graffing and replaced by loose connective tissue until solidification. The appearance of connective tissue was a kind of compensatory reaction, giving support and nutrition to islet cells and keeping them stable. Islet cells were arranged loosely in the connective tissue along the collagen fibers, while the in situ compact cell clumps were observed under the pressure of exocrine division.

It is easier to transplant pancreatic islets when they are capsuled and to dislodge them when the rejection is serious during the early period of transplantation. This is very important when a clinical trial is carried out. According to the *in vitro* experiments and transplant experiments, the semi permeable membrane used in our study had a favorable permeability, some degree of rigidity, lighter foreign body reaction and toxicity.

It was reported that cerebrospinal fluid (CSF) could ensure islet survival with sufficient oxygen and nutrients[10]. We made a tunnel into the ventricle, which could connect capsules with CSF immediately. Accordingly, islets were supplied with nutrients in the earlier period, which is beneficial for their survival. However, how many islet nutrients can be obtained in this way remians unclear. We also found that the implanted B cells showed classic apoptosis by insulin-TUNEL double staining and electron microscopy. The death of implanted heterogeneous B cells is associated with apoptosis. Why apoptosis occurs and how to delay or block this apoptosis are the subjects to be studied[11-14].

Surgical procedures injure brain tissue and integrality of the blood-brain barrier. Wet compressing with dexamethasone on the injured brain can decrease the blood-brain barrier permeability and non-specific exudation of inflammatory cells[15].

Abstract

AIM: To investigate the expression and distribution of HBV in the ovaries and ova.

METHODS: The immunohistochemistry method was used to detect the HBsAg and HBcAg in the ovaries of patients with chronic hepatitis B.

RESULTS: Expression of HBsAg in the ova, granular and interstitial cells of the ovaries was located in the cytomembrane and cytoplasm. Expression of HBcAg in the ova, granular, interstitial and endothelial cells of interstitial blood vessels of the ovaries was found in the cytomembrane, cytoplasm, and nuclei.

CONCLUSION: HBV can infect the ova at different stages of development and replicate in it.

INTRODUCTION

In Asian countries such as China, vertical infection plays a major role in transmitting HBV. The infected babies will eventually develop liver cirrhosis or hepatocellular carcinoma in their adulthood, and female babies will continue the cycle of vertical transmission to their offsprings[1-3]. Recent data indicate that intrauterine infection is one of the important routes of HBV vertical transmission, and the rate of intrauterine HBV infection is 10-44.4%[3,4]. Furthermore, studies have proved that most intrauterine infections can be prevented by inoculation with HBVac and HBIG in the perinatal stage, but 5-10% of the infections cannot be prevented by the combination of HBIG and HBVac[5,6]. The mechanism for this fact is controversial. Some researchers suspected that the infection of ova with HBV may be a factor in this mechanism[7]. But this was just a supposition, and little data exist to prove it.

To explore if HBV could infect the ovaries and ova, we detected the expression of HBsAg and HBcAg in the ovaries and ova of patients with chronic hepatitis B (CHB) by immunohistochemistry method.

MATERIALS AND METHODS

Ovary tissues were obtained from 18 patients with CHB who received surgery for ovary disease at the First Hospital of Xi'an Jiaotong University in China. The specimens were collected after surgery. Serum samples from these patients were tested for different HBV markers including HBsAg, HBeAg, anti-HBc, anti-HBe (HBVM) using a commercially available ELISA kit (Sino-America Biological Technology, Inc., Beijing, China) prior to surgery. HBsAg was positive while HCV, HIV, HAV, and HEV were negative in 18 patients. All reactions were performed at the Immunohistochemistry Laboratory in Xi'an Jiaotong University.

Ovary tissues were fixed in 40 g/L formaldehyde, embedded with paraffin and cut into 4 μm thick sections. Mouse (McAb) against HBsAg (Dako, Denmark) and rabbit polyclonal antibodies against HBcAg (Baoxin, China) were used for immunohistochemical test. DAB staining kits were purchased from Wuhan BoShiDe Biological Engineering Ltd. Company.

HBsAg and HBcAg were detected by immunhistochemical staining using the avidin-biotin complex (ABC) method on the sections of ovarian tissues. In brief, formalin-fixed, paraffin-embedded sections were deparaffinized in xylene and passed through ethanol series. After the endogenous peroxidase activity was blocked, the sections were rinsed in 0.01 mol/L PBS. Non-specific binding was blocked by treatment with 5% normal serum for 30 min. Primary antibody was applied to the sections and incubated in a moist chamber overnight at 4 ℃. After the sections were washed in 0.01 mol/L PBS, second antibody was applied and sections were incubated for 30 min at 37 ℃ in

a moist chamber. After being washed, the sections were incubated with avidin-biotin-peroxidase complex for 30 min at 37 ℃ in a moist chamber and washed again. The chromogen, 3-3-diaminobenzidine (DAB) was added to the sections for 10 min.

The sections of HBsAg and HBcAg positive livers from autopsy were used as positive control, and the sections of ovaries from HBVM negative women served as negative control. At the same time, PBS was used as blank control instead of the first antibody in immunohistochemical test. Dark brown yellow in cytoplasm, cytomembrane or nuclei was regarded as strongly positive, brown yellow as positive, and light brown yellow as weakly positive.

RESULTS

Expression of HBsAg in the ova and granular cells of the ovaries was located in the cytomembrane and cytoplasm. The positive rate was 11% (2/18). Negative control and blank control were negative. (Figures 1A and B)

Expression of HBcAg in the ova, granular, interstitial and endothelial cells of interstitial blood vessels of the ovaries was found in the cytomembrane, cytoplasm, and nuclei. HBsAg and HBcAg in the ovaries were strongly positive. The positive rate was 45% (8/18). Negative control and blank control were negative. (Figures 1C-H).

DISCUSSION

Much attention has been paid to the effective prevention of vertical HBV transmission[1-4]. It was reported that intrauterine HBV is transmitted through HBV-infected placenta and HBV could enter the blood of infant through placental leak[8]. But this cannot explain why HBV can infect the embryo (46 d). Chen *et al*.[7], showed that HBV cannot infect the embryo through placenta. They believe there is another mechanism by which HBV infects the embryo.

Yu *et al*.[9], proved that hemorrhagic fever virus exists in the ova of rodent. Bovine viral diarrhea virus can infect the ova of bovine[10]. Tagawa *et al*.[11], found that duck HBV

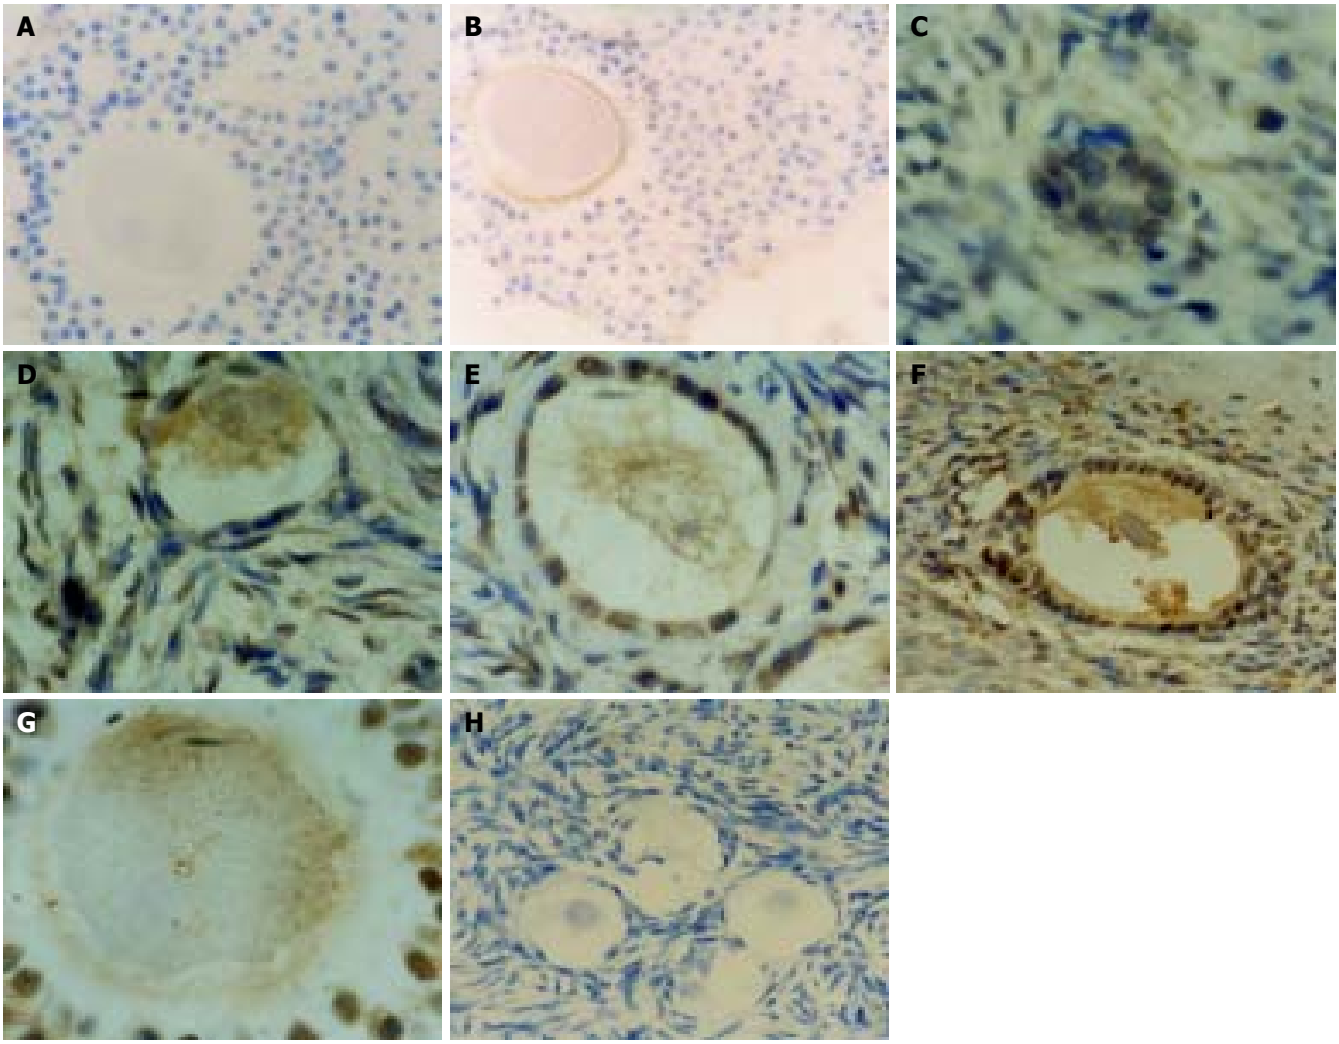

Figure 1 Expression of HBsAg and HBcAg in the ovaries and ova. **A**: HBsAg negative control (original magnification:10×40); **B**: expression of HBsAg in plasma and membrane of ova and granular cells (original magnification:10×40); **C**: expression of HBcAg in plasma, membrane and nuclei of sinus ova, granular and interstitial cells (original magnification: 10×100); **D** and **E**: expression of HBcAg in plasma, membrane and nuclei of primary ova, granular and interstitial cells (original magnification: 10×40); **F**: expression of HBcAg in plasma, membrane and nuclei of secondary ova, granular and interstitial cells (original magnification: 10×40); **G**: expression of HBcAg in plasma, membrane and nuclei of mature ova, granular and interstitial cells (original magnification: 10×100); **H**: HBcAg negative control (original magnification: 10×40).

(DHBV) is expressed in yolk of duck with hepatitis B, and that DHBVDNA is present in liver of embryo after 6 d of incubation, suggesting DHBV could infect the egg of duck and replicate in it. Zhao *et al*.[12], reported that DNA of TTV is found in the ovaries of CHB patients by hybridization *in situ*. Zhou *et al*.[13], reported that HBVDNA is present in plasma of ova and in interstitial cells of the ovaries of a patient who died of serious hepatitis B. Taylor *et al*.[14], have detected HBsAg in follicular fluid of CHB patients by immunohistochemistry method.

In this study, HBsAg and HBcAg were expressed in ova and granular cells of the ovaries. HBcAg was expressed in ova at different stages of development, suggesting that HBV can infect the ovaries and ova, and replicate in them. The fact suggests that HBV-infected ova may cause the vertical transmission of HBV, which cannot be prevented by inoculation of HBV vaccine and HBIG because the embryo is infected as zygote is formed.

In this study, the positive rate of HBsAg (11%) was lower than that of HBcAg (45%). We consider that the primary antibody against HBsAg is monoclonal antibody (McAb), but the primary antibody against HBcAg is polyclonal antibody. Since the binding epitope of McAb is less than that of polyclonal antibody, the positive rate of HBsAg is lower. On the other hand, in the ova, the synthetizing and expression of HBcAg by HBV may be higher than that of HBsAg in the ovaries. The amount of HBsAg is more than that of HBcAg in liver cells[15,16]. Of course, a little sample may be a reason.

In conclusion, HBV can infect the ovaries and ova and replicate in them. But how does HBV infect the ovaries and ova and whether HBV-infected ova results in HBV vertical transmission remain unknown.

Abstract

AIM: To study the relationship of human leukocyte antigen (HLA)-DRB1 and -DQB1 alleles with the genetic susceptibility to HBV infection and the response to interferon (IFN) in HBV-infected patients.

METHODS: Low-resolution DNA typing kit was used to determine HLA-DR-1 and -DQB1 genes in 72 patients with chronic hepatitis B (CHB) and HLA-DRB1 in 200 healthy people ready to donate their bone marrow in Shanghai. Among CHB patients, 35 were treated with IFNα-1b for 24 wk.

RESULTS: The frequencies of HLA-DRB1*06, DRB1*08 and DRB1*16 alleles in 72 patients were higher than in 200 healthy people (2.08% *vs* 0%, OR = 3.837, *P* = 0.018; 11.11% *vs* 5.50%, OR = 2.148, *P* = 0.034; and 6.94% *vs* 3.00%, OR = 0.625, *P* = 0.049, respectively); whereas that of DRB1*07 allele was lower (2.78% *vs* 7.75%, OR = 0.340, *P* = 0.046). The frequency of HLA-DRB1* 14 allele was higher in 11 responders to IFN compared with 24 non-responders (18.18% *vs* 2.08%, OR = 10.444, *P* = 0.031), whereas that of DQB1*07 allele was inverse (9.09% *vs* 37.50%, OR = 0.167, *P* = 0.021).

CONCLUSION: The polymorphism of HLA class II may influence the susceptibility to HBV infection and the response to IFN in studied CHB patients. Compared with other HLA-DRB1 alleles, HLA-DRB1*06, DRB1*08, and DRB1*16 may be associated with chronicity of HBV infection, HLA-DRB1*07 with protection against HBV infection, and HLA-DRB1*14 allele may be associated with a high rate of the response of CHB patients to IFN treatment. Compared with other HLA-DQB1 alleles, HLA-DQB1*07 may be associated with low response rate to IFN.

INTRODUCTION

It is generally accepted that viral clearance or chronic viremia following HBV infection is determined by the host immune response against HBV, in which human leukocyte antigens (HLA) play a central role. The progressions of antigen-presenting cells presenting viral antigens to B and T cells, B and T cells recognizing antigens, and B and T cells being reactivated are all restricted by HLA. The genes of HLA are polymorphous and difficult types of HLA are combined with difficult motifs of the antigens. It is, therefore, presumed that the HLA polymorphism possibly determines the pathogenesis and outcome of HBV infection. It has been reported that the HLA polymorphism correlates with the outcome of HBV infection, but this relationship is not universal on the basis of the investigated population. In Caucasia[1,2] and Korea[3], for example, HLA-DRB1*1301-02 has been found to be associated with acute self-limited hepatitis B. In Taiwanese, HLA-DRB1*0406 is associated with recovery from HBV infection in Han Chinese, and so is HLA-B*4001 in Aborigines[4]. Han Chinese with HLA-DR12 (especially one of its alleles of DRB1*1201) or HLA-DRB1*1101/1104, respectively, have been shown to be able to resist HBV infection, and those with HLA-DR9, DQ9, HLA-DRB1*0301, HLA-DQB1*0301 (one of DQ7 isoforms)[5,6] and DRB1*10, respectively, have been revealed to have a relationship with susceptibility to chronic HBV infection[7]. DRB1*15 and its link-inequilibrium haploid-DRB1*15-DQB1*05 have been found to be associated with sustained response to interferon (IFN) treatment in Taiwanese patients with chronic hepatitis C[8]. It has not been known, however, whether HLA genes correlate with the responsiveness to IFN treatment in patients with chronic hepatitis B (CHB). The aim of this study was therefore to assess whether HLA class II alleles play a critical role in the susceptibility to HBV infection and the response rate to IFN treatment in CHB patients.

MATERIALS AND METHODS

Subjects

A total of 72 patients with chronic HBV infection in the present study were positive for HBV surface antigen (HBsAg), e antigen (HBeAg) or anti-HBe and anti-HBc paralleled with serum ALT elevation for at least 6 mo. None of the patients were positive for hepatitis C virus antibody, hepatitis D virus antibody and HIV antibody; 62 of them were males and 10 were females with mean age of 32±7 years; 200 healthy people ready to donate their bone marrow in Shanghai were selected as control group; 112 of them were males and 88 were females with mean age of 35±7 years. All participants had no relative relationship.

Thirty-five of seventy-two patients without immunosuppressive or antiviral therapy within 1 year before entry, and without alcoholism, intravenous drug abuse, fatty liver, cirrhosis, pregnancy, or other serious diseases that may interfere with IFN-α therapy or that were forbidden for IFN therapy were treated with IFN-α-1b (Sinogen, Kexing Company, Shenzhen) at a dose of 3 MU per 2 d for 24 wk. Thirty-one of thirty-five patients were males and four were females with mean age of 31±7 years. Response to IFN-α treatment was defined as normalization of serum elevated ALT, undetectable HBV DNA by PCR method, and HBeAg seroconversion to anti-HBe until 6 mo after the treatment had ended; and non-response as detectable HBV DNA by PCR, and/or presence of HBeAg regardless of serum ALT level.

Methods

HLA class II typing Genomic DNA was extracted from peripheral blood using guanidine sulfocyanate method and the reagents were supplied by Shanghai blood center. HLA class II alleles were determined by low resolution DNA typing method, one of polymerase chain reaction-sequence specific primers techniques (Pel-Freez, USA) according to the manufacturer's instruction. Gene typing was performed with the use of software supplied by the company.

Serological testing

HBsAg, HBeAg, and antibodies to HBsAg, HBeAg and HBcAg were tested by an ELISA (Roche, Switzerland).

Quantification of HBV DNA

Serum HBV DNA was quantitated by fluorescence PCR performed in LightCycle amplifier (Roche, Switzerland) using domestic commercial kit (Piji Company, Shenzhen).

Statistical analysis

The frequency of HLA class II alleles was calculated by direct counting. The statistical significance of the associations of HLA class II alleles with the clinical outcome or the response to IFN-α was determined by the two-tailed Fisher's exact test using the SPSS 10.0 data analysis software package (Chicago, USA); P values <0.05 were considered statistically significant.

RESULTS

Relationship between HLA-DRB1 and the susceptibility to HBV infection

Frequency distribution of HLA-DRB1 in CHB patients and wealthy controls is illustrated in Table 1. The frequency of DRB1*06 allele in CHB patients was higher than in wealthy controls (2.08% *vs* 0%, $P = 0.018$, odds ratio [OR] = 3.837, 95% confidence interval [95%CI] 3.329-4.422), so are those of DRB1*08 allele (11.11% *vs* 5.50%, $P = 0.034$, OR = 2.148, 95%CI 1.094-4.216) and DRB1*16 allele (6.94% *vs* 3.00%, $P = 0.049$, OR = 0.625, 95%CI 0.252-1.552); the frequency of DRB1*07 allele was lower in CHB patients than in wealthy controls (2.78% *vs* 7.75%, $P = 0.046$, OR = 0.340, 95%CI 0.118-0.981). No significant differences of other HLA-DRB1 alleles' distribution were found between the two groups.

Relationship of HLA-DRB1 and HLA-DQB1 with the response to IFN therapy in patients with CHB

Frequency distribution of HLA-DRB1 and -DQB1 in responders and non-responders to IFN treatment is shown in Table 2. The frequency of DRB1*14 allele in 11 responders was higher than in 24 non-responders (18.18% *vs* 2.08%, $P = 0.031$, OR = 10.444, 95%CI 1.092-99.855); that of DQB1*07 allele was inverse (9.09% *vs* 37.50%,

Table 1 Distribution of HLA-DRB1 alleles in CHB patients and wealthy people

HLA-DRB1	Patients with CHB		Wealthy people		OR (95%CI)	P
	N1	Allele frequency $n = 144$	*N2*	Allele frequency $n = 400$		
DRB1*01	2	1.39	3	0.75	1.864 (0.308–11.269)	0.612
DRB1*04	14	9.72	53	13.25	0.705 (0.378–1.314)	0.303
DRB1*06	3	2.08	0		3.837 (3.329–4.422)	0.018
DRB1*07	4	2.78	31	7.75	0.340 (0.118–0.981)	0.046
DRB1*08	16	11.11	22	5.50	2.148 (1.094–4.216)	0.034
DRB1*09	34	23.61	75	18.75	1.339 (0.846–2.120)	0.225
DRB1*10	4	2.78	4	1.00	2.829 (0.698–11.462)	0.217
DRB1*11	11	7.64	29	7.25	1.058 (0.514–2.178)	0.854
DRB1*12	20	13.89	66	16.50	0.816 (0.475–1.402)	0.507
DRB1*13	2	1.39	15	3.75	0.362 (0.082–1.601)	0.262
DRB1*14	9	6.25	25	6.25	1.000 (0.455–2.197)	1.000
DRB1*15	9	6.25	39	9.75	0.617 (0.291–1.308)	0.234
DRB1*16	10	6.94	12	3.00	2.413 (1.019–5.713)	0.049
DRB1*17	6	4.17	26	6.50	0.625 (0.252–1.552)	0.409

P = 0.021, OR = 0.167, 95%CI 0.035-0.796). No significant differences of other HLA-DRB1 and -DQB1 alleles' distribution were found between the responders and non-responders.

DISCUSSION

It has been well known that human HLA-II antigens are expressed in the member surface of antigen presentation cells and immune response cells, taking part in the regulation of host immune response against foreign antigens, which is determined by the HLA genes' polymorphism and their expression levels in the above-mentioned cell member surface. It is generally acknowledged that some HLA polymorphisms are associated with auto-immune diseases. A close attention has been recently paid to the relationship between HLA polymorphisms and viral hepatitis.

It has been reported that in western Caucasians the frequencies of HLA-DRB1*1301/1302 in German patients with acute self-limited hepatitis B and USA patients with spontaneous viral clearance after HBV infection are both higher than in respective patients with CHB[1,2], whereas in the USA, Afro-American persistent HBV infection is associated with HLA-II gene homozygotes, and DQA1*0501 and DQB1*0301, and their haploids DQA1*0501-DQB1*0301 and DQA1*0501-DQB1*0301-DRB1*1102[9]. It has also revealed that in Korea DR6 and DR13 (especially DR13) have a close relationship with spontaneous viral clearance and DR9 is associated with disease chronicity following HBV infection[2]. These findings suggest that there are different relationships between HLA gene polymorphisms and HBV infection in different racial population, implying that various HLA molecules could present different HBV epitopes to induce effective immune responses[4].

It has been found that in China, the frequencies of HLA-DR10, -DRB1*0301 and -DQB1*0301 all increase in patients with CHB compared with wealthy people, whereas that of HLA-DRB1*1101/1104 is inverse[6,7]; the frequency of HLA-DR12 (especially one of its alleles DRB1*1201) declines compared with those with spontaneous cure following HBV infection, whereas frequencies HLA-DR9, -DQ9 are inverse[5]. In the present study the frequencies of HLA-DRB1*06, -DRB1*08 and -DRB1*16 were all higher in CHB patients than in wealthy people, and that of HLA-DRB1*07 lower in CHB patients than in wealthy people, suggesting that individuals with HLA-DRB1*06, -DRB1*08 or -DRB1*16 alleles were susceptible to HBV infection, whereas those with HLA-DRB1*07 allele was resistant to HBV infection in Shanghai people. Four HLA genes mentioned above, however, are all infrequent among the Shanghai population, the proportion of which accounts for 16.25% of the whole population, suggesting that HLA polymorphism has a less of a role in pathogenesis of CHB.

A lot of domestic and foreign studies including this one demonstrate that some of HLA alleles were susceptible genes to HBV infection and some were resistant genes to HBV infection, but the different genes associated with the outcome of HBV infection were found in different studies. This divergence may be elucidated by gene background of different nations of subjects, research designs and the fact that disease chronicity following HBV infection is probably not influenced by HLA gene polymorphisms.

Whether hepatitis B onsets and disease chronicity occurs after HBV infection is dependent on immune response condition of host who is infected. If there are no primary and secondary immune defects, host's age can reflect his/her mature level of immune functions. Hyams *et al*., reviewed the literatures on chronic HBV infection and found that chronicity rate is about 80-90%, when infection occurs in infants and young persons less than 6 years; that there are usually no self-conscious symptoms accompanying HBV

Table 2 Distribution of HLA class II alleles in IFN responders and non-responders

HLA	Responder		Non-responder		OR (95%CI)	*P*

that clear on their own and immunity being acquired, and only a minority with HBV infection show clinical manifestations of acute hepatitis B, chronicity rate less than 5% when infection occurs in adults[10]. The result of a study has shown that only 0.3% of patients become chronic HBV carriers in which a total of about 300 000 patients with HBV infection due to inoculations of yellow fever vaccine populated by HBV were followed up for 40 years[11]. In China 30-50% of population are detected with one antibody or more antibodies to HBV in their whole life, suggesting that they have been infected with HBV and virus has been cleared spontaneously and immunity against HBV has been acquired, which demonstrates that acute transient infection is a principal pattern of HBV infection[12]. These phenomena are not obviously explained by individual discrepancy of human gene background, including HLA polymorphisms.

The effects of HLA genes on IFN treatment to CHB patients have not yet been reported, although domestic and foreign studies have shown that gene polymorphisms of HLA-I and -II antigens have an influence on host immune response to HBsAg vaccine[13-15]. Our study has revealed that HLA-DRB1*14 may be associated with a high rate of the response of CHB patients to IFN treatment, compared with other HLA-DRB1 alleles and HLA-DQB1*07 may be associated with low response rate to IFN, compared with other HLA-DQB1 alleles.

DRB1*14 is also an infrequent HLA gene in Shanghai, its frequencies in 200 wealthy people and 72 CHB patients being 6.25% and 7.14%, respectively. DRB1*14 was found in five patients treated with IFN, four of them were responders. Among these five patients, four of them were infected with type B HBV and one was infected with type C HBV, and serum HBV DNA level was low (data not shown). It has been generally accepted that low level of serum HBV DNA has benefit to IFN treatment and the response rate to IFN treatment is higher in patients with type B HBV infection than in those with type C HBV infection[16]. Therefore, it is not excluded that HLA-DRB1*14 had an occasional relationship with IFN therapy in our study.

Further studies are required for elucidating whether HLA-DQB1*07 allele can serve as one of the indices for selecting patients to be treated with IFN because of a small sample in our study, though it is a frequent HLA gene in the Chinese and has been found to be associated with low response rate to IFN treatment in the present study.

Abstract

AIM: To explore a simple, effective, safe and operable pretreatment for conferring tolerance against ischemia-reperfusion (I-R) injury in rat livers.

METHODS: Forty-five rats were divided into five groups (each group n = 9). Group C: control group; group G: geranylgeranylacetone (GGA) was administered without heat stress; group S: local heat stress alone; group WG: GGA plus whole-body heat stress; group SG: GGA administration plus local heat stress. After completion of the I-R procedure, the ischemic-reperfused liver lobes in five groups were resected and tested for heat shock protein (HSP70) by RT-PCR, Western blotting analysis and immunohistochemical staining. The blood samples were collected for ALT and AST measurement at the end of occlusion of blood supply, 30 min after reperfusion, 24, 48, 72 h after surgery from the inferior vena cava. Survival was monitored for 1 wk.

RESULTS: The production of HSP70 after I-R injury increased, the liver enzyme levels after reperfusion decreased rapidly, and the survival rates increased in groups C-SG.

CONCLUSION: The combination of GGA plus local somatothermal stimulation is a simple, effective, safe and operable pretreatment to induce HSP70 in patients with liver tumor and cirrhosis before hepatectomy and in donors before harvesting graft for liver transplantation.

INTRODUCTION

Ischemia-reperfusion (I-R) injury is the main cause of hepatic damage induced by temporary clamping of the hepatoduodenal ligament during liver resection (Pringle maneuver), and severe complications of liver transplantation such as primary graft nonfunction or malfunction are also the consequence of reperfusion injury[1,2]. Furthermore, even moderate reperfusion damage that does not severely affect the graft can impair long-term hepatic recovery and enhances the patient's susceptibility to infections and multiple organ failure[1]. Though improvements in liver preservation and surgical techniques have been achieved, hepatic ischemia/reperfusion remains an important clinical problem. Furthermore, because of the shortage of organs for transplantation, the use of steatotic livers, which have a lower tolerance to hypoxia and are more susceptible to reoxygenation damage, greatly increase the risks related to reperfusion injury[3,4]. Therefore, it is clinically significant to find a simple, effective, safe and operable preconditioning combination before liver surgery to protect liver against I-R injury.

Hepatic preconditioning can be induced by transient I-R[5-9], short-term hyperthermia[10,11], oxidative stress[12], or ANP infusion[13,14]. All these stimuli improve postischemic sinusoidal perfusion, leukocyte infiltration, bile production, and aminotransferase release 48 h after their application to liver. Among these stimuli, hyperthermic preconditioning has been proved to be a potential clinical application measurement. After heat shock preconditioning, organisms may produce endogenous cytoprotective substances which can ameliorate I-R injury in subsequent hepatectomy or liver transplantation.

The cytoprotective action of heat shock preconditioning is closely related to the endogenous cytoprotective protein, heat shock protein (HSP), which has been proved to play an important role in protection against I-R injury[16,17]. In

the HSP family, inducible form of HSP70 is the main cytoprotective protein[18,19]. Research on how to apply the cytoprotective action of HSP70 during liver surgery by certain heat shock preconditioning form is scarce. Therefore, how to find out a clinically feasible heat shock stress form remains to be elucidated.

Generally, heat shock stress includes two types: whole-body heat and local heat. By heating the whole body in warm water or on electronic pad, body temperature must be above 41 ℃-the critical temperature[11,20] to activate heat shock stress of viscera where the inducible form of HSP70 is induced to play the cytoprotective action[18,21]. Local somatothermal stimulation (LSTS), a kind of local heat stress on designated skin area, is speculated to be the consequence of a somatovisceral reflex through a heat-sensitive neural release of NO. It is well known that NO is a strong inducer of gene expression of HSP[22-24], and it is interesting that LSTS also has the same critical temperature 41 ℃. Chiu *et al*.[26], have applied LSTS on the right seventh intercostal nerve territory[25] and left median nerve territory[27] respectively (they are regarded in Chinese medicine as sites to cure hepatobiliary and cardiovascular diseases), and found that HSP70 gene expression increases in liver and heart, and I-R injury in liver and heart was also relieved. Thus, for the two types of heat stress, this study aimed to estimate which type is more simple, effective, safe and operable for clinical application.

Besides, in view of the induction of HSP70, the use of pharmacologic inducers might be different. Although most chemicals that are able to induce HSP expression are cellular toxins[28-30], geranylgeranylacetone (GGA, teprenone or Selbex; Eisai Co., Ltd, Tokyo, Japan) is a commercially available medication used to treat gastric ulcer, which has been used in clinic in Japan for decades. Hirakawa *et al*.[31], reported that GGA has the potential to activate HSP70 gene expression in gastric mucosal cells in response to ethanol stress or water-immersion stress. In addition, the cytoprotective effect of GGA has been reported in liver[32,33] and small intestine[34]. Mizushima *et al*.[35], reported that pretreatment with low concentrations of ethanol, as well as GGA-induced HSPs in cultured guinea pig gastric mucosal cells, can prevent DNA fragmentation[35], but further investigation is necessary to know whether ethanol is efficacious in liver pretreatment because the liver has a strong activity of alcohol dehydrogenase. Bimoclomol is a new nontoxic compound, introduced by Vígh *et al*.[36] in 1997, which facilitates the formation of chaperone molecules by inducing or amplifying expression of heat shock genes. It was reported that four- to fivefold HSP70 gene is transcribed by the simultaneous application of bimoclomol and heat. The potency of GGA to enhance HSP70 induction under heat shock stress is as high as that of bimoclomol[21]. In this sense, pharmacologic modulation of heat shock preconditioning by GGA may have a clinical priority because its nontoxicity to human subjects has been proven during the long-term clinical use.

Therefore, the other aim of this study was to explore whether there is any difference in the induction of HSP70 in liver between administration of GGA and heat shock stress, and whether there is an additive effect if GGA is used in combination with heat shock stress.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats weighing 250-300 g were obtained from Animal Center of the Fudan University, Shanghai, China. They were housed in chip-bedded cages at room temperature (24±1 ℃) in a 12-h light/dark cycle. Rats were permitted free access to water and standard rat chow. The study was approved by the Committee on Experimental Animals of Second Military Medical University.

Grouping

Forty-five rats were divided into five groups (each group n = 9). Group C: experiment for I-R injury (as a control); group G: GGA was administered 2 h before experiments for I-R injury (administering GGA without heat stress); group S: LSTS was performed 12 h before experiment for I-R injury (local heat stress alone); group WG: GGA was administrated 2 h before whole-body heat shock exposure, and experiment for I-R injury was performed 48 h after whole-body heat shock exposure (GGA plus whole-body heat stress); group SG: GGA was administered 2 h before LSTS, and experiment for I-R injury was performed 12 h after LSTS (GGA administration plus local heat stress).

Extraction of mRNA and reverse transcriptase polymerase chain reaction

Total RNA was isolated from rat liver using a modified single-step guanidinium thiocyanate method (Tri Reagent, T-9424, Sigma Chemical Co., St. Louis, MO, USA)[37]. Reverse transcription (RT) was performed using a reverse transcription kit. One microgram of rat tissue RNA was used as a template and RT-generated cDNA encoding Hsp70 and β-microglobulin (β-MG internal control) were amplified using PCR. The primers used in this study were Hsp70 (354 bp), sense: 5'-AAC-GTG-CTG-CGG-ATC-ATC-AA-3', anti-sense: 5'-CGT-GAT-GGA-CGT-GTA-GAA-GT-3', and rat-β-MG (100 bp), sense: 5'-AAT-ATC-GAG-ATG-TCA-GAT-CTG-TC-3', anti-sense: 5'-GCT-TCA-ATG-AGT-GTT-TTG-ATC-AG-3'. The possible contamination of any PCR component was excluded by performing a PCR with these components in the absence of RT products in each set of experiments (negative control). Twenty microliters of RT-PCR products was checked by 2% agarose gel electrophoresis containing 0.2 mg/mL ethidium bromide, followed by photography under ultraviolet transillumination.

Antibody and Western blot analysis for hsp70 expression

Mouse monoclonal antibody against inducible HSP70 was purchased commercially (HSP 70 K-20: sc-1060, Santa Cruz Biotechnology, Inc.). Liver tissue was snap-frozen *in situ* using stainless steel tongs precooled in liquid nitrogen. Tissue homogenates from rat liver were obtained in the presence of protease inhibitors on ice, and the homogenate protein was assayed by the Bradford method[38]. After protein concentrations were measured, samples were applied to a 10% polyacrylamide gel with 0.1% sodium dodecylsulfate.

The gel-resolved proteins were transferred to polyvinylidene difluoride membranes (Marsh Biomedical Products Inc., Rochester, NY, USA). The blots were incubated with primary antibody (monoclonal K-20: sc-1060) and anti-mouse immunoglobulin horseradish peroxidase-linked secondary antibody (NA 931; Amersham International, Buckinghamshire, UK). They then reacted with enhanced chemiluminescence detection reagent (Amersham). The bands were recorded on X-ray film (Hyper film ECL, Amersham). Intensity of the blots was then measured densitometrically using a GS-700 imaging densitometer. To standardize the blotting as well as the visualization of each film, 0.005 μg of HSP70 (SPP-755, StressGen Biotechnologies Corp.) was simultaneously electrophoresed on each gel as an external standard. Anti-β-actin (monoclonal: clone AC-74, Sigma Inc.) was used as an internal control.

Immunohistochemical staining

Tissue samples fixed overnight in Bouin's solution[39] were immersed first in 50% ethanol for 24 h and then in 70% ethanol for 24 h for their dehydration and the removal of picric acid. Specimens were then embedded in paraffin and cut into 3.5-μm-thick sections. The slightly modified avidin-biotin complex method was used for immunohistochemical staining with a monoclonal antibody (1.0 μg/mL) against the inducible form of HSP70 (monoclonal K-20: sc-1 060.12) normal rabbit serum (diluted to 1:75) as an inhibitor of nonspecific binding of the secondary antibody. Biotin-labeled rabbit anti-mouse IgG serum (diluted to 1:300) as a secondary antibody and avidin-biotin-alkaline phosphatase complex (diluted to 1:100) were purchased from Dako (Kyoto, Japan). The substrate for alkaline phosphatase (black) was obtained from Vector Laboratories (Burlingame, CA, USA).

Administration of GGA

After overnight fasting, each rat in groups G, WG and SG was given 8 mL/kg of an emulsion composed of 200 mg/kg GGA in a 5% gum arabic solution (vehicle). The dose was administered intragastrically through a metal tube. In the groups not receiving GGA (groups C and S), only the vehicle was administered in a similar fashion. GGA used in this study was a generous gift from Eisai Co., Ltd (Tokyo, Japan). We chose a dose of 200 mg/kg, in which abundant HSP70 was produced with whole-body heat shock stress at 41-42 ℃ [21].

Whole-body heat shock exposure

Rats were anesthetized with intramuscular injections of atropine sulfate (0.05 mg/kg) and ketamine (50 mg/kg) 2 h after the GGA administration. They were then immersed in a warm water bath to elevate their rectal temperature to 41-42 ℃ for 15 min. Rectal temperature was measured by a digital thermometer. The timing of 2 h between GGA administration and heat shock treatment was decided according to the reports of *in vivo* metabolism of GGA in rats by Nishizawa *et al*.[40,41]. They showed that tissue level of GGA in the liver reaches plateau 2 h after oral administration in rats. Subsequent experiments for I-R injury were performed 48 h after whole-body heat shock exposure[19].

Local heat stress by local somatothermal stimulation

Local heat stress was confined to LSTS on a designated skin area but no direct contact with the skin surface. LSTS could induce relaxation of the sphincter of Oddi in cats and rabbits and as well as internal sphincter in rabbits[42,43]. In brief, LSTS was achieved by application of a heat generator 0.5 cm on and above the right seventh intercostal nerve territory, just at the junction of right midclavicular line and the seventh intercostal space (Figure 1, under light anesthesia with atropine sulfate, 0.05 mg/kg and ketamine 50 mg/kg, im). The skin temperature at the heating point fluctuating above and below the critical point 41 ℃ was obtained by intermittently turning the switch of the heat generator on and off, namely 4 min on and 5 min off for three courses. Usually, it took 27 min to compete one dose of LSTS. Subsequent experiment for I-R injury of the liver was performed 12 h after the preconditioned LSTS[25].

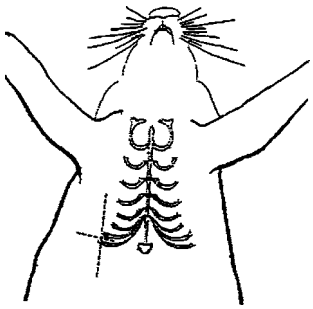

Figure 1 The heating site of LSTS.

Animal model and parameters for liver ischemia-reperfusion injury

The I-R injury rat model was established as described previously[44,45]. In brief, male Sprague-Dawley rats were anesthetized with diethyl ether (1.25 g/kg, ip), and the trachea was cannulated for artificial respiration with a ventilator. The liver was exposed through an upper midline incision, and one clamp for dog's ear was used to clamp the left branches of hepatic hilum and to allow occlusion of the blood supply to either the median or the left lobes (left branch). For I-R injury study, ischemia of left of the median lobes was maintained for 60 min, followed by reperfusion of the left/median lobes with occlusion of the right branches of hepatic hilum for another 30 min. After completion of the reperfusion procedure, the initial ischemia-reperfused left lobes were resected and tested for HSP70 by PT-PCR, Western blotting analysis and immunohistochemical staining. All rats were given 10 mL/kg of 5% glucose solution subcutaneously immediately after completion of the surgery, and all rats were allowed free access to 10% glucose solution after they recovered from the anesthesia. The blood samples were collected for ALT and AST measurement at 60 min after occlusion of the blood supply to the left branch; 30 min after reperfusion to the left branch: 24, 48, and 72 h after surgery from the vena caudalis. Signs of distress and survival were monitored for 1 wk.

Statistical analysis

The data were expressed as mean±SD. SPSS for Windows, version 11.0, was used with *t*-test, LSD, and Wilcoxon. $P<0.05$ was considered statistically significant.

RESULTS

Figure 2 shows the expression of HSP70 mDNA detected by RT-PCR and production of protein HSP70 detected by Western blotting in the five groups after I-R injury. Liver tissues in groups C and G exhibited the most pallid bands of HSP70 compared to that in the other three groups ($P<0.05$). Liver tissue in groups S and WG showed comparative bands of HSP 70 ($P>0.05$), while liver tissue in group SG showed the higher bands compared to that in groups C, G, and S ($P<0.05$). Generally, the production of HSP70 after I-R injury increased in groups C-SG.

Figure 3 shows immunohistochemical staining of HSP70 in liver tissue from groups C to SG. The accumulation of HSP70 in groups C, G, and S was significantly less than

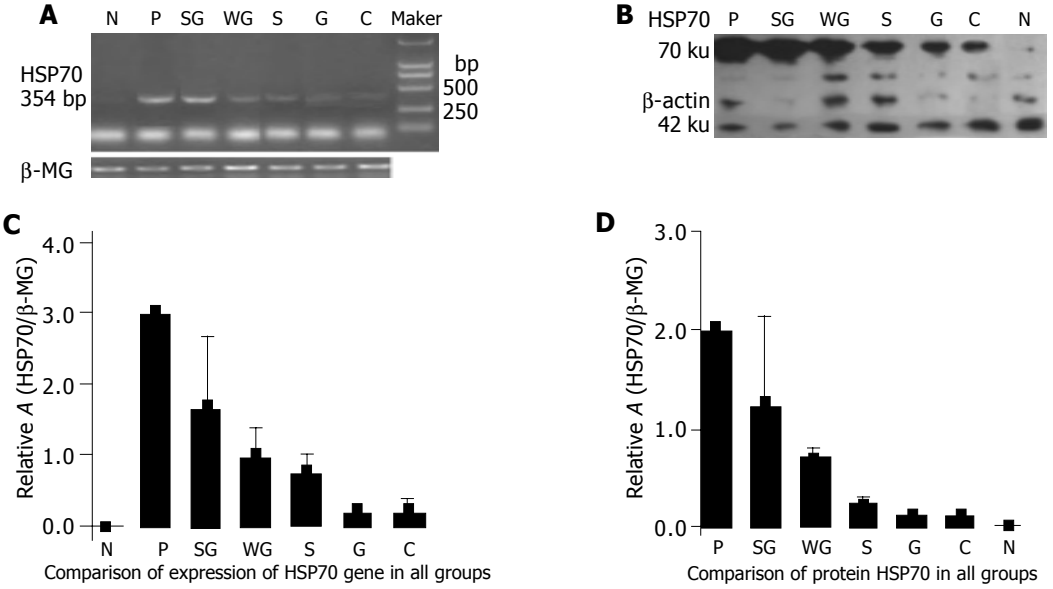

Figure 2 Detection of HSP70. **A**, **B**, The expression of HSP70 gene detected by RT-PCR is shown. **C**, **D**, The production of HSP70 protein detected by Westem blotting is shown. P, positive control. N, nagetive control. SG WG G S C N, group name. The mean difference is significant compared with group G and C at the 0.05 level. The mean difference is significant compared with group S at the 0.05 level.

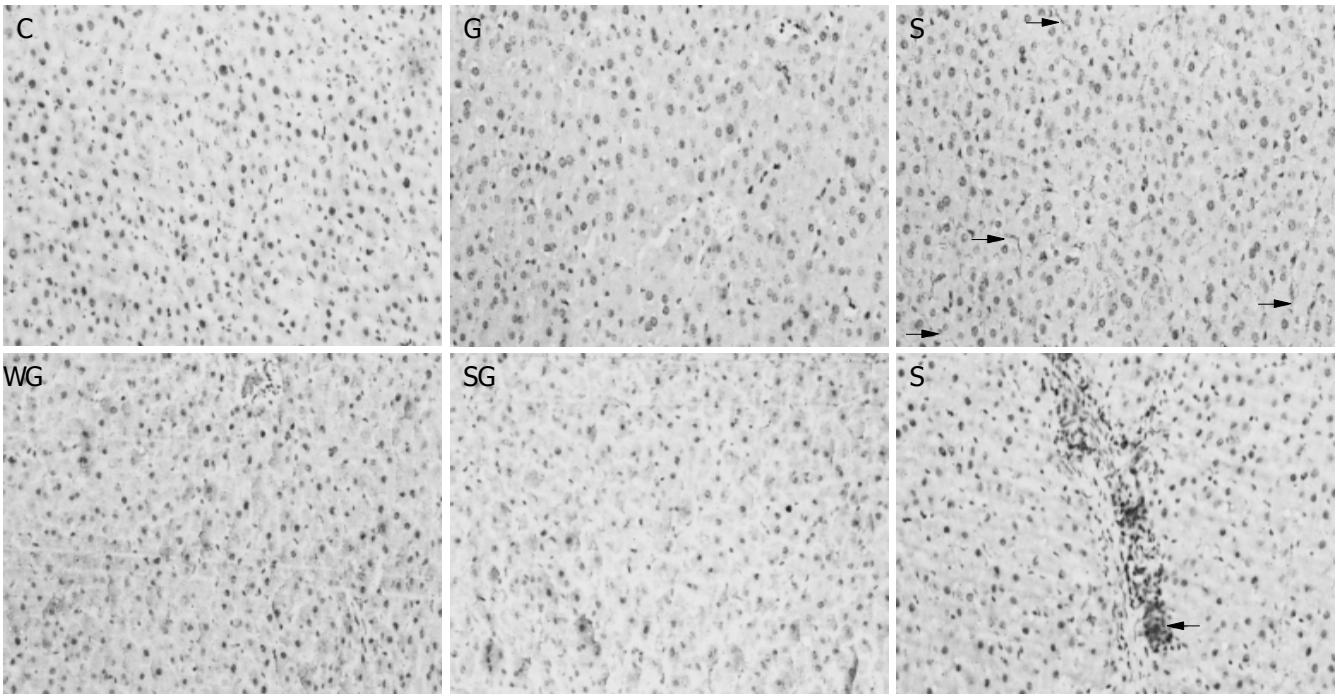

Figure 3 Immunohistochemical staining of HSP70 in liver tissue in group C,G, S,WG and SG HSP70-positive cells in group S were located in the hepatic sinusoid (→) and periportal areas (←).

[a]P<0.05 *vs* group S, WG, SG; [c]P<0.05 *vs* group WG and SG LSD.

that in groups WG and SG, whereas a great deal of parenchymal hepatocytes contained HSP70 preferentially in their nuclei and cytoplasm (Figure 3, WG and SG). These results were consistent with those of Western blot and RT-PCR analysis. HSP70-positive cells in group S were located in the hepatic sinusoid and periportal areas (Figure 3, S, arrow).

Tables 1 and 2 show the changes in serum levels of AST and ALT in the five groups. At the end of a 60-min period of clamping, all these parameters remained at low levels in the five groups, and there were no significant differences in these parameters among the groups. During reperfusion, however, these enzyme levels elevated rapidly. Thirty minutes after reperfusion, the levels of AST and ALT in five groups were significantly higher than before reperfusion. But the serum enzyme levels in groups S and G were significantly higher than those in any of the other three groups (P<0.05). The peak of serum enzyme level occurred at 48 h after surgery in groups S, WG, and SG.

Table 3 shows the survival rates at 24, 48, 72 h and 7 d after surgery in all groups. Within 72 h, all rats in groups C and G died, which may be due to the hepatic failure caused by I-R injury after surgery. While in groups SG and WG, the survival rates on d 7 after surgery were as high as 77.8% (7/9) and 44.4% (4/9) respectively, being significantly higher than that in group S (22.2%, P<0.05).

DISCUSSION

It is still controversial that whether certain stress is necessary to the induction of HSP70 after GGA administration, which is related to the application of GGA in clinic to ameliorate I-R injury. Yamagami *et al*.[21], reported that GGA itself does not directly induce HSP70, but it markedly augments the heat shock response in rat liver, leading to the suppression of I-R injury, suggesting that GGA has only a supplementary action in helping other stressors, such as heat stress, ethanol, or water-immersion stress, to activate the cascade of stress response. Oda *et al*.[46], also agree with this. On the other hand, Fudaba *et al*.[47,48], reported that HSP70 could be detected in liver before I-R, and much more after I-R, after administration of high dose of GGA (400 mg/kg per d, for 3 wk) without any form of stress. It was recently reported that administration of a high dose of GGA (200 mg/kg per day for 4 wk) enhances HSP70 induction in transplanted livers and prevented warm ischemic injury and primary graft nonfunction in recipient rats[49]. Our viewpoint is that may be high dose is effective, but it is not applicable because of the long administration schedule before liver transplantation or hepatectomy. But GGA is slowly absorbed from the gastric mucosa, and the uptake by the rat liver is only 5% of that by the gastric mucosa[40], indicating that administration of normal dose GGA without any stimuli cannot enhance HSP70 induction in rat liver and protect liver against I-R injury, which has been proved by our result in group G (200 mg/kg, once a day before surgery). Therefore, it is necessary to find an operable form of stress for clinical application of GGA. Our results showed that GGA plus whole-body heat (group WG) or LSTS (group SG) could significantly enhance HSP70 induction.

As mentioned above, the whole body must be heated in warm water or on electronic pad above 41 ℃ for a certain period of time, which makes this stress form cumbersome and impractical in some circumstances as in the case of

conscious animals or patients.

Compared to whole-body hyperthermia, LSTS has the following three merits. (1) LSTS has a simple and operable manipulation protocol (see Materials and methods) which can be accepted by patients and performed correctly by doctors or nurses before liver surgery. (2) LSTS is performed intermittently to keep the temperature above and below the critical point 41 ℃, so that the heat-sensitive neural transmission would not cause tolerance and patients would feel better. (3) LSTS is a specific stimulation site and can improve the expression of Hsp70 in designed visceral organs. For example, LSTS on left median nerve skin territories increases myocardial but not hepatic Hsp70 expression[25-27], which is the main difference from whole-body hyperthermia. These merits make LSTS be a potential stress form which can be used in clinic.

However, in order to heat the designated skin area above 41 ℃, LSTS needs certain stimulation intensity which is likely to make patients feel a bit of discomfort. This can be relieved by two methods: lowering the stimulating temperature and reducing the time or intensity of stimulation. The latter method is more likely to limit critical temperature. Yamagami *et al*.[21], reported that GGA can achieve a reduction in the duration of whole-body heat shock exposure, which makes us think about what could happen if GGA is administered before LSTS and whether GGA plus LSTS has an additive effect on the induction of HSP70. This hypothesis has been proved in this study by the facts that group SG exhibited a significant higher production of HSP70 than groups G and S (Figures 2 and 3). Liver-related enzymes in group SG presented better liver function recovery 24-72 h after surgery than those in groups G and S (Tables 1 and 2), which is coincident with the conclusion that HSP70 plays an important role lasting for up to 2-4 d in tolerance to reperfusion injury[19,50]. Survival rates 7 d after surgery in group SG was better than that in groups G and S (Table 3). These facts demonstrate that the combination of GGA plus LSTS pretreatment (group SG) has an addictive effect on the induction of HSP70 and the recovery of liver function compared to GGA (group G) or LSTS (group S) alone. Furthermore, GGA plus LSTS (group SG) is comparable to GGA plus whole-body hyperthermia (group WG), but is more simple, safe and operable as a pretreatment to induce HSP70.

In conclusion, the combination of GGA plus LSTS can be used in patients with liver tumor and cirrhosis before hepatectomy and in donor before harvesting graft for liver transplantation.

Abstract

AIM: To evaluate the effect of perioperative parenteral nutrition on serum immunoglobulin, weight change, and post-operative outcome in severely malnourished patients with Crohn's disease.

METHODS: Thirty-two severely malnourished patients with Crohn's disease who had undergone surgery in our hospital were reviewed. Sixteen patients who received perioperative parenteral nutrition were enrolled in the study group, and the other 16 patients who did not receive parenteral nutrition were enrolled in the control group. Serum immunoglobulin, body mass index (BMI), liver function, weight change, and postoperative complications were evaluated.

RESULTS: Serum IgM levels elevated 1 wk before surgery in both groups, and decreased to normal value (from 139±41 to 105±29 mg/dL, $P = 0.04$) 4 wk after operation in the study group, while no significant changes was noted in the control group (from 133±16 to 129±13 mg/dL, $P = 0.34$). There were no significant changes in concentrations of IgG and IgA. The BMI of the study group increased from 13.9±0.6 to 15.3±0.7 kg/m^2 ($P = 0.02$) with no significant change in the control group (14.1±0.7 and 14.5±0.5, respectively, $P = 0.81$). The percentage of resuming work was higher in the study group than in the control group.

CONCLUSION: Perioperative parenteral nutrition possibly ameliorates the humoral immunity, reverses malnutrition, and facilitates rehabilitation.

INTRODUCTION

Most cases of Crohn's disease are complicated by malnutrition and require surgical intervention. Surgery is needed for complications such as perforation, complete bowel obstruction, etc.[1,2].

The effectiveness of parenteral nutrition used alone or in combination with other therapeutics in Crohn's disease patients has been recently reported by clinical trial[1]. However, little is known about the effect of perioperative parenteral nutrition on severely malnourished patients with Crohn's disease.

It was reported that Crohn's disease is caused by excessive immune reactivity in the gut wall[2]. Studies have shown that in active Crohn's disease peripheral B cells are activated as indicated by an increased expression of lymphocyte-activated antigens and by the enhanced *in vitro* spontaneous immunoglobulin production[3]. Immunoglobulin change in the severely malnourished patients receiving perioperative parenteral nutrition *in vivo* is still unclear.

In the present study, the serum immunoglobulin and outcome (weight changes, postoperative complications, and rate of work resumption after 6 mo) in severely malnourished patients with Crohn's disease were evaluated after they were given perioperative parenteral nutrition.

MATERIALS AND METHODS

Patients

Thirty-two patients with Crohn's disease who had undergone surgery were enrolled in the study. All of them were severely malnourished with their body mass indexes (BMI) being less than 15.0 kg/m^2. Sixteen patients entered the study group who received perioperative parenteral nutrition. The other 16 patients who did not receive perioperative parenteral nutrition entered the control group. All had different kinds of bowel surgery for intestinal obstruction and received perioperative parenteral nutrition after 3 wk. The clinical characteristics of the two groups are shown in Table 1. The study group received bowel resection procedures and began to receive perioperative parenteral

nutrition 1 wk before the operation and continued for 2 wk from the next day after surgery. The parenteral nutrition formula was as follows: Crystal amino acid (18 s) was used to provide nitrogen: 0.2 g/kg per d; energy: 30 kcal/kg per d; fat: 40%; glucose: 60%. Patients in the study group received parenteral nutrition through a central venous catheter with the dosages increased over 48 h to a daily goal. Patients in the control group received 5-d intravenous transfusions containing energy 20 kcal/kg per d, normal water, and diet containing the same amount of energy as used in the study group. Average intraoperative blood transfusion was 400 mL in the two groups, which also did not receive steroids 2 wk before and after surgery. All the patients were monitored for complications.

Table 1 Clinical characteristics of two groups before parenteral nutrition

Group	Non-malnutrition group	Malnutrition group	*P*
Patients	16	16	
Age (yr)	28 (20–73)	30 (18–71)	0.47
Sex (M/F)	9/7	10/6	0.60
Localization			
Small bowel	5	6	0.59
Colon	5	3	0.28
Ileocolic	6	7	0.61
Medication			
Corticosteroid	No	No	
Sulfasalazine	7/16	6/16	0.61
Former body weight (%)	92.6±5.3	77.9±6.1	0.03

Serum parameters

Blood samples were drawn before breakfast in the morning and at beginning and end of the study, centrifuged and stored at -20 ℃ before assay.

Serum IgM, IgG, and IgA values were quantitated by ELISA (Sigma, USA)[4].

Liver function and bilirubin levels were also assayed (BD, USA).

Weight change

Body height and weight were recorded; BMI was then calculated at the beginning and end of the study[5].

Follow-up

All the patients were followed up for 6 mo on work resumption after they were discharged from the hospital.

Statistical analysis

The results were expressed as mean±SD. Statistical analyses were performed with the analysis of variance or Student's *t*-test or χ^2 test. $P<0.05$ was considered statistically significant.

RESULTS

Crohn's disease was confirmed in all patients by pathological examination of the surgical samples.

IgM levels elevated before surgery in both groups (control group: 133±16 mg/dL; study group: 139±41 mg/dL; normal value: 110±35 mg/dL; $P = 0.04$), and decreased to normal value (105±29 mg/dL, $P = 0.02$) 3 wk after surgery in the study group with no significant changes in the control group (129±13 mg/dL, $P = 0.34$). There were no significant changes in concentrations of IgG and IgA ($P = 0.20$-0.57, Table 2).

The BMI increased from 13.9±0.6 to 15.3±0.7 kg/m^2 ($P = 0.02$) in the study group and had no significant change in the control group (14.1±0.7 and 14.5±0.5, respectively, $P = 0.81$).

The overall complication rates of both groups were similar (control group: 7 cases, 26.5%; study group: 6 cases, 27.3%; $P = 0.86$). Serum total bilirubin level (mainly indirect bilirubin) was slightly elevated in each group near the end of parenteral nutrition. These results are shown in Table 3.

Table 3 Complications observed during perioperative parenteral nutrition

Type of complications	Non-malnutrition group	Malnutrition group
Infectious		
Pneumonia	2 (*Pneumococcus*)	1 (*Pneumococcus*)
Bacteremia	1 (*Escherichia coli*)	0
Abdominal Abscess	1 (*Enterococcus*)	1 (*E.coli*)
Noninfectious		
Anastomotic leak	1	1
Wound dehiscence	1	2
Liver cholestasis	1 (Tbil = 1.6 mg/dL)	1 (Tbil = 1.4 mg/dL)
Catheter-related	0	0
Total	7	6

DISCUSSION

It was reported that significant B-cell activity is present in Crohn's disease patients and is accompanied with an increase or decrease in immunoglobulin production related to an augmented B-cell clone size, which subsequently induces the humoral immunological action toward the bowel wall[6,7]. However, there are different opinions as to which immunoglobulin is subjected to change[6]. Our study identified the change of IgM.

IgM is the only immunoglobulin that mainly exists in

Table 2 Levels of immunoglobulin before and after parenteral nutrition (mean±SD)

Immunoglobulins	Normal value (mg/dL)	Non-malnutrition group		Malnutrition group	
		Before PN	After PN	Before PN	After PN
IgA	203±50	195±42	218±53	201±38	215±41
IgM	110±35	133±16[1]	129±13	139±41[2]	105±29[3]
IgG	1 210±300	1 160±280	1 250±210	1 305±185	1 409±213

PN, parenteral nutrition. [1]$P = 0.04$ *vs* normal value. [2]$P = 0.04$ *vs* normal value. [3]$P = 0.02$ *vs* before PN.

the circulatory system and not in the tissue. IgG, however, exists in both blood and tissue. Therefore, the change in the concentration of serum IgM instead of IgG represents the total amount of its kind.

In the present study, serum IgM levels rose before surgery in both groups and decreased in the malnourished group after perioperative parenteral nutrition (we excluded the data of the patients complicated by infection to obviate its influence on the results) demonstrates that perioperative parenteral nutrition can ameliorate the humoral immunity of the severely malnourished patients. But the role of circulating B cells and cytokines such as IL-2, TNF-γ, and IL-4 needs to be clarified.

The main effects of parenteral nutrition on humoral immunity may be due to its ability to repair the bowel wall and promote recovery of the disease by avoiding the stimulation of food[8,9], reduce the energy supply for the bacterial proliferation can reduce the antigen load[10], and improve the nutritional status. Our study showed that perioperative parenteral nutrition was efficacious in ameliorating malnutrition without increasing the rate of catheter-related complications. This is beneficial for the repair of lesions, thus attenuating the immune reaction as the anabolism increases[11].

Parenteral nutrition can lead to liver cholestasis, has decreased with reduced energy supply and adequate use of fat emulsions[12,13]. In the present study, one patient had a mild elevation of serum bilirubin (predominantly indirect bilirubin) in each group, which decreased after the patients took a small amount of parenteral nutrition.

In the present study, the 6-mo follow-up showed that the rate of resuming work was higher in the perioperative parenteral nutrition group than in the control group, suggesting that perioperative parenteral nutrition support has a long-lasting effect on recovery, possibly due to the amelioration of immunity[14].

In conclusion, perioperative parenteral nutrition possibly ameliorates the humoral immunity, reverses malnutrition, and facilitates rehabilitation.

Received: 2005-03-12 Accepted: 2005-04-11

Abstract

AIM: To investigate the expression of fragile histidine triad (FHIT) protein, and the possible relationship between FHIT expression and clinicopathological indices in gastric carcinoma.

METHODS: FHIT protein expression was examined in 76 cases of gastric carcinoma, 58 cases of intraepithelial neoplasia, and 76 cases of corresponding normal mucosae by immunohistochemical method to analyze its relationship to histological grade, clinical stage, metastatic status and prognosis.

RESULTS: The FHIT protein expression was positive in 28/76 (36.8%) cases of adenocarcinoma tissue, 22/58 (37.9%) cases of adjacent dysplastic tissue and 76/76 (100%) cases of distal normal gastric mucosa. There was a significant difference in the expression of FHIT protein between cancer or adjacent intraepithelial neoplasia and normal gastric mucosa ($P = 0.000$). FHIT protein expression was found in 64.3% (18/28) of grades I and II cancers, and 20.8% (10/48) of grade III cancers ($P = 0.000$), in 56.3% (18/32) of stages I and II cancers and 22.7% (10/44) of stages III and IV cancers ($P = 0.004$), and in 63.6% (14/22) of cancers without metastasis but only 25.9% (14/54) of those with metastasis ($P = 0.003$). The significant difference in the expression of FHIT was found between histological grade, clinical stage and metastatic status of cancer. Follow-up data showed that there was a significant difference in median survival time between cancer patients with expression of FHIT (71 mo) and those without (33 mo, log rank = 20.78, $P = 0.000$).

CONCLUSION: FHIT protein is an important tumor suppressor protein. Loss of FHIT protein expression may be associated with carcinogenesis, invasion, metastasis and prognosis of gastric adenocarcinoma.

INTRODUCTION

Fragile histidine triad (FHIT) gene, localized on chromosome 3p14.2 is an important tumor suppressor gene identified after Rb, p53, and p16 genes[1,2]. It spans not only the *t* (3:8) (p14.2; q24) translocation breakpoint found in familial renal cell carcinoma but also the most common human fragile site, FRA3B[2,3]. Alterations in the FHIT gene and/or its expression have been found in primary tumors and cell lines of lung[4,5], breast[6-8], head and neck[9], esophagus[10-12], stomach[13-15], colon and rectum[16-18], pancreas[19], kidney[20,21], cervix[22-25], and hepatocellular carcinoma[26-30]. Abnormal protein expression and allelic deletion of FHIT in lung cancer are associated with the history of smoking and prognosis[31,32]. The finding of decreased expression of FHIT in 93% of precancerous lesions of the lung suggests that this gene might be used as an intermediate biomarker for early diagnosis and/or prevention of lung cancers[32]. Gastric cancer, like lung cancer, is thought to be induced by carcinogens such as *Helicobacter pylori*, alcohol, smoking, high salt and nitrosamine, and low antioxidant vitamins and is increasing in frequency among males in many countries. Therefore, it is imperative to determine whether FHIT plays a role in this second-ranked tumor in male cancer mortality, which has been increasing in China since the 1990s. Only a few reports have evaluated the FHIT gene in primary gastric carcinoma so far[13-15,34-36]. Photomicrographs of FHIT protein expression in gastric carcinoma have been reported[34-36]. However, there is no detailed investigation of FHIT protein expression during gastric carcinogenesis in Chinese patients. Based on the study carried out in 76 gastric adenocarcinomas with 58 abutting intraepithelial neoplasia tissues and 76 distal normal gastric mucosae, the FHIT protein expression in Chinese patients is altered in a high proportion of gastric carcinomas as well as adjacent intraepithelial neoplasia and the loss of FHIT expression is significantly correlated with more advanced clinical stage, poorer differentiation, metastasis and worse prognosis of gastric cancer.

MATERIALS AND METHODS

Biopsy specimens

Paraffin-embedded sections of 76 gastric carcinomas with corresponding 58 adjacent intraepithelial neoplasia mucosae

and 76 distal normal gastric tissues were obtained from the Department of Pathology, Chinese People's Liberation Army General Hospital (Beijing, China). The age of patients ranged from 35 to 84 years, averaged 59±11.58 years. Sixty-six were men and 10 women. Among them, 22 had grade I carcinoma, 6 had grade II carcinoma and 48 had grade III carcinoma, according to their histological grading; while 20 had stage I carcinoma, 12 had stage II carcinoma, 38 had stage III and 6 had stage IV carcinoma, according to the clinical staging of TNM, respectively. Lymphatic metastasis in regional nodes was confirmed during surgery in 54 cancers.

Immunohistochemistry

All samples were fixed in 10% buffered formalin and embedded in paraffin. Four-micrometer-thick sections were cut from wax blocks, mounted onto APES-coated glass slides. Slides were deparaffinized twice in xylene for 10 min, rehydrated through graded ethanol to distilled water before incubation for 30 min with 3% hydrogen peroxidase-methanol to inhibit endogenous peroxidase activity, and heated in 0.01 mol/L citrate buffer (pH 6.0) in a microwave oven for 5 min at 100 ℃ for antigen retrieval. Then the slides were taken out of the microwave oven to be cooled at room temperature for 30 min. After being incubated for 15 min in a blocking solution containing 10% normal goat serum in PBS, sections were incubated at 4 ℃ overnight in a humidified chamber with rabbit polyclonal antibody to human FHIT (Zymed Laboratories Inc., South San Francisco, CA, USA) diluted 1:200 in blocking solution. The sections were rinsed in PBS and incubated for 30 min with biotinylated secondary antibody (Histostain-SP, Zymed). After being washed in PBS, the sections were then incubated for 30 min in streptavidin–HRP (Histostain-SP, Zymed). 3,3'-Diaminobenzidine was used as the chromogen. Slides were counterstained for 3 min with hematoxylin solution. Normal liver tissue was used as a positive control for each lesion, whereas the primary antibody was replaced by normal rabbit serum IgG at a similar dilution or PBS as a negative control.

Evaluation of score

In scoring FHIT protein expression, both the extent and intensity of immunopositivity were considered, according to Hao *et al*.[18]. The intensity of positivity was scored as follows: 0, negative; 1, weak; 2, moderate; 3, strong as the normal stomach. The extent of positivity was scored as follows: 0, <5; 1, >5-25%; 2, >25-50%; 3, >50-75%; 4, >75% of the cells in the respective lesions. The final score was determined by multiplying the intensity of positivity and the extent of positivity scores, yielding a range from 0 to 12. Scores 9-12 were defined as preserved or strong staining pattern (++), 5-8 as weak staining pattern (+), and 0-4 were markedly reduced or negative expression (-).

Statistical analysis

Fisher's exact test (two-sided), Pearson's χ^2 test for trends in proportions and Kaplan-Meier method with log rank test for survival analysis were used to assess the associations between FHIT expression and pathological indices by SPSS 10.0 for Windows (Chicago, IL, USA). $P<0.05$ was considered statistically significant.

RESULTS

FHIT expression in normal, adjacent dysplastic mucosae and adenocarcinoma

FHIT protein was predominantly strongly expressed in the cytoplasm of epithelial cells in 76/76 distal normal stomach mucosae (Figure 1A) and 22/58 (37.9%) adjacent intraepithelial neoplasia. Some stromal cells, such as fibroblasts, endoepithelial cells, and macrophages, also expressed FHIT protein, both in nuclei and cytoplasm. FHIT protein was positively expressed in 28/76 (36.8%) of gastric adenocarcinomas. The carcinomas with markedly reduced or loss of FHIT protein were 48/76 (63.2%), in which the extent and intensity of FHIT expression were markedly reduced or absent in cancer cells (Figure 1B). A significant difference was found in the expression of FHIT protein between normal gastric mucosae and adenocarcinoma or adjacent intraepithelial neoplasia ($P = 0.000$). There was no difference in FHIT expression between carcinoma and adjacent intraepithelial neoplasia ($P = 1.000$).

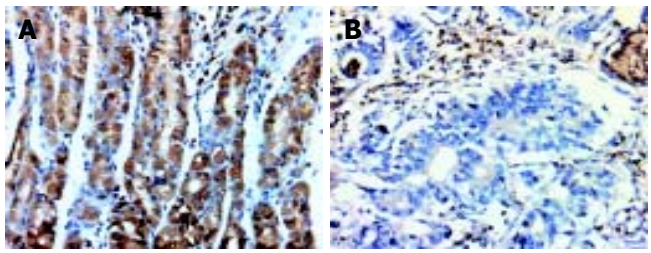

Figure 1 Positive FHIT expression in the normal gastric mucosa (**A**) and negative FHIT expression in cancer cells (**B**). (SP ×200).

Relationship between FHIT expression and histological grade, clinical stage and prognosis

The proportion of carcinomas with expression of FHIT protein showed a decreasing trend from 18 of 28 (64.3%) well- and moderately-differentiated cancers (grades I and II) to 10 of 48 (20.8%) poorly-differentiated carcinomas (grade III), and a significant inverse association was found between FHIT expression and histological grade ($P = 0.000$). A decreasing trend in FHIT expression was also observed in clinical stage, from 18 of 32 (56.3%) in stages I and II adenocarcinomas to 10 of 44 (22.7%) in stages III and IV adenocarcinomas and there was a significant difference in FHIT expression between clinical stages ($P = 0.004$) as well. FHIT expression was present in 14 of 54 (25.9%) cancers with metastasis or in 14 of 22 (63.6%) of tumors without metastasis, thus a significant difference in expression of FHIT was found between the adenocarcinomas with different biological behaviors ($P = 0.003$). Follow-up data showed that there was a significant difference in median survival time between the carcinoma patients with FHIT expression (71 mo) and those without FHIT expression (33 mo, log rank = 20.78, $P = 0.000$, Figure 2).

DISCUSSION

Although FHIT protein is expressed in most types of normal human tissues, it is frequently reduced or lost in a variety

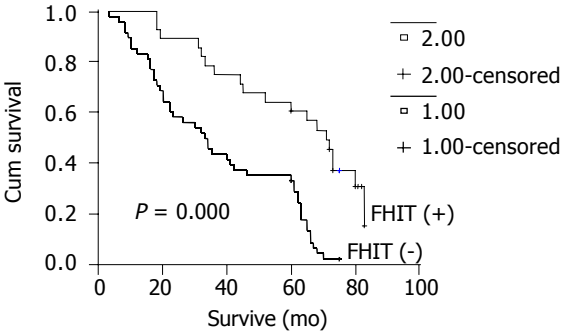

Figure 2 Difference in median survival time between carcinoma patients with and without FHIT expression (n = 76). The y-axis represents the percentage of patients, the x-axis represents their survival time. The red line represents FHIT-positive patients with a better survival, the green line represents FHIT-negative gastric carcinoma patients (log rank = 20.78; P = 0.000).

of human tumors due to alterations in its gene transcription or gene deletion[1-3]. It has thus been suggested that FHIT gene is a candidate tumor suppressor gene for multiple carcinomas. FHIT gene protein is a member of histidine triad family and the mechanism of its suppression on tumor cells remains obscure[1-3]. The following possible mechanisms have been considered as a tumor suppressor[33]. First, the tumor-suppressing function of FHIT might catabolize ApppA (Ap_3A) or related substrates. Ap_3A is an analog of ATP, which can provide phosphates as a substrate to raise the activity of protein kinase. Loss of FHIT protein may lead to the loss of Ap_3A hydrolase activity and the resulting elevated levels of Ap_3A or similar compounds may enhance the transductive signals of growth, thus contributing to carcinogenesis. Second, the activity of FHIT on mRNA cap analogs raises the possibility that failure of a decapping function might be tumorigenic, but the properties of FHIT are quite different from those of enzymes known to decap mRNA, making this an unlikely mechanism. Third, the tumor-suppressing function of FHIT might be the signaling of FHIT-substrate complexes or compounds as an active form of FHIT. Fourth, FHIT might have a nucleotide-independent role as a tumor suppressor[33]. The loss of FHIT protein corresponds to the carcinogenesis and evolution of gastric adenocarcinoma. Capuzzi *et al*.[34], found that 49% of tumors show complete loss plus 29% partial loss of expression in FHIT protein. The absence of FHIT protein is related to higher histological grade and higher tumor stage. Lee *et al*.[35], observed that FHIT expression correlates with the prognosis of gastric cancer. Rocco *et al*.[36], showed that loss of FHIT protein expression is associated with progression and poor differentiation of gastric cancer. Our results are consistent with those reported outside China[34-36], and our previous finding in Chinese colorectal cancer and hepatocellular carcinoma patients[17]. Besides adenocarcinoma, we have also investigated the adjacent intraepithelial neoplasia mucosa and found only 37.9% of which could express FHIT protein, slightly higher than that of carcinoma (36.8%). Therefore, it is also further suggested that like lung and esophageal cancers associated with environmental carcinogens, loss of FHIT protein plays an important role in gastric cancer transformation at its early stage and thus the treatment of FHIT in molecular approach can prevent the carcinogenesis of precancerous gastric lesions.

In conclusion, FHIT protein, like Rb, p53 and p16, may be a universal tumor-suppressor protein, and plays an important role in the carcinogenesis, progress and prognosis of Chinese gastric carcinoma patients. The FHIT expression status detected by immunohistochemistry may be used as a simple and useful molecular marker for the prognosis of gastric adenocarcinoma patients.

Abstract

Placement of self-expandable metal stents (SEMS) is an effective mode of palliative treatment for patients with malignant gastrointestinal obstruction. Gastrointestinal mucosal bleeding complicates about 5% of placement of SEMS but is not well described. We report three cases of gastrointestinal bleeding post-SEMS placement and suggest that bleeding is caused by direct mucosal infringement by the sharp edges of the ends of the stents.

INTRODUCTION

Placement of self-expandable metal stents (SEMS) has emerged as an effective mode of palliative treatment for patients with malignant gastrointestinal obstruction[1,2]. This is particularly true in patients with locally advanced disease or patients with multiple co-morbidities, where open or laparoscopic surgical by-pass is associated with high post-operative mortality and morbidity[3,4]. Although placement of SEMS is successful in almost 100% of cases, complications of SEMS do occur and include re-obstruction (10%), stent migration (10%), pain (5%), perforation (4%), and rarely, death (1%)[5,6]. Bleeding has been reported to occur in 5% of patients following placement of SEMS. The mechanisms to explain such bleeding have not been well described. In this report, we describe three cases of bleeding post-SEMS placement and suggest that stent-induced ulcers were caused by infringement of the raw ends of the stents onto the mucosa that may be the cause of such bleeding.

CASE REPORT

The first patient was a 93-year-old female with a past history of diabetes mellitus, hypertension, cerebrovascular accident, who presented with subacute intestinal obstruction. Sigmoidoscopy showed a large tumor at the recto-sigmoid junction, causing almost complete obstruction of the intestinal lumen. The CF240 endoscope (Olympus Pte Ltd, Singapore) could not be passed to cross the structure (Figure 1). In view of her poor pre-morbid status, the family and the attending gastroenterologist opted for palliative stenting. Stenting was done with 85 mm×25 mm Ultraflex® stent (Boston Scientific Pte Ltd, Singapore), which was successful and uneventful. The patient was able to pass motion after the stenting and was discharged one day after the procedure. Unfortunately, she was readmitted 8 wk later for fresh per rectal bleeding. A repeat sigmoidoscopy showed a patent stent with a circumferential mucosal ulcer being impinged upon by the proximal sharp edges of the stent (Figure 2). The bleeding stopped spontaneously and no specific treatment was required. The patient was well till 4 wk post-discharge.

The second patient was a 51-year-old man who presented with gastric outlet obstruction one year after cholecystectomy with hepaticojejunostomy for gallbladder carcinoma. CT scan of the abdomen showed local recurrence at the head of pancreas with liver metastasis. Gastroscopy showed pyloric stenosis due to extrinsic compression, which was not passable by the XQ240 endoscope (Olympus Pte Ltd, Singapore). In view of the metastatic disease and previous laparotomy, the family and the attending gastroenterologist decided on placement of SEMS for palliation of the gastric outlet obstruction. A 60 mm×22 mm uncovered Enteral Wallstent® (Boston Scientific Pte Ltd, Singapore) was subsequently placed successfully. The patient was able to tolerate oral diet and remained well until 4 wk later, when he was noted to have a drop in hemoglobin to 3.9 g/dL from a baseline level of 9 g/dL. A repeat gastroscopy showed a patent stent with circumferential ulcers on the mucosa of the first part of duodenum being impinged upon by the distal end of the stent (Figure 3). Hemostasis was secured by application of argon plasma coagulation (Erbe, JDH Medical System, Singapore). He recovered well with stable hemoglobin and absence of rebleeding up to 4 wk post discharge.

The third patient was an 80-year-old man with adenocar-

cinoma at the gastroesophageal junction, presenting with dysphagia. Despite seven previous dilatations using savary dilators, his dysphagia persisted. A 16 cm×24 mm Flamingo stent (Boston Scientific Pte Ltd, Singapore) was subsequently inserted uneventfully with relief of his dysphagia. He was readmitted 16 wk later for melena and anemia, requiring blood transfusion. A repeat gastroscopy showed oozing from the esophageal mucosa at the proximal end of the stent (Figure 4). No endoscopic therapy was applied as no focal site of active bleeding was noted at that time. The patient was given oral sulcralfate and tranexamic acid. He succumbed to his metastatic disease 8 wk later although his rebleeding did not occur.

Figure 1 A large tumor at the recto-sigmoid junction was seen almost obstructing the entire lumen.

Figure 2 A circumferential ulcer in the rectum was seen being impinged upon by the sharp edges of the Wallstent.

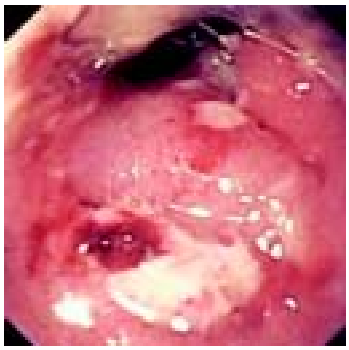

Figure 3 A circumferential ulcer with an adherent clot in the first part of duodenum was seen being impinged upon by the sharp edges of the Wallstent.

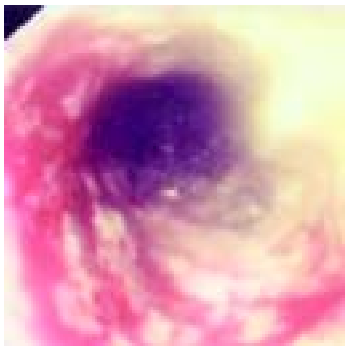

Figure 4 Circumferential ulcer with mild oozing was noted at the proximal end of the stent in the esophagus.

DISCUSSION

Gastrointestinal cancers are among the commonest cancers in most developed countries. Unfortunately, less than half of the patients are candidates for curative surgery, and maintaining patency of the gastrointestinal tract becomes one of the most important aspects of palliative management[7,8]. Among the different modes of palliation, SEMS placement offers the advantage of a high success rate and a low procedure-related complication rate[9]. However, 10-20% of complications, including stent migration, reobstruction by tumor ingrowth, and perforation, have been reported[10]. Bleeding post-stent placement is considered rare at <5%, and has not been studied well.

In this study, we encountered three cases of delayed bleeding post-stent placement, which occurred 4-16 wk after placement. The bleeding originated from ulcers that arose as a result of impingement by the sharp flaring edges of the stents. No active bleeding was noted from the tumor itself. Bleeding stopped spontaneously in one case, and was arrested by argon plasma coagulation application in one and sulcrafate plus tranexamic acid in another. The bleeding appeared to be self-limiting, as no rebleeding was seen after 4-8 wk of follow-up.

Mucosal response to stents is not well understood. Previous animal studies suggest that stents could cause inflammation and collagenous reaction at the underlying mucosa[11]. Another human autopsy study suggests that stents could cause pressure necrosis in the underlying tumor, followed by chronic inflammatory response in the tumor, and epithelialization of the stent lumen[12]. However, these studies did not evaluate the cause of bleeding post-tent insertion.

We believe that direct impingement of gastrointestinal mucosa by the sharp edges of the metallic stent may be an important cause of ulcer formation and bleeding post-stent placement. Manufacturers of SEMS should be aware of this potential technical complication and consider making stents with blunt and softer edges, which may help in avoiding such a complication.

Hirschsprung's disease (HD) is a disorder associated with congenital malformation of the enteric nervous system with segmental aganglionosis. Prevailing therapy includes a resection of the affected part of the bowel. However, patients often do not obtain complete functional improvement after surgical treatment. We present the case of a 25-year-old woman who had surgical treatment of HD in early childhood. After that procedure she had clinical features of constipation for years in the end, passing of stool once a week, requiring laxatives and enemas. We diagnosed an incomplete resection of the aganglionic bowel via rectal biopsy and resected the remaining aganglionic segment. Two months after surgery the patient's bowel function improved to a frequency of 1-4 stools per day. We conclude that regular follow-up is required to identify HD patients with persistent alterations of bowel function after surgery. In patients presenting with constipation, recognition of a remaining aganglionic segment or other alterations of the enteric nervous system should be aimed at in an early stage.

Hirschsprung's disease (HD) is a birth defect affecting the bowel with segmental aganglionosis of the distal part of the gut due to disturbances in the development and migration of neural crest-derived cells which comprise the enteric nervous system. This dysfunction leads to constipation and, in the worst case, to *megacolon congenitum*. HD occurs in one of 5 000 live births and has a male predominance of about 4:1[1, 13]. Most patients are diagnosed in early childhood and treated by resection of the involved part of the colon. However, patients often do not obtain complete functional recovery after surgical treatment[2]. Studies on the therapeutic outcome in HD have so far mainly focused on the efficacy of different surgical techniques[3-6]. We present a case underscoring the necessity of appropriate diagnostic and therapeutic procedures in patients with HD where alterations of bowel function persist even after surgery.

A twenty-five year old woman, who suffered from constipation for years, was referred to our out patient clinic by her family physician. Symptoms worsened after an episode of diarrhea eight months ago. Currently she passed stool only once a week with the help of enemas.

A colon contrast-medium enema showed a dilated colon proximal to a stricture of the rectum, located at about 8 cm proximal of the anus forming a megacolon (Figure 1). The dilated section of the colon reached mid-transverse colon, proximally followed by colon of normal filling pattern.

Three months after birth the patient underwent abdominal surgery because of clinical features of acute constipation suggesting HD. A two-step procedure was performed with colostomy and sigmoideostomy three months after birth. Four months later a definitive surgical solution was intended by resection of the aganglionic bowel and reanastomosis of the proximal normal bowel to the normal anal canal after Rehbein[7]. Resection of 16 cm gut was performed, including a constricted distal part and a dilated proximal segment with a coprolith in it. The complete

excision of aganglionic bowel was confirmed by a pathologist.

At the age of nine years, a complete obstruction of the small intestine occurred, and therefore resection of 9 cm of jejunum and removal of adhesions were required. During surgery a dilated hypertrophic descending colon was observed. After this surgical procedure, colonoscopy was performed with removal of tissue samples from the site of anastomosis of colon and anal canal. The colonoscopist reported no dilatation of the bowel, differing from the surgeon's report. In contrast, the pathologist diagnosed aganglionosis in gut biopsies from aboral of the anastomosis. There was no enhanced activity of acetylcholinesterase in the segment proximal to the anastomosis. However, the patient was discharged with no definitive treatment for her constipation.

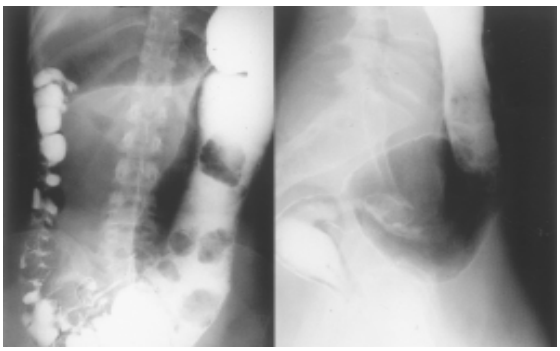

Figure 1 Contrast medium enema of the distal bowel shows a distal stenosis and a megacolon proximal to the stenosis.

At initial presentation in our out-patient clinic, physical examination of the 25-year old patient with moderate adipose revealed surgical scars at the left lower abdomen and a longish palpable mass in the left abdomen reaching from left lower up to the left upper quadrant. Initial laboratory tests were normal with exception of hypercholesterinaemia. Anorectal manometry displayed absence of the anorectal inhibitory reflex at inflation of the balloon in the distal rectum (Figure 2).

Rectal biopsies were taken and showed increased activity of acetylcholinesterase (Figure 3) in mucosal and submucosal layers and no ganglia of the plexus submucosus. Re-examination of slides of the specimen from the initial surgery 24 years ago revealed aganglionosis of both distal and proximal transection margins of the resected segment and extremely thickened nerve fibers replacing plexus myentericus.

We therefore concluded that at the abdominal surgery 24 years ago, removal of the entire aganglionic bowel was missed and an overseen aganglionic segment remained *in situ*. To remove the megacolon (Figure 4) and establish

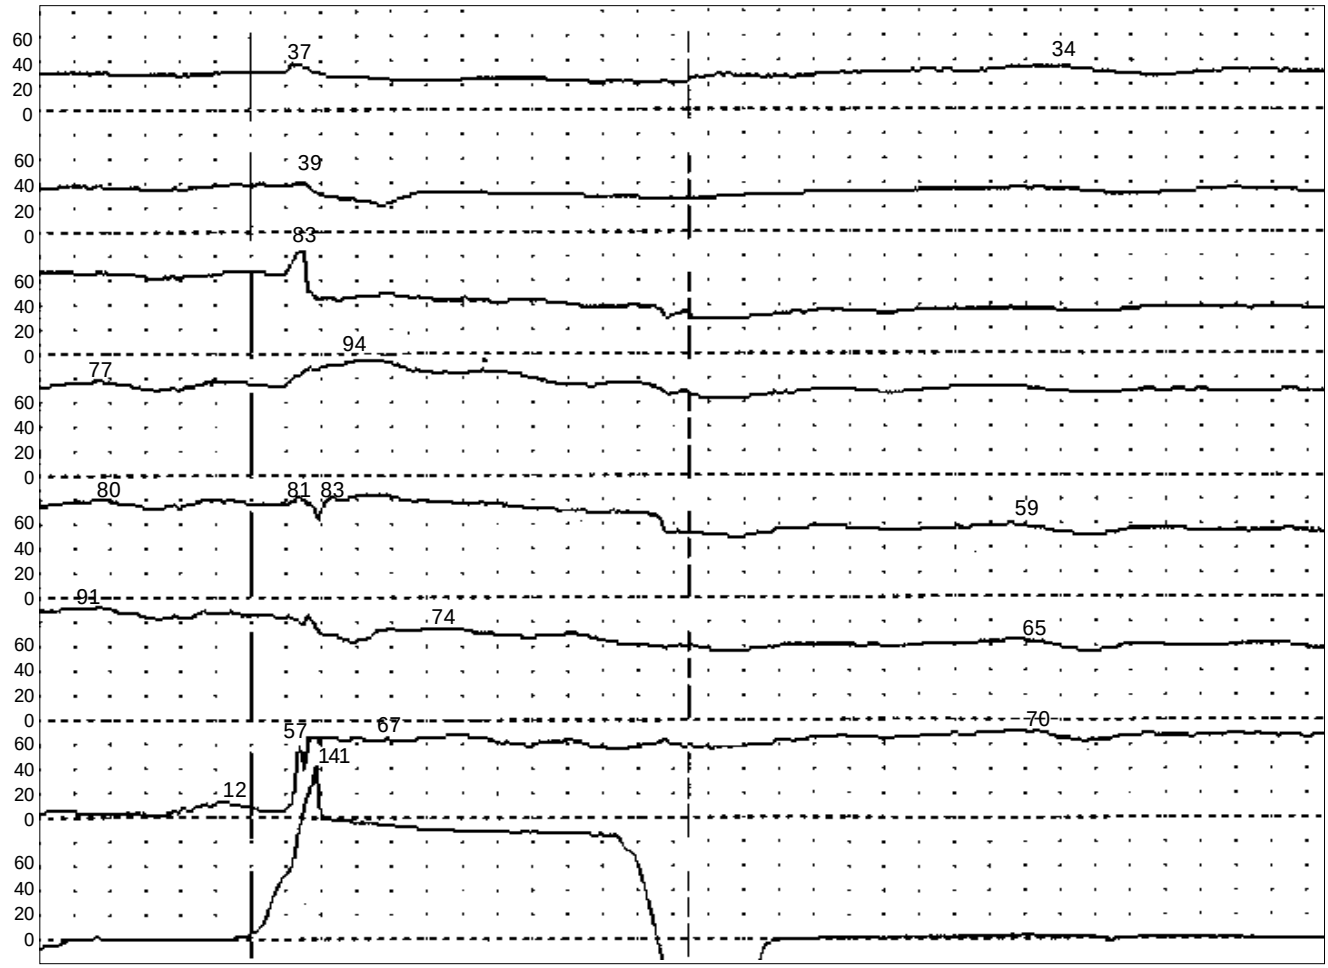

Figure 2 Anorectal manometry shows absence of the recto-anal inhibitory reflex after inflation of an intrarectally placed balloon with 40 mL of air.

normal transit of stool through the bowel, we referred the patient to the surgical department where resection of the aganglionic segment with end-to-end anastomosis was performed. Complete resection of the aganglionic segment was confirmed via instantaneous sections during surgery (Figure 5).

A 51 cm long segment of the distal colon was resected up to that point in the more proximal colon where the instantaneous sections showed a physiological account of ganglia.

After surgery, microscopic examination of the mucosal, submucosal and muscular layers showed presence of a hypoganglionic segment in the distal part of the resected segment (Figure 6A) and presumptive secondary aganglionosis in the mid-part of the specimen. At the proximal transection margin, a number of normal-sized ganglia were present (Figure 6B).

The patient had a rapid recovery from surgery and was discharged after a few days. Upon re-examination two months after the surgery, the patient reported an excellent functional improvement. She passed stool regularly 1-4 times a day without the use of laxatives.

Newborns who fail to pass meconium within the first 48 h should be suspected of having Hirschsprung's disease (HD) as one of the possible differential diagnoses[1]. However, if HD is not recognized at an early stage, it can present later in one or more of the following ways: delayed passage of meconium, complete intestinal obstruction (sometimes associated with a *megacolon congenitum*), and enterocolitis.

If diagnosis is confirmed by contrast enema, anorectal manometry and, as gold standard, a rectal biopsy with increased activity of acetylcholinesterase and absence of the plexus submucosus, sufficient resection has to be done, as the only successful treatment for HD is the resection of the aganglionic part of the bowel, including a dilated segment proximal to it. For definitive surgical treatment, several procedures have been developed[6-10].

In studies to elicit the long-term follow-up situation in patients who underwent surgical treatment of HD as infants[2-5], depending on the performed procedure, about 50% of patients report occasional complaints such as fecal soiling (43.5%), abdominal pain (34.8%), constipation (14.4%).

Constipation is a frequent finding among patients who underwent surgical treatment for HD (10.4%[3] to 14.4%[2]). Except for common reasons for constipation in adults, one has to consider additional differential diagnoses in patients who have had a surgical procedure because of HD in early childhood. Firstly, an incomplete resection of the aganglionic segment proximal to the anastomosis has to be ruled out. Secondly, a "transition zone", i.e. a congenital hypoganglionosis or hyperganglionosis adjacent to the aganglionic segment[11] that causes constipative symptoms due to malfunction of the enteric nervous systems of this segment of the bowel has also to be ruled out. Thirdly, an intestinal neuronal dysplasia type B (INDB) has to be considered. This disease

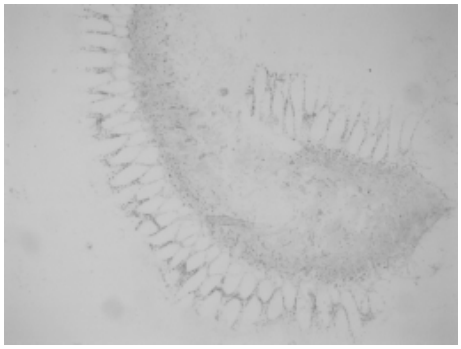

Figure 3 Rectal biopsy (AChE-staining) shows increased activity of acetylcholinesterase in the mucosal layer of the dilated segment.

Figure 4 Megacolon *in situ*.

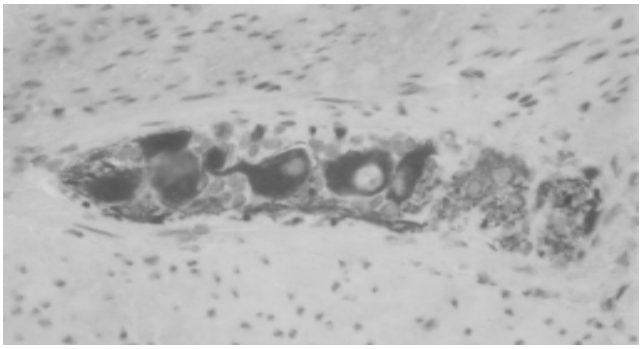

Figure 5 Instantaneous section (Peripherin-immmunohistochemistry) shows normal formation of plexus myentericus.

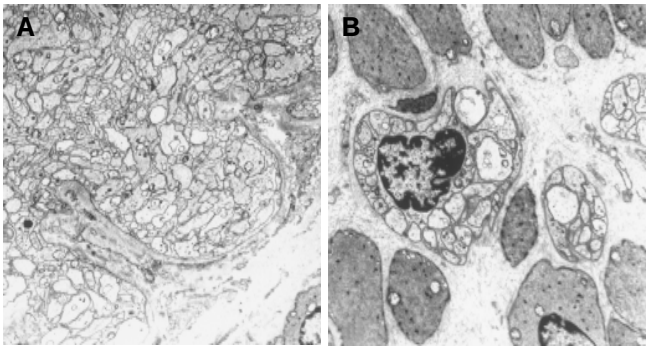

Figure 6 Electron microscopic sections show thickened parasympathetic nerve fibers in the distal part of the resected segment (A) and normal numbers of ganglia in the proximal part (B).

shows slowed intestinal transit time and an intractable constipation. Though aganglionosis is never present in INDB, there may be an increase of extrinsic nerve fibers in the affected gut as in HD[12,13] which could be mistaken for HD by rectal biopsy. Furthermore, HD often includes a region of INDB-like characteristic proximal to the aganglionic segment[11].

Another possibility is the secondary involution of the enteric nervous system and fibrosis of the bowel wall due to recurrent infections, causing features of constipation.

Depending on the diagnosis and if normal bowel function is not sustainable by conservative therapy, surgical treatment should be considered, as it was in our patient. Especially in young patients a long-lasting dependency on strong laxatives and enemas means a significant reduction in quality of life.

In Hirschsprung's disease, regular follow-up examinations are required to identify patients with persisting alterations of bowel function after surgery. In HD patients with consatipation or other symptoms of impaired bowel movement after surgery, remaining of an aganglionic segment should be considered in differential diagnosis. Identification of this and other alterations of the enteric nervous system mentioned above should already be aimed at in an early stage, in order to prevent secondary harms, such as development of a megacolon, as it happened in our patient.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG,* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published jointly by
The WJG Press and Elsevier Inc.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the Editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Elsevier Inc., and may not be reproduced by any means, in whole or in part without the written permission of both the Authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com for assistance. If you submit manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4(297×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

World Journal of Gastroenterology
Apartment 1066 Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors originating from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be involved. Titles should be concise and informative (removing all unnecessary words), emphasize what is NEW, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initials and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or Figures and Tables, not both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should add into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) and not RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by Freehand and Illustrator, or TIFF from Photoshop. EPS files must be accompanied by a version in native file format for editing purposes. Scans of existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size at which they will appear when printed, not smaller. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...;C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be involved under the tables. This part should add into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data which is not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used; Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^1F, ^2F, ^3F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

References

Cited references should mainly be drawn from journals covered in the Science Citation Index (http://www.isinet.com) and/or Index Medicus (http://www.ncbi.nlm.nih.gov/PubMed) databases. Mention all references in the text, tables and figure legends, and set off by consecutive, superscripted Arabic numerals. References should be numbered consecutively in the order in which they appear in the text. Abbreviate journal title names according to the Index Medicus style (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=journals). Unpublished observations and personal communications are not listed as references. The style and punctuation of the references conform to ISO standard and the Vancouver style (5th edition); see examples below. Reference lists not conforming to this style could lead to delayed or even rejected publication status. Examples:

Standard jounal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

PMID requirement

From the full reference list, please submit a separate list of those references embodied in PubMed, keeping the same order as in the full reference list, with the following information only: (1) abbreviated journal name and citation (e.g. *World J Gastroenterol* 2003;9(11): 2400-2403; (2) article title (e.g. Epidemiology of gastroenterologic cancer in Henan Province, China; (3) full author list (e.g. Lu JB, Sun XB, Dai DX, Zhu SK, Chang QL, Liu SZ, Duan WJ; (4) PMID (e.g. 14606064). Provide the full abstracts of these references, as quoted from PubMed on a 3.5 inch disk or CD-ROM in Microsoft Word format and send by post to The *WJG* Press. For those references taken from journals not indexed by *Index Medicus*, a printed copy of the first page of the full reference should be submitted. Attach these references to the end of the manuscript in their order of appearance in the text.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean±SD and mean±SE.

Statistical expression

Express *t* test as *t*(in italics), *F* test as *F*(in italics), chi square test as χ^2 (in Greek), related coefficient as *r*(in italics), degree of freedom as γ(in Greek), sample number as *n*(in italics), and probability as *P*(in italics).

Units

Use SI units. For example: body mass, m(B) = 78 kg; blood pressure, p (B)=16.2/12.3 kPa; incubation time, t(incubation)=96 h, blood glucose concentration, c(glucose) 6.4±2.1 mmol/L; blood CEA mass concentration, p(CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23,243,641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italicization

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *Helicobacter pylori, H pylori, E coli, etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the WJG Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of WJG to acquire copyright in all contributions. Papers accepted for publication become the copyright of WJG and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

Abstract

AIM: To establish whether there are fundamental differences in the biochemistries of adenocarcinomas of the gastroesophageal junction (GEJ) and the squamous cell carcinomas of the lower third of the esophagus (LTE).

METHODS: Between February 1, 1997 and February 1, 2000, we obtained tissue samples at the moment of resection from 54 patients for biochemical analysis. The full set of data could be comprehensively analyzed in 47 of 54 patients' samples (81%). Of these, 29 were adenocarcinomas of the GEJ Siewert type I (n = 8), type II (n = 12), type III (n = 9), and 18 presented as squamous cell carcinomas of the LTE. We evaluated the mean values of 11-lysosomal enzyme and 1-cytosol protease activities of the tumorous and surrounding mucosae as well as their relative activities, measured as the ratio of activity in tumor and normal tissues from the same patient. These data were further analyzed to establish the correlation with tumor localization, TNM stage (lymph-node involvement), histological type (papillary, signet-ring cell, tubular), state of differentiation (good, moderate, poor), and survival ($\leqslant$24 or $\geqslant$24 mo).

RESULTS: In adenocarcinomas, the activity of α-mannosidase (AMAN), cathepsin B (CB) and dipeptidyl-peptidase I (DPP I) increased significantly as compared to the normal gastric mucosa. In squamous cell carcinomas of the esophagus, we also found a significant difference in the activity of cathepsin L and tripeptidyl-peptidase I in addition to these three. There was a statistical correlation of AMAN, CB, and DPP I activity between the level of differentiation of adenocarcinomas of the GEJ and lymph node involvement, because tumors with no lymph node metastases histologically confirmed as well-differentiated, showed a significantly lower activity. The differences in CB and DPP I activity correlated well with the differences in survival rates, since the CB and DPP I values of those who died within 24 mo following surgical intervention were significantly higher than of those who survived for 2 years or more.

CONCLUSION: Adenocarcinomas of the GEJ form a homogenous group from a tumor-biochemical aspect, and differ from the biochemical characteristics of squamous cell carcinomas of the LTE on many points. When adenocarcinomas of the GEJs are examined at the preoperative phase, the ratio of the performed AMAN, CB, and DPP I enzymatic activity of the tissue sample from the tumor and adjacent intact mucosa within 2 cm of the tumor may have a prognostic value even in the preoperative examination period, and may indicate that ranking of these patients into the neo-adjuvant treatment group should be considered.

Key words: Prognostic value; Lysosomal enzymes; Cardiac adenocarcinomas; Siewert classification; Esophageal squamous cell carcinoma

Altorjay A, Paal B, Sohar N, Kiss J, Szanto I, Sohar I. Significance and prognostic value of lysosomal enzyme activities measured in surgically operated adenocarcinomas of the gastroesophageal junction and squamous cell carcinomas of the lower third of esophagus. *World J Gastroenterol* 2005; 11(37): 5751-5756
http://www.wjgnet.com/1007-9327/11/5751.asp

INTRODUCTION

While the majority of carcinomas located in the upper and middle third of the esophagus are squamous cell carcinomas, the incidence of adenocarcinomas in the lower third of the esophagus (LTE) is increasing in the Western world. Although their etiology is not clear, esophageal adenocarcinomas almost always arise in areas of Barrett's metaplasia, usually in the specialized intestinal-type mucosa in the lower esophagus, and predominantly affect elderly white men, often those with a history of heavy smoking. Barrett's metaplasia

is an accepted complication of gastroesophageal reflux disease, but gastric cancer is not linked to reflux disease. Thus, it is of interest to note that the incidence of proximal gastric adenocarcinomas is increasing. At Temple University Hospital, the percentage of cardiac carcinomas within gastric carcinomas has increased from 16% to 25% between 1976-80 and 1991-95[1]. Antonioli and Goldman[2] reported that the incidence of cardiac carcinomas has increased from 0% to 27% of all gastric carcinomas in Boston. They also showed that the number of signet-ring cell carcinomas is increased with a decrease in the male to female ratio, and an increase in the age of patients.

The classification system described by Siewert[3], which organizes adenocarcinomas of the gastroesophageal junction (GEJ) into tumors of the distal esophagus as type I (Si I), true carcinomas of the cardia as type II (Si II) and subcardial carcinomas as type III (Si III), has allowed for a comparative assessment of the data of the various sites and has facilitated the choice of surgical therapy. This classification brings light into the "Black Box" of GEJ carcinomas. The classification itself can easily be performed by summarizing all available information from contrast radiography, endoscopy, and intraoperative findings.

Following surgical resection, there is a clear survival advantage for patients with early-stage tumors over patients with late-stage tumors, regardless of tumor location. There is, therefore, no difference in the survival rates between any of the three locations[4]. Although much effort has been made to obtain a more accurate understanding and to apply more effective therapy for carcinomas in the lower esophagus and proximal stomach, patient survival rates are still not satisfactory.

A number of molecular markers have been analyzed as possible prognostic factors in patients with esophageal cancer including expression of proliferating cell nuclear antigen, epidermoid growth factor receptor, cyclin Dl, p53, and p21. However, none of these markers are of clinical value[5-7]. Merely aberrant expression of pRB and high serum immunosuppressive acidic protein concentration seems to be useful as a prognostic factor for esophageal squamous cell carcinoma[8,9].

As the etiology of tumors may well be different, it is important to establish whether there are fundamental differences in the biochemistries of adenocarcinomas of the GEJ and the squamous cell carcinomas of the LTE. In order to answer this question, it seems evident that proteolytic enzyme activities in the tumor tissue and the histologically intact mucosa bordering, it should be measured and compared, since peptidases are primarily responsible for intracellular catabolism and turnover. The increased level of lysosomal enzymes in tumors, together with their ability to degrade extracellular matrix proteins, has led to the hypothesis that they could be involved in the process of invasion and metastasis[10-12].

MATERIALS AND METHODS

Between February 1, 1997 and February 1, 2000, we obtained tissue samples at the moment of resection from 54 patients for biochemical analysis. The average age was 57.8 years and the M/F ratio was 35/19 (65%/35%). The full set of data could be comprehensively analyzed in 47 of 54 patients' samples (81%). Of these, 29 were adenocarcinomas of the GEJ Siewert type I (n = 8), type II (n = 12), type III (n = 9), and 18 presented as squamous cell carcinomas of the LTE. Tissue samples obtained during surgery were further separated into two groups: cancer tissue and normal tissue closely surrounding the cancer tissue, within 2 cm of the tumor border. The latter was checked histologically to confirm it to be tumor-free. For enzyme assays the mucosal layer was used. Reasons for exclusion included histologically confirmed synchronous multiple carcinoma (n = 3), death within early postoperative period (n = 2) and intolerance of study protocol (n = 2).

All patients in the study were so-called advanced cancer cases. Thus, the TNM stage and number of esophageal tumors were IIA:6, IIB:6, and III:6, while the tumors of the GEJ were II:10, IIIA:11, and IIIB:8.

The central-European reality is that almost 90% of malignant carcinomas in this area of the gastrointestinal tract are discovered at an advanced stage, and this fact is well reflected in this group of patients.

We evaluated the mean values of 11-lysosomal enzyme and 1-cytosol protease (as control) specific activities of the tumorous and surrounding mucosae as well as their relative activities, measured as the ratio of activity in tumor and normal tissues from the same patient. These data were further analyzed to establish the correlation with tumor localization, TNM stage (lymph-node involvement), histological type (papillary, signet-ring cell, tubular), state of differentiation (good, moderate, poor), and survival ($\leqslant$24 or $\geqslant$24 mo). The term of relative activity was used for the mean ratio of enzyme activity values for tumorous and intact mucosae in individual patients expressed as a decimal fraction.

Tissue samples from the tumor and intact surrounding area were frozen on dry ice immediately after dissection and stored at -70 ℃ prior to use.

Samples were thawed on ice, placed in 50 volumes (w/v) of 0.15 mol/L NaCl, 0.1% Triton X-100 and homogenized with a Brinkmann Polytron homogenizer. A soluble supernatant was prepared by centrifugation at 12 000 g for 25 min at 4 ℃.

Glycosidase activities were measured using 4-methylumbelliferyl (4-MU) substrates as previously described[13]. Protease assays using 7-amino-4-methylcoumarine (AMC) substrates were conducted as described by Sleat *et al*.[14], and Sohar *et al*.[15]. Reactions were initiated by adding 40 μL of substrate (various concentrations 20 μmol/L-1 mmol/L)-buffer (100 mmol/L) solution to 5 μL (cathepsin B) or 10 μL (other enzymes) of sample (supernatants diluted two-, four-, and eightfold in homogenization buffer in duplicate), incubated at 37 ℃, and terminated by the addition of 100 μL of 0.5 mol/L glycine, pH 10.5 (4-MU substrates) or 0.1 mol/L monochloroacetic acid in 0.1 mol/L acetate, pH 4.3 (AMC substrates). Buffers consisted of 0.1 mol/L citric acid or 0.1 mol/L sodium acetate adjusted to the indicated pH using sodium hydroxide, acetic acid, or HCl respectively, contained 0.1% Triton-X-100 with 0.15 mol/L NaCl. Substrates were purchased from Sigma and prepared as stocks in dimethyl sulfoxide (remaining substrates) that

were added to the reaction buffer immediately prior to assay. Samples added to substrate solutions after the addition of the termination buffer were used as blanks. Fluorescent reaction products were determined using a CytoFluor II fluorescence multiwell plate reader (PerSeptive Biosystems, Framingham, MA, USA) with excitation at 360 nm and emission at 460 nm.

Since our variables were normally distributed, Microsoft Excel *t*-test with two samples, correlated *t*-test and single factor analysis of variance were used for the statistical analysis. Permission for the investigations was sought and obtained from the appropriate local ethical committee.

RESULTS

The analysis of 11-lysosomal enzyme and 1-cytosol protease-thimet oligopeptidase (THP)-activity levels in adenocarcinomas of the GEJ and squamous cell carcinomas of the LTE showed that α-mannosidase (AMAN), cathepsin B (CB) and dipeptidyl-peptidase I (DPP I) had a significant increase in adenocarcinoma (Table 1). AMAN, CB, DPP I, cathepsin L (CL) and tripeptidyl-peptidase I (TPP I) showed a significant increase in squamous cell carcinoma as compared to the levels of activity measured in the bordering intact mucosa (Table 2).

When relative activity values were compared (Table 3) for α-glucosidase (AGLU), CB, CL, and DPP I enzymes, the activity level was twofold higher in squamous carcinomas than in adenocarcinomas.

The values of peptidase activity in cardiac tumors with Si I, II, and III localization did not differ significantly (Table 4). There was no significant correlation between lysosomal enzyme activities and adenocarcinomas of different histological types (papillary, signet-ring cell, tubular). There was no significant difference between carcinomas of stages II, IIIA, and IIIB. However, we found a significant and relatively strong relationship between the level of differentiation of adenocarcinomas of the GEJ and the level of activity of AMAN (H: 0.78), CB (H: 0.76), and DPP I (H: 0.67) lysosomal enzymes. The lysosomal enzyme activities in well-differentiated adenocarcinomas were significantly lower than those in poorly differentiated ones. The changes of the activity of certain enzymes correlated well with lymph node involvement. Tumors with no lymph-node metastases showed a significantly lower value of activity. A moderate relation was detected between the relative activities and the presence of lymph-node metastases (H: 0.61). The change in CB and DPP I activity sensitively reflected the differences in survival rates too.

Tables 2 and 3 show that the lysosomal enzyme activity increased significantly in the so-called advanced esophageal carcinomas compared to that in adenocarcinomas of the GEJ. However, we found no statistically measurable correlation between the rate of increased lysosomal enzyme activities and maturity of tumors, as well as the involvement of lymph nodes and TNM stage. Moreover, in contrast to adenocarcinomas of the GEJ, the significantly increased lysosomal enzyme activities in squamous cell carcinomas of the LTE did not correlate with survival time. Thus, these parameters in stages II and III had no prognostic value.

DISCUSSION

The incidence of adenocarcinomas of the esophagus (Si type I) is increasing[16,17]. These cancers are associated with Barrett's specialized epithelium and appear to be part of the continuum of gastroesophageal reflux disease. To date, no data suggest that the prevalence of gastroesophageal reflux disease has changed over the past 20 years and thus the cause of this current "epidemic" remains unclear[18].

The epidemiology of adenocarcinomas of the "classic" gastric cardia (Si type II-III) remains even less clear. Very few studies have examined this as a distinct entity. Overall, it seems that the incidence of cancer in this location, mainly Si type II, has not changed significantly in the past 50 years[1]. Some cases of gastric cardia cancer may be associated with chronic gastritis and *Helicobacter pylori* infection, whereas other cases may be related to Barrett's specialized epithelium in the proximal stomach[19-21].

A number of reports suggest that the synthesis, transport, and processing of lysosomal enzymes and their phosphorylated derivatives are altered in cancer, making these proteins interesting subjects for investigation[22]. The ability of tumor cells to invade tissues and metastasize is thought to involve an increased expression of proteinases and/or a decrease in the levels of proteinase inhibitors. Peptidases may facilitate metastasis in a number of different ways, including detachment of individual cells from the primary tumor, invasion of surrounding tissues to allow contact with vascular channels, degradation of the basement membrane during both intravasation and extravasation, and invasion of tissues during the formation of secondary tumor sites. Several classes of proteinases have been implicated in this process including matrix metalloproteinases, cysteine proteinases as CB or CL, aspartic proteinase cathepsin D, and serine proteinase plasminogen activators[23-28]. It is possible that human tumors may use combinations of these enzymes working synergistically to facilitate invasion or alternatively one specific proteinase may play a dominant role in tissue invasion for a given cancer, while some tumors exhibit an alteration in the synthesis or processing of many or all lysosomal enzymes. Defining the role of proteinases in the invasiveness of different tumors is important with regard to understanding the biology of this process and searching for potential prognostic markers and targets for therapeutic intervention.

The results of clinical investigations on cysteine cathepsins and their endogenous inhibitors in human breast, lung, brain, liver, and head and neck tumors, as well as in body fluids of ovarian, uterine, melanoma and colorectal carcinoma bearing patients, have shown that these molecules are highly predictive for the length of survival and may be used for risk assessment of relapse and death in cancer patients[29-32].

By examining the correlation of cysteine protease CB and laminin degradation, Khan *et al*.[33], demonstrated that increased CB expression and decreased tumor-associated laminin levels may suggest a mechanism underlying the progression of colorectal adenomas to carcinomas.

As for the relationship of gastric tumors and proteolytic enzymes, β hexosaminidase and its isoenzymes[34], and plasminogen activators are in the center of interest. Cathepsins B, L and tissue type plasminogen activator activities are higher in gastric cancer tissues than in normal gastric tissues. Chung and Kawai[35] also revealed that inhibitory activities of CL, CB, urinary and tissue type plasminogen activators are stronger in normal tissue closely surrounding the gastric cancer compared to normal tissue distant from the tumor border, as a result of a defense mechanism of the host against cancer invasion.

Yamamoto *et al*.[36], reported that the matrix metalloproteinase matrilysin may play a key role in the progression of esophageal carcinoma and that its detection may be useful in predicting recurrence and poor prognosis, and possibly in selecting patients for anti-matrix metalloproteinase therapy. Another study on esophageal adenocarcinoma demonstrated that amplicon at 8p22, the locus of the CB gene, is identified and associated with amplification and overexpression of the CB gene in esophageal adenocarcinoma[37].

Prior to this study, no lysosomal enzyme activity measurements have been performed in adenocarcinomas of the GEJ. During our examinations we measured the

activity of 11 different lysosomal enzymes and one cytosol protease THP in Si type I-III adenocarcinomas of the GEJ and in squamous cell carcinomas of the LTE. The activity of AMAN, CB, and DPP I in adenocarcinoma increased significantly as compared to that in normal gastric mucosa. In squamous cell carcinomas of the esophagus (Table 1) we also found a significant difference in the activity of CL and TPP I in addition to these three (Table 2). Moreover, when the relative activity values were compared for AGLU, CB, CL, and DPP I in adenocarcinoma of the GEJ and in squamous cell carcinoma of the LTE, marked differences in the relative activity levels by a factor of 2-5 respectively could be observed in squamous cell carcinomas as opposed to adenocarcinomas (Table 3).

From a tumor-biochemical aspect, adenocarcinomas within the Si I-III localization system did not show any differences, nor were there any significant differences in their lysosomal enzyme activities. Similarly to this there was no significant correlation between protease activities and adenocarcinomas of different histological types (papillary, signet-ring cell, tubular). However, we found a statistically measurable correlation to AMAN, CB and DPP I between the level of differentiation of adenocarcinomas of the GEJ and lymph node involvement, because histologically well-differentiated tumors with no lymph node metastases showed a significantly lower activity. The change of two proteases with cysteine catalytic site, namely CB and DPP I, activity correlated well with differences in survival rates, since the CB and DPP I values of those who died within 24 mo following surgical intervention were significantly higher than the same values for those who survived for 2 years or more (Table 4). At the same time, no statistically measurable correlation was found in relation to the proteases despite of displaying significantly higher activity levels as compared to the normal mucosa, the level of differentiation of tumors, their lymph node state or survival rates for squamous cell carcinomas of the LTE.

We conclude that adenocarcinomas of different locations in the GEJ form a homogenous group and differ in many aspects from malformations and neoformations within similar locations, though they possess a different histological structure. This conclusion is supported by data from Izutani *et al*.[38]. The difference in radiation sensitivity could be attributed to the tissue type difference. The increased MnSOD mRNA and MnSOD proteins in adenocarcinoma are believed to indicate the activity of strong defense mechanisms protecting the active form of cysteine catalytic center at CB and DPP I against reactive oxygen species, and this activity could be a cause of resistance against radiation therapy and quinone anticancer drugs.

Our results suggest that when adenocarcinomas of the GEJ are investigated at the preoperative phase, the ratio of the actual AMAN, CB, and DPP I enzyme activity in the samples taken from the tumor and its adjacent tissues may have some prognostic value. Relative activity values within the range of 1, signaling a comparatively more favorable prognosis pattern mean that a specific kind of "static warfare" prevails between the tumor tissue and the surrounding intact mucosa. This may be due not only to the diminished invasiveness of a given tumor, but also to the more effective defensive properties of the intact bordering mucosa, or it may be a consequence of a reduction in protease inhibitor synthetic activity. It seems, therefore, that the activity levels of AMAN, CB, and DPP I in adenocarcinoma may assist us in formulating our preoperative therapeutic strategy for adenocarcinomas of the GEJ.

ACKNOWLEDGMENTS

The authors are grateful for the opportunity to measure lysosomal enzyme activities in the laboratory of Dr. Peter Lobel at CABM, UMDNJ, Piscataway, NJ, USA. We also thank Professor Charles J. Filipi, Creighton Medical University, Omaha, Nicola Pen Jackson and Laszlo Novak for critical reading of the manuscript before its submission.

Abstract

AIM: To explore whether polymorphisms of the CYPIA1 and GSTM1 genes are associated with susceptibility of stomach cancer.

METHODS: A total of 102 stomach cancer cases and 62 healthy persons were diagnosed by pathology in 1998-2000 in the Qilu Hospital of Shandong University. Gene polymorphisms were detected by the PCR using sequence-specific primers. Data analysis of the case-control study was carried out using the unconditional logistic method.

RESULTS: After adjustment for age, sex, educational levels, and occupation, the risk factors for stomach cancer were shown to be smoking, *Helicobacter pylori* (*H pylori*), and presence of the CYPIM G/G and GSTM1 O/O genotypes. Interaction was observed between the combined genotypes of either CYPIA1 G/G and GSTM1 O/O or *H pylori* infection, or GSTM1 O/O and *H pylori* infection or smoking.

CONCLUSION: Polymorphisms of the CYPIA1 and GSTM1 genes, *H pylori* infection and smoking are related to susceptibility to stomach cancer.

INTRODUCTION

It has been found that the progression of precancerous lesions to gastric cancer is associated with cigarette smoking, alcohol drinking, and *Helicobacter pylori* (*H pylori*) infection in high-incidence areas of China[1-3].

Individual susceptibility to cancer may be partly due to exposure to environmental risk factors, which can be partly explained by genetic variability in metabolic activities related to phases I and II detoxification enzyme pathways. Polymorphisms in these metabolic susceptible genes have been linked to increased risk of cancer in several case-control studies[4].

Cytochrome p450 enzymes, which represent a large multigene family with different substrate specificities, are important in phase I detoxification reactions. The CYPIA1 gene product, aromatic hydrocarbon hydroxylase, catalyzes the first oxidative step in the metabolism of polycyclic aromatic hydrocarbons, such as those found in tobacco smoke, to carcinogens. This gene is induced by exposure to agents such as dioxin, benzo [α] pyrene and other aromatic hydrocarbons[5].

Various CYPIA1 gene polymorphisms have been found to be differentially associated with increased risk of several cancers (including cancer of the lung, breast, and colon) in different specific ethnic groups[6-9].

Phase II enzymes, glutathione *S*-transferase (GSTs), also have activated metabolites of carcinogens to be subjected to metabolic conjugation and other kinds of detoxifications. Homozygous deletions or null genotypes of GSTT1 (theta class) and GSTM1 (mu class) genes may be associated with an increased risk of cancer[5,7-9].

The polymorphisms of these metabolic enzymes result from a difference of the genotypes. Some of these forms cannot metabolize carcinogens into non-cytotoxic agents as is observed in the wild-type proteins[10]. Otherwise some of them metabolize cytotoxic agents into compounds that have the potential to damage DNA associated with high susceptibility to many kinds of diseases or drug resistance[11].

Few studies have evaluated the relationship between CYPIA1, GSTM1, and the risk of gastric cancer, as well as the potential interactions between these genetic markers and other risk factors for gastric cancer in the Chinese population. The present study was to investigate the interaction between CYPIA1- and GST-susceptible genotypes of gastric cancer and *H pylori* infection or smoking.

MATERIALS AND METHODS

Patients with stomach cancer were recruited between January 1998 and January 2000 in the Affiliated Hospital of Shandong University. A biopsy was taken under gastroscope from all patients for their pathologic diagnosis. Of these patients, 102 (86 males and 16 females) had stomach cancer as the

case group, and 62 (33 males and 29 females) had normal gastrointestinal mucous membrane and were used as the control group. All subjects were interviewed using a standardized questionnaire concerning their education, occupation, and cigarette smoking, etc. Blood samples (5 mL) were obtained from patients and controls, and 0.5 mL anti-clot solution of ACD was added. DNA was isolated from peripheral WBC by digestion with proteinase K, followed by phenol/chloroform extraction, and ethanol precipitation prior to resuspension in buffer containing 0.05 mol/L Tris, 5 mol/L EDTA, pH 7.6.

CYPIA1 genetic polymorphisms were determined as described previously[10]. Two pair primer sets were used to detect the polymorphism within exon 7 of the CYPIA1 gene by PCR. One pair primers were sense primer 1A1A: 5'-GAAGTGTATCGGTGAGACCA-3' and antisense primer c53: 5'-GTAGACAGAGTCTAGGCCTCA-3'; the other pair primers were sense primer 1A1G: 5'-GAAGTGTATCGGTGAGACCG-3' and antisense primer c53: 5'-GTAGACAGAGTCTAGGCCTCA-3' located about 190 bp downstream of the polymorphism site (Figure 1).

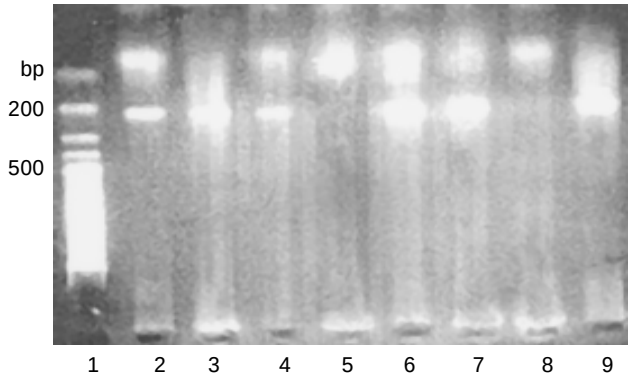

Figure 1 CYPP1A1 genotypes:lanes 2,3 and 6,7 recoded as A/G, lanes 4,5 recoded as A/A, lanes 8,h9 recoded as G/G, lane 1 indicates the molecular-weight marker.

PCR was carried out in two tubes with a total volume of 30 μL containing 0.4 μg of genomic DNA, 1 μL of each of 1A1A and C53 primers 1A1G and C53 were added into the other tube, 2.5 μL of 10×PCR buffer, 2.5 μL of 25 mmol/L Mg^{2+}, 1.5 μL of 10 mmol/L dNTP, 1 U Taq DNA polymerase. The program was initiated 8 min of denaturation at 95 ℃, followed by 35 cycles of amplification with denaturation for 90 s at 95 ℃, annealing for 60 s at 65 ℃ and an extension at 72 ℃ for 120 s, a final elongation at 72 ℃ for 6 min and 40 s on a water incubation PCR amplifier.

The PCR products were then subjected to electrophoresis on 1.8% agarose gels. If there was only a faint band of 190 bp in the 1A1A tube, the genotype was recorded as A/A. If there was only a faint band in the 1A1G tube, the genotype was determined to be G/G.

If both 1A1A and 1A1G tubes showed the faint bands, the genotype was recorded as A/G.

Two primers (G5: 5'-GAACTCCCTGAAAAGCTAAAGC-3' and G6: 5'-GTTGGGCTCAAATATACGGTGG-3') and the primer of β-protein (5'-CAACTTCATCCACGTTCACC-3' and 5'-GAAGAGCCAAGGACAGGTAC-3'), which is located about 215 and 286 bp, downstream of the polymorphic sites, were used to determine the GSTM1 genetic polymorphism as previously described[11] (Figure 2).

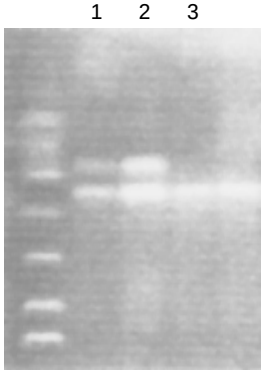

Figure 2 GSTM1 genotypes: lane 1: GSTM1+/o, lane 2: GSTM1 +/+, lane 3: GSTM1 0/0. (lane 1 and lane 2 indicating wild heterozygote; lane 3 indicating null homozygote), left arrow indicates biomarker 242 bp of PBR322 gene/MSPI internally tangent fragments.

PCR were carried out in two tubes of a total volume of 30 μL containing 0.4 μg of genomic DNA, 0.5 μL of each primer, 3.0 μL of 10×PCR buffer, 2.5 μL of 25 mmol/L Mg^{2+}, 3.0 μL of 10 mmol/L dNTP, 2 U of Taq DNA polymerase. The program was initiated for 4 min of denaturation at 94 ℃, followed by 30 cycles of amplification with denaturation for 30 s at 94 ℃, annealing for 30 s at 57 ℃ and an extension at 72 ℃ for 45 s, a final elongation at 72 ℃ for 5 min on a Perkin Elmer PCR amplifier.

The PCR products were then subjected to electrophoresis on 1.8% agarose gels. If there were light intensity bands at 215 and 268 bp, the genotype was recorded as +/+. If there was only a light band of 268 bp, the genotype was determined to be O/O. If there was a faint band of 215 bp and a more intense band of 268 bp, the genotype was recorded as +/O.

All subjects were tested with an antibody against *H pylori* for evidence of infection using an ELISA kit.

To examine the association between CYPIA1 and GSTM1 genotypes and stomach cancer, we calculated the odds ratio (OR) and 95% confidence interval (CI) by unconditional logistic regression. The ORs were adjusted for potential confounding factors, including age, sex, education, and occupation.

Possible modification of the association between genetic polymorphism and stomach cancer risk was also evaluated by stratifying cases and controls into tertiles based on *H pylori* infection and smoking.

RESULTS

We initially assessed the risk of stomach cancer using a variety of parameters. As reported previously, both smoking and *H pylori* infection led to a significant increase in risk (Table 1).

Table 1 Distribution of cases and controls by age, sex, education, and occupation

Variable	Value level	Gastric group		Control group		χ^2	*P*
		n	%	*n*	%		
Age (yr)	<35	4	3.9	18	29.0

	Card	18	17.6	20	32.3	8.573	= 0.014

There was no evidence for an increased risk of gastric cancer associated with sauerkraut and mildew food consumption or imbibing white spirit in Chinese population. However, frequent consumption of raw garlic was associated with an apparently reduced risk. The most significant factor associated with increased risk of stomach cancer was a CYPIA1 G/G genotype where the OR was 4.84 compared to the A/A and A/G genotypes. The GSTM1 O/O genotype was also associated with an increased risk of gastric cancer (Table 2).

When the ORs were calculated for the combined CYPIA1 and GSTM1 genotypes, a combination of CYPIA1 A/A and GSTM1 +/+ or +/O gave a baseline of 1.0 as shown in Table 3. The OR for GSTM1 O/O genotype was 3.34 (95%CI: 1.13-9.87). The OR for CYPIA1 G/G was 4.16 (95%CI: 0.40-43.45). However, combined CYPIA1 G/G and GSTM1 O/O enhanced the risk of gastric cancer (OR = 16.48, 95%CI: 2.36-115.0). There was a significant interaction.

When the ORs were calculated for the combined CYPIA1 genotypes and *H pylori* infection, a combination

[1]Non-adjusted OR, [2]adjusted for age, sex, education, and occupation, [3]drinking index=white alcohol/month×number of drinking years, [4]smoking index = cigarette/day×number of smoking years.

of CYPIA1 A/A and no *H pylori* infection at a baseline of 1.0, the OR of *H pylori* infection alone was 7.19 (95%CI: 1.98-26.11), and the OR of CYPIA1 G/G genotype alone was 13.18 (95%CI: 0.42-414.9). The OR significantly enhanced for the combined CYPIA1 G/G genotype and *H pylori* infection compared to the baseline group (Table 4).

As shown in Table 4, when compared to the combined CYPIA1 A/A genotype and non-smoking at a baseline of 1.0, the OR of smoking alone was 1.53 (95%CI: 0.47-4.96), and the OR of CYPIA1 G/G genotype alone was 4.90 (95%CI: 0.90-26.73), both of them did not reach a significant level. However, the ORs were significantly higher for the combined CYPIA1 G/G genotype and smoking as compared to the baseline group (Table 5).

As shown in Table 5, when compared to the combined GSTM1 +/+ or +/O genotype with no *H pylori* infection at a baseline of 1.0, the OR of *H pylori* infection alone was 4.19 (95%CI: 1.16-15.13). In combined GSTM1 O/O genotype and *H pylori* infection group, the OR was 12-fold higher than that in the baseline group (Table 6).

As shown in Table 7, when compared to the combined GSTM1 +/+ or +/O genotype with no smoking at a baseline of 1.0, the OR of smoking alone was 1.22 (95%CI: 0.37-4.01), and the OR of GSTM1 O/O alone was 3.08 (95%CI: 1.11-8.54). An interaction between the GSTM1 O/O genotype and smoking was also observed with a fourfold increase compared to that in the baseline group.

DISCUSSION

In this study, since the biopsy from cases and controls was tested by gastroscopy, there was no bias caused by misclassification.

	+	7	37	4.32	1.27	14.69

[1]Adjusted for age, sex, education, and occupation; CI: confidence interval; [2]two cases missing.

The results of this study showed that smoking and *H pylori* infection had an association with stomach cancer after being adjusted for age, sex, education, and occupation. Jarebinski *et al*.[12], in 1992 first reported that there is a weak association between smoking and stomach cancer. Liu and Wang[13] in 2002 made a meta-analysis of the relationship between smoking and stomach cancer, and found that cigarette smoking is a risk factor for gastric cancer, especially for male smokers. Finding from most case-control and cohort studies support the causal relation between smoking and gastric cancer[14-16]. Epidemiological evidence relating *H pylori* infection to the etiology of gastric cancer showed that at least 30% of gastric cancers in the developing world and 50% of gastric cancers in the developed world may be attributed to *H pylori* infection[17-20]. Studies indicate that *H pylori* infection is a frequent finding in patients with gastric adenocarcinoma and benign peptic ulcer[21-23]. With respect to carcinogenic mechanism, *H pylori* affects several aspects of gastric epithelial cell function[24-26]. The result from the present study is in agreement with these reports.

There are a number of studies on cytochrome p450 and GSTs associated with cancers, such as breast, lung, liver, esophagus, and stomach cancer[6-8,11].

It was reported that in the presence of p450, CYPIA, CYP2E1, and CYP3A in stomach cancer, the expression of CYPIA (51%) and CYP3A (28%) increases in stomach cancer[27-29]. Liakhovich *et al*.[30], reported that the frequency of CYPIA1-val allele in lung, stomach, and intestine cancer groups was three to five times higher than in the healthy control group. The carriers of homozygous GSTM1 gene deletion are also higher lung cancer risk.

Cai *et al*.[31], in 1999 reported that GSTM1 null genotype correlates with the susceptibility to gastric cancer (OR = 2.03, 95%CI of OR = 1.09-3.80). The risk for gastric cancer in those with GSTM1 null and GSTT1 non-null genotype is significantly higher than that in those with GSTM1 non-null and GSTT1 null genotype, with an OR of 2.91 (95%CI, 1.09-7.89). The risk for gastric cancer in smokers with GSTM1 null genotype increases significantly (OR = 8.06, 95%CI, 2.83-23.67)[31].

Setiawan *et al*.[32], reported that the prevalence of GSTM1 null genotype is 48% in gastric cancer cases, 60% in CG patients, and 51% in controls; after controlling for age, gender, education, pack-years of smoking, alcohol drinking, body mass index, *H pylori* infection, fruit and salt intake, the adjusted OR for GSTT1 and gastric cancer was 2.50 (95%CI, 1.01-6.22); when gastric cancer cases are compared to CG patients, the adjusted OR for GSTT1 is 2.33 (95%CI, 0.75-7.25).

In conclusion, CYPIA1 G/G and GSTM1 O/O genotypes are associated with the increase of stomach cancer in Chinese people. When the CYPIA1 G/G genotype for patients is combined with GSTM1 O/O genotype, then the risk factors involved are *H pylori* infection or smoking. A study needs to be carried out in future.

Abstract

AIM: To investigate the effect of *N*-(4-hydrophenyl) retinamide (4-HPR), the derivative of retinoic acid, on inhibition of migration, invasion, cell growth, and induction of apoptosis in hepatocellular carcinoma cells (HCCs) and malignant melanoma cells.

METHODS: 4-HPR was chemically synthesized. Cellular migration and invasion were assayed by Borden chamber experiment. Cell growth was assayed by MTT chromometry. Apoptosis effect was measured using Hoechst 32258 staining and flow cytometry. Gene transfection was performed with lipofectamine.

RESULTS: We observed that the migration of HCC and melanoma cells was significantly suppressed by 4-HPR and the migration cells were reduced to 58±5.03 (control 201±27.2, $P<0.05$, $n = 4$) in SMMC 7721-k3 HCC, and to 254±25.04 (control 302±30.1, $P<0.05$, $n = 4$) in melanoma cells after 6-h incubation with 4-HPR. The invasion through reconstituted basement membrane was also significantly reduced by 4-HPR treatment to 11.2±3.3 in SMMC 7721-k3 HCC (control 27±13.1), and to 24.3±3.2 in melanoma cells (control 67.5±10.1, $P<0.05$, $n = 3$). Cell growth, especially in melanoma cells, was also significantly inhibited. Furthermore, 3 μmol/L of 4-HPR induced apoptosis in B16 melanoma cells (37.11±0.94%) more significantly than all-trans retinoic acid ($P<0.05$), but it failed to induce apoptosis in SMMC 7721-k3 HCC. The mechanism for 4-HPR-induced apoptosis was not clear, but we observed that 4-HPR could regulate p27^{kip1}, and overexpression of cerebroside sulfotransferase (CST) diminished the apoptosis induced by 4-HPR in melanoma cells.

CONCLUSION: 4-HPR is a potent inhibitor of HCC migration and inducer of melanoma cell apoptosis. CST and p27^{kip1} expression might be associated with 4-HPR-induced apoptosis.

INTRODUCTION

The incidence of malignancy is increasing, especially hepatocellular carcinoma and malignant melanoma. Patients with these tumors usually have poor prognosis and short survival because of early metastasis, and also have the highest morbidity rate among all tumors[1-3]. The tumor cells of these diseases have early metastasis potential, which makes the leading cause of cancer-related death[4,5]. However, there is some lack of knowledge regarding the mechanism of tumor cell migration and metastasis, although some metastasis modes or general process have been suggested by previous study[6]. The mechanism by which one or several neoplastic cells escape from the primitive tumor to start the metastatic process is still a matter of discussion[7,8]. The neoplastic cells escape, migration, invasion of blood vessel basement membrane, and growth at new locations are all involved in the process and potential of metastasis. It is completely unclear that what kind of circumstances and conditions will produce the escape and that what situation will favor tumor cells migration or invasion, although the invasion is correlated with matrix metalloproteinases activity[9,10]. The patients' situations get worse due to lack of effective therapy and prevention of tumor metastasis. Hence, it will be more important to find an alternative approach or therapeutic agent that can inhibit the growth or metastasis of HCC and malignant melanoma.

Synthetic derivative of retinoic acid holds a great promise in the treatment against tumors[11]. With an artificial modification of the structure, *N*-(4-hydrophenyl) retinamide (4-HPR) shows a different activity with retinoic acid and has apoptosis-inducing potential[12]. To investigate its anti-tumor effects on HCC and melanoma cells, we used the synthetic analog and compared 4-HPR with retinoic acid. This study is supposed to present the evidence of inhibition of HCC and melanoma cells by 4-HPR and provide the experimental base for further application of anti-tumor activities.

MATERIALS AND METHODS

Materials

Agarose, propidium iodide (PI), *p*-nitrophenyl phosphate (pNPP), all-trans retinoic acid, and 3-(*N*-morpholino) propane-sulfonic acid (MOPS) were from Sigma-Aldrich. Bovine serum albumin (BSA, V) was from Roche. Culture medium RPMI 1640 and fetal bovine serum (FBS) were the product of GIBCO. Transfection reagent lipofectamine was purchased from Life Technologies. Matrigel was from BD Bioscience. Transwell (Borden Chamber), 24- and 96-well cluster plates were from Costar Corning Company. Arsenic (III) oxide was from the Pharmaceutical factory, Harbin Medical University. 4-HPR was synthesized by us by achieving recrystal with the purity of 99.95%. Mouse mAbs against $p27^{kip1}$ and $p21^{waf1}$ were from NeoMarker Co. O4 mAb against lactosyl sulfatide and galactosyl sulfate was from Chemicon. Bicinchonic acid (BCA) protein assay reagent kit was from Pierce.

F1/B16 melanoma cell was purchased from ATCC. The 7721-k3 cell was a subline[13] selected from SMMC-7721 cells for the high migration capability.

Cell migration assay

Cell migration assay was performed as described in our previous report[13]. The assay was performed in Transwell with an insert in 6.5 mm diameter, which has a polycarbonate filter at the bottom. The filter is a microporous membrane and has 8.0 μm sized pores in the membrane. In the chamber under the insert, 600 μL DMEM containing 5 mL/L FBS was added as an attractant for cell migration. In control, 5 mL/L BSA, instead of 5 mL/L FBS, was added, which had no attraction to cells. The cells were digested with 2.5 mmol/L EDTA, washed twice with serum-free medium, resuspended in serum-free DMEM, and adjusted to a concentration of 2×10^5/mL. The cell suspension of 100 μL was added into the insert and incubated at 37 ℃ in 50 mL/L CO_2 for 6 h. After gentle scraping, the adherent cells on the top of the filter by cotton in 30 g/L acetic acid, the cells in the bottom of the filter were then fixed in methanol for 30 min and stained with 5 g/L crystal violet for 5 min. All the cells in the bottom of the filter were counted and the average cell number of four independent assays represented cell migration capacity. In the control group containing 5 mL/L BSA under the filter, few cells migrated through the polycarbonate filter with an average of 2.50±0.02, whereas in the test group containing 5 mL/L FBS under the filter, 334.70±24.57 (n = 3) cells migrated to the bottom of the filter. Therefore, in the following experiment, 5 mL/L FBS was used as chemoattractant in chemotaxis assay.

Invasion assay

Tumor cell invasion assay was also conducted in Transwell, but the polycarbonate filter was precoated by 20 μg matrigel per insert. After incubation at 37 ℃ for 1-2 h, the gel was dried and formed a thin layer to reconstitute base membrane. Like the migration assay, 600 μL of DMEM containing 5 mL/L FBS was added to the well under the filter as chemoattractant. Cell suspension (100 μL) containing 1×10^5 cells was added into the insert. To observe the inhibition of tumor cell invasion, 3 μmol/L 4-HPR was added into the cell suspension. In the control group, 3 μmol/L 4-HPR was replaced by same amount of ethanol. After incubation at 37 ℃ with 50 mL/L CO_2 for 36 h, the top surface of the filter was gently scrapped by a cotton stick and then the filter was fixed by methanol for 30 min and stained by 5 g/L crystal violet for 5 min. Cells on the bottom surface of the filter were all counted.

MTT assay

Cells are prepared in medium at a concentration of 3×10^4/mL and 0.1 mL of cell suspension was placed on the 96-well plate. After incubation, 10 μL of 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazolium bromide (MTT) solution (5 mg/mL) was added to each well and incubated at 37 ℃ for further 2 h. Then all the media in the well was discarded and the plate was washed with PBS. The plate was inverted onto an absorbent diaper to pull off the remaining solution in each well. Then 0.1 mL of DMSO was added to each well and the plate was gently shaken for 15 min. Data were read at 570 nm with a reference wavelength of 630 nm.

Acid phosphatase assay

Acid phosphatase assay was performed according to our previous report[14] and the activity correlated well with cell number and MTT assay. Briefly, 3×10^3 cells were placed on each well of a 96-well cluster plate. In the test group, 3 μmol/L 4-HPR was added, whereas the same amount of ethanol was added in the control group. After 12-48 h of incubation, the plate was washed twice with PBS (pH 7.4) and 100 μL reaction buffer (0.1 mol/L sodium acetate pH 5.0, 1 g/L Triton X-100, 5 mmol/L pNPP) was added into each well. After incubation at 37 ℃ for 2 h, the reaction was stopped by adding 10 μL of 1 mol/L NaOH. The data were read at 405 nm wavelength.

Flow cytometry analysis

Cells were cultured at an initial density of 2×10^5 cells/mL. The test group cells were incubated with 3 μmol/L 4-HPR (control with ethanol) at 37 ℃ for 6, 18, and 24 h, followed by washing twice with PBS. Cell pellets were then resuspended in 1 mL of hypotonic PI working solution (50 μg/mL PI, 1 g/L sodium citrate, 1 g/L Triton X-100) and incubated at 4 ℃ overnight. On the 2nd day, the cells were analyzed by a FACScalibur machine. Each sample containing at least 20 000 cells was acquired and measured by CellQuest software. The data of cell cycle were analyzed by ModFit LT version 2.0 software, fitting apoptosis mode.

Fluorescent staining

Cells attached onto a glass slide were treated with 3 μmol/L 4-HPR. After washing twice with PBS, the slide was stained by Hoechst 32 258 and examined under a fluorescent microscope to count the cells with condensed, shrunk, and crumpled apoptosis nucleus among 200 cells, which were examined.

Western blot

Cell cultures, maintained for the indicated time periods, were

washed twice with ice-cold PBS, lysed with lysate buffer (50 mmol/L Tris-HCl, pH 7.4; 2 g/L Triton X-100, 1 mmol/L EDTA, 1 mmol/L PMSF). After being sonicated in ice for 5 min, protein concentration was determined using the BCA assay. Equal amounts of protein extracts were loaded onto 100 g/L sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), electroblotted onto PVDF membrane, probed with antibodies against $p27^{kip1}$ and $p21^{waf1}$, developed using the ECF Western blotting kit, and visualized in Kodak X-ray film.

Gene transfection

A full-length of cerebroside sulfotransferase (CST) gene expression frame[15] was inserted into an expressional vector pCXN2 and linearized by a restriction enzyme *Sxp*I. The vectors were then transfected into HCC and B16 melanoma cells. Transfection was performed with lipofectamine following the protocol provided by the manufacturer. After 48 h of transfection, all cells were screened with 400 μg/mL G418, and the colonies in clonal growth were selected, among which nine colonies with CST and six colonies with the vector pCXN2 transfection (Mock) were achieved. All the transfectants were further screened by Northern blot to determine mRNA expression level and by immunology assay with specific mAb O4 to confirm the products of CST enzyme.

Northern blot

A total of 20 μg RNA extracted from all transfectant cells was kept in a solution containing 500 mL/L formamide, 60 g/L formaldehyde, 20 mmol/L MOPS (pH 7.0), denatured at 65 ℃, and then loaded onto 10 g/L agarose. After electrophoresis, RNA was blotted onto a nylon membrane and hybridized with a digoxigenin-labeled probe, which was a RNA fragment synthesized from pSVK-hCST (*Xho*I) by T7 RNA polymerase *in vitro*. Digoxigenin-labeled nucleotide was incorporated into the probe during RNA synthesis. After hybridization at 68 ℃ overnight and washing, the membrane was then incubated with mAb Fab2 against digoxigenin. Bands on the membrane were detected by a DIG Detection kit according to the manufacturer's instructions.

Statistics

The data were expressed as mean±SD. Difference analysis was made by Student's *t*-test. $P<0.05$ was considered statistically significant.

RESULTS

Inhibition of cell migration

SMMC 7721-k3 HCC and B16 melanoma cells were both incubated at an initial concentration of 2×10^5/mL with 3 μmol/L 4-HPR, which was dissolved in ethanol. The control cells were not incubated with the same amount of 0.1 g/L ethanol instead of 4-HPR. After 6-, 18-, or 24-h treatment, the cells were assayed for migration. The inhibitory effects of 4-HPR are shown in Figure 1. After a short period (6 h) treatment with 4-HPR, the migration ability of both cells was significantly inhibited and the migration rate in B16 melanoma cells declined to 84.1% of the control (Figure 1). After 18-h treatment with 4-HPR, the inhibitory effect became stronger. The migration rate after 24-h treatment got further down to 30.5% of the control. In HCC, the inhibitory effect was most significant after 18-h treatment (Figure 1).

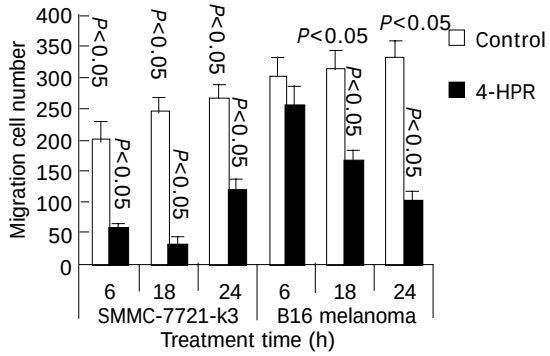

Figure 1 Inhibition migration of hepatocellular carcinoma and melanoma cells by 4-HPR treatment within a short period. SMMC 7721-k3 and B16 melanoma cells were treated with 4-HPR for 6, 18, and 24 h, respectively. After treatment, the cells were assayed for migration in the Transwell.

Effect on the invasion ability

The invasion behavior of tumor cells is important in the metastasis process of hepatocellular carcinoma or melanoma cells. Tumor cell invasion ability can be evaluated and measured *in vitro* by means of the migration and penetration through a reconstituted base membrane. After 4-HPR treatment, 7721-k3 HCC and B16 melanoma cells were assayed for invasion capacity through the reconstituted base membrane (matrigel-coated chemotaxis filter). We observed a significant reduction of cells invading and migrating through the reconstituted base membrane in both SMMC 7721-k3 HCC and melanoma cells even after a short time period of 6-h incubation with 4-HPR. Melanoma cell invasion ability was inhibited more significantly and the cells invading and migrating through the membrane were reduced to 36% of the control. Moreover, invasion of HCC decreased to 41.4% of the control (Figure 2).

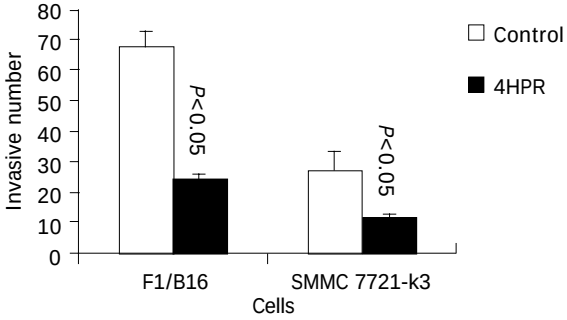

Figure 2 Effect of 3 μmol/L 4-HPR on cell invasion. SMMC 7721-k3 and B16 melanoma cells were treated with 4-HPR for 6 h. The cells penetrating matrigel membrane and migrating to the bottom of the filter were counted and data were expressed as an average from six independent assays.

Effect on the cell growth

Cell growth was evaluated *in vitro* in a time-dependent manner. The treated cells were measured by MTT assay as well as acid phosphatase assay to indicate cell number after the treatment. HCCs seemed to be slightly resistant to low concentration (3 μmol/L) of retinoic acid treatment (ATRA). High concentration of ATRA (10 μmol/L) was needed for the inhibitory effect on the growth of SMMC-7721-k3 HCC. However, 4-HPR was able to inhibit SMMC-7721-k3 HCC growth at 3 μmol/L (Figure 3). After 72-h treatment, the inhibitory effect became significant as shown by the MTT assay (Figure 3). B16 melanoma cells were quite sensitive to 4-HPR treatment and the growth rate was significantly inhibited by 3 μmol/L 4-HPR. After 48-72 h treatment with 3 μmol/L 4-HPR, B16 melanoma cell growth was completely inhibited because the cell number did not increase, but decreased. The growth of B16 melanoma cells also decreased after treatment with 10 μmol/L ATRA, but the cell could still grow. The inhibitory effects of ATRA on B16 melanoma cell growth was not as significant as the inhibitory effects of 4-HPR (Figure 4).

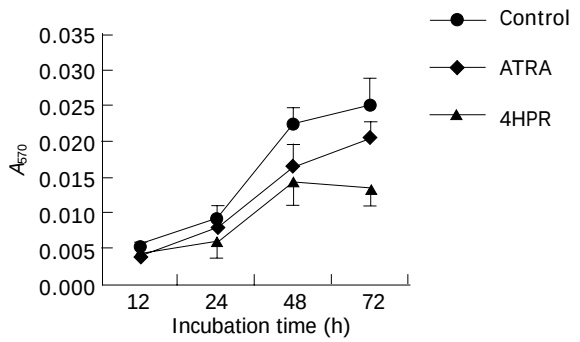

Figure 3 Growth inhibition of SMMC 7721-k3 cells by ATRA and 4-HPR. SMMC 7721-k3 cells were cultured in the 96-well cluster plate and incubated with 10 μmol/L ATRA, 3 μmol/L 4-HPR, or ethanol in the control.

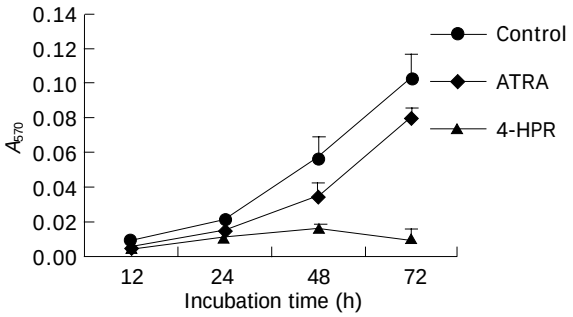

Figure 4 Growth inhibition of B16 melanoma cells by ATRA and 4-HPR. B16 melanoma cells were cultured in the 96-well cluster plate and incubated with 10 μmol/L ATRA, 3 μmol/L 4-HPR, or ethanol in the control. The data were achieved by an average from eight independent groups.

Regulation of cell cycles

SMMC 7721-k3 HCCs were proliferated and the cell cycle was analyzed by flow cytometry. After 18-h treatment with 4-HPR, SMMC 7721-k3 HCCs at G_0/G_1 stage were significantly fewer, but at G_2/M and S stage were significantly increased. After 24-h treatment with 4-HPR, cells at G_2/M stage increased significantly (Figure 5), indicating that the cells were accumulated at this stage. However, cells at G_0/G_1 stage were the majority of the cells in control group, which accounted for 73.3%. Cells at S stage accounted for 22.95% and cells at G_2/M stage were the minority (Figure 5). Total proteins extracted from the cells treated with ATRA or 4-HPR for 24 h was used to analyze $p27^{kip1}$ and $p21^{waf1}$ expression. We observed that 4-HPR treatment significantly induced $p27^{kip1}$ expression, while $p21^{waf1}$ retained the same expressional level after the treatment with either ATRA or 4-HPR (Figure 6). B16 melanoma cells were treated with 4-HPR for 18-24 h and the cycle did not change so much as SMMC 7721-k3 HCCs did. The percentage of different cell cycles remained at the similar level as control cells. However, 24 h after 4-HPR treatment, a peak of apoptosis appeared in B16 melanoma cells as detected by flow cytometry.

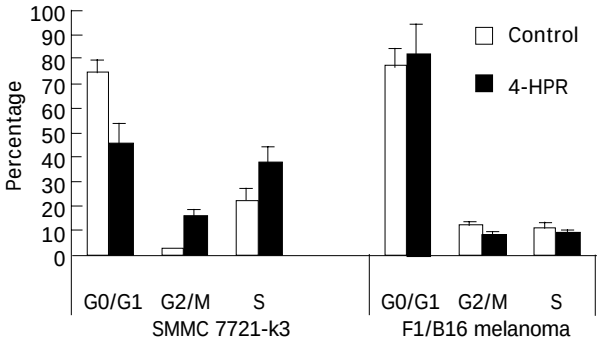

Figure 5 Regulation of cell cycles by 4-HPR. SMMC 7721-k3 cells and B16 melanoma cells were treated with 4-HPR for 24 h, respectively. Data were expressed as an average from three independent assays.

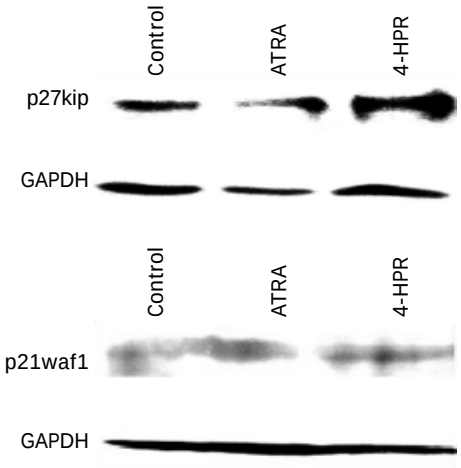

Figure 6 Western blot analysis of effects of 4-HPR on $p27^{kip1}$ and $p21^{waf1}$ expression. SMMC 7721-k3 cells were treated with 10 and 3 μmol/L 4-HPR for 24 h, respectively.

Induction of apoptosis by 4-HPR

Apoptosis was evaluated using both Hoechst fluorescent staining and flow cytometry analysis by PI staining. SMMC

7721-k3 cells were not sensitive to 3 μmol/L 4-HPR induction and only few cells were induced into apoptosis. After 6-48 h treatment with 3 μmol/L 4-HPR, apoptotic cell population was less than 8% of all SMMC 7721-k3 cells, which was not significantly different from that in negative control. In positive control, the cells were treated with 3 μmol/L arsenic (III) oxide, 24.3% of SMMC 7721-k3 cells was induced into apoptosis, which was significantly different from that of negative control. B16 melanoma cells were treated with 3 μmol/L 4-HPR for 24 h and apoptotic cell population reached to 12.52% of the total cells. After 48-h treatment with 3 μmol/L 4-HPR, apoptotic cells accounted for 37.11% (Table 1). This indicated that 4-HPR might be a potent inducer of apoptosis for melanoma cells, but not HCCs. As for comparison, we observed the effect of ATRA on both SMMC 7721-k3 cells and B16 melanoma cells at the same time. No significant apoptosis could be detected after treatment with 3 μmol/L ATRA for 24-48 h, whereas about 20% apoptosis was observed in both hepatocellular carcinoma and melanoma cells after treatment with 20 μmol/L ATRA for 72 h (Table 1).

Table 1 Apoptotic effects induced by 4-HPR (mean±SD, n = 3)

	Control	4-HPR	ATRA	As_2O_3
7721-k3 cells	4.27±0.06	8.53±0.12	5.05±0.03	24.27±0.39

P		<0.05	>0.05	

ND, not determined.

Influence of CST overexpression on 4-HPR induction

Our previous study demonstrated that retinoid compounds could inhibit cellular CST activity[16]; however, the inhibitory mechanism was unclear. Whether higher CST expression and activity would affect the action of retinoid compounds requires further investigation. In this study, we observed high CST expression influenced on 4-HPR induction in HCC and melanoma cells. After B16 melanoma and HCCs were transfected with whole expressional frame of CST cDNA in pCXN2 vector and CST mRNA expression was confirmed by Northern blot in the transfectants. All the cells were further screened using immune thin-layer chromatography with specific mAb against sulfolactosyl sulfatide and sulfogalactosyl sulfatide to select the clones with high expression of CST enzyme products. CST-transfected melanoma cell clones 1, 3 and CST-transfected HCC clone 6, 8 were chosen for the study. CST-transfected HCCs did not have any alteration in proliferation and cell growth, but the cell mobility, migration, and adhesion behaviors changed significantly, which led to promote metastasis of HCC in nude mice. The sensitivity to 4-HPR induction in CST-transfected HCCs remained the same as in vector-transfected cells (mock) or in parent HCC.

Table 2 4-HPR-induced apoptosis in CST overexpressed B16 melanoma cells (mean±SD, n = 3)

	Parent cells	Mock cells	CST1	CST3
Control	1.64±1.16	1.37±0.30	2.61±0.61	1.37±0.374
4-HPR	37.11±0.95	38.030±1.002	32.65±1.98[a]	33.59±0.91[a]

[a]P<0.05 *vs* mock cells.

CST-transfected B16 melanoma cells, however, proliferated and grew in a faster rate than mock and parent B16 melanoma cells. Interestingly, CST-transfected B16 melanoma cells became less sensitive to 4-HPR induction than mock and parent melanoma cells. After treatment with 3 μmol/L 4-HPR for 48 h, 38.03±1.002% apoptotic cells were detected in mock transfectants. Moreover, after treatment with 3 μmol/L 4-HPR, parent B16 melanoma cells showed 37.11±0.95% apoptosis (Table 2). However, no significant difference of apoptotic rate was observed between the mock cells and parent melanoma cells (n = 4). The CST transfectant CST1 and CST3 of B16 melanoma cells became less sensitive to 4-HPR induction. After treatment with 3 μmol/L 4-HPR, there were only 32.65±1.98% and 33.59±0.91% apoptosis in CST1 and CST3 transfectants, respectively, which were significantly lower than those in mock cells (P<0.05, n = 3). The results from flow cytometry analysis are similar to these. B16 melanoma cells were treated with 3 μmol/L 4-HPR and a peak of apoptosis appeared before peak G_1 (Figure 7). Mock cells had a similar peak of apoptosis as the parent cells. However, the size and height

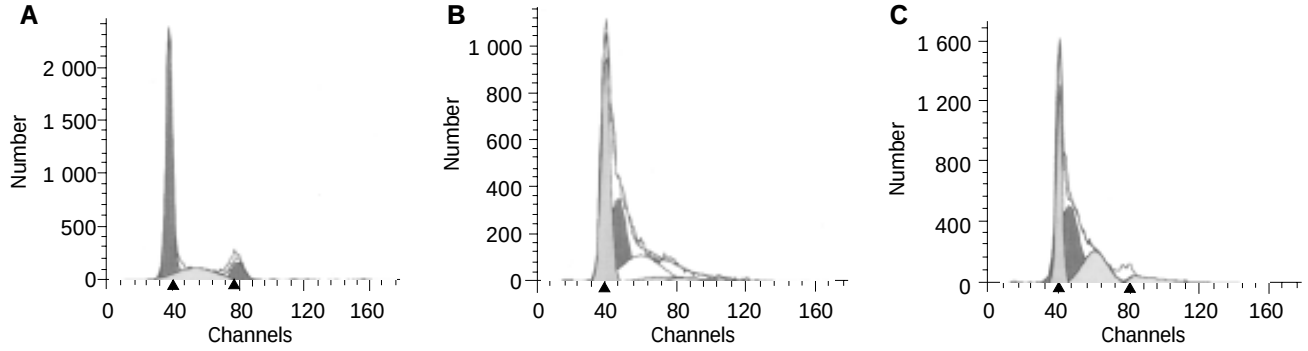

Figure 7 Comparison of apoptosis peak between CST- and vector-transfected cells. Control cells either of vector- or CST-transfected could not show any apoptosis (A). After being treated with 4-HPR, the vector-transfected cells produced a large apoptosis peak (B), while in CST-transfected cells only a small apoptosis peak could be seen (C).

of apoptosis peak in both CST transfectants, CST1 and CST3, were much smaller or shorter than those of mock cells, which indicated that CST transfectant B16 melanoma cells produced fewer apoptosis cells after 4-HPR treatment. But, to ATRA the sensitivity remained the same in CST transfectants as those in mock cells.

DISCUSSION

Hepatocellular carcinoma is one of the most common malignant tumors. Up to now, there is no effective approach for treatment of the patients with HCC except surgical therapy. We have previously used all-trans retinoic acid to induce differentiation of HCCs and in clinical trials in some cases[17]. Although ATRA could induce HCCs differentiation and resulted in shrinkage of tumor mass in some patients, a higher dose of ATRA was required to achieve the effectiveness. The *in vitro* concentration induction needed 10 μmol/L, which was 10 times higher than that for leukemia cells[18,19]. ATRA also was used for the induction of melanoma cells. Due to side effects, especially liver lesion, ATRA has a limited application for some patients. 4-HPR is a kind of synthetic retinoid derivative, which has been considered as the product with fewest side effects up to now. Several documents and clinical trials have suggested that 4-HPR is an effective agent for chemoprevention of breast cancer. Holven *et al*.[20], reported that 4-HPR could inhibit liver secretion of retinoic acid binding protein and enhance the induction effect of retinoic acid.

In this study, we used the synthetic 4-HPR to observe the effect on hepatocellular carcinoma and melanoma cells. Quite different actions and effects were noted between 4-HPR and ATRA. To inhibit cell growth or migration of hepatocellular carcinoma and melanoma cells required relatively lower 4-HPR concentration as compared with ATRA. Our data showed that 3 μmol/L 4-HPR could significantly inhibit the migration of HCC and melanoma cells. After 6-h incubation with 3 μmol/L 4-HPR, the migration of B16 melanoma cells was inhibited to 84.1%. After 18-h incubation with 3 μmol/L 4-HPR, B16 melanoma cell migration was decreased to 52.4%. Similarly, the invasion ability of B16 melanoma cells through reconstituted basement membrane was significantly inhibited by 4-HPR treatment. Tumor cell migration and invasion were closely related with the metastasis behavior[21,22]. Thus, we consider that 4-HPR potentially inhibits the biological behaviors related with metastasis of melanoma cells and HCC and may have a potential application as the alternative treatment and prevention of tumor metastasis. In this study, we also observed the difference in effects between 4-HPR and ATRA. When B16 melanoma cells were treated with 3 μmol/L 4-HPR only for 24 h, a significant apoptosis rate was observed, no significant apoptosis could be detected after treatment with 3 μmol/L ATRA for 24 h. Induction of apoptosis in B16 melanoma cells or HCC needed a much higher concentration of ATRA and much longer incubation time (72 h) compared to 4-HPR. However, the mechanism of 4-HPR-induced apoptosis is not fully understood, although some lines of evidence have suggested the involvement of super oxygen reaction[23].

In our previous investigation[24], we observed that CST expression was closely associated with metastasis of tumor cells. When HCCs were inhibited by 10 μmol/L ATRA, the activity and products of cellular CST were significantly reduced. Overexpression of CST in HCC altered cell behaviors of migration through chemotaxis filters and adhesion to extracellular matrix. Overexpression of CST in melanoma cells promoted cell growth. Therefore, we observed 4-HPR induction, sensitivity, and other biologic behavioral changes in CST-expressing B16 melanoma cells. Interestingly, the induction of 4-HPR in such cells seemed to be less effective than in mock or parent cells because there were fewer apoptosis cells in CST highly expressing B16 melanoma cells than the mock cells. Although the possible mechanism is unclear, this result suggests that CST expression might be involved in 4-HPR-induced apoptosis in melanoma cells. Several studies have suggested that CST is closely related with some growth factors, such as HGF[25] and EGF[26,27], which stimulate cell growth. A recent report has suggested that HER2/neu can reduce the sensitivity of breast cancer cells to 4-HPR by activation of Akt, which further induces cyclooxygenase-2 (COX-2) expression[28]. Furthermore, 4-HPR has been recently reported to increase cellular ceramide levels, which is considered to be a cytotoxic messenger that may regulate the proliferation, survival, and death of cells[29,30]. The increased ceramide biosynthesis is required for 4-HPR-induced endothelial apoptosis[29]. Therefore, the metabolism or catabolism of cellular ceramide could affect the induction and sensitivity of 4-HPR. CST catalyzes sulfation of lactosylceramide or galactosylceramide[31], and thus promotes the metabolism of cellular ceramide.

Abstract

AIM: To investigate the prevalence and penetrance of hMSH6 mutations in Spanish HNPCC families that was negative for mutation in hMLH1 or hMSH2.

METHODS: We used PCR-based DGGE assay and direct sequencing to screen for hMSH6 gene in 91 HNPCC families.

RESULTS: we have identified 10 families with germ-line mutations in the DNA sequence. These mutations included two intronic variation, three missense mutation, one nonsense mutation, and four silent mutations. Among the 10 germ-line mutations identified in the Spanish cohort, 8 were novel, perhaps, suggesting different mutational spectra in the Spanish population. Detailed pedigrees were constructed for the three families with a possible pathogenic hMSH6 mutation. The two silent mutations H388H and L758L, detected in a person affected of colorectal cancer at age 29, produce loss of the wild-type allele in the tumor sample. Immunohistochemical analysis showed that expression of MSH6 protein was lost only in the tumors from the carriers of V878A and Q263X mutations.

CONCLUSION: Altogether, our results indicate that disease-causing germ-line mutations of hMSH6 are very less frequent in Spanish HNPCC families.

INTRODUCTION

The link between defective DNA mismatch repair and the development of tumors has been firmly established. Inherited mutations in DNA mismatch repair genes are associated with the autosomal-dominant cancer susceptibility syndrome, hereditary non-polyposis colorectal cancer (HNPCC [MIM 114400; MIM 114500]). Patients with HNPCC are at high risk for colorectal and endometrial cancer and a variety of other malignancies. Tumors from HNPCC patients frequently show mutations in repetitive sequences, giving rise to a molecular phenotype referred to as microsatellite instability (MSI). Not surprisingly, a significant fraction of sporadic colorectal and endometrial cancers also show MSI.

The hMSH6 (MIM 600678) protein is a member of the MMR system; it interacts with hMSH2 to form the MutSα heterodimer[1-3]. Besides hMSH6, the hMSH2 protein also interacts with the hMSH3 protein to form the MutSβ heterodimer. The MutSα heterodimer is efficient in the repair of both base-base mismatches and insertion-deletion loops, whereas the MutSβ heterodimer is mainly active in the repair of insertion-deletion loops and not in the repair of base-base mismatches[4,5]. These data indicate that the hMSH6 and hMSH3 proteins are partially redundant in their DNA repair function.

Most families with clinically recognized HNPCC and MSI high, have mutations in either hMLH1 or hMSH2. Mutations in hMSH6 gene, appear to be associated with atypical HNPCC and in particular with the development of endometrial carcinoma[6-9]. The age of onset of cancers in HNPCC kindred's with hMSH6 mutations is higher than in hMSH2 or hMLH1 mutation carriers, and it has been reported that tumors from affected family members are less likely to have high MSI than tumors from hMSH2 or hMLH1 mutation carriers[10].

The estimate frequency of hMSH6 mutations in patients with colorectal cancer ranges between 0% based on a tumor immunohistochemistry study of a consecutive series and 1.5% based on mutation analysis of a combination of sporadic and familial cases[11,12]. Only a few of these germ-line mutations have been reported in families that fulfill the Amsterdam criteria[12,13]. To date, there have been no studies

to determine the frequency of germ-line hMSH6 mutations in Spanish HNPCC families. The aim of this study was to verify the contribution of hMSH6 defects to cancer susceptibility in 132 HNPCC Spanish families that have been previously tested for hMSH2 and hMLH1 mutations[14,15].

MATERIALS AND METHODS

Patients

Families were selected through the clinic for familial cancer at the San Carlos University Hospital in Madrid, and they were Spanish by descent. Informed consent was obtained from each participant. Personal and family cancer histories were obtained from the proband and participating relatives, and cancer diagnoses and deaths were confirmed by reviewing the medical records, pathology reports, or death certificates.

We classified each pedigree by whether they fulfilled the original Amsterdam I criteria (n = 56 families), Amsterdam II (n = 11 families), Bethesda guidelines (n = 37 families), or none of these criteria (n = 28 families)[16-18]. This last category we refer to as "HNPCC-like" where the tumor spectra are reminiscent of HNPCC but not fulfilling Amsterdam I, Amsterdam II, or young age at onset criteria.

All probands, had been previously tested for MSI status and hMLH1/hMSH2 mutations/deletions by either DGGE and direct genomic sequencing and multiplex ligation-dependent probe amplification (MLPA, MRC-Holland).

Control subjects

One hundred unrelated healthy individuals from the Blood Transfusion National Service in Madrid (Spain) were used as controls.

DNA isolation

Genomic DNA was isolated from peripheral blood lymphocytes according to the salting out procedure[19]. Paraffin-embedded tumor samples were used to confirm segregation of identified mutations and to study MSI and LOH. In these cases, DNA was extracted from paraffin blocks as described previously by de la Hoya *et al*.[20].

Tumor MSI analysis

One hundred and thirteen paired normal and tumor DNA were analyzed for MSI with the five markers of the Bethesda panel (BAT25, BAT26, D2S123, D5S346, and D17S250). Analysis of microsatellite sequences for instability was performed using an ABI Prism 310 Genetic Analyzer (Applied Biosystems, Foster City, CA, USA). PCR reactions were performed in a PTC-100 thermocycler (MJ Research, Waltman, MA, USA) and AB/ABI GeneScan software was used for data interpretation. Primer sequences were as described[21,22] and both fluorescent labeled and unlabeled primers were obtained from Applera Hispania SA. PCR reactions were carried out in a 10 μL reaction volume containing 50-100 ng of DNA, 1× PCR buffer (Ecogen SRL, Spain), 2.5 mol/L $MgCl_2$, 200 μmol/L of each deoxynucleotide triphosphate (Promega, Madison, WI, USA), 0.4 μmol/L of each primer, and 1 U Eco Taq DNA polymerase (Ecogen SRL, Spain). The thermocycling conditions were 1 cycle of 10 min 95 ℃, followed by 40 cycles consisting of 30 s 98 ℃; 1 min 55 ℃; 1 min 72 ℃, followed by 1 cycle of 7 min 72 ℃. Normal and tumor samples were prepared for analysis by pooling 0.5 μL of each reaction, 12 μL of formamide and 0.5 μL GeneScan 500 (Tamra; PE/ABI). The resulting suspension was heated at 95 ℃, for 3 min, and then loaded on an ABI 310 sequencer for automated detection. The GeneScan software analyzed the data. Microsatellite stable (MSS) was defined as no observed instability, MSI-H was defined as two unstable loci of the five reference loci.

DNA amplification

The entire *MSH6* coding region and the splice-junctions were amplified using the PCR from genomic DNA using 23 primer pairs. All amplicons were subjected to DGGE (below). The sequences of the primers are available upon request.

All DNA amplifications were performed in a 50-μL volume containing 100 ng DNA, 1× PCR buffer (Ecogen SRL, Spain), 0.4 μmol/L of each primer, 200 μmol/L of each deoxynucleotide (Promega, Madison, WI, USA), 1 U Eco Taq DNA polymerase (Ecogen SRL, Spain). Amplification was carried out in a PTC-100 thermocycler (MJ Research, Waltham, MA, USA). After denaturation at 95 ℃ for 5 min, 35 cycles at 95 ℃ for 30 s, 55 ℃, or 58 ℃ for 30 s and 72 ℃ for 60 s were performed, followed by a final extension step of 10 min at 72 ℃. Subsequently, PCR fragments were subjected to one round of complete denaturation and renaturation that is 98 ℃ for 10 min, 55 ℃ for 30 min, and 37 ℃ for 30 min to create heteroduplex molecules.

DGGE

DGGE analysis was performed in a denaturing gradient gel electrophoresis D-Code System (Bio-Rad Hercules, CA, USA). A 6-μL aliquot from the PCR reaction volume was mixed with 2 μL of standard dye-loading buffer and then loaded onto a 10% AA/bis-acrylamide (37.5:1) gel (0-60% or 20-80% urea-formamide chemical gradient according to melting profiles of each PCR fragment) in 1× TAE (40 mmol/L Tris-base, 20 mmol/L NaAC, 1 mmol/L EDTA pH 8) for 16 h at 80 V and 60 ℃. The DNA fragments were visualized and photo-documented under ultraviolet transillumination after staining with an ethidium bromide solution.

In addition to mutation analysis, we used DGGE to perform DGGE-LOH analysis where appropriate tissue was available, for tumors belonging to families with identified germ-line mutations in *hMSH6*. All available tumor tissue was sectioned and subjected to hematoxylin-eosin staining to determine the proportion of tumor cells. Only samples with >95% tumor cells were selected by macrodissection.

DNA sequencing

DNA fragments that displayed an abnormal DGGE pattern were analyzed by cycle sequencing. PCR products were purified with the QIAquick PCR purification Kit (Qiagen, Hilden, Germany) following the manufacturer's instructions. Cycle sequencing reactions were performed with the ABI Prism dRhodamine Terminator Sequencing Kit (Applied Biosystems, Forest City, CA, USA) and analyzed in the ABI

Prism 310 Genetic Analyzer (Applied Biosystems). All mutations were confirmed by two independent sequencing PCR reactions and sequenced in both directions.

hMSH6 immunohistochemistry

Immunohistochemical staining of *hMSH6* was performed for the 60 MSS cases and for the 12 MSI-H cases negative for mutation in hMLH1 and hMSH2. The tissue sections were cut at 6 μm and mounted on ChemMate Gap microscopy slides (DAKO A/S, Denmark) and dried at 37 ℃. After deparaffinization, slides were steam pretreated in EDTA buffer, pH 8-0, in a Magefesa Handy Steamer Plus (Magefesa, Spain) for 30 min, and then cooled and washed in PBS.

The antibody to *hMSH6* (clone 44; 1/100; catalog number G70220; Transduction Laboratories, Becton Dickinson, Lexington, UK) is a mouse mAb generated with an NH2-terminal fragment (codons 225-333) of the hMSH6 protein. For the immunohistochemical analysis, avidin-biotin complex immunoperoxidase technique was performed by using a commercial ChemMate detection kit (DAKO A/S) in a Techmate automate machine. Endogenous peroxidase was blocked by incubation in hydrogen peroxide with methanol. Incubation with no immune horse serum was followed by incubation with primary antibody. The sections were then incubated in biotinylated second antibody and peroxidase-labeled avidin-biotin complex. All dilutions were made in PBS (pH 7.2). The stainings were visualized with diaminobenzidine tetrahydrochloride solution. The sections were counterstained in Mayer's hematoxylin, rinsed with water, and mounted in an aqueous mounting media (Aquamount, BDH, Poole, UK). The percentage of positive nuclei was evaluated by two pathologists. Cases with more than 10% of nuclei staining were considered as positive protein expression. Normal colonic epithelium and lymphocytes exhibited strong nuclear staining for hMSH6 and, thus, served as positive internal controls for the staining of this protein.

RESULTS

MSI testing was carried out in 113 of the 132 families enrolled in our study. Of these 113 families, 60 had tumors that exhibited a non-MSI-high (MSS) phenotype and 53 had tumors that exhibited an MSI-high (MSI-H) phenotype. Nineteen families were not typed for MSI. All families were tested for mutations in hMLH1 and hMSH2, 24 families had a mutation in hMLH1 and 17 had a mutation in hMSH2 and were not studied further (Table 1). The remaining families were studied for mutations in hMSH6. In the 91 index cases tested for mutations in hMSH6, we identified 14 DNA variants. Of these, one was a novel definite deleterious mutation, nine were unclassified variants, six of them not described previously (Table 2) and four were polymorphisms described previously (Table 4). None of the unclassified variants were found in 100 control subjects.

The deleterious mutation Q236X, was found in an Amsterdam II family FC-100; change of cytosine for thymine at position c.706 leads to the formation of a termination codon at amino acid residue 236 that produces an 235 amino acid product instead of the normal 1 360 amino acid product. This mutation was found in a patient with two tumors, one colorectal and one endometrial (Figure 1). MSI testing was carried out in both tumors, colorectal and endometrial, and they exhibited a MSS phenotype; the immunohistochemical analysis of MSH6 showed an absence of staining (Table 3). In this family, we could test atleast two affected members, her father affected of colorectal cancer who was a carrier of the mutation and her sister also affected

Table 1 Classification of colorectal cancer families, frequencies of pathogenic mutations in hMLH1 and hMSH2 genes and MSI phenotype

[1]Patients harboring/patients screened.

of colorectal cancer that resulted not to be a carrier. Both members had MSS tumors and MSH6 protein staining was absent in the carrier and was present in the non carrier.

The missense mutation V878A was detected in two Amsterdam families, FC-73 and FC-94, this mutation has been reported previously and had been considered as possibly pathogenic[6]. FC-94 (Figure 1) is also a carrier of the unclassified variant K618A in the MLH1 gene (Table 3). Both mutations (V878A in MSH6 and K618A in MLH1) were found in two affected members of the family, the proband (affected with colorectal and prostate cancer at ages 51 and 52) and his sister (affected with endometrial cancer at age 45). MSI study in tumors from carriers showed a MSI-H phenotype and the immunohistochemical analysis of hMSH6 showed absence of staining. Mutation V878A was also detected in FC-73 (Figure 1). This mutation was found in four affected members of the family, the proband was affected of three different cancers (two small intestine cancer and one colorectal cancer at ages 42, 47, and 49), his mother (affected of colorectal cancer at age 48), his brother (affected with gastric cancer at age 29) and his sister (affected with colorectal cancer at age 48). MSI study in tumors from carriers showed a MSI-H phenotype and the immunohistochemical analysis of hMSH6 showed absence of staining (Figure 2).

The missense mutation R1242L was detected in FC-3 (Table 2); it is located in a conserved amino acid in exon 8 of the gene and causes substitution of a polar amino acid arginine to a non-polar amino acid leucine. This family also carries the mutation V716M in hMLH1 gene. Both mutations (R1242L in hMSH6 and V716M in hMLH1) were found in two members of the family, in the proband (affected with glioma, colorectal adenoma, meningioma, fibrosarcoma, and colorectal cancer at ages 42, 43, 52, 52, and 53), and in his father who was healthy. The MSI status of the colorectal cancer showed a MSI-H phenotype and the MLH1 and MSH6 staining were present (Table 3).

The silent mutation L773L was detected in FC-11 (Table 2). This mutation was found in an HNPCC-like criteria family with two members affected with colorectal cancer (ages 58 and 64), one affected with gastric cancer (age 60) and one with breast cancer (age 60). The mutation was found only in the proband, the other affected members were of wild type. The MSI status of the colorectal cancer showed a MSI-H phenotype and the hMSH6 staining was present (Table 3).

The silent mutation C559C was detected in FC-138 (Table 2), the proband was affected of two colorectal and one ureter cancers and the first age at diagnostic was at 43 years. The MSI status of the colorectal cancer showed an MSI-H phenotype and the hMSH6 staining was present (Table 3). Mutations H388H and L758L were detected in FC-68 (Table 2). These mutations were found in a patient with early onset colorectal cancer (age 29), the MSI status of the tumor was MSS and the hMSH6 staining was present (Table 3). The intron five mutation IVS 5-16 C>T was detected in two families FC-81 and FC-121 (Table 2). FC-81 has four members affected by colorectal cancer in two generations. The mutation was found in two affected members of the family, the proband (affected with colorectal cancer at age 66), and his brother (affected with colorectal cancer at age 61); the two other members of the family, his father who was not tested and his other brother (affected with colorectal cancer at age 50) was wild type. The two members who carry the hMSH6 mutation, were also carriers of K618A in the MLH1 gene. The MSI status of the tumors from the three affected brothers was MSS. The hMSH6 staining was present in the member wild type and in the two carriers of hMSH6 mutation. The MLH1 staining was present in the tumors of the carriers and the non-carriers of K618A (Table 3). FC-121 has three members affected of colorectal cancer (ages 60, 75, and 55), one with gastric cancer (age 73) and one with brain cancer (age 70, Table 2). We could only test the proband (affected with colorectal cancer at age 60). The MSI status of the tumor was MSS and the MSH6 staining was not determined (Table 3).

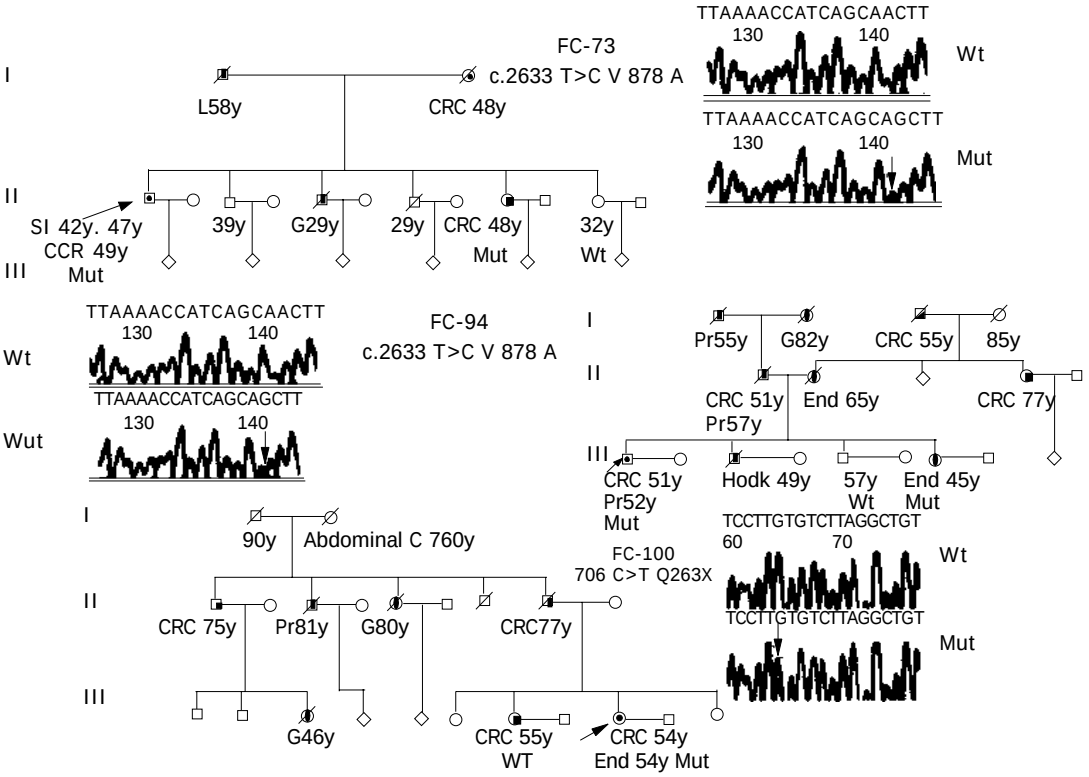

Figure 1 Pedigrees and DNA nucleotide sequence of the three families with disease-causing mutations of *hMSH6* gene. Squares, males; circles, females; diagonal bars, deceased; unblackened symbols, no tumor; semi-blackened symbols, patients with histological-verified carcinomas; arrows, probands; mut, carries the indicated mutation. Abbreviations indicating type of tumor: CRC, colorectal; SI, small intestine; G, gastric; H, Hodgkin; End, endometrium; Pr, prostate; L, liver. Number after abbreviation indicates age at which tumor was diagnosed. Electropherograms of the wild type and mutant nucleotide sequences for V878A and Q263X mutations located in exon 4 of the hMSH6 gene.

DGGE-LOH analysis was done to further characterize the role of these variants. Figure 3 shows a typical DGGE analysis of different hMSH6 exons amplified from tumor and peripheral blood DNA. Examples of missense mutations R1242L, V878A, and nonsense mutation K263X are shown. The silent mutations H388H and L758L were identified in the same individual. LOH analysis showed loss of the wild-type allele in both informative loci, indicating that these changes were located in the same chromosome. Taking into account our results, no evidence for LOH acting as a second-hit in the hMSH6 locus was found.

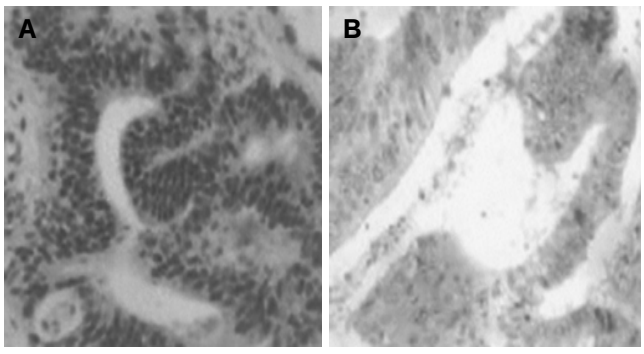

Figure 2 Representative examples of positive (A) and negative (B) immunohistochemical staining for hMSH6 protein (clone 44, Transduction laboratories/Becton Dickinson, Lexington, UK). A: Tumor from family 60, exhibited positive nuclear staining for hMSH6; B: tumor from family 73 carrier of V878A mutation, exhibited loss of hMSH6 expression.

DISCUSSION

Carrier frequencies of germ-line hMSH6 mutations in selected HNPCC families have been extensively described[6,10,12,23,24]. However, there is no evidence in the literature on this point regarding the Spanish population. We screened 91 HNPCC families (24 Amsterdam I, 7 Amsterdam II, 32 Bethesda guidelines, and 28 HNPCC-like) for the presence of germ-line mutations in the hMSH6 gene and identified 14 DNA changes. Seven of them were previously unreported DNA changes, including the intronic change at -16 base position of intron 5 (intronic mutation) found in two HNPCC-Like families, 1 amino acid substitution, 1 protein truncation mutation, and 4 silent mutations (Tables 2 and 3). The remaining seven DNA changes were reported previously, four of which were attested polymorphisms, one was the silent mutation H388L and the other 2 were V878A substitution that have been described as a possible disease causing mutation by other authors[6,9,25]. In our study, the Val878Ala substitution was detected in all affected members tested of both families, FC-73 (Amsterdam I) and FC-94 (Amsterdam II), suggesting that the hMSH6 germ-line mutation segregated with the disease. The MSI study of the tumors revealed an MSI-H phenotype. Moreover, immunohistochemical analysis revealed loss of hMSH6 protein in tumors from these patients. Our data suggest that this alteration may be a disease-causing mutation. However, we cannot discard that another mutation not detected could be linked to V878A in our population. Peterlongo *et al.*[24], has found the V878A in 4 out of 190

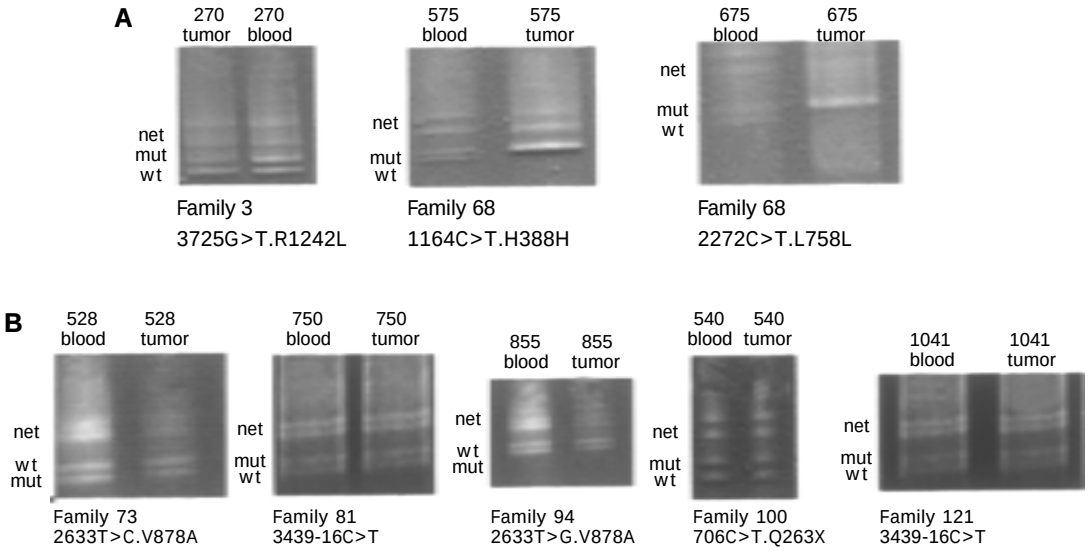

Figure 3 DGGE-LOH analysis of different *hMSH6* exons, amplified from both tumor and blood DNA. Analysis of 7 patients (270, 675, 526, 750, 855, 940, and 1 041) harboring the mutations R1242L, H388L, L758L, V878A, 3439-16 C>T, and Q263X. Bands corresponding to wild-type (Wt), mutant (Mut) alleles and the heteroduplex (Het) are indicated in all cases. Panel A shows LOH of the mutant allele in patient 270 and LOH of wild-type allele in patient 675. Panel B shows retention of both alleles (wt and mut) in all patients.

controls (from 18 000 volunteers of varying ethnic backgrounds who live in the New York metropolitan area), suggesting that this variant may not be linked to the disease in their population.

From the study presented here, we propose the following interpretations concerning the role of each previously unreported DNA change in the susceptibility to CRC. We interpret the $hMSH_6$ 3 435-16 C>T mutation found in two HNPCC-like families (FC-81 and FC-121) as a non disease-causing mutation for the following reasons: the 3 435-16 C>T did not segregate in the families, the tumors showed a MSS phenotype and the immunohistochemical analysis showed normal expression of the hMSH6; moreover, the wild type and mutant alleles were both retained in the tumor (LOH study, Figure 3). The $hMSH_6$ c.706 C>T mutation produces a stop codon, Q236X, and presumably causes the synthesis of a truncated hMSH6 protein of 235 amino acids (instead of 1 360), the immunohistochemical analysis showed lack of expression of hMSH6 and reduced expression of hMSH2 proteins from cancer cells. Reduced expression of hMSH2 was observed in CRC and endometrial cancer cases with a germ-line mutation in hMSH6[26,28]. We could study three affected members of the family, and we have seen that the mutation segregate with the disease because the father of the index case is also a carrier. Her sister, diagnosed of colorectal cancer at age 55, resulted not to be a carrier, this case could be a phenocopy. We can conclude that the mutation could be responsible for the susceptibility to cancer in this family. Mutation c.3725 G>T (R1242L) was found in a patient with multiple tumors and he is also a carrier of K618A in hMLH1 gene, his father is also a carrier of both mutations but he is still healthy. The immunohistochemical study showed expression of all MMR proteins and the study of LOH in the tumor cells showed loss of mutant allele. We could not study any other member of the family because the pedigree was very short (no more members, the index case was alone). Mutations c.1164 C>T and c.2272 C>T occur in the same chromosome in a patient from a short family (the index case diagnosed of colorectal cancer at 29, her brother was healthy, and her father was diagnosed of larynx cancer at 50 years). The hMSH6 protein was present in the tumor cells and the LOH study showed retention of mutant allele and perhaps, this fact could produce chromosomal instability, and therefore, mutational events that led to hyperproliferation. At the end, the silent mutation c.1677 C>T (C559C) was found in a patient with two CRCs at age 43 and one urothelial cancer at age 47. This patient was also a carrier of another silent mutation in hMLH1 gene (P350P) and both colorectal tumors showed a MSI-H phenotype and the immunohistochemical study showed expression of hMLH1 and hMSH6 proteins. With these results, we cannot conclude if the silent mutations are responsible for the tumors in our patient.

Our data indicate that the frequency of hMSH6 mutations is low in Spanish HNPCC, they can be found either in families with MSI-H or MSS tumors, which on average had an older age at diagnosis of cancer and are associated with other HNPCC tumors-overall gastric and endometrium. These data are consistent with the results of other published studies[24,27-29].

Thus, we can conclude from our study, that the two possible pathogenic mutations of hMSH6 were found in three families, in two of them the patients had tumors exhibiting a MSI-H phenotype and had been tested negative for mutations in hMLH1 and hMSH2. The remaining family was also negative for mutations in hMLH1 and hMSH2 but the tumors of the two carriers were MSS. The frequency of hMSH6 mutations in our series was low, as they were found only in 3 out of 91 families studied (1 of 19 Amsterdam I and 2 of 8 Amsterdam II). The mean age of dx cancer was higher than in hMLH1- and hMSH2-related families. On the other hand, we have not found these variants in site-specific CRC families but in families with a broad

spectrum of cancer types. Therefore, we suggest that hMSH6 testing should be pursued in Amsterdam families that have been negative for mutation in hMLH1 and hMSH2 genes or, as the literature suggests, in families with a history of endometrial, gastric, or other cancers in addition to a history of CRC.

ACKNOWLEDGMENTS

We thank the families for participating in the study. We thank C Corbacho, Dr. J Sanz Garcia and Dr. C Saez for their technical work.

Abstract

AIM: To study the immunological effects of physiological doses of purple sweet potato leaves (PSPL).

METHODS: The randomized crossover study (two periods, each lasting for 2 wk) involved 16 healthy non-smoking adults of normal weight. The 6-wk study consisted of a run-in (wk 1) PSPL diet (daily consumption of 200 g PSPL) or a control diet (low polyphenols, with the amount of carotenoids adjusted to the same level as that of PSPL) (wk 2-3), washout diet (wk 4), and switched diet (wk 5-6). Fasting blood was collected weekly in the morning. T-lymphocyte function was assessed via the proliferation and secretion of immunoreactive cytokines. Salivary IgA secretion and the specific cytotoxic activities of cytotoxic T lymphocytes and natural killer (NK) cells were determined.

RESULTS: The plasma β-carotene level increased with time in both groups, while the plasma polyphenol level decreased in the control group, and no significant difference was detected between the two groups. Although plasma polyphenol levels did not significantly increase in the PSPL group at the end of the study, they were significantly elevated in urine. PSPL consumption produced a significant increase in proliferation responsiveness of peripheral blood mononuclear cells (PBMC) and their secretion of immunoreactive IL-2 and IL-4. As well, lytic activity in NK cells was elevated in a time-dependent fashion. Salivary IgA secretion significantly decreased in control group after 2 wk, and returned to baseline following dietary switch to PSPL.

CONCLUSION: Consumption of PSPL modulates various immune functions including increased proliferation responsiveness of PBMC, secretion of cytokines IL-2 and IL-4, and the lytic activity of NK cells. The responsible determinants of PSPL remain to be elucidated, as does the biological significance of the present observations.

INTRODUCTION

The high consumption of vegetables and fruits has been linked epidemiologically to a decreased risk of cancer and cardiovascular disease[1]. Their beneficial effects have been attributed partly to the presence of numerous polyphenolic compounds, which display antioxidant and free radical scavenging properties[2]. Polyphenols are the major phytochemicals in fruits and vegetables. A variety of *in vitro* studies have shown that polyphenols such as flavonoids are antioxidants[3], immunomodulators[4], and exhibit antigenotoxic effects[5].

Purple sweet potato leaves (PSPL), which are easily grown in tropical areas such as Taiwan, have the highest polyphenolic content, in particular flavonoids, of all the commonly grown vegetables, and exhibit free radical scavenging ability[6]. Supplementation of diets with PSPL would seemingly be prudent. However, this recommendation is premature, since little is known from human experimental studies about the physiologic effects of dietary PSPL on the immune system.

As with many vegetables and fruits, PSPL are rich in carotenoids. The immunomodulatory activity of carotenoids in animals and human beings is well known[3-5]. Presently, we sought to evaluate whether physiological doses of polyphenol via consumption of PSPL affected the immune status of healthy subjects. In order to calibrate the

immunomodulatory effect of carotenoids, the amount of carotenoids consumed by the test and control groups was similarly adjusted. The results are consistent with a beneficial immune effect of PSPL.

MATERIALS AND METHODS

Subjects

Sixteen non-smoking healthy adults (seven men and nine women, aged 20-22 years), with normal weight (body mass index 20.9-21.6 kg/m^2) were recruited for the study. All subjects were in good medical health. Their screening histories did not reveal indications of any gastrointestinal disorder. Vitamin supplements or medications were not taken 1 mo preceding the study and during the study period. The study was approved by Medical Ethical Committee of the Taipei Medical University and all participants gave their written consent.

Sample collection and processing

Study design The leaves used were obtained from purple sweet potatoes planted and tended at the Taoyuan District Agriculture Improvement Station, Taipei Branch, Taiwan.

The randomized crossover study was conducted during September to November 2003. Subjects were randomly divided into control group and experimental group, all of them ran in a low polyphenol diet for 1 wk (wk 1). After that, control group consumed a control diet (low polyphenols, with the amount of carotenoids adjusted to the same level as that of PSPL) for 2 wk, experimental group consumed a PSPL diet (daily consumption of 200 g PSPL) for 2 wk (wk 2-3). The washout diet (a low polyphenol diet) was followed for 1 wk (wk 4), and then, the control and experimental groups were given switched diet for 2 wk (wk 5-6). Results were presented in a total study period of 6 wk.

Subjects were provided PSPL and control diet for lunch and dinner by the Department of Dietetics of Taipei Medical University Hospital. The meals were eaten in the hospital cafeteria. Each subject returned any uneaten food to allow food intake to be recorded. A list of the food products that the subjects were not allowed to eat was provided. Each subject kept a record of food consumption, which was checked to ensure compliance with the diet.

Collection and preparation of blood samples Blood from fasting subjects was collected once weekly in the morning between 07.00 a.m. and 09.00 a.m. Blood was drawn from an antecubital vein into the tubes containing 1.6 g/L of EDTA or Li-heparin, which were immediately placed on ice in the dark. Plasma collected by centrifugation at 1 500 r/min for 10 min at 4 ℃ was stored at -80 ℃ until analysis.

Collection and preparation of urine samples Before and at the end of the intervention period all volunteers were asked to provide a 24-h urine sample. During the collection period urine was stored at 4 ℃ and kept in dark bottles. Exact sampling time and urine volume were determined, and each sample was stored at -20 ℃ until analysis.

Analytical methods

Total polyphenols in urine and plasma Total polyphenols in urine and plasma were measured using the Folin-Ciocalteau method[10]. The absorption at 750 nm was measured spectrophotometrically. The total polyphenol content was expressed as gallic acid equivalents (GAE).

Plasma β-carotene Carotenoids were extracted from plasma with absolute ethanol (containing 1% pyrogallol) and hexane, separated by C18 reverse phase high-pressure liquid chromatography using spherical 3 micron packing. β-carotene was identified and quantified using an external standard[11].

Preparation of peripheral blood mononuclear cells (PBMC) PBMC were isolated by density gradient centrifugation using Ficoll-Paque (Amersham Biosciences, Buckinghamshire, UK) and resuspended in complete RPMI-1640 culture medium (Invitrogen, Carlsbad, CA, USA), containing 50 mL/L heat-inactivated fetal bovine serum (FBS, Invitrogen), 2 mmol/L L-glutamine, 100 000 U/L penicillin, and 100 mg/L streptomycin.

Lymphocyte proliferation PBMC (1×10^9 cells/L) in medium containing 5% of FBS were stimulated by T cell mitogen concanavalin A (Con A; 5 mg/L; Sigma Chemical Co., St. Louis, MO, USA) for 120 h at 37 ℃. Proliferation was measured using the BrdU proliferation enzyme immunoassay kit (Oncogene, Merck, Darmstadt, Germany).

Quantification of cytokine secretion PBMC were stimulated with Con A as described above for 48 h to measure IL-2 and IL-4 secretion. Cell-free supernatants were collected and stored at -80 ℃ until analysis. IL-2 and IL-4 were measured by ELISA kit (Biosource, Camarillo, CA, USA).

Cytotoxicity activity assay of NK cells The specific cytotoxic activities of natural killer (NK) cells were tested using a Promega CytoTox 96 kit (Promega, Madison, WI, USA). K562 cells were susceptible target cells to the cytotoxic effects of NK cells. K562 cells and PBMC including NK cells, resuspended in phenol red free RPMI-1640 culture medium containing 5% FBS were coincubated in 96-well round bottomed plates for 4 h at 37 ℃. The following PBMC/ K562 cell ratios 30:1, 20:1, 15:1, 10:1, and 7.5:1 were used to find a good effect between NK cells and K562 cells. During the incubation, the NK cells destroyed the target cells and lactate dehydrogenase (LDH) was released. Spontaneous release of PBMC or target cells was controlled by separate incubation of the respective population and detergent was added to lyse all target cells into a complete cytotoxicity. At the end of incubation, the cells were lysed and centrifuged. Fifty microliters of aliquot of each well was transferred into another 96 well flat-bottomed plate and 50 μL of fresh LDH substrate solution was added to each well. The plates were incubated at room temperature for 30 min, and the reaction was stopped by the addition of 1 mol/L acetic acid. The resulting light absorbance was measured in microplate reader at 490 nm. The percentage of cells exhibiting cytotoxic activity was calculated.

Salivary IgA secretion A small absorbent pad was used to collect saliva before brushing of the teeth in the morning. All samples were centrifuged at 13 000 *g* in a microliter tube. The supernatant was stored at -20 ℃ until analysis. Salivary immunoglobulin A (IgA)[12] was measured using an immunoassay kit (Salimetrics, State College, PA, USA).

Statistical analysis

All values were expressed as mean±SD. The data were analyzed using SPSS version. Statistical significance was determined using pairs *t* test. $P<0.05$ was considered statistically significant.

RESULTS

All participants tolerated the intervention well and completed the study. Physical characteristics of the subjects are summarized in Table 1. Body mass index and the percentage of body fat did not vary significantly during the study. PSPL-related daily dietary intake was 902 mg GAE of total polyphenol and 23.42 mg of β-carotene. Control subjects ingested the same amount of β-carotene from 40 to 45 g carrots (268.76 μg/g of β-carotene) each day.

The concentrations of plasma β-carotene and polyphenol measured throughout the study are summarized in Table 2. Plasma β-carotene level increased with time in the PSPL and control groups. However, plasma polyphenol levels decreased in the control group, although the decrease was not significantly different from the PSPL group. In the latter group, the urine levels of polyphenol were significantly elevated (8.20±0.95 to 10.27±1.39 mg GAE/dL).

Table 1 Physical characteristics of subjects (mean±SD)

Subjects	Before		After	
	Male	Female	Male	Female

significance (data not shown). The percentage of lytic activity of NK cells in a PBMC/target cell ratio of 30:1 was elevated in the PSPL group after 1 wk, and then was further elevated. Salivary IgA secretion in the control group decreased significantly, but returned to the basal levels after 2 wk of PSPL consumption (Figure 4).

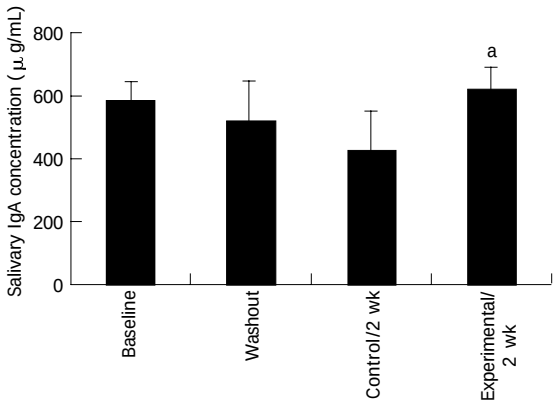

Figure 4 Concentration of salivary IgA detected by immunoassay kit. $^aP<0.05$ for experimental 1 wk *vs* experimental 2 wk.

DISCUSSION

The present study demonstrates that consumption of polyphenol-rich PSPL results in a marked total polyphenol increase in the urine. Most polyphenols peak in plasma 1-2 h after a single polyphenol intake, and are quickly eliminated from the circulation[13]. The prolonged ingestion of polyphenol-rich PSPL did not result in increased plasma polyphenol concentrations as expected. We also measured the total polyphenol in plasma 0, 2, 4, 8, 12, 24 h after consumption of PSPL in a previous study. The plasma polyphenol level raised 2 and 4 h after consumption of PSPL and further increased after 24 h, but there was no significance (data not shown). Although polyphenol was not different in plasma from fasting subjects throughout the whole study period, physiological functions were significantly modified.

β-Carotene-rich carrots were used to calibrate the effect of carotenoids from PSPL. As expected, β-carotene concentration in plasma was not significantly different. In another study, the dietary supplementation with β-carotene (8.2 mg) or lycopene (13.3 mg) for 12 wk does not enhance cell-mediated immunity in healthy free-living elderly humans beings[14]. A low-carotenoid diet reduces T-lymphocyte function, which cannot be restored by the daily supplementation with carrot juice containing 21.6 mg β-carotene, 15.7 mg α-carotene, and 0.5 mg lutein[9]. Presently, control subjects ingesting 23.42 mg of β-carotene each day do not display a significantly altered T-lymphocyte function.

The immune system provides markers for determining the biological health benefits of phytochemicals. Flavonoids suppress a variety of immune functions including lymphocyte proliferation, lytic activity of NK cells, and cytokine secretion *in vitro*[4]. The same study demonstrated that supplementing a low polyphenol diet with polyphenol-rich fruit juices results in significantly increased lymphocyte proliferative responsiveness, IL-2 secretion by activated lymphocytes, and the lytic activity of NK cells in healthy subjects[17]. These results are in agreement with the findings in our present study.

Many health benefits are associated with the consumption of tea, and are mainly attributed to the polyphenolic constituents. In animals, these constituents exert antioxidative activities and improve the antidotal capability of the liver. We found similar oxidative effects following the 2-wk regimen of PSPL consumption in humans beings (data not shown). Free radicals impair the integrity and functionality of membrane lipids and affect signal transduction and gene expression in immune cells[18]. One potential mechanism underlying the immunomodulatory effect of polyphenols is their ability to act as an antioxidant, resulting in a lower generation of free radicals.

IL-2 and IL-4 are both produced by activated T cells following *in vitro* stimulation by T-cell mitogens such as Con A. IL-2 is primarily produced by T-helper-1 cells, and IL-4 by T-helper-2 cells[19]. In our study, consumption of polyphenol-rich PSPL resulted in increased secretion of IL-2 and IL-4, which paralleled an enhanced proliferative response of these cells.

Pure flavonoids suppress a variety of immune mechanisms including lymphocyte proliferation, lytic activity of NK cells *in vitro*[4]. In animal models, quercetin also increases lytic activity of NK cells[20]. A study of healthy human subjects clearly showed that supplementing a low-polyphenol diet with polyphenol-rich fruit juices significantly increases lymphocyte responsiveness to mitogen activation and enhances lytic activity of NK cells[17]. The present findings are entirely consistent with the prior observations and support the suggestion that polyphenol possesses immunoactivity *in vivo* that differs from the activity observed *in vitro*. Possibly the polyphenol doses used *in vitro* are different from polyphenol in plasma concentrations and/or have the specific function of the metabolites of polyphenol.

IgA is the most important immunoglobulin in saliva, serving as a main immunological defense of mucosal surfaces[16]. Salivary IgA is a sensitive indicator of the humoral immune response to infection[17]. In our study, salivary IgA secretion significantly decreased when subjects consumed low polyphenol diet and returned to the basal level after PSPL consumption, indicating that PSPL consumption may protect mucosal surfaces.

In conclusion, dietary intervention in the form of PSPL consumption can modulate various immune functions. The active constituents in PSPL need to be determined in further investigations.

ACKNOWLEDGMENTS

We thank Drs. Yuan-Tsong Chen, Huey-Fang Shang, and Sung-Ling Yeh for their excellent technical assistance. We also thank the volunteers for taking part in this study and Dr. Tsan-Ju Chang, Agriculture Improvement Station, Taipei Branch, Taiwan, for generously providing the PSPL.

Abstract

AIM: To observe the anti-liver fibrosis effect of *Astragalus complanatus* flavonoids (ACF) in rats.

METHODS: The liver fibrosis model in rats was established by injecting interperitoneally 0.2 mL/100 g 0.5% dimethylnitrosamine, thrice a week. Meanwhile, the rats were administered ACF (30, 60, 120 mg/kg) or colchicine (0.1 mg/kg) once a day for 1 mo. Serum *N*-propeptide of type I procollagen (PINP) and type III procollagen (PIIINP) was measured using ELISA. Malondialdehyde (MDA) and superoxide dismutase (SOD) in hepatic tissue were evaluated. Matrix metal protease-1 (MMP-1) mRNA expression was assayed by RT-PCR and the protein expression of tissue inhibitor of metal protease-1 (TIMP-1) was analyzed by immunohistochemistry.

RESULTS: In the ACF groups, SOD activity increased and MDA content decreased in comparison to the liver fibrosis model group. The serum PINP and PIIINP contents in ACF-2 and -3 group decreased compared to those in model group. In ACF-2 and -3 group, the expression of MMP-1 mRNA increased significantly and the protein expression of TIMP-1 decreased compared to that in model group.

CONCLUSION: The antifibrotic mechanisms of ACF are associated with its influence on lipid peroxidation and collagen synthesis and degradation.

INTRODUCTON

Fibrosis is a common manifestation in most chronic liver diseases. The progression of hepatic fibrosis often leads to cirrhosis and is associated with liver cancer. Therefore, interrupting or reversing hepatic fibrosis is very important in preventing cirrhosis. Semen *Astragali* (SA) is a tonic traditional Chinese medicine for liver and kidney. We previously reported that SA has a protective effect on liver[1]. Our further investigation has revealed that the flavonoids extracted from SA are useful in preventing rat liver fibrosis induced by dimethylnitrosamine (DMN)[2]. However, how *Astragalus complanatus* flavonoids (ACF) interrupt the formation of liver fibrosis remains unknown. This study was designed to observe the anti-liver fibrosis effect and mechanisms of DMN in rats.

MATERIALS AND METHODS

Materials

Astragalus complanatus (AC) was obtained from Leiyunshang Pharmaceutical Corporation (Suzhou, China) and identified by a chief pharmacist (Suzhou Drug Administration Bureau). Colchicine was obtained from Kunming Pharmaceutical Corporation (Kunming, China). DMN was purchased from Shanghai Chemical Company (Shanghai, China). All other chemicals were of analytical grade.

Preparation of ACF

After being extracted with ligarine, the seed powder of AC was extracted with 80% ethyl acetate (EtOH). The 80% EtOH extract was further subjected to ZTC-5 adsorptive resin (Nankai University) column and eluented with water, 50% and 95% EtOH to afford three fractions. The 50% EtOH fraction was dried under vacuum, recrystallized with EtOH and ACF was obtained as a yellow powder containing complanatuside, neocomplanatuside, myricomplanoside, rhomnocitrin-3-O-β-D-glucoside and astragalin, etc. The complanatuside content in ACF was about 20% by RP-HPLC and determined on a Shim-pack VP-ODS analytical column (4.6 mm×150 mm, 5 μm) with the mobile phase consisting acetonitrile-1% acetic acid (18:82) as eluent at the flow rate of 1 mL/min. The UV detection was set at 266 nm. The total ACF was 80%, determined at 266 nm by UV spectroscopy with complanatuside as a standard substance.

Animals

Sixty male Wistar rats weighing 130-160 g were housed in conventional cages with free access to water and rodent chow at 20-22 ℃ with a 12-h light-dark cycle. All procedures involving the use of laboratory animals were in accordance with National Institutes of Health Guidelines. Rat liver fibrosis was produced according to the established protocol[3]. Except for the normal group, rats in other groups were injected interperitoneally 5 g/L DMN (0.2 mL/100 g, thrice a week). Meanwhile, the rats were administered 30 mg/kg ACF-1, 60 mg/kg ACF-2, 120 mg/kg ACF-3 or 0.1 mg/kg colchicine, respectively, once a day for 1 mo. The doses of ACF and its course of treatment were based on a pilot experiment. The rats in the normal control group and DMN model group received saline by gavage instead of ACF. After 4 wk of ACF treatment, all rats were anesthetized, sera were collected and liver tissues were removed rapidly. Liver tissue samples were immediately rinsed in sterile saline, snap-frozen in liquid nitrogen, and stored at -70 ℃ until analysis.

MDA and SOD determination

The livers were homogenized at 100 g/L in cold saline at 0-4 ℃ using a glass-potter-type homogenizer at 500-800 r/min in ice. The homogenates were centrifuged at 100 000 *g* for 20 min at 4 ℃ to obtain supernatants of tissue homogenates. The resultant supernatants were immediately pipetted for measuring the content of malondialdehyde (MDA) and the enzymatic activity of superoxide dismutase (SOD) by the test kits. Data were expressed as nanomolar MDA per gram wet liver tissue and units SOD per milligram wet liver tissue.

PINP and PIIINP determination

Serum *N*-propeptide of type I procollagen (PINP) and *N*-propeptide of type III procollagen (PIIINP) were measured by ELISA (LIFEKEY BioMeditech Corporation).

Immunohistochemistry

Five-micrometer-thick sections of formalin-fixed and paraffin-embedded livers were processed routinely. Tissue inhibitor of metal protease-1 (TIMP-1) was stained with polyclonal antibody (Santa Cruz Biotechnology, Inc.). Briefly, sections were deparaffinized in xylene and hydrated in a series of graded alcohol, and endogenous peroxidase was blocked with 5% hydrogen peroxide. The sections were then incubated with primary antibodies (1:50) against TIMP-1 at 37 ℃ for 1 h, followed by incubation with goat anti-rabbit IgG conjugated-horseradish peroxidase (1:200). The signals were visualized by ABC immunostaining system. The images were captured and digitized with an image analysis system (Jieda 501, version 3.10). The TIMP-1 positive cell ratios were automatically evaluated. For each specimen at least five fields were analyzed at 20× magnification.

RT-PCR reaction

Semiquantitative RT-PCR with β-actin as internal control was performed to examine the expression of matrix metal protease-1 (MMP-1) mRNA. Total RNA was extracted from liver by TRIzol method (GIBCO specification). The first-strand cDNA was synthesized from the total RNA using 40 μL reverse transcription mixture containing 2 μg total RNA, 1.0 μg M-MLV reverse transcriptase (Promega) and random primers (Sangon, Shanghai), 10 mmol/L dNTP. Reverse transcription reaction was preformed at 37 ℃ for 1 h. At the end of reverse transcription, the mixture was heated at 95 ℃ for 5 min and immediately cooled in ice for 5 min.

PCR amplification was carried out with 2 μL cDNA product in a 40 μL reaction volume containing 10 pmoL of each specific oligonucleotide primer (Table 1), 10 mmol/L dNTP, and 2.5 IU Taq DNA polymerase. Amplification was performed for 30 cycles of denaturation (at 94 ℃ for 30 s), annealing (at 58 ℃ for 30 s), and elongation (at 72 ℃ for 50 s). PCR products were electrophoresed on 20 g/L agarose gel and visualized by ethidium bromide staining under UV light. This semiquantitative measure was expressed as ratios compared to β-actin.

Table 1 Primers for PCR amplification of MMP-1 and β-actin mRNA

Primer name	Primer sequence	Product Size/bp	GenBank acc. no.
MMP-1	Sense: 5′-tactagccaccgcttcttcc-3′ (192–211)	311	U53605
	Anti-sense: 5′-ggccagaaatagctgaatgc-3′ (483–502)		
β-actin	Sense: 5′-ctgtgcccatctatgagggt-3′ (485–504)	199	NM-031144
	Anti-sense: 5′-gccatctcttgctcgaagtc-3′ (664–683)		

Statistical analysis

All numerical data were expressed as mean±SD. Statistical analyses were done using the SPSS for Window release 11.0 (SPSS Inc., USA). The parameters were evaluated with one-way ANOVA and Dunnett's *t* test. $P<0.05$ was considered statistically significant.

RESULTS

Effect of ACF on MDA and SOD in liver tissue of rats

As shown in Figure 1A, the SOD activity decreased and the MDA content increased significantly in model group in comparison to those in normal group ($P<0.01$, $P<0.01$). However, the SOD activity in ACF groups increased and MDA contents decreased in comparison to those in model group ($P<0.01$).

Effects of ACF on PINP and PIIINP contents in rat serum

The serum PINP and PIIINP contents in ACF-2 and -3 group decreased ($P<0.05$, $P<0.01$) compared to those in model group (Figure 1B).

Expression of MMP-1 mRNA in rat hepatic tissue

There was no significant difference in expression of MMP-1 mRNA between normal group and model group. But the expression of MMP-1 mRNA in ACF groups tended to increase. In ACF-2 and -3 group, the expression of MMP-1 mRNA increased significantly as compared to that in model group (Figure 2).

TIMP-1 protein expression in rat hepatic tissue

The positive expressions of TIMP-1 protein were observed in all groups. In normal group, the mild expression was

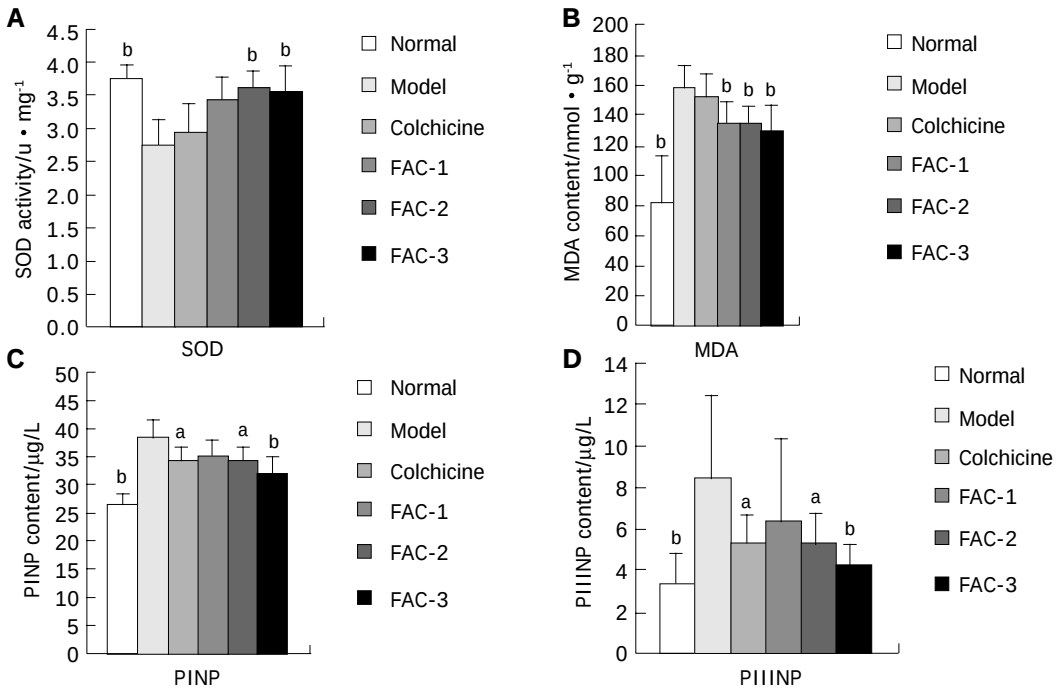

Figure 1 Effects of ACF on SOD activity and MDA content in rat liver tissue (A) and on PINP and PIIINP contents in rats serum (B). [a]$P<0.05$, [b]$P<0.01$ *vs* model group.

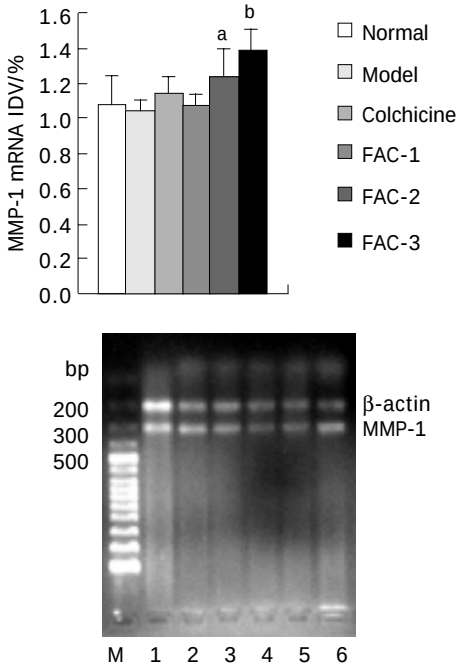

Figure 2 Analysis of MMP-1 mRNA expression in rat hepatic tissue. M: molecular weight markers (bp); lane 1: normal group; lane 2: model group; lane 3: colchicine group; lane 4: ACF-1 group; lane 5: ACF-2 group; lane 6: ACF-3 group; $n = 4$. [a]$P<0.05$, [b]$P<0.01$ *vs* model group.

presented in vascular endothelial cells and sinusoidal space. However, in model group the strong expression was noted around lobule median vein and in portal areas with a positive ratio of 8.84%. After the rats were treated with ACF, TIMP-1 protein expression decreased significantly ($P<0.01$, Figure 3).

DISCUSSION

Following chronic liver injury of any etiology, there is progressive fibrosis. The fibrotic process recognizes the involvement of various cells and different factors, leading to excessive fibrogenesis with disruption of intercellular contacts and interactions and of extracellular matrix composition[4-6]. However, hepatic stellate cells (HSCs), together with recruited mononuclear cells and Kupffer cells are by far the key players in liver fibrosis[7-10]. Their cross-talk is triggered and favored by a series of chemical mediators, with a prominent role played by the transforming growth factor beta. Both expression and synthesis of this inflammatory and pro-fibrogenic cytokine are mainly modulated through redox-sensitive reactions. Furthermore, involvement of reactive oxygen species and lipid peroxidation products can be clearly demonstrated in other fundamental events of hepatic fibrogenesis, like activation and effects of stellate cells, expression of metalloproteinases and their specific inhibitors[11-14]. Therefore, anti-oxidative stress can inhibit the process of fibrosis.

Liver fibrosis is characterized by the deposition of excess extracellular matrix (particularly collagen types I and III) in the liver. The aminoterminal procollagen type-I peptide and type-III peptide, which release during collagen types I and III deposition, have been suggested as serum markers of fibrogenesis[15-17]. Their concentrations in serum reflect the ongoing collagen formation in the liver. Extracellular degradation of matrix protein is regulated by MMPs produced by HSCs, which in turn are regulated by several mechanisms including regulation at level of the gene (transcription and proenzyme synthesis), cleavage of the proenzyme to an active form and specific inhibition of activated forms by TIMPs[18].

Extracellular degradation of matrix proteins is regulated by a family of enzymes known as MMPs[19-21]-types I, II,

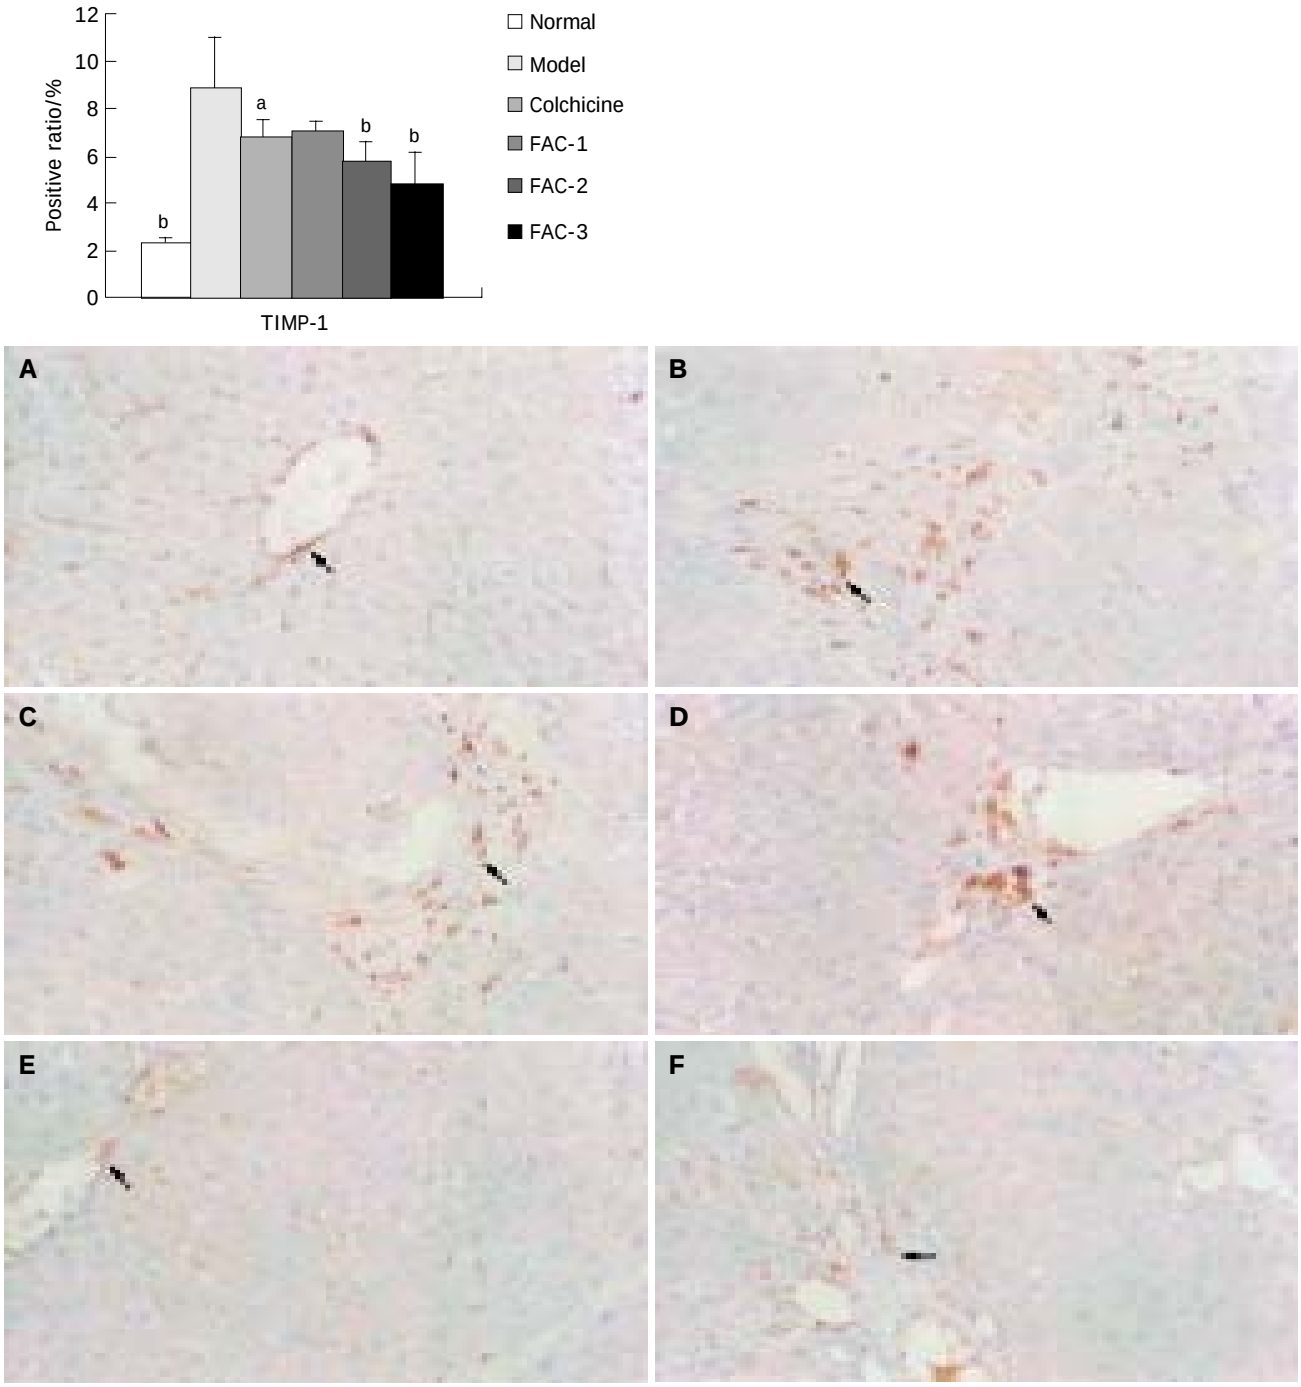

Figure 3 Immunohistochemical expression of TIMP-1 protein in rat hepatic tissue. (1) The positive ratio detected by Jieda 501 image-analysis system was used as the total protein expression. (2) TIMP-1 is shown as yellow grains in hepatic tissue (immunohistochemistry, ×200). A: normal group; B: model group; C: colchicine group; D: ACF-1 group; E: ACF-2 group; F: ACF-1 group; n = 5. $^{a}P<0.05$, $^{b}P<0.01$ *vs* model group.

and III collagenases degrade interstitial collagens. Type IV collagenases/gelatinases degrade basement membrane collagen and gelatins and stromelysins which degrade a broad range of substrates including proteoglycans, laminin, gelatins, and fibronectin. However, the activated forms of MMPs in turn are inhibited specifically by TIMPs, such as TIMP-1 and -2[22-26].

Based on this pathophysiological mechanism, therapeutic methods are developed to diminish collagen accumulation, stimulate the collagenolytic process, and/or inhibit stellate cell proliferation[27,28]. However, current therapies targeting at arresting or reversing liver fibrosis are largely ineffective and some have unacceptable side effects in long-term therapy. Recent clinical and experimental observations have demonstrated that Chinese medicines might be of some preventive and therapeutic values against fibrosis[29,30]. SA is a traditional Chinese medicine containing flavonoids, organic acids and triterpenoids, etc.[31]. It can protect animal livers against injury by CCl_4 and cirrhosis caused by DMN[1,2].

The present results indicate that ACF decreases the serum content of *N*-propeptide of types I and III procollagen,

elevates the activity of SOD and reduces the MDA content in DMN-treated rat hepatic tissue. In addition, the protein expression of TIMP-1 reduces and the MMP-1 mRNA expression increases in liver fibrosis rats with induced by DMN. The antifibrotic effect of ACF is associated with its influence on lipid peroxidation and collagen synthesis and degradation.

Abstract

AIM: To investigate the protective effects of *Astragalus membranaceus* (Am) against hapten-induced colitis in male Sprague-Dawley rats as well as its underlying mechanism.

METHODS: Experimental colitis was induced in rats by enema administration of 2,4-dinitrobenzene sulfonic acid (DNBS). Rats were either pretreated with Am extract (2 or 4 g/kg, p.o. once daily) starting from 10 d before DNBS enema, or received Am post-treatment (2 or 4 g/kg, p.o. twice daily) on the three consecutive days following DNBS administration. Colonic lesion area and histological damage were determined, while the activities of myeloperoxidase (MPO) and xanthine oxidase, as well as reduced glutathione (GSH) content were measured in the excised colonic tissues. Besides, protein expression of inducible nitrite oxide synthase (iNOS), intercellular adhesion molecule-1 (ICAM-1) and P-selectin was also detected by Western blot analysis.

RESULTS: Our findings had shown that both macroscopic lesion area and histological colonic damage induced by DNBS were significantly reduced by both Am pre- and post-treatments. These were accompanied by attenuation of the elevated colonic MPO activity and downregulation of the iNOS, P-selectin, and ICAM-1 protein expression. Besides, deprivation of colonic GSH level under colitis condition was also preserved.

CONCLUSION: These results demonstrate that Am possesses both preventive and therapeutic potential in experimental colitis. The anti-inflammatory actions involve anti-oxidation along with inhibition of adhesion molecule synthesis in the colonic tissues.

INTRODUCTION

Inflammatory bowel disease (IBD) consists of a group of idiopathic diseases of the intestine characterized by chronic inflammation of the bowel with periods of exacerbation and remission[1]. Moreover, patients with IBD have a higher risk of developing colorectal cancer than the general population[2]. There are two major categories of IBD, ulcerative colitis (UC) and Crohn's disease (CD), which are both histologically and clinically dissimilar. Despite the fact that etiology of IBD still remains poorly understood, complex interactions among genetic, environmental and immunological have been implicated in the pathogenesis of IBD[3,4]. In fact, activation of the central immune cell populations will lead to the production of a wide variety of non-specific mediators of inflammation, including cytokines, chemokines, growth factors, arachidonic acid metabolites (e.g. prostaglandins and leukotrienes) and reactive oxygen metabolites (ROM)[3,5]. In the past few decades, new chemotherapeutic agents such as 5-aminosalicylic acid, corticosteroids, immunosuppressive and immunoregulatory agents, antibiotics and probiotics, anti-tumor necrosis factor (TNF)-α, anti-inflammatory cytokines, and anti-intercellular adhesion molecule (ICAM)-1 therapy, etc., had been developed to tackle with these problems. However, none of them appeared to have been successful in achieving complete remission or preventing relapse, while some may even cause serious side effects.

Neutrophil infiltration in the extravascular space involves a complex sequence of interaction between circulating neutrophils and the vascular endothelium, including rolling, adhesion and transendothelial migration. Myeloperoxidase (MPO) is an enzyme mainly found in azurophilic granules of neutrophils. It is a good marker of neutrophil infiltration in gastrointestinal tissues[6], as well as inflammation and tissue injury. Besides, significant amounts of superoxide can be generated by a variety of endogenous enzyme systems such as the peroxisomal enzyme xanthine oxidase (XO) following tissue ischemia. XO activity is often increased in intestinal inflammation through the induction by TNF-α and activated neutrophils[7]. It has been suggested that XO is a significant source of superoxide in the inflammation of IBD[8]. Nonetheless, the concentrations of endogenous antioxidants, such as reduced glutathione (GSH), alpha-tocopherol and

cysteine, are all significantly decreased in IBD patients. As a result, the balance between antioxidants and ROM becomes seriously impaired[9,10]. Most currently used therapeutic drugs for IBD, in particular sulfasalazine and its active moiety 5-aminosalicylic acid, control the disease partly by their property as potent ROM scavengers[11].

Nitric oxide (NO) will react with superoxide to form peroxynitrite, which is a highly cytotoxic oxidant[12]. Inducible nitrite oxide synthase (iNOS) is the inducible form of the enzyme responsible for the synthesis of pro-inflammatory NO, which is mainly induced in the infiltrated inflammatory cells, such as neutrophils, macrophages and mononuclear cells by stimulants such as cytokines[13]. Several studies had shown that NO production and iNOS activity were increased in colonic mucosa from UC and CD patients[14]. Immunohistochemical studies also indicated that iNOS was localized in neutrophils, macrophages and epithelial cells in the active area of the inflamed colon in UC patients[15]. Other than NO generated by the iNOS isozyme, leukocytes migration in IBD patients also requires the interaction between different cell adhesion molecules[16]. They are surface bound glycoprotein molecules on endothelial cells that are essential for the capture and migration of leukocytes. P-selectin and ICAM-1 are adhesion molecules which are essential for migration of leukocytes from the blood stream into the inflamed tissue. P-selectin captures circulating leukocytes in the early extravasation process, while ICAM-1 is involved further in the migration of leukocytes across the connective tissue in the lamina propria, and in the interaction between leukocytes and epithelial cells[17]. Furthermore, P-selectin is susceptible to be activated by endotoxin and cytokines[18]. Semiquantitative analyses have shown that P-selectin expression was significantly increased in both UC and CD patients, primarily expressed on venules and capillaries near the small lymphocyte aggregates[19,20]. Moreover, the elevated P-selectin and ICAM-1 levels could persist for more than 48 h in the colonic tissues after a single stimulus.

Astragalus membranaceus (Am, Fisch.) Bge. *var mongholicus* (Bge.) Hsiao or (Fisch., Am), also called Huang-qi in Chinese, is the dried root of a perennial herbaceous plant. It is an important "tonifying" herb being prescribed to strengthen body defense against pathogenesis and to promote the discharge of pus as well as tissue restitution. Traditional herbal formulations containing Am can be used to treat chronic ulceration and sores[21], mellitus diabetes and albuminuria in chronic nephritis, etc.[22]. Rats injected with the herb extract (0.5 g/kg, i.p.) for 1 mo had not been developing abnormalities[23]. Two groups of bioactive chemicals have been isolated from Am, which are polysaccharides (i.e. astragalan I-III) and saponins (i.e. astragalosides I-VIII, acetylastragaloside I, isoastragalosides I-II and soyasaponin I), respectively. Besides, about 0.18-2.0% of *Astragalus* root consists of coumarin and flavonoid derivatives[24]. These compounds are capable of minimizing free radical damage to membranes by inhibiting lipid peroxidation[25] and by protecting the intestinal endothelium[26]. There had been a number of clinical studies on the treatment of IBD using herbal formulations with Am as leading drug, with results ranging from the relief of symptoms to the prevention of UC recurrence with increased serum superoxide dismutase activity (anonymous Chinese case reports). However, there is no experimental or clinical study about the sole effect of Am on IBD.

The present investigation aimed to determine the preventive and therapeutic effects of Am extract on experimental colitis induced by 2,4-dinitrobenzene sulfonic acid (DNBS), and to delineate the underlying anti-oxidation mechanisms and modulation of colonic synthesis of inflammatory mediators and adhesion molecules.

MATERIALS AND METHODS

Animals and treatments

Male Sprague-Dawley rats, weighing 180-200 g, were acclimatized under constant temperature (22±1 ℃) and humidity (40-45%) with 12-h light-dark cycles for 10 d before experimentation. Groups of six animals each were housed in rack-mounted wire cages. They were reared on a standard laboratory diet (Purina, USA), and given tap water *ad libitum*. Both body weight and food intake of the rats were measured daily throughout the entire experimental period. In addition, the appearance of stools (normal, loose/watery, or bloody) was also observed as part of index to determine disease activity.

Animals were anesthetized with a mixture of 75 mg/kg ketamine and 10 mg/kg xylazine (Alfasan, the Netherlands) intraperitoneally before colitis induction. Following this, 250 μL of 500 mL/L ethanol containing 30 mg of DNBS dihydrate (Aldrich, USA) was slowly infused into the lumen of the colon through a siliconized catheter (12 cm long, 2-mm external diameter) inserting to an 8-cm position proximal to the anus. Animals of the normal untreated group (normal) received enema saline administration. The entire infusion process took approximately 10 s to complete, with the catheter remaining inside the colonic lumen for 5 min before the withdrawal in order to prevent possible leakage.

The concentrated powder of Am was obtained from Purapharm (Hong Kong) and was used throughout the entire experiment. The herbal compound was extracted from the dried roots of Am (Fisch.) Bge. var. *mongholicus* (Bge.) Hsiao, and was manufactured under Good Manufacturing Practice standard. A pilot study was undertaken to determine the dose-response relationship of the herbal extract prior to the actual investigation. It was found that 2 and 4 g/kg are being optimal pharmacological doses for the anti-inflammatory action against experimental colitis formation. Groups of rats received oral pre-treatment of the concentrated Am extract (2 or 4 g/kg in 10 mL/kg tap water) once daily for 10 d prior to DNBS induction. Alternatively, other groups of animals received oral Am treatment (2 or 4 g/kg in 10 mL/kg tap water) twice daily on the three consecutive days following DNBS induction. Control animals (control) received oral administration of normal drinking water instead. All animals were killed by intraperitoneal injection of 100 mg/kg of ketamine, followed by cervical dislocation, at 4 d after colitis induction. This time was chosen on the basis that development of acute inflammation arrives at peak level in DNBS-evoked colitis, whereas active tissue repair and regeneration begins afterwards[27].

Assessment of macroscopic colonic lesion area and inflammation

The entire segment of the colon from the rectum to the cecocolic junction was removed, opened and rinsed thoroughly with normal saline. The isolated colon was examined for the presence of gross macroscopic damage and inflammation. Lesion area was recorded by tracing onto a plastic transparency, and measured by using 1-mm^2 grids. Macroscopic lesion area was represented in square millimeter. Other disease activity index was also measured, including the ratio of colon weight to body weight, which was used as a parameter to assess the degree of tissue edema and reflects the severity of colonic inflammation. Moreover, a 6-8-mm sample block of the inflamed colonic tissue with the full thickness was excised from a region of grossly visible damage for histological analysis, while the remaining colonic segment was pulverized and stored at -80 ℃ for subsequent assays.

Histological study of the colonic tissue

After 48 h of 10% buffered formalin fixation, the excised tissue block was processed for histological analysis. After fixation, tissues were dehydrated by a 4-h successive immersion in ethanol and cleared with xylene for 45 min. The specimens were then immersed in melted paraffin at 80 ℃ for 3½ h for embedment into a cast. Six-micrometer sections were sliced with a microtome (Leica RM2135, Germany) and prepared on Vectabond-coated glass slides. The slides were then processed for subsequent staining. After hydration, the processed sections were immersed into periodic acid for 5 min. The sections were then dipped in Schiff's reagent for 5 s. After rinsing in running tap water and washed with distilled water, the tissue sections were dipped into Harris' hematoxylin for 3 s and rinsed in running tap water (for a few seconds) and washed with distilled water. Following hematoxylin counter-staining, tissues on slides were dehydrated and finally mounted in Permount (Sigma, USA). Colonic tissues were scored for histological damage using the criteria of Wallace and Keenan: 0=intact tissue with no apparent damage; 1 = damage limited to surface epithelium; 2 = focal ulceration limited to mucosa; 3=focal, transmural inflammation and ulceration; 4 = extensive transmural ulceration and inflammation bordered by normal mucosa; 5 = extensive transmural ulceration and inflammation involving entire section[28].

Measurement of MPO activity in the colonic tissue

MPO activity is used as a quantitative index of inflammation and a marker of neutrophil infiltration in the tissue[29]. MPO activity was measured by a modified method described by Suzuki and co-workers[30]. Pre-weighed colonic tissues were homogenized with a homogenizer (IKA Labortechnik T25 basic, Germany) in ice-cold 50 mmol/L PBS (pH 6) containing 0.5% hexadecyl-trimethylammonium bromide and 0.336% EDTA (9 μL/mg tissue) for 30 s. The homogenized samples were freeze-thawed and sonicated for 20 s thrice, and then centrifuged at 30 000 *g* (Beckman coulter, Avanti™ J-25I, USA) for 20 min at 4 ℃. Following this, 20 μL of resulting supernatant with dilution by 80 mmol/L PBS (pH 5.4) was mixed with 7.5 μL of 2 mmol/L 3, 3', 5, 5'-tetramethylbenzidine dissolved in 80 mL/L *N*,*N*-dimethylformamide and 2.5 μL of 0.3 mol/L hydrogen peroxide. The final mixture was incubated at 25 ℃ for 25 min. Finally, 125 μL of 0.5 mmol/L sulfonic acid was added to stop the reaction. The end-point absorbance of the mixture was measured at 450 nm in a spectrophotometer (Packard, Fusion™, Canada) using horseradish peroxidase (HRP, Sigma, UK) as standard. The final value of MPO activity was represented as unit per milligram protein.

Measurement of XO activity in the colonic tissue

One unit of XO activity is defined as that could convert 1 μmoL of xanthine to uric acid per min at pH 7.5 and 25 ℃. The XO activity assay was modified from the method of Parks and co-workers[31]. Colonic tissues were homogenized in the 50 mmol/L sodium phosphate buffer (pH 7; 3 μL/mg tissue) containing 0.1 mmol/L EDTA-2Na, 10 mmol/L dithioerythritol and 1 mmol/L phenylmethyl sulfonyl fluoride (PMSF) for 30 s. The mixture was centrifuged at 20 000 *g* (Beckman coulter, Avanti™ J-25I, USA) for 15 min. Then, 12 μL of the supernatant was mixed with 1 mmol/L xanthine (Sigma, UK), 2 mmol/L EDTA-2Na, 200 μg/mL of bovine saline albumin (BSA) and 50 mmol/L of $NaPO_4$ buffer. The mixture was incubated at 25 ℃ for 5 min. Finally, the reaction was terminated by the addition of 400 μL of 0.5 mol/L HCl. XO activity was assessed spectrophotometrically by measuring the absorbance at 295 nm (Packard, Fusion™, Canada). The final values of XO were expressed as milliunit per milligram protein.

Measurement of GSH level in the colonic tissue

The amount of GSH in colonic tissues was determined following the procedures of Cho's research team[32]. Colonic tissues were homogenized in ice-cold 125 mmol/L sodium phosphate buffer with 6.3 mmol/L EDTA (pH 7.5, 3 μL/mg tissue) for 30 s. The crude homogenate was centrifuged (Beckman coulter, Avanti™ J-25I, USA) at 30 000 *g* at 4 ℃ for 30 min. Then, 200 μL of 40 g/L sulfosalicylic acid was added to 100 μL of supernatant and allowed to stand on ice for 5 min to precipitate protein. The mixture was centrifuged again at 5 000 r/min (Eppendorf centrifuge, model 5417R, Germany) at 4 ℃ for 10 min. Subsequently, 100 μL of the de-proteinized supernatant was mixed well with 300 μL of 125 mmol/L sodium phosphate buffer (pH 8) and 2 μL of 10 mmol/L 5,5' dithiobis-(2-nitrobenzoic acid). The solution was allowed to stand at room temperature for 15 min to develop a yellow color. The absorbance was then read against the reagent blank at 412 nm in a spectrophotometer (Packard, Fusion™, Canada). A standard curve of reduced GSH (Sigma, UK) was used for the calculation of the concentration of GSH in the colonic tissues. The final values were expressed as nanomole per milligram protein.

Measurement of protein concentration in the colonic tissue

Total protein contents of the colonic samples were determined for a series of Western blot analyses. Colonic tissues were weighed and homogenized for 30 s at 4 ℃ in RIPA lysis buffer (50 mmol/L Tris, 150 mmol/L NaCl, 0.5% deoxycholate, 0.1% sodium dodecyl sulfate (SDS), 2 mmol/L EDTA, 1% Triton X-100 and 10% glycerol)

with 1 mmol/L PMSF, aprotinin (5 mg/mL), and pepstatin A (5 mg/mL) added freshly. The sample was then centrifuged at 13 000 *g* for 20 min and the resulting supernatant was collected. Five microliters of tissue sample supernatant was diluted with normal saline. Seventy-five microliters of a 1 000× diluted sample was mixed with 75 μL of Coomassie Plus Reagent (Pierce, UK). The mixture was then incubated at room temperature for 10 min. The samples' absorbance was measured at 595 nm by a spectrophotometer (Packard, Fusion™, Canada). The stock concentration of the standard protein BSA was made up to 100 μg/mL. A standard curve in the range of 0-25 μg protein was used for the calculation of the protein concentration present in the colonic tissue. The results are used to quantify the protein sample for electrophoresis in Western blotting and act as a unit of the biochemical assays.

Analysis of the protein expressions of iNOS, P-selectin, and ICAM-1 in the colonic tissue

The protein samples (ICAM-1: 50 μg of total protein; P-selectin and iNOS: 200 μg of total protein) were denatured and separated on 10% SDS-polyacrylamide gel electrophoresis, and then transferred to nitrocellulose membrane (Bio-Rad, USA). The membranes were blocked in blocking solution (5% skim milk powder in TBST containing 0.2 mol/L Tris, 1.37 mol/L NaCl, 1 mol/L HCl, and 0.1% Tween 20) for 30 min at room temperature. Subsequently, it was incubated in a 4 ℃ cold room overnight with the primary antibodies (anti-ICAM-1, anti-P-selectin, anti-iNOS; all in the dilution of 1:1 000) diluted in blocking solution. Membranes were washed six times and incubated with the secondary antibody (HRP-goat anti-rabbit IgG (H+L) conjugate; 1:5 000) in blocking solution for 45 min at room temperature. All antibodies were obtained from Santa Cruz, USA. Protein blots were developed by a chemiluminescence ECL Western blotting detection system (Amersham, USA). The protein bands were visualized by autoradiography using X-ray film (Fuji, Japan) and analyzed by the Bio-Rad Image Analysis System (USA).

Statistical analysis

Results were expressed as mean±SE. Differences between two groups were examined using the one-way analysis of variance (ANOVA) followed by the Dunnett's test. A *P*-value of less than 0.05 was considered significantly different.

RESULTS

Alleviation of DNBS-induced colitis by Am extract

Gross macroscopic observation had demonstrated that administration of DNBS resulted in mucosal lesion formation and inflammation in the distal colonic wall. There was also a drastic drop in body weight of the DNBS-induced rats. The animals also appeared to have diarrhea, soft stool, and rectal bleeding (in the first 2 d after colitis induction). Besides, ratio of the distal colon weight to animal body weight was also markedly increased due to tissue edema. Hyperemia of mesenteric arteries and fibrinous adhesion to other bowel tissues were frequently observed. Figure 1A shows that there was a significant reduction in macroscopic lesion area by both Am pre- and post-treatments in a dose-dependent manner. Microscopically, colonic tissues in all Am-treated groups had demonstrated significant reduction in histological damage scores (Figure 1B), as represented by well-organized mucosal architecture and less infiltrated leukocytes in the mucosal and submucosal layers of the inflamed colon. This was in contrast with the extensive morphological disorientation and generalized glandular disruption in the colonic tissues of the DNBS control group. These implicated that colonic protection produced by Am extract can be achieved at the histological level.

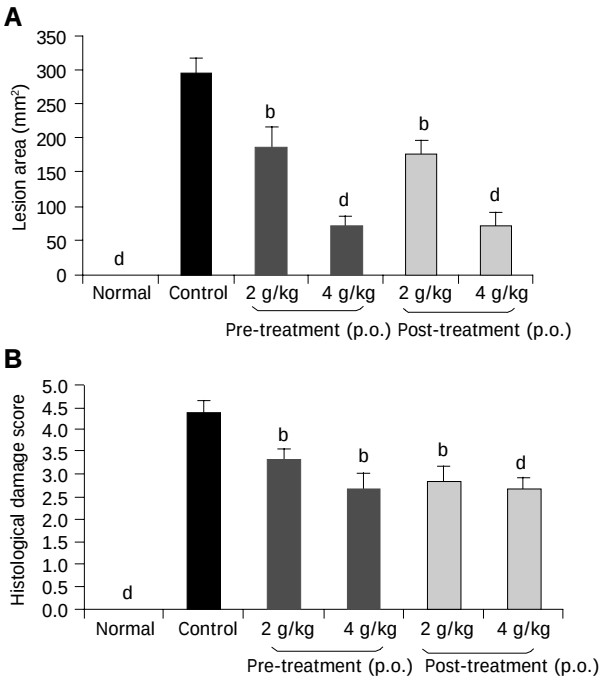

Figure 1 A: Effect of oral *Astragalus* extract (Am) treatment (2 or 4 g/kg) on DNBS-induced lesion formation in rat colon. Animals were either pre-treated with Am once daily for 10 d from 1 d after DNBS induction, or received Am post-treatment twice daily on the three consecutive days following DNBS induction. Control animals (control) received oral administration of normal drinking water only. Animals without colitis induction or drug treatment were regarded as normal animals (normal). All animals were killed 4 d after DNBS administration. Values are mean±SE (n = 6). ^{b}P<0.01, ^{d}P<0.001 *vs* control; B: Effect of oral *Astragalus* extract (Am) treatment (2 or 4 g/kg) on DNBS-induced histological damage score in rat colon. Animals were either pre-treated with Am once daily for 10 d from 1 d after DNBS induction, or received Am post-treatment twice daily on the three consecutive days following DNBS induction. Control animals (control) received oral administration of normal drinking water only. Animals without colitis induction or drug treatment were regarded as normal animals (normal). All animals were killed 4 d after DNBS administration. Values are mean±SE (n = 6). ^{b}P<0.01, ^{d}P<0.001 *vs* control.

Effects of Am extract on colonic activities of the oxidative enzymes MPO and XO and on content of the anti-oxidative enzyme GSH in inflamed colonic tissue

MPO activity was dramatically increased in the colonic tissue after DNBS administration (Figure 2A). Both Am pre- and post-treatments significantly reduced the elevated colonic MPO activity. The attenuating effect of Am on colonic MPO activity was consistent with its colonic protective actions both macroscopically and histologically (Figures 1A and B). Besides the MPO pathway, ROM can also be

generated through XO-catalyzed reactions. Nevertheless, there was no significant change in colonic XO activity after DNBS induction of colonic damages. Likewise, Am treatments also caused no alteration in XO activity. Therefore, it appeared that XO has no involvement in the pathogenesis of DNBS-induced colitis as well as in the mode of action of Am extract.

Figure 2B shows the effect of Am extract on the depletion of one of the key components of antioxidant defenses in the intestine, GSH. GSH concentration in the colonic tissue was dramatically decreased after DNBS enema. Pre- and post-treatment of Am (4 g/kg) significantly preserved the deprivation of the GSH level under colitis condition. The preservation of GSH in the colon by Am treatments could indeed strengthen the colonic defensive mechanism and thus reduce the susceptibility to tissue injury.

Effects of Am extract on protein expression of the pro-inflammatory enzyme iNOS, and adhesion molecules ICAM-1 and P-selectin in inflamed colon

There was a significant upregulation of colonic iNOS protein expression following DNBS administration. Such overexpression was attenuated by both Am pre- and post-treatments (Figure 3A). Similarly, the protein expression of both P-selectin and ICAM-1 was also dramatically upregulated under colitis condition (Figures 3B and C). Although there was a dose-dependent diminution of the P-selectin overexpression in all Am treatment groups (Figure 3B), only pre-treatment with 4 g/kg of Am was capable of inhibiting the elevated ICAM-1 protein expression in the colitic tissue, with no significant effect observed in other treatment groups (Figure 3C).

DISCUSSION

In the present study, DNBS was administrated intracolonically to stimulate cell-mediated immunity in rats[33]. This hapten molecule produces acute and chronic colonic inflammation as well as ulceration in rats[34]. Besides, the histopathologic

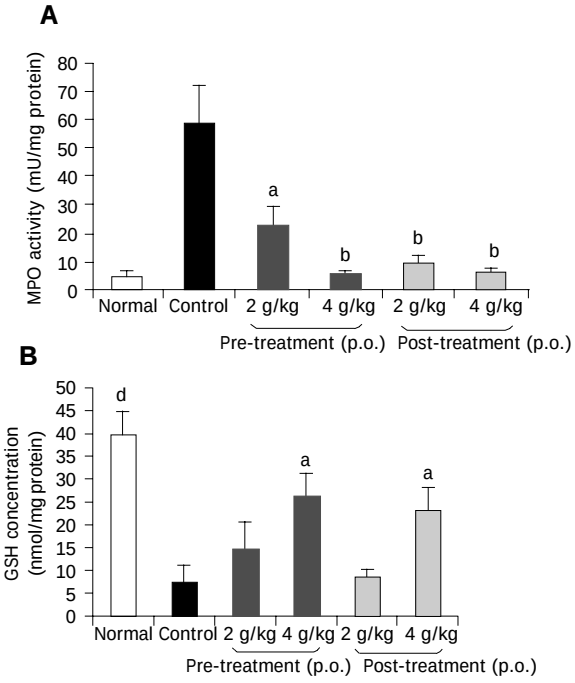

Figure 2 A: Effect of oral *Astragalus* extract (Am) treatment (2 or 4 g/kg) on MPO activity in rat colon. conditions have more features in common with human UC than with CD. The use of natural immunomodulatory and anti-oxidative products provides an innovative and relatively non-toxic/less toxic alternative to modulate inflammatory disorders, including IBD. Am had exhibited marked antioxidant and immunomodulatory properties in both clinical and experimental studies. However, there is a lack of information regarding its effect on intestinal inflammatory disorders and the associated mechanism of action. The current study is the first one of its kind to demonstrate the effect of Am on experimental colitis. Our findings had indicated that DNBS could lead to a considerable degree of inflammation and tissue injury in the rat colon, with the concomitant infiltration of neutrophils into the colonic tissues. These were reflected by significant colonic lesion formation, high score in histological damage grading, as well as elevated MPO activity in the DNBS-induced animals. Such detrimental effects were alleviated by either pre- or post-treatment of oral Am.

The main pathological feature of IBD is an infiltration of polymorphonuclear neutrophils and mononuclear cells into the intestinal tissues. Neutrophils and monocytes migration is in turn triggered by chemotactic bacterial cell wall products and locally produced cytokines[35,36]. The neutrophil-generated ROM such as superoxide anions, hydrogen peroxide, *N*-chlorinated derivatives, as well as the release of granule enzymes[37] are responsible for the endothelial cell damage. Sedghi and co-workers reported the increase of chemiluminescence in inflamed colonic mucosa and suggested that neutrophils are the likely cellular sources of ROM in the inflamed colon in UC patients[38]. MPO activity was significantly increased and correlated with laboratory parameters and endoscopic grade of inflammation in stool from IBD patients[39]. Besides, MPO conversion of hydrogen peroxide to hypochlorus acid seems closely related to ROM-mediated tissue injury[38]. ROM can be generated through two pathways. The first one is via NADPH oxidase activation in the infiltrated neutrophils, which induces the release of large amount of ROM and oxidants derived from MPO[37]. Alternatively, the other pathway acts through XO induction after periods of hypoxia[40]. In this study, MPO-catalyzed reaction was found to be activated after DNBS administration and attenuated by Am treatments. However, induced production of ROM and reduction of oxidative damage caused by Am did not seem to act through the XO pathway. This result is consistent with a clinical study illustrating that colonic XO activity was not elevated in UC patients[41]. In fact, it had been suggested that XO may not be a major source of superoxide and ROM production in UC[42]. The data presented here actually implicates that the anti-oxidative effect of Am mainly involves the modulation of MPO in the inflamed colon.

The imbalance of ROM generation and antioxidant defense in the colon is an important contributor to the initiation and maintenance of inflammation in IBD[43]. Reduced colonic GSH level is crucial in inducing inflammatory changes. The decrease in colonic GSH concentration following colitis induction could be due to over-production of ROM that deplete GSH by inhibiting the synthetic enzymes for GSH production in the colonic tissue[44]. In the present study, depletion of GSH was significantly preserved by Am, with concurrent attenuation of the elevated MPO activity. This finding implicates that Am could maintain the free radical-scavenging ability of the colonic defense system. Consequently, this diminishes the burden of colonic ROM accumulation (e.g. superoxide), and could further improve the imbalance between ROM and endogenous antioxidants. It is implicit that Am exhibits anti-oxidative activities in several ways, including the inhibition of oxidative stress due to lipid peroxidation and protein oxidative modification, as well as direct removal of free radicals[45]. Among different Am constituents, the total flavonoids appear to possess the strongest free radical-scavenging potential, while total saponins and polysaccharides are somewhat weaker free radical-scavenging agents. In addition, *Astragalus* polysaccharides could modify the increase in malondialdehyde content and diminution of GSH level in the liver of *E-coli* endotoxin-induced rats, and is capable of antagonizing the reduction of GSH peroxidase and superoxide dismutase activities in spleen, thymus and intestinal lymph nodes of traumatic rats[46].

Our findings had demonstrated that iNOS protein expression was significantly upregulated in the colonic tissue after DNBS enema, which was attenuated by oral Am administration. iNOS synthesis can be induced by pro-inflammatory cytokines or bacterial toxins in a variety of cells such as neutrophils, macrophages, endothelial cells and enterocytes, etc.[47]. Therefore, the reduction of neutrophil infiltration, as indicated by the decrease of MPO activity during the anti-inflammatory action of Am, may contribute at least partly to the alleviating effect of Am on iNOS expression in the colonic tissue. Elevated iNOS expression will result in the production of a huge amount of colonic inflammatory NO radicals. Increased production of NO as a result of the overexpression of iNOS protein and mRNA had been demonstrated in affected areas of the intestine in patients suffering from UC or CD[14]. Overwhelming production of iNOS-produced NO causes mucosal vasodilation and modulation of intestinal water and electrolyte transport, which together increase vascular permeability[48]. One of the underlying mechanisms of NO in inducing colonic toxicity involves the interaction with superoxide to produce peroxynitrite, a potent oxidant that can initiate membrane lipid peroxidation, sulfhydryl oxidation of proteins and nitration of acromatic amino acids[29]. In turn, peroxynitrite was found to inhibit superoxide production in a dose-dependent manner[49]. Together with our findings concerning GSH level, Am treatment could reduce superoxide and NO production by preservation of GSH and attenuating iNOS protein expression. As a result, these actions could reduce peroxynitrite formation and in turn diminish the damaging effect of DNBS-induced colonic injury. In addition, it is possible that hydroxyl radicals could be formed by the interaction of NO and hydrogen peroxide[50], which was prevented by Am through inhibition of iNOS synthesis.

Gene expression of cell adhesion molecules is induced by pro-inflammatory cytokines and lipopolysaccharide, such as the cytokines TNF-α, interleukin (IL)-1 and interferon (IFN)-γ[51]. P-selectin was considerably increased in the

colonic endothelium early after colitis induction, which could last for at least 3 wk[52]. In this study, protein expression of P-selectin and ICAM-1 was significantly upregulated after DNBS induction, leading to continuous influx of leukocytes to maintain the local inflammation. Both Am pre-treatment and post-treatment significantly downregulated the protein expression of P-selectin, while ICAM-1 expression was only significantly inhibited in the 4 g/kg Am pre-treatment group. In general, these findings suggest that Am could reduce neutrophil infiltration into colonic tissues through the attenuation of P-selectin and ICAM-1 synthesis evoked by DNBS. Moreover, the subsequent attenuation of MPO activity could further lead to reduction of iNOS synthesis and ROM production. In the study of McCafferty's group, increased P-selectin expression was observed 3 d after induction of acetic acid induced colitis[53]. Moreover, Jones and co-workers reported that there was local upregulation of ICAM-1 in UC and CD patients[54]. ICAM-1 will be manifested during the early inflammatory status of the intestine, while P-selectin expression can only be detectable in a slightly later stage. It is imminent that ICAM-1 plays a pivotal role in determining the initial inflammatory events, while P-selectin will be manifested later in time and is responsible for the maintenance of such responses. Am pretreatment actually prepared the colonic mucosa for subsequent insult by suppressing ICAM-1 synthesis. Nevertheless, after colitis was induced, Am could no longer be capable of inhibiting ICAM-1 production as the inflammatory reactions had already been started.

In conclusion, the results of the present study have shown that Am have both preventive and therapeutic potential in experimental colitis by its modulation of inflammatory mediators and anti-oxidation. It could significantly inhibit P-selectin and ICAM-1 protein expression, attenuate neutrophil infiltration and iNOS synthesis, as well as preserve the deprivation of GSH in colonic tissue following DNBS challenge. Our findings indeed open up a new avenue in deriving new chemotherapeutic strategies against IBD.

Abstract

AIM: To study the protective effects and mechanisms of Se-enriched lactobacillus on liver injury caused by carbon tetrachloride (CCl_4) in mice.

METHODS: Seventy-two ICR mice were randomly divided into four groups: normal group, CCl_4-induced model group, low Se-enriched lactobacillus treatment group (L-Se group), and high Se-enriched lactobacillus treatment group (H-Se group). During a 3-wk experimental period, the common complete diet was orally provided daily for normal group and model group, and the mice in L-Se and H-Se groups were given a diet with 2 and 4 mg of organoselenium from Se-enriched lactobacillus per kg feed, respectively. From the 2nd wk of experiment, the model group, L-Se group, and H-Se group received abdominal cavity injection of olive oil solution containing 500 mL/L CCl_4 (0.07 mL/100 g body mass) to induce liver injury, and the normal group was given olive oil on every other day for over 2 wk. In the first 2 wk post injection with CCl_4, mice in each group were killed. The specimens of blood, liver tissue, and macrophages in abdominal cavity fluid were taken. Then the activities of the following liver tissue injury-associated enzymes including glutathione peroxidase (GSH-Px), superoxide dismutase (SOD), alanine aminotransferase (ALT) and aspartate aminotransferase (AST) as well as malondialdehyde (MDA) content were assayed. Changes of phagocytic rate and phagocytic index in macrophages were observed with Wright-Giemsa stain. Plasma TNF-α level was measured by radioimmunoassay. The level of intracellular free Ca^{2+} ($[Ca^{2+}]_i$) in hepatocytes was detected under a laser scanning confocal microscope.

RESULTS: During the entire experimental period, the AST and ALT activities in liver were greatly enhanced by CCl_4 and completely blunted by both low and high doses of Se-enriched lactobacillus. The Se-enriched lactobacillus-protected liver homogenate GSH-Px and SOD activities were higher or significantly higher than those in model group and were close to those in normal group. CCl_4 significantly increased MDA content in liver homogenates, while administration of Se-enriched lactobacillus prevented MDA elevation. Phagocytic rate and phagocytic index of macrophages decreased after CCl_4 treatment compared to those in normal control, but they were dramatically rescued by Se-enriched lactobacillus, showing a greatly higher phagocytic function compared to model group. CCl_4 could significantly elevate plasma TNF-α and hepatocyte $[Ca^{2+}]_i$ level, which were also obviously prevented by Se-enriched lactobacillus.

CONCLUSION: Se-enriched lactobacillus can intervene in CCl_4-induced liver injury in mice by enhancing macrophage function activity to keep normal and beneficial effects, elevating antioxidant-enzyme activities and reducing lipid peroxidation reaction, inhibiting excessive release of TNF-α, preventing the dramatic elevation of $[Ca^{2+}]_i$ in hepatocytes.

INTRODUCTION

Hepatic fibrosis represents the response of the liver to diverse chronic insults such as parasitic disease, chronic viral infection (hepatitis B and C), immunologic attack (autoimmune hepatitis), hereditary metal overload, toxic damage, etc. Because of the worldwide prevalence of these insults, liver fibrosis is a common pathological process of hepatic disease, leading to the development of irreversible cirrhosis[1,2]. If treated properly at fibrosis stage, cirrhosis could be prevented[3]. However, there are no effective anti-fibrosis drugs till date. Selenium (Se), an essential nutrient element, can prevent the malignant transformation of normal cells and the activation of oncogenes with anticarcinogenic effects within a physiological dosage range[4,5]. It has been found in clinical investigations that the blood selenium of hepatocarcinoma patients is

low, and the progress of liver injury and carcinomatous change are related to the degree of selenium deficiency[6]. In addition, some studies indicate that selenium is closely related to the inhibition of hepatic fibrosis[7,8]. However, the supplement of selenium is relevant to selenium style and dosage[5]. Se-enriched lactobacillus is an organoselenium agent. We have demonstrated that concomitant Se-enriched lactobacillus administration to mice and rats subjected to CCl_4-induced liver injury results in a reliable hepatoprotection against hepatic damage, as well as an effective action on enhancing peripheral blood lymphocyte proliferation activity and RBC immune function[9,10]. Therefore, the aim of this study was to further evaluate the beneficial action of Se-enriched lactobacillus on reversing a well-established liver injury and the possible mechanisms by analyzing the activities of several liver tissue injury-associated enzymes, phagocytic function activities in macrophages, plasma TNF-α level and change of hepatocyte intracellular free Ca^{2+} $[Ca^{2+}]_i$ homeostasis.

MATERIALS AND METHODS

Preparation of a complete diet with Se-enriched lactobacillus

Lactobacillus was grown to a density of 5.88×10^7/mL in a medium containing sodium selenite to obtain Se-enriched lactobacillus. The Se-enriched lactobacillus was then processed into an organoselenium agent with 11.45 mg of selenium/g, then mixed into the common complete feed to produce the palletized complete diet with 2 and 4 mg of organoselenium/kg feed according to compound feed processing method in a feed processing plant.

Animals

Seventy-two ICR mice, equal number of males and females, weighing 27.74±0.37 g, were obtained from Experimental Animal Center of Nanjing Medical University, China. The mice were housed at room temperature (20-25 ℃) in a 12-h light and dark cycle. Free access to water and food was allowed during the experimental period. All mice were randomly divided into four groups: normal control group (n = 18), model control group (n = 18), low Se-enriched lactobacillus treatment group (L-Se group, n = 18), and high Se-enriched lactobacillus treatment group (H-Se group, n = 18). During a 3-wk experimental period, the common complete diet was orally provided daily for normal group and model group, and the mice in L-Se and H-Se groups were given a diet with 2 and 4 mg of organoselenium from Se-enriched lactobacillus/kg feed, respectively. In the 2nd wk of experiment, hepatic injury was induced in mice by carbon tetrachloride (CCl_4). The mice in model group, L-Se and H-Se groups were given abdominal cavity injection of olive oil solution containing 500 mL/L CCl_4 (0.07 mL/100 g body mass) every other day for over 2 wk. The mice in normal group received abdominal injection of olive oil at the same dose and frequency.

Phagocytic function detection of macrophage

The macrophage activities were observed in six mice of each group in the first 2 wk post injection with CCl_4. The mice received abdominal cavity injection of 1 mL saline suspension containing 5% chicken's erythrocytes, followed by 1 mL saline after 1 h. Abdominal cavity fluid was collected from the killed mice and incubated for 30 min at 37 ℃, then centrifuged at 1 000 r/min for 10 min to obtain the remaining deposit for smearing and staining with Wright-Giemsa stain. The phagocytic rate and phagocytic index of macrophages were counted under a light microscope.

Collection of specimens

In the first 2 wk post injection with CCl_4, six animals were chosen from each group and anesthetized with ether before they were killed to collect blood samples by enucleating eyeballs, which were put into test tubes containing anticoagulant heparin sodium (1:500). Plasma was obtained by centrifugation at 3 000 r/min for 20 min and stored for analysis. Then, the animals were killed and the liver was quickly washed *in situ* with ice-cold isotonic saline, followed by stripping the capsules. Parenchyma (0.5 g) was sheared into broken bits and put into test tubes with 4 mL physiological saline for tissue homogenates. Tubes were centrifuged at 4 000 r/min for 30 min at 4 ℃ to separate upper fluid, which was stored at -20 ℃ for analysis.

Laser scanning confocal microscopic analysis of intracellular free Ca^{2+} in hepatocytes

Hepatocyte isolation In the 1st wk post injection with CCl_4, six mice from each group were exsanguinated and liver was minced with dissecting scissors into approximately 1 mm^3 pieces. The pieces of liver were placed into 3 mL D-Hank's solution containing 0.25% trypsin (1:250, Amresco Co. USA) for 1 h digestion at 37 ℃, and then added into small 1640 medium (pH 7.2) containing 10% neonatal bovine serum (Sijiqing Co., Hangzhou, China). Streptomycin and penicillin (1×10^5 U/L for each) were used to terminate the digestion. The released cells were filtered through sterilized nylon membranes and washed in D-Hank's solution via two centrifugations at 1 000 r/min for 5 min after erythrocytes were dissolved with 0.85% amchlor solution, and then resuspended in 1640 medium containing 10% neonatal bovine serum.

Fluo-3/AM loading of hepatocytes Twenty microliters of suspension samples containing freshly isolated hepatocytes from each group was placed in 13 mm culture dishes. The glass bottom of the culture dishes were covered with a layer of 0.1 mg/mL ConA (Fluka Co., USA) and dried at 37 ℃ in order to allow cells to adhere. The cells were loaded with 15 μL of 0.1 μg/mL Fluo-3/AM (Calbiochem Co., USA) for 30 min at 37 ℃, and washed thrice with Hank's solution (pH 7.2) to remove the extracellular Fluo-3/AM.

The fluorescence intensity of $[Ca^{2+}]_i$ in hepatocytes was determined by ACAS Ultima-312 laser scanning confocal microscopy. Total images were scanned in each experiment and the data were stored in disks for analysis.

Parameters of plasma and liver homogenates in mice with hepatic injury

The activities of glutathione peroxidase (GSH-Px), superoxide dismutase (SOD), alanine aminotransferase (ALT) and aspartate aminotransferase (AST) as well as malondialdehyde (MDA) content in liver tissue homogenates were assayed by spectrophotometry using commercial kits (Nanjing Jiancheng Biotechnology Institute, China). Plasma TNF-α

level was measured by ^{125}I-based radioimmunoassay using commercial reagents (Radio-Immunity Institute of General Hospital of Chinese Liberation Army). In general, the procedures indicated by the kits were performed strictly according to the manufacturer's protocol.

Statistical analysis

Results were expressed as mean±SE. Statistical analysis was performed by Student's *t*-test (STATISTICA, Statsoft Inc., Tulsa, USA) on a conventional personal computer. $P<0.05$ was considered statistically significant.

RESULTS

Effect of Se-enriched lactobacillus on AST and ALT activities of liver homogenates in mice with CCl_4-induced hepatic injury

As shown in Table 1, during the entire experimental period, CCl_4 significantly increased AST activity in liver homogenates compared to normal control ($P<0.05$). This effect was completely prevented by both low and high doses of Se-enriched lactobacillus ($P<0.05$). Upon exposure to CCl_4, ALT activity in liver homogenates was not affected in the 1st wk of treatment, but significantly enhanced in the 2nd wk ($P<0.05$). This effect was also blunted by a high dose of Se-enriched lactobacillus ($P<0.05$).

Table 1 Changes of AST and ALT activities in mice with hepatic injury after Se-enriched lactobacillus treatment (mean±SE)

Index	Group	Post-injection with CCl_4	
		1 wk	2 wk
AST (U/mg tissue)	Normal	20.43±0.54[a]	17.68±1.21[a]

Effect of Se-enriched lactobacillus on GSH-Px and SOD activities of liver homogenates in mice with CCl_4-induced hepatic injury

As demonstrated in Table 2, GSH-Px activity in the liver homogenates slightly decreased in the 1st wk, and significantly decreased in the 2nd wk after CCl_4 treatment. This effect was blunted by a high dose of Se-enriched lactobacillus ($P<0.05$). Similarly, during the entire period of treatment, SOD activity dramatically decreased after CCl_4 treatment ($P<0.05$), which was rescued by both low and high doses of Se-enriched lactobacillus.

Effect of Se-enriched lactobacillus on MDA content in liver homogenates of mice with CCl_4-induced hepatic injury

Figure 1 shows that CCl_4 significantly increased MDA content in liver homogenates compared to normal control during the entire experimental period ($P<0.05$). However, administration of Se-enriched lactobacillus prevented MDA elevation.

Table 2 Changes of GSH-Px and SOD activities in mice with hepatic injury after Se-enriched lactobacillus treatment (mean±SE)

Index	Group	Post-injection with CCl_4

Effect of Se-enriched lactobacillus on macrophage activities in mice with CCl_4-induced liver injury

During the entire experimental period, the phagocytic rate of macrophages significantly decreased after CCl_4 treatment compared to normal control ($P<0.05$), and was dramatically rescued by both low and high doses of Se-enriched lactobacillus, showing an obviously higher phagocytic rate than that in model group ($P<0.05$). The phagocytic index of macrophages slightly decreased in the 1st wk, and significantly decreased in the 2nd wk after CCl_4 treatment. This effect was protected by high dose of Se-enriched lactobacillus ($P<0.05$, Table 3).

Effect of Se-enriched lactobacillus on plasma TNF-α in mice with CCl_4-induced liver injury

During the entire experimental period, CCl_4 significantly

elevated plasma TNF-α level compared to normal control ($P<0.05$). This effect was completely prevented by both low and high doses of Se-enriched lactobacillus, showing an obviously lower value than that in model group ($P<0.05$) and no significant difference as compared to normal group (Figure 2).

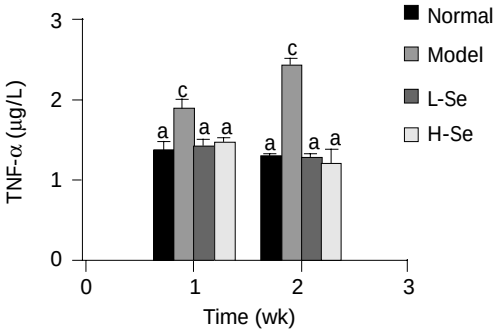

Figure 2 Change of plasma TNF-α level in mice with hepatic injury after Se-enriched lactobacillus treatment. [a]$P<0.05$ *vs* model group; [c]$P<0.05$ *vs* normal group.

Effect of Se-enriched lactobacillus on hepatocytes $[Ca^{2+}]_i$ in mice with CCl_4-induced liver injury

Figure 3A shows changes of hepatocyte $[Ca^{2+}]_i$ fluorescent visualizations in mice with hepatic injury after Se-enriched lactobacillus treatment. In model group, the hepatocyte $[Ca^{2+}]_i$ content significantly raised and was 5.5-fold higher than that in normal group ($P<0.05$), but hepatocytes $[Ca^{2+}]_i$ in mice with liver injury after Se-enriched lactobacillus treatment was significantly downregulated ($P<0.05$) and close to that in normal control (Figure 3B).

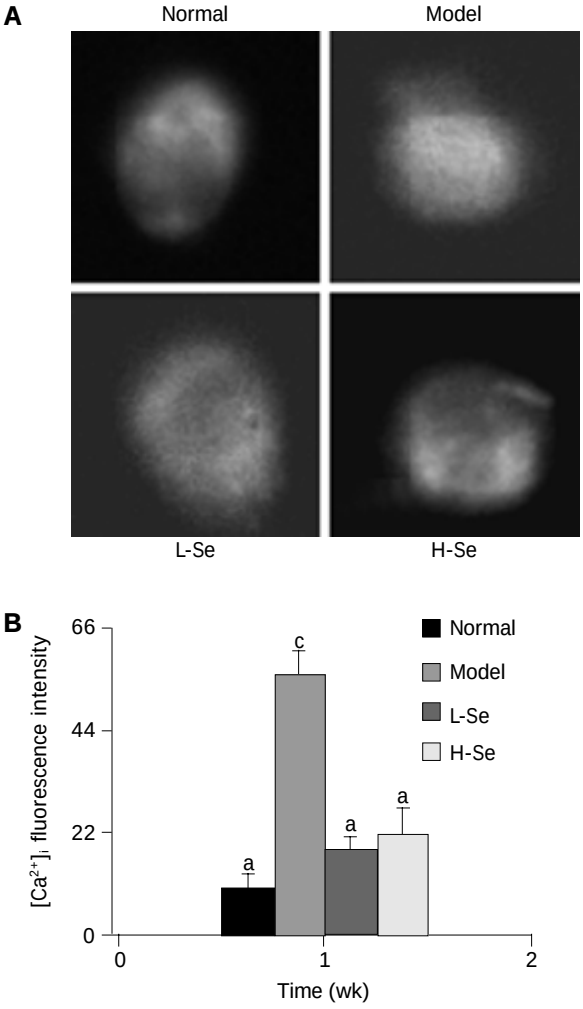

Figure 3 $[Ca^{2+}]_i$ fluorescence visualizations (A) and intensities (B) in mice with hepatic injury after Se-enriched lactobacillus treatment. [a]$P<0.05$ *vs* model group; [c]$P<0.05$ *vs* normal group.

DISCUSSION

Liver fibrosis is a common pathological process of hepatic disease, leading to the development of irreversible cirrhosis in patients. In recent years, the mechanism of hepatic fibrosis has been partly disclosed[11]. If treated properly at fibrosis stage, cirrhosis could be prevented[3]. Several drugs, including cytokines, antioxidants, chemical drugs, soluble type II receptor for TGF-β_1, and antibodies directed against TGF-β_1 have been used to block liver fibrosis, but their effects are not as good as expected[12]. The present study has demonstrated that Se-enriched lactobacillus is effective in treating mice hepatic injury and fibrosis based on both lipid peroxidation reaction and functional analysis. The underlying protective mechanism may involve enhanced immunity, and downregulation of TNF-α release and equilibration of hepatocyte $[Ca^{2+}]_i$ homeostasis.

There are various kinds of liver injuries all over the world, causing great affliction to patients. Searches for effective ways to inhibit fibrogenesis and to prevent the development of cirrhosis are of great significance. Selenium can prevent the malignant transformation of normal cells and the activation of oncogenes with anticarcinogenic effects within a physiological dosage range[4,5]. Selenium is closely related to the inhibition of hepatic fibrosis[7,8]. Se-enriched lactobacillus is an organoselenium agent. The present study showed that ALT, AST and MDA in mice after Se-enriched lactobacillus treatment dropped significantly when compared to those in model group, indicating that Se-enriched lactobacillus reduces the violent lipid peroxidation reaction induced by CCl_4 and prevents hepatic injury.

GSH-Px, a selenium-containing enzyme, is a primary selenium-dependent, glutathione-utilizing peroxidase in the liver[13-15]. The decreased GSH-Px activity has been implicated in animals fed with a selenium-deficient diet[16,17]. Conversely, selenium supplement can also impact GSH-Px activity directly[18,19]. In this study, CCl_4 caused an obvious decrease of GSH-Px activity in liver homogenates, but the enzyme activity was higher after Se-enriched lactobacillus treatment, suggesting that Se-enriched lactobacillus can ameliorate GSH-Px activity or enhance its activity by participating in GSH-Px biosynthesis in mice with CCl_4-induced liver injury. SOD is one of the potent antioxidant enzymes in cells and catalyzes the conversion of superoxide ions into oxygen and hydrogen peroxide. In our study, SOD activity was dramatically decreased by CCl_4, but the effect was rescued by both low and high doses of Se-enriched lactobacillus. GSH-Px and SOD are the important antioxidant enzymes of antioxidant

defense systems for stabilizing oxidative reactions. Decreased activity and content of these enzymes cause the descent of antioxidant ability in the body[20]. Therefore, Se-enriched lactobacillus may prevent experimental liver injury by modulating or enhancing GSH-Px and SOD activities.

Macrophages are important immune cells of the immune system and the first line of defense to infection and inflammation in the body, and play a very important role in regulating the body immune status. Many experiments have demonstrated that the macrophage phagocytosis in mice with CCl_4-induced liver injury can be reduced[16,21,22]. In our study, Se-enriched lactobacillus was found to be able to enhance the immunity of the body by increasing the phagocytic rate and phagocytic index in macrophages in L-Se group and H-Se group. This fact may be relevant to the protection of its biomembrane against oxidative destruction. Mayanski *et al*.[22], showed that structural and functional integrity of the cell membrane system including macrophages in mice with CCl_4-induced liver injury is damaged, thus depressing the activity of macrophages.

To understand the mechanism, we evaluated the effect of Se-enriched lactobacillus treatment on blood TNF-α concentration in mice with liver injury. There is evidence that TNF-α is a primary and key endogenous mediator inducing acute inflammatory conditions[23-25]. When an inflammatory reaction occurs, TNF-α is expressed by both infiltrating inflammatory cells such as macrophages in the blood and hepatocytes in liver injuries. Excessive TNF-α can indirectly induce liver damage by further enhancing the release of mass inflammatory mediators including free radicals, prostaglandin, leukotriene, thromboxane, interleukin-1, and TNF-α from macrophages, and also promote liver injury by increasing nitric oxide production from liver cells[26,27]. The present study showed that plasma TNF-α level due to CCl_4 increased obviously, but the effect was significantly blunted by Se-enriched lactobacillus, indicating that Se-enriched lactobacillus downregulates excessive release of TNF-α.

It was reported that changes of intracellular cation homeostasis are closely related to the mechanism of hepatic cell injury[28,29]. Elevation of $[Ca^{2+}]_i$ concentration is associated with the development of cell damage[30,31]. In the present study, CCl_4 caused the increase of hepatocyte $[Ca^{2+}]_i$, suggesting that the dramatic elevation of hepatocyte $[Ca^{2+}]_i$ due to CCl_4 is closely related to CCl_4-induced hepatocellular injury. However, the hepatocyte $[Ca^{2+}]_i$ level in mice with liver injury after Se-enriched lactobacillus treatment was significantly lower than that in model group, indicating that Se-enriched lactobacillus may prevent disturbance of $[Ca^{2+}]_i$ homeostasis. Other investigations showed that hepatocyte $[Ca^{2+}]_i$ elevation is caused by the decreased activities of Na^+/K^+- and Ca^{2+}-ATPases in hepatocyte membranes[32,33]. In addition, it is possible that CCl_4 may release Ca^{2+} by inhibiting the endoplasmic reticulum Ca^{2+} pump so that a passive leak of Ca^{2+} from the endoplasmic reticulum results in the increase of $[Ca^{2+}]_i$ and induces cell death[30,34,35]. Thus, Se-enriched lactobacillus may play an important role in preventing liver injury. The exact mechanisms remain to be explored.

In conclusion, Se-enriched lactobacillus can significantly reduce CCl_4-induced liver injury in mice by enhancing macrophage function activity to keep normal and beneficial effects, elevating antioxidant-enzyme activities and reducing lipid-peroxidation reaction, inhibiting excessive release of TNF-α and preventing dramatic elevation of hepatocyte $[Ca^{2+}]_i$ concentration.

ACKNOWLEDGMENT

We thank Dr. Chao-Ying Zhang at the College of Life Sciences, Nanjing Normal University for assistance with laser scanning confocal microscopic analysis of $[Ca^{2+}]_i$ in hepatocytes.

Abstract

AIM: To isolate and identify the soybean conglycinin peptides that selectively stimulates the growth of bifidobacteria *in vitro*, and to investigate the effect of soybean conglycinin peptides on intestinal ecosystem *in vivo*.

METHODS: Soybean conglycinin was purified from soybean seeds by gel filtration (Sepharose-CL-6B). These proteins were submitted to hydrolysis by pepsin. Several growth-stimulating peptides for bifidobacteria were isolated chromatographically from pepsin hydrolysis of soybean conglycinin and identified by means of matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF-MS). Parallel to *in vitro* study, *in vivo* experiments with soybean conglycinin peptides were performed in mice. Ninety male KM mice were randomly assigned into five groups of 16 mice each, and each group was administered for 21d intragastrically with physiological saline (control), conglycinin, pepsin-treated conglycinin (PTC), the most active fraction which isolated from pepsin-treated conglycinin (P2-PTC) and HCl-full hydrolysis of conglycinin (HCl-FHC), respectively. Intestinal microflora were evaluated by standard microbiologic methods and biochemical assays of cecal content samples after treatment.

RESULTS: The results showed that the peptides which were isolated from soybean conglycinin could stimulate the growth of bifidobacteria *in vitro*, and the molecular mass of purified peptides with MALDI-TOF-MS ranged from 693.32 to 1829.55. Compared with control group, *in vivo* experiments showed that P2-PTC group decreased cecal pH (7.08±0.08 *vs* 7.21±0.09, $P<0.05$) and *enterococci* counts (5.38±0.26 $\log_{10}$CFU/g *vs* 5.78±0.19 $\log_{10}$CFU/g, $P<0.05$), significantly increased sIgA level (172.08±35.40 ng/g *vs* 118.27±33.93 ng/g, $P<0.01$) and β-galactosidase activity (1.28±0.23 U/g *vs* 1.82±0.58 U/g, $P<0.05$).

CONCLUSION: The results have shown that conglycinin is good source for enzyme-mediated production of peptides which stimulate the growth of bifidobacteria. These peptides are inactive within the sequence of the parent protein but can be released during enzymatic hydrolysis, and *in vivo* experiments demonstrate that conglycinin peptides may be beneficial for improving gastrointestinal health.

INTRODUCTION

In recent years, a large number of biologically active peptides have been isolated from bacterial, fungal, plant, and animal sources. The concept that peptides with potential biological activity might be present in food is not new. Soybean storage proteins are composed mainly of two major components, conglycinin and glycinin[1]. Many studies have demonstrated that the enzymatic hydrolysis of conglycinin improved its functional properties and had various physiological activities such as antihypertensive[2], immunostimulating[3] and antioxide activities[4].

It is now generally accepted that the human gastrointestinal tract is host to various species of microorganisms and these bacteria play a significant role in health and disease[5]. Bifidobacteria are gram-positive anaerobic bacteria, which normally inhabit the gut of human beings and animals, the presence of a great deal of bifidobacteria has been considered essential to promote intestinal health and to strengthen the local immune response[6]. The use of bifidobacteria as food supplements and therapeutical pharmaceuticals has been limited because of their slow growth. Several growth stimulating substances have been investigated, most of which derived from human and bovine milk[7,8], however, the effect of peptides isolated from soybean conglycinin has not been understood well.

In this paper, we report that peptides obtained from the digestion of conglycinin with pepsin are effective growth factors for bifidobacteria, based on experiments *in vitro*. We

also evaluated the *in vivo* effects of soybean conglycinin peptides on gut ecosystem in mice.

MATERIALS AND METHODS

Separation of conglycinin from soybean

The conglycinin was prepared from soybean seeds by the procedure of Iwabuchi[9] and Lovati[10] , as reported briefly below. Soybeans were finely ground and defatted with hexane at room temperature. Ground meals, extracted with 30 mmol/L Tris-HCl buffer (pH 8.0) containing 0.01 mol/L β-mercaptoethanol for 1 h at room temperature, were spun by centrifugation (20 min at 4 000 r/min, 20 ℃). The supernatant (adjusted to pH 6.4) was spun by centrifugation (15 000 r/min, 20 min, 4 ℃), the precipitates were discarded, and the supernatant was adjusted to pH4.8. The crude conglycinin was collected by the same centrifugation procedure as described above. The precipitated conglycinin was dissolved in 30 mmol/L Tris-HCl buffer (pH 8.0) containing 0.01 mol/L β-mercaptoethanol. The supernatant proteins were fractionated by ammonium sulphate precipitation. The 51-100% saturation fraction was dialyzed against water and applied to a Sepharose-CL-6B column (Pharmacia). Elution was performed with the phosphate buffer (2.6 mmol/L KH_2PO_4, 32.5 mmol/L K_2HPO_4, 0.4 mol/L NaCl, 10 mmol/L β-mercaptoethanol, pH 7.6). Finally the purified conglycinin was dialyzed against water. After readjusted to pH7.0 and analyzed for protein concentration by the method of micro-Kjeldahl, the protein solutions were freeze-dried and stored at 4 ℃. These materials were used as protein samples.

Sodium dodecyl sulfate gel electrophoresis(SDS-PAGE)

SDS-PAGE was performed according to Laemmli [11], using 10% polyacrylamide gels, The protein was stained with Coomassie brilliant blue(R-250), scanned, and the profiles of each lane were analyzed by densitometry in the Kodak Digital Science Software 1DTM.

Hydrolysis of conglycinin by pepsin

Conglycinin was hydrolyzed by pepsin (Amersico) using a 1:30 enzyme: substrate ratio. Enzymatic hydrolysis was performed after acidification to pH1.4 with 1 mol/L HCl, and mixture of pepsin and conglycinin was incubated for 2 h at 37 ℃. The reaction was terminated by heating at 70 ℃ for 30 min, and the solution was adjusted to pH 7 with 1 mol/L NaOH. After centrifugation (20 min, 3 000 r/min, 4 ℃), the supernatant was collected and lyophilized. The nitrogen concentrations of the conglycinin digestion were evaluated by the method of micro-Kjeldahl.

Full hydrolysis of conglycinin by hydrochloric acid

The conglycinin was fully hydrolyzed with 6 mol/L HCl at 110 ℃ for 24 h. The solution was composed of amino acid composition of conglycinin. The hydrolysates were neutralized and lyophilized.

Separation of peptides

Components of pepsin-treated conglycinin were separated using Sephadex-G15 (Pharmarcia) gel filtration chromatography, tracking the maximum growth stimulatory activity of the resulting fractions on *Bifidobacterium longum* (FCM1192) which was endorsed by Professor Ming-Sheng Dong (Nanjing Agricultural University). The elution was carried out with 0.05 mol/L acetate, and the absorbance of the column effluent was monitored at 280 nm. The molecular mass of the most active fraction was identified by means of MALDI-TOF-MS (BIFLEXTM III, BRUKER). In this study, α-cyano-4-hydroxy-cinnamic acid solution was used as matrix. Peptide concentrations in a sample throughout the purification were determined with the method of micro-Kjeldahl.

Bacterial growth assays in vitro

The basal medium used for a bioassay *in vitro* was a fully synthetic medium as described by Hassinen[12]. For growth assays, the assay medium (5 mL) was mixed with 0.15 mg/mL (nitrogen concentration) samples and inoculated with 100 μL of bacteria culture. The control contained ammonium acetate which has equal nitrogen concentration with samples. Culture was done under anaerobic conditions at 37 ℃. The extent of growth was measured by the absorbance at 460 nm after 48 h of cultivation. The growth experiments were done in triplicates.

Animals and diets

Ninety male KM mice (21 d old, body weight 10-13 g, Shanghai SLAC Experimental Animals Co.Ltd, China) were housed in a room with controlled lighting (12 h/d), and constant temperature. During the first week, all mice had a commercially available basal diet and then randomly assigned into five groups of 16 mice each. Each group was administered for 21 d intragastrically with physiological saline (control), conglycinin, pepsin-treated conglycinin (PTC), the most active fraction which was isolated from pepsin-treated conglycinin (P2-PTC), and HCl-full hydrolysis of conglycinin (HCl-FHC), respectively. The volume of every treatment for the latter four groups was 0.5 mL with equal amount of nitrogen (0.3 mg/mL).

Preparation of sample and enumeration of bacteria

At the end of the experimental period, mice were killed by decapitation. Blood samples were collected and spun by centrifugation at 3 000 r/min for 10 min to obtain sera. Serum level of IL-2 was assayed by radioimmunoassay (Beijing North Institute of Biotechnology) using RIA methods. Cecal samples were collected and immediately frozen and stored at -30 ℃ until analysis and subsequent testing for microbial composition. The following media were used: MacConkey agar for *E.coli*, bile esculine azide agar for *enterococci*. Cecal contents were cultured with triplicate plates for the microbial colony count. After incubation at 37 ℃ for 24 h, results were expressed as colony-forming units per gram of cecal contents. The pH of the cecal contents was measured using a pH meter. Contents of small intestine were also collected and diluted by water a ratio of 1:10. After centrifugation at 3 000 r/min for 10 min, sIgA level of supernatant was assayed by radioimmunoassay (Beijing North Institute of Biotechnology) using RIA methods.

Enzyme assays

A protocol for detecting fructose-6-phosphate phosphoketolase (F-6-PPK) activity in the extracts from cecum samples was employed based on the assay as previously described by Orban *et al*.[13]. A positive reaction was recorded if an immediate red-violet color change was visible, and color formation was recorded spectrophotometrically at 505 nm. Quantitative determinations of β-galactosidase enzyme activities were performed in cecal contents suspensions. The method was used for measuring β-galactosidase activity described by Brigidi *et al*.[14]. One unit of β-galactosidase activity was defined as the amount which released 1 μmoL of *p*-nitrophenol per minute and results were expressed as Units/g of wet sample.

Statistical analysis

Data were expressed as mean±SD. Statistical significance was determined by applying one-way analysis of variance (ANOVA). $P<0.05$ was considered statistically significant.

RESULTS

Soybean conglycinin separation

The procedure for fractionation of conglycinin was based on the isoelectric precipitation and size exclusion chromatography. The elution profile of crude conglycinin on sepharose-CL-6B is shown in Figure 1. The conglycinin was mainly detected in peak II. The gel electrophoretic pattern of purified conglycinin is illustrated in Figure 2. The major bands in the conglycinin were the α, α' and β subunits, the purification rate of conglycinin was 90.13%.

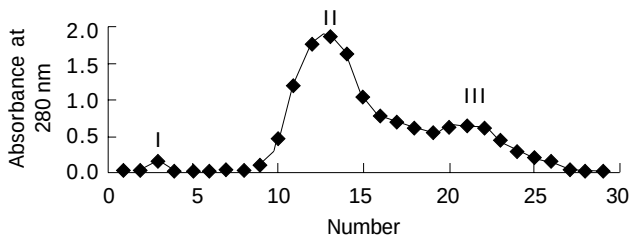

Figure1 Chromatography of soybean conglycinin on sepharose-CL-6B. Bed size,1 cmx100 cm, flow rate 30 mL/h, absorbance at 280 nm.

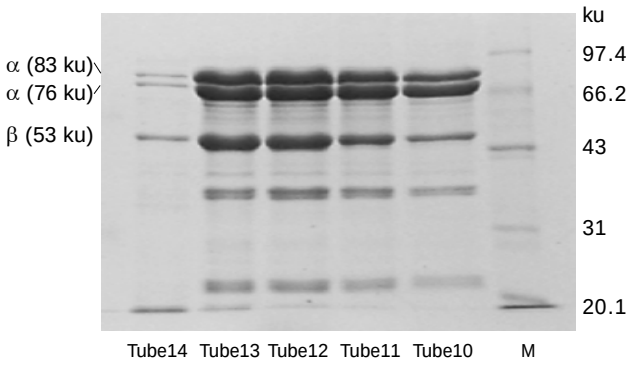

Figure 2 SDS-PAGE pattern of purified conglycinin. α, α' and β indicate subunits of conglycinin. M: standard molecular weight proteins.

Growth-stimulating activity of conglycinin hydrolysates in vitro

The results of the *in vitro* experiments of the effect of soybean conglycinin hydrolysates on the regulation of growth activity for *Bifidobacterium longum* is shown in Table 1. Compared with control, pepsin-treated conglycinin (PTC) could significantly promote the growth of *Bifidobacterium longum* ($P<0.01$), while HCl-full hydrolysis of conglycinin (HCl-FHC) had no significant effect on the growth of *Bifidobacterium longum* after 48 h .

Table 1 Effect of soybean conglycinin hydrolysates on the growth of *bifidobacterium longum* (n = 9)

Group	Control	Conglycinin	PTC	HCl-FHC
A_{460}	0.11±0.04	0.31±0.11	0.66±0.07[bd]	0.12±0.02

Values are expressed as the mean±SD. [b]*P<0.01 vs* control group, [d]*P<0.01 vs* HCl-FHC group.

Separation of peptides

Five fractions (P1-P5) were separated from pepsin-treated conglycinin using Sephadex-G15 gel filtration column chromatography based on absorbance at 280 nm (Figure 3). Results of bacterial growth assays showed that P2 had the maximum growth stimulatory activity (Table 2). MALDI-TOF-MS analysis of P2 is shown in Figure 4. The molecular mass ranged from 693.32 to 1829.55. It demonstrated that the fraction P2 was comprised of peptides with short lengths.

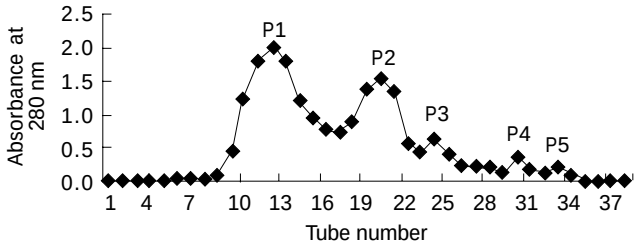

Figure 3 Chromatography of soybean conglycinin hydrolysates on sephadex-G15. Bed size, 1.0 cmx100 cm, flow rate 15 mL/h, absorbance at 280 nm.

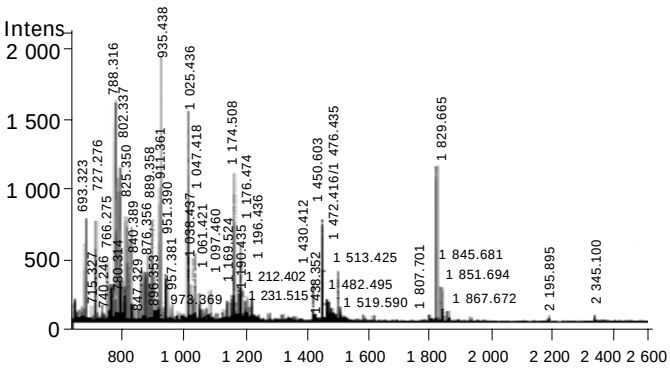

Figure 4 MALDI-TOF-MS analysis of fraction P2.

Table 2 Growth-stimulating activity of the isolated fractions from pepsin-treated conglycinin on bifidobacteria (n = 9)

	Control	P1	P2	P3	P4	P5	PTC	Conglycinin	HCl-FHC
$A_{460\,nm}$	0.35±0.05	0.38±0.05	0.50±0.10[a]	0.45±0.09[a]	0.33±0.08	0.36±0.07	0.42±0.06	0.37±0.05	0.36±0.08

Values are expressed as the mean±SD, [a]P<0.05 *vs* control group.

Effect of conglycinin peptides on serum IL-2 levels and sIgA concentrations of small intestine in mice

Serum IL-2 levels and small intestine sIgA concentrations are presented in Table 3. Level of sIgA in P2-PTC group was higher than that in control group (P<0.05) and HCl-FHC group (P<0.01). The level of serum IL-2 showed no significant difference among the five treated groups.

F-6-PPK activities in cecal contents

The detection of F-6-PPK was considered to be the most reliable indicator that the bacteria belong to the genus *Bifidobacterium*[15]. The results in Table 4 showed that the enzyme F-6-PPK was detected in all samples. Activities of F-6-PPK in the PTC and P2-PTC groups were significantly higher than that in the control group (P<0.01) and HCl-FHC group.

β-galactosidase activities in cecal contents

Compared with control group, β-galactosidase activities in cecal contents of P2-PTC group were significantly increased by 42.2% (1.82±0.58 U/g *vs* 1.28±0.23 U/g, P<0.05). The β-galactosidase activities of conglycinin group were significantly lower than that in P2-PTC group (1.27±0.34 U/g *vs* 1.82±0.58 U/g, P<0.05). But no significant difference was found between P2-PTC and PTC groups, and between P2-PTC and HCl-FHC group (1.82±0.58 U/g *vs* 1.43±0.38 U/g, 1.82±0.58 U/g *vs* 1.30±0.47 U/g, P>0.05) .The result is shown in Figure 5.

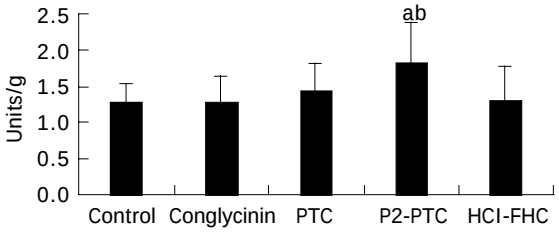

Figure 5 Effect of conglycinin peptides on β-galactosidase activities in cecal contents (n = 8). Values are expressed as the mean±SD, [a]P<0.05 *vs* control group, [b]P<0.01 *vs* conglycinin group.

Bacterial concentrations and cecal pH

As shown in Table 5, compared with control, cecal pH level and the population of *Enterococci* in P2-PTC group were significantly decreased (P<0.05).

DISCUSSION

In recent years, modification of the human intestinal microbiota has become an important objective of dietetics[16]. This goal can be achieved in two ways: (1) administration of beneficial bacteria with the expectation that they will be able to colonize the intestinal tract; (2) providing prebiotics, which have shown an ability to promote the growth of desirable bacteria[17-19]. Bifidobacteria are part of the beneficial microbiota of the human intestine[20], and they are considered to be important in maintaining intestinal microbiota balance [21]. Therefore, many attempts have been made to increase the number of bifidobacteria in the intestine.

Soybean proteins and their derived foods have been consumed for a long time in the diets of the people in China and other Asian countries. The health promoting properties of soybean proteins have been accepted worldwide. Peptides derived from soybean proteins with short lengths, produced during *in vitro* and *in vivo* digestion, are considered to have pharmacological and physiological activities[22]. However, the effect of conglycinin peptides on growth of bifidobacteria had not been reported yet. In this study, we used pepsin to hydrolyze the conglycinin *in vitro* and results demonstrated that conglycinin was a good raw material for enzyme-mediated production of growth-stimulating peptides for bifidobacteria. The peptides, which were obtained as a consequence of screening for highly active growth stimulators during the separation, were highly hydrophilic and comprised of 6-10 amino acid residues, and these peptides were inactive within the sequence of the parent protein, but could be released during enzymatic hydrolysis. Compared with the HCl-full hydrolysis of conglycinin, the results also indicated that the function of conglycinin peptides was not nutritional but it had physiological properties. Different enzymes in the gastrointestinal tract have different effects on various kinds

of foods, which contain numerous sorts of protein. The process above may release prolific bioactive peptides, which have physiological and metabolic programming function on the body.

In conjunction with *in vitro* studies, pepsin-treated conglycinin was administered to mice in an effort to determine the effects of these peptides on intestinal ecosystem. The results showed that administering these peptides could significantly increase β-galactosidase enzyme activity. It had been reported that the increase in galatosidase was presumably a consequence of elevated numbers of bifidobacteria, which have high levels of this enzyme[13]. This suggests that conglycinin peptides could induce the change of bifidobacteria in the intestine. From our results, conglycinin peptides could lower cecal pH markedly and decrease the population of *E.coli*. We also observed that conglycinin peptides decreased the population of *enterococci*, which not only appears to share the main characteristics of lactic acid bacteria (LAB), but also comprises pathogenic species. *Enterococci* show an extensive range of resistance to various antibiotics, and the evolution of its virulence has been documented[23]. In the present study, the result indicated that conglycinin peptides did not promote the growth of all species of LAB, especially pathogenic species. It had been reported that bifidobacteria could prevent colonization of pathogens in gastrointestinal tract by lowering gut pH, and have health-promoting effects such as enhancement of immune system[24,25]. Gibson *et al*.[26] suggested that the higher bifidobacteria population, detrimental to other anaerobic bacteria species, may lead to changes in the microbial ecology of the colon. The accepted mechanism that bifidobacteria are inhibitory is related to the higher production of acetic and lactic acids. Increased acid production resulted in a lower pH which prevented enteric colonization of potentially pathogenic microorganisms and growth of putrefactive bacteria[27]. Furthermore, bifidobacteria stimulate immune function. There is considerable evidence from animal studies that probiotic organisms could modulate the mucosal and systemic immune systems[28]. This stimulation of host immunity is thought to relate to the ability of microorganisms to adhere to intestinal cells and interact with the gut-associated lymphoid tissue (GALT)[29,30]. This ability can increase immunoglobulin output into the intestinal lumen [31-33]. sIgA is one of the principal factors preventing bacterial translocation, which can result in sepsis and death of the host. The classic view is that sIgA exerts its effect by aggregating bacteria, thereby mediating clearance of those bacteria from the gut and preventing invasion of bacteria to the body[34]. Some bifidobacteria strains have recently shown to stimulate sIgA production in intestine[35]. Therefore, bifidobacteria may stimulate active IgA production, thereby reducing infections. Our study also showed that local production of sIgA in the small intestine increased significantly, suggesting that the higher amount of bifidobacteria in the cecum of mice caused by ingestion of conglycinin peptides might produce beneficial effects within the gastrointestinal tract. Thus, the health-promoting effect of conglycinin peptides in human beings may have relationship with bifidobacteria of gastrointestinal tract.

In conclusion, our work placed emphasis on the activity (*in vitro* and *in vivo*), physiological and biochemical properties of the mixture peptides. The proteolysis of soybean conglycinin with the gastrointestinal protease pepsin results in the generation of growth-promoting peptides for bifidobacteria. Using the MALDI-TOF-MASS strategy, we were able to identify several low-molecular-mass peptides responsible for this activity. The digestion of conglycinin represents an important mechanism to obtain peptides which exhibit significant physiological roles in addition to their nutritional importance. Pepsin is an endopeptidase responsible for the hydrolysis of a wide range of proteins, we may infer that the mixture is a group of bioactive peptides that have identical C-terminus or N- terminus. Further characterization of the composition of the conglycinin hydrolysates, elucidation of the relationship between peptide structure and activity awaits future study.

Abstract

AIM: To describe the imaging features of hepatic mesenchymal hamartoma with emphasis on magnetic resonance imaging (MRI) compared to histopathologic results.

METHODS: Spin-echo sequence(SE),fast spin-echo sequence(FSE) were performed in 12 children (7 males,5 females) with mesenchymal hamartoma of the liver (MHL), aged 1.2 months to 12 years;(mean age, 6.3 years) axial, saggital, coronary plain imaging with an Elscint 2.0T MR equipment. Their main symptoms were abdominal mass (5 cases), enlarged liver (8 cases), abdominal pain (1 case) and anemia (2 cases), and negative alphafetoprotein. Dynamic enhancement examination was added in 2 cases.

RESULTS: Six cases had single mass type of MHL, in which 3 cases had solid masses showing slight low-signal-intensity in T1WI, and irregular high-signal-intensity in T2WI, 1 case had a cystic-solid mixed mass showing several border-clear cysts in a solid mass, 2 cases had cystic masses with multi-septa. Five cases had diffuse and multifocal lesions type of MHL with its signal intensity being similar to that of the solid mass. One case had a combined diffuse and single cystic mass. In the early dynamic enhancement examination, the lesions were slightly circum-enhanced , and the center was enhanced in the later scan images. Inner hepatic vessels were compressed in 5 cases, vena cava and abdominal aortae were compressed in 3 cases. Pathological findings included fiber hyperplasia, hyaline degeneration, biliary duct hyperplasia, lobule-like array.

CONCLUSION: MR imaging is a better way to differentiate and diagnose MHL. MHL may be recognized by its characteristic occurrence in infancy and MR imaging features.

INTRODUCTION

Mesenchymal hamartoma of the liver (MHL) is one of the rare hepatic benign tumors in children, which was first reported by Edmanson in 1956. It is usually present under 5 years of age, mostly under 2 years of age. One hundred and fifty cases of MHL are reported in English, 30 cases in Japanese, 21 cases in Chinese[1-3]. A few reports have discussed the X-ray, ultrasound and CT characteristics of MHL [5-9]. MHL is often misdiagnosed as other pathological lesions, because of its diversified image characteristics. MR has been widely used in the diagnosis of MHL . We have reviewed 12 MHL cases with MR scan in our hospital since 1996. The MR imaging features can help recognize and diagnose MHL.

MATERIALS AND METHODS

Twelve children with MHL (7 males and 5 females) were reviewed from January 1996 to 2002.They aged 1.2 months to 12 years with a mean age of 6.3 years.Their Clinical manifestations are list in Table 1.

MR imaging was performed with an Elscint 2.0T MR equipment. Patient was on his back, and chloral hydrate lysis was performed before scan. Spin-echo sequence (SE), fast spin-echo sequence (FSE) were performed with body coil. For T1-weighted MR imaging, the repetition time (TR) was 500 ms and the echo time (TE) was 15 ms. For T2-weighted imaging, the TR was 2500–3000 ms and the TE was 96 ms. Routine axial and coronary scan was performed 1-2 times. Dynamic enhancement examination was added in 2 cases, and CT scan was performed in 2 cases.

RESULTS

The pathologic types of MHL are showed in Table 2. The

Table 1 Clinical manifestations of 12 cases

Age	Cases	Gender		Clinical manifestations				
		Male	Female	Abdominal mass	Mega-liver	Abdominal pain	Anemia	Alphafetoprotein negative
1 mo¬12 mo	3	2	1	1	3			3
1 yr–2 yr	6	4	2	3	3		1	6
3 yr–4 yr	2	1	1	1	1	1		2
12 yr	1		1		1		1	1

Table 2 Pathologic types of MHL in 12 cases

	Cases	Hepatic lobes		Pathologic types		
		Right	Left	Solid	Cystic	Mixed cystic-solid
Single	6	5	2	3	2	1
Diffuse and multifocal	5	5	5	5		
Diffuse and single combined	1	1	1			1

envelopes of most masses were intact in general. Sections of the solid type mass were white and tough. The fluid in the cystic type was clear or turbid and pale yellow or coffee-like.

Fiber hyperplasia, hyaline degeneration, biliary duct hyperplasia and lobule-like array were seen. Lymphatic dilation was observed in a few cases. In crystic type, simple pavement epithelium or bile duct epithelium was seen at the inner layer of the cystic wall. The cyst contained fluid or gelatinoids. The separates consisted of mesenchyme and fibrostroma. In solid type, fibroadenoid structure consisting of remarkable hyperplastic biliary duct and fibrosis around it was seen. There were compacted hepatic tissues between the masses.

MRI finding in MHL

Single focal type of MHL was found in right hepatic lobe of 5 cases, in left hepatic lobe of 1 case with a big size and a clear border. The biggest one involved both lobes, with its diameter being 28 cm. Solid, cystic and mixed cystic-solid subtypes were classified based on the pathologic examination. In all lesions of solid subtype (n=3), MR images showed a slightly low signal intensity on T1-weighted images, an irregular high signal intensity on T2-

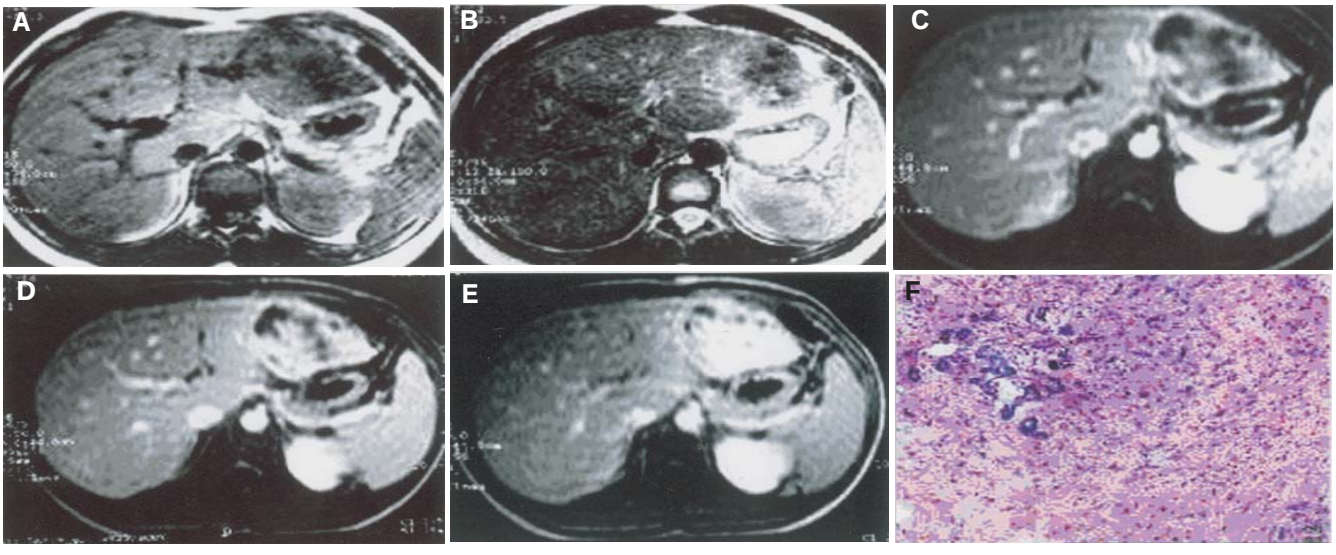

Figure 1 solid chief dingle mass type of MHL on T1WI(**A**), T2WI(**B**), and dynamic enhancement in artery phase(**C**), portal rein phase(**D**), and latency phase(**E**), and its pathologic lesions(**F**).

weighted images, and a higher signal intensity area inside. After intravenous administration of a gadolinium-based contrast agent, the lesions demonstrated mild annular enhancement in artery phase, moderate enhancement in portal phase, magnificent enhancement in delay phase (Figure 1). In the lesion of mixed cystic-solid subtype (n=1), MR images showed a slightly low signal intensity on T1-weighted images, a slightly high signal intensity on T2-weighted images. There were several cystic foci with varying sizes and clear borders. The gallbladder-like signal intensity was scattered or congregated, but not syncretized (Figure 2).

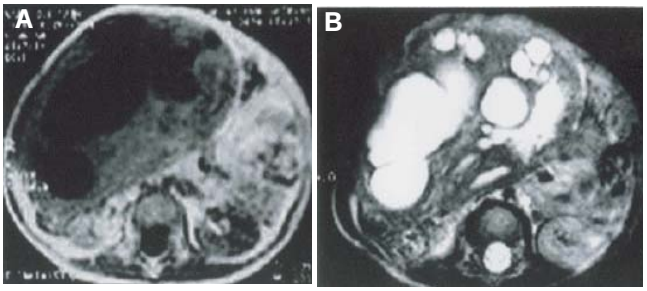

Figure 2 mixed cystic-solid single mass type of MHL on T1WI(**A**) and T2WI(**B**).

In the lesions of cystic subtype (n=2), MR images showed multi-cyst foci with varying sizes and thickness, low or normal signal intensity on T1-weighted images, high signal intensity on T2-weighted images, and varying signal intensity in different cysts, fluid-fluid plane in some cysts (Figure 3).

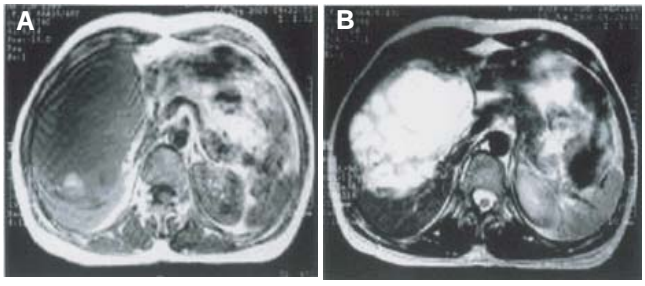

Figure 3 cystic single mass type of MHL on T1WI(**A**), T2WI(**B**).

Diffuse and multifocal type of MHL was found in 4 case. MR images showed enlarged liver with smooth border, multiple foci with slightly low signal intensity on T1-weighted images, slightly high signal intensity on T2-weighted images. After intravenous administration of a gadolinium-based contrast agent, the lesions demonstrated annular enhancement in artery phase, no enhancement in early stage, enhancement in delay phase. In 1 case, MR images showed multifocal masses in the liver, slightly low and normal signal intensity on T1-weighted images, very high signal intensity on T2-weighted images. The cotton-like masses with clear borders, did not syncretize each other (Figure 4).

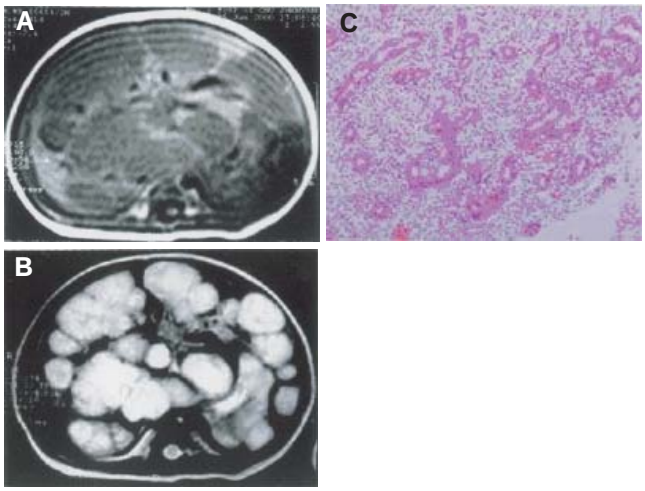

Figure 4 Diffuse and multifocal type of MHL on T1WI(**A**), T2WI(**B**) and Pathologic picture(**C**).

Combined diffuse and single type was found in 1 case. MR images showed big isolate multi-loculus cystic foci in the diffuse tubers, fluid-fluid plane in some cysts (Figure 5).

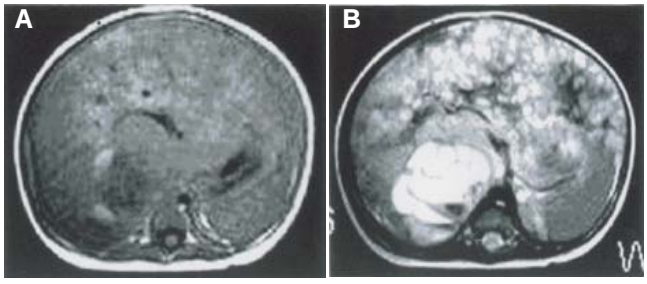

Figure 5 Diffuse and single combined type of MHL on T1WI(**A**) and T2WI(**B**).

The CT finding in MHL

In the multifocal type, CT images showed enlarged liver, multifocal low density foci of varying sizes from 1 cm × 1 cm to 2 cm×3 cm, lower density in the center. In the single focal type, CT images showed low density focus round in shape with a clear border.

Relationship between lesions and vessels

Inner hepatic vessels were compressed in 5 cases, vena cava and abdominal aortae were compressed in 3 cases. No portal vein was compressed in all the 12 cases.

DISCUSSION

MHL is a rare hepatic benign tumor, occurring most in children and rarely in adults [4]. MHL in fetus has also been reported [1].

Pathologensis

The exact pathologenesis is not clear. It has been reported that MHL is a kind of developmental deformity or the result of abnormal reaction procedure [8]. The abnormality appears in the late stage of embryo formation that grows along the portal vein system and surrounds the hepatic tissue island when the liver maintains lobular structure connecting to bile duct tree [7]. It was reported that MHL comes from the local area of bile duct atresia, inducing obstruction of distant bile ducts and necrosis of hepatic cells [5]. Some studies showed that MHL correlates with the developmental deformity of vessels and the rupture of 19q13.4 [12,13]. It was reported consider that most of MHL are diploid, but the set of chromosomes of MHL prompt that MHL is not the developmental deformity or the result of abnormal reaction procedure[7,12].

Clinical manifestations

MHL has no special clinical manifestations. The most common symptom is abdominal mass or enlarged liver. The mass increases rapidly in specific cases, leading to inappetence, obvious dyspnoea or obvious obstruction of inferior vena cava. Other symptoms are fever, vomit, constipation, diarrhea and weight loss [6]. Malnutrition, anemia and cachexia are occasionally found . AFP is normal. Some reports indicates that AFP increases in the infancy under 4 month [1]. Surgical operation is the best choice of treatment.

Radiologic finding

Solid type of MHL may have a single focus or multiple foci. In our study MHL was located at right lobe of liver in 5 of 6 cases of solid type, being consistant with other reports [6,8]. In the solid part of MHL, there were remarkably proliferated bile ducts and fibrosis around them to form fibroglandular structure. In 1 multifocal solid MHL, there was fluid retention in mesenchymal tissue (Figure 4). The higher the protein content in the fluid, the higher the signal intensity on T1-weighted images. Some studies showed that the solid part of MHL is formed during perinatal period. The mass enlarges rapidly, because of mesenchyme cystic degeneration with fluid retardation, obstruction and dilation of lymph duct or both [8]. With the growth of MHL, the cystic area in the mass enlarges significantly, taking up greater part of the lesion, because of mesenchyme atrophy, bile duct dilation, lympha retardation. Therefore, the lesion may be solid-cystic type or cystic type, which may be the pathological basis of it (Figure 3). There is no blood supply for MHL[6,8]. The masses shift the vessels in angiography. The septa are thick when there are more solid contents. There are areas surrounded by tumor vessels with no blood supply. Enhanced CT images can show cord-like enhancement [3]. We consider that the lesions with no blood supply may be cystic type, the lesions with less blood supply may be solid type. The part of annular enhancement may compress the hepatic tissue around the lesions. Intrahepatic vessels, inferior vena cava, abdominal aorta and other organs are compressed and shifted by huge MHL masses [1] with blood vessels or peripheral tissues invaded. Calcification is seldom found in MHL, but septum calcification is reported [9].

Treatment and prognosis

MHL seldom cancerates, but canceration can be found in specific cases [10]. In this research, no case was cancerated. Surgical operation is the best choice to treatment. MHL seldom relapses, and its prognosis is good. Surgery should be executed after diagnosis.

Differential diagnosis

Due to the different imagings of MHL, it should be differentiated from hepatic abscess, metastasis, caroli's disease, undifferentiated embryo sarcoma of the liver and hepatoblastoma. In conclusion, MR imaging is a better way to differentiate and diagnose MHL. MHL may be recognized by its characteristic occurrence in infancy and MR imaging features.

<cSize:><cLeading:><cFont:><ParaStyle:<0x4E00><0x7EA7><0x6807><0x9898><0x6B63><0x6587>><cLeading:11.800000>MHL is a rare hepatic benign tumor, occurring most in children and rarely in adults <cLeading:><cLeading:11.800000><cPosition:Superscript>[4]<cLeading:><cPosition:><cLeading:11.800000>. MHL in fetus has also been reported <cLeading:><cLeading:11.800000><cPosition:Superscript>[1]<cLeading:><cPosition:><cLeading:11.800000>.
<cLeading:><ParaStyle:<0x4E8C><0x7EA7><0x6807><0x9898>><cLeading:11.900000>Pathologensis
<cLeading:><ParaStyle:<0x4E8C><0x7EA7><0x6807><0x9898>><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>The exact pathologenesis of MHL is not clear. It has been reported that MHL is a kind of developmental deformity or the result of abnormal reaction procedure <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond><cPosition:Superscript>[8]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>. The abnormality appears in the late stage of embryo formation that grows along the portal vein system and surrounds the hepatic tissue island when the liver maintains lobular structure connecting to bile duct tree <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond><cPosition:Superscript>[7]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>. It was reported that MHL comes from the local area of bile duct atresia, inducing obstruction of distant bile ducts and necrosis of hepatic cells <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond><cPosition:Superscript>[5]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>. Some studies showed that MHL correlates with the developmental deformity of vessels and the rupture of 19q13.4 <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond><cPosition:Superscript>[12,13]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>. It was reported that most of MHLs are diploid, but the set of chromosomes of MHL prompt that MHL is not the developmental deformity or the result of abnormal reaction procedure<cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond><cPosition:Superscript>[7,12]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>.
<cTypeface:><cLeading:><cFont:><ParaStyle:<0x4E8C><0x7EA7><0x6807><0x9898>><cLeading:12.000000>
<cLeading:><ParaStyle:<0x4E8C><0x7EA7><0x6807><0x9898>><cLeading:11.900000>Clinical manifestations
<cLeading:><ParaStyle:<0x4E8C><0x7EA7><0x6807><0x9898>><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>MHL has no special clinical manifestations. The most common symptom is an abdominal mass or an enlarged liver. The mass increases rapidly in specific cases, leading to inappetence, obvious dyspnoea or obvious

obstruction of inferior vena cava. Other symptoms are fever, vomit, constipation, diarrhea and weight loss <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond><cPosition:Superscript>[6]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>. Malnutrition, anemia and cachexia are occasionally found . AFP is normal. Some reports indicates that AFP increases in the infancy under 4 months of age <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond><cPosition:Superscript>[1]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.000000><cFont:Garamond>. Surgical operation is the best choice of treatment.

<cTypeface:><cLeading:><cFont:><ParaStyle:<0x4E8C><0x7EA7><0x6807><0x9898>><cLeading:12.000000>
<cLeading:><ParaStyle:<0x4E8C><0x7EA7><0x6807><0x9898>><cLeading:12.000000>Radiologic finding
<cLeading:><ParaStyle:<0x4E8C><0x7EA7><0x6807><0x9898>><cTypeface:Regular><cLeading:12.100000><cFont:Garamond>Solid type of MHL may have a single focus or multiple foci. In our study MHL was located at the right lobe of liver in 5 of 6 cases of solid type, being consistant with other reports <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.100000><cFont:Garamond><cPosition:Superscript>[6,8]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.100000><cFont:Garamond>. In the solid part of MHL, there were remarkably proliferated bile ducts and fibrosis around them to form fibroglandular structure. In 1 multifocal solid MHL, there was fluid retention in mesenchymal tissue (Figure 4). The higher the protein content in the fluid, the higher the signal intensity on T1-weighted images. Some studies showed that the solid part of MHL is formed during perinatal period. The mass enlarges rapidly, because of mesenchyme cystic degeneration with fluid retardation, obstruction and dilation of lymph duct or both<cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.100000><cFont:Garamond><cPosition:Superscript>
[8]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.100000><cFont:Garamond>. With the growth of MHL, the cystic area in the mass enlarges significantly, taking up greater part of the lesion, because of mesenchyme atrophy, bile duct dilation, lympha retardation. Therefore, the lesion may be solid-cystic type or cystic type, which may be its pathological basis (Figure 3). There is no blood supply for MHL<cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.100000><cFont:Garamond><cPosition:Superscript>[6,8]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.100000><cFont:Garamond>. The masses shift the vessels in angiography. The septa are thick when there are more solid contents. There are areas surrounded by tumor vessels with no blood supply. Enhanced CT images can show cord-like enhancement <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:12.100000><cFont:Garamond><cPosition:Superscript>[3]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:12.100000><cFont:Garamond>. We consider that the lesions with no blood supply may be cystic type, the lesions with less blood supply may be solid type. The part of annular enhancement may compress the hepatic tissue around the lesions. Intrahepatic vessels, <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:11.900000><cFont:Garamond>inferior vena cava, abdominal aorta and other organs are compressed and shifted by huge MHL masses <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cLeading:11.900000><cFont:Garamond><cPosition:Superscript>[1]<cTypeface:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cLeading:11.900000><cFont:Garamond> with blood vessels or peripheral tissues invaded. Calcification is <cTypeface:><cLeading:><cFont:><cTypeface:Regular><cHorizontalScale:0.900000><cLeading:11.900000><cFont:Garamond>seldom found in MHL, but septum calcification is reported <cTypeface:><cHorizontalScale:><cLeading:><cFont:><cTypeface:Regular><cHorizontalScale:0.900000><cLeading:11.900000><cFont:Garamond><cPosition:Superscript>[9]<cTypeface:><cHorizontalScale:><cLeading:><cFont:><cPosition:><cTypeface:Regular><cHorizontalScale:0.900000><cLeading:11.900000><cFont:Garamond>.<cTypeface:><cHorizontalScale:><cLeading:><cFont:><cTypeface:Regular><cLeading:11.900000><cFont:Garamond>

Abstract

AIM: To establish the rapid, specific, and sensitive method for detecting O157:H7 with DNA microchips.

METHODS: Specific oligonucleotide probes (26-28 nt) of bacterial antigenic and virulent genes of *E. coli* O157:H7 and other related pathogen genes were pre-synthesized and immobilized on a solid support to make microchips. The four genes encoding O157 somatic antigen (*rfbE*), H7 flagellar antigen (*fliC*) and toxins (*SLT1*, *SLT2*) were monitored by multiplex PCR with four pairs of specific primers. Fluorescence-Cy3 labeled samples for hybridization were generated by PCR with Cy3-labeled single prime. Hybridization was performed for 60 min at 45 ℃. Microchip images were taken using a confocal fluorescent scanner.

RESULTS: Twelve different bacterial strains were detected with various combinations of four virulent genes. All the O157:H7 strains yielded positive results by multiplex PCR. The size of the PCR products generated with these primers varied from 210 to 678 bp. All the rfbE/fliC/SLT1/SLT2 probes specifically recognized Cy3-labeled fluorescent samples from O157:H7 strains, or strains containing O157 and H7 genes. No cross hybridization of O157:H7 fluorescent samples occurred in other probes. Non-O157:H7 pathogens failed to yield any signal under comparable conditions. If the Cy3-labeled fluorescent product of O157 single PCR was diluted 50-fold, no signal was found in agarose gel electrophoresis, but a positive signal was found in microarray hybridization.

CONCLUSION: Microarray analysis of O157:H7 is a rapid, specific, and efficient method for identification and detection of bacterial pathogens.

INTRODUCTION

In 1982, two outbreaks of hemorrhagic colitis occurred among patrons of a fast-food restaurant chain in Oregon and Michigan. The disease is characterized by watery diarrhea progressing rapidly to grossly bloody diarrhea and abdominal cramping with no fever. An investigation by state health departments and Centers for Disease Control (CDC) indicates that *E. coli* O157:H7, a rare strain not previously linked to human disease, is the cause of the disease[1]. In 1983, Karmali *et al*.[2], reported that *E. coli* O157:H7 is related with hemolytic uremic syndrome (HUS), a leading cause of kidney failure in children. Since then, *E. coli* O157:H7 has been recognized as the leading cause of HUS in the USA, Japan, and in our country. Infection with *E. coli* O157:H7 can be entirely asymptomatic or presents with watery diarrhea, bloody diarrhea, HUS, thrombotic thrombocytopenic purpura, leading to death[3]. Antimicrobial agents have no proven value in the treatment of *E. coli* O157:H7 infections. It was reported that patients receiving antimicrobial agents are more likely to develop HUS than patients not receiving such drugs[4]. It may be prudent to avoid the use of antimicrobial agents in patients with diagnosed or suspected *E. coli* O157:H7 infection. Traditionally, *E. coli* O157:H7 is identified by microbiological culture techniques and immunological methods that are used to detect the O157 and H7 antigens[5]. These methods are slow and complicated, and sometimes yield false-positive results when other variants of *E. coli* O157:H7 are occasionally isolated in the initial culture. Therefore, accurate and rapid identification is important for the diagnosis of O157:H7 infection.

DNA and oligonucleotide microchip (microarray) technology play an increasingly important role in gene expression, phylogenetic classification of bacteria, mapping of genes, analysis of single-nucleotide polymorphisms, drug discovery, multiple microbial diagnosis, and toxicological research[6-8]. Since microchips with short (8-30 nt) synthetic oligonucleotides are more sensitive to genetic differences, they are more appropriate for discriminating microorganisms.

In the present study, we used gene *rfbE* encoding an enzyme involved in the biosynthesis of O157 antigen (the somatic antigen), and gene *fliC* encoding the H7 flagellar antigen, and gene Shiga-like toxin (SLT) 1 and 2, encoding virulent factors, for the diagnosis of *E. coli* O157:H7 infection diagnosis by microarray analysis. It seems very useful for automatic identification and characterization of bacterial pathogens.

MATERIALS AND METHODS

Bacterial strains and other pathogens

O157:H7, *Vibrio cholerae, Shigella, Salmonella, DH5α,* and other *E. coli* strains were from National Institute for the Control of Pharmaceutical and Biological Products, CDC of Jiangsu and Shandong Provinces, and our laboratory. All strains were stored at -80 ℃ in Luria-Bertani broth containing 15% glycerol. *Schistosoma japonicum, hemorrhagic fever and renal syndrome virus (HFRSV), Leptospira interrogans, Rickettsia Tsutsugamushi,* and *Plasmodium* were also from CDC of Jiangsu, Guangdong, Fujian Provinces and our laboratory.

PCR primers and oligonucleotide probes

Primers used to amplify the fragments of antigenic genes and virulent genes are shown in Table 1. One primer was labeled with Cy3 (TaKaRa Co.). BLAST search was used to retrieve the homologous sequences of each of the four genes analyzed. For each gene, one conserved region containing approximately 26-28 nucleotides was chosen as the target sequence probe. The probes and their BLAST search results are also shown in Table 1.

Microchip design and fabrication

Microchips were printed on silylated (aldehyde-coated) glass slides (8 cm×2.5 cm, Sigma Co.) by the contact microspotting robotic system 7 500, the PixSys 5 500 workstation microspotting software (Cartesian Technologies, Inc.), and the ChipMaker Pin 40 microspotting device. Microchip design maps are shown in Table 2. The final spotting mixture contained 100 μmol/L specific oligonucleotide probe (TaKaRa Co.) in 0.25 mol/L acetic acid. A range of 70-75% humidity was maintained in an environmental chamber to prevent rapid evaporation of spotted drops and efficient coupling of amino-modified oligonucleotides with the aldehyde groups on the glass surface. Six identical probe area arrays were printed on each slide, allowing analysis of six samples on one glass slide simultaneously. The size of spots did not exceed 150 μm in diameter. Printed slides were incubated at 37 ℃ for 60 min, then overnight at room temperature. The next day, slides were washed twice with 0.2% sodium dodecyl sulfate (SDS) in water for 5 min, twice with distilled water for 5 min each, and then dried in air. Before hybridization, to make the bonds between oligonucleotides and glass surface irreversible, the slides were incubated for 30 min in a freshly prepared 0.6% aqueous solution of $NaBH_4$, then washed twice with 0.2% SDS for 1 min and twice with distilled water for 1 min. Microchips prepared according to this protocol could be stored for 2 mo at room temperature.

Multiplex PCR

E. coli cultures were grown overnight at 37 ℃ in Luria-Bertani broth. One milliliter of the culture sample was centrifuged, and the pellet was washed and resuspended in 100 μL of distilled water. The suspension was boiled for 10 min followed by centrifugation at 10 000 *g* for 10 min to remove denatured proteins and bacterial cell membranes. Five-microliter aliquot of the supernatant was used as the template for multiplex PCR amplification. Briefly, 50 μL of the reaction mixture containing 5 μL, 10×PCR buffer, 0.2 mmol/L dNTPs, 2.0 mmol/L $MgCl_2$, 0.5-1.0 pmol/L each primer and 1.5 U of Taq polymerase (TaKaRa Co.) was used. Temperature conditions consisted of an initial pre-denaturation step at 95 ℃ for 5 min, followed by 35 cycles at 94 ℃ for 30 s, at 57 ℃ for 45 s, and at 72 ℃ for 60 s, a final extension at 72 ℃ for 5 min. The PCR products were analyzed by electrophoresis on 1% agarose gel in TAE (40 mmol/L Tris-acetate, 2 mmol/L disodium EDTA). DNA bands in the gels were stained with 0.5 μg/mL of ethidium bromide. The interested DNAs were extracted using DNA fragment purification kit Ver. 2.0 (TaKaRa Co.) and dissolved in 50 μL of distilled water

for the next Cy3 labeling.

Synthesis of Cy3-labeled PCR samples

Fluorescence-labeled samples for hybridization were generated by PCR as described above, except that the annealing temperature was 42 ℃, and the template was the first multiplex PCR products (5 μL), the primer was only one Cy3-labeled (0.2 μmol/L) primer or four different Cy3-labeled (0.2-0.4 μmol/L) primers.

Microarray hybridization and scanning

Immediately before hybridization, 8 μL Cy3-labeled PCR samples was mixed with 3 μL hybridization buffer containing Cy3-labeled quality control (0.3 μmol/L) probe, and denatured for 5 min at 95 ℃, then chilled on ice for 1 min. This concentration could ensure rapid and efficient hybridization of a fluorescent sample with immobilized probes. Five-microliter aliquots from each sample was applied to the microarray area and covered with a glass coverslip to prevent evaporation of the sample during hybridization in the incubation chamber. Hybridization was performed for 60 min at 45 ℃. Slides were then washed twice with 2×SSC containing 0.1% SDS for 5 min at 60 ℃, twice with 0.1×SSC containing 0.1% SDS for 5 min at room temperature, and once with 0.1×SSC, once with distilled water and dried by an air stream to completely remove any remaining solution. Then microchip images were taken with the confocal fluorescent scanner ScanArray 3 000.

RESULTS

Multiplex PCR and microchip analysis of bacterial virulent genes

We detected 12 different bacterial strains with various combinations of four virulent genes. The results of multiplex PCR and microchip analysis generated by bacterial DNA and four primers or probes are shown in Table 3. All the O157:H7 strains yielded positive results. The size of the PCR products generated by these primers varied from 210 to 678 bp. The other non-O157:H7 strains were not positive. The pitfalls of agarose gel analysis of multiplex PCR are illustrated in Figure 1. The difference of SLT1 and SLT2 was too small (only 18 bp) to be distinguished in agarose gel electrophoresis.

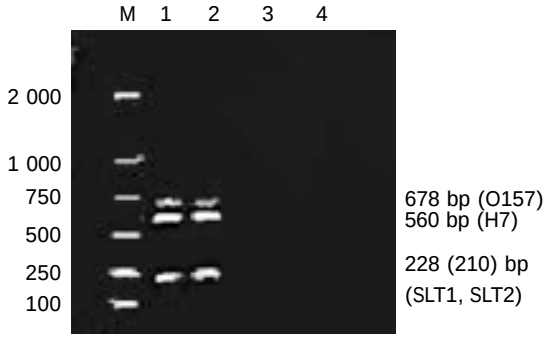

Figure 1 Result of multiplex PCR. Lane 1: O157:H7 882364 strain; lane 2: O157:H7 933 strain; lane 3: *Vibrio cholerae*; lane 4: DH5α.

Microarray hybridization specificity and sensitivity

All the rfbE/fliC/SLT1/SLT2 probes specifically recognized Cy3-labeled fluorescent samples from O157:H7 species, or strains containing O157 and H7 genes. Neither the cross hybridization of O157:H7 fluorescent samples to other probes (Figures 2A-C), nor cross hybridization of rfbE/fliC/SLT1/SLT2 probes to other pathogens (Figure 2D) was detected. If the Cy3-labeled fluorescent product of O157 single PCR was diluted 50-fold, no signal was visible in agarose gel electrophoresis, but a positive signal was found in microarray hybridization (Figure 2E).

DISCUSSION

E. coli is a normal inhabitant in the intestinal tract of human beings and warm-blooded animals. Although usually harmless, various strains such as *enterotoxigenic E. coli* (ETEC), *enteropathogenic E. coli* (EPEC) and *enterohemorrhagic E. coli* (EHEC), have virulent genes and render them pathogenic for both human beings and animals. *E. coli* O157:H7 is an important cause of hemorrhagic colitis and HUS. Conventional methods for detecting O157:H7 involve growth of non-sorbitol-fermenting *E. coli* colonies on sorbitol MacConkey agar culture (SMAC)[9]. These methods are time consuming, laborious, and expensive. More importantly, routine biochemical and serologic tests for pathogen identification can only type the species or serogroup level, but cannot directly characterize virulent genes. Thus, these assays cannot provide any information

about the potential pathogenicity or virulence of O157:H7[10]. Several genetic markers such as *rfbE*[11], *fliC*[12], and certain virulent genes as attachment and effacing gene (*eaeA*), hemolysin A (*hlyA*)[13,14], *SLT1*, *SLT2*[15] are useful targets for multiplex PCR amplification and differentiation of O157:H7. Although multiplex PCR amplification is a simple and sensitive method[16], it has some inherent shortcomings. When multiplex PCR is used for detection of several genetic markers, it tends to generate more nonspecific DNA products. If the size of PCR products is similar, it is difficult to discriminate these products. Therefore, it is necessary to establish high-throughput specific and sensitive methods for detecting O157:H7.

Hybridization of DNA samples to miniature arrays (microchips) of immobilized gene-specific DNA or oligonucleotide probes has recently become a powerful tool. A number of different ways can make oligonucleotide microchips, including *in situ* synthesis of oligonucleotides directly on the microchip surface[17] and immobilization of pre-synthesized oligonucleotides on a solid support[18]. We designed four genotype-specific oligonucleotide probes (*rfbE*, *fliC*, *SLT1*, and *SLT2*) for O157:H7, and immobilized them on a modified glass surface to create the microchip. *RfbE* and *fliC* are the specific marker genes encoding O157 somatic antigen and H7 flagellar antigen. *SLT1* and *SLT2* are the important virulent genes. Schmidt *et al*.[19], reported that the bacteriophage-encoded SLT plays a very important role in the pathogenesis of diseases caused by O157:H7, and in HUS through its cytotoxic effects on cells of the kidneys, intestines, central nervous system, and other organs. If infected with O157:H7 strain with SLT, many patients would develop HUS. Using these microchips, we can not only characterize the species of pathogens, but also identify their virulent factors SLT1 and SLT2. The major advantage of the microarray assay over agarose gel analysis of multiplex PCR products is that the microarray requires the internal sequences of DNA fragments to be complementary to the oligonucleotide probes on the microchip, but does not solely rely on the length of PCR products. In our study, only O157:H7 strains and SLT1, SLT 2 presented positive fluorescent signals. The successful demonstration of hybridization specificity led us to address the second critical parameter of microarray, assay sensitivity. When the Cy3-labeled product was diluted 50-fold, no positive signal was visible in agarose gel electrophoresis, but a positive hybridization signal was found in microchip, suggesting that microarray is more sensitive than agarose gel analysis.

In this study, to assess the synthesis of Cy3-labeled samples by multiplex and single PCR, we examined the same O157:H7 882364 strain in different ways. Multiplex and single PCR could display positive hybridization in microchip. Compared to multiplex PCR, the fluorescent signals of single PCR synthesis were more homogeneous and easier to control the PCR mixture concentration and microarray sample content. In conclusion, microarray analysis is a fast, sensitive, specific, and high throughput method for detecting O157:H7.

Abstract

AIM: To investigate the distribution of 12 high-pathogenicity island (HPI) genes and the relation between HPI genes and expression of yersiniabactin (Ybt) in enteroaggregative *E.coli* (EAggEC) isolated from Chinese diarrhea patients.

METHODS: The distribution of 12 HPI genes was investigated by PCR and DNA hybridization in two prototype strains of EAggEC, EAggEC 17-2, EAggEC O42, and 6 clinical EAggEC isolates from China. The production of siderophore Ybt in HPI-positive strains was detected by reporter gene bioassay to determine the relation between HPI genes and expression of Ybt. Flow cytometry was used to detect fluorescent signal of the reporter strain that could designate production of Ybt.

RESULTS: Seven strains were HPI-positive and one strain was HPI-negative. Six of the seven HPI-positive strains were inserted into *asnT-tRNA* site. Moreover, seven EAggEC HPI-positive strains revealed enhanced fluorescence signal but the EAggEC HPI-negative strain did not. However, there was a difference in Ybt expression condition and level among these seven EAggEC HPI-positive strains. Although UFT073 strain, the prototype strain of uropathogenic *E.coli* (UPEC), carried the complete HPI core part, we did not detect the expression of Ybt in it.

CONCLUSION: EAggEC HPI-positive strains can express the Ybt system, but the presence of HPI core part does not mean the functional expression of Ybt.

INTRODUCTION

High-pathogenicity island (HPI) encoding synthesis and uptake of the siderophore yersiniabactin (Ybt) has been primarily identified in mouse lethal *Yersinia*: *Yersinia pestis*, *Yersinia pseudotuberculosis* serotypes O1-O3, and *Yersinia entercolitica* 1B biotype[1-5]. The *Yersinia* HPI consists of a 30.5 kb highly conserved functional core region termed Ybt locus and a 5- to 13-kb AT-rich variable part[1]. The core part comprises genes, *irp1-irp5* and *irp9* for the biosynthesis of the Ybt, *irp6-irp8* and *fyuA* for the uptake of Fe-Ybt, the AraC-like regulator *ybtA* and the integrase *intB* resides on the 5' end of the HPI right-end extremity next to the *asn-tRNA* bacterial attachment site[6-9]. Ybt-mediated iron acquisition is the main function of HPI[8,10]. Recently, HPI is subsequently identified in other bacterial genera such as *E.coli*, *Citrobacter diversus*, various species of *Klebsiella*[11-16]. Whether HPI in *E.coli* has the functional expression of Ybt is the premise to understand that HPI contributes to virulence or ecological fitness. Schubert *et al*.[14], reported that 93% EAggEC, 5% enteropathogenic *E.coli*, 27% enteroinvasive *E.coli* and 5% enterotoxigenic *E.coli* carry HPI by hybridization with an *irp2* probe, but none of enterohemorrhagic *E.coli* harbors it. It is still unclear why the distribution frequency of HPIs is different among various *E.coli* strains. Considering the high prevalence of HPI in EAggEC, in the present study, we detected all the12 genes of HPI by PCR and DNA hybridization in the EAggEC 17-2, EAggEC O42, and 6 EAggEC clinical isolates from Chinese diarrhea patients. By reporter bioassay, products of Ybt in these strains were determined under iron-rich or -poor conditions to demonstrate the function of *Yersiniae* HPI in EAggEC strains. The relation between HPI genes and their function was discussed.

MATERIALS AND METHODS

Bacterial strains and growth conditions

EAggEC O42 (O44:H18), 17-2 (O3:H2), CFT 073, JM109, and *Y. entercolitica* WA (O:8) were provided by Key Laboratory for Molecular Bacteriology in Chinese Center for Disease Control and Prevention. Six EAggEC strains isolated from Chinese diarrhea patients were confirmed by PCR and DNA hybridization with EAEC specific primer[17]. The codes of these strains were EAEC 47/37, EAEC 66, EAEC SS23, EAEC B86-2, EAEC E1073, and EAEC 52/46. The reporter strain *WA-CS irp1*:*KN* [14,18,19] was kindly provided by Professor A. Rakin. *Yersinia* strains were grown in Luria Bertani (LB) broth with shaking at 28 ℃ for 48 h and other *E.coli* strains at 37 ℃ for 24 h. The iron-deficient medium (LBD) was obtained by the addition of 0.2 mmol/L dipyridyl (Sigma) to LB broth. *Y. enterocolitica* WA (O:8) was used as positive control, while *E.coli* JM109 as negative control for PCR amplification and DNA blotting and Ybt assay.

Primers and PCR amplification

PCR was carried out in a 50 μL reaction volume containing template DNA (5 μL of boiled lysate), 1.5 mmol/L $MgCl_2$, 0.4 mmol/L of each of dNTPs, 0.5 μmol/L of each primer, and 25 U of Taq polymerase (TAKARA, Japan) with an automated thermal cycler (GeneAmp 9700, PE Biosystems, USA). The primers were designed according to the HPI sequence of *Yersinia* from GenBank and synthesized by Sangon (Shanghai, China).

Each set of primers and size of the amplified fragments are listed in Table 1. The pre-denaturation (94 ℃, 5 min) was followed by 30 cycles of denaturation (94 ℃, 1 min), annealing (53-58 ℃, 40 s-1 min), and extension (72 ℃, 30 s-2 min 30 s) with an additional extension step (72 ℃, 7 min). In this study, we amplified all the 12 genes within HPI functional core part. Among them, *asnT-tRNA-intB* fragment included 3' end partial sequence of *asnT-tRNA* gene and complete *intB* gene, while others contained the partial fragment within the internal of the corresponding gene. PCR products were electrophoresed in 1-1.5% agarose gels stained with ethidium bromide and visualized under UV light.

Dot blotting

Dot blotting for the *fyuA* and *irp2* genes was performed on DNA extracted from each strain and spotted on positively charged pyroxylin membranes. Hybridization was performed at 65 ℃ in 1% SDS/1 moL NaCl/Tris 50 mmol/L HCl, pH 7.5/1% blocking reagent. The membranes were washed in 2× SSC for 15 min at room temperature, then in 2× SSC/0.1% SDS for 30 min at 65 ℃, finally in 0.1× SSC for 5 min at room temperature. The probes were produced by PCR according to the manufacturer's instructions (PCR DIG Probe Synthesis kit, Roche), using the primers and amplification procedure described above. Digoxigenin labeling was probed and hybridized with a DNA labeling and detection kit (DIG Luminescent Detection kit for nucleic acids, Roche) according to the manufacturer's instructions.

Yersiniabactin assay

A reporter strain system, *Y. enterocolitica* strain *WA-CS irp1:KN* (pCJG3.3N), constructed by Schubert *et al.*[18], was used to monitor the expression of Ybt. This strain was deleted in the Ybt biosynthesis gene (*irp1*) and carried the *fyuA-gfp* reporter plasmid pCJG3.3N. As the expression of the *fyuA* gene was unregulated in the presence of the extracellular Ybt, supernatants of bacteria grown under normal (LB medium) or iron-deficient conditions (LBD medium) were applied to this reporter strain, which could lead to increased expression of the *fyuA-gfp*, if Ybt was present.

We streaked the bacteria on Luria broth agar plates and inoculated about 5 mL LB medium for overnight culture as a start culture. From this preculture we inoculated the main culture on LB and LBD medium, respectively. The strains were incubated in the media for at least 7 d. Supernatants of the strains were added to the reporter strain, and flow cytometry for the reporter strain was done with an Epics flow cytometer (FACSCalibur, Becton Dickinson) and an argon 488-nm laser was used. The scale was logarithmic, and fluorescence data determined in arbitrary units were collected from 50 000 bacteria.

RESULTS

Integration analysis of HPI genes in EAggEC strains

We examined eight EAggEC strains for the presence of all the 12 HPI genes. *irp1-irp9*, *fyuA*, and *ybtA* genes were detected in seven strains of EAggEC by PCR and the amplification products were the same as *WA* positive control in lengths (Figure 1). One strain (EAEC 47/37) isolated from diarrhea patients did not yield any amplification products of these 12 gene primers.

In *Yersinia*, the site of HPI integration, bacterial chromosomes sharing homologies with the bacteriophage P4 attachment site are located within an *asn-tRNA* locus[4,20]. The *asnT-tRNA-int* fragment was also identified in six of seven HPI-positive strains, but not in EAEC B86-2, indicating that the strain might have a different insert site from others or the edge of HPI was damaged. We also confirmed the results by DNA-blot hybridization, using *irp2* and *fyuA* genes as probe (data not shown). All the 12 HPI genes were detected also in CFT073 strain, the prototype strain of UPEC, demonstrating that the core region of HPI was present in EAggEC strains with a high frequency. Moreover, HPIs in most of these strains were inserted in *asn-tRNA*, as in *Yersinia*.

Detection of yersiniabactin production in EAggEC strains carrying Yersinia HPI

We detected the expressions of Ybt in eight *EAggEC* strains and UFT073 strain under normal (LB medium) and iron-deficient conditions (LBD medium) using the reporter strain *WA-CS irp1:KN*. *WA* stain was used as positive control while *WA-CS irp1:KN* and *HB101* as negative control.

Figure 2 shows that the culture supernatants of these

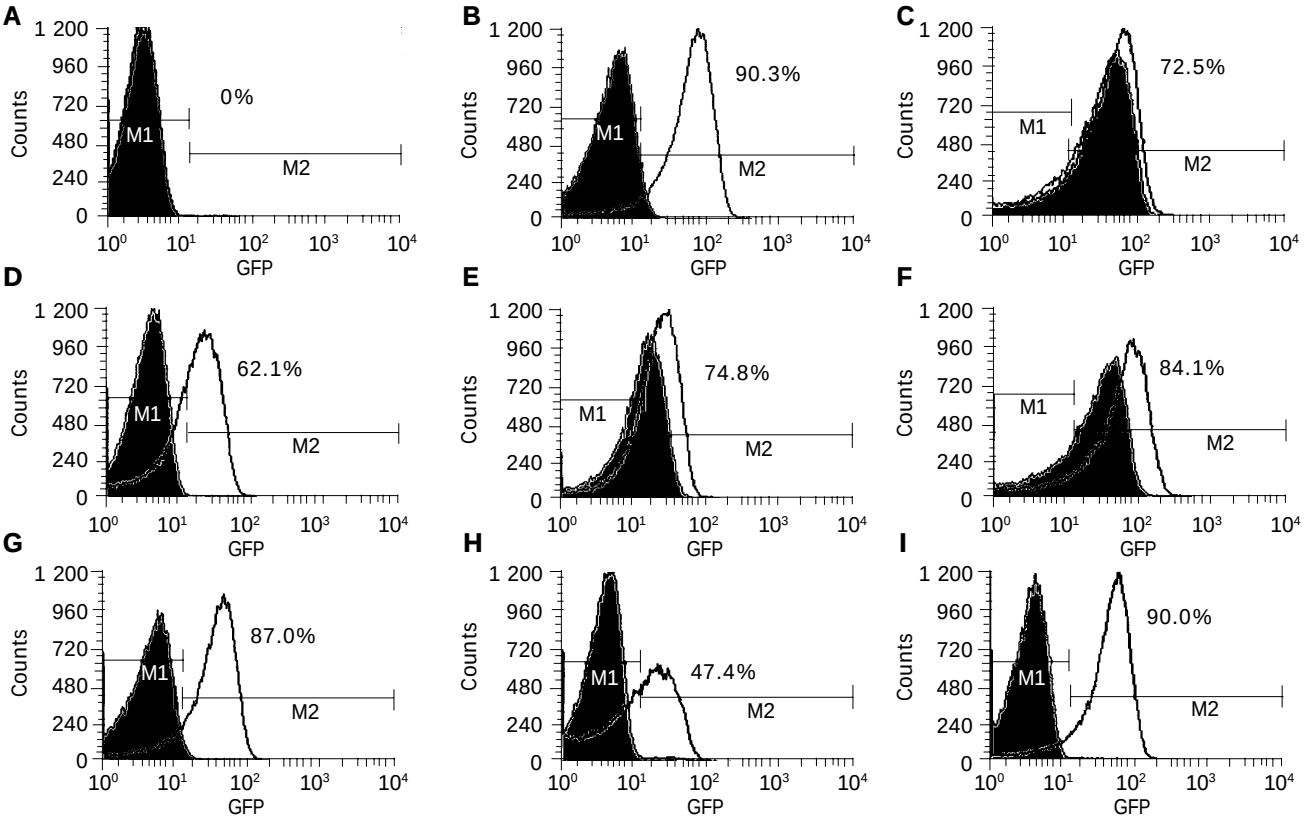

Figure 2 Fluorescence of *fyuA-gfp* in *E.coli* grown on LB media (green curve) and LBD media (black curve). A: *WA-CS irp1::KN(pCJG3.3N),* CFT073(HPI$^+$), HB101(HPI$^-$) and EAEC 47/37(HPI$^-$); B: WA(HPI$^+$); C: EAEC 66(HPI$^+$); D: EAEC SS23(HPI$^+$); E: EAEC B86-2(HPI$^+$); F: EAEC E1073(HPI$^+$); G: EAEC 52/46(HPI$^+$); H: EAEC 17-2 (HPI$^+$); I: EAEC O42 (HPI$^+$); M1: specified range of background of fluorescence signal; M2: specified range of enhanced florescence signal.

seven HPI-positive EAggEC strains grown on iron-deficient medium exhibited apparently enhanced fluorescent signals of the *fyuA-gfp* reporter strain. Among these seven strains, EAggEC O42 had the strongest expression of Ybt (90%), which was nearly equal to the positive control strain WA (90.3%), and EAggEC 17-2 had a comparatively weak signal (47.4%), indicating that the seven EAggEC strains could express Ybt under iron-deficient conditions. Interestingly, the supernatants of three isolates, EAEC66, EAEC B86-2 and EAEC E1073, grown on normal media could stimulate the reporter strain too, but the fluorescent signals were weaker than those grown on the iron-deficient medium. On the other hand, in WA strain, EAggEC 17-2, EAggEC O42, and two other HPI-positive isolates, EAEC SS23 and EAEC 52/46, the fluorescence signals were not enhanced when the bacteria were grown on LB medium. In addition, whether bacteria were grown under iron-rich conditions or iron-deficient conditions, the supernatants of two HPI-negative strains, HB101 and EAggEC 47/37, and one HPI-positive strain, CFT 073, did not affect the expression of the *fyuA-gfp* reporter gene.

The results suggested that EAggEC HPI-positive strains could express the Ybt system, but there was a difference in expression condition and level of Ybt among them.

DISCUSSION

In the genus *Yersinia*, *irp1-irp5* and *irp9* genes are essential for Ybt synthesis, and *irp6*, *irp7*, *fyuA* genes for Ybt transport. The pathway of Ybt uptake is blocked if any one of these genes mutates or misses. In this study, we investigated whether EAggEC strains carrying *Yersinia* HPI genes could express the corresponding products and whether the series of products could synthesize functional Ybt. In order to understand these events, we should know if these EAggEC strains carry the integrated functional core region of HPI.

The presence of HPI in enterobacteriaceae strains has been confirmed only by PCR amplification of *irp2*/*fyuA* and DNA hybridization, but the results of *irp2*/*fyuA* detection are not always identical[11,14]. Usually, the detection rate of *fyuA* is lower than that of *irp2*, which might be explained by the fact that *fyuA* gene is located in the boundary of HPI functional core region, and during the process of evolution it is liable to be damaged or changed due to the instability of HPI. As the exact mechanisms of transport, excision and synthesis of HPI are still unclear, the detection results of individual genes are not sufficient to confirm the presence of integrated functional core region. To avoid this problem, in this study, all the 12 genes in the functional core region of HPI were amplified by PCR. HPI was positive in seven of eight EAggEC strains, and six of seven HPI-positive EAggEC strains were positive *for asnT-tRNA-int* gene but not for EAEC B86-2 strain, indicating that the seven HPI-positive EAggEC strains carry the necessary genes for synthesis, transport and regulation of Ybt. HPIs in these EAggEC strains are often inserted into *asnT* locus on the chromosome, while HPI of EAEC B86-2 strain might be inserted into different loci of other strains or its border sequence is damaged.

To demonstrate the production of Ybt, we used a detection system based on Ybt-induced upregulation of a Ybt reporter gene *fyuA-gfp*. Schubert *et al.*[18], found that 49 of 60 HPI-positive enterobacteriaceae isolated from blood cultures and urine samples can produce Ybt using this system. Our study showed that Ybt could be synthesized in the seven HPI-positive EAggEC strains, including the strain of EAEC B86-2 with an incomplete *asn-tRNA-int* gene. However, not all HPI-positive strains could express Ybt. Based on the HPI transfer mechanism and bacterial evolution, we can make one intriguing hypothesis that under certain selective pressure, bacteria can obtain HPI, and then mutations occur during the process of evolution, thus resulting in the loss of function. However, bacteria could survive by changing themselves to adapt to the environment in the evolutionary process. Another hypothesis is that various bacteria can obtain HPI independently, a kind of random event rather than necessary for living, and the non-functional HPI remains in bacteria. The results suggest that the presence of *irp2*/*fyuA* does not necessarily mean that the integrated 'functional core region' of HPI is complete, and the presence of integrated functional core region of HPI does not necessarily mean that functional Ybt is synthesized.

Under iron-deficient condition (LBD medium), the seven HPI-positive EAggEC strains of Ybt were differently expressed, and some strains were different from WA strain in characteristics of Ybt expression. Only under iron-deficient condition, the Ybt system of WA strain could be activated. On the contrary, in our study expression of Ybt under normal condition could also be detected in three HPI-positive EAggEC strains. The reason why Ybt systems in these strains are easy to be activated remains to be clarified. A possible explanation might be that the difference in genetic structure of bacteria can result in the different need of iron. Though most enterobacteriaceae carry genes encoding high-affinity iron uptake systems, such as enterobactin system and aerobactin system, the fact that most *E.coli* HPI-positive strains have the ability to synthesize Ybt while others do not, may mean that the expression of Ybt possess more specific functions during different infection phases. It was reported that Yen-HPI core genes are insufficient to confer a positive chrome azurol S (CAS) phenotype and mouse virulence to the siderophore-deficient strain *Y. enterocolitica* NF-O (BG 1A), but sufficient to confer MRS40 (serotype O:9, BG 2; phenotype, CAS negative)[21]. Therefore, it is conceivable that the expression of Ybt may also be regulated by genes outside the HPI to adjust bacteria to make a living in iron-limited environment. More studies are needed to clarify the contribution of *Yersinia* HPI to the virulence of *E.coli*.

ACKNOWLEDGMENTS

The authors thank Rakin A (Max von Pettenkofer Institute, Germany) for kindly providing *WA-CS irp1:KN* (pCJG3.3N) reporter strain system and Schubert S (Max von Pettenkofer-Institute, Germany) for technical assistance and helpful discussion.

Abstract

AIM: The permissible exposure limit (PEL) of vinyl chloride monomer (VCM) in developed country was 1 p/m (2.79 mg/m^3); and threshold limit value-short term exposure limit (TLV-STEL) in China was 11 times higher [11 p/m (30 mg/m^3)] than it, till 2002. The mechanism of vinyl chloride monomer (VCM)-related carcinogenesis remains unclear. We aimed to analyze occupational health hazards exposure to doses lower than the Chinese occupational health standard in a selected VC polymerization plant in China, and also to elucidate the relationship between genetic polymorphisms and genetic susceptibility on liver lesions of workers exposed to VCM.

METHODS: In order to explore the mechanism of VCM-related health effects, we used a case-control design to investigate the association between the genetic polymorphisms of metabolic enzymes and liver lesions in workers occupationally exposed to VCM. Genotypes of *CYP2E1*, *GSTT1, GSTM1, ALDH2* and *ADH2* were identified using PCR and PCR-RFLP.

RESULTS: Even when the concentration of VCM was lower than the current Chinese occupational health standard, neurasthenia, pharyngeal irritation, liver ultrasonography abnormalities and hemoglobin disorders were significantly higher in exposure subjects compared to non-exposure subjects, and the relative risks (*RR* and 95% *CI*) were 1.74 (1.06-2.85), 1.97 (1.56-2.48), 10.69 (4.38-26.12), and 2.07 (1.20-3.57). *CYP2E1 c1c2/c2c2* genotype was significantly associated with liver damages (*OR* 3.29, 95% *CI* 1.51-7.20, *P*<0.01).

CONCLUSION: The incidences of neurasthenia and liver ultrasonography abnormalities significantly increase when the cumulative exposure dose increases. The genotypes of metabolic enzymes (*CYP2E1 c1c2/c2c2*, null *GSTT1* and *ADH2 1-1*) play important roles in VCM metabolism. Polymorphisms of *CYP 2E1*, *GSTT1* and *ADH2* may be a major reason of genetic susceptibility in VCM-induced hepatic damage.

INTRODUCTION

Vinyl chloride monomer (CH_2 = CHCl, VCM) is a colorless gas and a synthetic chemical that does not naturally occur. It is also known as monochloroethylene and chloroethene. At normal temperature it has a mild, sweet odor. Because VCM is easily polymerized to polyvinyl chloride, it is widely used in industry primarily. In fact, in the seventies of last century, 95% of the vinyl chloride produced was polymerized, and the rest is used in the formation of other chemicals. VCM was found to be easily absorbed through the respiratory tract, where it passed into the blood. Most studies concluded that the target organs for the VCM action are the liver, brain, lung, lymphohematopoietic system and skin, and hepatic lesion is its characteristic manifestation[1-3]. In 1974, the US National Institute of Occupational Safety and Health and US Centers for Disease Control and Prevention (CDC), reported that several deaths at one of their plants in a chemical company could be related to occupational exposures of vinyl chloride[4,5]. VCM has been classified by the International Agency for Research on Cancer (IARC) as a Group I carcinogen[6]. Since vinyl chloride is a known carcinogen, it has caused great concern to people who may be exposed to it.

PVC manufacture is a major industry in China, with total annual production of two or three million tons till now. In 1970's, China began to produce PVC, the output increased from 780 000 tons in 1990 to nearly 2 400 000 tons in 2000, and the figure will increase to 3 million tons

in the near future. Thousands of workers could be exposed to VCM. The permissible exposure limit (PEL) of VCM in developed country was 2.79 mg/m^3, and in China which was 11 times higher (30 mg/m^3) than it till 2002. Some studies of health hazards of workers exposure to VCM in China had been done. The results of these studies showed a high prevalence of abnormal liver function and neurasthenia as well as other symptoms due to exposure to VCM[7,8], and more tumors in VCM-exposed workers can be expected in future. However, the workers studied in the aforementioned studies were exposed to VCM at levels higher than the Chinese PEL. There is a general lack of information on estimates of health effects of workers exposed to lower levels of VCM exposure.

Earlier studies were more concerned with exposure levels and effects of vinyl chloride. More recently, there have been studies done on how vinyl chloride reacts in the body leading to cancer, both how it is bioactivated and how it interacts with DNA and forms DNA adducts. An earlier animal study has reported that VCM is primarily metabolized in the liver by CYP2E1 into active chloroethylene oxide (CEO), some of the CEO reacts to form adducts, 7-(2-oxoethyl) guanine. This adduct has been found in the most abundance, but it has not shown mispairing during DNA replication. Since CEO is unstable, it rearranges to chloroacetaldehyde (CAA)[9]. Once CAA is formed, it reacts with adenine, cytosine and guanine to form adducts. Reactions with guanine are less frequent than adenine and cytosine. There are four known etheno-adducts: 1, N^6-ethenoadenine (εA); 3, N^4-ethenocytosine (εC); N^2, 3-ethenoguanine (N^2, 3-εG); and 1, N^2 ethenoguanine (1, N^2 εG)[10]. These adducts contain an additional five-membered ring system. Although these adducts are known to be formed, it is still unclear which one induces errors during DNA and RNA synthesis, for both of which may be reactive with DNA to form DNA adducts[11], and are mutagenic in bacterial systems and mammalian cells[12].

Most of population-attributable cancer heritability is related not to the rare deleterious gene defects but to polymorphic variations in the DNA sequence. CYP2E1 has already been reported to be associated with lung cancer in smokers[13]. In a recent study performed in the Caucasian population, CYP2E1 can account for only a small proportion of the variability in mutagenic response to VCM exposure[14]. Furthermore, CEO may then be metabolized by GSTs, and simultaneously CAA may be metabolized by ALDH2 and ADH2. Thus, those with appropriate types of ALDH2, ADH2, and GSTs may also have elevated reactive intermediates, which can lead to increased liver damages. The metabolism of VCM is mostly concerned with the enzymes CYP2E1,GSTT1, GSTM1, ALDH2 and ADH2. Several studies have shown that all the enzymes exhibit their genetic polymorphisms[15-17], thereby causing different biological effects of metabolizing enzymes.

We aimed to analyze occupational health hazards exposure to doses lower than the Chinese occupational health standard in a selected VC polymerization plant in China, and provide information whether occupational health standard of VCM exposure needs to be revised in China, and also to elucidate the relationship between genetic polymorphisms and genetic susceptibility on liver lesions of workers exposed to VCM.

MATERIALS AND METHODS

Study subjects and epidemiological data

Information was collected from workers at the VC polymerization plant by using interviewer-administered questionnaires, subsequent to informed consent having been obtained during the medical surveillance process. The structured questionnaire contained questions that covered demographic characteristics, lifestyles, including cigarette-smoking habits and alcohol consumption, as well as compiling a detailed occupational history. Individuals who smoke once a day for over 6 mo were defined as smokers, and individuals who consumed once or more alcohol drinks a week for over 6 mo were considered drinkers.

Study subjects exposed to VCM for a period of >1 year in the plant were selected if the following criteria were met: detailed questionnaires had been completed; the hepatitis B, C viruses' status were known; and a blood sample could be provided. At final tally, a total of 163 male and 75 female workers in the industry, with an average age of 33 years (range, 19-54 years) and an average exposure time of 7 years, and who had been occupationally exposed to VCM were included for analysis. One hundred and twenty four male and 88 female employees, with an average age of 38 years (range, 23-60 years), were selected as the non-exposure group, who worked in the same industry as the exposure subjects but not occupationally or environmentally exposed to VCM previously. The workers infected with hepatitis B, C viruses were excluded from the study because hepatitis B, C also leads to liver lesions.

Based on the results of medical examination, we divided the workers in the VCM exposure group into two groups. Fifty eight workers were selected as "liver lesion group" for their liver ultrasonography abnormality and/or alanine aminotransferase (ALT) >40 for at least 2 years and did not get acute hepatitis, chronic hepatitis and cholelithiasis. The "control subjects" were employees who worked at the same worksites as the liver damage group and also had exposure to VCM. Each control was matched for gender, duration of work, worksite, and cumulative exposure dose.

Assessment of vinyl chloride exposure

Exposure levels of VCM in the plant were based on existing environmental monitoring data. The plant kept VCM air concentration data, and the data were generated at different worksites since the beginning of its establishment. The level of VCM was calculated at different worksites of the company, which ranged from 0.3 p/m (0.85 mg/m^3) to 17.8 p/m (48.41 mg/m^3) in air, with a geometric average concentration was 2.6 p/m (7.11 mg/m^3). And then the cumulative exposure dose of each worker was estimated relatively exact. The following equation was used to calculate cumulative exposure dose: Cumulative exposure dose (mg) = Σ (C * M * T) * A* 70%/10^6, where C (mg/m^3): Geometric mean of VCM exposure concentration each year in a special workplace, calculated for all different worksites; M: number of exposure months of each year for a VCM worker; T: 2 h exposure time at each working day, 20 d in each month (exposure time per month was 2 400 min); and A: alveolar ventilation (male average: 6 500 mL/min, female average: 4 300 mL/min, 30% dead space).

Cumulative exposure dose in VCM exposure group ranged from 1 047.41 mg to 33 357.11 mg. Then the VCM exposure subjects were divided into high-exposure and low-exposure groups. The individuals placed into the high-exposure group had been exposed to a cumulative dose of >15 000 mg and those in the low-exposure group with their cumulative dose of ⩽15 000 mg.

Genotyping of polymorphic metabolic enzymes

GSTT1 and *GSTM1* genotypes were determined by co-amplification of two genes as previously described[18,19]. Amplification of human *β-globin* (350 bp) was also performed as a positive control in each reaction to confirm the presence of amplifiable DNA in the samples. The primers used for *β-globin* were 5'-GCC CTC TGC TAA CAA GTC CTA C-3' and 5'-GCC CTA AAA AGA AAA TCG CCA ATC-3'. Individuals with one or more *GSTT1* alleles had a 459-bp fragment and individuals with one or more *GSTM1* alleles had a 350-bp fragment (Figure 1A).

Polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) was applied to detect polymorphisms of the *CYP2E1*[20]. The primers used for *CYP2E1* were 5'-TTC ATT CTG TCT TCT AAC TG-3' and 5'-CAG TCG AGT CTA CAT TGT C -3'. The PCR products were digested with restricted endonuclease *P*st I. Homozygous *c1c1* individuals exhibited a product fragment of 410 bp, whereas homozygous *c2c2* individuals revealed a 290-bp and a 120-bp fragment, and heterozygous *c1c2* individuals demonstrated all the three fragments (Figure 1B).

The *ALDH2-Mbo*II polymorphism was determined by a modification of the methods developed by Harada and Zhang[21]. The sequences of *ALDH2* primers were 5'-CAA ATT ACA GGG TCA ACT GCT ATG-3' and 5'-CCA CAC TCA CAG TTT TCT CTT-3'. Homozygous *2-2* individuals demonstrated a single product fragment of 135 bp, whereas homozygous *1-1* individuals revealed both 125- and 10-bp fragments, and heterozygous *1-2* individuals exhibited all three of the fragments (Figure 1C).

According to Chen *et al*.[22], the sequences of *ADH2* primers were 5'- AAT CTT TTC TGA ATC TGA ACA G-3' and 5'- GAA GGG GGG TCA CCA GGT TGC-3', and the PCR products were digested with *Mae* III. Homozygous *1-1* individuals demonstrated a single product fragment of 95 bp, whereas homozygous *2-2* individuals revealed both 60- and 35-bp fragments, and heterozygous *1-2* individuals exhibited all three of the fragments (Figure 1D).

Statistical analysis

SPSS 10.0 version and Epi-info 6.0 software packages were used for statistical analysis. Maentel-Haenszel χ^2-test was used to compare the differences between basic characteristics of the non-exposure and exposure group. Stratified analyses were used to explore the correlation between liver damages and genotypes of *CYP2E1, GSTT1, GSTM1, ALDH2* and *ADH2* among the workers exposed to different levels of VCM. Logistic regression model was used to select the best model and to estimate the *OR* of related risk factors. A *P* value less than 0.05 was considered statistically significant.

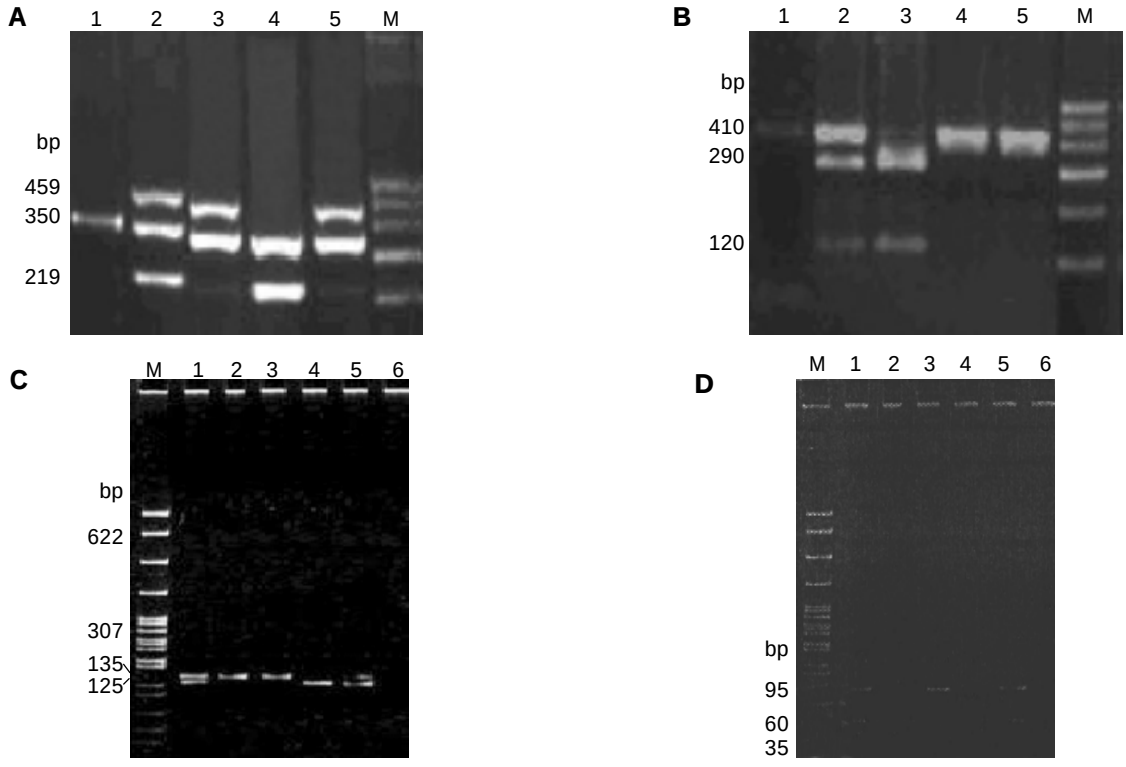

Figure 1 PCR products A: PCR products of GSTT1 and GSTM1. M: DNA marker; lanes 1-5 DNA products; lane 1: none; lane 2: GSTT1 and GSTM1; lane 4: GSTM1; lanes 3, 5: GSTT1. B: PCR-RLFP products of CYP2E1. M: DNA marker; lanes 1-5 DNA products. Homozygous c1c1 shows a single band with 410 bp; homozygous c2c2 shows two bands with 290 bp and 120 bp; and heterozygous c1c2 shows all three bands. C: PCR products of ALDH2. Lanes 1-6 DNA products; M: DNA marker. Homozygous 2-2 shows a single band with 135 bp; homozygous 1-1 shows two bands with 125 bp and 10 bp; and heterozygous 1-2 shows all the three bands. D: PCR products of ADH2. Lanes 1-6: DNA products; M: DNA marker. Homozygous 1-1 shows a single band with 95 bp; homozygous 2-2 shows two bands with 60 bp and 35 bp; and heterozygous 1-2 shows all the three bands.

RESULTS

Comparison of basic characteristics and clinical examinations between exposed and non-exposed groups

No significant difference was observed in age, duration of work, smoking, and drinking between the exposure and non-exposure subjects. All the standards of medical examination were selected as Chinese clinical diagnostic standards. There were significant differences in neurasthenia ($P<0.05$), pharyngeal irritation ($P<0.01$), liver ultrasonography abnormalities ($P<0.01$) and hemoglobin disorders ($P<0.05$) between the exposure and non-exposure groups, and relative risks were 1.74 (1.06-2.85), 1.97 (1.56-2.48), 10.69 (4.38-26.12), and 2.07 (1.20-3.57), respectively. Furthermore, abnormal ECG ($P<0.05$, *RR* 0.51, 95% *CI* 0.32-0.83) and fatty liver ($P<0.05$, *RR* 0.42, 95% *CI* 0.20-0.88) were found significantly higher in non-exposure subjects as compared to exposure subjects. Other symptoms and signs did not show any statistical difference (Table 1).

Stratified analysis of symptoms and signs caused by different cumulative exposure doses in exposure group

Trend chi-square test was used to compare symptoms and signs between the high-exposure and low-exposure groups. There were significant differences in neurasthenia, liver ultrasonography abnormality and pharyngitis between the high-exposure and low-exposure groups ($P<0.05$), with the chi-square values of 6.41, 5.33 and 4.56, respectively. Their incidences increased when the cumulative exposure dose increased (Table 2). However, the other symptoms and signs did not show any statistical difference.

Univariate analysis of genotypes of metabolic enzymes and variables for liver lesions in case-control design

Univariate analysis showed that *CYP2E1 c1c2/c2c2* genotype was significantly associated with liver damages (*OR* 3.29, 95% CI 1.51-7.20, $P<0.01$). Moreover, our results showed that the older or drinking subjects suffered from a higher frequency of liver damages but without statistical significance (OR 2.10, 95% *CI* 0.73-3.43, and *OR* 2.48, 95% *CI* 0.80-7.66). However, other factors did not show any association with liver damages (Table 3).

Correlation between cumulative exposure dose and genotypes of metabolic enzymes in the case-control design

ORs of liver lesions were calculated to investigate the joint effect of VCM exposure and genotypes. *CYP2E1* c1c2/c2c2 genotype was significantly associated with liver lesions (*OR* 4.6, 95% *CI* 1.4-15.1, $P<0.05$) in high-exposure group; and in low-exposure group, the distribution of non-null *GSTT1* was higher in the control group compared to liver lesion group (*OR* 0.3, 95% *CI* 0.1-0.9, $P<0.05$), and *ADH2 1-2/2-2* genotype was the same (*OR* 0.2, 95% *CI* 0.1 -1.0, $P<0.05$).

Table 1 Prevalence of symptoms and signs between exposure and control groups

Symptoms and signs	Exposure group	Control group	Relative risk (RR)
	n = 238(%)	n = 212(%)	
Neurasthenia[a]	40 (16.81)	21 (9.91)	1.74 (1.06-2.58)

[b]*P*<0.01 *vs* control.

The distribution of other genotypes did not have significant difference (Table 4).

Logistic regression analysis of liver lesions of workers exposed to VCM

Logistic regression analysis was employed to model the relationship between liver damages and genotypes of metabolic enzymes and related indicator among VCM workers. We observed a significant association between *CYP2E1 c1c2/ c2c2* and liver lesions (*P*<0.001, *OR* 3.173, 95%*CI* 1.329-7.572) and drinking (*P* = 0.10, *OR* 3.10, 95%*CI* 0.78-12.64), which might be associated with increased OR on liver lesions. But, we could not found any association between liver damages and age, duration of work, smoking and gender (Table 5).

Table 5 Logistic regression analysis of liver lesions

	Logistic regression analysis

DISCUSSION

Several studies have proved VCM as a human carcinogen, and hence VCM exposure has strictly been regulated in many countries. In the USA, the Occupational Safety & Health Administration (OSHA) has adopted a permissible exposure limit (PEL) of 1 p/m for VCM as an 8 h time-weighed average (TWA). Taiwan has also adopted 1 p/m as the health standard. In many developing countries, for some reasons, they have not restricted the emissions of VCM to satisfy this standard. Therefore, their occupational health standard for VCM is still at a relatively higher level, for example, in China, the maximum allowable dose was 25 mg/m^3 which was 9-fold higher than that in the advanced countries (Since June 2002 the TWA has been revised to 10 mg/m^3 in China, and the

maximum allowable dose modified to 25 mg/m^3).

In this study, the level of VCM was lower than National Occupational Health Standard of China, but the incidences of neurasthenia, pharyngeal irritation and liver USG abnormality in the exposure group were still higher compared to non-exposure group, which indicated that even the concentration is around 9 p/m, we should also pay attention to the damage induced by VCM. By modeling the relationship between the symptoms and cumulative exposure dose, the results showed that when cumulative exposure dose increased, the incidence of the symptoms increased in accordance.

We found that, under the same working environment and exposure to the same level of VCM, not all but only some workers in VCM-exposure group had got liver damages, which indicated that there are genetic susceptible differences among the workers. Then we used case-control design to investigate the association between the gene polymorphisms of metabolic enzymes and liver lesions.

VCM is metabolized to CEO (chloroethylene oxide) and chloroacetaldehyde (CAA) by *CYP2E1*, which bind to macromolecular surface and form the electrophilic metabolites that can induce liver lesions, even worsen to hepatic angiosarcoma. A study showed the efficiency of conversion of c2 was higher than c1[23]. Studies by Huang *et al*.[24], and Li *et al*.[14], showed that the frequency of the *CYP2E1* c2c2 genotype was higher in the case group compared to the control group, but the degree of *CYP2E1* necessary to influence genetic susceptibility due to exposure to VCM was different between the Chinese and the Caucasian population. In our study, we found that the frequency of *CYP2E1 c1c2/c2c2* was higher in liver lesions group than that in controls. Stratified by cumulative exposure dose, in high dose group, the *CYP2E1 c1c2/ c2c2* genotype had higher frequency in liver lesions group than that in controls, indicating that *CYP2E1 c1c2/c2c2* genotype might be the main cause of genetic susceptibility of liver damage, which is consistent with previous reports.

All the metabolizing products are further metabolized and detoxified by GSTs; VCM metabolites can also directly bind to glutathione (GSH) after catalyzation by GSTs. This investigation showed that in liver lesions group, the frequency of the *GSTT1*-null genotype was 63.8%, which was higher than 47.4% as reported by Taiwan scholars[24]. And the frequency of the *GSTM1*-null genotype was 62.1%, which was consistent with 60.5% as reported by other scholars[23,24]. The study manifested that *GSTT1* non-null genotype protected the workers from exposure to low level VCM, but another study indicated that *GSTT1* non-null genotype could form reactive metabolites and produce adverse effects[25], which resulted in liver damages. However, we could not see any correlation between *GSTM1* and liver damage.

CEO may spontaneously transform into CAA, which may be subsequently metabolized by *ALDH2*. Although individuals with variant *ALDH2*2* allele have a lower enzyme activity, polymorphism of *ALDH2* has been reported to be associated with alcoholism[26]. Previous studies manifested that CEO produced DNA alkylating agent but CAA could not, suggesting that *ALDH2* had little effect on liver damage[27]. Our study also supports these results.

We found that *ADH2* genotypes *ADH2 1-2/2-2* and *1-1* were significantly different between liver lesions and controls in low-exposure group, which might be because the metabolized efficiency of *ADH2*2* was higher than *ADH2*1* [28]. Moreover, the incidence of liver damage in *ADH2 1-2/2-2* might be lower than *1-1*, if they were exposed to the same concentration of VCM.

The workers in our control group might have some potential VCM exposure based on environmental monitoring in the factory. However, our multivariate adjustment corroborates the possible mechanisms of VCM metabolism and carcinogenesis. In conclusion, VCM workers exposed to high concentration of VCM and with *CYP2E1 c1c2/c2c2* genotype may have a higher risk of liver lesions, and the incidence of liver damage in *ADH2 1-2/2-2* maybe lower than *1-1*, if they were exposed to the same concentration of VCM.

ACKNOWLEDGMENTS

We thank Dr. Shang-Jian Chai and Yu-Fang Li for their help in medical examination and VCM exposure data collection. We are very grateful to Dr. Li Jin (Department of Environmental Health, University of Cincinnati, 3223 Eden Ave, Cincinnati Ohio 45267-0056) for his critical review and scientific editing.

Abstract

AIM: To investigate whether NSAIDs/ASA lesions in the colon can histologically be diagnosed on the basis of ischemic necrosis similar to biopsy-based diagnosis of NSAIDs/ASA-induced erosions and ulcers of the stomach.

METHODS: In the period between 1997 and 2002, we investigated biopsy materials obtained from 611 patients (415 women, 196 men, average age 60.5 years) with endoscopic focal erosions, ulcerations, strictures or diaphragms in the colon. In the biopsies obtained from these lesions, we always established the suspected diagnosis of NSAID-induced lesions whenever necroses of the ischemic type were found. Together with the histological report, we enclosed a questionnaire to investigate the use of medication. The data provided by the questionnaire were then correlated with the endoscopic findings, the location, number and nature of the lesions, and the histological findings.

RESULTS: At the time of their colonoscopy, 86.1% of the patients had indeed been taking NSAID/ASA medication for years (43.9%) or months (29.5%). The most common indication for the use of these drugs was pain (64.3%), and the most common indication for colonoscopy was bleeding (55.5%). Endoscopic inspection revealed multiple erosions and/or ulcers in 60.6%, strictures in 15.8%, and diaphragms in 3.0% of the patients. The lesions were located mainly in the right colon including the transverse colon (79.9%). A separate analysis of age and sex distribution, endoscopic and histological findings for NSAIDs alone, ASA alone, combined NSAID/ASA, and for patients denying the use of such drugs, revealed no significant differences among the groups.

CONCLUSION: This uncontrolled retrospective study based on the histological finding of an ischemic necrosis shows that the histologically suspected diagnosis of NSAID-induced lesions in the colon is often correct. The true diagnostic validity of this finding and the differentiation from ischemic colitis should, however, be investigated in a prospective controlled study.

INTRODUCTION

The first publications of NSAID-induced strictures in the small bowel[1,2] and colon[3,4] were followed by a number of reports that the intake of NSAIDs leads not only to such pathological changes as chemically-induced reactive gastritis, subepithelial bleeding, erosions and ulcerations complicated by bleeding or perforation in the stomach and duodenum[5,6], but also to erosions, ulcerations, perforations, bleeding[12,13,17], strictures and symptomatic diverticular disease[14-16] in the small and large bowel[7-11]. In animal experiments, it has been shown that as little as a single dose of NSAIDs can result in a high incidence of mortality after 3 d due to intestinal lesions and perforations[18-20].

With regard to the incidence of NSAID-induced lesions in the ileum and colon, the literature contains no reports on data obtained from controlled prospective endoscopic or endoscopy/biopsy studies. From the large Arthritis, Rheumatism, and Ageing Medical Information System databank of arthritic patients, however, it can be seen that 32% of gastrointestinal (GI) hospitalizations in osteoarthritis patients, and 13% of GI hospitalizations of patients with rheumatoid arthritis are due to lower GI diagnosis. In addition, studies of patients with spondyloarthropathy receiving conventional NSAID treatment over the long term have shown that 30-70% of these patients developed a macroscopic or microscopic ileitis, and, with varying frequency, inflammation of the cecum or colon[22-24].

In a post hoc analysis of 8 076 patients with rheumatoid arthritis who were treated with a non-selective NSAID (naproxen) or coxib (rofecoxib), serious lower intestinal events (bleeding, perforation, obstruction, ulceration, and

diverticulitis) were found. The rate of events per 100 patient years was 0.41 for rofecoxib and 0.89 for naproxen. Serious lower GI events accounted for 39.4% of all serious GI events among patients taking naproxen, and 42% among those taking rofecoxib[25].

NSAIDs preparations not only inhibit prostaglandin synthesis via COX inhibition[26], but also uncouple mitochondrial oxidative phosphorylation[27]. These substances also cause local topical toxicity[28], since they are lipid-soluble weak acids that can lead to interaction with surface membrane phospholipids and thus disruption of the gastric epithelial cell barrier and to back diffusion of acid into the mucosa[29,30].

Mucosal injuries in the gastrointestinal tract (GIT) are also a consequence of NSAID-induced liberation of vasoconstricting leukotrienes[31,32], free radicals, platelet thrombi and proteases[33,34,36]. Other publications have demonstrated a connection between NSAID-induced microcirculatory disorders and the adhesion of neutrophil granulocytes to vascular endothelium. In addition, liberation of TNF-α is triggered, which is responsible for the liberation of the intracellular adhesion molecule-1 at the vessel walls, and which can lead to local microcirculatory disorders due to vascular spasms[35,37]. All these synergistic interactions[38,39], particularly the microcirculatory disorders caused by spasms of the tiny blood vessels, can give rise to ischemic erosions and ulcerations in the GIT[40-44] and to diaphragm-like strictures[46,48-51]. Since these lesions may be the cause of blood in the stools or a positive hemoccult test, and the bleeding may lead to chronic hemorrhagic anemia[45,54], the indication for colonoscopy is now being established more frequently in this group of patients. Since colonoscopic biopsies are always taken from macroscopically identifiable lesions, the question arises as to whether the pathologist can establish a suspected diagnosis of NSAID-induced lesions in the biopsy material, and how reliable this suspected diagnosis is. Having already shown that NSAID-induced erosions[52] and ulcerations[56] of the gastric mucosa can often be identified on the basis of necrosis of the ischemic type, we have now examined the question whether this type of necrosis might not also be a suitable diagnostic criterion for NSAID-induced lesions in the colon.

MATERIALS AND METHODS

From 1997 to 2002, we investigated biopsy materials obtained from 611 patients (415 women, 196 men, average age 60.5 years) with focal erosions, ulcerations, strictures or diaphragms at endoscopy. In the biopsies obtained from these lesions, we always established the suspected diagnosis of NSAID-induced lesion whenever necroses of the ischemic type were found (homogeneous cell-poor eosinophilic necroses) to merge imperceptibly into the lamina propria (Figures 1 and 2), and when the clinical and endoscopic pictures and the location of the lesions militated against ischemic colitis. Together with the histological report, we enclosed a questionnaire with the aim of establishing the patient's use of medication (Table 1). The data provided by the questionnaire were subsequently correlated with the endoscopic findings, localization, number and nature of the lesions, and the histological findings.

Use of NSAID/ASA	Yes/no
If yes, which drug:.....	
- What dose……	
- How long……..	
Indication for NSAID/ASA…….....	
Indication for colonoscopy……..	

RESULTS

An analysis of the information provided on NSAID/ASA ingestion by the 501 patients with a histologically suspected diagnosis of NSAID/ASA-induced lesion in the colon is presented in Table 2 and shows that 86.1% of those patients actually were on NSAID/ASA medication at the time of their colonoscopy. In most cases, NSAIDs had been used for a period of years or months (Table 3). The most common indication for the use of these drugs was pain (Table 4). The symptoms that had led to an indication for colonoscopy are shown in Table 5. Lumping together the symptoms melena and anemia, and the positive occult blood test, it can be seen that bleeding complications occur in 55.5% of the cases, and are the most common indication for colonoscopy.

The most commonly cited medication (70.5%) was diclofenac (Table 6). In 60.6% of the cases, endoscopy revealed multiple lesions (erosions or ulcers), strictures (15.8%), while diaphragm-like formations (3.0%) were relatively rare. The distribution of the location of these

lesions identifies the right colon, in particular Bauhin's valve, as the most frequently affected site (Table 7).

An analysis of the frequency of the various lesions in terms of solitary or multiple lesions showed that multiple lesions were most commonly ulcers or ulcers in combination with erosions, while solitary lesions were mostly focal erosions. Strictures or diaphragms were also frequently associated with multiple lesions (Table 8).

A separate analysis of patient's age and sex distribution and endoscopic findings, after dividing cases into those with NSAID use alone, ASA use alone, combined use of NSAID and ASA, and cases denying NSAID/ASA intake, are shown in Table 9. A similar analysis of the histological findings is shown in Table 10. These two analyses revealed no statistically significant differences among the four groups of patients.

DISCUSSION

Our analysis showed that the histologically established diagnosis of suspected NSAID/ASA-induced lesion of the colonic mucosa is probably correct in a high percentage of cases (86.1%), and focal lesions were found, mainly in the right colon, such as Bauhin's valve, cecum and ascending colon. However, since our study was an uncontrolled retrospective study based on histological findings, the results must be considered preliminary, and needs to be checked in prospective studies.

The topographic clustering of the lesions at Bauhin's valve, in the cecum and ascending colon prompts the hypothesis that the lesions are not very likely caused by a

generalized, but by a topical local injurious effect of the NSAID/ASA preparations. This hypothesis is supported by the fact that these lesions were, in many cases, associated with the use of retard preparations, and that in particular the "bottleneck" at Bauhin's valve was involved. In those patients using non-retard preparations, it might be interesting to establish whether diarrhea associated with rapid transit of the medication into the colon was present. This point would have to be clarified in a prospective study, since we did not request information about a temporal relationship to diarrhea and the use of the medication. In support of a topical mucosa-injuring effect of NSAID/ASA, there are also numerous case reports on the use of retard preparations and on the preferential sites of the lesions in the right colon[42,44,50,51,53].

An unclear finding of our analysis that appeared surprising at first sight was the relatively high percentage of patients taking ASA (20%). It has, however, been shown in earlier publications that ingestion of ASA can cause bleeding not only in the upper GIT, but also in the lower GIT[10,11]. In the present study, we did not specifically investigate the indication for ASA use. However, since chronic ingestion of ASA is usually found in patients with arteriosclerosis, in particular in patients with coronary heart disease[57], cerebral circulatory disorders[58] and peripheral arterial occlusive disease[59], the question must, of course, be considered whether these necroses of the ischemic type might not be due to the underlying disease rather than to the use of ASA. Militating against this possibility, however, is the fact that ischemic colitis in arteriosclerosis[60,61] has other predilection sites, particularly the left colon, in the "borderland area" of the arterial supply between the left colic artery and the inferior mesenteric artery, where the endoscopic picture is of an accumulation of erosions rather than focal erosions and ulcers, and that in these patients, acute perianal bleeding is often found.

Also surprising are the results of our comparative analysis of the four groups of patients (only NSAIDs, only ASA, NSAIDs in combination with ASA, and no known use of NSAID/ASA). Neither the endoscopic nor the histological findings differed among these four groups; this might indicate either that the patients in the no NSAID/ASA group often simply denied using such medication, or that the physicians had not questioned the patients specifically about over-the-counter painkillers.

Our retrospective study should prompt a prospective study. Ideal would be a prospective colonoscopic investigation of patients taking NSAIDs, with consideration being given to the nature and duration as also of the galenic formulation of the preparations employed. Of particular interest would be an investigation of the side effects of COX-1 inhibitors in comparison with COX-2 inhibitors, which also can cause lesions in the lower GIT[21,25]. Only in this way could we obtain data on the incidence, localization and type of lesions as a function of the medication. Such a study in patients with no colon-specific symptoms would, however, hardly be ethically justifiable. Worthy of discussion, however, is the question whether, in patients on NSAIDs, a hemoccult test could be performed and, in the event of positive results, an indication for colonoscopy established. Also, an investigation of the incidence of NSAID-induced lesions in the small intestine employing capsule endoscopy should receive consideration.

What the results of our retrospective study definitely show, however, is that the pathologist who finds focal erosions, ulcers and strictures, together with necroses of the ischemic type in biopsies from the (mainly right) colon, should, more than previously, suggest in his report the possibility of an NSAID-induced mucosal injury. This would then prompt the care-providing physician to look into the patient's use of NSAIDs, the type of preparation employed, its dosage and galenic formulation, and then possibly replace or discontinue the medication with the aim of clarifying the etiopathogenesis of the lesion and preventing such serious complications such as perforation, chronic bleeding, and strictures. In principle, however, the NSAID/ASA-induced lesions cannot be differentiated histologically from ischemic lesions. This, too, should be emphasized in the histological report. Although arteriosclerosis-induced ischemic colitis is usually located in the left colon, and often manifests as multiple lesions distributed over a large area, other rare causes of ischemic colitis (e.g., vasculitis, distension colitis, emboli) may also give rise to irregularly distributed focal lesions at atypical locations. In our experience as consultant pathologists investigating biopsy and surgical material, the most common endoscopic and histological wrong diagnosis in NSAID-induced colonopathy is Crohn's disease established on the basis of the discontinuous changes due to NSAID colonopathy. This diagnostic error can, however, be avoided by giving consideration to the age of the patient, since NSAID-induced colonopathy is seen mainly in the elderly people. However, also in the case of young patients with

no other clinical and laboratory findings suggestive of Crohn's disease, the physician should be prompted to enquire about the use of NSAIDs, and if such use is denied, to apply ASA serology to test for possible misuse of painkillers[54].

In conclusion, the present study shows that our retrospective suspected diagnosis of NSAID/ASA-induced lesions based on the histological finding of a focal ischemic necrosis of the colonic mucosa, located mainly in the right colon, is often correct, and may serve to prevent serious complications of NSAID-induced colonopathy. The actual utility of such histological findings and the differential diagnosis vis-α-vis ischemic colitis must, however, be checked in a prospective controlled study.

Abstract

AIM: To evaluate the prevalence of genetic and acquired prothrombotic risk factors and their association with the extent of fibrosis and fatty infiltration in patients with non-alcoholic fatty liver disease (NAFLD).

METHODS: Forty-four patients with chronic hepatitis (28 men and 16 women, with mean age of 45±11 and 49±12 years, respectively) constituted the patient population of this study. The groups were divided as follows: 15 patients with fatty liver (FL); 15 with non-alcoholic steatohepatitis (NASH); 14 with chronic viral hepatitis (CH) diagnosed by histology and liver technetium scan or ultrasound; and 10 healthy individuals. Thrombophilic, coagulation factors and genetic mutations were diagnosed by standard hemostatic and molecular coagulation assays.

RESULTS: Activated protein C (APC) resistance and protein S were the most prevalent thrombotic risk factors (6% and 10% in NAFLD *vs* 21% and 14% in CH; $P<0.01$ and $P<0.05$, respectively). One thrombotic risk factor was identified in 41% of patients (23% mild fibrosis, 18% severe fibrosis) and two thrombotic risk factors in 6% of patients with NAFLD and severe fibrosis. While no differences in APC ratio, lupus anticoagulant, fibrinogen, factor V Leiden, prothrombin, and MTHFR mutation were found. Protein S levels were significantly lower in NASH patients than in patients with FL alone (92±19 *vs* 106±2, $P<0.01$). Protein C levels were markedly higher in patients with NAFLD and mild or severe fibrosis as compared to the patients with CH, respectively (128±40 *vs* 96±14, $P<0.001$ or 129±36 *vs* 88±13, $P<0.01$).

CONCLUSION: Up to 46% of patients with NAFLD may have thrombotic risk factors, and the presence of thrombotic risk factors is correlated with the extent of hepatic fibrosis, suggesting a crucial role of the coagulation system in the pathogenesis of hepatic fibrosis.

INTRODUCTION

The clinical implications of non-alcoholic fatty liver disease (NAFLD) are derived mostly from its common occurrence in the general population (10-24%) and the potential of the condition to progress to fibrosis (40%) and cirrhosis (30%)[1-3]. Non-alcoholic steatohepatitis (NASH) is the most common cause of cryptogenic cirrhosis and is an increasingly common indication for liver transplantation[3]. Obesity, diabetes mellitus, and hyperlipidemia are conditions frequently associated with NASH[4,5]. Although the pathogenesis of NASH is unknown, it has been suggested that hepatic fatty infiltration may stem from continuous delivery of free fatty acids to the liver after ingestion of fatty foods and from increased splanchnic lipolysis of visceral fat, both of which increase hepatic insulin resistance[6]. Recently, two additional mechanisms were reported: oxidative stress/lipid peroxidation; and TNF-α/endotoxin-mediated injuries[7]. To our knowledge, it is still unclear what causes progression from steatosis to steatohepatitis and from steatohepatitis to bridging fibrosis and cirrhosis. Alcohol consumption, hepatic iron deposition[8], drugs, endotoxin[9,10], and polymorphism in cytochrome p450 enzymes[11] have been proposed as putative mechanisms. However, the definitive mechanism is yet to be determined.

Thrombosis of the intrahepatic veins is frequently observed in cirrhosis and has been associated with its progression[12], while occlusion of small intrahepatic veins and sinusoids has been considered as a potential triggering factor of liver tissue remodeling[13]. More recently, Wanless and Shiota[14] proposed a four-step model in patients with NAFLD, including steatosis facilitated by insulin resistance (first step), necrosis induced by lipid peroxidation (second step), release of lipid from hepatocytes into the interstitium leading to direct and inflammatory injury to small hepatic veins (third step), and the venous obstruction with secondary collapse and ultimately fibrosis (fourth step). The involvement of various genetic and acquired thrombotic risk factors in the pathogenesis of vein thrombosis is well established but their role in

NAFLD progression, to our knowledge, has not yet been investigated. The present study was designed to determine whether genetic and acquired thrombotic risk factors might be observed at some stage of liver disease progression in patients with NAFLD as well as their possible association with the extent of fatty infiltration and the extent of hepatic fibrosis.

MATERIALS AND METHODS

Patient population

Forty-four patients (28 men and 16 women, mean age of 45±11 and 49±12 years, respectively) were divided into three groups for the purpose of this study: 15 patients with fatty liver (FL); 15 with steatohepatitis (NASH); 14 with chronic viral hepatitis (CH) diagnosed by histology and liver technetium scan or ultrasound. Ten healthy controls were also included in this study. Patients with antiviral therapy within the past 6 mo, hepatocellular carcinoma, other forms of chronic liver diseases, positive anti-human immunodeficiency antibodies, previous venous thrombosis, chronic immunosuppression therapy, contraceptives or any current anticoagulation therapy were excluded.

Laboratory studies

All laboratory studies including coagulation assays were done within 6 wk of liver biopsy. Full blood count, platelets count, prothrombin time (PT), or INR, partial thromboplastin time (PTT), fibrinogen, liver enzymes including aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphates, γ-glutamyl transferase (GGT), glucose, insulin, cholesterol, and triglycerides were measured using commercially available assays. The following parameters were considered as thrombotic risk factors: deficiency in anti-thrombin, protein S, protein C, presence of lupus anticoagulant, activated protein C (APC) resistance with factor V Leiden mutation, fibrinogen, G20210A mutation in the prothrombin gene and MTHFR mutations. Deficiency in anti-thrombin III, protein S, and protein C were diagnosed when the protein level was below 80%, 60%, and 70%, respectively. Blood samples were collected into the vacuum tubes containing trisodium citrate. Platelet poor plasma was prepared by double centrifugation at 2 000 r/min for 15 min at room temperature. The assay, performed on fresh plasma or aliquots stored at -70 ℃ until assay, included factor VIII coagulant activity using factor VIII deficient plasma (Dae Behring) and Platelin-LS (Organon Tecknica, Durham, NC, USA). Antithrombin activity using an amidolytic assay (Coamatic antithrombin, Chromogenix, Montpellier, France), protein C activity using a clotting assay (IL Pro Clot, Instrumentation Laboratory, Lexington, MA, USA) and protein C antigen using an immunoenzymatic assay (Asserachrom protein C, Diagnostica Stago, France), free protein S using an immunoenzymatic assay (Asserachrom free protein S, Diagnostica Stago), and the presence of lupus anticoagulant were determined as previously described[15]. Molecular diagnosis of the factor V Leiden mutation was performed as described by Ridker *et al*.[16]. The G20210A mutation in the prothrombin gene was detected as described by Poort *et al*.[17]. Body mass index (BMI) was calculated as weight in kilograms divided by the square of height in meters. Insulin resistance was estimated using the homeostasis model assessment index (HOMA index) derived from the following equation: HOMA index = (fasting plasma glucose level mg%×0.055)×(fasting plasma insulin level μIU/mL)/22.5.

Histological evaluation

Liver biopsy specimens were fixed in Bouin's and embedded in paraffin, and the sections were stained with hematoxylin-eosin and Masson's trichrome. The diagnosis of NASH was established, if abnormal liver enzymes were associated with steatosis more than 10% in the presence of lobular and/or portal inflammation, with or without Mallory bodies, ballooning degeneration or fibrosis and the exclusion of other viral, metabolic or immunologic liver diseases for more than 3 mo[18]. The histological classification of NASH was made according to Brunt classification[19]. Steatosis was graded as follows: mild (5-30% of hepatocytes affected); moderate: (30-60% of hepatocytes affected); and severe (>60% of hepatocytes affected). Fibrosis was scored on a scale from 0 to 4, with 0 denoting no fibrosis, 1 describing focal pericellular fibrosis in zone three, 2 describing perivenular and pericellular fibrosis confined to zones two and three with or without portal/periportal fibrosis, 3 describing bridging fibrosis with architectural distortion but no cirrhosis, and 4 determining cirrhosis. Inflammatory grade was scored on a scale from 0 to 4, with 0 denoting no inflammation, grade 1 = sparse zone three inflammation, grade 2 = mild focal zone three hepatocyte inflammation, grade 3 = moderate zone three hepatocyte inflammation, and grade 4 = severe zone three hepatocyte inflammation. The histological classification of chronic viral hepatitis was made according to the new classification of Desmet *et al*.[20].

Statistical analysis

Data were expressed as mean±SD or as median and range. Kruskall-Wallis test for two-way analysis of variance (ANOVA) was used to evaluate difference between three or four groups. The difference between two groups was assessed by the two-tailed Mann-Whitney *U*-test for continuous variables and by χ^2 test for categorical variables. Bonferroni method was employed to correct for multiple comparisons. Correlations coefficient was evaluated by the Spearman's test and by simple linear or multiple stepwise regression analysis. The Winstat computer program was used for all calculations. Two-tailed *P* values less than 0.05 were considered statistically significant.

RESULTS

Epidemiological, biochemical, and histological characteristics of all patient populations are presented in Table 1. The patients with NAFLD were older and had increased BMI and increased insulin resistive index as compared to the patients with chronic viral hepatitis and to healthy controls ($P<0.001$). Inflammation score and ALT levels were obviously less pronounced in patients with NASH as compared to the patients with chronic viral hepatitis (inflammation score, 8.7±2.4 *vs* 10.4±5.0, $P<0.01$; and ALT, 43±18 *vs* 79±25, $P<0.001$). There was no significant difference in the severity

of fibrosis stage between patients with NASH and patients with chronic viral hepatitis (1.4±1.6 *vs* 1.5±1.6).

APC resistance and protein S were the two most prevalent thrombotic risk factors observed in patients with NAFLD and in patients with chronic viral hepatitis (6% and 10% in NAFLD *vs* 21% and 14% in CH, $P<0.01$ and $P<0.05$, respectively, Table 2). While the prevalence of antithrombin III was more frequent in NAFLD as compared to chronic hepatitis (6% *vs* 0%, $P<0.01$), there was no significant difference between the two groups in APC ratio, lupus anticoagulant, and fibrinogen levels. There were also no significant differences in the genetic risk factors including factor V Leiden, prothrombin 20210A mutation, and MTHFR mutation. Finally, one patient in the NAFLD group was heterozygous for MTHFR mutation.

Table 2 Prevalence of thrombotic risk factors in 44 patients of study population (*n*, %)

Thrombotic risk factors	NAFLD (%)	CH (%)	Total (%)
Protein C deficiency	1 (3)	1 (7)	2 (10)
Protein S deficiency	2 (6)	3 (21)	5 (27)
Anti-thrombin III deficiency	2 (6)	0 (0)	2 (6)
Lupus anticoagulant	2 (6)	1 (7)	3 (13)
APC resistance	3 (10)	2 (14)	5 (24)
PT20210A mutation	None	None	None
Factor V Leiden	None	None	None
MTHFR mutation	1 (3)[1]	None	1 (3)

[1]Heterozygous mutation.

One thrombotic risk factor was present in 23% of patients with NAFLD and mild fibrosis as compared to 36% of patients with chronic hepatitis and mild fibrosis. Two thrombotic risk factors were present in 6% of patients with NAFLD. Absence of thrombotic risk factors was seen in 47% of patients with NAFLD and mild fibrosis and 6% with severe fibrosis (Table 3). No healthy individuals showed evidence of thrombotic risk factors.

Table 3 Number of thrombotic risk factors per patient in patients with NAFLD with mild and severe fibrosis score (*n*)

Number of thrombotic risk factors per patient fibrosis (%)	Mild fibrosis(%)	Severe
No risk factors	8 (47)	1 (6)
One risk factor	4 (23)	3 (18)
Two risk factors	1 (6)	0 (0)

Levels of thrombophilic and coagulation factors as well as the prevalence of thrombotic risk factors for the study population are presented in Tables 2 and 4, respectively. The patients with NASH had significantly more decrease in protein S levels as compared to the patients with FL alone (92±19 *vs* 106±20, $P<0.01$). Anti-thrombin III tended to be lower in NASH patients but did not reach statistical significance.

The association of fibrosis staging with patient characteristics and with levels of thrombophilic and coagulation factors is presented in Table 5. The patients with NASH and severe fibrosis had markedly more decrease in protein S levels compared to the patients without fibrosis (84±16 *vs* 100±22, $P<0.01$). An important finding was that protein C levels were higher in NASH patients at mild or severe fibrosis stage as compared to patients with chronic viral hepatitis (for mild fibrosis, 128±40 *vs* 96±14, $P<0.001$; or for severe fibrosis, 129±36 *vs* 88±13, $P<001$, Table 5, Figure 1A) and that protein C levels were correlated strongly with the extent of fatty infiltration ($r = 0.6$, Figure 1B). Table 6 shows the capacity of combined thrombotic risk factors, including protein S, antithrombin III, and fibrinogen to predict correctly the diagnosis of simple FL *vs* NASH. They classified the outcome correctly in 70% of cases. Finally, we observed a significant correlation between fibrotic score and proteins S level in patients with NAFLD ($r = 0.4$, $P<0.05$, Figure 2).

DISCUSSION

Our study has evaluated the association between thrombotic risk factors and the extent of hepatic fibrosis and fatty

Results/ LNB	Actual number of patients	Predicted group	
		NASH (%)	FL(%)
NASH	15	11 (73)	4 (27)
FL	15	5 (33)	10 (67)

[1]70% of the cases were classified correctly.

infiltration in patients with NAFLD. Thrombotic risk factors were detected in 46% of patients with NAFLD with APC resistance and protein S as the most common. While the patients with NASH and advanced fibrosis demonstrated a greater decrease in protein S levels compared to the patients with FL alone, the patients with NAFLD had a greater increase in protein C levels as compared to the patients with chronic viral hepatitis and healthy individuals.

The mechanism by which the patients with NAFLD display a decrease in some hemostatic parameters remains to be established. Since protein C, protein S, and antithrombin

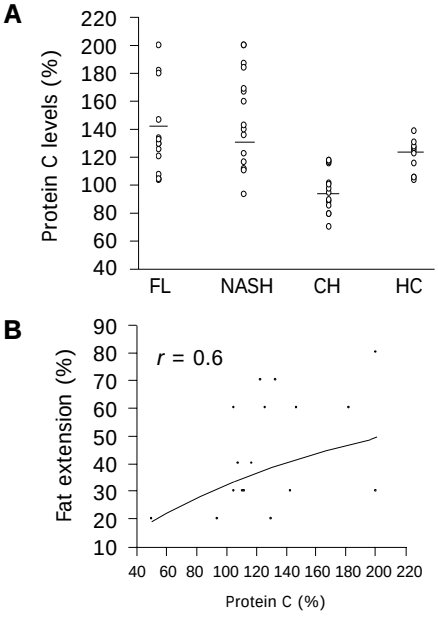

Figure 1 A: Protein C levels (normal 70-130%) in all study population (- median levels). B: Correlation between fat extension and protein C levels ($r = 0.6$, $P<0.001$).

III are produced by the liver, their levels may be decreased in patients with advanced chronic liver diseases[21]. This is considered to be the case in patients with established cirrhosis. However, patients with cirrhosis were excluded from our study and only four patients with NAFLD had severe bridging fibrosis. More important was the finding that protein C levels were obviously correlated with the extent of fatty infiltration and were higher in the patients with NAFLD when compared to the patients with chronic viral hepatitis and to healthy individuals (Figure 1A). This increase in protein C levels is related either to increased hepatic synthesis or impaired clearance of plasma protein C[22]. Bruckert *et al*.[23], has suggested that steatosis may be one of the factors leading to an increase in protein C levels resulting from accelerated turnover of triglycerides. Moreover, an increased level of protein C has been reported in patients with diabetes, hypertriglyceridemia, nephrotic syndrome, abuse of anabolic steroids, and alcoholism[22]. Diabetes and hypertriglyceridemia are predisposing conditions to fatty infiltration of the liver[4] and were present in 23% and 73% of our cases, respectively. The remaining conditions were excluded by clinical and biochemical findings.

Thrombotic risk factors have been found to be independently associated with the extent of fibrosis in patients with chronic viral hepatitis C and hepatitis B[21]. In particular, anti-thrombin III deficiency was associated with more extensive fibrosis. On contrary, in our study, anti-thrombin III deficiency was not associated with increased fibrosis, rather, protein S deficiency showed the greatest decrease in NASH with advanced fibrosis. The presence of combined thrombotic risk factors as the only independent variable associated with advanced fibrosis supports the hypothesis of vascular obstruction for the histological progression of NAFLD but does not indicate a cause and effect relationship.

Obliteration of small portal and hepatic veins due to thrombosis and phlebitis has been proposed as an important factor for the progression of chronic liver diseases[12-14]. Thus, changes in the composition of blood towards a hypercoagulability state in combination with changes in the endothelium of intrahepatic vessels and intrahepatic blood flow[24-26] certainly favor the development of thrombosis in intrahepatic veins. More recently, Wanless and Shiota[26] suggested a four-step model for the progression of FL towards NASH with fibrosis in which the fourth step is venous obstruction with secondary collapse and ultimately fibrous septation and cirrhosis. We have also demonstrated the beneficial effect of aspirin and enoxaparin on fibrosis progression in a rat model of cirrhosis, which supports the hypothesis of vascular thrombosis in hepatic fibrosis[27]. Again, a cause and effect relationship remains to be determined since more than half (54%) of the patients with NAFLD do not have thrombotic risk factors.

While APC, factor V Leiden, prothrombin mutation 20210A and MTHFR mutations had no association with advanced fibrosis, protein S deficiency was the only thrombotic risk factor associated with advanced staging (Table 5). Sixty percent of protein S plasma concentration is bound to a complement binding protein, which increases in inflammatory conditions (acute phase reactant), and only 40% of the concentration represent the active free form of protein S, which is a cofactor of APC but not a direct anticoagulant[28,29]. Thus, laboratory findings of protein S deficiency may not always reflect abnormal anticoagulation activity.

A link between thrombotic risk factors and hepatic fibrosis has been demonstrated. Liver inflammation resulting from NASH leads to activation of the coagulation system. In patients with protein S deficiency, the degree of activation is enhanced leading to increased thrombin activity and fibrin production. Thrombin is a stellate cell mitogen, and therefore activation of the coagulation cascade may stimulate stellate cell activation and fibrosis[30,31]. Recently, treatment with thrombin antagonist has been shown to reduce liver fibrogenesis in the rat via downregulation of TIMP-1 mRNA levels[32].

Increased levels of anticardiolipin or the presence of lupus anticoagulant were not associated with histological staging in our study. Anticardiolipin antibody has been reported to be present in up to 44% of patients with chronic hepatitis C, but the clinical significance remains controversial[33]. Positive anticardiolipin antibodies were detected in only 6% and 7% of our NAFLD and CH patients, respectively. None of our patients with positive anticardiolipin antibody had a history of thrombotic episodes or clinical signs of portal hypertension. Only one patient had advanced histological staging and one with low platelet count. Taken together, our data are in agreement with previous reports that anticardiolipin antibodies are epiphenomenona without any clinical relevance[34].

The deficiency in protein S is likely to result from an acquired defect, since in the healthy population, the prevalence of heterozygous deficiency has been estimated at 0.2%[35]. Decreased liver synthesis appears as the most plausible mechanism for the high prevalence of protein S deficiency in patients with NASH and advanced fibrosis. The 6% prevalence of protein S deficiency found in the group with NAFLD and the 21% in the group with CH strengthens this hypothesis. On the other hand, increase in protein C levels may explain the non-progression of fibrosis in some patients with NAFLD via its anti-coagulant and anti-inflammatory effects[36].

In conclusion, our data suggest that thrombotic risk factors are detected in approximately half of the patients with NAFLD and that the presence of one or more risk factors is associated with more fibrosis. This does not indicate a cause and effect relationship, but has a significant clinical implication. Whether it is a primary or secondary phenomenon needs further evaluation.

Abstract

AIM: To analyze the risk of cardiovascular complications in patients with indication for surgical treatment of Chagasic esophageal achalasia and to correlate the surgical risks with the degree of esophageal dilation, thereby proposing a risk scale index.

METHODS: One hundred and twenty-four patients with Chagasic esophageal achalasia, who received surgical treatment at the Hospital das Clinicas of the Federal University of Goiás, were included in this study. The patients were mostly related to the postoperative complications due to the cardiovascular system. All the patients were submitted to: (1) clinical history to define the cardiac functional class (New York Heart Association); (2) conventional 12-lead electrocardiogram at rest; and (3) contrast imaging of the esophagus to determine esophageal dilatation according to Rezende's classification of Chagasic megaesophagus.

RESULTS: An assessment of the functional classification (FC) of heart failure during the preoperative period determined that 67 patients (54.03%) were assigned functional class I (FC I), 46 patients (37.09%) were assigned functional class II (FC II), and 11 patients (8.87%) were assigned functional class III (FC III). None of the patients were assigned to functional class IV (FC IV). There was a positive correlation between the functional class and the postoperative complications (FC I×FC II: $P<0.001$; FC I×FC III: $P<0.001$). The ECG was normal in 44 patients (35.48%) and presented abnormalities in 80 patients (64.52%). There was a significant statistical correlation between abnormal ECG (arrhythmias and primary change in ventricular repolarization) and postoperative complications ($P<0.001$). With regard to the classification of the Chagasic esophageal achalasia, the following distribution was observed: group II, 53 patients (42.74%); group III, 37 patients (29.83%); and group IV, 34 patients (27.41%). There was a positive correlation between the degree of esophageal dilation and the increase in postoperative complications (grade II×grade III achalasia: $P<0.001$; grade II×grade IV achalasia: $P<0.001$; and grade III×grade IV achalasia: $P = 0.017$). Analyzing these results and using a multivariate regression analysis associated with the probability decision analysis, a risk scale was proposed as follows: up to 21 points (mild risk); from 22 to 34 points (moderate risk); and more than 34 points (high risk). The scale had 82.4% accuracy for mild risk patients and up to 94.6% for the high risk cases.

CONCLUSION: The preoperative evaluation of the cardiovascular system, through a careful anamnesis, an ECG and contrast imaging of the esophagus, makes possible to estimate the surgical risks for Chagas' disease patients who have to undergo surgical treatment for esophageal achalasia.

INTRODUCTION

Preoperative clinical evaluation, a common practice in our midst, aims to estimate the risk of postoperative complications. The patient's clinical status is assessed and emphasis is given to cardiac function, as well as to the inherent risk of the surgical procedure performed, through the use of the several indexes available in the literature. According to Dias *et al*.[1], the clinical status during the preoperative period answers two questions: what is the surgical risk, and what can be done to reduce it? The adequate management of perioperative risk factors, such as normalizing blood pressure and diabetes mellitus, treating chronic pulmonary obstructive disease and the utilization of endovenous beta-blockers perioperatively in patients with coronary disease, can significantly decrease perioperative complications. Determining perioperative risk factors can be useful as it can provide elements to choose the best procedure or even if surgical treatment should be

performed[2]. The most commonly used risk indexes are those from the American Society of Anesthesia[3] and the Goldman index[4]. It is important to point out that Chagasic cardiopathy is not specifically evaluated in risk indexes, since Chagas' disease is not found in Western countries.

Cardiovascular complications in patients who have to undergo noncardiac surgery and changes in cardiac function caused by Chagas' disease have a direct influence over the morbidity and mortality rate of the surgical procedure[5]. Establishing guidelines, which identify Chagasic patients at high risk for complications arising from noncardiac surgery, as well as minimizing the onset of such complications during the perioperative period, are very important. The patients with Chagasic esophageal achalasia may have high cardiovascular system impairment.

In view of the scarce literature regarding the surgical risks for noncardiac procedures on the patients with Chagasic esophageal achalasia, and because of the frequent association between cardiopathy and digestive diseases, the purpose of the study was to analyze the risk of cardiovascular complications in patients with indication for surgical treatment of Chagasic esophageal achalasia and to correlate the surgical risks with the degree of esophageal dilation, and thereby proposing a risk scale index.

MATERIALS AND METHODS

A total of 124 patients with Chagasic esophageal achalasia submitted to surgical treatment at the Hospital das Clínicas, Federal University of Goiás from January 1995 and December 2000, were included in this study. Of them, 68 (54.83%) were males and 56 (45.16%) were females, with a mean age of 39 years. All the patients were subjected to: (1) clinical history to define the cardiac functional class [3] (New York Heart Association); (2) conventional 12-lead ECG at rest; and (3) contrast imaging of the esophagus to determine esophageal dilatation according to Rezende's classification of Chagasic megaesophagus[6,7] as follows: group I: esophagus with normal caliber but with slow contrast progression and small retention of barium contrast 1 min after ingestion; group II: esophagus with small to moderate dilatation and considerable radiological contrast retention; group III: hypotonic esophagus with important dilatation, poor motor activity and great retention of radiological contrast; and group IV: esophagus elongated that lies over the diaphragm with great retention of radiological contrast (dolico-megaesophagus, Figure 1).

All the patients were submitted, according to the radiological classification of the Chagasic megaesophagus, to surgical treatment of achalasia (Table 1), utilizing conservative techniques for the non-advanced esophageal achalasia (Grades II and III), employing Pinotti's operation (cardiomyectomy with fundoplication) and resective techniques using Serras Doria operation (Grondahl cardioplasty with hemigastrectomy and Roux en Y diversion) for advanced achalasia (Grade IV). Postoperative complications, directly related to the cardiovascular system, during the hospitalization period, were analyzed.

For statistical analysis, the variance analysis was used for comparisons between continuous numerical variables of distinct (independent) groups; the χ^2 and the Fisher's tests were used for comparisons between the quantities in which each patient was situated at a given level of classification; and multivariate regression and probabilistic decision analyses were used in the final phase of the study to create the surgical risk index.

Table 1 Patients according to the grade of esophageal dilatation and surgical treatment adopted

Esophageal dilatation	Surgical technique	Patients (%)
Group II		53
	Cardiomyectomy with fundoplication (Pinotti's technique)	53
Group III		37
	Cardiomyectomy with fundoplication	32
	Grondahl cardioplasty with hemigastrectomy and Roux-en-Y diversion (Serras Doria operation)	5
Group IV		34
	Grondahl cardioplasty with hemigastrectomy and Roux-en-Y diversion	26
	Mucosectomy	4
	Merendino's operation	2
	Gastrostomy	2

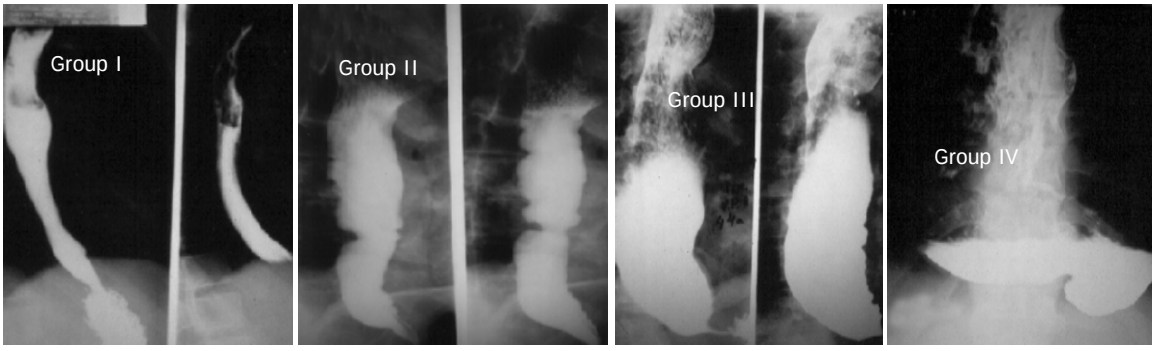

Figure 1 Contrast imaging of the esophagus according to Rezende's classification of Chagasic megaesophagus. Group I: esophagus with normal caliber but with slow contrast progression and small retention of barium contrast 1 min after ingestion; group II: esophagus with small to moderate dilatation and considerable radiological contrast retention; group III: hypotonic esophagus with important dilatation, poor motor activity and great retention of radiological contrast; and group IV: esophagus elongated over the diaphragm with great contrast retention.

RESULTS

An assessment of the functional classification (FC) of heart failure patients with Chagasic achalasia during the preoperative period determined that 67 patients (54.03%) were assigned functional class I (FC I), 46 patients (37.09%) were assigned functional class II (FC II), and 11 patients (8.87%) were assigned functional class III (FC III). None of the patients were assigned to functional class IV (FC IV). There was a positive correlation between the functional class and the postoperative complications (Table 2).

The ECG results are shown in Table 3. The ECG was normal in 44 patients (35.48%) and presented abnormalities in 80 patients (64.52%). We observed that a single patient could exhibit more than one change in the ECG and the most frequently observed abnormalities were complete right bundle branch block (CRBBB) and ventricular extrasystole in 28 patients (22.58%). We also observed a significant statistical correlation between abnormal ECG (arrhythmias and primary change in ventricular repolarization) and postoperative complications ($P<0.001$, Table 4).

With regard to the classification of the Chagasic esophageal achalasia, the following distributions were observed: 53 patients (42.74%) were classified into group II; 37 patients (29.83%) into group III; and 34 patients (27.41%) into group IV. The cardiovascular complications related to the esophageal dilation are shown in Table 5. A positive correlation between the degree of esophageal dilation and postoperative complications was observed, i.e., the higher the degree of esophageal dilation, the higher the risk of complications (grade II×grade III: $P<0.001$; grade II×grade IV: $P<0.001$; and grade III×grade IV: $P = 0.017$).

Cardiovascular complications, defined as any change detected in the cardiovascular system during the in-hospital postoperative recovery period, are described in Table 6. Four patients (3.22%) died. The cause of death was classified as: cardiogenic shock (one patient); pulmonary embolism (one patient); stroke (one patient); and non-defined causes (one patient) at the 5th postoperative day, although the presence of tachyarrhythmias was suspected.

Analyzing these results and using a multivariate regression analysis associated with the probability decision analysis, with direct and specific application to the Chagasic megaesophagus patient, we proposed a risk scale (Table 7). In terms of classifying preoperative risks, the point scale was as follows: up to 21 points (mild risk); from 22 to 34 points (moderate risk); and more than 34 points (high risk). The scale had 82.4% accuracy for mild risk patients and up to 94.6% for the high risk patients.

Table 2 Postoperative complications according to the functional class classification

Results	Functional class/number of patients					
	I (n = 67)[b,d]		II (n = 46)[1]		III (n = 11)

Risk levels	Probability (%)
Mild	82.4
High	94.6

DISCUSSION

The caseload of 124 patients is quite representative of the high incidence of megaesophagus with the indication for surgical treatment in a region where Chagas' disease is endemic. Although there may be an overlapping of clinical and morphological characteristics among dilated cardiomyopathies, it is very important to take into consideration the inherent characteristics of the Chagasic cardiomyopathy, such as autonomic denervation, fascicular and atrioventricular blocks, in addition to arrhythmogenic foci in the ventricles[8-11]. These peculiar characteristics are enough to elicit different responses to the surgical trauma relative to those observed in non-Chagasic patients[12-14].

Thus, it is our opinion that in order to estimate the surgical risk for these patients, it is imperative that the risk index developed should be simple and low-cost. These characteristics, however, should compromise neither its validity nor its feasibility.

In the score scale, the clinical history of the patients, used to determine precisely the functional class through the symptoms of myocardial dysfunction, associated to simple and inexpensive tests which are readily available, such as ECG, can estimate the risk for complications for the Chagasic achalasia patient. In view of the frequent association between a compromised digestive system and an equally compromised cardiovascular system[15], the positive predictive value of the scale is increased when the degree of dilation of the esophagus is included.

FC presents some problems because of the subjective interpretation of terms, such as "routine activity", and "excessive fatigue". They cause the consequent limitations in terms of precision and reproducibility[16]. However, our findings showed that the functional class of the patient was determined with a good degree of security.

Naturally, indexes, such as Goldman index, are not as precise for the analysis of specific groups, such as those with Chagasic cardiopathy[17-23]. These patients, according to the Goldman index, would have been classified as low risk.

Our findings equally suggested that the longer the degree of evolution of Chagasic esophageal achalasia, the higher the tendency for advanced cardiomyopathy. Our results showed a positive correlation between the degree of esophageal dilation and postoperative complications. The risk scale, which is being proposed[24] with a considerable degree of confidence, can provide an adequate and reliable predictor of cardiovascular complications in the patients with Chagasic esophageal achalasia during the postoperative period.

In conclusion, the evaluation of the cardiovascular system, through a careful anamnesis, an ECG and contrast imaging of the esophagus, makes it possible to estimate the surgical risks for the patients with Chagasic esophageal achalasia.

Abstract

AIM: To study the role of focal adhesion kinase (FAK) and its association with Src in hepatocyte growth factor (HGF)-induced cell signaling in cholangiocarcinoma progression.

METHODS: Previously isolated HuCCA-1 cells were re-characterized by immunofluorescent staining and reverse transcriptase-polymerase chain reaction assay for the expression of cytokeratin 19, HGF and c-Met mRNA. Cultured HuCCA-1 cells were treated with HGF and determined for cell proliferation and invasion effects by MTT and invasion assays. Western blotting, immunoprecipitation, and co-immunoprecipitation were also performed to study the phosphorylation and interaction of FAK and Src. A novel Src inhibitor (AZM555130) was applied in cultures to investigate the effects on FAK phosphorylation inhibition and on cell proliferation and invasion.

RESULTS: HGF enhanced HuCCA-1 cell proliferation and invasion by mediating FAK and Src phosphorylations. FAK-Src interaction occurred in a time-dependent manner that Src was proved to be an upstream signaling molecule to FAK. The inhibitor to Src decreased FAK phosphorylation level in correlation with the reduction of cell proliferation and invasion.

CONCLUSION: FAK plays a significant role in signaling pathway of HGF-responsive cell line derived from cholangiocarcinoma. Autophosphorylated Src, induced by HGF, mediates Src kinase activation, which subsequently phosphorylates its substrate, FAK, and signals to cell proliferation and invasion.

INTRODUCTION

Hepatocyte growth factor (HGF) is a known multifunctional cytokine that affects a variety of cell types and plays roles in various cell behaviors. It has a potent mitogenic effect on hepatic cells during the process of regeneration after the liver injury[1]. It stimulates motility of some normal and tumor cells[2,3] and it contributes to the progression of cancers such as the invasiveness of hepatocellular carcinoma[4]. In addition, HGF has a protective effect on liver progenitor cells against apoptosis while enhancing angiogenesis and tumorigenesis[5-7]. Previous evidences have indicated that HGF is secreted from liver myofibroblasts and its functional role is initiated by the interaction with the receptor (c-Met) on the target cell surface[4]. The binding of HGF to c-Met induces receptor dimerization and autophosphorylation at the intracellular tyrosine kinase domain of the β-subunit of the receptors. This tyrosine kinase activation mediates the binding of signaling molecules such as Src, PI3K, PLC, and Grb2 to c-Met multifunctional docking site, which will further activate several signaling pathways leading to functional alterations of the cells[8,9] such as growth and motility[10].

Src is a 60-ku non-receptor protein tyrosine kinase, encoded by a proto-oncogene *c-Src*. It consists of a unique N-terminal segment, an SH3 domain, an SH2 domain, a catalytic domain, and a short C-terminal tail[11]. Src SH2 domain is available for binding with phosphotyrosine residues of the other molecules such as c-Met and focal adhesion kinase (FAK)[10,12]. It could be mutated and constitutively activated in transformed cells[13]. Increase in Src expression has been reported in several human cancers including colorectal cancer[14], pancreatic carcinoma[15] and breast cancer[16]. Studies on Src activation in cancer cell lines[17] and in animal model[18] have implicated it to the invasiveness of the cells.

FAK is a 125-ku cytoplasmic protein tyrosine kinase that is implicated in integrin-mediated signaling pathways involved in the process of cell cycle, cell spreading and migration and prevention of cell apoptosis[19-21]. FAK overexpression has been observed in a variety of invasive tumors[22-25] as well as in tumor cell lines[26,27]. The function of FAK in the promotion of cancer cells' proliferation has been previously demonstrated in an animal model[28].

Both Src and FAK seem to play a crucial role in the transformation and progression of tumor cells. The relationship between them has been extensively investigated, but the mechanism remains unclear. Evidences have indicated that in integrin-mediated signaling or adhesion-dependent pathway, the binding of integrin to its extracellular ligands recruits FAK to aggregate at the focal contact and initiates its autophosphorylation at tyrosine 397[29,30]. The activated FAK functions as a binding site for several downstream signaling molecules including Src[29,30], which interacts with autophosphorylated FAK by its SH2 domain[12,31]. Then, Src phosphorylates FAK at other tyrosine positions such as 576, 577, 861, and 925[32,33]. Phosphorylated FAK, especially at tyrosine 925, becomes a binding site for Grb2, one of the upstream molecules in Ras/MAPK pathway, which consequently activates this signaling pathway and eventually facilitates cell proliferation and migration[29-31]. The downstream pathway after Src and FAK interaction also involves the interaction of phosphorylated FAK with PI3K[34] or Grb7[35] that participated in actin cytoskeleton organization and cell migration. In the adhesion-independent pathway, however, evidence from the study in Phe397-FAK mutant cells has indicated that the SH3 domain of *v-Src* (a mutated and constitutive activated form of *c-Src*) could bind with the proline rich region of FAK and is able to mediate cell transformation without external stimuli[13]. The downstream pathway after Src and FAK interaction in these cells could be similarly involved with PI3K or Grb7 as in the adhesion-dependent pathway. Moreover, both FAK and Src have binding association with the exchange factors of the small GTPases in the Rho family, which are then activated by phosphorylation. These in turn regulate cytoskeleton organization and initiate cell migration[36,37].

In this study, we have attempted to clarify the associated function between Src and FAK in HGF-mediated cell proliferation and invasion, using human cholangiocarcinoma cell line, HuCCA-1, as a model. This cell line was isolated and established from a Thai patient who had cancer of the intrahepatic bile duct epithelium[38,39]. This is one of the most aggressive cancers that cause a high fatality rate in Thailand. It rapidly metastasizes to other parts of the body and there is no effective treatment available to date. The relative function of Src and FAK in the cancer cells was determined from their phosphotyrosine activities before and after Src inhibition by using a novel Src inhibitor (AZM555130).

MATERIALS AND METHODS

Materials

Mouse mAbs to cytokeratin 19, α-smooth muscle actin (SMA), FAK and phosphotyrosine (PY20) were purchased from DAKO, Sigma, Pharmingen, and Santa Cruz, respectively. Rabbit polyclonal antibody to FAK (α-KC) was produced in the laboratory at Cornell University, Ithaca, NY, USA. Rabbit polyclonal antibody to Src was purchased from Santa Cruz. Goat anti-mouse IgG-FITC, anti-mouse IgG-HRP, and anti-rabbit IgG-HRP were purchased from Zymed Laboratories Inc. Protein A-Sepharose 4B beads were purchased from Sigma. Recombinant human hepatocyte growth factor (rhHGF) was purchased from Biosource International. Src inhibitor (AZM555130) was a gift from AstraZeneca.

Cell culture

Human cholangiocarcinoma cell line, HuCCA-1, was cultured in HamF-12 medium (Hyclone) containing 10% fetal bovine serum (FBS) at 37 ℃ in 50 mL/L CO_2 incubator. To characterize the cells, immunofluorescent staining for cytokeratin 19 was performed to confirm the epithelial origin of these cells.

Immunofluorescent staining

HuCCA-1 cells were seeded on 12-mm coverslips and placed on a 24-well plate at the density of 5×10^4 cells/well. The cells were cultured until 80-90% confluence. The coverslips from each well were removed and placed on parafilms in cell-side up position. The cells were fixed by immersing in ice-cold methanol: acetone (1:1) and kept at -20 ℃ for 10 min, air dried at room temperature and rinsed thrice with PBS. Cells were covered with blocking buffer (1% BSA in PBS) at 37 ℃ for 30 min. After that, the blocking buffer was removed and the cells were incubated with mAbs against cytokeratin 19 (CK-19) or SMA, at room temperature for 1 h. The primary antibodies were removed and the cells were washed thrice with PBS. Then, cells on the coverslips were covered with FITC-conjugated goat anti-mouse IgG for 1 h at room temperature, and washed thrice with PBS. The stained cells were visualized under the Nikon fluorescent microscope at a wavelength of 450-490 nm.

Reverse transcriptase-polymerase chain reaction (RT-PCR)

Evaluation of mRNA expression for HGF and c-Met in HuCCA-1 cells were semiquantitated by RT-PCR. Total RNA was isolated from the cells using TRIzol reagent and RT-PCR was performed using OneStep RT-PCR kit (QIAGEN), following the manufacturer's instructions. Two micrograms of total RNA and 0.6 μmol/L of each primer were used in each reaction. The specific primer pairs included (1) for hHGF: "5'-GCCTGAAAGATATC-CCGACA-3' " and "5'-TTCCATGTTCTTGTCCCACA-3' "(523 bp), (2) for *c-Met*: "5'-TCTTGGGACATCAG-AGGGTC-3' "and "5'-TGACTGCAGGACTGGAAATG-3' "(222 bp), (3) for GAPDH (internal control): "5'-TGATGA-CATCAAGAAGGTGGTGAAG-3' "and "5'-TCCTTG-GAGGCCATGTG GCCAT-3' "(240 bp).

Immunoprecipitation and Western blotting assays of FAK and Src phosphorylation

Cultured HuCCA-1 cells were washed with ice-cold PBS and digested with radioimmunoprecipitation assay (RIPA) lysis buffer containing phosphatase and protease inhibitors

(50 mmol/L sodium fluoride, 1 mmol/L sodium orthovanadate, 1% aprotinin, 2 mmol/L phenylmethylsulfonyl fluoride and 10 μg/mL leupeptin). Whole cell lysates that contained ⩾500 μg of total protein were pre-cleared by incubation with protein A-Sepharose beads at 4 ℃ for 30 min. The beads containing lysates were centrifuged and supernatants were collected. Rabbit polyclonal anti-FAK or anti-Src antibody was added and incubated overnight at 4 ℃. Then, protein A-Sepharose beads were added and incubation was continued at 4 ℃ for an additional 1.30 h. Immunocomplexes were collected by centrifugation and the supernatants were discarded. The beads with immunocomplexes were washed with RIPA lysis buffer, mixed with SDS-PAGE sample buffer, boiled for 5 min and resolved by SDS-polyacrylamide gel electrophoresis. Western blotting was performed using mouse monoclonal anti-phosphotyrosine (PY20) antibody followed by HRP-conjugated goat anti-mouse IgG. The desired protein bands on the membrane were detected by using the enhanced chemiluminescence system (Lumiglo, KPL). To confirm the amount of total FAK or Src in each sample, the same membranes were stripped and reprobed with mouse monoclonal anti-FAK or rabbit polyclonal anti-Src antibody. The density of the bands was measured by densitometry.

Co-immunoprecipitation assay of Src and FAK

HuCCA-1 cells were washed with ice-cold PBS and lysed with NP-40 lysis buffer without salt (1% NP-40, 50 mmol/L Tris-HCl pH 7.4) containing phosphatase and protease inhibitors. Whole cell lysates were processed as above, but the immunoprecipitation was first complex with rabbit polyclonal anti-Src antibody. Then, the complex was resolved by SDS-PAGE and proteins were transferred to nitrocellulose membrane. The membrane was incubated with mouse monoclonal anti-FAK antibody followed by HRP-conjugated goat anti-mouse IgG. The desired protein bands were evaluated as above. The same membrane was stripped and reprobed with anti-Src antibody to confirm the amount of total Src used in each sample.

Cell proliferation assay

Cell proliferation assay was performed by using the *In Vitro* Toxicology Assay Kit MTT Based (Sigma) following the manufacturer's instruction. Briefly, HuCCA-1 cells were seeded in a 96-well plate at a density of 1×10^4 cells/well in 100 μL of HamF-12 media containing 10% FBS and cultured overnight in 37 ℃, 50 mL/L CO_2 incubator. Then, cells were starved in 100 μL of serum-free HamF-12 media for 24 h. Fresh medium (200 μL) with or without 10 or 20 ng/mL rhHGF were replaced and further incubated for 24-48 h. Then, the medium was changed to 100 μL of HamF-12, and 10 μL of reconstituted MTT was added into each well. The plate was incubated at 37 ℃ in 50 mL/L CO_2 incubator for 4 h. After incubation, 100 μL of MTT solubilizing solution (10% Triton X-100, 0.1 mol/L HCl in anhydrous isopropanol) was added into each well to dissolve the resulting formazan crystals. Absorbance at a wavelength of 570 nm was measured using a microplate reader. The negative control of the system was performed as the experimental one but without cells. Absorbance at 690 nm was measured to determine the background of the system, and was subtracted from each measurement. The data was statistically analyzed using Student's *t*-test and compared with the untreated group. A *P* value lesser than 0.05 was considered significant.

Cell invasion assay

HuCCA-1 cells, in the density of 1×10^5 cells/200 μL of HamF-12 and 0.1% BSA, were seeded on each upper chamber of 24-well transwell plate (8-μm pore-sized membrane, Costar) coated with 100 μL of 30 μg matrigel (Becton-Dickinson). In the lower chamber, 400 μL/well of HamF-12 with or without 20 ng/mL rhHGF was added. After incubation at 37 ℃ in 50 mL/L CO_2 incubator for 48 h, the media in both chambers were removed. The cells that remained on the upper surface of the membrane were wiped off with wet cotton buds. Invasive cells bounded on the lower surface of the membrane were fixed with 25% methanol and stained with 5% crystal violet in 25% methanol. The number of invading cells on each membrane was counted, under light microscope at 40× magnification, for six random microscopic fields per membrane and averaged. Each assay was performed in triplicate.

Inhibition assay of Src-FAK interaction

Cultured HuCCA-1 cells were treated with 0, 0.1, 0.5, and 1.0 μmol/L of Src inhibitor (AZM555130) for 1 h. Then, they were further incubated with 20 ng/mL rhHGF or without rhHGF for 48 h. The whole cell lysates were extracted for immunoprecipitation and Western blotting assay to determine the level of Src and FAK phosphorylation. Cell proliferation was performed by MTT assay as described above. The effect on cell invasion was performed by incubation of the cells with 0, 0.1, or 1.0 μmol/L of AZM555130 for 1 h and then seeded onto the upper chambers of 24-well transwell plates. HamF-12 medium with or without 20 ng/mL rhHGF was added in the lower chambers and the cells were cultured for 48 h. The number of cells invading through matrigel was analyzed as described above.

RESULTS

Characterization of HuCCA-1 cells

HuCCA-1 cells were intensely labeled with anti-cytokeratin-19 (CK19, Figure 1A) but not with SMA antibodies (Figure 1B), which indicated the epithelial origin of the cells. This confirms the previous characterization by the establishers[38,39]. The semi-quantitative determination of mRNA expression for HGF and its receptors (c-Met), by RT-PCR analysis, showed a high level of c-Met but a low level of HGF mRNA gene expression (Figures 2A-C). Liver myofibroblasts and hepatocellular carcinoma cell line, HepG2, were used as positive controls for HGF and c-Met gene expression, respectively.

Effect of HGF on HuCCA-1 cell proliferation and invasion

HuCCA-1 cell proliferation and invasion were enhanced by treatment with rhHGF, in a time-dependent fashion (Figures 3A and B). After 24-48 h treatment with 10 ng/mL

rhHGF, HuCCA-1 cell proliferation was significantly increased when compared to the control (P<0.05 and 0.01 at 24 and 48 h, respectively, Figure 3A). The number of invading cells was also increased significantly when 20 ng/mL rhHGF was added into the lower chamber without the serum (P<0.001 and 0.001 at 24 and 48 h, respectively, Figure 3B).

Effect of HGF on phosphorylation of FAK and Src

The immunoprecipitation and Western blotting assays demonstrated that HGF promoted FAK and Src phosphorylation in a time-dependent manner. The maximal level of tyrosine phosphorylation on FAK was reached after 60 min of HGF induction and then declined to the basal level after 120 min (Figures 4A and B). For Src phosphorylation, the level was peaked at 30 min after HGF induction (Figures 5A and B).

The interaction between Src and FAK after HGF induction

Co-immunoprecipitation of Src and FAK in HGF-induced cells revealed that HGF promoted Src and FAK interaction. The Src-FAK immunoprecipitation level reached a maximum at 30 min (Figures 6A-C). This was well correlated to the level of Src phosphorylation (Figure 5) indicating that the Src-FAK complex was formed before FAK became phosphorylated.

Effect of Src inhibitor (AZM555130) on Src and FAK phosphorylation

After 48 h treatment, Src inhibitor had no inhibition effect on Src phosphorylation (Figure 7A) both in HGF-induced and non-induced cells, but it had inhibition effect on FAK phosphorylation in a dose-dependent manner (Figure 7B). In HGF-induced FAK phosphorylation, a low dose at 0.1 μmol/L was not inhibited, but higher doses (0.5 and 1.0 μmol/L) were gradually inhibited. In non-HGF-induced cells, the inhibition effect was significant at a higher dose (1.0 μmol/L) than for HGF-induced cells.

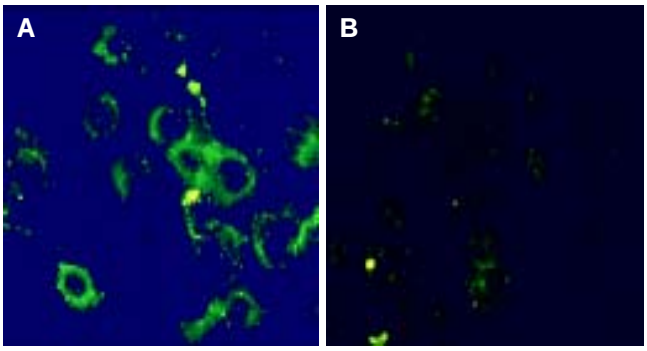

Figure 1 Immunofluorescent study in HuCCA-1 cells shows positive staining to human CK-19 mAb (A) and negative staining to SMA mAb (B) (40× magnification).

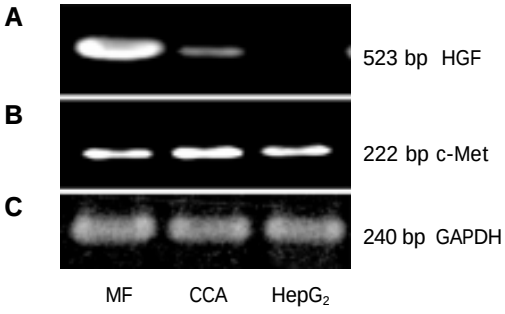

Figure 2 mRNA expression level of HGF (A) and c-Met (B) was observed by RT-PCR technique. HuCCA-1 (CCA) expressed low HGF but a high level of c-Met mRNA. Liver myofibroblasts (MF) and hepatocellular carcinoma cell line (HepG2) were used as positive controls for HGF and c-Met, respectively. Equal amount of total RNA from each cell was confirmed by GAPDH (C).

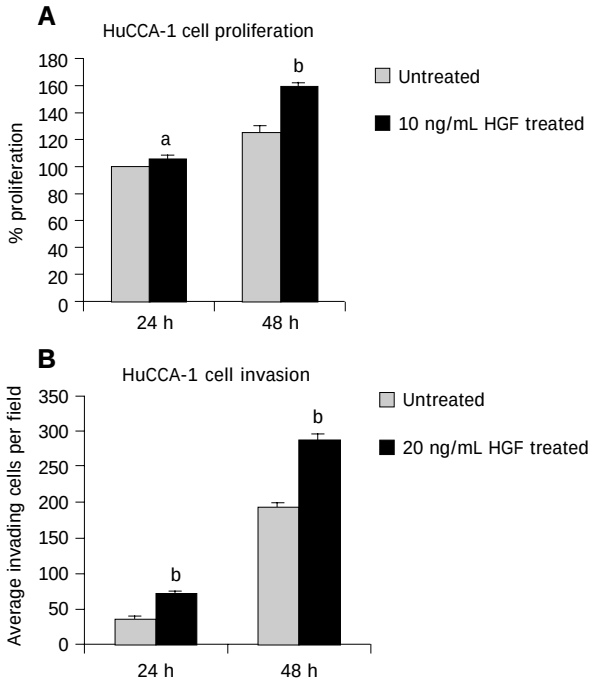

Figure 3 Cell proliferation assay showed significantly increased proliferating cell number after 10 ng/mL rhHGF treatment in HuCCA-1 cells for 24 and 48 h (A). Invasion assay also showed significantly increased invading cells after 24 and 48 h treatment of 20 ng/mL rhHGF (B). Data are expressed as mean±SE, ^aP<0.05 and ^bP<0.01, compared to the HGF-untreated cells at the corresponding time.

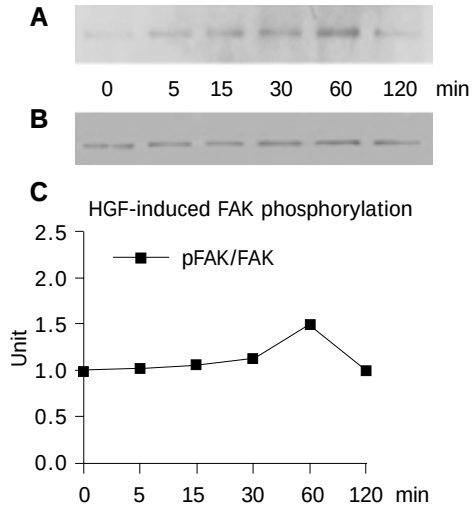

Figure 4 Treatment of HuCCA-1 cells with 20 ng/mL rhHGF for 0, 5, 15, 30, 60, and 120 min showed increased degree of FAK phosphorylation in a time-dependent manner. The maximal level of FAK phosphorylation was reached at 60 min and then sharply decreased at 120 min (A). Equal amount of FAK protein used in each time point was confirmed by reprobing the membrane with anti-FAK antibody (B). The density of bands was measured and pFAK/FAK value was plotted in a graph (C).

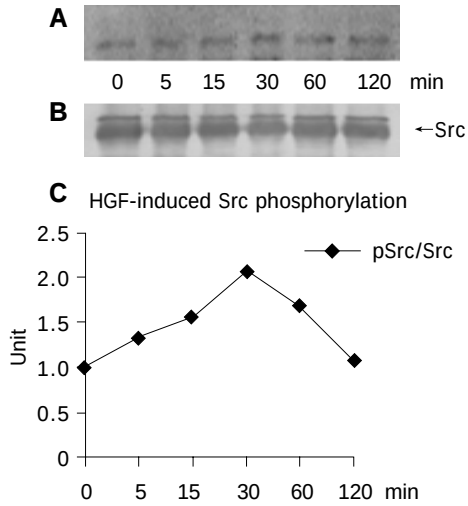

Figure 5 Treatment of HuCCA-1 cells with 20 ng/mL rhHGF for 0, 5, 15, 30, 60, and 120 min showed an increased degree of Src phosphorylation in a time-dependent manner. The maximal level of Src phosphorylation was reached at 30 min (A). Equal amount of Src protein (upper bands) used in each time point was confirmed by reprobing the membrane with anti-Src antibody (B). The density of bands was measured and pSrc/Src value was plotted in a graph (C).

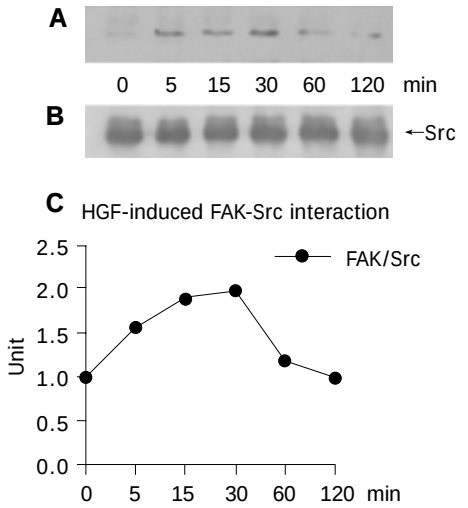

Figure 6 The interaction between Src and FAK was demonstrated in HGF-treated HuCCA-1 cells by co-immunoprecipitation at varied time points. The resulting bands showed a positive correlation of FAK with Src phosphorylation, which reached a maximum at 30 min and then declined (A). The amount of Src protein (upper bands) used in each time point was confirmed (B). The density of bands was measured and the ratio between FAK and Src was plotted in the graph (C).

Effect of Src inhibitor (AZM555130) on HuCCA-1 cell proliferation

HuCCA-1 cell proliferation in both HGF-induced and non-induced conditions was significantly inhibited by the treatment with AZM555130 (Figure 8). The non-induced cells were more affected than the induced cells. In HGF-induced cells, cell proliferation was reduced by 25% and 34% at the doses of 0.5 and 1.0 μmol/L, respectively (P<0.01, both). In the non-induced cells, the cell proliferation was reduced by 9% (P<0.05), 33% (P<0.01) and 41% (P<0.01) at the doses of 0.1, 0.5, and 1.0 μmol/L, respectively.

Effect of Src inhibitor (AZM555130) on HuCCA-1 cell invasion

Treatment of HuCCA-1 cells with AZM555130 reduced cell invasiveness in both HGF-induced and non-induced conditions, in a dose-dependent manner (Figure 9). The induced cells were more sensitive than the non-induced cells at the low dose, but the non-induced cells were more sensitive than the induced cells at the high dose. At the concentration of 0.1 and 1.0 μmol/L, AZM555130 significantly decreased the invasive ability of the HGF-induced cells by 32% and 85%, respectively and of the non-induced cells by 23% and 98%, respectively (P<0.01, all).

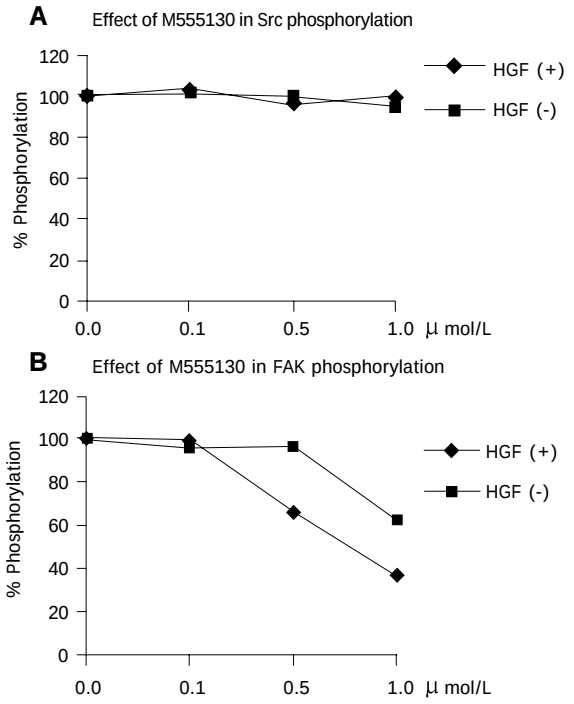

Figure 7 Treatment of cells with 0.1, 0.5, and 1.0 μmol/L of AZM555130 for 48 h showed no inhibition of Src phosphorylation both in HGF-treated and untreated cells (A). The HGF-induced FAK phosphorylation was not inhibited after 48 h treatment of 0.1 μmol/L AZM555130 but showed 34% and 63% inhibition by 0.5 and 1.0 μmol/L treatment, respectively. The 37% inhibition of FAK phosphorylation was observed by treatment of 1.0 μmol/L AZM555130 in non-induced cells (B). These values were compared with the levels of Src and FAK phosphorylation in AZM555130-untreated cells which is equal to 100%.

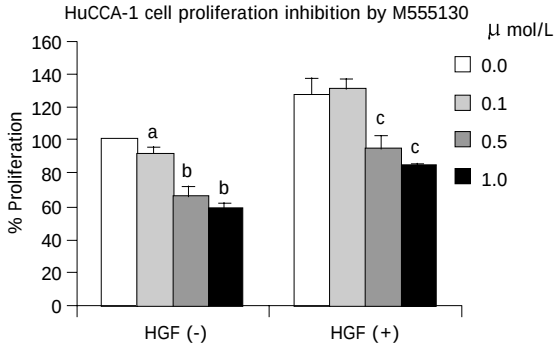

Figure 8 The HGF-mediated cell proliferation was not inhibited by 0.1 μmol/L AZM555130 but was significantly inhibited by 0.5 and 1.0 μmol/L of AZM555130 for 25% and 34%, respectively. Without HGF, cell proliferation was inhibited by 0.1, 0.5, and 1.0 μmol/L of AZM555130 for 9%, 33%, and 41%, respectively. All values are mean±SE, ^{a}P<0.05 and ^{b}P<0.01, compared to the control in HGF-untreated cells; ^{d}P<0.01, compared to the control in HGF-treated cells.

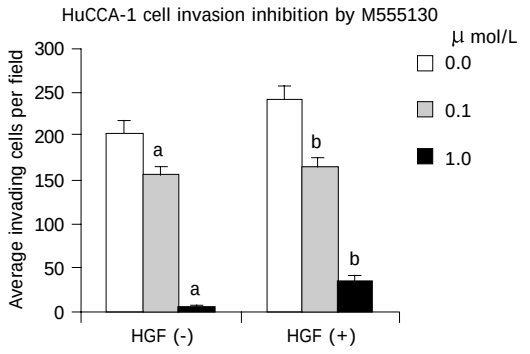

Figure 9 The HGF-mediated invasion of HuCCA-1 cells was significantly decreased by 0.1 and 1.0 μmol/L of AZM555130 for 32% and 85%, respectively. Without HGF, cell invasion was also significantly decreased by 0.1 and 1.0 μmol/L of AZM555130 for 23% and 98%, respectively. All values are mean±SE, $^{b}P<0.01$, compared to the control in HGF-untreated cells; $^{d}P<0.01$, compared to the control in HGF-treated cells.

DISCUSSION

Cholangiocarcinoma cells (HuCCA-1) showed high c-Met mRNA expression, thus they responded well to HGF induction. The profound effects of HGF in enhancing HuCCA-1 cell proliferation and invasion demonstrated here reflect the events in cholangiocarcinoma patients with high HGF (produced from the liver myofibroblasts) that exerted its action through c-Met to promote the rapid progression of cancer. Since various cancers respond differently to various growth factors and/or cytokines, their signaling mediators were believed to be very diverse[3,40]. The signaling molecules mediated by growth factors and/or cytokines to regulate normal-cell proliferation have been previously determined[41,42]. The implication of FAK activation via integrin-mediated signaling to promote cell migration in normal and embryonic cells has also been reported[29,43]. This study emphasized the signaling mechanism mediated by Src and FAK after the binding of HGF to c-Met. We found that in association with its promoting cell proliferation and invasiveness, HGF was also found to maximize the cytoplasmic tyrosine phosphorylation of Src and FAK in HuCCA-1 cells (Figures 4 and 5). FAK phosphorylation increased slightly at 30 min after the induction and reached the maximum level at 60 min. Src phosphorylation occurred prior to FAK phosphorylation and the level peaked at 30 min after the induction. Although the basal levels of both Src and FAK phosphorylation were high in the non-induced stage, the earlier and higher effect of HGF on Src phosphorylation was observed than on FAK phosphorylation in the induced stage. These results suggest that HGF-mediated signaling via Src. When Src was co-immunoprecipitated with FAK in the HGF-induced cells, Src phosphorylation pattern and time course level was similar to the pattern and level of the non-induced cell. It was suggested that Src phosphorylation and Src-FAK interaction occurred side by side and Src probably was the upstream effector molecule to FAK. Therefore, the sequences of signaling mechanism in HGF-induced HuCCA-1 cells could be (i) The binding of HGF to c-Met induced the conformational change and autophosphorylation of the receptors[44]. (ii) The binding of Src SH2 domain to the phosphorylated receptors at tyrosine 1349 and 1356 positions of the c-Met multifunctional docking site[45]. (iii) The phosphorylation of Src, and (iv) Src further activated FAK by Src kinase activity. However, previous investigation has indicated that FAK has no specific binding site on c-Met but Src was a substrate and a binding partner of FAK[29,46]. Apparently, the functional relationship between Src and FAK molecules was reversed in the induced HuCCA-1 cells. To act on its substrate FAK, Src might have to use its SH2 domain to bind c-Met and SH3 domain to bind the proline-rich region of FAK[12,21,47]. Subsequently, Src catalytic domain phosphorylates FAK at other tyrosine residues leading to the cascade of signaling pathways for cell proliferation such as activation of Ras/MAPK pathway. This pathway has been raised in the study of human embryonic kidney 293 cells under the induction of HGF, where FAK was suggested as an adaptor molecule in Src phosphorylation[48]. In addition, the activation through Src/p130Cas-signaling cascade was believed to use FAK as a mediator necessary for HGF-induced cell growth and invasiveness in MDCK cells[49].

To confirm that the signaling pathway mediated by HGF-c-Met interaction has Src as an upstream molecule to FAK, we inhibited Src by using a novel Src inhibitor (AZM555130). The results showed that AZM555130 could not inhibit Src phosphorylation (Figure 7A) but inhibit FAK phosphorylation (Figure 7B) since the inhibitor AZM555130 acted by specifically binding to its tyrosine kinase domain to block the enzyme activity[50], not to its tyrosine phosphorylation. Therefore, Src tyrosine phosphorylation remained stable (Figure 7A). However, when Src kinase activity was inhibited, the downstream signaling molecules, which were substrates for Src including FAK could not be further phosphorylated (Figure 7B). The effect of inhibitor to Src on FAK phosphorylation was concentration-dependent and more sensitive in HGF-induced cells than in the non-induced cells (Figure 7B). This further supported that Src was an intermediate linker between c-Met and FAK and Src enzyme activity was directly inhibited by AZM555130. Without HGF, the response of Src (as a kinase for FAK) to the inhibitor was low and required higher concentration of AZM555130 to reduce FAK phosphorylation.

The proliferation of HGF-induced cells was decreased after Src inhibitor treatment, at the concentration of 0.5-1.0 μmol/L, which was well correlated with FAK phosphorylation inhibition. In the non-induced cells, decreased cell proliferation by Src inhibitor was also detected but at the lower extent. Inhibition of HuCCA-1 cell invasion was found to be dependent on AZM555130 concentration both in cells with and without HGF induction indicating the high efficiency of the inhibitor.

The overall results implied that Src and FAK were the pivotal signaling molecules that mediated signaling pathway for HGF-induced cells. Src catalytic activity was enhanced in HGF-induced cells and functioned as a kinase for FAK. FAK was phosphorylated and further led to the downstream pathways to cell proliferation and invasion. In order to effectively stop the progression of cancers such as cholangiocarcinoma, in which FAK phosphorylation was specifically induced by the paracrine effect of HGF,

inhibition of FAK or blocking of Src-FAK interaction should be taken into consideration.

Abstract

AIM: To evaluate the protective effect of lysozyme chloride on betel quid chewing (BQC) aggravated gastric oxidative stress and hemorrhagic ulcer in rats with diabetes mellitus (DM).

METHODS: Male Wistar rats were challenged intravenously with streptozotocin (65 mg/kg) to induce DM. Rats were fed with regular pellet food or BQC-containing diets. After 90 d, rats were deprived of food for 24 h. Rat stomachs were irrigated for 3 h with normal saline or simulated gastric juice. Rats were killed and gastric specimens were harvested.

RESULTS: An enhancement of various gastric ulcerogenic parameters, including acid back-diffusion, mucosal lipid peroxide generation, as well as decreased glutathione levels and mucus content, were observed in DM rats. After feeding DM rats with BQC, an exacerbation of these ulcerogenic parameters was achieved. Gastric juice caused a further aggravation of these ulcerogenic parameters. Daily intragastric lysozyme chloride dose-dependently inhibited exacerbation of various ulcerogenic parameters in those BQC-fed DM rats.

CONCLUSION: (1) Gastric juice could aggravate both DM and BQC-fed DM rat hemorrhagic ulcer; (2) BQC exacerbated gastric hemorrhagic ulcer in DM rats via enhancing oxidative stress and reducing defensive factors; (3) lysozyme chloride effectively protected BQC aggravated gastric damage in DM rats.

INTRODUCTION

Betel quid chewing (BQC) is a habit of human beings in most parts of the world. It has been estimated that more than 10% of the world's population chew betel quid for its mild psychoactive effects[39]. Ample documents demonstrate that BQC is a carcinogenic agent either in animal[4] or in human beings[7]. BQC can result in cancer of buccal cavity[26], esophagus[31], stomach[8], lung, and liver[4]. Since the stomach is the organ that directly contacts BQC, it is likely that gastric mucosa can also be damaged after its long-term consumption.

On the other hand, diabetes mellitus (DM) is an important fatal disease that is frequently found in the clinic. Gastrointestinal disturbance, such as gastric hemorrhagic ulcer, is one of the main manifestations observed in poor controlled DM patients. Previous document demonstrates the importance of acid back-diffusion in the formation of hemorrhagic ulcer in DM rats[22]. Whether BQC can aggravate DM-induced gastric hemorrhagic ulcer is unknown.

During gastric oxidative stress, the imbalance of aggressive and defensive factors in the stomach plays a pivotal role in gastric hemorrhage and ulcer formation. The aggressive factors include gastric acid back-diffusion and oxyradical generation, while defensive factors involve glutathione (GSH) and mucus biosynthesis[17]. Aggravation of aggressive factors and/or attenuation of defensive substances may result in high risk of gastric hemorrhage and ulcer formation.

When gastric mucosal barriers are inflamed or disrupted by acid, ethanol or aspirin, the intraluminal free acid may diffuse back into gastric mucosa through damaged mucosal barriers and consequently causes exacerbation of hemorrhage and ulceration. This acid back-diffusion is considered as a sensitive marker of gastric mucosal integrity[10,21]. In fact, gastric acid back-diffusion is greatly associated with hemorrhage and ulcer formation in various inflammatory diseases[12,17]. In the disease state, oxidative stress of the stomach may occur and result in an elevation of mucosal lipid peroxide (LPO) that are generated from the reaction of oxyradicals and cellular polyunsaturated fatty acid. Whereas reduced GSH is a sulfhydryl compound, which may act to prevent lipid peroxidation produced by noxious oxyradicals that can damage gastric mucosal cells[3]. Various studies have demonstrated a decrease in GSH level in inflammatory and ulcerated gastric mucosa[14,19]. The mucosal protective effect

of GSH on gastric damage induced by nonsteroidal anti-inflammatory drugs[35], ethanol[36] or lipopolysaccharide[17] has been well documented. Nevertheless, the role of mucosal GSH and oxyradicals in BQC-induced hemorrhagic ulcers are unknown. Gastric mucus, which plays an important role in the mucosal protection, can be eliminated by acid or noxious agents[1]. Nevertheless, the influence of BQC on gastric mucus secretion in DM rats also remains obscure.

Lysozyme (muramidase), which widely distributes in various human tissues[27] is a stable polypeptide containing 18 amino acids. High content of lysozyme is found in mammalian milk, chicken eggshell membrane, and matrix[13]. This compound may possess multiple pharmacological actions, including analgesic[5], anti-inflammatory[33], hemostatic, anti-allergy[2], anticancer[25], and antibiotic[24] effects. The aim was to study the influence of chronic consumption of BQC on gastric oxidative stress, mucus production, and mucosal hemorrhagic ulcer in DM rat gastric mucosa. The mucosal protective effects of lysozyme chloride on this ulcer model were also evaluated.

MATERIALS AND METHODS

Chemicals used

The following chemicals in reagent grade were used: acivicin, alcian blue, lysozyme chloride, 1-butanol, *o*-phthaldialdehyde, pyridine, rat hemoglobin (Hb), reduced GSH, sodium laurylsulfate, trichloroacetic acid, 1,1,3,3-tetramethoxypropane, and 2-thiobarbiturate were purchased from Sigma (St. Louis, MO, USA). The purity of all drugs was over 98%. All chemical solutions were freshly prepared before use.

Drug administration

Intragastric lysozyme chloride (0-500 mg/kg) was challenged once daily to normal and those rats fed with BQC for 90 d. The control group received normal saline instead of chemicals.

Animals

Male specific pathogen-free Wistar rats, weighing 150±20 g, were housed individually in a room with a 12-h dark-light cycle and with central air conditioning (25 ℃, 70% humidity). Animal care and experimental protocols were in accordance with the guidelines of the National Sciences Council of Taiwan (NSC 2002). Prior to the experiments, rats were injected intravenously with streptozotocin (65 mg/kgt) to induce DM. Non-DM rats received vehicle only. Blood glucose level over 2 500 mg/L was considered as DM. All rats were divided into groups. Control rats received laboratory rodent diet (the Richmond standard, PMI feeds, St. Louis, MO, USA). Test groups were fed with the BQC diet prepared by mixing the laboratory rodent diet with chopped and crushed BQC (30%, w/w), which contained areca nuts (40%, w/w), gambir lime (30%, w/w) and betel stems (30%, w/w). The calories of BQC-diet were compensated near the control pellet diet (4.25 kcal/g) by adding adequate amounts of sugar and eggs. The BQC-diet was then dried in cold air and stored in a refrigerator (4 ℃). The rats were given fresh diet every day at 8 a.m. While chewing the test food, rats mimicked human beings in chewing and spitting the fiber contained in the BQC diet. The consumption of the diet, water, and the body weight of the animal were recorded every day before feeding, respectively.

Surgical procedures

After 90 d, rats were deprived of food for 24 h and anesthetized with diethylether. Rat stomachs were surgically exposed for the ligation of pylorus and lower esophagus. To prevent the spontaneous gastric secretion, a bilateral diaphragmatic vagotomy was performed in all rats. A small incision was then made in the forestomach. A polypropylene tube (3.5 mm internal diameter×20 mm long) was inserted through the same incision and secured with a ligature. The stomach was subsequently rinsed meticulously with warm normal saline (37 ℃). Care was taken to avoid injury to blood vessels. The residues were gently removed.

Measurement of gastric acid back-diffusion

Gastric acid back-diffusion (the H^+ loss in the gastric lumen) was quantified by the method previously described[21]. Either normal saline or simulated gastric juice (7 mL) containing 100 mmol/L HCl, 17.4 mmol/L pepsin and 54 mmol/L NaCl was instilled into the cleansed stomach with a syringe. Luminal contents were mixed with the same syringe by three repeated aspirations and injections, and 3 mL of the fluid was taken as an initial sample. The forestomach was tightly closed. The abdominal wound was sutured. After 3 h, rats were killed with an overdose of diethylether. Gastric contents (final sample) were collected. Both initial and final samples were centrifuged at 3 000 r/min for 20 min. The volumes of the initial and final samples were measured. The acidity of samples was assessed by titrating 1.0 mL of gastric contents sample with 0.1 mol/L NaOH to pH 7.0 on an autoburette titrator (Radiometer, Copenhagen, Denmark). The net flux of ions through the gastric mucosa was calculated as follows:

$$\text{Ionic net flux} = F_v \times I_v - (7 - I_v) \times I_c$$

where F_v and I_v are the volume (mL) of the final sample and initial sample, respectively, and F_c and I_c are the ionic concentrations (in mmol/L) of the final sample and the initial sample, respectively. A negative value for net flux indicates luminal electrolyte loss and a positive value indicates luminal electrolyte gain.

Morphological and histological studies of gastric mucosa

As soon as the final sample was collected, the stomach was filled with 8 mL of 4 g/L formaldehyde for 10 min. The mucosa was exposed by opening the stomach along the greater curvature. The length (mm) and the width (mm) of ulcer on the mucosa were measured with a planimeter ($1\pi/4$).

The total ulcer area (mm^2) of each stomach was recorded. Histological studies of the stomach also were conducted by methods as previously described[21]. Sections were scored as 0-5, in which (0) indicated normal appearance, (1) mild injury in the epithelial cells, (2) mild injury in the upper part of mucosal cells, (3) hemorrhage or edema in the mid or lower part of mucosal cells, (4) degranulation or necrosis of the epithelial cells, and (5) serious cell disruption of lower part of the mucosa. The index score of each section was evaluated on a cumulative basis to give a maximal score of 15.

Determination of hemoglobin (Hb)

Cleansed rat stomachs were irrigated for 3 h with either normal saline or gastric juice. Initial and final samples were collected by methods described above.

The blood attached to the gastric mucosa was carefully scraped and added to the final sample. Subsequently, both initial and final samples were adjusted to pH 1.5 with 0.1 mol/L HCl. The Hb content of the samples was measured spectrophotometrically[22]. The absorption maximum of Hb was measured at 376 nm. Appropriate irrigating solutions, adjusted to pH 1.5, were used as blank. Absorbances of the samples were measured against a standard curve (r^2>0.98) constructed with freshly prepared rat Hb (0.05-1.00 mg/mL) treated in the same manner as gastric samples. The luminal Hb content was calculated as:

$$\text{Hb content} = F_v \times F_{Hb} (7\text{-}I_v) \times I_{Hb},$$

where F_v and I_v are the volume (mL) of final sample and initial sample, respectively, and F_{Hb} and I_{Hb} are the luminal Hb concentrations (mg/mL) in the final and initial samples, respectively. The results obtained from gastric samples were expressed in mg Hb per stomach.

Mucosal GSH assay

The quantitation of gastric mucosal GSH was performed by following the methods that were described previously[19]. As soon as the final sample was collected, the rat stomach was dissected. The corpus mucosa was scraped using two glass slides on ice, weighed and homogenized immediately in 2 mL phosphate buffer (0.1 mol/L NaH_2PO_4 plus 0.25 mol/L sucrose, pH 7.4). Acivicin (250 μmol/L), an irreversible inhibitor of γ-glutamyltransferase, was added to the homogenate to inhibit the catabolism of GSH. Samples were then centrifuged at 4 000 r/min for 15 min at 4 ℃.

To determine the recovery of reduced thiol, GSH (200 μmol reduced GSH contained in phosphate buffer solution, pH 7.0) was added to the supernatant. Subsequently, 0.5 mL, 0.25 mol/L trichloroacetic acid was added to 1.0 mL of the supernatant. The mixture was kept for 30 min at 4 ℃. After centrifugation for 15 min at 3 000 r/min, the supernatant was used to determine GSH using 2,2-dinitro-5,5-dithio-dibenzoic acid. The optical density was measured at 412 nm on a spectrophotometer (model U-3210, Hitachi, Tokyo, Japan). All samples were measured in duplicate. Recovery of added internal standard was greater than 90% in all experiments. Absorbances of the samples were measured against a standard curve constructed with freshly prepared GSH solutions (0.05-0.5 mmol/L) that were treated in the same manner as the tissue samples. The results obtained from tissue samples were expressed as μmol GSH/g wet tissue.

Determination of lipid peroxides (LPO)

The concentration of gastric mucosal LPO was determined by estimating malondialdehyde using the thiobarbituric acid test[30]. Briefly, the stomachs of rats were promptly excised and rinsed with cold normal saline. To minimize the possibility of interference of Hb with free radicals, any blood adhering to the mucosa was carefully removed. The corpus mucosa was scraped, weighed and homogenized in 10 mL 100 g/L KCl. The homogenate (0.5 mL) was added with a solution containing 0.2 mL 80 g/L sodium laurylsulfate, 1.5 mL 200 g/L acetic acid,1.5 mL 8 g/L 2-thiobarbiturate and 0.3 mL distilled water. The mixture was incubated at 98 ℃ for 1 h. Upon cooling, 5 mL of 1-butanol/pyridine (15:1) was added. The mixture was vortexed for 1 min and centrifuged for 10 min at 400 r/min. The supernatant was measured at 532 nm. The standard curve was obtained by using 1,1,3,3-tetramethoxypropane. The recovery was over 90%. All samples were measured in duplicate. The results were expressed as nmol malondialdehyde/g wet tissue.

Measurement of gastric mucus

Gastric mucus was assessed by the method as described by Corne *et al*.[9]. Briefly, the rat stomach was excised and washed with tap water. The sample was immersed in 10 mL of a solution containing alcian blue (1.0 mg/L), sucrose (0.16 mol/L) and sodium acetate (0.05 mol/L) for 2 h. To remove the unbound dye, the sample was washed for 15 min and then for 45 min in a 0.25 mol/L sucrose solution. The mucus-bound dye was eluted by immersing gastric mucosa in 10 mL of 0.5 mol/L $MgCl_2$ solution for 2 h. The obtained solution was mixed with 10 mL diethylether. The absorbance of the color aqua solution was measured on a spectrophotometer (U3210, Hitachi) at 605 nm. The amount of alcian blue was extracted from known graded concentrations (5-50 mg/L) of alcian blue solution. All samples were measured in duplicate. The results were expressed as μg alcian blue/g wet tissue.

Statistical analysis

The data were expressed as mean±SE. Significant differences in single measurement traits were analyzed statistically by using the Tukey truly significant difference test for pairwise comparison after ANOVA or by using the Student's *t*-test[28]. Statistical significance was set at P<0.05.

RESULTS

Changes in gastric parameters in normal, DM, and BQC-fed DM rat stomachs irrigated with either normal saline or gastric juice

Table 1 indicated that in normal diet rat stomachs irrigated with normal saline no gastric acid back-diffusion but only little gastric acid secretion was achieved. Mucosal GSH and LPO generation were at normal levels. No mucosal ulceration and hemorrhage was observed in these rats (photo not shown). In saline-irrigated stomachs of DM rats, an enhancement of LPO generation as well as an attenuation of GSH and mucus secretion was obtained. After receiving the BQC-diet, marked necrotic ulcers accompanied by a further decrease in mucosal GSH and mucus were achieved in DM rats. The generation of mucosal LPO also was further aggravated in those rats, despite that no acid back-diffusion occurred.

When gastric juice was present in the stomachs of normal diet rats, the mucosa looked normal. Except when a normal level of acid back-diffusion occurred, various gastric parameters were not significantly different from those in saline-irrigated stomachs of normal rats. When DM rat stomachs were irrigated with gastric juice, a significant (P<0.05) increased acid back-diffusion and LPO generation accompanied with an attenuation of mucosal GSH and mucus

Data are mean±SE (n = 8). [a]P<0.05 *vs* corresponding control group. [c]P<0.05 *vs* corresponding group in saline-treatment. MDA = malondialdehyde, BQC = betel quid chewing, DM = diabetes mellitus.

secretion was observed and an exacerbated hemorrhagic ulcer also was produced. Further aggravation of gastric acid back-diffusion and LPO generation as well as decreased GSH and mucus production was found in those BQC-fed DM rats. More severe gastric hemorrhage and ulcer also was observed in these rats.

Histological examination of gastric mucosa of DM and BQC-fed DM rats

Figure 1 shows the microscopic examination of normal, DM, and BQC-fed DM rat stomachs irrigated with gastric juice. Marked upper gastric mucosal damage was observed in DM rats. More severe mucosal damage in BQC-fed DM rat stomachs than those in DM rats was obtained. The comparisons of degrees of histological tissue damage in normal, DM and BQC-fed DM rat stomachs irrigated with saline or gastric juice are illustrated in Figure 2. When the stomachs of normal diet rats were irrigated with either saline or gastric juice, no appreciable damage of gastric mucosal cells was observed. In DM rats, normal saline-irrigation produced more mucosal cell damage than those were irrigated with normal saline or gastric juice in normal diet rats. A pronounced aggravation of mucosal cell damage was observed in gastric juice-irrigated stomach of DM rats. Further exacerbation of gastric damage was achieved in DM rats fed with BQC. In most cases, gastric edema also was observed in DM and BQC-fed DM rats.

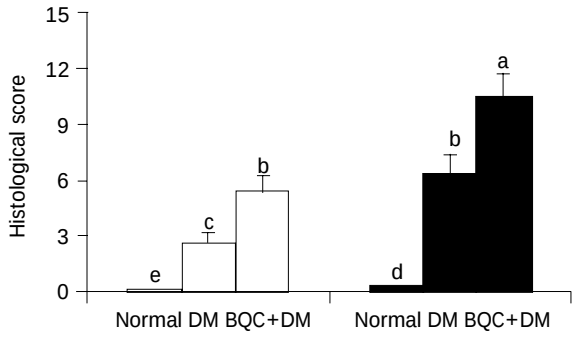

Figure 2 Histological scores of gastric mucosa in normal, DM, and BQC-fed DM rats. Rats were fed with normal diet or BQC diet for 90 d. Diabetes was induced by intravenous streptozotocin. Rat stomachs were irrigated for 3 h with normal saline (□) or gastric juice (■). Values are mean±SE, n = 6-8. Bars labeled with different letters are significantly different at P<0.05 based on Tukey statistic method.

Effects of lysozyme chloride on gastric parameters in gastric juice-irrigated stomachs of BQC-fed DM rats

As demonstrated in Table 2, low mucosal GSH levels and mucus secretion accompanied with high degree of acid back-diffusion and LPO generation were observed in 90-d BQC-fed DM rat stomachs irrigated with gastric juice. Severe gastric hemorrhage and mucosal ulceration also were achieved. Daily intragastric lysozyme chloride dose-dependently suppressed

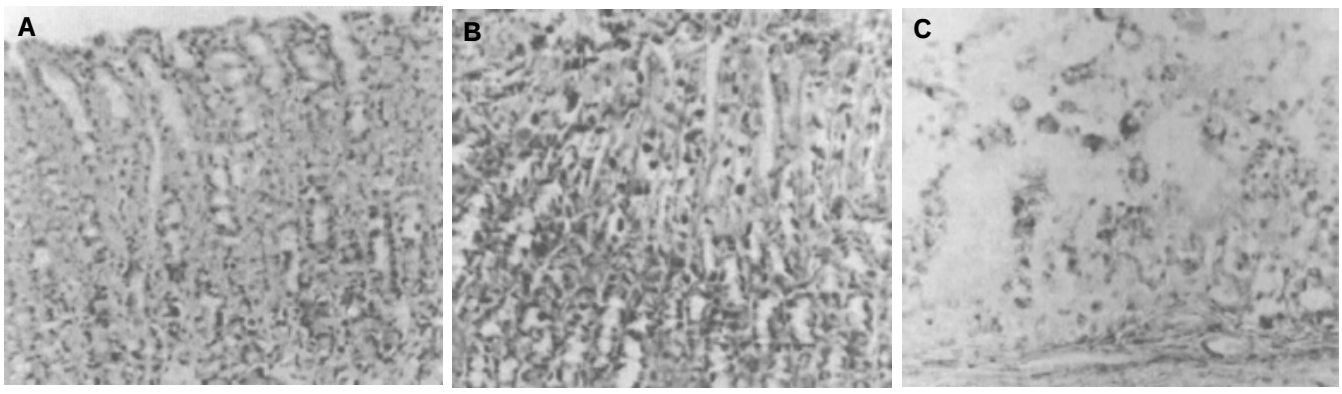

Figure 1 Histological studies of gastric mucosa exposed for 3 h gastric juice in normal, DM, and BQC-fed DM rats. Note that in normal rat stomachs irrigated with gastric juice (A), gastric mucosal cells look intact. However, gastric juice-irrigated DM rat mucosa (B), a disruption of gastric epithelial layer is observed. When stomachs of BQC-fed DM rats are irrigated with gastric juice (C), a complete disruption of the upper mucosal cells and lamina propria is obtained. The injured cells are characterized by karyorrhexis and dense homogenous acidophilic cytoplasm. In most cases, gastric edema also is observed (×150).

gastric hemorrhage and ulcer. This drug also inhibited the decreased mucosal GSH and mucus liberation as well as increased acid back-diffusion and mucosal LPO generations in BQC-fed DM rats in a dose-related manner. No visible side effects or toxicity of lysozyme chloride were observed in all experiments.

DISCUSSION

The pathological mechanisms underlying BQC-fed DM ulcer may be complex. Our previous paper demonstrates that chronic consumption of BQC can result in severe gastric hemorrhagic ulcer in rats[20]. In the present study, a remarkably increased acid back-diffusion was observed in those DM rat stomachs irrigated with gastric juice. Further aggravation of these ulcerogenic parameters was obtained in those DM rats fed with BQC. Obviously, chronic consumption of BQC diet could enhance various ulcerogenic parameters and result in greater gastric inflammation and breaking effects of gastric mucosal barriers in DM rats. Mechanisms of barrier-disruptive effect of BQC in DM rats are totally unknown. However, since BQC contained large amounts of gambir lime (which contains about 7-30% catechol, 20-50% catechu tannic acid and small amounts of quercetin waxes and oils; Merck Index, 1983) and calcium, the damage of mucosal barrier probably results from caustic injury from this component of BQC and DM-induced gastric cell degeneration. In clinical studies, it is reported that calcium polysulfite ingestion produces hemorrhagic necrosis of gastric mucosa[16]. BQC also contained arecoline, the main ingredient of areca fruit. Arecoline is a cholinergic agent that can cause gastric contraction and induce gastric secretion. Our previous paper demonstrates that arecoline causes seizure and results in gastric mucosal damage[17]. Therefore, after chronic consumption of BQC, gastric mucosal barriers might be severely disrupted and thus allowed copious free acid to diffuse back into the gastric mucosa during ulcer development.

Aggravation in LPO generation also was observed in gastric mucosa of BQC-fed DM rats. Apparently, the disruption of the mucosal barrier accompanied by gastric oxidative stress occurred in DM rats receiving BQC. In practice, oxyradicals can directly cause cell injury[3]. This cell damaging effect may associate with the occurrence of many diseases, including tissue inflammation and sepsis[17], hemorrhagic shock[11], and DM[29]. The initiation of gastric mucosal oxidative stress and inflammation might result from direct BQC-induced damage and degeneration of gastric mucosal cells induced by DM.

The lower mucosal GSH levels found in stomachs of DM or BQC-fed DM rats might be due to an increase in their consumption for scavenging oxyradicals and a decrease in cellular biosynthesis in damaged mucosal cells. In fact, depletion of neuronal GSH can cause an increase of neuronal nitric oxide synthase activity and cell death[6]. Moreover, GSH is used as a substrate or as a co-factor by several cytosolic and membrane-bound enzymes. A previous study demonstrated that exogenous GSH can produce a significant increase in mucosal GSH levels and a reduction in concentrations of mucosal LPO that associate with severe gastric hemorrhagic ulcers in acid-irrigated stomachs of septic rats[17]. Taken together, the imbalance between mucosal GSH biosynthesis and oxyradicals generation (gastric oxidative stress) was important in modulating BQC-induced ulcer in DM rats. A decreased gastric mucus also was found in DM or BQC-fed DM rats. Since BQC is an ulcerogenic substance, it might also damage gastric mucus cells and lead to attenuation of mucus biosynthesis. In fact, ulcerogens, such as aspirin and other non-steroidal anti-inflammatory drugs, have been reported to attenuate gastric mucus secretion[32]. Increase in mucus secretion can retard acid back-diffusion and is beneficial to the healing of mucosal damage[37].

In the present study, lysozyme chloride dose-dependently inhibited various aggressive parameters and elevated defensive factors in BQC-fed DM rats. It also ameliorated BQC-induced hemorrhagic ulcer in DM rats. This compound remarkably enhanced biosynthesis and secretion of gastric mucus, which is a potent gastroprotective substance. Lysozyme chloride also can enhance antral ulcer healing via stimulating mucus biosynthesis[18]. Indomethacin, a specific antagonist of prostaglandins, effectively reversed lysozyme chloride-induced cytoprotection of gastric mucosa. This implied that gastric mucosal protective effect of lysozyme chloride was partly mediated by stimulating biosynthesis and release of prostaglandins. Additionally, this drug has been reported to have analgesic and anti-inflammatory effects on pulpectomy and root canal filling[15]. It has also been shown to contribute

to the advantageous effects in the treatment of patients and experimental animals with cancer[34,38]. The attenuation of LPO generation produced by lysozyme chloride in BQC-fed DM rats explained that this compound might possess potent antioxidant effect, thus reduced consumption of GSH. Moreover, lysozyme chloride may stimulate GSH biosynthesis in mucosal cells. Considering the above-mentioned, this drug can increase the total levels of BQC-fed DM rat mucosal GSH and contribute to the ulcer healing.

In conclusion, long-term consumption of BQC produces aggravation of DM-induced hemorrhage and ulcer in rats via enhancing oxidative stress that can be ameliorated by lysozyme chloride.

Abstract

AIM: To determine the prevalence of ulcerative colitis (UC) in Malaysian patients and to establish the spectrum of the disease seen in Malaysian patients.

METHODS: Data were obtained retrospectively from a review of the medical records of in- and out-patients with a diagnosis of UC at the University Hospital, Kuala Lumpur between 1985 and 1998.

RESULTS: There were 45 confirmed cases of UC, of which 3 were foreigners, who were excluded from analysis. Thirty new cases of UC were diagnosed during the study period. Their mean age at presentation was 33.0±10.0 years. The highest prevalence of UC was 17.9/100 000 hospital admissions in the Indians, followed by 11.2/100 000 hospital admissions in the Chinese. The lowest prevalence was 3.7/100 000 hospital admissions in the Malays. The prevalence of UC was significantly higher in the Indians and the Chinese when compared with the Malays with an OR of 4.89 (CI = 2.02-12.24; χ^2 = 15.45, P<0.001) and 3.06 (CI = 1.24-7.78; χ^2 = 6.30; P = 0.012) respectively. The extent of colonic disease was similar in the Malay and Indian patients. In contrast, distal or left-sided colitis predominated in the Chinese with an OR of 8.17 (95%CI = 1.31-64.87; χ^2 = 5.53, P = 0.02). Extraintestinal manifestations were uncommon (11.9%).

CONCLUSION: UC is an uncommon disease in Malaysia, but racial differences exist. The Indians had the highest prevalence of UC with the Chinese demonstrating the least extensive disease.

INTRODUCTION

Ulcerative colitis (UC) is a common disease in the Western population. It is well recognized that the incidence of inflammatory bowel disease is among the highest in individuals of Anglo-Saxon descent and from the Scandinavian countries[1-3] and there is a suggestion that the incidence of UC may be on a rising trend[4-6]. The disease is also prevalent in Ashkenazi Jews[7,8]. There is a relative paucity of epidemiological studies from this region as compared to the West. Studies from Hong Kong and Singapore[9-14] suggest that this disease is uncommon in Asian countries. There have been only two published papers on the prevalence of UC in Malaysian patients[15,16]. Both are old papers reporting on a relatively small number of patients.

Malaysia epitomizes the multiraciality of an Asian country, where three major Asian races Malay, Chinese, and Indian -co-exist. Of the three major races in Malaysia, there appears to be a predisposition towards the Indian race. A more recent study by Lee *et al*.[14], in neighboring Singapore reported similar findings with an estimated prevalence among the Indians of 16.2/100 000 as compared to 6/100 000 among the Chinese and 7/100 000 among the Malays. The overall prevalence was 6/100 000. These figures are low in comparison to that of the West, where more than 10-fold excess in prevalence rates is reached. Observations of racial differences in the prevalence of upper gastrointestinal as well as liver diseases have been a major interest in Malaysia where three major Asian races co-exist[17-21].

The aim of this study was firstly to determine the prevalence of UC and the existence of ethnic differences in the prevalence of UC and secondly, to establish the spectrum of disease seen in Malaysian patients.

MATERIALS AND METHODS

Retrospective data were obtained from the careful review of the medical records of all patients who attended the outpatient clinics or were admitted to University Hospital, Kuala Lumpur between 1985 and 1998, and had the International Classification coding for UC (ICD-556). The diagnosis of UC was established based on a combination of clinical, radiographic, endoscopic, and histopathological evidence. As infective colitis is common in the tropics and can mimic the features of UC, this was routinely sought for and excluded. Stools were sent for microscopy and culture. Blood tests included serology for *Entamoeba histolytica* and the Widal-Weil-Felix test.

The following information was obtained: demographic characteristics, age at presentation, clinical presentation,

distribution of disease, requirement for surgical intervention and the presence of extraintestinal manifestations. The anatomical extent of the disease as determined by colonoscopy was classified as follows: distal colitis (i.e., limited to the rectum and sigmoid colon), left-sided colitis (i.e., disease distal to the mid-transverse colon) or "extensive"colitis (i.e., extending proximal to the mid-transverse colon).

Statistical analysis

The prevalence of UC for the three major ethnic groups was calculated per 100 000 hospital admissions of the respective racial group. The statistical significance of the difference in UC prevalence between the ethnic groups was assessed using the Yate's-corrected χ^2 test, the measure of association quoted as odd ratios (OR) with a 95% confidence interval (CI).

RESULTS

There were 45 confirmed cases of UC, of which 30 patients were diagnosed during the study period. All but three (6.7%) patients (an Albanian and two Pakistanis) were born in Malaysia. The non-Malaysians were excluded from analysis. There were 19 males and 23 females giving a male:female ratio of 0.8:1. The age distribution at presentation is shown in Figure 1. The mean age at presentation was 33.0 ± 10.0 years. They comprised 8 (19.0%) Malays, 16 (38.1%) Chinese, and 18 (42.9%) Indians. The prevalence of UC by ethnic origin is shown in Table 1. The highest prevalence of UC was 17.9/100 000 hospital admissions in the Indians, followed by 11.2/100 000 hospital admissions in the Chinese. The lowest prevalence was 3.7/100 000 hospital admissions in the Malays. The prevalence of UC was significantly higher in the Indians and the Chinese when compared with the Malays with an OR of 4.89 (CI = 2.02-12.24; χ^2 = 15.45, P < 0.00 1) and 3.06 (CI = 1.24-7.78; χ^2 = 6.30; P = 0.012) respectively.

Clinical presentation

Thirty-four (81.0%) patients presented with bloody diarrhea, 5 (11.9%) presented with rectal bleeding only and 3 (7.1%) had diarrhea without rectal bleeding. Other associated complaints were the passage of mucus (66.7%) and abdominal pain (54.8%).

Extent of UC, requirement for surgery and extraintestinal manifestations Eighteen (42.9%) patients had the disease confined to the distal colon, 8 (19.0%) had left-sided colitis and 16 (38.1%) had the disease extending beyond the mid-transverse colon. The extent of colonic involvement in the different ethnic groups is shown in Table 2. The extent of the disease was similar in the Malay and Indian patients. In contrast, distal or left-sided colitis predominated in the Chinese with an OR of 8.17 (95%CI = 1.31-64.87; χ^2 = 5.53, P = 0.02). No case of toxic megacolon was reported, but five (11.9%) patients required surgical intervention. These included two (4.8%) patients with intestinal perforation and one (2.4%) with massive rectal bleeding. Total colectomy was also required in two (4.8%) patients who developed colorectal cancer.

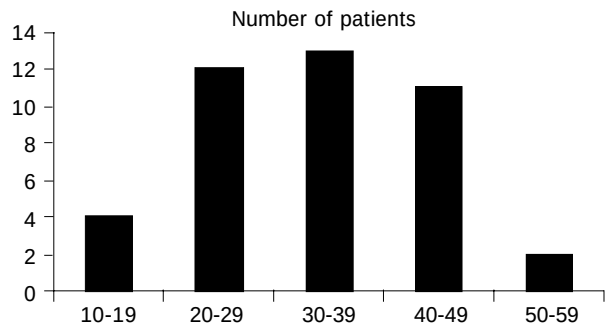

Figure 1 Age at presentation (by age-groups).

Table 2 Extent of colonic disease in the different ethnic groups

Ethnic origin	Distal colitis *n* (%)	Left-sided colitis *n* (%)	Pan-colitis *n* (%)
Malay	3 (37.5)	1 (12.5)	4 (50.0)
Chinese	11 (68.8)	3 (18.8)	2 (12.5)
Indian	4 (22.2)	4 (22.2)	10 (55.5)
Overall	18 (42.9)	8 (19.0)	16 (38.1)

(**%** of the ethnic group)y.

Extraintestinal manifestations occurred in only five (11.9%) patients. Three (7.1%) patients had arthropathy including one (2.4%) patient with sacroiliitis. Erythema nodosum occurred in two (4.8%) and pyoderma gangrenosum in one (2.4%).

DISCUSSION

This study is in agreement with previous studies around this region that UC is an uncommon entity in populations of Asian origin. Only 30 new cases were diagnosed in a 13 year span in a large public hospital. The majority of patients presented during young adulthood. Among the three major ethnic groups in Malaysia, UC was most prevalent in the Indians with an OR of 4.89 (CI = 2.02–12.24), followed by the Chinese with an OR of 3.06 (CI = 1.24-7.78) in comparison with the Malays who had the lowest prevalence for UC. The predominance of Indians with UC has been

Table 1 Prevalence of UC by ethnic origin at the University Hospital, Kuala Lumpur

Ethnic origin	Total number of hospital admissions by race	Number with UC	Prevalence per 100 000	Odds ratio (95%CI) (Malay as reference group)	*P*
Malay	218 019	8	3.7	1.00	-
Chinese	142 575	16	11.2	3.06 (1.24-7.78)	0.012
Indian	100 250	18	17.9	4.89 (2.02-12.24)	<0.001

observed previously[11,14].

It has been thought that the reason for the disparity of UC prevalence among Malaysians is largely due to genetic factors and seems to reflect the prevalence of the disease of their original native countries. There are very limited data of UC in the indigenous population (Malay), suggesting that the disease must be very rare in this race. Among the people of Mongoloid stock, UC is also uncommon. Morita *et al*.[22], reported an incidence and prevalence per 100 000 population per annum of 1.95 and 18.12, respectively in Japan. Studies from the Indian subcontinent have confirmed that UC is not uncommon in Indians, who are ethnically related to Caucasian stock[23-26]. However, there is growing evidence that environmental factors play an important role in the pathogenesis of the disease. An epidemiological study of Indian migrants to Leicestershire showed a significantly higher incidence of UC in the immigrant population than the local Europeans[27]. Montgomery *et al*.[28], reported that young Asians (ethnic origins in India and Pakistan) who were born in Britain were at a significantly higher risk of developing inflammatory bowel disease than the indigenous European population and suggested the role of environmental factors in uncovering the genetic predisposition to disease.

The extent of UC was similar in the Indian and Malay populations and not considerably different from those in Western countries. The Chinese on the other hand showed a significantly marked predominance of distal UC with an OR of 8.17 (CI = 1.31-64.87). The predominance of distal UC in the Chinese race has also been reported from China[29].

In our experience, treatment of UC was mainly medical (88.1%) with surgical intervention required because of complications of UC or the development of colorectal cancer. The remarkable features of the disease in our population are the relatively mild severity, indolent course of the disease and the paucity of extraintestinal manifestations. These observations are similar to those previously reported from the Asian region[11,12,29].

Time trend studies would be important to determine whether there would be an increase in the incidence of UC in our part of the world as has been observed in other gastrointestinal diseases such as gastroesophageal reflux disease[21,30]. If environmental factors predominate in the etiology of the disease, with the rapid Westernization and socio-economic development sweeping through the whole continent, an increase in the incidence of the disease would be inevitable.

In summary, UC remains uncommon despite greater awareness of the disease and better diagnostic facilities that distinguish UC from other diseases such as infective colitis, which is prevalent in developing countries. Among the three major ethnic groups in Malaysia, the Indians have the highest prevalence of UC and the Chinese demonstrate a less extensive disease. As Malaysia undergoes a transition to become a developed society in time, it remains to be seen if a shift in emphasis from racial factors to specific environmental factors in the etiology of UC is uncovered.

Abstract

AIM: To evaluate the effect of various methods of small bowel preparation on the transit time and the quality of visualization of the entire small bowel mucosa.

METHODS: Ninety-five patients underwent capsule endoscopy (CE) by easily swallowing the capsule. They were divided into three study groups according to the preparation used: group A (n = 26) by polyethylene glycol (PEG) liter or with sodium phosphate (SP) 12 h prior to the CE study; group B (n = 29) by erythromycin 1 h prior to the CE study; and group C (n = 40) without any preparation. Visualization ranged from good to satisfactory to poor.

RESULTS: The gastric emptying time in the group prepared with erythromycin was shorter but without statistical significance and the small bowel transit time was unaffected. In elderly subjects prepared by PEG or SP, the gastric emptying time was significantly longer (163.7 min, P = 0.05). The transit times of the three sub-groups were not affected by gender or pathology. The grade of cleaning of the entire study group was 3.27±1.1. The erythromycin group presented significantly the worst quality of images (P = 0.05) compared to the other sub-groups. Age, gender, and pathology had no effect on the quality of the cleaning of the small bowel in the sub-groups. One (1.05%) case had no natural excretion.

CONCLUSION: Erythromycin markedly reduces gastric emptying time, but has a negative effect on the quality of the image in the small bowel. The preparation of elderly subjects with PEG or SP has a negative effect on the small bowel transit time.

INTRODUCTION

The capsule endoscopy (CE) is well accepted as a tool for evaluating small bowel pathology[1-5]. However, this new technology has several limitations, i.e., the time required to study the video, it takes an hour to watch the video of the small bowel and the residual material, especially in the ileum adversely affects the image[5-7]. Stomach emptying and small bowel motility depend upon a number of factors, such as the composition of the food and fluid in the gastrointestinal (GI) tract, diseases, etc. In addition, transit time differs according to whether the individual has eaten or is in a fasting state. The initial capsule experiences showed that the cecum could not be viewed in approximately 20% of the study population because of the short battery life, because the capsule had remained in the stomach for more than 60 min[5,6], and for a variety of other reasons. A shorter transit time would be directly beneficial in obviating the first two problems.

The CE is completely different from the standard endoscopy that allows the endoscopist to remove all the residual material to improve the image. In most CE studies, the image quality in the proximal small bowel is much superior to that in the distal ileum, due to residual material.

The reasons that some physicians refuse to adopt the CE study are the time consuming viewing procedures and the frustration of being unable to view the entire small bowel because of the residual material. So far there is still no definite answer to the question of which is the best way to prepare patients for the CE study. The Given Imaging Ltd recommendation is a 12-h fast prior to the CE study with no other preparation. Most of the published studies followed this recommendation and although other methods of preparations were mentioned, no comparative study was made.

In this study, we designed to determine the best preparation to provide the most complete visualization of the entire small bowel, as well the best preparation for rapid gastric emptying times.

MATERIALS AND METHODS

Study population

A retrospective study was performed on 97 patients who underwent the CE study (Given® M2A video capsule system, Given Imaging Ltd, Yokneam, Israel) between August 1st,

2001 and March 30, 2003. The study group participants were patients suffering from obscure GI bleeding, suspected small bowel illness of an unclear nature or unexplained abdominal pain for over 6 mo with negative GI evaluation. All patients underwent small bowel X-ray, and there were no signs of intestinal obstruction, major abdominal surgery, and diabetes mellitus. Pregnant women were excluded from the study. Two cases were excluded because in one case the CE "stuck" in the stomach for 6 h (without any pathological evidence) and the other had a mechanical software problem, i.e., image quality. All the patients signed the informed consent agreement.

Capsule endoscopy

After an overnight fast of 12 h, all patients ingested the CE (Given® M2A video capsule system). An array of eight sensors was attached to the abdominal wall, and a belt holding a recorder with a battery was fastened around their waists. Patients were allowed to drink 2 h after ingesting the capsule and to eat a light meal 3 h later. After ingesting the capsule with a small amount of water, patients were free to go about their own activities. Seven to eight hours after ingestion, the recorder was disconnected and the sensors removed. The recorded digital information was downloaded into the computer, and images from the stomach and all along the small bowel were analyzed using the proprietary RAPID® software.

Patients were asked to look for the capsule in the feces. All capsules were retrieved 24 h to 5 d after ingestion, except for one patient who had a non-natural excretion (the patient underwent surgery and was found to have Meckel's diverticulum). All patients signed an informed consent agreement approved by the Local and Governmental Helsinki and Ethical Committees.

Preparation of the sub-groups

They were divided into three study groups according to the preparation used. Group A (n = 26) was prepared with 3 L polyethylene glycol (PEG 400, Taro, Israel), given in two divided 2 doses, i.e., 1.5 L, 12 h before swallowing the capsule and 1.5 L, 1 h after swallowing the capsule, or with 90 mL of sodium phosphate (SP, Dexxon, Israel), given in two divided 2 doses, i.e., 45 mL, 12 h before swallowing the capsule and 45 mL, 1 h after swallowing the capsule. When we analyzed each preparation separately, we realized that there was no statistical significance and so made them into one group. Group B (n = 29) was prepared by 200 mg erythromycin (Teva, Israel) in liquid from 1 h prior to the CE study and group C (n = 40) without any preparation. All patients ingested the CE after an overnight fast of 12 h. We arbitrarily divided them into three age groups: 17-40, 41-60, and above 60 years of age.

There were several reasons for colonic preparation. The subjects who needed GI evaluation (e.g., unexplained iron deficiency anemia, etc.) underwent colonoscopy on the same day. Another reason was that part of the clinical study was to compare standard colonoscopy with wireless colonoscopy (unpublished data). In our initial experience with the capsule, we found that the distal part of the ileum was not clean enough for visualization and we, therefore, decided that one group of patients had to undergo colonic preparation. Another problem is the short battery life of the capsule (approximately 7 h), which may not be sufficient to image the entire small bowel. We hypothesized that some colonic preparation or erythromycin might accelerate the movement of the capsule and also provide a better view of the entire small bowel.

Reading of the capsule endoscopy

The transit time, from the first view of the gastric mucosa up to the pyloric region and the small bowel transit, was calculated from the first view of the duodenum up to the ileocecal region. The video results produced from the data recorded by each capsule were reviewed independently by one of the experts (FZ) who was unknown to the clinical data. Capsule transit times were evaluated by analysis of the videos generated during the CE passage.

The quality of the image, on a scale of 1-5, ranged from good (1) with more than 10% of the view with residual material, to poor (5) with more than 90% with residual material.

Statistical analysis

The gastric emptying time and the small bowel transit time was analyzed by computerized software SPSS. The differences in transit time and sub-groups preparation (correlated to age, gender, and normal or abnormal findings) were analyzed by ANOVA multi-changes test. The differences in transit time and preparation were analyzed separately, by ANOVA test, in each of the three sub-groups.

RESULTS

Ninety-five patients (55 men and 40 women, aged 18-91 years, mean age 50.1±17.5 years) were enrolled in the study (Table 1). The reasons for the CE studies: iron deficiency anemia (49 patients); abdominal pain/irritable bowel syndrome (27 patients); suspected Crohn's disease (9 patients); and miscellaneous disease (10 patients) (celiac disease, familial adenomatous polyposis, intestinal lymphoma, ulcerative colitis, Table 1).

There were pathological findings in 54 (56.8%) patients, such as angiodysplasia, ulcer, suspected Crohn's disease, erosions, polyps, edematous mucosa, etc. In 17 cases (17.9%), the capsule failed to reach the cecum before the end of the -420 min recording time.

Table 1 Characteristics of study groups (n)

No. of patients	95
Gender male/female	55/40
Mean age (yr)	50.1
Indications of the CE study	
Iron deficiency anemia	49
Abdominal pain/irritable bowel syndrome	27
Suspected Crohn's disease	9
Miscellaneous disease	10

Miscellaneous disease includes celiac disease, familial adenomatous polyposis, intestinal lymphoma, and ulcerative colitis.

The mean gastric emptying time was 41.7±51.5 min and the transit time of the small bowel was 225±80.6 min of the entire study group. The gastric emptying time in the group prepared with erythromycin was shorter but not statistically significant (Table 2). In elderly subjects prepared by PEG or SP, the gastric emptying time was significantly longer (163.7 min) compared to the other preparations ($P = 0.05$, Table 3). The small bowel transit times were similar in the three age sub-groups; however, a non-significant shorter transit time was seen in the mid-age group (41-60 years) prepared with PEG or SP (Table 3). The gender and pathology neither affected the transit time of the whole study group nor that of the three age sub-groups.

The grade of the cleaning of the entire study group was 3.27±1.1, on a scale of 1 (best image) to 5 (worst, Table 4). In comparison with the other sub-groups, the erythromycin group significantly presented the worst quality of image ($P = 0.05$). Age, gender, and pathology had neither effect on the quality of the cleaning of the entire small bowel study group nor on the arbitrarily selected three age sub-groups (Table 4).

The capsule passed through without difficulty in all cases except for one (1.05%) patient who had no natural excretion, and was found to have Meckel's diverticulum (the Meckel scan that was done prior to the CE study was interpreted as normal).

The average amount of time needed for an expert to review one video was about 50 min.

Table 2 Effect of preparation on transit time

Groups	Emptying gastric time (min)	Small bowel transit time (min)	*P*
Group A ($n = 26$)	53.1	216	NS
Group B ($n = 29$)	26.4	240	NS
Group C ($n = 40$)	45.5	218	NS

Group A: prepared by PEG or with SP, group B: prepared by erythromycin, group C: without any preparation, NS: non-significant.

Table 4 Effect of preparation on cleaning of small bowel

Groups	Grade of cleaning
Group A ($n = 26$)	3.1±1.18
Group B ($n = 29$)	3.7±1.09
Group C ($n = 40$)	3.0±1.06

Group A: prepared by PEG or with SP; group B: prepared by erythromycin; and group C: without any preparation; $P<0.05$, group B *vs* groups A and C.

DISCUSSION

The Given® Diagnostic Imaging System M2A™ Capsule is a new system designed to aid the gastroenterologist in diagnosing small bowel diseases[5,7-9].

The ingestible capsule records video images during natural propulsion through the digestive system. Averages of 50 000 images are obtained during the 8-h passage of the capsule. The CE is propelled by peristalsis through the intestinal tract and permits direct viewing of the entire small intestine[2-5]. From the initial capsule experience, we learned that in approximately 20% of the study population, the capsule did not reach the cecum (the view not the capsule) for several reasons: short battery life (7±1 h); the capsule remaining in the stomach for more than 60 min; and as well the quality of the image, especially in the distal part of the ileum. Practical experience has shown that visualization of the entire small bowel mucosa may sometimes be hindered by the presence of residual material. For these reasons, in some of the CE studies, it was impossible to visualize the entire small bowel[5-7].

More than 180 000 patients worldwide have swallowed the CE. It is estimated that 19 million people in the USA alone may suffer from diseases related to the small intestine, including obscure bleeding, irritable bowel syndrome, Crohn's disease, chronic diarrhea, and cancer. Hence, these will expand the need for CE, and endoscopy services are under increasing strain and to read one CE study takes approximately 1 h of the very expensive time of an expert endoscopist. This could well be the reason that some physicians refuse to adopt the CE study[5-9]. CE is a diagnostic tool with enormous potential and our expectations are that it will yield answers that other procedures are not capable of providing, and with time demand for CE, studies will grow.

There is a lack of data of the effect of colonic preparation on the stomach and the small bowel. Recently, Basit *et al*.[10], have demonstrated that PEG 400 has a marked accelerating effect on small intestinal liquid transit, which, in turn, has implications with PEG 400. In addition, SP effectively shortens small bowel transit time[11]. On the other hand, Sood *et al*.[12], found no significant difference in the mean transit time in the stomach, duodenum, and small bowel between PEG 400 and plain water. The macrolide antibiotic erythromycin has been known to be associated with increased GI motility because of its introduction more than 35 years ago and evidence for its therapeutic efficacy in gastroparesis[13,14]. However, regarding the effect of erythromycin on the transit time of small bowel and its cleaning effect, we have no data. At present, the two major requisites are image quality improvement and reduction of

Table 3 Effect of age on transit time

Groups	Emptying gastric time (min) Age (yr)			Small bowel transit time (min) Age (yr)		
	17–40	41–60	>60	17–40	41–60	>60
Group A ($n = 26$)	16.8	46.5	163.7[1]	234.0	178.1	315.5
Group B ($n = 29$)	31.6	27.7	22.5	235.3	220.1	214.8
Group C ($n = 40$)	54.2	46.9	34.5	218.0	239.4	250

Group A: prepared by PEG or with SP, group B: prepared by erythromycin, and group C: without any preparation, [1]$P = 0.05$.

the time spent in viewing the CE videos.

As shown by our study, the gender and the presence of pathology lesions had no impact on the cleaning and transit time. Preparation with erythromycin reduced the transit time in the stomach (especially in 40-60-year-old age group), but had a negative effect on the quality of the image in the small bowel. In elderly patients, small bowel transit time and gastric emptying time were significantly longer in those prepared with PEG or SP when compared to the other preparations ($P = 0.05$), but with no effect on the quality of the image.

To the best of our knowledge, this is the first time a study tried to deal with the problems of image quality improvement and reduction of CE viewing time through evaluation of various preparation techniques. After testing the various preparations, we had to concede that they neither offered any improvement in the time needed to read the study nor in image quality over the 12-h fasting period as recommended by the Given Company. Even though erythromycin has the best effect on gastric emptying time, the quality of the view in the small bowel is the worst, for which we have no explanation and preparation with PEG or SP has a negative effect on the transit time of the small bowel. We need other pharmaceutical tools and/or technical aid to improve the time and the quality of the CE study.

Abstract

AIM: Diagnosis of atrophic body gastritis (ABG) is based upon histological examinations of body mucosa biopsies obtained during gastroscopy. However, gastroscopy is invasive and expensive, and biopsy sampling of body mucosa prolongs the procedure increasing discomfort to the patient. Artificial neural networks (ANNs) and linear discriminant analysis (LDA) may be used as computer-based decision-support systems. Thus, this pilot study aimed at investigating whether ANNs and LDA could recognize patients with ABG in a database, containing only clinical and biochemical variables, of a pool of patients with and without ABG, by selecting the most predictive variables and by reducing input data to the minimum.

METHODS: Data was collected from 350 consecutive outpatients (263 with ABG, 87 with non-atrophic gastritis and/or celiac disease [controls]). Structured questionnaires with 22 items (anagraphic, anamnestic, clinical, and biochemical data) were filled out for each patient. All patients underwent gastroscopy with biopsies. ANNs and LDA were applied to recognize patients with ABG. Experiment 1: random selection on 37 variables, experiment 2: optimization process on 30 variables, experiment 3: input data reduction on 8 variables, experiment 4: use of only clinical input data on 5 variables, and experiment 5: use of only serological variables.

RESULTS: In experiment 1, overall accuracies of ANNs and LDA were 96.6% and 94.6%, respectively, for predicting patients with ABG. In experiment 2, ANNs and LDA reached an overall accuracy of 98.8% and 96.8%, respectively. In experiment 3, overall accuracy of ANNs was 98.4%. In experiment 4, overall accuracies of ANNs and LDA were, respectively, 91.3% and 88.6%. In experiment 5, overall accuracies of ANNs and LDA were, respectively, 97.7% and 94.5%.

CONCLUSION: This preliminary study suggests that advanced statistical methods, not only ANNs, but also LDA, may contribute to better address bioptic sampling during gastroscopy in a subset of patients in whom ABG may be suspected on the basis of aspecific gastrointestinal symptoms or non-digestive disorders.

INTRODUCTION

Atrophic body gastritis (ABG), a condition characterized by atrophy of the gastric oxyntic mucosa, hypo/achlorhydria, and, in turn, hypergastrinemia, is a disorder considered as increased risk for gastric neoplasms[1,2].

In general, ABG does not give rise to symptoms of the upper gastrointestinal tract, such as epigastric pain or burning. Some patients may complain of dyspeptic symptoms, such as epigastric discomfort or postprandial bloating, complaints which are frequently found in the general population[1]. More frequently, the only relevant clinical finding is the presence of anemia[3-5], and, indeed, ABG is often considered synonymous with the presence of pernicious anemia[6,7]. Moreover, ABG may also present with iron-deficiency anemia, a consequence of the impaired iron absorption due to hypo/achlorhydria[8]. Finally, ABG may be associated with autoimmune disorders, such as autoimmune thyroid disease, vitiligo, and alopecia[7], and, in the presence of vitamin B_{12} deficiency, also with neurological symptoms[9].

However, the gold standard for the diagnosis of ABG is based, despite its limits, such as sampling error and inter-observer variability, on the histological examination of biopsy specimens of body mucosa obtained during gastroscopy[10,11]. Gastroscopy, however, is an invasive and expensive procedure, which is often accepted with reluctance

by patients without gastric symptoms. Moreover, the biopsy sampling of body and antral mucosa prolongs the endoscopic procedure increasing discomfort to the patient. Furthermore, the processing of multiple gastric biopsy specimens for histological examination is time- and cost-consuming.

Non-invasive screening methods, such as serum levels of gastrin and pepsinogen I and II, have been tested for gastric antral and body atrophy, respectively. Unfortunately, however, because of the high specificity but low sensitivity[12-14], these methods need to be further improved before their use in serological screening for atrophic gastritis can be considered feasible[15].

Thus, reliable tools to select patients with suspected ABG requiring gastroscopy with collection of body mucosa specimens for histological diagnosis of ABG are still lacking. Decision-support systems, based on conventional statistical methods, made their entry into medicine several years ago[16,17]. Recently, efforts to improve predictive and prognostic performance of these systems have led to the application of artificial neural networks (ANNs) as tools for clinical decision-making[17-19]. ANNs are highly flexible computerized mathematical models for understanding and predicting complex and chaotic dynamics in complex biological systems, and have been effectively used to solve non-linear problems related to diagnostic or prognostic queries even for single patients, and not necessarily for the groups of patients as in the case with conventional statistics[17,20]. Thus, ANNs would appear to be a promising tool for clinical decision-making and have been applied in various areas of medical research[21-24]. Recently, the role of ANNs has been investigated in two important aspects of clinical decision-making in gastroenterology: Das *et al*.[25], have proposed a prediction model of outcome in acute lower gastrointestinal hemorrhage based on ANNs; and Selaru *et al*.[26], have reported that ANNs are able to distinguish among subtypes of neoplastic colorectal lesions. To our knowledge, studies applying advanced statistical methods in patients with suspected ABG have not yet been performed. This pilot study, therefore, aimed to investigate the role of ANNs and LDA in recognizing patients with ABG in the database of a pool of patients with ABG comprising only clinical and biochemical variables, by selecting the most predictive variables and by reducing input data to the minimum.

MATERIALS AND METHODS

Patients

This study was carried out using a database prepared ad hoc, comprising data from 350 consecutive outpatients (86 male, 264 female, median age 53 years, range 20-81 years), with a diagnosis of ABG (n = 263), chronic non-atrophic gastritis (n = 42), and celiac disease with or without chronic non-atrophic gastritis (n = 45). The 87 patients without ABG were considered as controls. These patients were evaluated, from 1994 to 1998, for long-standing dyspepsia, microcytic or macrocytic anemia, presence of autoimmune diseases or neurological disorders in our gastroenterology unit, which is part of an academic, urban, tertiary-care medical institution.

For each of these patients, a structured questionnaire was filled out, composed of 22 items concerning anagraphic, anamnestic, clinical, and biochemical data. The items with their respective variables of the structured questionnaire are shown in Table 1. Replies of the patients to questionnaire items regarding symptoms were considered positive, when present for at least three consecutive months during the previous year.

All patients underwent gastroscopy with standardized biopsy sampling from the antrum (n = 3), body (n = 3), and duodenum (n = 2) for conventional histopathological examination, as previously described[3,4,27,28]. The degree of gastritis was assessed according to the Updated Sydney System[10]. Atrophy of the body and antral mucosa was defined as focal or complete replacement of oxyntic or pyloric glands by metaplastic pyloric or intestinal glands, respectively, as previously described[3,4]. Celiac disease was diagnosed and classified according to the classification of Marsh[29].

Furthermore, all patients also underwent serological studies: fasting gastrin levels were evaluated by means of a specific radioimmunoassay (RIA) using polyclonal antibody (No. 4562, kindly provided by Prof. J. Rehfeld, Copenhagen), which is able to detect the entire pool of molecular forms of gastrin, as described earlier (normal values $\leqslant$40 ng/L)[3]. Pepsinogen I levels were measured using a commercial RIA kit (Pepsik, Sorin, Saluggia, Italy), as previously reported (normal values 20-80 ng/mL)[3]. Antibodies against anti-parietal cells were assayed using a commercial kit (Autostat, Cogent Diagnostic Ltd, Edinburgh, UK), as previously described[3,4].

All patients gave written informed consent to the study, which was approved by the Local Ethics Committee.

Statistical methods

Artificial neural networks (ANNs) ANNs were applied to the data set from a structured questionnaire containing 22 clinical and biochemical items for each of the 350 patients (263 with ABG, 87 without ABG [controls], Table 1). The items with three or more levels were recoded in binary variables. The final data set was thus composed of 37 variables for each of the 350 patients, these being considered as independent variables (input). As dependent variable (output), we considered the presence or absence of diagnosis of ABG based on the histological examination of gastric biopsies obtained during gastroscopy. Endoscopic and histological data were not included in the data set.

Since the aim of our investigation was to study ANNs as a tool to recognize the presence of ABG on the basis of clinical and biochemical data, which in mathematical language is referred to as "classification problem", we applied the hetero-associated ANNs[19,20]. Thus, the samples of 350 patients were randomly subdivided several times into two equal and balanced sub-samples of patients with ABG and controls (random selection) as follows: one for the training phase (training) and one for the prediction phase (testing). During training phase, ANNs learn, on the basis of linear and non-linear relations existing between the variables of the data set, including the outcome variable, to perform the required classification, i.e., to correctly recognize the patients with ABG with respect to controls. ANNs were used with the following learning methods: (i) feed forward back propagation (BP)[30] e sine learning law (SP)[31]; (ii)

auto-recurrent (ARCR) and cluster recurrent (TASM)[32,33]. After several training cycles, the dependent variables (presence/absence of ABG) were excluded from the data set, and the ANNs showing the best performance during the training phase were applied to the second sub-sample of patients, not previously exposed to the network, whereby ensuring an unbiased testing phase during which the capability of trained ANNs to recognize patients with ABG with respect to controls was evaluated.

In order to reduce the number of input variables, selecting those most informative to predict the output, we used the "Training and Testing" (T&T) model, associated with the input selection (IS) system[34]. The T&T algorithm is a population of ANNs managed by an evolutionary system, in which a separate ANN represents a model of distribution of the complete data set in a training and a testing set. The score that each ANN reaches in the testing phase represents its goodness-of-fit and, consequently, its probability of evolution. The evolutionary algorithm called "Genetic Doping Algorithm" (GenD)[35], at each generation, combines the different hypotheses of distribution of each ANN according to the goodness-of-fit criterion. In this way, the best distribution of the entire data set, in a training set and in a testing set, is reached after a finite number of generations. The IS system becomes operative on a population of ANNs, each of them with the ability to select independent variables for the validation set. Each ANN learns from the training set, and is evaluated on the testing set[34]. Through the GenD evolutionary algorithm, different hypotheses of each ANN change over time, and generation after generation. When the evolutionary algorithm no longer improves, the process stops, and the best hypothesis of the input variables is selected and employed on the validation subset. The goodness-of-fit rule of GenD promotes, at each generation, the best testing performance with the minimal number of inputs[34].

All software used for the ANNs analysis, including the T&T model associated with the IS system, and the GenD have been developed and were applied by the Semeion Research Center, Rome, Italy[36].

Linear discriminant analysis (LDA) LDA was also used to analyze the predictive performance of conventional statistics. In order to optimize the predictive ability, different models were assessed and, as for the ANNs procedure, the samples were randomly divided into two sub-samples for the training and testing phases. For the analysis of LDA, the SAS version 6.04 (SAS Institute, Cary, NC, USA) using forward stepwise procedure was employed. This was performed by the Semeion Research Center, Rome, Italy. The application protocols of ANNs and LDA are schematically illustrated in Figure 1.

Study design

The first experiment was performed by random selection on the original database using all independent input variables. In the second experiment, the T&T algorithm, associated with the IS system, was applied using the independent input variables, which were reduced to the most informative ones.

The application of statistically-based decision supports, in clinical practice, should be simple and require little time for data entry. Thus, the number of inputs should be reduced to the bare minimum. Therefore, in order to verify the prediction capability of ANNs by using a reduced amount of input data, ANNs, in the third experiment, were performed using only the eight independent variables identified by LDA in the second experiment as having the most predictive power for the diagnosis of ABG. In the fourth experiment, the serological variables were removed from the eight independent variables used in the third experiment, thus verifying the prediction capability of ANNs and LDA for the presence of ABG by using only five clinical input variables. Finally, in the fifth experiment, only the serological variables were used. The study design is outlined in Figure 2.

RESULTS

Experiment 1

After random selection of patients, the ANNs training sets were used on a sub-sample of 175 patients (132 with ABG

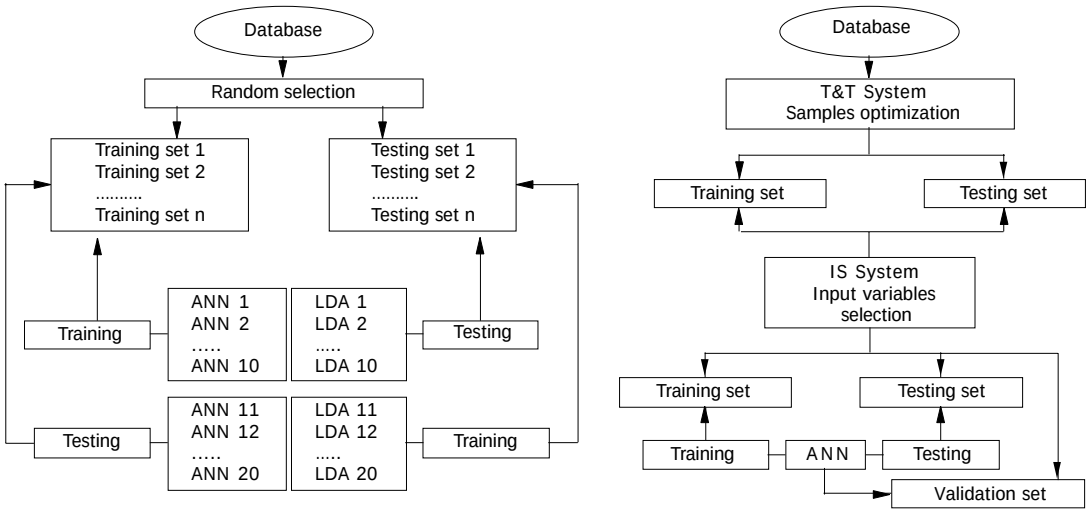

Figure 1 Application protocol of ANNs, LDA, T&T, and IS.

and 43 controls), and the ANNs tests were employed on the second sub-sample of 175 patients (131 with ABG and 44 controls) by using the original data set (37 independent variables). The best ANNs identified 128 of the 131 patients with ABG (sensitivity 97.7%), and correctly matched 42 of the 44 controls (specificity 95.5%), yielding an overall accuracy of 96.6%. The yield of LDA was slightly lower with a sensitivity of 95.4% (identifying 125 of the 131 patients with ABG), a specificity of 93.2% (recognizing 41 of the 44 controls), and the overall accuracy being 94.6% (Table 2).

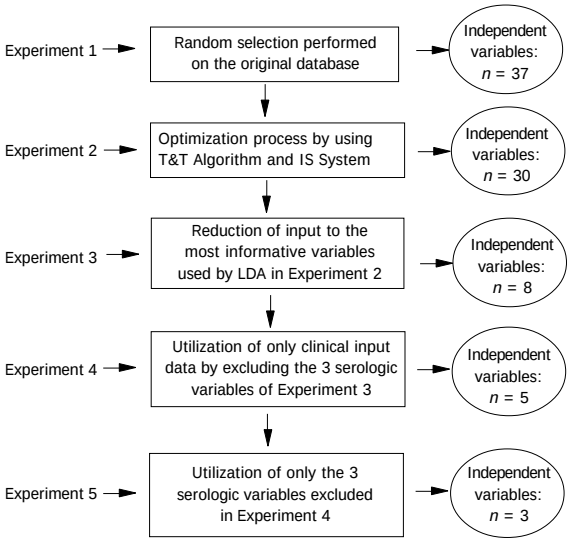

Figure 2 Study design: progressive reduction of independent input variables.

Experiment 2

The T&T algorithm, associated with the IS system, selected as the most informative 30 out of the 37 initial independent variables, removing the 7 variables such as mean corpuscular volume, absence of gastrointestinal symptoms, association with thyroid disease, family history for gastric ulcer, referred from the Department of Hematology, motility-like dyspepsia and hemoglobin was carried out.

The sub-samples of ANNs training, testing, and validation sets comprised 78, 60, and 125 patients with ABG, and 30, 17, and 40 controls, respectively. Following the optimization process, the performance of both the ANNs and the LDA increased with respect to the first experiment. In fact, on the validation set, ANNs' sensitivity rose to 98.4% (identifying 123 of the 125 patients with ABG) and specificity to 100% (correctly matching all 40 controls), thus yielding an overall accuracy of 98.8%. LDA recognized 119 of the 125 patients with ABG and failed to recognize only one out of the 40 controls, thus achieving a sensitivity, a specificity, and an overall accuracy of 96%, 97.5%, and 96.75%, respectively (Table 2).

Experiment 3

The eight independent variables used in this experiment are shown in Table 3. The performance of ANNs was good (overall accuracy 98.4%): only 4 out of the 125 patients with ABG (sensitivity 96.8%) were misclassified, but all 40 controls (specificity 100%) were correctly matched. The performance of LDA, which was the same as in the previous experiment, was slightly lower than that of ANNs (Table 2).

Table 1 Structured questionnaire containing anagraphic, anamnestic, clinical, and biochemical variables considered as independent variables (input)

Variables	Independent variables (input) levels
1. Sex (2)	Male; female
2. Age[1] yr	
3. Referred from the Department of… (5)	Hematology, gastroenterology, dermatology, endocrinology, other
4. Presentation symptom (5)	Anemia, GI symptoms/disorders, dermatological symptoms/disorders, endocrinological symptoms/disorders, other
5. Onset of presentation symptom (mo)	
6. GI symptoms (4)	Dyspepsia motility-like, dyspepsia ulcer-like, other GI symptoms, absence
7. Neurological symptoms (2)	Yes/no
8. Other symptoms (2)	Yes/no
9. Family history (1st degree relatives) autoimmune diseases (2)	Yes/no
10. Family history (1st degree relatives) for gastric neoplasms (2)	Yes/no
11. Family history (1st degree relatives) for duodenal ulcer or gastric ulcer (3)	No family history, family history for duodenal ulcer, family history for gastric ulcer
12. Association with thyroid disease (2)	Yes/no
13. Association with dermatological disease (2)	Yes/no
14. Association with neoplasms (2)	Yes/no
15. Association with duodenal ulcer or gastric ulcer (2)	Yes/no
16. Association with other diseases not mentioned previously (2)	Yes/no
17. Anemia (3)	No anemia, macrocytic (pernicious) anemia, microcytic (iron-deficiency) anemia
18. Hemoglobin[1]	
19. Mean corpuscular volume (MCV[1])	
20. Fasting gastrin[1]	
21. Pepsinogen I[1]	
22. Parietal cell antibodies (2)	Presence/absence

GI, gastrointestinal; ABG, atrophic body gastritis; [1]continuous variables. The number of levels of each variable is indicated in the brackets.

Table 2 Performance of ANNs and LDA for diagnosis of ABG

Experiments	ANNs			LDA		
	Accuracy (%)	Sensitivity (%)	Specificity (%)	Accuracy (%)	Sensitivity (%)	Specificity (%)
Experiment 1	96.6	97.7	95.5	94.6	95.4	93.2
Experiment 2	98.8	98.4	100	96.8	96.0	97.5
Experiment 3	98.4	96.8	100	96.8	96.0	97.5
Experiment 4	91.3	91.7	90.9	88.6	93.2	84.1
Experiment 5	97.7	95.4	100	94.5	94.9	94.2

Experiment 4

In this experiment, of the eight variables used in the previous experiment, the three serological variables, namely gastrin, pepsinogen I, and anti-parietal cell antibodies, were excluded. Using only the five clinical variables (Table 3), ANNs showed a sensitivity of 91.7% (121 of the 132 ABG patients identified), a specificity of 90.9% (40 of the 44 controls recognized), and an overall accuracy of 91.3%. On the other hand, LDA showed a sensitivity of 93.2% (123 of the 132 ABG patients identified), a specificity of 84.1% (37 of the 44 controls correctly matched), and an overall accuracy of 88.6% (Table 2).

Table 3 Independent variables identified by LDA as most predictive for the diagnosis of ABG with respective correlation coefficients

Independent variables	Correlation coefficients
Pepsinogen I[1]	0. 42
Gastrin[1]	–0.40
Age, yr	–0.37
Association with other diseases not previously mentioned[2]	0.35
Other (not gastrointestinal) symptoms[3]	0.34
Onset of presentation symptoms (mo)	0.25
Other gastrointestinal symptoms[4]	0.25
Antibodies against parietal cells[1]	0.23

[1]Serological variables; [2]represented in data set by cardiovascular diseases, diabetes type II and other causes of iron-deficiency anemia; [3]represented in data set by asthenia, fatigue, and headache; [4]represented in data set by diarrhea, abdominal pain, and bloating.

Experiment 5

In the final experiment, using only the three serological variables (gastrin, pepsinogen I, and anti-parietal cell antibodies), ANNs showed a sensitivity of 95.4%, a specificity of 100%, and an overall accuracy of 97.7%. LDA showed a sensitivity of 94.9%, a specificity of 94.2% and an overall accuracy of 94.5% (Table 2).

DISCUSSION

The results emerging from this pilot study suggest that advanced statistical methods, not only ANNs, but also LDA, are able to predict, with great accuracy, the presence of ABG using only clinical and serological variables. These methods may thus, after appropriate validation, be taken into consideration as potential clinical decision-support tools for identifying those patients with suspected ABG requiring gastroscopy with body mucosa biopsy sampling for the assessment of atrophy of the oxyntic mucosa. However, gastroscopy is an invasive and expensive procedure, which is often accepted with reluctance by patients without specific gastrointestinal symptoms or presenting with non-digestive disorders, such as thyroiditis, anemia or neurological symptoms. Furthermore, in this particular clinical setting, the cost-effectiveness of bioptic sampling during gastroscopy still needs to be determined[37]. Thus, a computer-based decision-support system, which is able to select with a high predictive accuracy, those patients with a high probability of having ABG, would enable the endoscopic/histologic investigation to be better addressed. Indeed, in the third experiment, the advanced statistical systems correctly identified all patients without ABG.

For the clinical applicability of computer-based decision support systems and their acceptance by physicians, it is necessary to offer a system, which is simple, with entry of data that requires little time, thus using a limited number of variables, which are readily available to the clinician. In the present study, we, therefore, progressively decreased the input variables in order to use less input data with a high predictive power for ABG. It is of interest that, despite the reduction in the number of input variables from the initial 37 to only 8, the accuracies of ANNs and LDA were still 98.4% and 96.8%, respectively. Surprisingly, the performance of ANN and LDA was still acceptable (91.3% and 88.6%, respectively) despite the reduction in the input variables to only five variables, readily available in the clinician's office by clinical history. However, four of these five clinical variables are non-specific, such as other gastrointestinal symptoms, namely diarrhea, abdominal pain and bloating, and other non-gastrointestinal symptoms, such as headache and asthenia. Thus, these findings need to be confirmed by a prospective study using these systems.

It was not surprising that of the most informative variables for the prediction of ABG, we find gastrin and pepsinogen I, which are parameters previously tested as serological screening tools for ABG[12-14]. In fact, in these studies, an overall accuracy of about 80% for the diagnosis of atrophic gastritis had already been obtained. The results of the present study support these findings: indeed, by using only the serological variables, gastrin and pepsinogen I together with parietal cell antibodies, the overall accuracy of ANNs was almost 98%. However, our study also shows that the accuracy of these serological markers for the identification of patients with suspected ABG may potentially be improved by almost 100%, associating them with a few clinical data and applying advanced statistical systems.

Albeit the clinical variables identified as those having the highest predictive power for the diagnosis of ABG were quite unexpected: age, onset of presentation symptoms, other gastrointestinal symptoms (diarrhea and bloating),

other non-gastrointestinal symptoms (headache, asthenia), and the association with other,not previously mentioned diseases(cardiovascular diseases and diabetes) . In general, the presence of a statistical relationship between a predictor variable and the outcome alone does not imply causality[38]. This is even more the case for ANN-based models, which process data in a non-linear way, and the network logic of prediction cannot be broken down into simple elements of clinical reasoning[17,18]. Thus, the variables with the most predictive power selected by the advanced statistical systems should not be viewed as independent predictive variables as perceived by a clinician[17,38].

However, these findings also show the crucial importance of coding variables during the setting up of a database to be used for advanced statistical analysis, which obviously affects the results of analyses. In fact, in our data set, three out of the five most informative variables were coded as cumulative variables (other gastrointestinal symptoms, other non-gastrointestinal symptoms, and association with other diseases not previously mentioned) and thus considered of little importance at the time of data collection. On the contrary, these five variables alone were able to distinguish between patients with and without ABG with an overall accuracy of approximately 90%. Thus, data sets for the use of advanced statistical methods need to be developed without considering a single data a priori as less important, but all available data should be entered in detail, since advanced statistical methods recognize complex linear and non-linear relationships, not valuable a priori[39].

It is of interest that, although a comparison of the two statistical approaches was not performed, ANNs somewhat outperformed LDA, but both technologies showed good predictive results. In fact, in 24 out of the 37 independent variables (64.9%), a non-linear relationship with the output (diagnosis of ABG) was observed, as shown by the values of the correlation coefficients, which were less than 0.06 (data not shown). However, the values of correlation coefficients of the remaining 13 independent variables ranged between 0.063 and 0.302, showing that these variables were, to some extent, related in a linear way to the output. This finding is in agreement with that of previous studies in which conventional statistical methods were compared to neural networks and no differences in overall predictive performance were observed[38,40,41]. However, it has been argued that performance improves merely by structuring information, making it difficult to assess how much improvement could be related to any specific statistical analysis[42].

However, the aim of the present study has been not to emphasize that advanced statistical decision support systems should replace or substitute experienced clinicians, but to stress that, in our opinion, these systems should be viewed as a potential decision aid, particularly in times of shortages of financial resources, in order to better address invasive investigations to save costs and to use resources when effectively necessary, as described in other fields of medical settings[43].

We are aware that the current study had some pitfalls, including the fact that external validation has not yet been carried out; in fact, our results need to be considered as preliminary and be validated in a prospective and large-population study. Secondly, these findings may not be generalized "tout-court" to the general population, since, in this pilot study, the frequency of ABG was higher than that of controls.

In conclusion, this preliminary study suggests that advanced statistical methods, not only ANNs, but also LDA, may contribute to better address bioptic sampling during gastroscopy in a subset of patients in whom ABG may be suspected on the basis of aspecific gastrointestinal symptoms or non-digestive disorders.

Abstract

AIM: To study the levels of adiponectin in nondiabetic patients with nonalcoholic fatty liver disease (NAFLD) in comparison with control group.

METHODS: Thirty-five patients who had elevated serum aminotransferase levels with bright liver and 34 healthy volunteers without liver disease were evaluated. Age, gender and body mass index (BMI) were recorded. Fasting plasma glucose, insulin, adiponectin, proinsulin and lipid profile were measured. A standard oral glucose tolerance test (OGTT) with insulin response was performed and the index of insulin resistance was calculated according to the homeostasis model assessment (HOMA) method.

RESULTS: According to the OGTT results, none of the participants had diabetes. Serum adiponectin levels were statistically significantly lower in patients with NAFLD than in control group (8.14±3.4 μg/mL *vs* 12.4±9.4 μg/mL, respectively, $P<0.01$). A statistically significant correlation was found between adiponectin and BMI (r: -0.33, $P<0.01$), HOMA (r: -0.26, $P<0.05$), proinsulin (r: -0.32, $P<0.01$), AST (r: -0.25, $P<0.05$), ALT (r: -0.26, $P<0.05$) or GGT (r: -0.22, $P<0.05$). In multiple regression analysis models, adiponectin levels were the only predictor of NAFLD in males, whereas in female group it was the BMI.

CONCLUSION: Low adiponectin level might be a predictor of NAFLD especially in male nondiabetics.

INTRODUCTION

The growing epidemic of obesity has led to many studies on the role of adipose tissue as an endocrine organ that secretes many factors termed as adipokines, which mediate many of the vascular and metabolic complications of adiposity. These products, namely free fatty acids, TNF-α, interleukins, resistin, and leptin reduce insulin sensitivity[1-3].

Adiponectin is a plasma protein, which is secreted from adipose tissue, and serum levels are markedly reduced in obesity. Adiponectin levels are negatively correlated with body fat percent, central fat distribution, fasting plasma insulin, oral glucose tolerance and positively with glucose disposal during euglycemic insulin clamp[3-7]. It has two receptors; adipoR1 is abundantly expressed in skeletal muscle and at moderate levels in other tissues, whereas adipoR2 is predominantly expressed in the liver[8-10].

Adiponectin is a hepatic insulin sensitizer and also an inhibitor of tumor necrosis factor and therefore we studied its levels in nondiabetic patients with nonalcoholic fatty liver disease (NAFLD) and compared the results with healthy volunteers and looked for the effect of gender on adiponectin levels.

MATERIALS AND METHODS

Thirty-five patients admitted to the Department of Gastroenterology at Kartal Education and Research Hospital with elevated serum aminotransferase levels for longer than 6 mo and bright liver on ultrasound scan were included in this study. Thirty-four healthy volunteers without liver disease, who were gender and age matched with study group, were enrolled as the control group. Patients were excluded from this cohort if one of the following criteria was present: hepatitis B (hepatitis B surface antigen, antibody to hepatitis surface antigen, antibody to hepatitis B core antigen), hepatitis C (antibody to hepatitis C virus) and Epstein-Barr virus infection, non-organ specific autoantibodies (antimitochondrial antibody, antinuclear antibody, antismooth muscle antibody, and anti-liver/kidney microsomal antibody), hereditary defects (fasting serum iron, transferrin saturation, ferritin, ceruloplasmin, alpha-1-antitripsin levels), alcohol consumption (ethanol ingestion >20 g/d), use of amiodarone, corticosteroids, tamoxifen, methotrexate, or oral contraceptives, jejunoileal bypass or extensive small bowel resection, total parenteral nutrition, malignancy, hypo-hyperthyroid disease, pregnancy, other known liver diseases like cirrhosis and diabetes. The diagnosis of cirrhosis was based on the clinical and laboratory findings (hypoalbuminemia, prolongation of prothrombin time, hyperbilirubinemia, presence of ascites or other findings of portal hypertension). The absence of

diabetes was confirmed with oral glucose tolerance test (OGTT) in both groups.

The absence of liver disease in the control group was established based on clinical, laboratory and imaging criteria. All controls had normal liver biochemistries and lack of any evidence from physical examination of chronical liver disease. However, an abdominal ultrasound was performed to exclude bright liver in all of the controls. All subjects gave informed consent to take part in the study.

Age, gender, height, weight, and body mass index (BMI) were recorded. Fasting plasma glucose, insulin, proinsulin, lipid profile, uric acid, and serum proteins were measured. Adiponectin levels were measured by Adiponectin Human ELISA Kit. A standard 75 g OGTT with insulin response according to WHO criteria was performed on all patients.

The index of insulin resistance (IR) was calculated on the basis of fasting values of plasma glucose and insulin, according to the homeostasis model assessment (HOMA) method.

Ultrasound liver studies were carried out by the same experienced radiologist who was blinded to laboratory values. The diagnosis of bright liver was based on abnormally intense, high-level echoes arising from the hepatic parenchyma, with amplitude similar to that of echoes arising from the diaphragm.

Statistical analysis

Statistical analysis was performed with SPSS 11.5 program. Any *P* value less than 0.05 was considered statistically significant. Results are expressed as mean±SD. Comparison between the two groups was made with Student's *t*-test and Mann-Whitney *U* test. Pearson's and Spearman's rank correlations were used to detect the associations between serum adiponectin and various demographic, anthropometric, and metabolic variables. When necessary, multiple regression analysis was performed.

RESULTS

Demographic, anthropometric, metabolic, and laboratory characteristics of patients with NAFLD and their matched controls are shown in Table 1.

According to the OGTT results, none of the participants had diabetes. However, six patients in NAFLD group and three patients in control group had impaired glucose tolerance ($P>0.05$). The remaining had normal glucose tolerance.

Insulin (fasting, 60 and 120 min), HOMA, proinsulin and c-peptide levels were statistically significantly higher in NAFLD group than in control group (Table 2).

Serum adiponectin levels were statistically significantly lower in patients with NAFLD than in the control group (8.14±3.4 μg/mL *vs* 12.41±9.4 μg/mL, respectively, $P<0.01$; Table 2). A statistically significant correlation was found between adiponectin and BMI (r: -0.33, $P<0.01$), HOMA (r: -0.26, $P<0.05$), proinsulin (r: -0.32, $P<0.01$), AST (r: -0.25, $P<0.05$), ALT (r: -0.26, $P<0.05$) or GGT (r: -0.22, $P<0.05$). In multiple regressions analysis, gender was found to be a predictor of adiponectin but not the age and BMI (Table 3).

When we subclassified the patient and the control group according to gender, the adiponectin levels were found to be low in males compared to females ($P<0.05$). But there was no statistically significant difference in age, BMI, HOMA, and proinsulin between the subgroups of gender ($P>0.05$, Table 4). In multiple regression analysis, adiponectin levels were the only predictor of NAFLD in males (Table 5), whereas in female group it was the BMI (Table 6).

Table 1 Demographic, anthropometric, and biochemical measurements in NAFLD and control groups

	NAFLD (*n*: 35)	Controls (*n*: 34)	*P*
Age (yr)	39.1±7.8	36.1±6.0	NS
Gender (female/male)	20/15	20/14	NS
BMI (kg/m^2)	30.5±4.1	23.7±3.8	<0.001
Fasting glucose (mg/dL)	93±9	84±11	<0.01
Total cholesterol (mg/dL)	209±35	186±36	<0.01
HDL cholesterol (mg/dL)	50±12	51±12	NS
LDL cholesterol (mg/dL)	125±28	118±37	NS
Triglycerides (mg/dL)	177±100	103±57	<0.01
AST (IU/L)	36±10	18±5	<0.001
ALT (IU/L)	49±17	18±9	<0.001
GGT (IU/L)	43±16	16±8	<0.001

NS, nonsignificant.

Table 2 Comparison of IR parameters in NAFLD and control groups

	NAFLD (*n*: 35)	Controls (*n*: 34)	*P*
Fasting insulin (IU/L)	14.6±6.7	9.9±4.5	<0.01
Insulin 60 min (IU/L)	99.6±63.1	62.4±43.2	<0.01
Insulin 120 min (IU/L)	65.3±49	40.2±31.9	<0.01
HOMA index	3.3±1.5	2.1±1.1	<0.001
Proinsulin (pmol/L)	10.6±6.4	6.2±4.5	<0.001
C-peptide (ng/mL)	2.7±0.7	2.0±0.6	<0.001
Adiponectin (μg/mL)	8.14±3.4	12.41±9.4	<0.01

Table 3 Regression model of adiponectin as a dependent variable

Independent variables	*T*	Significance
Gender (male)	–2.791	0.009
Age (yr)	0.774	NS
BMI (kg/m^2)	–0.523	NS

NS, nonsignificant.

Table 4 Comparison of male and female patients in both NAFLD and control groups

	Female (*n:* 40)	Male (*n*: 29)	*P*
Age (yr)	37.0±7.1	38.6±7.1	NS
BMI (kg/m^2)	27.5±5.8	26.9±4.5	NS
HOMA	2.6±1.4	2.8±1.4	NS
Adiponectin (μg/mL)	11.7±8.9	8.2±3.3	0.025

NS, nonsignificant.

Table 5 Regression model of NAFLD as a dependent variable in

males

Independent variables	*B*	Exp (*B*)	Significance
Adiponectin (μg/mL)	0.466	1.593	0.045
Age (yr)	–0.086	0.918	NS
BMI (kg/m^2)	–0.237	0.789	NS
HOMA	–0.068	0.934	NS

NS, nonsignificant.

Table 6 Regression model of NAFLD as a dependent variable in females

Independent variables	*B*	Exp (*B*)	Significance
BMI (kg/m^2)	–0.505	0.972	0.007
Age (yr)	–0.028	0.604	NS
HOMA	–0.097	0.908	NS
Adiponectin (μg/mL)	0.003	1.003	NS

NS, nonsignificant.

DISCUSSION

Cytokines are mediators of cellular communication produced by multiple liver cell types such as Kupffer cells, stellate cells, hepatocytes and endothelial cells. Cytokines can directly induce necrosis or apoptosis. Increased levels of hepatotoxic cytokines such as tumor necrosis factor-α are documented in alcoholic liver disease and nonalcoholic steatohepatitis and have been shown to play a mechanistic role in both of these processes. There are also beneficial cytokines, such as interleukin (IL-10 and IL-6). Adiponectin, one of the beneficial cytokines, is made outside the liver and appear to protect against liver damage[11-13]. Adiponectin is an important adipokine specifically secreted by adipocytes that circulates at relatively high levels in the bloodstream[1]. Plasma levels of adiponectin are reduced in obese rodents and humans, as well as in humans with type 2 diabetes. It has been suggested that adiponectin might function as an adipostat in regulating energy balance and that its deficiency might contribute to the development of obesity and type 2 diabetes[14,15].

It has been shown that increased hepatic fat content is associated with hepatic IR in type 2 diabetic patients and IR was found in 85% of these patients by Willner *et al*.[16]. Insulin resistance and systemic hypertension features of the metabolic syndrome are also independently associated with advanced forms of NAFLD[17,18]. In our study, hyperinsulinemia was present in all the patients and a high value of HOMA index in NAFLD patients is present in comparison to control group which is an index of IR.

The euglycemic-hyperinsulinemic clamp is accepted as the gold standard in defining the IR, but it is difficult to perform and time consuming and can be used only in studies with limited number of patients. Therefore, we preferred to use HOMA, which is easy to perform and it has been shown that it is in correlation with the euglycemic-hyperinsulinemic clamp (*R*: 0.88, *P*<0.0001; *R*: 0.85, *P*<0.0001 and *R*: 0.73, *P*<0.0001). A literature search using Medline found that the use of the HOMA model has been reported in 572 published works. In >50% of reports, the model is used in nondiabetic populations[19-21].
