METHODS: All patients who received PEI treatment during the study period were included and stratified to one of the following treatment modalities according to physical status and tumor extent: combination of TACE and repeated single-session PEI, repeated single-session PEI alone, repeated TACE alone, or best supportive care. Prognostic value of clinical parameters including Okuda-classification, presence of portal vein thrombosis, presence of ascites, number of tumors, maximum tumor diameter, and serum cholinesterase (CHE), as well as Child-Pugh stage, α-fetoprotein (AFP), fever, incidence of complications were assessed and compared between the groups. Survival was determined using Kaplan-Meier and multivariate regression analyses.

RESULTS: The 1- and 3-year survival of all patients was 73% and 47%. In the subgroup analyses, the combination of TACE and PEI (1) was associated with a longer survival (1-, 3-, 5-year survival: 90%, 52%, and 43%) compared to PEI treatment alone (2) (1-, 3-, 5-year survival: 65%, 50%, and 37%). Secondary PEI after initial stratification to TACE (3) yielded comparable results (1-, 3-, 5-year survival: 91%, 40%, and 30%) while PEI after stratification to best supportive care (4) was associated with decreased survival (1-, 3-, 5-year survival: 50%, 23%, 12%). Apart from the chosen treatment modalities, predictors for better survival were tumor number (n < 5), tumor size (< 5 cm), no ascites before PEI, and stable serum cholinesterase after PEI (P < 0.05). The mortality within 2 wk after PEI was 2.8% (n = 3). There were 24 (8.9%) major complications after PEI including segmental liver infarction, focal liver necrosis, and liver abscess. All complications could be managed non-surgically.

CONCLUSION: Repeated single-session PEI is effective in patients with advanced HCC at an acceptable and manageable complication rate. Patients stratified to a combination of TACE and PEI can expect longer survival than those stratified to repeated PEI alone. Furthermore, patients with large or multiple tumors in good clinical status may also profit from a combination of TACE and reconsideration for secondary PEI.

INTRODUCTION

The prognosis of untreated HCC remains poor. The 3-year survival ranges from 21% to 28% and declines to about 8% for advanced tumors[1]. The only therapies that currently offer potential cure are surgical resection and liver transplantation. Despite improved surgical techniques, only about 20% of HCC are amenable to resection, mainly due to advanced tumor growth and the underlying cirrhosis[2]. Systemic chemotherapy has shown no significant survival benefit in comparison to best supportive care[3]. Hence, locoregional modalities like transarterial chemoembolisation (TACE), percutaneous ethanol injection (PEI), laser induced thermo therapy (LITT), and radiofrequency ablation (RFA) are employed widely in non-resectable HCC in an attempt to prolong survival[4-7]. TACE is the preferred modality for patients with large and disseminated HCC in good physical status, whereas repeated PEI has shown efficacy in cases of small tumors[8]. Both modalities have proven their effectiveness in terms of tumor response and survival, even more so when combined[9-17].

PEI has gained importance in small HCC due to its safety and ease of operation. The method is both effective and economically sound. The survival data of patients with small tumors after PEI are comparable to those after surgical resection with 5-year survival rates between 32%-59%[15, 18-22]. The amount of ethanol applicable during one session was initially limited. With the introduction of the single-session high-dose technique under general anaesthesia by Livraghi and co-workers, the indications for PEI have been extended[23]. The injection of higher quantities of ethanol during one session under mechanical ventilation offers the advantage of treating larger tumors and more lesions at a time, requiring fewer interventions. Furthermore, tumors in difficult accessible areas (e.g. liver segments 8, 1 or 2) can be better accessed in deep inspiration under mechanical ventilation.

According to physical status and tumor extent patients with non-resectable HCC were stratified in an interdisciplinary conference to repeated single-session PEI, repeated TACE sessions, a combination of TACE and repeated single-session PEI or to best supportive care[24]. Aim of this prospective study was to evaluate all patients of our institution who received PEI treatment from 1999 to 2003. Using multivariate regression analyses of pre-treatment variables, survival predictors were identified. In subgroup analyses, patients stratified to repeated PEI alone were compared to those stratified to a combination of TACE and PEI. Furthermore, long-term results of those patients who were reevaluated and switched secondarily to PEI treatment after being initially stratified to repeated TACE and of those patients who received PEI after being initially stratified to best supportive care for advanced disease were analysed[9].

MATERIALS AND METHODS

Patients

One hundred and one patients (age range 35-88 years, 85% male, mean observation time 26 ± 17 mo) with non-resectable histologically-confirmed HCC who received PEI treatment from July 1999 until July 2003 in our institution were included into the present study.

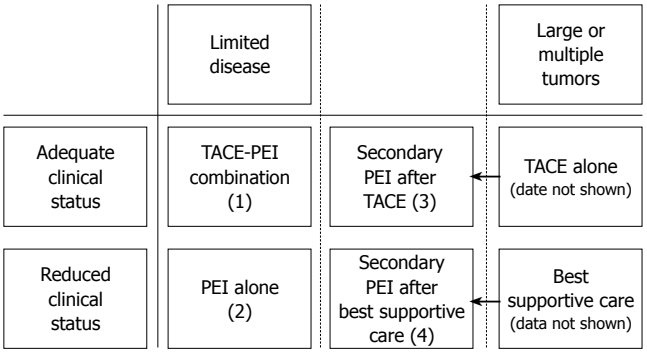

Figure 1 Stratification algorithm for the treatment of advanced unresectable HCC.

Stratification

In an interdisciplinary gastroenterological-radiological conference, patients were stratified to one of the following treatment modalities according to physical status and tumor extent (Figure 1): combination of TACE and repeated single-session PEI, repeated single-session PEI alone, repeated TACE alone, or best supportive care. After thorough explanation of the procedures, informed consent was obtained from each patient prior to therapy. The data of the TACE-PEI combination group (1) and of the PEI alone (2) group were analyzed. In addition, patients with extensive disease (large or multiple tumors) were reconsidered and in some cases restratified to secondary PEI treatment (Figure 1). These patients were evaluated in two separate subgroups: patients switched secondarily to PEI after being initially stratified to repeated TACE (3) or after being initially stratified to best supportive care (4).

Exclusion criteria

Contraindications against regional treatment were extrahepatic tumor manifestation, sepsis, hepatic encephalopathia, elevated serum ammonia > 47 μmol/L, platelet counts < 50 000/μL, prothrombin activity < 50%, serum creatinine >120 μmol/L, left ventricular ejection fraction < 50%, heart attack within the previous 12 mo, heart insufficiency >NYHA stage II. The inclusion into the liver transplantation program was not a contraindication.

Further contraindications against PEI were significant perihepatic ascites or inadequate parameters for general anaesthesia.

Further contraindications against TACE were portal vein thrombosis, impossible catheterization of the hepatic artery, cholinesterase (CHE) < 2 mU/mL (21℃), inadequate functional, hematological or biochemical parameters for chemotherapy.

Outcome assessment

Pre- and post-treatment evaluation included physical examinations, the assessment of clinical parameters, toxicities, adverse events and survival and the evaluation of tumor markers as well as hematological and biochemical parameters. To classify cardiac function and to detect right heart hypertrophism and pulmonary hypertension,

echocardiography, cardiac scintigraphy, and ECG were performed.

PEI treatment

Single-session PEI therapy was performed during general anaesthesia under realtime ultrasound guidance. Before each session the patients underwent a complete abdominal ultrasound examination. After thorough skin disinfection, absolute sterile ethanol (96%) was injected transcutaneously into the tumor using a 0.7 mm needle (Angiomed, Karlsruhe, Germany) and a biopsy-transducer (3.5 MHz, Toshiba, Neuss, Germany). Starting at the most distal part of the tumor, ethanol was continously injected while carefully retracting the needle until the tumor echogenicity became homogenous. After complete ethanol administration, short-term follow-up ultrasound control examinations were performed. Intravenous infusions of antibiotics and of fluid replacement were given before and for two days after PEI.

Six weeks after therapy, doppler ultrasound control examinations were performed. In case of detectable remaining tumor vascularisation (indicating remaining vital tumor tissue), tumor growth or new lesions, further PEI treatment was initiated. In case of uncertain vascularisation echocontrast enhanced ultrasound and a biphasic CT or contrast-enhanced MRI scan were performed. In case of no detectable tumor vascularization, patients were followed up every three months.

TACE treatment

TACE was performed under local anaesthesia. Before each TACE session, a biphasic CT scan of the abdomen was performed to show tumor extent, and to check for possible extrahepatic disease. After aortography and a selective mesentericoportography to verify vascular anatomy and the patency of the portal vein, a selective hepaticography was performed using a standard diagnostic catheter or, if necessary, a coaxial system. According to tumor vascularisation and distribution a mixture of cisplatin (50 mg/m²), doxorubicin (50 mg/m²), 450 to 900 mg degradable starch microspheres (Spherex, Pharmacia, Erlangen, Germany) and 5 to 30 mL iodized oil (Lipiodol© Ultra-Fluide, Guerbet, Sulzbach/Ts., Germany) were administered under fluoroscopic control. In case of stasis or reflux, the injection was stopped until the arterial flow resumed. After complete administration, a control hepaticography was performed to document the arterial perfusion and the reduction of tumor vascularisation. Intraarterial analgesia (Dolantin©, Pethidin, Aventis, Bad Soden/Ts., Germany) was sufficient to control local pain in all cases. Intravenous infusions of antibiotics and fluid replacement were given before therapy and for two days after TACE, accordingly.

Statistical analysis

Data analysis was performed employing the Statistical Package for the Social Sciences Version 12.0 for Windows (SPSS© Inc., Chicago IL, USA). For comparison of distributions the Wilcoxon-test was used, for metric variables the chi-square test and the Fisher's exact test for nominal variables. Results were presented as mean ± standard deviation or frequencies [*n* (%)].

Overall survival of all patients and survival of the subgroups were determined by Kaplan-Meier analyses. Kaplan-Meier curves were statistically compared by the log-rank-test. In order to quantify the influence of the treatment strategies on the survival outcome, a multivariate logistic regression analysis (enter method) was carried out. The clinical parameters that differed between the four treatment groups at baseline (Okuda-classification, presence of portal vein thrombosis, presence of ascites, number of tumors, maximum tumor diameter, and CHE) were entered into the regression model as well as Child-Pugh stage, α-fetoprotein (AFP), fever, incidence of complications, and the type of treatment administered. The model rendered the relevance of the variables tested competitively (R-square-value) and identified significant predictors for survival.

Subsequently, Kaplan-Meier curves were computed for all patients stratified separately for every significant predictor of the regression analysis in order to demonstrate the influence of the predictors on survival probabilities.

A P-value < 0.05 was considered significant, and a P-value < 0.001 was considered highly significant.

RESULTS

Disease severity at outset

The patient set included a high proportion of patients with advanced stages of liver cirrhosis and tumor extent. Forty-one percent of the 101 patients presented with cirrhosis of Child-Pugh stage B, 15% with stage C. Okuda-scores II and III were present in 62%. Portal vein thrombosis was found in 18% and ascites requiring intensified diuretic therapy in 42% of the patients. In only 14% uninodular tumors were detected, in 70% up to 5 tumor lesions and in 15% multiple tumors. The mean maximum tumor size was 53 (± 27) mm in diameter. High mean AFP levels of 1188 ng/mL (± 6802) were seen, and the mean CHE levels were reduced to 3.3 mU/mL (± 1.6). The hepatitis B status was positive in 27% of the patients, and hepatitis C status in 22%.

The baseline characteristics of the four subgroups differed due to the selection criteria employed. A comparison of the frequencies and mean values of clinical variables is shown in Table 1.

Significant deviations of the subgroups were shown for the Okuda score, the frequencies of portal vein thrombosis and ascites, the number of tumor lesions, the maximum size of tumor diameter and the liver parameters CHE, bilirubin, and AST.

Treatment

Overall, 268 PEI-interventions were performed in 101 patients (2.7 ± 1.7 sessions per patient). The mean injected ethanol volume was 42 mL (3-117) per session. The mean hospitalisation time was 6.8 ± 4.8 d. In 43 patients (40.5%) intensified diuretic therapy was needed to reduce pre-treatment ascites. According to the stratification algorithm 37 patients received combination treatment of TACE and repeated PEI (1) and 34 patients received PEI alone (2). Ten patients primarily stratified to repeated TACE treatment

NS: Not significant, [1] *n* (%), [2] Mean (standard deviation). TACE-PEI combination, PEI alone, secondary PEI after TACE discontinuation, and secondary PEI after best supportive care are displayed. The *P*-values for comparison of baseline characteristics between these subgroups are shown. CHE: Cholinesterase, AP: Alkaline phosphatase, G-GT: Gamma glutamyl transferase.

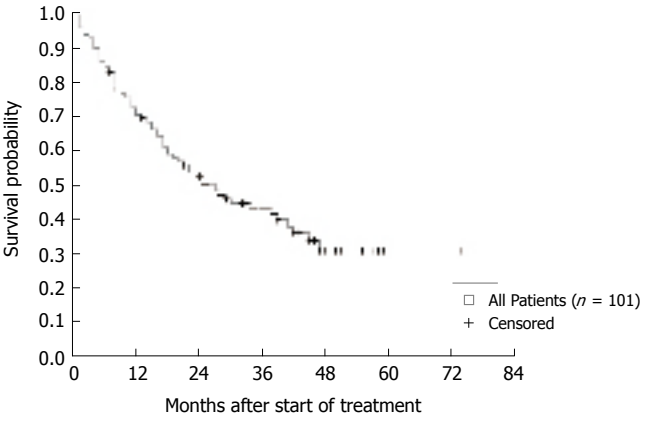

Figure 2 Kaplan-Meier curve showing the survival probabilities of all 101 patients.

only, were switched after TACE discontinuation to secondary PEI treatment (3). Another 20 patients who were primarily stratified to best supportive care, were considered treatable by PEI and received subsequently repeated PEI sessions in order to decrease tumor load in individual therapy settings (4).

Reasons for discontinuation of TACE in the patients continued secondarily on repeated PEI sessions were adverse events ($n = 6$), efficacy failure/progressive disease ($n = 3$) or achievement of preconditions for PEI treatment due to tumor regression ($n = 1$). In those patients primarily stratified to best supportive care secondary PEI treatment was performed because of improvement of general health status ($n = 9$), of patient´s request ($n = 7$), of reduction of ascites ($n = 2$), or as a bridge to liver transplantation ($n = 2$).

Seven of the 101 patients received liver transplants during follow-up (7%). Two of these patients had been stratified to combination treatment of TACE and PEI (1), four patients to repeated PEI alone (2), and one patient secondarily to repeated PEI after primary stratification to TACE (3).

Survival

The overall 1- and 3-year-survival rates of the 101 patients were 73% and 47%, respectively. Kaplan-Meier analyses of all patients rendered survival probabilities of 72% after 1 year, 43% after 3 years, and 32% after 5 years (Figure 2).

A comparison of the Kaplan-Meier survival curves for the four subgroups is shown in Figure 3. Survival

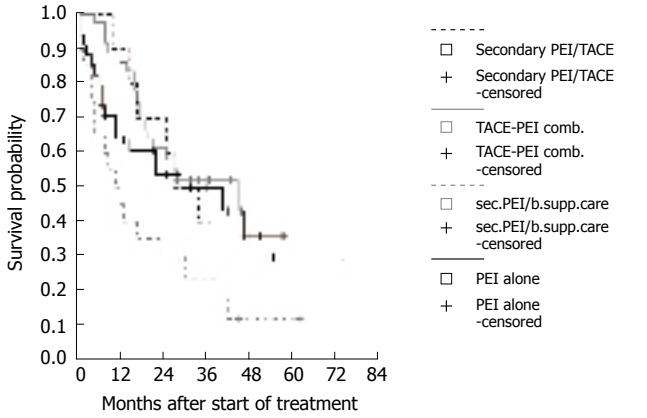

Figure 3 Comparison of Kaplan-Meier curves showing the survival probabilities of the four subgroups: TACE-PEI combination, PEI alone, secondary PEI after TACE, secondary PEI after best supportive care. The highest survival probabilities can be expected in the combination treatment group initially stratified to TACE followed by repeated single session PEI.

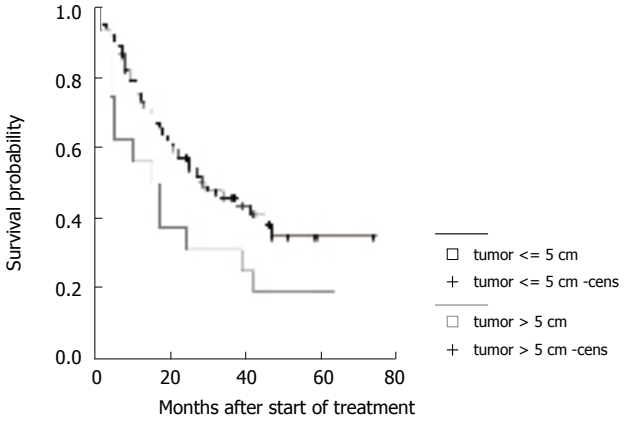

Figure 4 Comparison of the Kaplan-Meier curves for the parameter maximum tumor diameter (5 cm or less *vs* more than 5 cm) prior to stratification. The survival probabilities of the subgroup with smaller tumors are significantly higher (logrank: $P = 0.02$).

Table 2 Multivariate regression model of predictors for longterm survival of three years and more after start of therapy

Predictors	Cut-off	*P*-value	Odd's ratios	Confidence interval
AFP	< 400 ng/mL	NS		
Fever	< 38℃	NS		
CHE-level at follow up	Change < 1 mU/mL	0.05	6	2.4-10.1
No of tumor lesions	⩽ 5	0.01	11.1	3.3-22.3
Child-Pugh	Child A	NS		
Ascites	No ascites	0.03	12.2	4.7-30.3

Okuda	Okuda stage 1	NS		
Severe complications	No complication	NS		
Maximum tumor size	⩽ 5 cm	0.04	6.1	1.3-17.5
Type of treatment	TACE-PEI comb (I) *vs* other groups	0.05	4.3	1.2-14.7

P-values, Odd's ratios and confidence intervalls are shown for all significant variables. $R^2 = 43\%$.

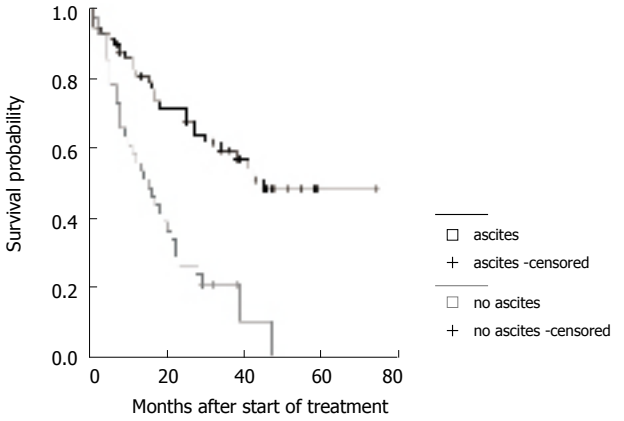

Figure 5 Comparison of the Kaplan-Meier curves for the parameter ascites prior to stratification (ascites *vs* no ascites). Significantly higher survival probabilities can be expected for the subgroup without ascites (logrank: $P < 0.001$).

probabilities differed between the subgroups. Significant differences were detected by log rank-tests comparing secondary PEI after best supportive care (4) to combination treatment of TACE and PEI (1) ($P < 0.001$) and to PEI treatment alone (2) ($P < 0.05$). There was a trend towards better survival in the combination group (1) compared to PEI alone (2) ($P = 0.1$).

The 1-, 3-, and 5-year survival probabilities of the subgroups were 90%, 52%, 43% for the combination group (1); 65%, 50%, 37% for the PEI alone group (2); 91%, 40%, 30% for the secondary PEI group after TACE discontinuation (3); and 50%, 23%, 12% for the secondary PEI group after best supportive care stratification (4).

Predictors of three-year-survival

From all clinical baseline characteristics that differed between the four subgroups at the outset of the study, pre-treatment ascites, the number of tumor lesions, the maximum tumor size, and CHE were significant predictors in the multivariate enter-model (Table 2). Additionally, the type of treatment administered proved to have independent predictive value in the model.

The probability to survive longer than three years was 6-fold higher in patients with stable CHE levels under therapy and in patients with tumors of less than 5 cm in maximum diameter, 11-fold higher in patients with five tumor lesions or less and 12-fold higher in patients without ascites prior to therapy. Treatment with TACE and PEI combination (1) led to a 4-fold higher survival probability compared to the other subgroups (2-4) independently of the clinical parameters tested in the model.

Stratification of predictors in Kaplan-Meier analyses

Survival curves were generated for all significant parameters of the prediction model and stratified according to the cut-offs employed (Figure 4, Figure 5, Figure 6 and Figure 7). The differences of the stratified subgroups were significant in all parameters shown (logrank-test: $P < 0.05$).

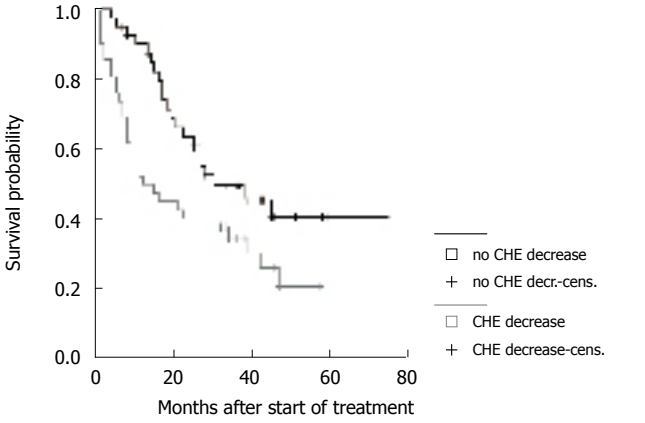

Figure 6 Comparison of the Kaplan-Meier curves for the parameter decrease in serum CHE-levels after PEI (decrease >1 mU/mL *vs* no decrease). The subgroup with stable CHE levels can expect significantly better survival probabilities (logrank: $P = 0.02$).

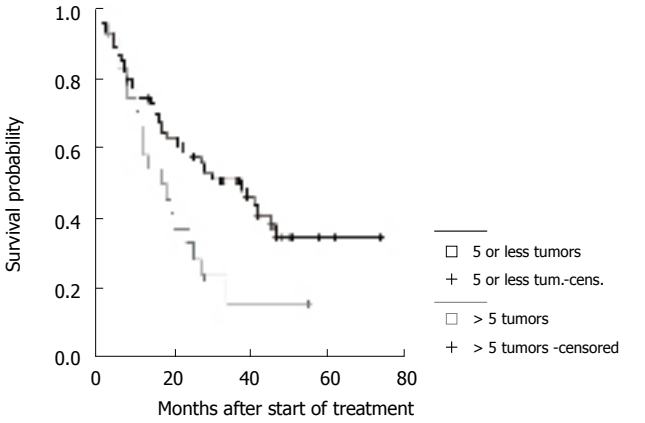

Figure 7 Comparison of the Kaplan-Meier curves for the parameter number of tumor lesions (5 or less tumors *vs* more than 5 tumors). The survival probabilities of the group with 5 or less tumors are significantly higher (logrank: $P < 0.05$).

The survival was improved significantly in patients with stable CHE-levels under therapy as a parameter of the liver function, in patients without ascites prior to therapy, in patients with a maximum tumor diameter of less than 5 cm, and in patients with five or less tumor lesions.

TACE complications

A total of 67 TACE procedures were performed. After 7 (10.4%) procedures complications were recorded. There were two cases of reversible leukopenia, one case of reversible pancytopenia, two cases of dissection of the hepatic artery, one case of reversible liver failure, and one inguinal hematoma.

PEI complications

Sixty-nine (25.7%) complications occurred after the 268 PEI sessions performed. Forty-five of these (16.8%) were considered minor [40 ascites (29 discrete, 7 intermediate, 4 severe), 3 pleural effusion, 1 oedema of the lower leg]. In 24 interventions (8.9%) major complications were observed (5 segmental liver infarctions, 2 focal liver necroses, 4 liver abscesses, 1 pulmonary embolism, 5 bleedings into liver or abdomen, 3 thromboses of the portal vein, 1 thrombosis of the superior mesenteric vein, 1 pancreatitis, 1 cholecystitis, and 1 cholangitis). All complications were managed non-surgically, and one liver abscess needed local drainage. There were no instances of needle-track seeding.

The mortality within 2 wk after PEI was 2.8% (3 patients). Two patients died with the signs of an acute right heart decompensation (one patient suffering from pre-existing alcoholic congestive heart disease with pulmonary hypertension, the other suffering from previously unknown right ventricular hypertrophy). The third patient developed a hypertensive crisis followed by an apoplectic insult.

DISCUSSION

In patients with HCC, survival is influenced by the etiology and characteristics of the tumors as well as the degree of cirrhosis and the remaining hepatic function. Since the degree of cirrhosis is rarely affectable in most cases, improval of survival can be expected mainly through effective tumor treatment. To date, there is still no standard treatment for advanced, unresectable HCC. The lack of efficient systemic chemotherapy against HCC and the non-resectability in most cases led to the development of various locoregional treatment modalities[22]. Increased anti-tumor efficacy might be achieved through a combination of different modalities carefully tailored to each patient.

PEI was introduced in 1983 and has become a standard treatment for small HCC[25]. The rationale for PEI is complete tumor necrosis resulting from cellular dehydration, protein denaturation, and chemical occlusion of tumor-feeding vessels. The method is best applicable in those HCCs that are surrounded by firm liver cirrhosis reducing the washout of ethanol. Ultrasound guidance allows for realtime monitoring of ethanol injection and distribution. Although regular PEI can be performed under local anaesthesia, general anaesthesia and endotracheal intubation have greatly facilitated the implementation of the single-session technique in terms of reduced pain and patient movement, thus extending the range of treatable tumors[23]. The major draw-back of PEI is a comparatively high recurrence rate of more than 30%[14]. Plausible reasons are inhomogeneous ethanol distribution within the tumor and the limited effect on extracapsular tumor spread. About 30% of small HCC (< 3 cm) have already developed invasive growth leading to microscopic intrahepatic metastases not detectable by current imaging[12]. The effect of PEI may be incomplete even in small tumors[26].

It is postulated that while the visible tumors are ablated by PEI, microscopic metastases are effectively destroyed by TACE. Furthermore, TACE is supposed to break up intratumoral septae and to create a fibrous wall around the hypervascularized tumors thus leading to a more homogenous distribution of ethanol during subsequent PEI[27,28]. Hence, the combination of TACE and repeated PEI, introduced in 1991, has shown superior results

compared to PEI or TACE alone[11-14,29]. This concept was also adopted by our institution as described previously[24]. After careful interdisciplinary evaluation patients with non-resectable HCC were treated by a combination of TACE and repeated PEI, if possible. Those patients not amenable to combination treatment were stratified to either modality alone or to best supportive care according to their individual situation. Furthermore, patients with large or multiple tumors were reevaluated under therapy and secondarily switched to PEI when considered possible (Figure 1).

In the present prospective study there was a comparatively high proportion of patients with decreased liver synthesis Child-Pugh B (41%) and C (15%) and portal vein thromboses (18%). Only 14% of the patients had single tumors while 15% had multiple disease and the mean tumor size was 53 mm (Table 1). Because both liver function and tumor extent affected therapy decisions, the present study was not a controlled trial but a prospective therapy evaluation based on a stratification scheme according to individual patient characteristics. The results were therefore not unexpected: patients stratified to PEI-therapy alone had worse pre-treatment conditions in terms of clinical status and liver function compared to those stratified to the combination of TACE and PEI (Table 1).

Overall observed 1- and 3-year-survival of all 101 patients was 72% and 47%. Kaplan-Meier analyses revealed a 1, 3, and 5 year survival probability of 90%, 52%, and 43% after initial stratification to TACE followed by PEI and of 65%, 50%, and 37% after PEI alone (Figure 3). Superior survival of combining TACE and PEI compared to either modality alone has been proven by several investigators. Bartolozzi *et al* detected superior recurrence-free survival of patients after combination of TACE and PEI (100% and 72% after 1 and 3 years), compared to repeated TACE alone[13]. Allgaier *et al* found a survival benefit of patients stratified to combination of TACE and PEI (*vs* PEI alone) due to a lower recurrence rate [11]. Koda *et al* showed superior survival after 1, 3, and 5 years (100%, 80%, and 40%) for patients after combination treatment (*vs* PEI alone), and Kamada *et al* recorded 1-, 3-, and 5-year survival rates of 90%, 65%, and 50% after combination treatment[12,14].

Our results are hence in line with the above data; however, there are differences in terms of patient criteria. The former studies did apply comparatively strict inclusion criteria in terms of tumor number and size. It should be noted that the patients consecutively included into the present study were in more advanced stages of both tumor extent and liver cirrhosis. Being a liver transplantation center in Northern Germany, advanced stages of tumor extent and cirrhosis were included in an attempt to prolong survival of those patients awaiting possible liver transplantation: patients with multinodular disease up to 5 tumors with less than 5 cm diameter or singular tumors up to 7 cm in diameter were primarily stratified to combination treatment. In this setting, the present survival data were higher than expected. The overall survival of our patients after combination therapy is comparable to reported survival data of tumor-free patients with liver cirrhosis[30]. Consequently, the present combination treatment of HCC can be considered effective for our patients with advanced disease.

The 10 patients with large (>7 cm) or multiple ($n > 5$) tumors who were switched from repeated TACE treatment to secondary PEI after re-evaluation (Figure 1), were indeed amenable to secondary PEI after receiving initial TACE as stated by other investigators[31]. Interestingly, 1-, 3-, and 5-year survival of this group (91%, 40%, and 30%) was comparable to those patients with limited disease who were primarily stratified to combination treatment (90%, 52%, and 43%) (Figure 3). From our experience it may be advisable to reconsider patients for PEI even after repeated TACE treatment, especially if TACE therapy cannot be continued.

The 1-, 3-, and 5-year-survival of the 20 patients with severely impaired liver function and advanced tumors, who were switched to repeated PEI after initially being stratified to best supportive care, was comparatively poor (50%, 23%, and 12%). However, it was superior to a large set of patients treated by best supportive care only or systemic therapy from our institution (1- and 3-year-survival: 32% and 2%)[24]. Large tumors can technically be treated by PEI as a salvage therapy, however, at the increasing risk of systemic, toxic side-effects and other severe complications as previously suggested[9]. From our experience we would not generally recommend single-session PEI as a salvage therapy in patients with both disseminated disease and severely impaired liver function who cannot receive TACE as initial treatment. Still, there may be patients in this group who might profit. It seems as if sufficient clinical status and/or the effect of initial TACE before PEI is needed to enhance anti-tumoral activity and survival.

In the multivariate analyses the parameters of limited tumor size and number, no ascites prior to therapy, and stable levels of CHE under therapy were associated with better survival. The type of treatment administered seemed to have independent predictive value, however, the significance of this result may be reduced due to the limited patient numbers (Table 2). Although screening programs improved the early detection of HCC, large non-resectable tumors are still frequently encountered and remain a major therapeutic challenge[32]. As expected, tumor size did affect survival. This might be explained by the fact that small tumors tend to have lower gradings than large tumors. Histological studies revealed that tumors up to 3 cm diameter are mostly well differentiated while large tumors are in general less differentiated[18,33,34]. Furthermore, there is a greater risk in larger HCC of peripheral satellite tumors that escape pre-treatment staging[35]. The functional status of the liver has been known to be a major predictor in PEI treatment as it is reflected in the significance of pre-treatment ascites and CHE-levels under therapy in the present study[19]. Both TACE and PEI might further impair the remaining liver function. The regeneration of functional liver parenchyma is possibly delayed as indicated by decreased liver synthesis parameters after treatment (data not shown).

While regular PEI is considered a low-risk procedure, severe complications, including death have been reported[36-38]. In the present study on repeated single-session PEI in advanced tumors the overall complication

rate was 25.7% (n = 69) including 8.9% (n = 24) major complications, however, all could be managed non-surgically. We consider these instances acceptable because single session PEI represents a more aggressive approach than regular PEI[37]. Giorgio *et al* stated a mortality of 1.8% after single-session PEI[31]. There were also three deaths (2.8%) within 14 days after PEI among our patients. Two patients died with the signs of right ventricular decompensation, one patient with a hypertensive crisis followed by an apoplectic insult. Although there was no direct link to PEI, a connection seems possible, as other authors stated cases of pulmonary hypertension after PEI were possibly due to shunting[23]. We did not observe any instance of needle track seeding, as described by others[21].

In conclusion, in our set of patients with advanced non-resectable HCC the combination of TACE and repeated single-session PEI is effective and shows superior results compared to repeated single-session PEI alone. Even for patients with large (>7 cm) or multiple (n > 5) tumors initially stratified to repeated TACE treatment alone PEI treatment is effective in terms of survival at an acceptable complication rate. The predictors including limited tumor size and number, no pre-treatment ascites, and stable levels of CHE under therapy are independently associated with better survival. Our experience further suggests that in advanced disease carefully tailored combination therapy is more advantageous than single therapy. The optimal strategy against advanced HCC, however, has still to be determined by future trials.

Abstract

AIM: To assess if a specific cytotoxic T cell response can be induced in patients with malignant liver tumors treated with radio-frequency ablation (RFA).

METHODS: Six Patients with liver metastases of colorectal cancer and 6 with hepatocellular carcinoma (HCC) underwent RFA. Blood was sampled before, 4 and 8 wk after RFA. Test antigens were autologous liver and tumor lysate obtained from each patient by biopsy. Peripheral T cell activation was assessed by an interferon gamma (IFNγ) secretion assay and flow cytometry. T cells were double-stained for CD4/CD8 and IFNγ to detect cytotoxic T cells. The ratio of IFNγ positive and IFNγ negative T cells was determined as the stimulation index (SI). To assess cytolytic activity, T cells were co-incubated with human CaCo colorectal cancer and HepG2 HCC cells and release of cytosolic adenylate kinase was measured by a luciferase assay.

RESULTS: Before RFA SI was 0.021 (± 0.006) for $CD4^+$ and 0.022 (± 0.004) for $CD8^+$ T cells against nonmalignant liver tissue and 0.018 (± 0.005) for $CD4^+$ and 0.021 (± 0.004) for $CD8^+$ cells against autologous tumor tissue. Four weeks after RFA SI against tumor tissue increased to 0.109 (± 0.005) for $CD4^+$ and 0.11 (± 0.012) for $CD8^+$ T cells against HCC, and to 0.115 (± 0.031) for $CD4^+$ and 0.15 (± 0.02) for $CD8^+$ cells for colorectal metastases ($P < 0.0001$). No increased SI was observed with nonmalignant tumor tissue at all time points. Before RFA cytolytic activity against the respective cancer cells was low with 2.62 (± 0.37) relative luminescence units (RLU), but rose more than 100 fold 4 and 8 wk after RFA. Spontaneous release was < 2% of maximum release in all experiments.

CONCLUSION: Patients with primary and secondary tumors of the liver show a significant tumor-specific cytotoxic T-cell stimulation with a dramatically increased tumor specific cytolytic activity of $CD8^+$ T cells after RFA.

INTRODUCTION

Open surgery is still the gold standard for the treatment of hepatocellular carcinoma (HCC) and liver metastases of colorectal cancer. However, more than 75% of these patients are non-resectable for various reasons, such as size and location of the tumor. Radio-frequency thermal ablation (RFA) is a common therapy option for unresectable liver tumors. Thus it was shown that RFA and laser-induced thermo-therapy (LiTT) can achieve survival times comparable to surgery in selected patients[1-3]. RFA uses a radio-frequency current to induce coagulation necrosis which results in a local thermal necrosis accompanied by

local inflammation around the necrotic center and by a hemorrhagic rim with lymphoplasmacellular infiltrates[4]. This rim is supposed to be a hot spot for recruitment and activation of tumor-specific T lymphocytes. By using the VX2 hepatoma model in rabbits we could show that RFA can induce a strong mononuclear infiltration around the implanted tumor. It remained unclear if the observed T cell response was merely directed to papilloma viral antigens that are derived from the VX2 hepatoma compared to a tumorspecific T-cell reaction. However, we could recently demonstrate a marked tumor-specific peripherial T cell response in RFA-treated *vs* untreated rabbits with the VX2 hepatoma[5].

The aim of the present study was to demonstrate if an antitumor T cell response is also inducible in patients who are subjected to RFA. Therefore, we studied the cytotoxic ($CD8^+$ and $IFN\gamma^+$) T cell and T-helper cell ($CD4^+$ and $IFN\gamma^+$) response of peripheral blood mononuclear cells (PBMC) against autologous nontumoral and tumoral liver tissue in patients with primary and secondary neoplasms of the liver. In addition, we measured the cytolytic activity of the $CD8^+$ and $IFN\gamma^+$ T cells against CaCo colorectal cancer and HepG2 HCC cells.

MATERIAL AND METHODS

The study was approved by the ethical committee of the University of Erlangen-Nuremberg and performed according to the declaration of Helsinki. All treated hepatocellular carcinomas and colorectal cancer metastases were confirmed histologically prior to therapy. All patients enrolled into the study signed an informed consent prior to inclusion.

Patients

In this preliminary group patients with up to 3 tumor nodules within the liver, with a maximum diameter of 6 cm per lesion, were enrolled in the study. Prior local ablative therapy (LiTT, RFA, ethanol injection) or prior chemoembolisation of the malignant liver tumor was an exclusion criterion. Additionally, a curative option by resection or liver transplantation was ruled out. Patients with at least one of the following findings were also excluded: Karnofsky index < 60, thrombocytes < 50 000μL, prothrombin activity < 50%, partitial thromboplastin time > 80 s. No transfusion of platelets or fresh frozen plasma was allowed. Informed consent was obtained from every patient no later than 24 h before treatment.

The size and number of tumor nodules were determined sonographically and by means of computerized tomography (dynamic spiral CT with *iv* application of contrast medium) prior to RFA.

Twelve consecutive patients (10 male, 2 female) with 14 tumors who met the inclusion criteria were enrolled. Mean patient age was 74 years (range 59 to 80 years). Six patients with six tumors had liver metastases from colorectal cancer, six patients with eight tumors had HCC (Table 1). All patients with HCC had underlying liver cirrhosis (Child A: $n = 4$, Child B: $n = 2$) due to chronic hepatitis C ($n = 2$) or alcohol ($n = 4$). Mean tumor size was 32 mm (range 10 to 51 mm) with two tumors up to 20 mm, six between 21 and 40 mm and six larger than 40 mm. Mean tumor diameter was 35 mm for HCC (range 24 to 45) and 30 mm for the liver metastases (range 10 to 51mm)

CP: Child Pugh-Score of patients with liver cirrhosis; LC: liver cirrhosis; SI: Stimulation index, showing the ratio of IFNγ secretion of stimulated *vs* unstimulated T cells; HCC: hepatocellular carcinoma ; CRC metastasis: patients with colorectal cancer metastatic to the liver; Primary: location of the primary tumor; m.d.: missing data. [b]$P < 0.0001$ *vs* SI before RFA.

RF ablation technique

The whole procedure was performed under ultrasound guidance (Elegra Advanced®, Siemens, Erlangen, Germany) under sterile conditions. The proposed puncture site was infiltrated with a local anesthetic (2% mepivacain hydrochloride) and the perfused radio-frequency (HF) needle (Berchtold, Tuttlingen, Germany) advanced into the tumor under sonographic guidance. Midazolam (0.5-5 mg) and/or pethidin (25-100 mg) were administered iv as necessary. Patients were monitored by pulse oximetry during the entire procedure.

RFA needle applicators of 2 mm (14 G) diameter and a 15 mm active electrode with microbores were used. During HF application (40 W power output) the RFA needle was continuously perfused with isotonic saline via the bore holes. RF energy was delivered by a computer-assisted radiofrequency generator (Elektrotom 106 HF®, Berchtold, Tuttlingen, Germany) and continuous perfusion of the RFA needle was secured by a syringe pump (Pilot C, Fresenius Medical Care, Alzenau, Germany) linked to the RF generator. Perfusion was adjusted as to impedance by

means of an electronic interface between generator and perfusor, automatically increasing in response to a rise in impedance (> 400 Ohm). The RF energy was applied for 10-15 min at each needle position, leading to a coagulation zone of 30-35 mm in diameter. Tumors larger than 20 mm were targeted from different applicator positions to create overlapping coagulation zones, in order to treat the entire lesion with a safety margin > 5 mm. Larger tumors were treated with up to 3 simultaneous needle insertions arranged in a triangle (2 to 4 cm) or square (for larger tumors). After completion of the procedure patients were required to rest in bed for 4 h.

IFNγ secretion assay and lymphocyte staining

Heparinized blood (LI-Heparin 10 mL) was obtained before, 4 and 8 wk after RFA. The samples were stored at 4℃ and tests performed < 12 h after sampling. A liver biopsy of nontumorous and tumorous tissue was obtained from every patient directly before RFA and stored at -20℃.

Tissue-lysates were freshly prepared in cold phosphate buffer (50 mmol/L, pH 7.2) using a glass homogenizer as described[5]. The suspension was filtered with a filter tip (pore size 1.2 μm) to adjust the fragment size to less than 1.2 μm. The protein concentration was measured photometrically according to Bradford and adjusted to 1 mg/mL, followed by sterilization at 600 Gy.

Autologous test antigens (nontumorous liver and tumor lysate, 12.5 μg) were added to 250 μL heparinized blood and cultured in a 15 mL conical polypropylene tube for 16 h at 37℃ under 50 mL/L CO_2. A negative control without addition of antigen lysate was included, while staphylococcal enterotoxin B served as positive control antigen. Thereafter the samples were put on ice and washed with ice cold washing solution (phosphate buffer saline containing 0.5% bovine serum albumin and 2 mmol/L EDTA, pH 7.4) and the cell suspension centrifuged at 300 g for 10 min at 4℃. The cell pellet was resuspended with 80 μL cold culture medium (RPMI 1640 containing 10% human AB serum). "Catch" reagent (20 μL) containing a bivalent CD45 capture and IFNγ binding antibody (Miltenyi Biotec GmbH, Bergisch Gladbach, Germany) were added, the suspension was kept for 5 min on ice and after adding 5 mL culture medium the cells were incubated in closed roller tubes for 45 min at 37℃. Thereafter 20 μL phycoerythrin (PE) labelled IFNγ detection antibodies diluted 1:5 as well as 10 μL fluoresceine-thiocyanate (FITC) labelled anti-CD 4 or anti-CD8 antibodies diluted 1:400 (both from Miltenyi Biotec GmbH, Bergisch Gladbach, Germany) were added to the cooled and washed cells and incubated for 10 min on ice. Five mL erythrocyte lysis buffer, containing 0.155 mol/L NH_4Cl, 10 mmol/L $KHCO_3$ and 0.1 mmol/L EDTA diluted 1:10, were added for 10 min and the cells centrifuged at 300 g for 10 min. The washed cells were resuspended in 500 μL cold washing buffer and immediately analysed in a flow cytometer (FACSCalibur, BD Biosciences, Heidelberg, Germany) after addition of 0.25 μg propidium iodide in 5 μL destilled water. FACS data were evaluated using WinMDI Version 2.8 (free version by Joseph Trotter).

T-cell conservation

PBMC containing T cells were isolated in Leukosep separation tubes by density-gradient centrifugation (PAA Laboratories GmbH, Vienna, Austria). After repeated washing with PBS (Biochrom, Berlin, Germany) containing 50 000 IU/liter heparin (Liquemin N 25 000; Roche, Grenzach-Whylen, Germany), cells were adjusted to a concentration of 10^6 cells/mL and cultured in RPMI 1640 (Biochrom) containing 10% AB serum (heat-inactivated and sterilized at 600 Gy), 5% HEPES buffer, and 1 μg/mL penicillin/streptomycin.

For further experiments 5 Mio PBMC were resuspended in 1.8 mL cold freezing medium, containing 80% AB serum and 20% DMSO (Sigma-Aldrich, Seelze, Germany), and stored at -80℃. After 24 h cells were transfered into liquid nitrogen for long term storage.

For revitalization cells were defrosted in a waterbath at 37℃ and were immediately diluted in warm culture medium (RPMI 1640 (Biochrom) containing 10% AB serum (heat-inactivated and sterilized), 5% HEPES buffer, and 1 μg/mL penicillin/streptomycin).

Cytotoxicity Assay

Cytolytic activity of T-cells was measured by an adenylate kinase (AK) release assay. 10 000 target cells were incubated with 1000 effector cells in a final volume of 200 μL fetal calf serum growth medium (FCS-GM) in round-bottom 96-well microtiter plates. After incubation for 4 h at 37℃ 100 μL of supernatant were harvested and stored at -20℃ for further analysis.

The human hepatocellular carcinoma cell line HepG2 and the human colorectal cancer cell line CaCo served as target cells for the patients suffering from HCC and colonic cancer metastases, respectively. All cell-lines were HLA matched (ABO-system) and tested before.

Maximum AK release was obtained by incubating target and effector cells with 1% v/v Triton-X-100, and baseline AK release with medium alone. Baseline release from T cells and tumor cells was < 10% of maximal release in all experiments and subtracted from each value.

The activity of AK was determined by detection of autoluminescence using a luciferase assay (ToxiLight Kit, Cambrex Corporation, NJ, USA). Twenty μL of supernatant were incubated with AK-detection reagent (Cambrex Corporation, NJ, USA) for 5 min at room temperature. The bioluminescence was measured by a luminometer (BD Monolight 3096 Microplate Luminometer, BD Biosciences, Heidelberg, Germany) and expressed as relative luminescence units (RLU).

Statistical analysis

The stimulation index of $CD4^+$ and $CD8^+$ T cells (SI) was determined by the ratio of $IFN\gamma^+$ *vs* $IFN\gamma^-$ $CD4^+$ and $CD8^+$ T cells, respectively, and calculated with Excel® 2000 software (Microsoft, Seattle, USA). Results were analyzed statistically by the SPSS® software package (Version 11.01 d, SPSS GmbH Software, Munich, Germany). SI values were divided into 2 groups according to the histological origin of the tumors. SI values were calculated numerically (Table 1) and are presented as Box-Whisker plots (Figure 1). The

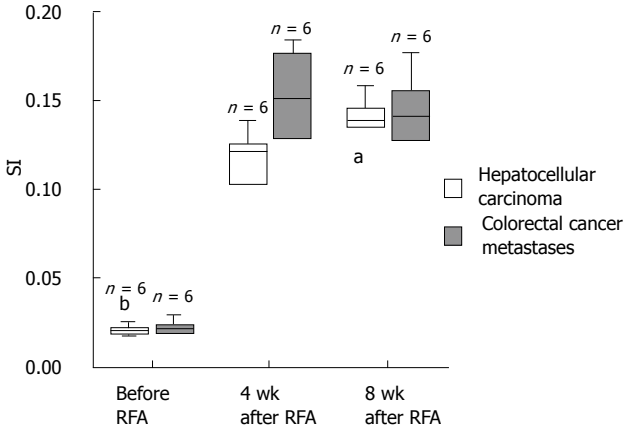

Figure 1 Stimulation indices of $CD8^+$ T cells. The Box-Whisker-plots show the ratio of IFNγ secretion of stimulated *vs* unstimulated $CD8^+$ T cells as determined by a cytokine secretion and capture assay before, 4 and 8 wk after RFA. White boxes represent the patients with HCC and grey boxes the patients with colorectal cancer metastases. Outlayers are marked with "a", extremes with "b". For significances refer to table 1.

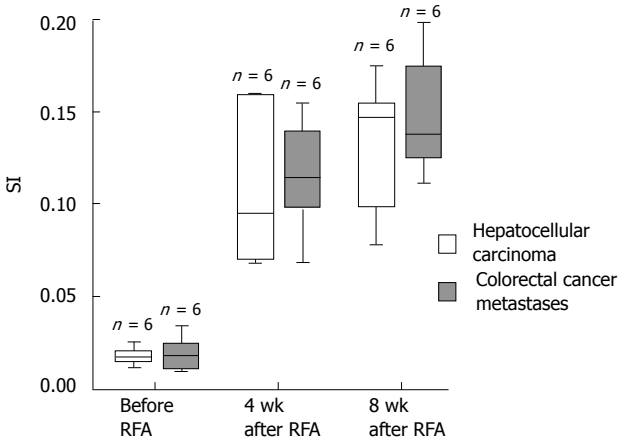

Figure 2 Stimulation indices of $CD4^+$ T cells. The Box-Whisker-plots show the ratio of IFNγ secretion of stimulated *vs* unstimulated $CD4^+$ T cells as determined by a cytokine secretion and capture assay before, 4 and 8 wk after RFA. White boxes represent the patients with HCC and grey boxes the patients with colorectal cancer metastases. Outlayers are marked with o, extremes with *. For significances refer to table 1.

significance of the enhanced SI after RFA treatment was tested with the Wilcoxon test for dependent samples. A *P*-value less than 0.05 was considered significant.

RESULTS

A total of 26 needle insertions were performed for 12 patients, i.e., 2.2 sessions per patient (range 1 to 3 sessions). Complete remission was achieved in all 12 patients. 2 patients developed a local recurrence within 4 months. One patient could be successfully retreated. The other patient with liver metastases from colorectal carcinoma could not be retreated successfully. Distant recurrences did not occur within the mean follow up-period of 6 months.

The cytokine secretion and capture assay showed that autologous nontumorous control liver tissue did not stimulate IFNγ secretion of circulating T cells before or after RFA. Before RFA: $SI_{[CD4+]} = 0.018$ (± 0.007) and $SI_{[CD8+]} = 0.019$ (± 0.004); 4 wk after RFA $SI_{[CD4+]} = 0.017$ (± 0.005) and $SI_{[CD8+]} = 0.019$ (± 0.008); 8 wk after RFA: $SI_{[CD4+]} = 0.018$ (± 0.006) and $SI_{[CD8+]} = 0.016$ (± 0.007). When exposed to autologous tumor tissue all patients displayed a mean $SI_{[HCC\ CD4+]}$ of 0.018 (± 0.005) and $SI_{[CRC\ CD4+]}$ of 0.019 (± 0.009) and $SI_{[HCC\ CD8+]}$ of 0.021 (± 0.005) and $SI_{[CRC\ CD8+]}$ of 0.021 (± 0.004) before RFA (Table 1).

Four wk after RFA all patients showed a strong increase of $IFN\gamma^+$ and $CD8^+$ cytotoxic T cells and $CD4^+$ T helper cells directed against autologous tumor tissue ($SI_{[HCC\ CD4+]} = 0.109$ (± 0.042); $SI_{[HCC\ CD8+]} = 0.120$ (± 0.012); $SI_{[CRC\ CD4+]} = 0.115$ (± 0.031); $SI_{[CRC\ CD8+]} = 0.150$ (± 0.028)). This increase was highly significant both for the patients with HCC and with colorectal cancer metastases ($P < 0.0001$) and was maintained until 8 wk after RFA (Table 1, Figures 1 and 2).

Four wk after RFA PBMC of both groups, HCC and metastasis patients, presented a highly elevated cytotoxic activity with a mean release of adenylate cyclase (AK, as represented by RLU) of 580.24 (± 190.81) and 677.15 (± 138.38) for HCC and colorectal cancer metastasis, respectively. This was maintained 8 wk after RFA with RLU values of 784.96 (± 181.73) and 954.59 (± 275.42). All data were highly significant compared to the baseline before RFA, with 4.42 RLU (± 0.68) for HCC and 2.62 RLU (± 0.37) for colorectal cancer metastasis ($P < 0.001$). The spontaneous release of AK was always < 2% of the maximum release (Figure 3 and Table 2).

DISCUSSION

Thermal treatments such as RFA or LiTT are increasingly used in the therapy of unresectable liver tumors. Survival of treated patients is encouraging. Thus for patients with liver metastases of colorectal cancer, 2 and 5 year survival rates after LiTT of 74% and 30%, respectively,[2, 3], and a 2 year survival of 67% after RFA[6] were reported. These data are comparable with results of surgical resection that can lead to 2 and 5 year survival rates of 64% and 28%, respectively, and to disease free survival rates of 35 and 15% for patients with liver metastases of colorectal cancer. Similar results have been obtained for patients with HCC[7, 8]. Here again, minimal invasive treatments seem to offer the same survival benefit as open surgery[9,10]. It appears improbable that the achieved results can merely be explained by physical effects like thermal tumor ablation or by a favourable patient selection in case of the nonsurgical group, since patients treated with RFA (or LITT) are often not eligible for hepatic resection due to poor liver function or advanced tumor disease.

Immunotherapy through T cell vaccination or vaccination with dendritic cells is regarded as a promising strategy for the treatment of various tumor entities such as malignant melanomas[11-16], and high expectations have been placed on cytokine-modulated immunotherapies for hepatic tumors[17,18]. It is well known that RFA can induce an unspecific immune stimulation[4]. Thus thermal coagulation causes an inflammatory reaction with lymphoplasmacellular infiltration that can be visualized as a hypervascular rim in contrast CT and contrast-enhanced ultrasound[19]. This

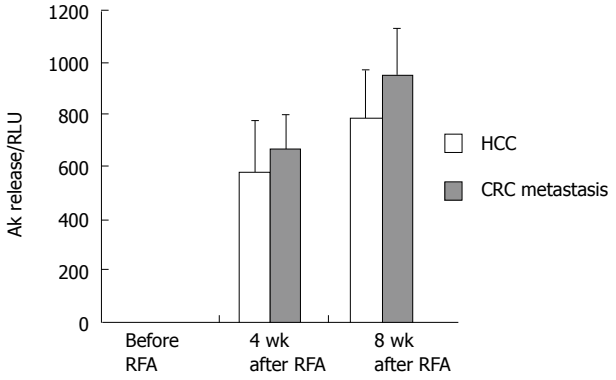

Figure 3 Adenylate kinase (AK) release of cultured tumor cells. Release of adenylate kinase (AK) from the human hepatoma cell line HepG2 and the hman colorectal carcinoma cell line CaCo co-incubated with PBMC isolated before, 4 and 8 wk after RFA. The release of AK correlates with the cytotoxic and NK T cell mediated damage to the cultured cells. HepG2 cells were used for PBMC from the patients with HCC and CaCo cells for the patients with metastasis of colorectal carcinoma.

hypervascular rim can be so intense as to impede proper assessment of treatment success.

We could recently demonstrate a specific T cell response towards the VX2-tumor implanted in rabbit livers after RFA was performed[5]. The VX2 hepatoma is a papilloma virus-induced tumor[20] which contains viral genomes[21] that are immunogeneic themselves. However, the vigorous T cell reaction was shown not to be directed against viral, but the non-viral tumor antigens. Thus the significantly prolonged survival of RFA-treated animals observed in preliminary studies[5,22,23] supports the hypothesis that tumor immunity induced by in situ vaccination via thermal necrosis may play an important role in the clinical effect of RFA.

It remained to be proven if RFA induces a tumor specific T cell reaction also in humans with hepatic tumors. In the present preliminary study we could clearly demonstrate that patients with HCC or colorectal cancer metastases experienced a 5-6 fold rise of peripheral tumor-specific IFNγ^+, CD4$^+$ T helper cells and CD8$^+$ T killer or cytotoxic T cells[24] 4 wk after RFA. Furthermore, this effect was maintained until 8 wk after RFA. The cytotoxic activity of the T cells derived from PBMC showed a dramatical, up to 300 fold increase compared to baseline already 4 and 8 wk after RFA as well.

Two patients with local recurrence (patient HCC4 and CRC 4 in Table 1 and 2) displayed a lower cytotoxic activity against the cancer cells (96.8 and 157.7 RLU 8 months after RFA), as compared to 2 patients without recurrence (patient HCC 2 and CRC 5 with 739.4 and 1004.6 RLU 12 mo after RFA). Due to the low number of cases this observation is not significant and has to be confirmed in a larger group of patients.

Thus it appears that the coagulation of tumor tissue through RFA leads to the enhanced release, exposure and/or denaturation of tumor antigens. Thermally altered tumor antigens are more likely to be phagocytosed by professional antigen presenting cells like dendritic cells[25]. In conjunction with the generation of thermally altered tumor antigens the unspecific inflammatory stimulus induced by RFA might help to overcome immune-tolerance or anergy towards the transplanted tumor, a common phenomenon observed in solid tumors[26,27]. The pro-inflammatory effects of necrotic cells are well documented and appear to be caused by the release of endogenous adjuvants, such as the nuclear protein high mobility group B1 (HMGB1) and heat shock proteins such as hsp70 or gp96[28-30]. RFA thus appears to create an in situ environment resembling T cell vaccination ex vivo.

Our study does not permit conclusions as to whether the stimulation of tumor-specific T cells was solely due to the creation of thermal necrosis, to the instillation of hot saline solution or to the application of a high-frequency current. The relevance and the impact of RFA-induced generation of tumor-specific cytotoxic and NK T cells for potential future multimodal antitumor therapies has to be investigated in prospective randomized multi center trials.

Table 2 Relative luminescence units (RLU) of cytosolic adenylate kinase released from the hepatoma cell line HepG2 for HCC patients and the colorectal carcinoma cell line CaCo for patients with colorectal carcinoma metastatic to the liver

Tumor entity	CP	Etiology of cirrhosis	AK release before RFA	AK release 4 wk after RFA	AK release 8 wk after RFA
HCC 1	A	alcohol	4.8	398.46	535.87
HCC 2	A	Hep C	3.26	421.66	645.9
HCC 3	B	Hep C	4.88	578.63	845.99
HCC 4	A	alcohol	3.95	865.66	1025.21
HCC 5	B	alcohol	5	465.7	732.13
HCC 6	A	alcohol	4.66	751.33	924.66
Mean			4.42	580.24[b]	784.96[b]
(SD)			0.68	190.81	181.73

Tumor entity	Primary	AK release before RFA	AK release 4 wk after RFA	AK release 8 wk after RFA
CRC metastasis 1	Sigma	2.13	568.32	816.55
CRC metastasis 2	Colon	3	947.47	1298.25
CRC metastasis 3	Colon	2.79	627.55	945.33
CRC metastasis 4	Sigma	2.56	699.45	845.54
CRC metastasis 5	Rectum	2.98	598.65	932.17

Abstract

AIM: To study the amino acid substitutions in the carboxy (C)-terminal part of E2 protein and in the interferon (IFN) sensitivity determining region (ISDR) and their correlation with response to IFN and viral load in 85 hepatitis C virus (HCV)-1b-infected patients treated with IFN.

METHODS: The C-terminal part of E2 (codons 617-711) including PKR/eIF2α phosphorylation homology domain (PePHD) and ISDR was sequenced in 85 HCV-1b-infected patients treated by IFN monotherapy.

RESULTS: The amino acid substitutions in PePHD detected only in 4 of 85 patients were not correlated either with response to IFN or with viral load. The presence of substitutions in a N-terminal variable region (codons 617-641) in the C-terminal part of E2 was significantly correlated with both small viral load (33.9% *vs* 13.8%, $P = 0.0394$) and sustained response to IFN (25.0% *vs* 6.9%, $P = 0.0429$). Four or more substitutions in ISDR were significantly correlated with both small viral load (78.6% *vs* 16.2%, $P < 0.0001$) and sustained response to IFN (85.7% *vs* 2.9%, $P < 0.0001$). In multivariate analysis, ISDR in nonstructural (NS) 5A ($OR = 0.39$, $P < 0.0001$) and N-terminal variable region ($OR = 0.51$, $P = 0.039$) was selected as the independent predictors for small viral load, and ISDR ($OR = 39.0$, $P < 0.0001$) was selected as the only independent predictor for sustained response.

CONCLUSION: The N-terminal variable region in the C-terminal part of E2 correlates with both response to IFN monotherapy and viral load and is one of the factors independently associated with a small viral load.

INTRODUCTION

Hepatitis C virus (HCV) is one of the most frequent and important causes of chronic viral hepatitis and approximately 170 million people are infected with the virus worldwide[1]. HCV usually causes chronic infection, which can result in chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma[2].

Interferon (IFN) monotherapy and combination therapy of IFN and ribavirin have been shown to be effective for eradicating chronic HCV infection[3,4]. Genotype 1b is resistant against antiviral therapy[5], and viral load is known as a predictor for response to IFN mono therapy[6]. While the combination therapy has significantly improved the effectiveness for patients with large viral load of genotype 1b, viral load still determines

the outcome of treatment[7].

RNA-activated protein kinase (PKR) is a mediator of IFN-induced antiviral resistance. PKR-binding domain (PKR-bD) comprising the interferon sensitivity determining region (ISDR) within the nonstructural (NS) 5A protein is known to be potentially important for antiviral therapy outcome. However, reported results concerning the correlation of the substitutions within PKR-bD/ISDR to treatment outcome are conflicting[8-12].

A PKR/eIF2α phosphorylation homology domain (PePHD, codons 659-670) within the carboxy (C)-terminal part of E2 protein has been found to interact with PKR and inhibit PKR in vitro, suggesting a possible mechanism of HCV to evade the antiviral effects of IFN[13]. Several studies have concluded that a correlation of substitutions in PePHD does not exist[14-17], while only 3 others have confirmed it[18-20]. PePHD-deleted HCV-1 mutants remain capable of binding to PKR to some extent, while C-terminal-truncated E2 protein loses activity of inhibiting PKR. Thus regions other than PePHD within C-terminal part of E2 protein may interact with PKR. It is possible that the mutations in regions other than PePHD within C-terminal part of E2 protein may correlate with response to IFN. Sarrazin *et al*[21] reported that substitutions in C-terminal part of E2 are linked with response to antiviral therapy.

In the present study, we investigated the amino acid substitutions in the C-terminal part of E2 protein and in ISDR and their correlation with response to IFN and viral load in 85 HCV-1b infected patients treated with IFN.

MATERIALS AND METHODS

Patients

Eighty-five patients infected with HCV genotype 1b, were retrospectively analyzed (Table 1). The patients received various IFN preparations in various schedules of administration. Thirty-six patients received lymphoblastoid IFNα, 14 IFNα 2a, 18 natural IFNβ, 3 IFNα 2b and 14 both lymphoblastoid IFNα and natural IFNβ. Total dose of IFN was 200-400MU in 32, 400-600MU in 40, and 600MU or more in 13 patients. All patients were positive for both serum anti-HCV antibody (second generation enzyme immunoassay, Abbott laboratories, North Chicago, IL) and serum HCV RNA (Amplicor HCV test, Nippon Roche, Tokyo). HCV genotype was determined as previously described[22] and classified according to Simmonds' the classification of simmonds *et al*[23]. Viral load was measured by branched DNA assay (Quantiplex HCV RNA assay, version 2, Chiron Corp., Emeryville, CA). Histological evaluations were done according to the grading and staging suggested by Desmet *et al*[24].

Patients who obtained normalization of alanine aminotransferase (ALT) levels and HCV RNA clearance for more than 6 mo after IFN therapy were considered as sustained virological responders (SVR). The other patients were grouped as nonresponders.

This study was approved by the local committee on medical ethics and adhered to the guidelines of the 1975 Declarations of Helsinki.

Table 1 Characteristics of patients with different response to IFN therapy

Sequencing of the C-terminal part of E2 protein comprising PePHD

HCV RNA was extracted from 100 μL of patients' sera before IFN therapy by Sepa Gene RV-R™ (Sanko Junyaku Co. Inc., Tokyo). cDNA was prepared from extracted RNA by reverse transcription using the random primer (Takara, Ohtsu, Japan). Nested polymerase chain reaction (PCR) was done for amplifying the C-terminal part of the E2 protein comprising PePHD (nt 2178-2462). Four primers designed from the nucleotide sequences of HCV-J were used for the nested PCR. The 1st round of PCR was performed using the external primers (sense primer; nt 2127-2143; 5' -GGGCCCTGGTTGACACC-3', and anti-sense primer; nt 2508-2524; 5'-GCGGACGCGCGCGTCTG-3') and the 2nd round of PCR was performed using the internal primers (sense primer; nt 2157-2174; 5' -GACTACCCATACAGGCTC-3', and anti-sense primer; nt 2496-2515; 5'-TTCCTTCTTCTGGCGGA-3'). All rounds of PCR were done with Taq polymerase (Takara, Ohtsu, Japan) by the following protocol: 35 cycles of denaturation for 1 min at 95℃, annealing for 1 min at 55℃, and extension for 1 min at 72℃, and a final extension for 7 min at 72℃.

Sequencing was performed by the PCR direct sequencing method. Amplified DNA was isolated by agarose gel electrophoresis and purified by EASYTRAP™ Ver.2 (Takara, Ohtsu, Japan). The nucleotide sequence was determined by the dideoxy method using a dye terminator cycle sequencing kit (Perkin-Elmer Japan, Tokyo, Japan).

Sequencing of ISDR in NS5A

cDNA of ISDR in NS5A was prepared by reverse transcription using 5ASRAW primer (nt 7177-7197; 5'-GT GCCCATATGGGCAACGCTG-3') with RNA extracted from 50 μL of serum and then amplified by nested PCR with a DNA thermal cycler (Lobocycler 40; Stratagene, La Jolla, CA). The 1st round of PCR was performed using the external primers (sense primer 5SPDV; nt 6825-6844; 5'-C

CGGATGTGGCAGTGCTCAC-3', and anti-sense primer 5ASRAW. The second round of PCR was performed using the internal primers (sense primer 5STDV; nt 6853-6874; 5 '-TCACCGACCCCTCTCATATTAC-3', and biotin-labeled anti-sense primer 5IASPKR; nt 7141-7161; 5'-GTTTTCGC AGGATCTCCGCCG-3'). Twenty-nine cycles of PCR were done as follows: denaturation for 1 min at 94℃, annealing for 1.5 min at 56℃, and extension for 1.5 min at 72℃. The PCR products labeled with biotin were recovered with streptavidin-coated magnetic beads (Dynal, Oslo, Norway). The sequencing reaction was performed using a thermo sequenase fluorescent-labeled primer cycle sequencing kit (Amersham, Buckinghamshire, England) with Cy5-labeled 5ISKRR fluorescent primer (nt6887-6906; 5'-CA AGCGTAGGCTGGCCAGGG-3') under the conditions recommended by the kit supplier. The reaction mixture was applied to the ALFII DNA sequencer (Amersham Pharmacia Biotech, Tokyo, Japan). Identification of the substituted amino acid was performed using a KINOP alignment software system (Otsuka-Fujitsu Collaborative Development, Tokyo, Japan).

Phylogenetic tree construction

A phylogenetic tree was constructed to determine the genetic relation using the Neighbour-joining method[25].

Statistical analysis

Data were analyzed by Student's *t* test, chi-square test, and linear regression test for each applicable analysis. Multivariate analysis was done by discriminant analysis by stepwise forward selection method. $P < 0.05$ was considered statistically significant.

RESULTS

Response to IFN therapy

Sixteen of 85 patients had sustained virological response (Table 1). Viral load was significantly smaller in sustained virological responders than in non-responders ($P = 0.0027$). Stage of liver histology was significantly lower in sustained virological responders than in non-responders ($P = 0.0154$).

Sequences of C-terminal part of E2 protein

All of the obtained sequences were aligned. The most popular amino acid at each position was determined as the consensus sequence. Since there were two amino acids (isoleucine and valine) equally popular at codon 705, we considered both of them as the consensus sequences. The number of amino acid substitutions in the C-terminal part of E2 protein (codons 617-711) was 0 in 2, 1 in 13, 2 in 30, 3 in 22, 4 in 10, 5 in 3 and 6 in 5 patients respectively (Figures 1A and B).

Amino acid substitutions in PePHD were seen only in 4 out of 85 patients and did not correlate either with viral load or with response to IFN (Figures 1A and B).

The number of substitutions in the C-terminal part of E2 protein was significantly larger in sustained virological responders than in non-responders ($P = 0.0149$, Table 1). The patients with 4 or more substitutions in the C-terminal part of E2 protein had sustained virological response to IFN therapy [38.9% (7/18)] more frequently than those with less than 4 substitutions [13.4% (9/67)]($P = 0.0358$).

In the molecular-evolutional analysis with phylogenetic tree, we could not find any specific clustering either in sustained virological responders or in non-responders (Data not shown).

Table 2 Characteristics of patients with small or large viral load

	Patients with small viral load	Patients with large viral load	*P*
Patients (*n*)	24	61	
Age (yr)	52.5 ± 11.0	52.0 ± 11.1	NS
Male/female	19/5	42/19	NS
History of blood transfusion (+/-)	8/16	18/43	NS
ALT (IU/I)	89.3 ± 64.1	102.0 ± 67.6	NS
Viral load (Meq/mL)	0.5 ± 0.1	7.8 ± 7.9	0.0001
Histology			
Grade	2.2 ± 0.8	2.3 ± 0.8	NS
Stage	2.3 ± 0.8	2.4 ± 0.9	NS
Number of amino acid Substitutions in			
ISDR	3.3 ± 2.5	0.8 ± 1.2	< 0.0001
C-terminal part of E2	3.1 ± 1.7	2.5 ± 1.2	NS
N-terminal variable region	1.5 ± 1.0	0.9 ± 0.9	0.0090
Substitution of aa 625 (+/-)	7/17	7/54	NS

N-terminal region in the C-terminal part of E2 protein

In the C-terminal part of E2 protein, there were four variable regions where amino acid sequences were variable (Figures 1A and B). The regions correlating with response to IFN and viral load were searched for. The number of substitutions in N-terminal variable region designated as variable region 1 was significantly larger in sustained virological responders than in non-responders ($P = 0.0148$, Table 1). The patients with substitutions in N-terminal variable region had sustained virological response to IFN therapy [25.0% (14/56)] more frequently than those without substitutions [6.9% (2/29), $P = 0.0429$]. The number of substitutions in N-terminal variable region was significantly larger in the patients with small viral load (HCV-RNA < 1Meq/mL) than in those with large viral load ($P = 0.0107$, Table 2). The patients with substitutions in N-terminal variable region had small viral load [33.9% (19/56)] more frequently than those without substitutions [13.8% (4/29), $P = 0.0394$]. Amino acid substitutions in other parts of C-terminal of E2 protein were not correlated with either viral load or sustained response to IFN therapy (Data not shown).

Specific amino acid substitutions correlated with viral load or with response to IFN therapy were searched for. Amino acid substitutions of threonine to serine at codon 625 were found to be significantly correlated with sustained virological response to IFN therapy ($P = 0.0213$) (Table 1).

Changes in sequences of C-termianl part of E2 after IFN therapy

The sequences of C-terminal part of E2 after IFN therapy

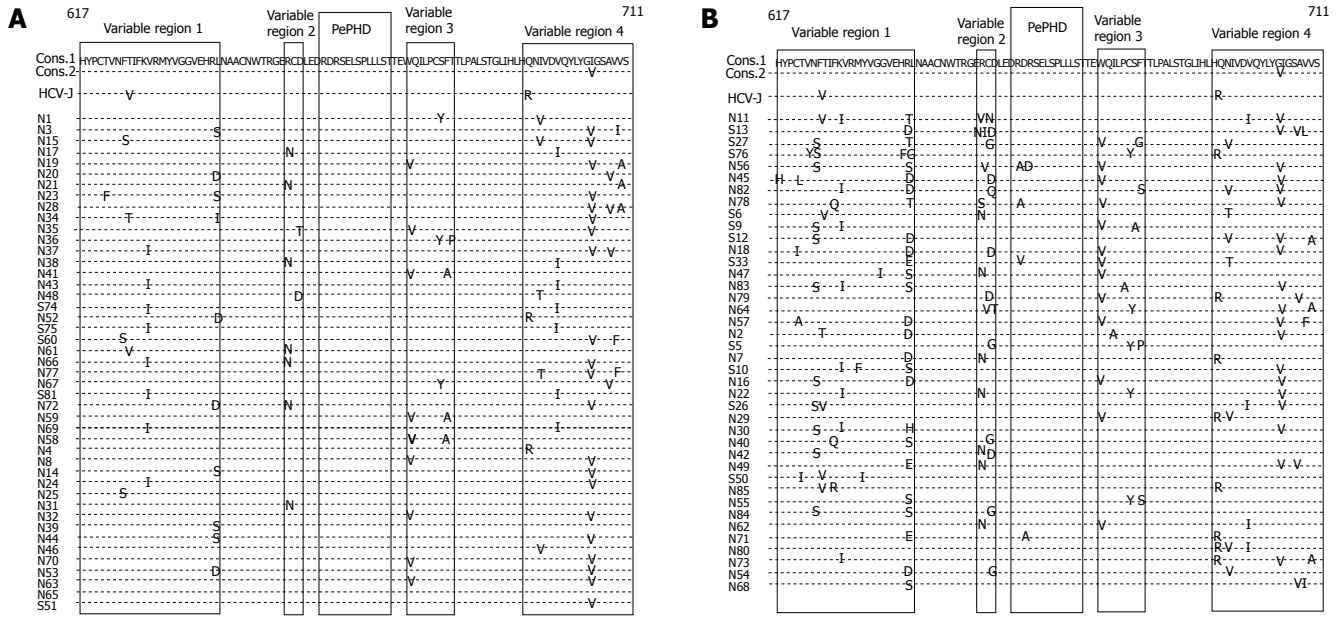

Figure 1 Amino acid sequences of C-terminal part of E2 protein with 0-2 substitutions (**A**) and 3-6 substitutions (**B**) in 45 and 40 HCV 1b-infected patients treated by IFN therapy respectively.

were determined in 16 non-responders (Figure 2). In 8 patients, the sequences did not change before and after IFN therapy, while in the other 8 patients, the sequences changed. The number of substitutions in C-terminal part of E2 decreased in 3 patients (from 5 to 2 in N45, from 3 to 2 in N7, and from 2 to 1 in N3), increased in 4 patients (from 2 to 3 in N28 and N36, and from 1 to 3 in N31 and N46), and did not changed in N38.

Sequences of ISDR

The sequences of ISDR were determined in 82 patients (Figure 3). The number of substitutions in ISDR was significantly larger in sustained virological responders than in non-responders ($P < 0.0001$, Table 1). The patients with 4 or more substitutions in ISDR had sustained virological response to IFN therapy [85.7% (12/14)] more frequently than those with less than 4 substitutions [2.9% (2/68), $P < 0.0001$]. The number of substitutions in ISDR was significantly larger in the patients with small viral load than in those with large viral load ($P < 0.0001$, Table 2). The patients with 4 or more substitutions in ISDR had small viral load [78.6% (11/14)] more frequently than those with less than 4 [16.2% (11/68), $P < 0.0001$].

Correlation between substitutions in C-terminal part of E2 and ISDR

The substitutions in C-terminal part of E2 and ISDR were significantly correlated with each other ($P = 0.026$, $r = 0.246$) (Figure 4). The number of substitutions in N-terminal variable region did not correlate with that in ISDR.

Multivariate analysis for factors independently associated with response to IFN therapy and viral load

In multivariate analysis, the number of substitutions in ISDR was selected as the only independent factor

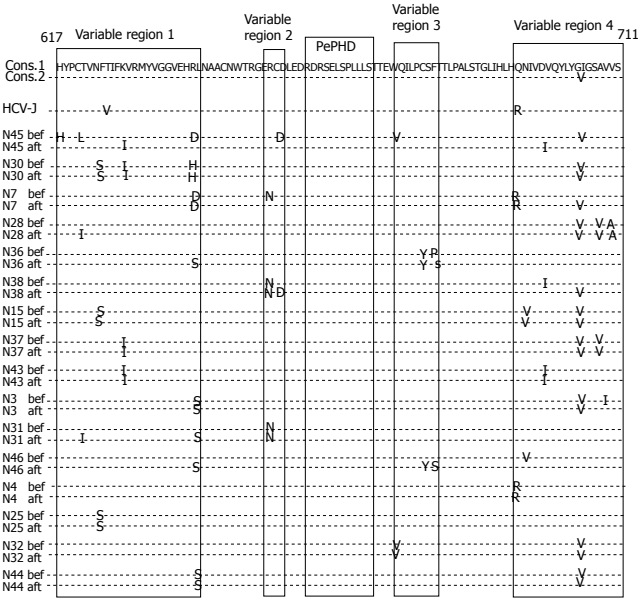

Figure 2 Amino acid sequences of C-terminal part of E2 before and after IFN therapy in 16 non-responders.

associated with sustained virological response to IFN therapy ($OR = 39.0$, $P < 0.0001$). The substitutions in ISDR ($OR = 0.39$, $P < 0.0001$) and N-terminal variable region ($OR = 0.51$, $P = 0.039$) were selected as the independent factors correlated with small viral load.

DISCUSSION

In the present study, the substitutions in C-terminal part of E2 were found to be significantly correlated with response to IFN therapy. Especially, the substitutions in N-terminal variable region were significantly correlated with response to IFN therapy and one of the factors independently

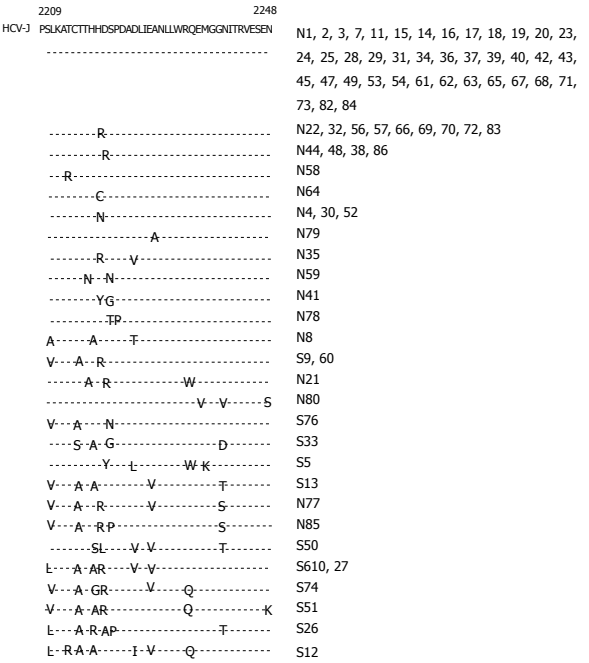

Figure 3 Amino acid sequences of ISDR in 82 HCV-infected patients.

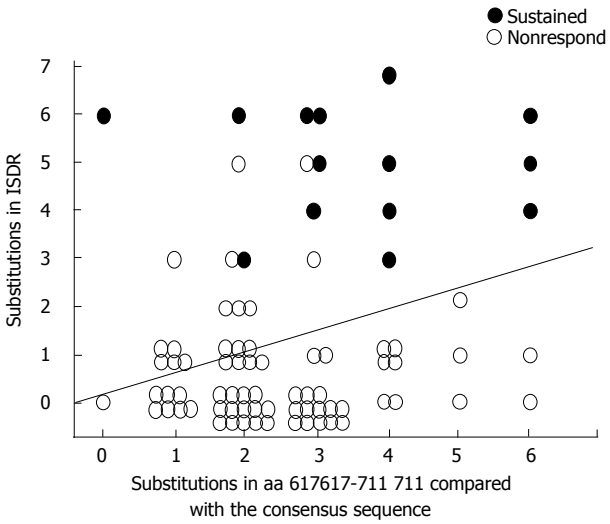

Figure 4 Correlation between the number of amino acid substitutions in ISDR and C-terminal part of E2 protein.

associated with small viral load. So far, only Sarrazin *et al*[21] have suggested the correlation of the substitutions in C-terminal part of E2 with response to antiviral therapy. They reported that normalized Shannon entropy as well as mean Hamming distances in C-terminal part of E2 are significantly lower in sustained responders than in non-responders by calculation of genetic complexity and diversity of amino acid sequences, although no significant correlation of specific mutations or number of mutations within C-terminal part of E2 with response to IFN therapy has been found[21]. Further studies are needed to assess the correlation of sequences of C-terminal part of E2 with response to the combination therapy of IFN and ribavirin as well as viral load.

Tayler *et al*[13] described that PePHD-deleted HCV-1 mutants remain capable of binding to PKR to some extent, while C-terminal-truncated E2 protein loses activity of inhibiting PKR. This finding indicates that regions other than PePHD within C-terminal part of E2 interact with PKR and play an important role in suppressing PKR, a mediator of IFN-induced antiviral resistance. The correlation of C-terminal part of E2 with response to IFN therapy and small viral load may suggest that the substitutions in the region abrogate the activity of suppressing PKR, resulting in susceptibility to IFN therapy and small viral load.

When the sequences of C-terminal part of E2 were compared before and after IFN therapy, the decrease in substitutions was observed in only 3 of 16 patients, indicating that resistant HCV becomes predominant after IFN therapy. The factors other than the number of substitutions of C-terminal part of E2 also play a role in resistance to IFN therapy.

The present study showed that PePHD was highly conserved and that there were no significant correlations of the substitutions of PePHD with the response to IFN therapy or with viral load. It was reported that PePHD has similar sequences with PKR and eIF2α in E2 region of HCV genotype 1a[13]. Other studies also showed that PePHD is highly conserved and that there are no significant correlations between the substitutions in PePHD and the response to IFN therapy[14-17]. Only three reports on genotypes 1, 2, and 3 have reported a correlation between substitutions of PePHD and the effect of IFN therapy[18-20]. Recently Bagaglio *et al*[26] reported that substitutions in PePHD correlate with hepatocellular carcinoma. Further studies on the correlation of substitutions of PePHD with clinical aspects of chronic HCV infection are needed.

In the present study, the substitution of threonine to serine at codon 625 significantly correlated with sustained response. No reports are available on the correlation of a specific amino acid substitution with response to IFN therapy. Both threonine and serine have side chains containing hydroxylic groups which are similar to each other. Thus this substitution makes only a slight difference in the structure of E2 protein. Further studies are necessary to elucidate the correlation of the substitution with response to IFN therapy.

The correlation of ISDR with viral load and response to IFN therapy was confirmed in the present study. Gale *et al*[27] reported that NS5A represses PKR through direct interaction and inhibits IFN-induced antiviral response. Multiple ISDR mutations probably abrogate this action of NS5A on inhibiting PKR[28]. This is probably the reason why patients with mutant ISDR are likely to obtain sustained virological response and have small viral load. Inhibition of antiviral activity of IFN by NS5A has been shown in mammalian cells using encephalomyocarditis virus and vesicular stomatitis virus[29]. However inconsistent association between type of ISDR and IFN sensitivity *in vitro* has been also reported[30].

The present study demonstrated the correlation between the number of substitutions in the C-terminal part of E2 and ISDR. Both regions bind to PKR and inhibit its activity. It may be the reason why the mutations

of the two regions occur simultaneously. They are probably adoptive mutations to the circumstances of individual hosts. The mutations may bring out some advantages for HCV to survive, while they may also make HCV susceptible to IFN or viral load smaller. Maekawa *et al*[31] reported that introduction of NS5A mutations enables HCV replicon derived from HC-J4 to replicate efficiently in Huh-7 cells[31]. The possible advantages of the mutations in the two regions require further elucidation. The mutations in ISDR also have been reported to correlate with development of hepatocellular carcinoma[32]. The role of the C-terminal part of E2 in the development of hepatocellular carcinoma is needed to be future studied.

In conclusion, N-terminal variable region in the C-terminal part of E2 correlates with both response to IFN therapy and viral load, and it is one of the factors independently associated with small viral load.

Abstract

AIM: Different strains of bifidobacteria were analysed for their effects on HT-29 intestinal epithelial cells (IECs) in *in vitro* models both of the non-inflamed and inflamed intestinal epithelium.

METHODS: A reporter gene system in HT-29 cells was used to measure levels of NF-κB activation after challenge with bifidobacteria or after bacterial pre-treatment following LPS challenge. IL-8 protein and pro-inflammatory gene expression was investigated using normal HT-29 cells.

RESULTS: None of the bifidobacteria tested induced activation of nuclear factor κB (NF-κB) indicating that bifidobacteria themselves do not induce inflammatory events in IECs. However, six out of eight bifidobacteria tested inhibited lipopolysaccharide- (LPS-) induced NF-κB activation in a dose- and strain-dependent manner. In contrast, NF-κB activation in response to challenge with tumor necrosis factor-α (TNF-α) was affected by none of the tested bifidobacteria, indicating that the inhibitory effect of bifidobacteria is specific for LPS-induced inflammation in IECs. As shown with two of the six inhibition-positive bifidobacteria, LPS-induced inhibition of NF-κB activation was accompanied by a dose-dependent decrease of interleukin 8 (IL-8) secretion and by lower mRNA levels for IL-8, TNF-α, cyclooxygenase 2 (Cox-2), and intercellular adhesion molecule 1 (ICAM-1).

CONCLUSION: Some strains of bifidobacteria are effective in inhibiting LPS-induced inflammation and thus might be appropriate candidates for probiotic intervention in chronic intestinal inflammation.

INTRODUCTION

Inflammatory bowel diseases such as Crohn's disease (CD) and ulcerative colitis (UC) are multifactorial disorders characterized by chronic inflammation of the intestinal epithelium. In addition to the genetic predisposition[1], the intestinal microflora seems to be involved in triggering inflammation, as observed in several animal models, where colitis was not induced in germ-free animals[2-4]. It has been suggested, that breakdown of tolerance towards the intestinal bacterial flora and dysfunction of regulatory T-cells are implicated in the development of chronic intestinal inflammation[5-8].

One of the central transcription factors mediating inflammatory responses is nuclear factor κB. Upon activation, through a wide range of stimuli such as TNF-α, IL-1β, or LPS, NF-κB translocates to the nucleus[9,10], where it regulates the transcription of a series of genes involved in acute responses to injury and in chronic intestinal inflammation including the genes for IL-1β, TNF-α, IL-6, IL-8, IL-12, Cox-2, ICAM-1, vascular endothelial growth factor-1, T-cell receptor-α, and major histocompatibility complex class II molecules[11,12]. LPS activates NF-κB through toll-like receptor 4 (TLR4)[13]. The events preceding the actual binding of LPS to TLR4 involve LPS-binding protein (LBP) and the intermediate receptor CD14[14,15]. LBP conveys LPS to CD14, which then promotes binding of LPS to the LPS receptor complex composed of TLR4 and MD-2, a co-receptor essential for LPS signalling via TLR4[16]. On monocytes and macrophages CD14 was shown to be membrane-bound by a glycosylphophoinositol anchor[17]. Stimulation of endothelial and epithelial cells with LPS requires the second form of CD14, i.e. soluble CD14 (sCD14)[18].

There is increasing evidence that in chronic intestinal inflammation expression of TLR4 and CD14 on IECs is abnormal. Under normal conditions, TLR4 and CD14

are expressed in IECs at very low levels *in vivo*[19,20] and are confined to undifferentiated cells of the crypts, which are not exposed to the overwhelming quantity of luminal antigens[21]. By contrast, expression of TLR4 and CD14 is significantly increased in IECs of both, animal models of colitis[22,23] and IBD patients[19]. A possible explanation for this increased expression could come from genetic studies. Higher frequencies of the Asp299Gly allele in the extracellular domain of TLR4 and the T allele and TT genotype at position -159 in the gene for CD14 have been positively associated with CD and UC[24-27]. Abnormal LPS signalling through increased levels of TLR4 and CD14 in IECs could contribute to the sustained mucosal inflammation in IBD.

Bifidobacteria are Gram-positive, anaerobic micro-organisms that inhabit mainly the colon of healthy infants and adults. In breast-fed infants, soon after birth, up to 90% of all bacteria in faecal samples detected by fluorescence *in situ* hybridisation are bifidobacteria[28] and they still make up 3%-5% of the adult microflora[29]. Thus, bifidobacteria undoubtedly constitute one of the predominant species of the human colonic microflora[30]. The analysis and annotation of the genome sequence of *B. longum* NCC2705 illustrated the close relationship of this bacterium with its human host[31]. Several beneficial health effects have been claimed to be related to the presence of bifidobacteria in the colon[32-41]. Based on these properties, bifidobacteria have become increasingly interesting for probiotic use, both in pharmaceutical application and dairy products[42]. One of these applications is their use in probiotic intervention in chronic intestinal inflammation. Probiotics containing bifidobacteria have been shown to be effective in reducing the severity of inflammation in several rodent models and patients with IBD[38,43-47].

In this study, the effects of a selection of bifidobacteria on IECs were investigated using an *in vitro* approach mimicking the situation of increased responsiveness of IECs to LPS. In this model, the antagonistic potential of several bifidobacteria on LPS-induced inflammatory responses in IECs was shown to be mediated by blocking NF-κB activation. This suggests that several *Bifidobacterium* strains, especially of *B. bifidum*, might be good candidates for probiotic intervention in IBD.

MATERIALS AND METHODS

Bacterial strains, cell lines and culture conditions

All bacterial strains used are shown in Table 1. For experiments, bacteria were cultured for 16 h at 37℃ (bifidobacteria: de Man-Rogosa Sharpe medium with 0.5 g/L cysteine, anaerobic; *E. coli*: brain heart infusion medium, aerobic; all media BD Difco, Basel, Switzerland). HT-29 cells were maintained at 50% CO_2 in DMEM (4.5 g/L glucose; Amimed, Basel, Switzerland) supplemented with 100 mL/L fetal calf serum (FCS; Amimed), 10 mL/L non-essential amino acids (NEAA, Sigma, Basel, Switzerland), 10 mL/L penicillin-streptomycin solution (pen-strep, Sigma). HT-29 clone 34 cells were obtained by stable transfection of the HT-29 cell line with the pNF-κB-SEAP-NPT plasmid[48]. This plasmid harbours the reporter gene for secreted alkaline phosphatase (SEAP). It contains

the κB4 enhancer element fused to a TATA-like promoter region from the Herpes simplex virus thymidine kinase promoter, which permits the expression of the reporter gene following activation of the NF-κB signalling pathway. The SEAP coding sequence is followed by the SV40 late polyadenylation signal to ensure proper and efficient processing of the SEAP transcript in eukaryotic cells. The vector backbone also contains a pUC origin of replication and an ampicillin resistance gene for propagation and selection in *E. coli*. In addition, it contains the neomycin phosphotransferase gene for the dominant selection marker of geneticin resistance in eukaryotic cells. After amplification in *E. coli* TG1, the plasmid was transfected into HT-29 cells using lipofectamine (Invitrogen, Basel, Switzerland) as described by Moon *et al*[48], and the stable clone 34, showing good kinetics of reporter gene activation using recombinant human TNF-α (10 μg/L, R&D Systems, Oxon, England) as a stimulus, was used for reporter gene assays. HT-29 clone 34 cells were cultured in DMEM with 100 mL/L FCS, 10 mL/L NEAA, and geneticin (0.5 g/L; Invitrogen). For experiments, both HT-29 and HT-29 clone 34 cells were seeded at 2×10^5 cells/mL in 12-well format cell culture plates (Falcon®, Milian, Geneva, Switzerland) and cultured in the respective medium until they reached 90%-100% confluence. At this stage, approximately 1×10^6 cells/well were counted.

LPS and TNF-α challenge of IEC lines

HT-29 or HT-29 clone 34 cells were grown as described above. At 90%-100% confluence, cells were washed and the medium was changed to 0.9 mL of DMEM with 100 mL/L FCS, 10 mL/L NEAA, 50 mmol/L Hepes (Invirogen), and penicillin G (100 kU/L; Fluka). Bacteria were grown as described above and added at the indicated multiplicity of infection (*moi*) in 0.1 mL of cell culture medium. In some experiments, cells were pre-incubated for 1 h with bacteria and subsequently stimulated with TNF-α (10 μg/L) or LPS (10 μg/L, serotype B55:O5; Sigma). Where indicated, a challenge was performed in the presence of 50 mL/L of human milk (HM). Milk was

sampled from different mothers (d 20 of lactation) and pooled. The pool of HM used for this study contained 26 mg/L of sCD14 (determined by ELISA; P. Serrant, personal communication). After 16 h of incubation, supernatants were collected by centrifugation and used for quantification of SEAP or IL-8. Viability of the eukaryotic cells was continuously checked by microscopic examination of trypan blue (Sigma) exclusion and was > 95% in all experiments.

Detection of SEAP and IL-8 protein

Phosphatase activity of SEAP was quantified by bioluminescence using the PhosphaLight™ kit (Tropix, MA, USA). Bioluminescence was measured as relative light units (RLU) in a TECAN SPECTRAFluor Plus spectrometer with an integration time of 100 milliseconds and gain set to 100. Data were analysed using the XFlour software version 4.40. RLU varied between experiments due to the nature of the assay. Where more than one experiment was used to present figures and for statistical analysis, correction for these day to day variations was performed by normalizing data to set 100 RLU units for the positive control (LPS + HM). In one experiment, levels of NF-κB activation were similar for 10 μg/L of TNF-α and 10 μg/L of LPS in combination with HM.

Secreted IL-8 protein was quantified by ELISA using the IL-8 Eli-pair kit (Diaclone, CT, USA). Absorbance was measured in a Dynex MRX microplate reader (Dynex Technologies, Worthing, England) at 450 nm.

Real-time PCR

For real-time PCR, RNA of HT-29 cells was isolated after bacterial pre-treatment and 4 h of LPS challenge in the presence of 5% (v/v) HM using the NucleoSpin® RNAII kit (Macherey-Nagel, Düren, Germany). RNA was quantified using Ribogreen® RNA quantification kit (Molecular Probes, Basel, Switzerland). Quality of RNA was verified using Agilent RNA 6000 Nano Assays and the 2100 Bioanalyzer (Agilent Technologies, CA, USA) with corresponding software (version A.01.16). 1 μg of total RNA was transcribed to cDNA using TaqMan Reverse Transcription Reagents. Real time reactions were set up using 5 μL TaqMan® 2 x PCR Master Mix, 0.5 μL of TaqMan® assays-on-demand primer/probe mixture (glyceraldehyde-3 phosphate dehydrogenase (GAPDH): Hs99999905_mL; IL-8: Hs00174103_mL; TNF-α: Hs00174128_mL; COX-2: Hs00153133_mL; ICAM-1: Hs00164932_mL; all reagents were purchased from Applied Biosystems) and 4.5 μL H_2O containing cDNA corresponding to 10-20 ng RNA, depending on the target gene. Real-time PCR was performed in an ABI Prism 7900HT Sequence Detection System (Applied Biosystems) and analysed with the SDS software package version 2.1. Results of the different RNA samples were normalised for RNA quantity using the gene for GAPDH.

RESULTS

Bifidobacteria do not induce NF-κB-dependent reporter gene activity in HT-29 clone 34 cells

To study the effect of bifidobacteria on inflammatory events in IECs, i.e. on NF-κB activation, a reporter gene assay in HT-29 clone 34 cells was used. Cells were incubated with bacteria (*moi* = 100) for 16 h. Subsequently, activity of the NF-κB-driven reporter protein SEAP was measured in culture supernatants (Figure 1). While non-pathogenic *E. coli* D2241 induced significant reporter gene activity, all bifidobacteria tested failed to induce any activation of NF-κB above background levels. The same cell-based assay was used to investigate the effect of bifidobacteria on LPS-induced inflammation in IECs. HT-29 clone 34 cells were challenged with LPS for 16 h and subsequently SEAP activity was measured in the culture supernatants (Table 2). Only a 2.5-fold induction of NF-κB activation by LPS alone compared to un-stimulated cells was observed. To mimic the situation in the intestinal epithelium of IBD patients where expression of CD14 is increased, 50 mL/L of HM, containing sCD14, were added to the assay. Addition of HM led to a 50-fold increase in LPS-induced NF-κB activation, whereas HM alone did not result in activation of NF-κB. Also, in the presence of HM none of the tested bifidobacteria induced NF-κB-dependent reporter gene activity above background levels while stimulation with *E. coli* D2241 was enhanced about 200-fold (data not shown), further supporting the results indicating that bifidobacteria do not induce inflammatory events in IECs.

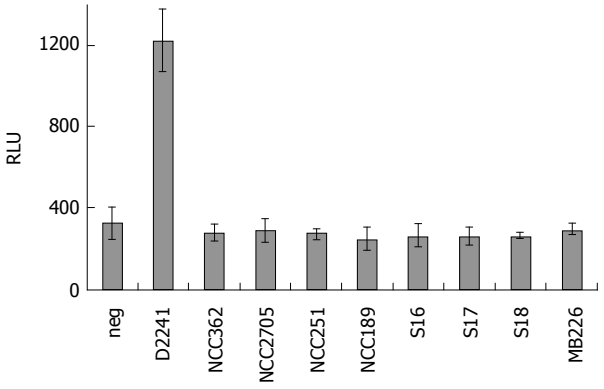

Figure 1 Quantification of NF-κB-driven SEAP activity in the supernatants of HT-29 clone 34 cells challenged with different bacterial strains at moi = 100 for 16 h. Results are shown as RLU and are mean ± standard deviation (SD) of triplicate measurements of one representative of three independent experiments. neg: negative control, no bacteria.

Table 2 Quantification of NF-κB-driven SEAP activity in the supernatants of HT-29 clone 34 cells

Treatment	RLU ± SD [1]
None (untreated control)	2 ± 1
HM	2 ± 1
LPS	5 ± 1
LPS + HM	100 ± 6

[1] Values are mean ± SD of at least 3 independent experiments for each condition performed in triplicate. For each individual experiment luminescence measurements were normalized to give 100 RLU for stimulation with LPS + HM.

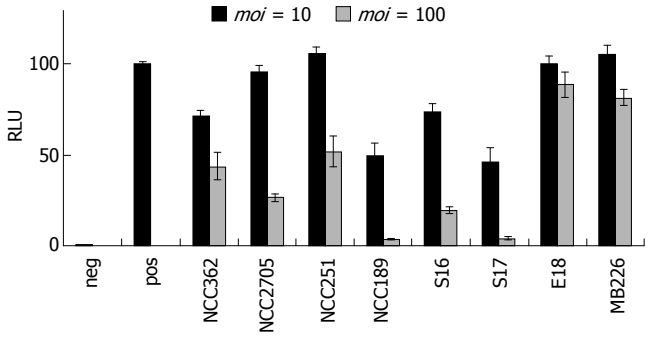

Figure 2 Dose- and strain-dependent inhibition of LPS-induced NF-κB activation by different bifidobacteria. SEAP activity was quantified in the supernatants of HT-29 clone 34 cells pre-incubated with different bifidobacteria at *moi* = 10 (dark grey bars) or *moi* = 100 (light grey bars) and subsequently stimulated with LPS + HM for 16 h. Cells treated with medium only served as negative control (neg; white bar) and positive controls (pos; black bar) were cells challenged with LPS + HM without bacterial pre-treatment. Results are means ± standard error of the mean (SEM) of three independent experiments performed in triplicate. RLU of indicidual experiments were normalised to give 100 RLU for the positive control.

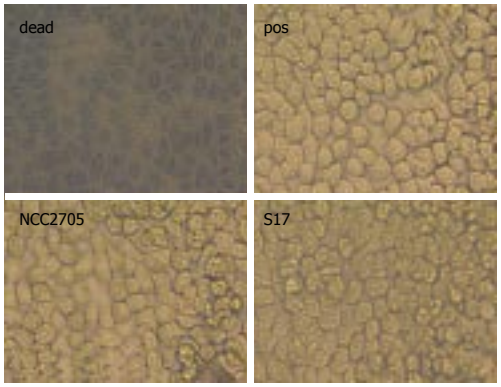

Figure 3 Microscopic examination of cellular viability. Trypan blue exclusion was monitored in HT-29 clone 34 cells challenged with LPS + HM for 16 after pre-incubation with bifidobacteria (*B. longum* NCC2705 or *B. bifidum* S17; *moi* = 100). Positive control (pos) was cells incubated with LPS + HM without bacterial pre-treatment. As a control for trypan blue staining cells were incubated for 16 h in cell culture medium at pH 4 (dead).

Strain- and dose-dependent inhibition of LPS-induced NF-κB activation by bifidobacteria

Several reports suggest anti-inflammatory effects of probiotics containing bifidobacteria[38,44,49]. Therefore, all bifidobacteria used in this study were assessed for their potential inhibitory effect on LPS-induced NF-κB activation at different bacterial doses. At a *moi* of 1, none of the bifidobacteria tested had an effect on NFκB-dependent reporter gene activity (data not shown). As shown in Figure 2, at a *moi* = 10, however, pre-treatment with *B. lactis* NCC362 and *B. bifidum* NCC189, S16, and S17 significantly decreased NF-κB-dependent reporter gene activity to 47%-71% of the positive control. When the bacterial dose for pre-treatment was further increased to 100 bacteria per cell (*moi* = 100), the inhibitory effect of *B. bifidum* NCC189 and that of *B. bifidum* S17 was almost complete (5% of positive control), while that of *B. lactis* NCC362, *B. longum* NCC2705, *B. adolescentis* NCC251 and *B. bifidum* S16 was intermediate (20%-52% of positive control). In contrast, *B. longum/infantis* E18 and *B. breve* MB226 had no or only very slight inhibitory effect on SEAP activation at either *moi*. To assess whether physical presence of bifidobacteria was required for their inhibitory effect, further experiments were carried out using cell culture medium pre-treated for 16 h with bifidobacteria followed by the removal of bifidobacterial cells using filter sterilization. Use of this conditioned medium did not result in any inhibition of LPS-induced NF-κB activation in HT-29 clone 34 cells (data not shown). These results show that six out of eight bifidobacteria tested significantly inhibited LPS-induced NF-κB activation in IECs and that this inhibitory capacity of bifidobacteria is strain- and dose-dependent. Furthermore, presence of bifidobacterial cells during LPS challenge is required for their anti-inflammatory effects indicating that this inhibition is not due to secreted compounds. To prove that decreased activity of the reporter protein was not a consequence of apoptosis due to high bacterial doses in combination with LPS, viability of the cells was confirmed by trypan blue exclusion. Microscopic examination of cells pre-treated with two representative strains (*B. longum* NCC2705 and *B. bifidum* S17), challenged with LPS + HM showed that viability was > 95% in all experiments demonstrating that inhibition of LPS-induced reporter gene activity by bifidobacteria is not due to cell death (Figure 3).

Table 3 IL-8 protein in the supernatants of HT-29 cells (mean ± SD, *n* = 3)

Treatment	IL-8 [μg/L] [1]	
	moi = 10	*moi* = 100
None (untreated control)	2 ± 1	
LPS+HM	36 ± 3	
NCC2705/LPS+HM 1	30 ± 2	7 ± 3
S17/LPS+HM 1	7 ± 2	2 ± 0

[1] Pre-incubation with *B. longum* NCC2705 or *B. bifidum* S17 at moi = 10 or 100 was followed by stimulation with LPS + HM for 16 h.

Inhibition of LPS-induced inflammatory events by B. bifidum S17 and B. longum NCC2705

To further investigate the effect of bifidobacteria on inflammatory events following NF-κB activation, IL-8 secretion and mRNA level of the genes encoding IL-8, TNF-α, COX-2, and ICAM-1 were monitored in normal HT-29 cells after bacterial pre-treatment with *B. bifidum* S17 and *B. longum* NCC2705 and a subsequent LPS challenge. Pre-incubation with *B. bifidum* S17 reduced IL-8 secretion of the IECs to about 20% of the positive control already at a *moi* = 10 and was able to completely inhibit IL-8 secretion at 100 bacteria per cell (Table 3). Effective inhibition with *B. longum* NCC2705 was only observed at a *moi* = 100. Thus, the dose-response of the IECs for IL-8 secretion was similar to that observed for NF-κB-driven SEAP reporter gene activity.

The effect of pre-treatment of HT-29 cells with bifidobacteria on mRNA levels for genes known to be regulated by NF-κB was investigated by real-time PCR. Pre-treatment with *B. longum* NCC2705 and *B. bifidum* S17 at a *moi* = 100 severely inhibited transcriptional activation of the genes for IL-8, TNF-α, COX-2, and ICAM-1 in

Table 4 Real-time quantification of mRNA levels of several genes in HT-29 cells

Treatment	Relative mRNA level [1] ± SD of gene for			
	IL-8	TNF-α	COX-2	ICAM-1
LPS+HM (positive control)	40.6 ± 17.4	37.4 ± 12.6	5.9 ± 1.7	28.0 ± 10.7
B. longum NCC2705/ LPS+HM [2]	11.4 ± 1.1[a]	12.7 ± 1.8[a]	2.5 ± 1.6	12.2 ± 9.2
B. bifidum S17/ LPS+HM [2]	3.5 ± 2.6[a]	2.9 ± 2.4[a]	1.4 ± 0.6[a]	2.0 ± 0.8[a]

[1] Results are mRNA levels relative to the negative control (no bacteria, no LPS) and are mean ± standard deviation (SD) of three independent pools of RNA for each condition. [2] Pre-incubation with *B. longum* NCC2705 or *B. bifidum* S17 at moi = 100 was followed by stimulation with LPS + HM for 4 h. [a] $P < 0.05$ *vs* positive control; Student's *t*-test.

HT-29 cells challenged with LPS in the presence of HM (Table 4). Again, *B. bifidum* S17 was more effective than *B. longum* NCC2705. Taken together, these results indicate that selected strains of bifidobacteria are able to inhibit LPS-induced inflammatory events in IECs.

TNF-α-induced NF-κB activation is not inhibited by bifidobacteria

NF-κB is activated through a wide range of stimuli other than LPS (see introduction). Therefore, it was interesting to test whether a similar inhibition of bifidobacteria could be observed for a pro-inflammatory stimulus other than LPS, such as TNF-α. At *moi* = 100, none of the tested bifidobacteria had any inhibitory effect on NF-κB-dependent reporter gene activity when 10 μg/L TNF-α was used to challenge HT-29 clone 34 cells (Figure 4). Further experiments were performed using a lower dose of TNF-α (1 μg/L) as stimulus and different doses of bacteria (*moi* = 10 and 100). In none of the tested conditions, an inhibitory effect of bifidobacteria on TNF-α induced NF-κB activation was observed (data not shown). These results suggest that the inhibitory capacity of bifidobacteria is specific for LPS-induced NF-κB activation in IECs.

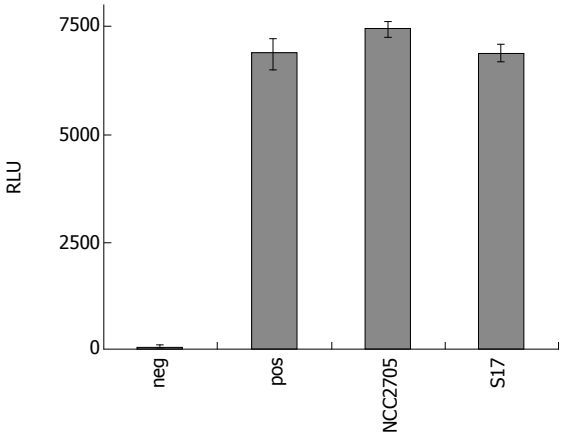

Figure 4 NF-κB-driven SEAP activity in the supernatants of HT-29 clone 34 cells pre-incubated with different bifidobacteria and subsequent stimulation with TNF-α (10 μg/L) for 16 h in the presence of 50 mL/L HM. Cells treated with medium only served as negative control (neg) and positive controls (pos) were cells challenged with TNF-α + HM without bacterial pre-treatment. Results are given as RLU and are means ± SD of triplicate measurements of a representative of two independent experiments.

DISCUSSION

Previous studies have shown that the intestinal microflora is implicated in the pathogenesis of IBD[2-4]. Increased expression of CD14 and TLR4 in IECs[19] might contribute to the sustained inflammation in the epithelium of patients of IBD. On the other hand, for several probiotic formulations, effects on inflammation in cultured IEC lines and in mouse models of chronic intestinal inflammation have been reported, yet there is a significant lack in our understanding of the molecular mechanisms by which probiotics downmodulate intestinal inflammation. Most studies on anti-inflammatory effects of probiotics were performed using mixtures of different probiotic strains, mainly lactobacilli and bifidobacteria[50]. For HT-29 and T84 cells, it was shown that incubation of these cells with VSL#3, a formulation containing eight different strains including 3 strains of bifidobacteria, resulted in decreased secretion of IL-8 in response to challenge with non-pathogenic *E. coli* or pathogenic *Salmonella dublin*[51]. In the IL-10 knock-out model of colitis, introduction of VSL#3 in the diet had an inhibitory effect on basal and LPS-stimulated TNF-α secretion in biopsies obtained from the colonic mucosa[44]. In the same mouse model, feeding a diet containing *B. infantis* 35624 was superior to *L. salivarius* UCC118 in effectively reducing the total gastrointestinal inflammatory score[38]. Finally, VSL#3 has been successfully used in the treatment of some IBDs[43,45].

Here, the effects of bifidobacteria on IECs were investigated with particular emphasis on LPS-induced inflammation. To our knowledge this represents the first attempt to characterize anti-inflammatory effects of whole cells of a single bifidobacterial strain. None of the tested bifidobacteria induced activation of NF-κB in HT-29 clone 34 cells, whereas a challenge with *E. coli* D2241 resulted in significant induction of NF-κB driven reporter gene activity in this cell line. Challenge of HT-29 clone 34 cells with LPS alone resulted in only a 2.5-fold induction of NF-κB-dependent reporter gene activity above background levels. This is consistent with results from other groups, which showed that colonic epithelial cells are poorly responsive to LPS[20]. However, using HM as a source of sCD14[52], the NF-κB response of HT-29 IECs to LPS was dramatically increased. This result supports previous studies showing increased responsiveness of HT-29 cells to LPS in the presence of HM[52-54]. This increased responsiveness of HT-29 cells to LPS in the presence of milk could be blocked by an anti-CD14 antibody[52].

NF-κB-dependent reporter gene activation by LPS in the presence of milk could be inhibited by pre-incubation with bifidobacteria in a strain- and dose-dependent manner, with the three *B. bifidum* strains (NCC189, S16, and S17) being most effective. To achieve this inhibitory effect, the presence of bifidobacterial cells was required, as filter-sterilized cell culture medium pre-treated with bifidobacteria did not show any inhibition of LPS-induced NF-κB activation. This indicates that the anti-

inflammatory compound is not actively secreted by bifidobacteria or released from lysed cells. Furthermore, incubation of HT-29 cells with *B. longum* NCC2705 and *B. bifidum* S17 prior to LPS challenge reduced IL-8 secretion and had a significant inhibitory effect on mRNA levels of the TNF-α, IL-8, ICAM-1, and COX-2 genes, all of which have been shown to be regulated by NF-κB[9]. In a similar study, VSL#3 inhibited NF-κB reporter gene activity and MCP-1 secretion after a challenge with TNF-α, in conditionally immortalised mouse colon cells[49]. In the presented experiments, none of the tested strains of bifidobacteria inhibited NF-κB activation in response to TNF-α. These results suggest that bifidobacteria interfere with pro-inflammatory signals upstream of the pathway of NF-κB activation common for LPS and TNF-α.

Lipoteichoic acids (LTA) of two lactobacilli strains were able to inhibit IL-8 secretion in response to LPS in HT-29 cells[54]. In a recent study, it was shown that the composition of LTA have an impact on the immunogenicity and anti-inflammatory capacity of *L. plantarum*[55]. Of note, a mutant lacking D-alanine substitutions to the back bone of LTA showed dramatically improved anti-inflammatory properties compared to the wild type. The mechanism by which bifidobacteria exert their inhibitory effect remains to be elucidated. One study investigating DNA from the VSL#3 mixture showed that the bifidobacterial strains' DNA was effective in limiting epithelial pro-inflammatory responses in IL-10-deficient mice and in HT-29 cells challenged with TNF-α. However, the pro-inflammatory response to LPS in HT-29 cells was not inhibited by the probiotic DNA[56]. This rules out, to a certain degree, that the effects observed in the presented experiments stem from DNA leaking from lysed bifidobacteria. Furthermore, it suggests that the mechanisms by which whole cells of bifidobacteria inhibit inflammatory responses are distinct from those described for their DNA.

Although anti-inflammatory activity of probiotics has been reported previously, to our knowledge, this is the first report on a specific inhibitory effect of bifidobacteria on LPS-induced inflammatory events in IECs, suggesting a role for bifidobacteria in down-modulation of pro-inflammatory cytokines[57]. Blocking of LPS-induced NF-κB activation by bifidobacteria could, at least in part, explain their positive effects on chronic intestinal inflammation *in vivo* through prevention of further amplification of the pro-inflammatory signal after exposure to LPS. Our results suggest that the capacity to inhibit LPS-induced NF-κB activation is strain-dependent. Especially, the strains of *B. bifidum* are promising candidates for probiotic intervention in inflammatory disorders of the gastrointestinal tract.

Abstract

AIM: To evaluate the histopathological and radiological findings of the gallbladder in patients with autoimmune pancreatitis (AIP).

METHODS: The radiological findings of the gallbladder of 19 AIP patients were retrospectively reviewed. Resected gallbladders of 8 AIP patients were examined histologically and were immunostained with anti-IgG4 antibody. Controls consisted of gallbladders resected for symptomatic gallstones (n = 10) and those removed during pancreatoduodenectomy for pancreatic carcinoma (n = 10), as well as extrahepatic bile ducts and pancreases removed by pancreatoduodenectomy for pancreatic carcinoma (n = 10).

RESULTS: Thickening of the gallbladder wall was detected by ultrasound and/or computed tomography in 10 patients with AIP (3 severe and 7 moderate); in these patients severe stenosis of the extrahepatic bile duct was also noted. Histologically, thickening of the gallbladder was detected in 6 of 8 (75%) patients with AIP; 4 cases had transmural lymphoplasmacytic infiltration with fibrosis, and 2 cases had mucosal-based lymphoplasmacytic infiltration. Considerable transmural thickening of the extrahepatic bile duct wall with dense fibrosis and diffuse lymphoplasmacytic infiltration was detected in 7 patients. Immunohistochemically, severe or moderate infiltration of IgG4-positive plasma cells was detected in the gallbladder, bile duct, and pancreas of all 8 patients, but was not detected in controls.

CONCLUSION: Gallbladder wall thickening with fibrosis and abundant infiltration of IgG4-positive plasma cells is frequently detected in patients with AIP. We propose the use of a new term, sclerosing cholecystitis, for these cases that are induced by the same mechanism as sclerosing pancreatitis or sclerosing cholangitis in AIP.

INTRODUCTION

Autoimmune pancreatitis (AIP) is a unique form of chronic pancreatitis characterized clinically and morphologically by irregular narrowing of the main pancreatic duct, enlargement of the pancreas, increased levels of serum γglobulin, IgG, or IgG4, the presence of autoantibodies, and responsiveness to steroid therapy. Patients with AIP frequently show stenosis of the bile duct system, including the intrahepatic and the extrahepatic bile duct[1-3]. Ultrasonography (US) or endoscopic ultrasonography (EUS) studies have demonstrated the bile duct wall thickening in segments without abnormalities on cholangiography, as well as in stenotic portions[4]. The histopathological findings in the pancreas of AIP are fibrosis and lymphoplasmacytic infiltration with abundant IgG4-positive plasma cells. However, these characteristics are also detected in the bile duct wall of patients with AIP[5,6]. These findings suggest a close relationship between AIP and sclerosing cholangitis[7], though there are only a few studies that have evaluated the gallbladder in AIP[8]. In the present study, we evaluated the histopathological and radiological findings of the gallbladders of AIP patients.

Figure 2 Moderate thickening of the gallbladder wall in a patient with autoimmune pancreatitis on US.

Figure 3 Transmural lymphoplasmacytic infiltration with fibrosis in the gallbladder wall of a patient with autoimmune pancreatitis.

MATERIALS AND METHODS

Patients

The study subjects were 19 patients with AIP in whom the gallbladder was examined by US and computed tomography (CT) before treatment for AIP. The patients were diagnosed based on the following criteria: (1) irregular narrowing of the main pancreatic duct (n = 19); (2) enlargement of the pancreas (n = 17); (3) pancreatic histology showing dense lymphoplasmacytic infiltration with fibrosis (n = 8); (4) elevation of serum γglobulin (≥ 2.0 g/dL, n = 13), IgG (≥ 1800 mg/dL, n = 13), IgG4 (≥ 136 mg/dL, n = 14); (5) presence of autoantibodies (n = 9); and (6) morphological and serological effectiveness of steroid treatment (n = 11). A clinical diagnosis of AIP was made in all patients who in addition to fulfilling criteria 1, met at least 2 of the remaining criteria.

Six patients had a pancreatoduodenectomy, and 2 had a bile duct resection, cholecystectomy, and a choledochoduodenostomy with a pancreatic biopsy. These 8 patients had obstructive jaundice due to marked stenosis of the extrahepatic bile duct and were suspected of having carcinoma of the head of the pancreas. Stenosis of the extrahepatic bile duct occurred in 16 patients (1 upper bile duct and 15 lower bile ducts).

Methods

The radiological findings of the gallbladders of all 19 patients were retrospectively reviewed. The degree of thickening of the gallbladder wall was classified into 3 categories: severe (thickness ≥ 8 mm, Figure 1); moderate (thickness from ≥ 4 mm to < 8 mm, Figure 2); and mild or none (thickness < 4 mm).

At least 3 sections of the resected gallbladder of the 8 AIP patients were histologically examined and immunostained by anti-IgG4 antibody (The Binding Site, Birmingham, UK) with avidin-biotin-peroxidase complex (ABC). The pattern of gallbladder inflammation was classified into 2 types: transmural in which the inflammatory infiltrates extended through the gallbladder wall and included involvement and focal destruction of the muscularis (Figure 3); and mucosal-based, in which the inflammatory infiltrates were prominently detected within the lamina propria. The degree of histological thickening of the bile duct wall was classified into 3 categories: severe (thickness ≥ 4 mm); mild (thickness from ≥ 2 mm to < 4 mm); and none (thickness < 2 mm).

The number of immunohistochemically identified cells per high power field (HPF) in each specimen was counted. The degree of infiltrated IgG4-positive plasma cells was classified as severe (>20/HPF, Figure 4); moderate (10-20/HPF); mild (5-9/HPF); and few (0-4/HPF). The gallbladders resected for symptomatic gallstones (n = 10), those removed during pancreatoduodenectomy for pancreatic carcinoma (n = 10), and the extrahepatic bile ducts and pancreases removed during pancreatoduodenectomy for pancreatic carcinoma (n = 10) were also examined histologically and immunohistochemically as controls.

RESULTS

Thickening of the gallbladder wall was detected on US and/or CT in 10 patients with AIP [3 severe (Figure 1) and 7 moderate (Figure 2)]. All of the 10 patients also had stenosis of the extrahepatic bile duct. The presence of gallstones was noted in only 2 patients.

Histologically, thickening of the gallbladder was

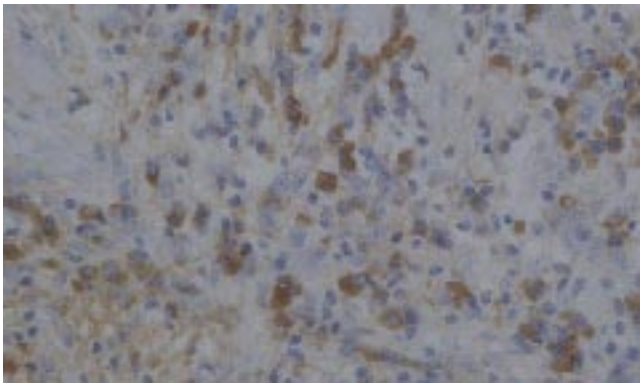

Figure 4 Severe infiltration of IgG4-positive plasma cells in the gallbladder wall of a patient with autoimmune pancreatitis.

Table 1 Relationship between thickening of the gallbladder wall and infiltration of IgG4-positive plasma cells in the gallbladder wall, bile duct wall and pancreas

Thickening of the gallbladder wall *n*	Infiltration of IgG4-positive plasma cells					
	Gallbladder wall		Bile duct wall		Pancreas	
	Severe	Moderate	Severe	Moderate	Severe	Moderate
Transmural: severe 4	4	0	4	0	4	0
Mucosal-based 2	2	0	2	0	2	0
None 2	0	2	1	1	2	0

detected in 6 of 8 (75%) patients with AIP who underwent surgery; 4 of these 6 patients had transmural lymphoplasmacytic infiltration with fibrosis (Figure 3), and 2 had mucosal-based lymphoplasmacytic infiltration. Lymphoid nodule formation was detected in 2 patients. No patients had dysplastic or neoplastic changes of the gallbladder epithelium. Considerable transmural thickening of the extrahepatic bile duct wall with dense fibrosis and diffuse lymphoplasmacytic infiltration was detected in 7 patients. However, transmural thickening of the gallbladder wall with lymphoplasmacytic infiltration and fibrosis was not detected in the controls.

Immunohistochemically, severe infiltration of IgG4-positive plasma cells was detected in the pancreas of all patients. Severe infiltration of IgG4-positive plasma cells was also detected in the gallbladder (Figure 4) and bile duct wall of 6 patients with thickening of the gallbladder wall. Moderate infiltration of IgG4-positive plasma cells was also detected in the non-thickened gallbladders. In all control cases, IgG4-positive plasma cell infiltration in the gallbladder, bile duct, and pancreas was classified as few (Table 1).

DISCUSSION

In AIP, stenosis of the bile duct system is detected from 94%[9] to 100%[10] of patients. In most patients, the lower bile duct is narrowed, and the intrahepatic bile duct or upper bile duct is occasionally involved. Histologically, dense lymphoplasmacytic infiltration with fibrosis, which is the characteristic finding in the pancreas of AIP patients, is also detected in the transmural bile duct wall of many patients with AIP[5,6]. Immunohistochemically, abundant infiltration of IgG4-positive plasma cells is specifically detected in the pancreas of AIP, but the infiltration is also detected in the bile duct wall of AIP patients[5,6]. Bile duct involvement in AIP is considered to be sclerosing cholangitis, which is induced by the same mechanism as sclerosing pancreatitis[7].

According to a report[8] on the pathology of gallbladder lesions in patients with AIP, 12 of 20 (60%) cases of AIP showed intense inflammatory infiltrates, and 7 cases (35%) showed transmural chronic cholecystitis. In the present study, severe or moderate thickening of the gallbladder wall was radiologically detected in 10 of 19 (53%) AIP patients; in these 10 patients, stenosis of the extrahepatic bile duct was also observed. Histologically, thickening of the gallbladder wall was detected in 6 of 8 (75%) AIP patients who underwent surgery; 4 of the 6 showed transmural inflammation and 2 showed mucosal-based inflammation. These 6 patients also showed severe transmural thickening of the extrahepatic bile duct wall. Immunohistochemically, severe or moderate infiltration of IgG4-positive plasma cells was detected in the gallbladder, bile duct, and pancreas of all 8 AIP patients in whom surgery was done, but was not detected in controls. These findings suggest that thickening of the gallbladder wall is one of the extrapancreatic lesions that is frequently detected in AIP patients and is characterized by transmural wall thickening with abundant infiltration of IgG4-positive plasma cells. Thus, we propose the use of a new term, sclerosing cholecystitis, to describe this condition that is induced by the same mechanism as sclerosing pancreatitis or sclerosing cholangitis in AIP.

In conclusion, sclerosing cholangitis is one of the extrapancreatic lesions that is frequently detected in AIP patients and is characterized by transmural wall thickening with abundant infiltration of IgG4-positive plasma cells.

Abstract

AIM: To clarify possible contributions of DNA mismatch repair (MMR) system in carcinogenesis of liver fluke infection-associated intrahepatic cholangiocarcinoma (ICC) by using immunohistochemical assay.

METHODS: A total of 29 ICC samples, which had been assessed for genomic instability by a PCR-based method, were used for study. They were examined immunohistochemically to demonstrate protein expression of two MMR genes, hMSH2 and hMLH1. Results obtained were compared with their mutator phenotype assessed previously.

RESULTS: Either hMSH2 or hMLH1 protein was obviously expressed in 28 of 29 (96.6%) ICC samples. Positive nuclear localization of hMSH2 or hMLH1 protein was observed in 86.2% (25/29) or 93.1% (27/29) ICC cases, respectively, while their negative nuclear reactivity was only detected in 13.8% (4/29) or 6.9% (2/29) ICC cases analyzed, respectively.

CONCLUSION: Our study, probably for the first time, showed through immunohistochemical detection of hMSH2 and hMLH1 gene that DNA MMR system does not play a prominent role in liver fluke infection-associated cholangiocarcinogenesis. These results confirm previous findings on mutational status of these genes assessed through a PCR-based method. The immunohistochemical analysis has proven to be an effective and sensitive approach for screening MMR deficiency regardless of somatic inactivation or promoter hypermethylation of hMSH2 and/or hMLH1 gene. Furthermore, immunohistochemistry is more advantageous compared to mutator phenotyping assay in terms of simplicity, less time consuming and cost effectiveness for screening possible involvements of target MMR genes in tumorigenesis.

INTRODUCTION

The multistep process of carcinogenesis results from multiple genetic changes in oncogene(s), tumor suppressor gene(s) and/or DNA integrity gene(s)[1,2]. hMSH2 and hMLH1, the common human mutS homolog 2 and mutL homolog 1, respectively, are two key genes implicated in DNA mismatch repair (MMR) machinery[3]. They are among other stability genes that function as DNA mismatch restorers for the maintenance of genomic integrity[2]. Defects in this repair system are involved in the failure to recognize and/or repair spontaneous errors during the replication process. MMR deficiency leads to the accumulation of secondary mutations resulting from base-base mismatches and/or short insertion or deletion mispairings throughout the genome; this deficiency affects important growth regulatory genes and thereby leads to carcinogenesis[4]. Most cells that are deficient in this repair

system often display a high level of microsatellite instability (MSI), which generates a mutator phenotype, a hallmark of human cancers, as a consequence of DNA replication errors and homologous recombination[5,7]. Defects in MMR genes have recently been described as an alternative pathway in the pathogenesis of and predisposition toward a significant proportion of certain inherited and sporadic human malignancies[8-11].

Intrahepatic cholangiocarcinoma (ICC), a primary adenocarcinoma and the second most common cancer of the liver, develops from the overgrowth of cholangiocytes, which are epithelial cells that line intrahepatic ducts. Patients with this disease have a poor prognosis: ICC is usually fatal because of the difficulty in detecting it at an early stage[12,13]. Based on an epidemiological study, the incidence of ICC is dependent on geography[14]. This disease is most common in Southeast Asia[15], especially Thailand[15-16], and its etiology is thought to be multifactorial. Documented risk factors include sclerosing cholangitis, hepatolithiasis, congenital cysts and, especially, liver fluke infection[17]. Furthermore, regular alcohol consumption has also recently been found to be one of the risk factors for this tumor[18]. Known predisposing conditions, such as mechanical irritation and chronic inflammation, exert marked and long-term effects on the development and progression of this tumor by inducing epithelial proliferation and promoting the subsequent susceptibility of these tissues to exogenous and/or endogenous carcinogenic exposure, leading to cholangi ocarcinogenesis[19]. In Thailand, ICC is one of the most common cancers and lethal diseases in the North and Northeast regions[20]. In Khon Kaen province, where liver fluke (*Opisthorchis viverrini*) infection is prevalent[20,21], 90% of the local inhabitants are or have been infected with this parasite[22]. In this same region, ICC occurs at its highest rate worldwide[16,18,21,23].

Although the roles of hMSH2 and hMLH1 genes in the pathogenesis of colorectal cancer (CRC), especially the hereditary nonpolyposis colon cancer (HNPCC), have been described[24], little is known about their involvement in cholangiocarcinogenesis. An analysis of the mutational status of the hMSH2 and hMLH1 genes in ICC from Thai patients was carried out via assessments of genomic instability in repeat sequences of microsatellites. The low frequency of somatic mutations in hMSH2 and hMLH1 genes indicated a minor involvement of this repair system[25]. However, MMR gene inactivation is not always caused by somatic mutations, but rather can be achieved by hypermethylation at the gene promoter, as reported in the hMLH1 gene[26,27]. Currently, the identification of a mutator phenotype in tumors still requires molecular testing. As an alternative screening tool for detecting DNA MMR deficiency derived from either somatic mutations or promoter hypermethylation of target MMR genes, we used immunohistochemical staining for cellular expression of hMSH2 or hMLH1 protein in archival tissues from Thai ICC that had previously been assessed for mutator phenotype by mutational inactivation using the PCR-based method. Nuclear localization of encoded proteins evaluated from the current study and the mutator phenotype assessed from the previous investigation were comparatively analyzed.

MATERIALS AND METHODS

Tissue samples

A total of 29 cases consisting of 11 fresh-frozen and 18 formalin-fixed, paraffin-embedded ICC tissues were used for this study. Samples were obtained with informed consent and the project was approved by the Ethical Committee of the National Cancer Institute of Thailand. After surgery, parts of specimens were promptly fixed in neutral formalin and processed histologically to prepare tissue sections for further immunohistochemical analysis.

Immunohistochemical study

Immunohistochemical staining for hMSH2 and hMLH1 proteins was performed with a standard avidin-biotin-peroxidase complex technique[28], using diaminobenzidine (DAB) as a chromogen. Formalin-fixed, paraffin-embedded tissue sections (4-μm thick) of the ICC were processed immunohistochemically. Tissue sections were first dipped in three changes of xylene for 5 min each and three changes of absolute ethanol for 5 min each, followed by two washes with distilled water and a final wash in PBS for 5 min. Antigen retrieval was performed by immersing tissue sections in sodium citrate buffer (0.01 mol/L, pH 6.0), autoclaving for 10 min at 121℃, cooling and rewashing the sections in distilled water prior to incubating for 15 min in 30 mL/L H_2O_2 in methanol to block endogenous peroxidase activity. To eliminate non-specific protein binding, after three washes with PBS for 3 min each, tissue sections were incubated at room temperature for 10 min with 100 mL/L normal goat serum in PBS. Immunostaining was performed by incubating tissues with a primary antibody against hMSH2 protein (clone FE11, Oncogene Research, 1:50 dilution), hMLH1 protein (clone 14, Oncogene Research, 1:10 dilution) or PBS (as a negative control) in a humidified chamber at 4℃ overnight. Tissue sections were washed three times with PBS, 3 min each, followed by incubation with biotinylated rabbit anti–mouse IgG (1:1000 dilution) for 30 min at room temperature. After three washes for 3 min each in PBS, sections were incubated in a streptavidin-peroxidase reagent for another 30 min. After three PBS washes, the peroxidase reaction was initiated by incubating tissue sections in DAB reagent for 5-20 min at room temperature. Sections were washed three times in distilled water for 3 min each. Immunostained tissue sections were then lightly counterstained with Mayer hematoxylin, washed with distilled water, dehydrated with ascending graded ethanol and xylene and mounted with mounting medium for further viewing under the light microscope.

The expression of hMSH2 or hMLH1 protein is normally observed in the nucleus. A case was considered immunoreactively positive or negative when nuclear staining for either target protein was present in or completely absent from tumor cells in ICC tissues, respectively.

Assessment of mutator phenotype

MS alterations were previously assessed in each normal DNA and paired tumor DNA in the majority of this same set of samples (except cases 26 and 27) using

a panel of 12 known highly polymorphic MS loci in nuclear DNA: five Bethesda markers including BAT-25, BAT-26, D2S123, D5S346 and D17S250; and seven other markers including D2S119, D3S1277, D3S1298, D3S1561, D3S1611, D11S904 and TP53. Three different markers of repeat sequences in mitochondrial DNA, including the D-loop, NADH dehydrogenase subunit 1 and NADH dehydrogenase subunit 5, were also analyzed using a fluorescence PCR–based technique, as reported previously[25].

RESULTS

Immunohistochemical study

The immunohistochemical analysis for nuclear localization of two MMR genes, hMSH2 and hMLH1, in 29 ICC tissues demonstrated positive immunostaining in the majority of stained cases (Table 1). Intense nuclear expression of either hMSH2 or hMLH1 was observed in 96.6% (28/29) ICC cases. hMSH2 nuclear staining was readily visible in 86.2% (25/29) ICC cases (Figure 1 A and B), whereas positive immunostaining for the hMLH1 protein was detected in 93.1% (27/29) cases (Figure 1, C and D). Consequently, negative immunoreactivities for nuclear expression of hMSH2 and hMLH1 genes were verified in 4 (13.8%, cases 7, 8, 9 and 17) and 2 (6.9%, cases 7 and 19) of the 29 ICC cases, respectively (Table 1).

Among positively stained cases, different levels of expression of either MMR gene were noted. An intense immunohistochemical reaction was observed in cases 2, 12, 14 and 16 (16.0%) for hMSH2 and cases 18, 26, 27 and 29 (14.8%) for hMLH1. A relatively reduced degree of nuclear expression was observed in cases 1, 4, 5, 10 and 15 (20.0%) for hMSH2 and cases 4, 5, 10 and 21 (14.8%) for hMLH1.

Table 2 Correlation between hMSH2 and hMLH1 immunohistochemical expression and microsatellite profile in ICC studied *n*(%)

MS status	Number of cases	Pattern of nuclear expression/*n* (%)			
		hMSH2+ hMLH1-	hMSH2- hMLH1+	hMSH2+ hMLH1+	hMSH2- hMLH1-
MSI	8	0 (0)	2 (25)	5 (62.5)	1 (12.5)
MSS	19	1 (5.3)	1 (5.3)	17 (89.5)	0 (0)
NP	2	0 (0)	0 (0)	2 (100)	0 (0)
Total	29	1 (3.4)	3 (10.3)	24 (82.8)	1 (3.4)

MSI: Microsatellite instability; MSS: Microsatellite stable; NP: MSI assessment was not performed.

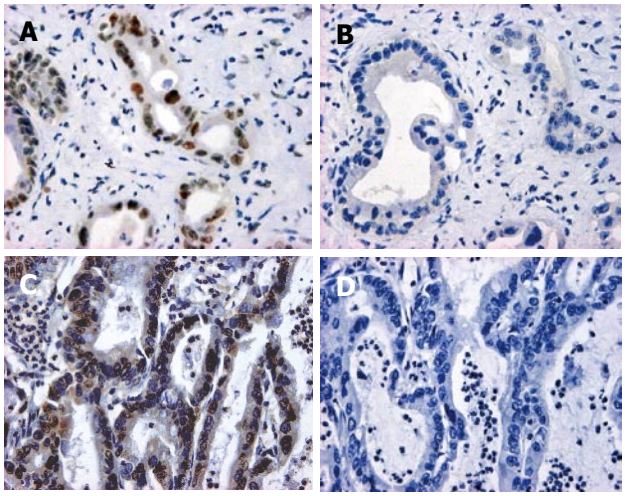

Figure 1 Representative data of the immunohistochemical expression of hMSH2 (case 26: A and B) or hMLH1 (case 22: **C** and **D**) protein in ICC. **A** and **C**: Stained with anti-hMSH2 and anti-hMLH1 antibodies, respectively; **B** and **D**: stained without the first antibodies as negative controls (immunoperoxidase, original magnification x 400).

Mutator phenotype study

Among the 15 microsatellite markers that were assessed, 8 loci were found to be aberrant. Low-frequency MSI was detected for BAT-25, D2S123, D11S904 and D17S250, and loss of heterozygosity (LOH) was detected for D3S1298, D3S1561, D5S346 and TP53. Most ICC samples were therefore classified as microsatellite stable (MSS), and a subset was classified as low-frequency MSI (MSI-L), as reported previously[25].

DISCUSSION

The assessment of MMR deficiencies has become an important tool for the characterization of genomic instability and of the molecular pathogenesis of both inherited and sporadic human cancers. Molecular defects in known MMR genes, especially hMSH2 and hMLH1, have been well defined in the HNPCC syndrome[29-31]. In subsets of sporadic human cancers, these two genes were also found to be involved in the pathogenesis with varying frequency[3]. Previous studies demonstrated that in a majority of sporadic MSI tumors, hMLH1 inactivation was frequently caused by an epigenetic rather than genetic mechanism, whereas the rest displayed somatic mutations in these two genes[32-34]. Methylation of the hMLH1 gene promoter is usually biallelic[35]. Assessments of microsatellite alterations are characterizations of a mutator phenotype through somatic mutational inactivation, however, do not identify aberrations in specific genes involved, which requires further investigation.

In ICC from Thai patients, hMSH2 and hMLH1 genes do make a minor contribution to cholangiocarcinogenesis, as shown by the assessment of the mutator phenotype through their somatic mutations, using a panel of highly polymorphic MS markers that are mainly related to these genes[25]. However, the inactivation of these genes via other genetic mechanisms has not yet been excluded. In the present study, using an immunohistochemical analysis, aberrations either through somatic mutations and/or promoter hypermethylation of hMSH2 and hMLH1 gene were sought at a protein level by evaluating the nuclear expression of their proteins in ICC carcinogenesis. Our results clearly showed immunoreactivity of either protein with different degree of expression level in the majority of cases, thereby indicating the minor involvement of these genes in the pathogenesis of this tumor (Table 1), which is consistent with results that were obtained through molecular assessments[25]. In a few cases of them, however, expression of one or both proteins was lost (Table 1). Considering the different degree of MMR gene expression noted in positively stained cases, a relatively lower degree of hMSH2 and hMLH1 immunostaining was observed in 20.0% (5/25) and 14.8% (4/27) immunopositive cases, respectively, giving rise to 21.4% (6/28) cases that presented with reduced expression of at least one MMR gene, suggesting that the down-regulation of the encoding genes occurred during their carcinogenic process. This phenomenon might have been due to hypermethylation at the gene promoter, at least in the case of the hMLH1 gene, of which was often accompanied by the down-regulation or absence of hMLH1 gene expression[34,36,37]. Hypermethylation-associated reduced expression of the hMLH1 gene has already been described in lung[38], gastric[39,40] and colorectal cancers[34,36].

There was a correlation between the nuclear expression of hMSH2 or hMLH1 protein and a previously assessed MSI/mutator phenotype in a given ICC tissue (Table 1). In hMSH2 immunostaining, 3 of 4 cases (cases 7, 8 and 17) that displayed negative nuclear staining also had MSI at D2S123, a hMSH2-related MS locus[25]. The remaining case (case 9), which also exhibited loss of hMSH2 gene expression, showed stability at this locus, suggesting the presence of other hMSH2-related MS loci that mapped to 2p is involved in hMSH2 somatic inactivation. Simultaneously, in hMLH1 immunostaining, two cases (cases 7 and 19) showed a loss of this gene expression. One of them (case 7) also exhibited LOH at two hMLH1-related MS loci, D3S1298 and D3S1561, whereas the other one was MSS[25] (Table 2), indicating an availability of other hMLH1-related loci that mapped to 3p, whose MSI/LOH are involved in the loss of expression of this gene.

In the current study, the majority of ICC samples (89.5%), almost all of which was previously assessed as MSS/MSI-L[25], consistently displayed positive nuclear staining for both MMR proteins (Table 2). Five (cases 4, 10, 12, 18, 21) of eight MSI cases (62.5%) retained both hMSH2 and hMLH1 protein expression (Tables 1 and 2). These results are in agreement with previous findings describing the presence of MSI tumors with positive immunohistochemical staining and without detectable somatic mutations in either MMR gene[41]. On the other hand, three (cases 1, 5, 15) of the MSS cases in this study had reduced expression of either or both MMR proteins. Nevertheless, previous findings demonstrated that relatively low level of hMSH2 and hMLH1 proteins may be sufficient to retain the MSS phenotype[42], which might also be the case for the current study. Certain incompatibilities between MSI and protein expression in cases 4, 10, 12, 18 and 21 might have been due to the existence of other as yet unknown stability gene(s) or another related gene(s) that function in or outside the DNA MMR complex and play a major role in the development of this tumor type. The present findings undoubtedly demonstrated and confirmed the previous findings that only a small fraction of ICC cases was affected by hMSH2 and/or hMLH1 functional inactivation and that these two MMR genes do not seem to be implicated in carcinogenesis steps in most ICC cases.

In conclusion, to our best of knowledge, we are the first to report the pattern of immunohistochemical expression of MMR genes in ICC. Results from previous mutator phenotype assays and the current immunohistochemical screening of hMSH2 and hMLH1 genes in ICC from Thai patients consistently confirm the minor involvement of the DNA MMR system, through malfunctional activity of the hMSH2 and/or hMLH1 genes, in ICC carcinogenesis. The immunohistochemical analysis has proven to be an effective and useful approach for the screening of defects in the DNA MMR complex derived from either somatic mutational inactivation or promoter hypermethylation of target MMR genes. It is more advantageous, in terms of simplicity, less time consuming and cost effectiveness, to screen mutator phenotype through inactivation of target MMR genes in cholangiocarcinogenesis by using the immunohistochemical method.

ACKNOWLEDGMENTS

We thank Drs. K Chindavijak and S Deerasamee, former directors of the National Cancer Institute of Thailand, for their valuable support for our work. Thanks are also due to Dr. Katsumi Takano for his suggestion concerning the immunohistochemical study.

Abstract

AIM: C-reactive protein (CRP) is an acute-phase reactant and a known indicator of the malignant potential of the tumour. The aim of this study was to investigate the significance of preoperative CRP as a parameter of the perioperative course and long-term prognosis in patients with squamous cell carcinoma and adenocarcinoma of the oesophagus.

METHODS: Serum CRP was determined preoperatively in 291 of 371 patients undergoing oesophagectomy for cancer from December 1989 to March 2004. Median patient age was 59 (28-79) year, 82.5% of patients were males. Squamous cell carcinoma was diagnosed in 151 (51.9%) and adenocarcinoma in 122 patients. Transhiatal oesophagectomy was done in 151 (51.9%) patients and 134 (46.0%) patients underwent the abdominothoracic procedure.

RESULTS: In 127 (43.6%) patients the preoperative serum CRP concentration was within the normal range (< 5 mg/dL), elevated CRP levels were measured in 164 (56.4%) patients. Tumour extension (P < 0.0005) and the number of lymph nodes affected by metastatic spread (P = 0.015) were significantly increased in the group with elevated CRP levels. Among the perioperative parameters both the number of blood transfusions (P = 0.006) and the general complication rate (P = 0.002) were higher in patients with elevated preoperative CRP levels. The long-term survival rate of 13.6 (0-109.8) mo was poorer in the group with elevated CRP levels compared to 18.9 (0-155.4) mo in the group with normal CRP levels (log-rank test: P = 0.107). Multivariate analysis with backward variables selection identified preoperative CRP as an independent prognostic factor of the long-term prognosis in patients with oesophageal carcinoma, with a hazard ratio of 1.182 (95% confidence interval: 1.030-1.356).

CONCLUSION: The preoperative serum CRP-level is an easily determined independent prognostic marker in patients with squamous cell carcinoma and adenocarcinoma of the oesophagus.

INTRODUCTION

C-reactive protein (CRP) is an acute-phase reactant and a known indicator of the malignant potential of tumours. The synthesis is regulated by proinflammatory cytokines, which serve as growth factors in neoplastic processes[1]. These include in particular IL (interleukin)-1, IL-6, TNF (tumour necrosis factor)-α, IF (interferon)-γ, TGF (tumour growth factor)-β, EGF (epidermal growth factor) and LIF (leukaemia inhibiting factor). CRP is produced in the liver and electrophoresis shows a location of the protein between the beta- and gamma-globulin fractions.

The preoperative serum elevation of CRP has been identified as a significant prognostic factor in patients with colorectal cancer[2]. However, raised CRP concentrations as an indicator of a poorer prognosis in patients with oesophageal cancer have been demonstrated solely for squamous cell carcinoma[3,4]. The aim of this prospective study was to investigate the significance of C-reactive protein for the perioperative course and long-term

prognosis in a patient population with histologic entities of both adenocarcinoma and squamous cell carcinoma of the oesophagus.

MATERIALS AND METHODS

C-reactive protein was determined preoperatively in 291 of 371 patients undergoing oesophagectomy for carcinoma from December 1989 to March 2004. Median patient age was 59 (range from 28 to 79) year; 240 (82.5%) of the patients were males. Squamous cell carcinoma was diagnosed in 145 and adenocarcinoma in 122 patients. An undifferentiated carcinoma was found in 18 patients and 4 patients had other malignant tumours of the oesophagus. Patients receiving neoadjuvant chemoradiotherapy were excluded from the study.

Transhiatal oesophagectomy was carried out in 151 (51.9%) patients and 134 (46.0%) patients underwent abdominothoracic oesophagectomy with two-field lymphadenectomy (abdominal and mediastinal). Reconstruction was accomplished by pulled-up gastric tube in 264 of 285 patients (93.0%), by colon interposition in 12 (4.2%), and by small intestine interposition in 7 (2.5%) patients. The anatomic prevertebral oesophageal bed was used for the majority of these procedures. The remaining two patients did not undergo a primary reconstructive procedure.

Abdominothoracic oesophagectomy was routinely performed for squamous cell carcinoma. A transhiatal procedure was selected only for tumours with a distal location and malignancies without oesophageal wall penetration, or in the presence of a high general risk. Transhiatal oesophagectomy with abdominal and posterior mediastinal lymphadenectomy was carried out in adenocarcinomas, the two-field procedure was done in the presence of advanced tumour growth or extended lymph node involvement.

Data were collected prospectively in a specially established database and analysed retrospectively. In addition to routine demographic data, preoperative and intraoperative variables, tumour characteristics, as well as postoperative morbidity and mortality were documented. Long-term survival data were finally recorded in April 2004 and collected by telephone interview with the patients or their primary physicians.

CRP measurement

Serum CRP was determined by latex-enhanced homogeneous immunoassay[5] (wide-range) (Hitachi 917; Skill, Munich, Germany). In this assay, serum levels < 5 mg/dL are considered as normal values, those of ⩾ 5 mL/dL are considered as indicators of existing pathology.

Statistical analysis

The SSPS 12.0 software package (SSPS, Chicago, IL, USA: 1999) and SAS 8.01 were used for statistical analysis. The patients were divided into two groups according to the C-reactive protein concentration measured preoperatively: those with CRP values in the normal range (< 5 mg/dL) and those with elevated CRP levels (⩾ 5.0 mg/dL). Median values with ranges (minimum-maximum) as well as absolute (relative) frequencies are shown for both groups. The χ^2-test with Pearson correction (χ^2) and Fisher's exact test (F) were used for the comparison of the categorical prognostic factors between the two groups. The t-test (t) was used for the comparison of continuous prognostic factors with symmetrical empirical distribution of the data. The Mann-Whitney U-test (U) served for the comparison of the other prognostic factors. The log-rank test (LR) was used for the comparison of survival times in the two groups. Morbidity, mortality, and long-term survival were assessed by multivariate analysis using Cox's proportional hazards regression model (HR). The logarithm was found for CRP, which served as a continuous variable. Backward variables selection was carried out with the Wald test (W) to the level of $\alpha = 0.05$.

Since no adjustment was made for the problem of multiple testing, all P values are descriptive.

Table 1 Tumour characteristics

Parameter	CRP < 5.0 mg/dL (n = 127)	CRP ⩾ 5.0 mg/dL (n = 164)	P-value
Histologic type (n = 289)			
-squamous cell carcinoma	56 (44%)	89 (55%)	
-adenocarcinoma	62 (49%)	60 (37%)	0.150
-undifferentiated	6 (5%)	12 (7%)	
-other	3 (2%)	1 (1%)	
Location (n = 288)			
-upper third	9 (7%)	15 (9%)	
-middle third	42 (33%)	49 (30%)	0.748
-lower third	76 (60%)	97 (60%)	
Tumour size (cm) (n = 281)	3 (0.5-12)	4.7 (0.7-20)	0.0001
Lymph nodes (n = 285)			
-dissected	23.5 (0-71)	27 (2-86)	0.015
-positive	1 (0-24)	2 (0-41)	0.015
pT-category (n = 287)			
-pT1	25 (20%)	19 (12%)	
-pT2	34 (27%)	31 (19%)	0.055
-pT3	61 (49%)	98 (60%)	
-pT4	5 (4%)	14 (9%)	
pN-category (n = 286)			
-pN0	54 (43%)	52 (32%)	
-pN1	69 (56%)	107 (66%)	0.062
-pN2	1 (1%)	3 (2%)	
pM-category (n = 283)			
-pM0	96 (78%)	116 (73%)	0.177
-pM1	27 (22%)	44 (28%)	

RESULTS

Preoperative CRP concentrations in the normal range (< 5 mg/dL) were found in 127 (43.6%) patients, elevated CRP levels were found in 164 (56.4%) patients. There were no significant differences between the two groups in age, gender, and ASA-classification ($P > 0.05$). No differences were observed for tumour type and location, although tumour extension (in cm) (measured from surgical specimen fixed in formalin) ($P < 0.0005$), the number of dissected ($P = 0.015$) and positive lymph nodes ($P = 0.015$) were significantly higher in the group with elevated CRP levels. The distribution of pT-, pN-, and pM-categories was similar in both groups ($P > 0.05$) (Table 1).

Table 2 Perioperative course

Parameter	CRP < 5.0 mg/dL (*n* = 127)	CRP ≥ 5.0 mg/dL (*n* = 164)	*P*-value
Blood transfusion (*n*) (*n* = 276)	0 (0-22)	1.5 (0-38)	0.006
ICU stay (d) (*n* = 276)	9.5 (2-107)	11 (1-115)	0.094
Internal complications (*n* = 288)	34 (27%)	74 (45%)	0.002
Surgical complications (*n* = 280)	46 (36%)	66 (41%)	0.469
-anastomotic leakage	22 (18%)	34 (21%)	0.549
-transplant necrosis	3 (3%)	7 (4%)	0.522
-mediastinitis	2 (2%)	3 (2%)	0.999
30-d-mortality (*n* = 286)	9 (7%)	12 (7%)	0.999
Hospital mortality (*n* = 280)	14 (11%)	21 (13%)	0.719

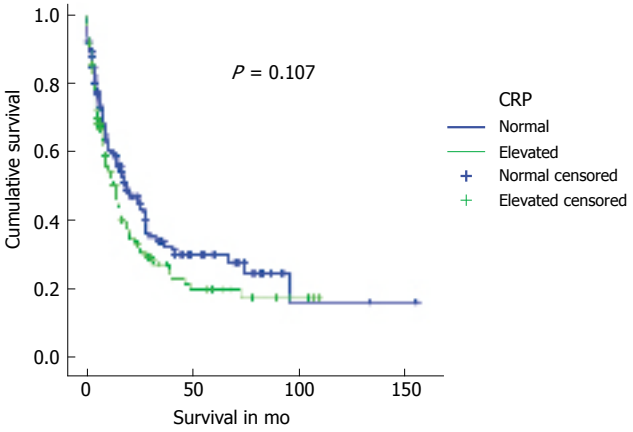

Figure 1 Kaplan-Meier survival curves for patients with elevated compared to normal preoperative CRP-values.

Perioperative course

Of the perioperative parameters, both the volume of blood transfusions ($P = 0.006$) and the number of internal medical complications ($P = 0.002$) were higher in patients with preoperative elevated CRP levels than in those with normal serum concentrations. No differences were found between the two patient groups in the length of the postoperative intensive care unit stay, the prevalence of surgical complications, or the morbidity and mortality rates (Table 2). Separate consideration of the two tumour entities showed that the squamous cell carcinoma was associated with a higher number of internal ($P = 0.010$) and surgical complications ($P = 0.083$) without a difference in the 30 d and hospital mortality rate, than adenocarcinoma where no significant differences were identified ($P > 0.05$). The comparison of the two groups showed that the preoperative CRP had no significant influence on the morbidity rate.

Long-term prognosis

A median survival of 13.6 (0-109.8) mo in patients with preoperative elevated CRP levels was markedly poorer compared to 18.9 (0-155.4) in those with normal CRP levels ($P = 0.107$). Estimated long-term survival rates calculated by the Kaplan-Meier method for both patient groups are shown in Figure 1.

For multivariate analysis, a model for the prediction of survival time was established by carrying out a backward variables selection, comprising patient age, gender, BMI (body mass index), ASA classification, computed CRP logarithms, tumour type and location, R-classification, pT-, pN- and pM-category, as well as tumour size. The data analysis was only done on those 253 patients in whom all data were available. The analysis identified that the preoperative CRP with a hazard ratio of 1.182 (95% confidence interval: 1.030-1.356) was as an independent factor, which has an influence on the long-term prognosis in patients with oesophageal carcinoma ($P = 0.0172$).

Additional relevant prognostic factors included the pT-category ($P < 0.0001$), R-classification ($P = 0.0113$), and the surgical procedures in which transthoracic was more favourable with regard to long term-prognosis than transhiatal ($P = 0.0345$) (Table 3). The forward likelihood ratio variables selection yields a similar model. A separate analysis of each of the two histologic tumour types did not identify CRP as an independent prognostic factor (squamous cell carcinoma: $P = 0.062$; adenocarcinoma: $P = 0.063$). However, multivariate analysis showed that the surgical procedure ($P = 0.0054$) was the most significant prognostic indicator on survival in patients with squamous cell carcinoma, whereas the pT-category ($P = 0.0002$) was the most significant prognostic indicator for survival in patients with adenocarcinoma.

Table 3 Independent prognostic factors in 253 patients with oesophageal resection for carcinoma

Variable	Hazard ratio	95% confidence interval (CI) Lower border	Upper border	*P*-value
pT-category[1]				< 0.0001
-pT2	2.316	1.158	4.629	0.0174
-pT3	4.240	2.211	8.131	< 0.0001
-pT4	4.432	1.854	10.596	0.0008
R-classification[2]				0.0113
0	1.992	1.231	3.224	0.0050
-R2 and R2	-0.618	0.190	2.008	0.4234
CRP (logarithm)	1.182	1.030	1.356	0.0172
Surgical approach[3]				0.0345

DISCUSSION

C-reactive protein as a marker of malignant potential in oesophageal carcinoma

In the present study, patients with preoperatively elevated CRP concentrations had significantly larger tumours, a higher number of lymph nodes affected by metastatic spread with a higher total number of dissected lymph nodes. The correlation between acute-phase protein

and biological behaviour in oesophageal cancer may be attributable to an inflammatory reaction, the endogenous response to tumour invasion[6,7].

The production of CRP is regulated by proinflammatory cytokines, in particular IL-6, IL-1 and TNFα, which serve as autocrine growth factors in neoplastic processes[2,8-11]. Acute-phase reactions of the organism have further been observed in tumour progression and tumour recurrence[12]. A correlation has been established between elevated serum CRP concentrations and malnutrition as well as impaired immunity in patients with oesophageal cancer[1].

While acute bacterial infections and collagen diseases are associated with a marked serum CRP elevation (> 10 mg/dL) at a latency period of 8-12 h for infections, only moderately elevated serum levels (< 10 mg/dL) have been observed in patients with malignomas[6,13].

Nozoe *et al* first presented immunohistochemical evidence of CRP expression in tumour cells of patients with squamous cell carcinoma of the oesophagus. The authors found that elevated serum levels of the protein, in addition the synthesis by hepatocytes as a response to the tumour, may be at least in part due to the production of CRP by the tumour itself[4]. In their study, the immunohistochemical expression of CRP in the tumour correlated with preoperative serum CRP levels. There were, however, no significant differences in the clinicopathologic characteristics, in particular the TNM-classification, between the patients with and without CRP expression of the tumour[4].

Comparable data on the adenocarcinoma have not been published to date.

C-reactive protein as a prognostic indicator of the perioperative course

Mortality rates after oesophagectomy cited in the literature range from 2%-25%[14]. These rates are in particular accounted by the development of pulmonary complications[15-17]. Various risk analyses have further described the impaired function of heart, liver and respiratory system, in addition to patient age and general status as independent predictors of perioperative morbidity and mortality[14,18-20]. A preoperative marker for the assessment of the intraoperative and postoperative course has not yet been established.

There was an increase in the required transfusion of packed erythrocytes in our patients with preoperatively elevated CRP, which may be due to the presence of larger tumours leading to extended operative times in this group. Furthermore, there were a greater number of general complications, especially those of pulmonary origin, in patients with a preoperative CRP value of ⩾ 5.0 mg/dL. With a view to the described cytokine interaction, Katsuta *et al* found a close association between preoperative TNF-α and IL-1β-production, and pulmonary complications after transthoracic oesophagectomy[21]. In their study, however, they did not find that either preoperatively determined CRP levels or IL-6 had an influence on the development of postoperative pneumonia[21]. A limitation of the assessment of the importance of C-reactive protein in our patient population is that the abdominothoracic procedure, which is associated with a higher pulmonary morbidity rate, was selected more frequently (80/134 patients) than the transhiatal approach (80/151 patients) in the group with elevated CRP concentrations. The difference in the occurrence of general complications was therefore of relevance only in patients with squamous cell carcinoma, but not in those with adenocarcinoma.

Significance of C-reactive protein for the long-term prognosis

In addition to the pT-category as the most significant prognostic factor, R-classification and the surgical procedure, preoperatively determined CRP was an independent prognostic factor in our patient population after surgical treatment for oesophageal carcinoma.

A number of different molecular biologic analyses have established a correlation between the expression of epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF), cyclin D, int-2, hst-1, p53-mutation, CD44-variants, MIB-1-proliferation and carcinogenesis in oesophageal carcinoma and its prognosis[22-28].

The importance of CRP as a prognostic indicator in oesophageal carcinoma has recently been described in patients with squamous cell carcinoma only[3,4,29], as well as by a study consisting to 6.5% of patients with adenocarcinoma[1]. Thus far there have been no studies conducted to investigate the role of CRP in patients with adenocarcinoma, or in patients comprising with both adenocarcinoma and squamous cell carcinoma. A search of the available literature demonstrates that this study is the first to identify preoperative CRP as an independent prognostic factor for long-term survival in a mixed patient population. The number of patients with squamous cell carcinoma was only slightly higher than that with adenocarcinoma (145/291 *vs* 122/291, respectively).

In summary, the results of this study show that preoperative CRP is an easily determined and independent prognostic marker in patients with squamous cell carcinoma and adenocarcinoma of the oesophagus. The significance of the role of this marker needs to be assessed in relation to that of other important prognostic factors of long-term survival, i.e. the pT-category and R-classification. However, the pT-category and R-classification become apparent only postoperatively, the assessment of CRP is a useful tool in the evaluation of the course prior to surgical intervention.

Abstract

AIM: Acute pancreatitis (AP) is the most common and often severe complication of endoscopic retrograde cholangiopancreatography (ERCP). The early step in the pathogenesis of acute pancreatitis is probably the capillary endothelial injury mediated by oxygen-derived free radicals. N-acetylcysteine - a free radical scavenger may be potentially effective in preventing post-ERCP acute pancreatitis and it is also known that N-acetylcysteine (ACC) can reduce the severity of disease in experimental model of AP.

METHODS: One hundred and six patients were randomly allocated to two groups. Fifty-five patients were given N-acetylcysteine (two 600 mg doses orally 24 and 12 h before ERCP and 600 mg was given iv, twice a day for two days after the ERCP). The control group consisted of 51 patients who were given iv. isotonic saline twice a day for two days after the ERCP. Serum and urine amylase activities were measured before ERCP and 8 and 24 h after the procedure. The primary outcome parameter was post-ERCP acute pancreatitis and the secondary outcome parameters were differences between groups in serum and urine amylase activity.

RESULTS: There were no significant differences in the rate of post-ERCP pancreatitis between two groups (10 patients overall, 4 in the ACC group and 6 in the control group). There were also no significant differences in baseline and post-ERCP serum and urine amylase activity between ACC group and control group.

CONCLUSION: N-acetylcysteine fails to demonstrate any significant preventive effect on post-ERCP pancreatitis, as well as on serum and urine amylase activity.

INTRODUCTION

Since their introduction, endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincterotomy (EST) have played a very important role in the diagnosis and treatment of biliary and pancreatic diseases. Magnetic resonance cholangiopancreatography (MRCP) is a very safe procedure and capable of providing diagnostic information similar to ERCP, but ERCP and EST still hold a key therapeutic role[1-3]. Although these procedures are generally considered being safe, they are associated with some complications, like cholangitis, haemorrhage, perforation and acute pancreatitis (AP). Acute pancreatitis is the most frequent major complication of ERCP. It is estimated that it occurs in 1%-15% of patients overall[4,5], with a higher incidence in subjects who have had therapeutic ERCP[6].

Post-ERCP pancreatitis usually is defined as new onset of abdominal pain persisting for more than 24 h after the procedure, and elevation of serum pancreatic enzymes 5 times above the normal limit. Asymptomatic increase in pancreatic enzyme activities may occur in up to 70% of all cases. Although the pathogenesis of post-ERCP pancreatitis is not clearly understood, it seems that the patient's inflammatory response to pancreatic

duct imaging and instrumentation plays a critical role[5]. An early step in the pathogenesis of acute pancreatitis is capillary endothelial injury manifested as increased capillary permeability[7]. An experimental study suggested that capillary injury might be mediated by oxygen-derived free radicals[8]. The manifestations of pancreatitis in experimental animal model can be ameliorated by blocking the action of oxygen-derived free radical scavengers[9-11]. Acetylcysteine is an excellent source of sulfhydryl groups, and is converted in the body into metabolites capable of stimulating glutathione synthesis and acting directly as free radical scavenger[12]. It has been shown that acetylcysteine can reduce severity of experimental acute pancreatitis[9,13,14]. Anecdotal reports suggest also that NAC could be effective in reducing complication of AP in humans[15]. N-acetylcysteine thus may be potentially effective in the prevention of post-ERCP acute pancreatitis.

Recently Katsinelos *et al*[16] have found that intravenous N-acetylcysteine does not prevent post-ERCP pancreatitis. The authors have pointed out that their findings cannot be generalized because larger cohorts may be needed to definitevly elucidate this problem. As combination of data from multiple, small (even underpowered) trials should enhance the precision and accuracy of any meta-analysis[17], we describe here the results of a prospective, randomized open-label study to determine the effect of N-acetylcysteine on the incidence of hyperamylasemia and pancreatitis after ERCP, which was previously reported only in the abstract form[18].

MATERIALS AND METHODS

Patients

Between January and December 2002, 345 consecutive patients undergoing ERCP in our institution were assessed for eligibility to enter the study. A total of 106 patients who fulfilled the entry criteria and gave their consent, were enrolled into the study. Exclusion criteria were as follows: presence of acute pancreatitis and/or severe chronic pancreatitis and/or hyperamylasemia, pregnancy and breast feeding, age under 18.

Patients were randomized to one of the two groups. In the treated group, 55 subjects received N-acetylcysteine (*ACC 600*, Hexal-Polska). Two 600 mg doses were given orally 24 h and 12 h before ERCP and 600 mg was given intravenously, twice a day for two days after the ERCP. The control group consisted of 51 patients who were given iv isotonic saline twice a day for two days after the ERCP. The present study was approved by the local ethics committee.

Endoscopic procedure

All endoscopic procedures were performed by the same experienced endoscopist. As a contrast medium 60% dilution of diatrizoate meglumine was used. All patients were fasted overnight and remained fasting for a minimum of 12 h after the ERCP. Patients stayed in the hospital for at least 48 h after the procedure. Biochemical parameters and clinical status were examined. Premedication consisted of pharyngeal anesthesia with xylocaine spray and intravenous administration of midazolam and hyoscine-N-butyl bromide titrated according to age and tolerance. ERCP was performed with the patient under general anesthesia with propofol and fentanyl, without airway intubation. At the end of each procedure, the endoscopist recorded also the details of the maneuvers performed, especially the ease or difficulty of cannulation, number of cannulations, number of pancreatic duct injections, presence of parenchymogram on radiography, or whether a needle-knife sphincterotomy was performed. Biochemical and clinical evaluation, serum and urine amylase activity were measured before ERCP and after 8 and 24 h of the procedure. Before the endoscopic procedure and 24 h after, blood samples were analysed for alanine and asparagine transaminases, bilirubin and white blood cells (leukocytosis was defined as a white cell count greater than 10000/ mm^3). The primary outcome parameter was frequency of AP post-ERCP, defined by clinical features consistent with acute pancreatitis beginning after ERCP and lasting for at least 24 h, associated with increase in serum amylase levels greater than five times above normal.

Secondary outcome parameters were differences between groups in serum and urine amylase activities measured at 8 and 24 h after the ERCP.

Table 1 Indications for ERCP in N-acetylcysteine treated group (ACC-group) and control group

ERCP indications	ACC group	Control group	*P*
Bile duct stones	35	32	NS
Recurrent pancreatitis	2	4	NS
Biliary pain, cholestasis	3	5	NS
Chronic pancreatitis	8	3	NS
Pancreatic cancer	3	1	NS
Other	4	6	NS

Statistical analysis

Univariate statistical analysis was performed using chi-square test, Fisher's exact test for count data or Student's *t*-test for comparison of means. Multivariate analysis was performed using forward logistic regression procedure and 0.05 and 0.1 as values to enter or remove the variables. Serum and urine amylase data were subjected to repeated measure analysis of variance with N-acetylcysteine treatment as between subject factor. $P < 0.05$ was considered statistically significant. The STATA software, version 8.2 for Macintosh (Stata Corporation, College Station, TX, USA) was used for statistical computations.

RESULTS

Of the 106 patients included, 55 were randomized to the ACC group and 51 to the control group. The groups were similar with respect to the main indications for ERCP (Table 1) and endoscopic procedures performed (Table 2). There were no significant differences in acute pancreatitis risk factors (female gender, multiple cannulations, pancreatic duct injections, precut papillotomy, common biliary duct diameter; diagnostic ERCP and failed procedure) between the groups (Table 3). Post-ERCP pancreatitis graded as mild or moderate was observed in 10 (9.4%) patients, 4

Table 2 ERCP procedure performed

ERCP procedure (patients)	ACC group	Control group
Diagnostic	4	2
Therapeutic	51	49
Endoscopic sphincterotomy	44	47

Table 3 Risk factors for acute pancreatitis

Risk factors (patients)	ACC group	Control group	Total	*P*
Gender (F/M)	33/22	33/18	66/40	NS
Multiple cannulations	9	7	16	NS
Pancreatic duct injections	13	12	25	NS
Diagnostic ERCP	5	1	6	NS
Failed procedure	2	3	5	NS
Precut papillotomy	12	9	21	NS
Small bile duct diameter	2	5	7	NS

Table 4 Unvariate analysis of group differences according to the presence of acute pancreatitis

Variables	Acute pancreatitis (*n* = 10)	No acute pancreatitis (*n* = 96)	*P*
N-acetylcysteine / Control	4/6	51/54	NS
Sex (F/M)	9/1	57/39	NS
Precut (Y/N)	6/4	15/81	0.004
Small bile duct diameter (Y/N)	1/9	6/90	NS
Multiple cannulations (Y/N)	5/5	11/85	0.006
Pancreatic duct injections (Y/N)	4/6	21/75	NS
Diagnostic ERCP (Y/N)	1/9	5/91	NS

(7.3%) patients in the ACC group and 6 (11.8%) in the control group (NS). In univariate analysis of differences between two groups according to the presence of acute pancreatitis, only two factors were significantly associated with an increased risk of pancreatitis: precut papillotomy and multiple cannulations. Female sex was on the verge of statistical significance (Table 4).

There were no significant differences in baseline and post-ERCP serum and urine amylase activity between ACC group and control group (Table 5). There were also no differences in total bilirubin, alanine and aspartate aminotransferases and WBC between the two groups (data not shown).

Initially the following variables including N-acetylcysteine treatment, precut papillotomy, multiple cannulations, common biliary duct diameter, injection of the contrast into pancreatic duct, failed procedure, sex and age, were entered into a logistic regression model.

On multiple logistic regression analysis, only precut papillotomy remained as a predictor of acute pancreatitis (Table 6).

DISCUSSION

Although certain risk factors have been identified, the development of post-ERCP pancreatitis remains unpredictable. The knowledge of risk factors for post-ERCP pancreatitis is often not helpful in avoiding pancreatitis in individual patients. For these reasons it would be beneficial to find prophylactic treatment capable of preventing post-ERCP pancreatitis. The present study was conducted to test the hypothesis that N-acetylcysteine might reduce the frequency and intensity of post- ERCP pancreatitis. Our results did not support this hypothesis. Similarly many other therapeutic agents including octreotide, low-molecular weight heparin, nifedipine, have no beneficial effect on the frequency of post-ERCP pancreatitis[19-26]. On the other hand, there are data suggesting that gabexate mesylate, diclofenac and heparin may reduce the frequency of post-ERCP pancreatitis[5,27-30]. Data concerning corticosteroids, IL-10 and somatostatin are contradictory[19, 31-33].

Oxygen reactive species (ROS) have been implicated in the initiation of acute pancreatitis[34]. Animal models of acute pancreatitis point out to the occurence of early and profound oxidative stress[35,36]. In human studies of acute pancreatitis, increased blood concentrations of the superoxide radical and lipid peroxides, as well as depletion of ascorbic acid and an increased fraction of dehydroascorbic acid have been found[37].

In experimental pancreatitis various forms of scavenger therapy for ROS, have been shown to mitigate the pancreatic tissue damage after induction of acute pancreatitis and to attenuate the extrapancreatic complications, suggesting that superoxide dismutase[35], polyethylene glycol-linked superoxide dismutase[38], allopurinol[11], CV 3611 (a synthetic ascorbic acid derivative)[10] and N-acetylcysteine[9,13], may play their role in attenuating the extrapancreatic complications. N-acetylcysteine is converted to metabolites capable of stimulating glutathione synthesis[12] and is an important antioxidant and essential cofactor for antioxi-

Table 5 Serum and urine amylase activity before ERCP, after 8 and 24 h in control and ACC groups (mean ± SD)

Serum and urine amylase activity levels		Control group (%)	ACC group (%)	*P*
before ERCP	serum	62.1 ± 59.7	79.0 ± 79.4	NS
	urine	272.9 ± 320.5	268.1 ± 355.2	NS
8 h after ERCP	serum	324.6 ± 487.1	270.1 ± 484.7	NS
	urine	596.3 ± 1108.3	775.9 ± 1500.4	NS
24 h after ERCP	serum	268.6 ± 590.9	183.56 ± 252.1	NS
	urine	1324.8 ± 2763.9	1033.7 ± 2499.6	NS

Table 6 Summary of the results of forward selection multiple logistic-regression analysis with development of post-ERCP acute pancreatitis as the outcome variable

Variable[1]	Odds ratio	95% CI	*P*
Precut (no precut *vs* precut)	0.108	0.026-0.456	0.003
Sex (F *vs* M)	7.432	0.841-65.689	0.071

[1] Other variables that were examined but did not enter the model including N-acetylcysteine treatment, multiple cannulations, bile duct diameter < 8 mm, injection of contrast into pancreatic duct, failed procedure and age.

dant enzymes, and is depleted in AP[39].

Nuclear factor-kappaB (NF-κB), an oxidant-sensitive transcription factor, may regulate the induction of cytokine gene expression, which in turn regulates inflammatory response[13]. NF-κB activation and cytokine production in pancreatic acinar cells are suppressed by N-acetylcysteine[13,40]. It was reported that of ACC use in patients suffering from acute pancreatitis and multiorgan failure can improve their clinical status[15].

The occurrence of pancreatic damage after ERCP may be due to extraductal leakage of the pancreatic juice present in the ducts, rupture of acini or alterations of the acinar cells. Such functional alterations cause leak of pancreatic enzymes into the interstitium and then into the blood, consequently leading to hyperamylasemia and hyperamylasuria. In our study, ACC treatment had no influence on post-ERCP serum and urine amylase activities, suggesting that ACC does not ameliorate pathophysiologic mechanisms operating post-ERCP, leading to leak of pancreatic enzymes.

Our results are consistent with those obtained by Katsinelos *et al*[16]. There are however some differences between the present study and that of Katsinelos and colleagues[16]. We used a lower dose of N-acetylcysteine, which is similar to that used for the prevention of nephrotoxicity by contrast agents[41]. Although in AP experimetal models doses are used as high as 1000 mg/kg[9], there is evidence that high doses might actually have deleterious effects on the course of AP by inducing apoptosis probably due to inhibiting NF-κB[42,43].

Although our study was underpowered, it should be noted that increasing sample size would probably not yield different results. We initially assumed 10% rate of post-ERCP pancreatitis, it would be 3% in the treatment group. Then the number of patients required for the study with a two-sided 5% significance test and a power of 80% was 194 per group. Interim analysis was performed after inclusion of 106 patients to determine if a larger sample might change findings. An effect size of 0.077 calculated from the power analysis indicated that a statistically significant difference did not occur even if the study was continued and enrolled preplanned number of patients. In fact it would be necessary to recruit at least 669 subjects in each group to demonstrate any statistical significance, a clearly untenable goal. In addition, N-acetylcysteine treatment had no statistically significant influence on serum amylase activity. Therefore a decision to terminate the study was made.

We also attempted to identify conditions predisposing patients to the development of AP post-ERCP. In the present study, precut papillotomy was significantly associated with increased risk of pancreatitis, suggesting that this factor reflects the technical difficulty of the procedure.

In conclusion, N-acetylcysteine fails to demonstrate any significant preventive effect on post-ERCP pancreatitis, as well as on serum and urine amylase activity. Pancreatic injury is related to endoscopic maneuvers performed to obtain biliary access, rather than to the patient-related factors. Hence, a therapeutic agent with significant prophylactic effect on post-ERCP pancreatitis is still needed and it is necessary to perform more studies[44].

Abstract

AIM: To elucidate the frequency and risk factors for retinopathy in patients with chronic hepatitis C who are treated by interferon-ribavirin combination therapy.

METHODS: We prospectively analyzed 73 patients with histologically confirmed chronic hepatitis C, who underwent combination therapy for 24 wk. Optic fundi were examined before, and 2, 4, 12 and 24 wk after the start of combination therapy.

RESULTS: Fourteen patients (19%) developed retinopathy, which was initially diagnosed by the appearance of a cotton wool spot in 12 patients. Retinal hemorrhage was observed in 5 patients. No patient complained of visual disturbance. Retinopathy disappeared in 9 patients (64%) despite the continuation of combination therapy. However, retinopathy persisted in 5 patients with retinal hemorrhage. A comparison of the clinical background between the groups with and without retinopathy showed no significant differences in age, gender, viral genotype, RNA level, white blood cell count, platelet count, prothrombin time, complications by diabetes mellitus or hypertension, or pretreatment arteriosclerotic changes in the optic fundi. However, multiple logistic regression analysis revealed that complication by hypertension was observed with a high frequency in the group with retinopathy (P = 0.004, OR = 245.918, 95% CI = 5.6-10786.2).

CONCLUSION: Retinopathy associated with combination therapy of interferon α-2b and ribavirin tends to develop in patients with hypertension.

INTRODUCTION

Chronic hepatitis C, which affects more than 170 million people in the world[1], may eventually lead to cirrhosis and/or hepatocellular carcinoma. The main treatment for this intractable disease is interferon administration. Published guidelines recommend interferon-ribavirin combination therapy as a first-line treatment[2]. Interferon is also used in the treatment of other viral and neoplastic diseases.

Various adverse effects have been reported due to use of interferon[3]. An influenza-like syndrome, characterized by fever, chills, myalgias, arthralgias, and headache, is the most common adverse effect. Toxicities of the central nervous, hematopoietic, gastrointestinal, urinary, cardiovascular, musculoskeletal and endocrine systems have also been described. However, ocular toxicity was not reported before the use of interferon for chronic hepatitis[3].

After the introduction of interferon for the treatment of hepatitis, retinal complications have been reported. Hayakawa *et al* showed that 17 of 43 patients developed retinopathy during interferon monotherapy. They also showed that the prevalence of retinopathy was higher in patients with diabetes[4]. Subsequently, several papers have shown that a substantial proportion of patients undergoing interferon monotherapy develop retinopathy[5-7]. However, the prevalence of retinopathy is variable, which is

presumably attributed to the difference in the treatment regimen and/or background of patients.

As mentioned above, interferon-ribavirin combination therapy has become the standard treatment for chronic hepatitis C. Results from recent studies have suggested that the prevalence of retinopathy associated with combination therapy may be higher than that associated with interferon monotherapy, which should be further investigated[8-10].

In spite of the high prevalence, risk factors for interferon-associated retinopathy are still unclear. Diabetes mellitus and the patients' age were reported to be possible risk factors for retinopathy associated with interferon monotherapy[4]. In interferon-ribavirin combination therapy, diabetes, hypertension[8], and response to treatment[10] were considered possible risk factors. However, the results are not conclusive because of the small number of patients examined.

The aim of the present study is to elucidate the prevalence and risk factors for retinopathy associated with interferon-ribavirin combination therapy.

MATERIALS AND METHODS

Patients

Seventy-three consecutive patients with histologically confirmed chronic hepatit is C (47 males and 26 females; median age, 53.4 years; ranges 26-73 years) were enrolled in this study from 2002 to 2004. The clinical backgrounds of the enrolled patients are shown in Table 1. All patients were treated with recombinant interferon α-2b (Intron A, Schering-Plough, Kenilworth, NJ, USA) and ribavirin (Rebetol; Schering-Plough, Kenilworth, NJ, USA) combination therapy. All the patients were treated daily with interferon α-2b at 6 MU for 2 wk followed by three times a wk treatment with interferon α-2b at 6 MU for 22 wk in combination with ribavirin. Ribavirin was given orally twice a day at a total daily dose of 600 mg for patients who weighed 60 kg or less and 800 mg for the remaining patients who weighed more than 60 kg for 24 wk.

All patients were assessed to determine the safety, tolerance, and efficacy of the treatment at the end of wk 1, 2, 4, and every 4 wk during the treatment. After the treatment was completed, patients were followed up on wk 4, 8, 12, and 24. The primary end point was indicated by a sustained loss of detectable HCV-RNA at 24 wk after the treatment.

Methods

Optic fundi were examined before, and 2, 4, 12 and 24 wk after the start of combination therapy. Ophthalmological examinations were carried out before the start of treatment and 2, 4, 12 and 24 wk after the start of treatment until the completion of treatment or until the retinopathy disappeared. Fundus photographs were taken for documentation and comparison when retinal abnormalities were detected.

Informed consent was obtained from each patient. The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Ethics Committees of our institutions.

Table 1 Profiles and initial laboratory data of patients with and without retinopathy during IFN-ribavirin combination therapy[1]

	Total	Retinopathy (+)	Retinopathy (-)
Patients			
Number	73	14	59
Age (yr)	53.4 ± 10.9	56.3 ± 10.5	52.8±38.6

RESULTS

Before the start of the combinaiton therapy, one patient had scars from laser coagulation of a previous interferon-associated retinopathy and another patient had retinal central vein occlusion. Arteriosclerotic changes of the optic fundi were observed in 12 patients.

After the start of interferon-ribavirin combination therapy, 14 out of 73 patients (19%) developed retinopathy. The clinical profiles and laboratory data of the patients with and without retinopathy are shown in Table 1.

We compared the characteristics of patients who developed retinopathy and those who did not. The two groups showed no statistical differences in age, gender, subtype of virus, RNA level, white blood cell count, platelet count, prothrombin time before treatment or prevalence of pretreatment fundic arteriosclerotic changes. The patients with retinopathy were more frequently complicated by hypertension ($P = 0.004$) (Table 1).

Logistic regression analysis of factors affecting retinopathy was also carried out. Hypertension was found to be a factor for predicting retinopathy (Table 2).

Table 3 shows the optic fundi findings of the 14 patients with retinopathy. Retinopathy was initially diagnosed by the appearance of a cotton wool spot in 12 patients. In three of the 12 patients, retinal hemorrhage was also observed simultaneously or sequentially. Two of the 14 patients who developed retinopathy were diagnosed by retinal hemorrhage without a cotton wool spot. No patient complained of the visual disturbance.

Table 2 Logistic regression analysis of factors associated with retinopathy

Table 3 Optic fundi findings of patients with retinopathy

No	Age	Sex	Underlying disease		Optic fundi before treatment		Optic fundi after treatment	
			Hyper tension	Diabetes mellitus	H	S	Cotton wool spot	Retinal hemorrhage
1	38	M	+	+	0	0	4 wk-	4 wk-
2	52	M	+	−	1	0	4-12 wk	−
3	40	M	−	−	0	0	6-36 wk	−
4	62	F	−	−	0	0	4-36 wk	−
5	61	M	+	−	0	0	12 wk-	−
6	58	M	−	−	1	1	12 wk-	−
7	73	M	−	−	2	2	4-28 wk	−
8	65	F	+	−	0	0	24-36 wk	−
9	59	F	+	−	2	2	2 wk-	4-24 wk
10	40	M	−	−	0	0	4-20 wk	−
11	62	F	−	−	1	2	2 wk-	4 wk-
12	65	M	−	−	1	1	2-24 wk	−
13	40	M	−	−	0	0	−	8-16 wk
14	40	M	−	−	0	0	−	2-4 wk

Retinopathy disappeared in 9 of the 14 patients despite the continuation of combination therapy. However, it continued in three patients with retinal hemorrhage and two without retinal hemorrhage.

Ocular manifestations other than retinopathy (e.g., ocular pain, a mild watery eye and conjunctivitis) were not observed in any patients.

DISCUSSION

Interferon associated retinopathy was first recognized in 1990 when Ikebe and associates reported a 39-year-old patient who developed retinal hemorrhages and cotton wool spots following intravenous administration of interferon[11].

The exact mechanism of interferon-induced-retinopathy is not known but is presumably related to the disturbance in retinal microcirculation[12]. Therefore, preexisting arteriosclerosis that affects microcirculation may promote interferon-induced retinopathy.

Our study shows that hypertension is a more frequent complication in patients with interferon-induced-retinopathy. Chronic hypertension is associated with the thickening of the walls of the arteries and small arterioles[13]. Therefore, systemic hypertension predisposes patients to interferon-induced-retinopathy. The fact that hypertensive retinopathy induces the formation of flame-shaped hemorrhages and white cotton wool spots, which are also seen in interferon-induced-retinopathy, implies that systemic hypertension and interferon-induced-retinopathy may be related each other.

Statistical analysis did not indicate pretreatment optic fundic changes or diabetes as predictive factors of retinopathy. This may be attributed to the following reasons: (1) pretreatment changes in the optic fundi as a predictive factor are included in hypertension; and (2) the number of patients with diabetes is too small. Regardless of these reasons, systemic hypertension is an important risk factor for interferon-related retinopathy.

The frequencies of interferon-induced retinopathy associated with interferon monotherapy and interferon-ribavirin combination therapy are reported to be 24%-58%[4-7,14,15] and 16%-64%[8-10,16], respectively. The frequency in the present study (20%) was lower than that in previous reports. Furthermore, the ocular side effects of ribavirin, which include a mild watery eye and conjunctivitis, were not seen in this study. Therefore, the frequency of induced retinopathy associated with combination therapy may be considered as high as that associated with interferon monotherapy.

Retinopathy developed by 12 wk in most (13/14, 93%) of the patients after the start of combination therapy and disappeared in majority (10/14, 71%) of the patients during the 4-8 wk period, in which the patients were receiving the treatment. This suggests that treatment can be continued despite the development of retinopathy in many patients. However, two patients who developed cotton wool spots early in the therapy (2 wk) therafter suffered from retinal hemorrhage in a prolonged manner. Therefore, patients who develop cotton wool spots early in the therapy should be carefully monitored. However, as reported in previous studies[4,8,17], most of the patients with retinopathy in this study were asymptomatic. Therefore, combination therapy may be continued in most patients.

The fact that retinopathy occurred more frequently in patients with hypertension, suggests that these patients should be carefully monitored. With periodic examination of the optic fundi, major bleeding that causes visual symptoms may be prevented or detected at an early stage. Therefore, patients who undergo interferon-ribavirin combination therapy, particularly those with hypertension, should undergo periodic examination of the optic fundi.

To conclude, retinopathy associated with combination therapy of interferon α-2b and ribavirin tends to develop in patients with hypertension.

Abstract

AIM: To examine the impact of imatinib mesylate (Glivec) on patient survival and response and its safety, and the correlation of the response rate with the kit gene mutation status.

METHODS: Thirty-three of 74 (44.6%) small bowel gastrointestinal stromal tumor (GIST) patients who developed recurrence after curative resection and not treated with Glivec were classified as group A patients. Twenty-two advanced small bowel GIST patients treated with Glivec were classified as group B patients. Clinicopathological features, post-recurrence and overall survival rates were compared. Each tumor in group B patients was investigated for mutations of kit or platelet-derived growth factor alpha (PDGFRA). The mutation type was correlated with clinical outcomes. The anti-tumor effect and safety of Glivec in group B patients were also assessed.

RESULTS: Advanced small bowel GIST patients treated with Glivec had substatntially longer post-recurrence survival and higher overall survival rates than those not treated with Glivec. A total of 15 patients had a partial response (PR) (67.8%). Activated mutations of c-kit were found in 16 of 19 tested patients and no PDGFRA mutant was identified. In 13 patients with GISTs harboring exon 11 kit mutations, the partial response rate (PR) was 69.3%, whereas two of three patients with tumors containing an exon 9 kit mutation had an overall response rate (ORR) of 66.7% (not significant).

CONCLUSION: Glivec significantly prolongs the post-recurrence and overall survival of Asian patients with advanced GISTs. Glivec induces a sustained objective response in more than half of Asian patients with advanced small bowel GISTs. Activated mutations of kit exon 11 are detectable in the vast majority of GISTs. There is no difference in the PR rate for patients whose GISTs have kit exon 9 and exon 11 mutations.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are soft-tissue sarcomas primarily arising from mesenchymal tissue in the gastrointestinal (GI) tract and abdomen. They are rare neoplasms, accounting for 0.1%-3% of all gastrointestinal tract tumors[1]. However, GISTs are the most common mesenchymal malignancy of the GI tract with the precise incidence unknown[2]. Approximately 5000 GISTs are diagnosed annually in the USA, distributing equally in men and women. GISTs appear to be related the interstitial cells of Cajal of the mesenteric plexus[3]. These cells are considered as GI pacemaker cells, from the interface between the automatic innervation of the bowel wall and its smooth muscle[4,5]. GISTs express the cell-surface transmembrane receptor kit with a tyrosin kinase activity and are the protein product of the kit proto-oncogene. There are frequent gain-of-function mutations of kit in GISTs. These mutations result in constitutive activation of kit signaling, which leads to uncontrolled cell proliferation and resistance to apoptosis. It has been recently reported that kit activation occurs in all cases of GISTs, regardless of the mutation status of kit.

Surgical resection remains the mainstay of therapy for GIST. However, recurrence is common, the 5-year survival rate after complete resection ranges from 40% to 65%[6-10]. Unresectable or metastatic GIST is a fatal disease that resists conventional chemotherapy. A recently study reported that the response rate to doxorubicin therapy is less than 5%[11]. The effectiveness of radiation therapy for unresectable or metastatic GIST has not been proved.

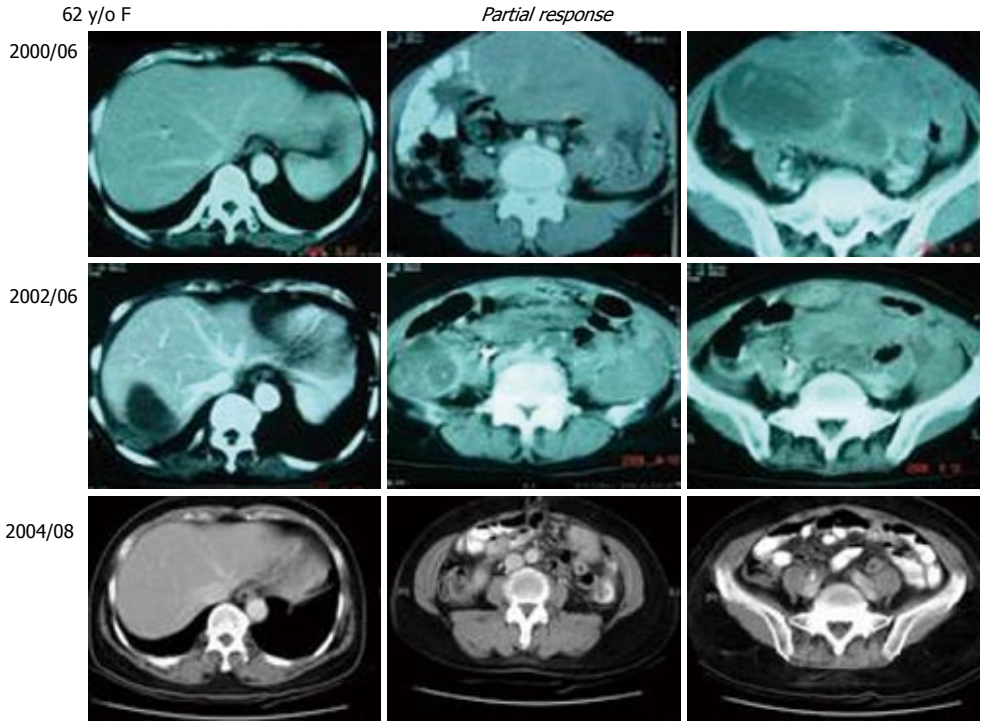

Figure 1 Sequential CT scans obtained in the same patient at base line (before treatment, upper row), middle row (2 year after Glivec treatment), and lower row (50 mo after Blivec treatment). The CT scans revealed partial response of the tumor at the same level.

The median length of survival is approximately 20 mo for patients with a metastatic GIST and 9 to 12 mo for patients with local recurrence[3]. Before the development of Glivec, the outlook for patients with advanced GIST is extremely poor. A significantly large number of patients with initial resection of GIST eventually experience recurrence, for which there is no effective treatment.

Imatinib mesylate (formerly STI571, now referred to as Gleevec or Glivec) selectively inhibits certain protein tyrosin kinases, such as intracellular ABL kinase, chimeric BCR-ABL fusion oncoprotein of chronic myeloid leukemia, transmembrane receptor kit, and platelet-derived growth factor (PDRGF) receptors[12-15]. Glivec induces a sustained objective response in more than half of patients in the West with advanced GISTs[16]. However, the implication of Glivec on patient survival, patient response to and safety of Glivec for Asian patients with advanced GIST has not been elucidated. This study examined the impact of Glivec on patient survival and response and its safety, and the correlation of the response rate with the kit gene mutation status.

MATERIALS AND METHODS

Patients

From January 1983 to December 2002, 77 small bowel GIST patients with positive kit immunostaining underwent curative resection at the Department of Surgery, Chang Gung Memorial Hospital, Taiwan. Patients with other concurrent malignancies at presentation as well as those with incidental findings of tumors on laparotomy (most tumors were < 2 cm and had trace mitotic count) were excluded. Clinical presentation, operative findings, and long-term outcomes were retrospectively reviewed. Curative operation was defined as negative resection margin observed during histopathological examination. Recurrent disease was defined as the presence of a histologically or radiographically identified tumor. Distant metastatic disease was defined as that occurring at structures noncontiguous with the primary tumor site. Regional intraperitoneal disease was deemed a local recurrence if it involved a recurrent solitary tumor or sarcomatosis.

During 2002 to June 2004, 22 histologically confirmed unresectable or metastatic small bowel GIST patients who expressed CD117 and CD34 (a marker of kit-receptor tyrosine kinase) were enrolled in this study. Criteria for inclusion were as follows: at least one measurable tumor; adequate hepatic, renal, and cardiac function; an adequate platelet count; and an Eastern Cooperative Oncology Group (ECOG) performance status of 3 or less. Patients could have previously received chemotherapeutic regimens (the last chemotherapy treatment must have been at least four weeks before study entry) and undergone radiotherapy, or surgery, or both. The study was approved by the Institutional Review Board of Chang Gung Memorial Hospital and written informed consent for drug administration and the analysis of tumor-associated genetic alteration was obtained from each patient.

Study design

A prospective, non-randomized, and single center trial was conducted to evaluate the role of Glivec in inducing objective response in GIST patients. Patients were administered 400 mg of Glivec in 100 mg capsules, taken orally once daily with food. Patients had regular physical examinations and evaluations of performance status, body weight, complete blood count, and serum chemistry. The administration of each dose and any adverse events were recorded for each patient. Standard computed tomography (CT) was performed on each patient every three months to assess patient response (Figures 1A-C). Standard [18F]

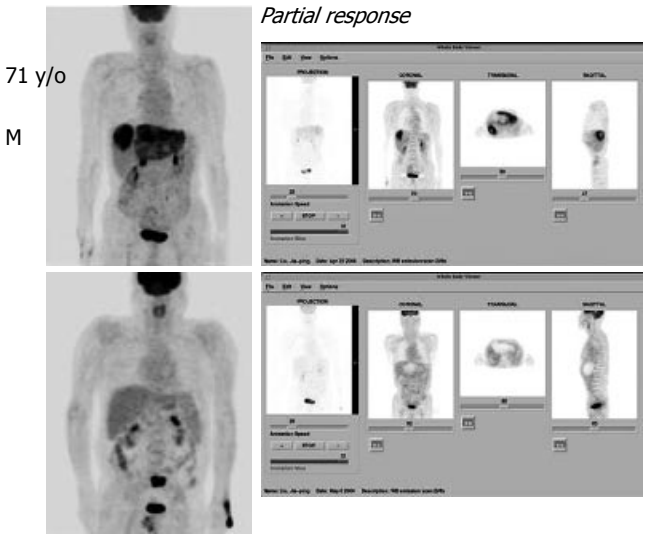

Figure 2 Sequential PET scans obtained in the same patient at base line (before treatment, upper row), and 1 mo after Glivec treatment (lower row). The PET scans revealed partial response of the tumor at the same level.

fluoro-2-deoxy-D-glucose positron-emission tomography (PET) scanning was performed on three patients to complement standard computed tomography (CT) and to assess changes in the metabolic profiles of the tumors (Figure 2).

Efficacy and safety evaluation

The response of the tumor to Glivec was evaluated after one month, three months, and every three months thereafter or whenever medical need was indicated. Assessments were performed according to the standard Southwest Oncology Group criteria and based solely on CT or PET[17]. Responses were classified as follows: complete response (CR) (disappearance of all the disease that could be measured and evaluated), partial response (PR) (> 50% of the decrease in the sum of the products of the perpendicular diameters of all measurable lesions, the absence of progression, and the absence of new lesions), stationary disease (SD) (a response that did not qualify as a complete response, a partial response, or disease progression), and disease progression (DP) (> 50 per cent increase or an increase of 10 cm, whichever was smaller) in the sum of the products of the perpendicular diameter of all measurable lesions, worsening of a lesion that could be evaluated, the reappearance of any lesion or the presence of a new lesion, or failure of the patients to return for evaluation because of disease progression. Toxic effects were recorded in accordance with the National Cancer Institute Common Toxicity Criteria[18].

Analysis of kit and PDGFRA mutations

Sections were prepared from formalin-fixed, paraffin-embedded pretreatment specimens trimmed to enrich tumor cells. Polymerase chain reaction amplification of genomic DNA for kit and PDGFRA was performed and amplification was analyzed for mutations as previously described[19] (Figure 3).

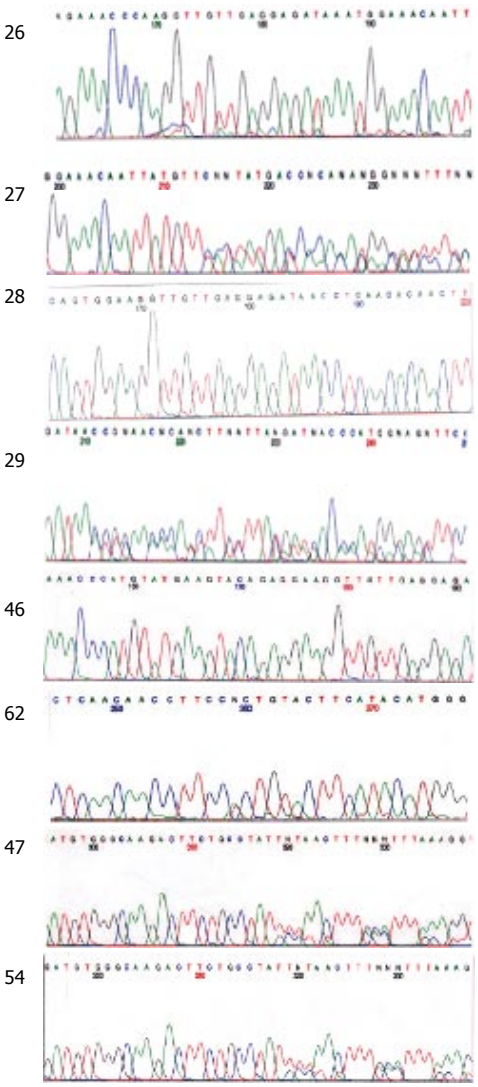

Figure 3 Mutation spectrum of the 8 small bowel GIST patients.

26, 27: Deletion mutation in exon 11; 28, 29: Deletion and insertion mutation in exon 11; 46, 62: Missense mutation in exon 11; 47, 54: Insertion mutation in exon 9.

Statistical analysis

All data were presented as percentages of patients or means with standard deviation. Numerical data were compared by an independent two-sample *t* test. Pearson chi-square test and Fisher's exact test were used for nominal variables. Survival rate was calculated and plots were constructed by the Kaplan-Meier method and compared between groups with a log-rank test. All statistical analyses were performed using SPSS computer software package (Version 10.0, Chicago, IL, USA). $P < 0.05$ was considered statistically significant.

RESULTS

Clinical features

Table 1 presents a summary of clinical features. A similar age distribution and gender ratio were observed in the two groups. The jejunum was the most common site for small bowel GISTs treated with or without Glivec. Liver was the most frequent site for metastasis of small bowel GISTs. There was no significant difference in tumor diameter between the two groups.

Treatment and outcomes

The median time of post-recurrent survival was 6.7 mo (range 1.2-90 mo). Although surgical re-resection is a better option for recurrent disease, complete re-resection for recurrent disease was only performed for 6 patients. The median time of post-recurrence survival in these patients was 15.7 mo. Chemotherapy (doxorubicin〔adriamycin〕and dacarbazine〔DTIC〕) was administered to 5 patients with median survival of 3.7 mo. Twenty-two patients with recurrence were given supportive treatments such as analgesics or nutritional supplements (median survival of 5.9 mo). Re-resection significantly prolonged post-recurrence patient survival when compared with the patients treated

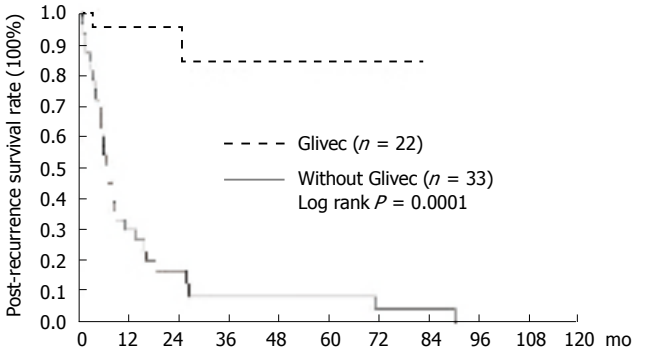

Figure 4 Post-recurrence survival rate of 55 small bowel GIST patients treated with and without Glivec.

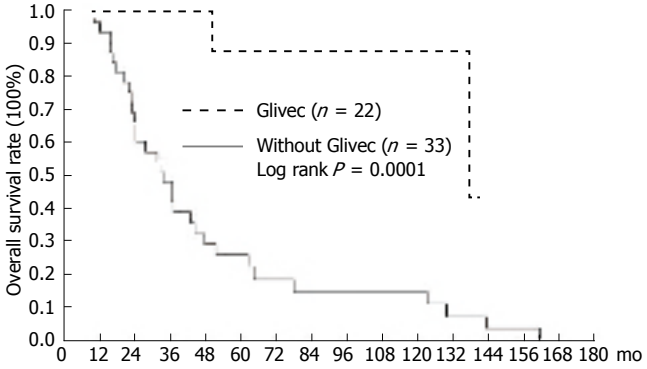

Figure 5 Overall survival rate of 55 small bowel GIST patients treated with or without Glivec.

with chemotherapy and conservative treatment (P = 0.00481), but did not improve overall survival rates (P = 0.1887). Glivec was administered to patients with unresectable or metastatic (advanced) small bowel GISTs from 2000. Twenty-two patients with advanced stages of the disease were given 400 mg Glivec per day. Advanced small bowel GIST patients treated with Glivec had significantly longer post-recurrence survival and overall survival than those not treated with Glivec (P = 0.0001) (Table 2) (Figures 4 and 5). The median follow-up time was 36.3 mo, range 8 mo to 142.4 mo. Although edema was common (14/22; 60.7%), therapy with Glivec was well tolerated. Overall, 15 patients (68.2%) had a partial response (PR), 4 stationary disease (SD) (18.2 %), 3 progressive disease (PD) (13.6%) (Table 3).

Spectrum of mutations in 22 small bowel GIST patients

Tumor specimens suitable for genetic analysis were available from 19 (86.4%) of the 22 small bowel GIST patients (Figures 3A-D and Table 4). Overall, 16 (72.7%) of the 22 examined GISTs had activated mutations of kit exons 9, 11, 13, or exon 17. No GIST had an activated mutation in more than one kit. Three of 19 GISTs expressed exon 9 mutation, 13 had exon 11 mutation, and three patients had no mutation of kit. No PDGFRA mutant isoforms were found. All the three GISTs had kit exon 9 mutation and displayed in-frame duplication of nucleotides, resulting in insertion of alanine (A) and tyrosine (Y) at condons 502 and 503. Among 13 GIST

15	Deletion and insertion mutations at codons 557-8 in the exon 11
22	Deletion and insertion mutations at codon 563-574 in exon 11
3	Missense mutation at codon 556 in exon 11
18	Missense mutation at codon 576 in the exon 11
21	Missense mutation at codon 557 in exon 11
7	Insertion mutation at codon 502-3 AY(alanine and tyrosin) in exon 9
9	Insertion mutation at codon 502-3 AY(alanine and tyrosin) in exon 9
17	Insertion mutation at codon 502-3 AY(alanine and tyrosin) in exon 9
10	No mutation
14	No mutation
20	No mutation

patients who had kit exon 11 mutations, 3 exhibited insertion/deletion, 7 showed deletion, and 3 demonstrated missense mutations (Table 4). Three of 19 tested GIST patients had no detectable kit mutation (kit wild-type) and no PDGFRA mutation. In 13 patients with GISTs harboring kit exon 11 mutations, the partial response rate (PR) was 69.3%, whereas two of three patients with tumors containing an exon 9 kit mutation had an ORR rate of 66.7% (Table 3, not significant).

DISCUSSION

The demographic features, tumor locations, and clinical features for Asian small bowel GIST patients are similar to those identified in other series[3,10,20-22]. Since the symptoms of small bowel GIST are vague, early diagnosis is not always easy and tumor sizes are usually large at diagnosis[3,10,20-22]. Before the introduction of Glivec, poor responses to radiation and chemotherapy have made surgery the only realistic treatment to cure the primary lesion[3,10,23-25]. A substantial number of patients with initial resection of GISTs eventually experience recurrence. The liver is the most frequent site for recurrence. There has been no effective treatment for advanced GISTs and the outlook for patients is extremely poor. As shown in this study, patients with recurrence who underwent further surgery with curative intention had a significant longer post-recurrence survival than those treated with chemotherapy or conservative treatment. However, the overall survival rates for both groups were similar. After treatment with Glivec, advanced small bowel GIST patients had significant longer post-recurrence and overall survival.

Therapeutic responses to targeted inhibition of activated tyrosine kinases have been demonstrated in certain types of leukemia, sarcoma, and breast cancer[19]. The mechanisms of kinase activation vary considerably among these cancers, but study of the influence of these mechanisms on drug response has been limited[19]. GISTs in particular, present a variety of genomic mutations across two different receptor tyrosine kinase genes. The kit or PDGFRA mutation in Asian clinically advanced small bowel GIST patients was examined in this study. Most small bowel GISTs expressed kit mutation (16/19, 84.2%). The kit kinase oncopproteins were intrinsically sensitive to Glivec, accounting for the excellent overall clinical response to Glivec, and coincident with results obtained by Heinrich *et al*[19]. Similar to that in report by demetri *et al*[16], the PR rate for Glivec in this study was 68.2%.

Gain-of-function mutations of PDGFRA has been recently discovered in GISTs[26] and studies have reported that PDGFRA and kit mutations are mutually exclusive[19]. However, no PDGFRA mutations were detectable in this series. More cases should be studied to clarify the racial differences regarding the incidence of PDGFRA mutation in GIST patients. A subset of GIST tumors in this study lacked detectable kit or PDGFRA mutations. Although such GISTs lack apparent genomic mutations, they can express phosphorylated kit or PDGFRA proteins that likely contribute to tumor proliferation or survival[19]. Contrary to the observation of Heinrich *et al*[26], GISTs lacking a detectable kinase mutation had a similar PR rate for Glivec to tumor with an exon 11 mutation or an exon 9 mutation (100% *vs* 69.2% *vs* 66.7%, $P = 0.527$).

In contrast to Heinrich *et al*[26], the PR rate did not differ between the groups of patients whose GISTs had kit exon 9 and exon 11 mutation (66.7% *vs* 69.2%), suggesting that the kit oncoproteins encoded by exons 9 and 11 are equally sensitive to Glivec *in vitro*[19].

In conclusion, Glivec significantly prolongs the post-recurrence and overall survival of Asian patients with advanced GISTs. Glivec induces a sustained objective response in more than half of Asian patients with advanced small bowel GISTs. Activated mutations of kit exon 11 are detectable in the vast majority of GISTs. There is no difference in the PR rate for patients whose GISTs have KIT exon 9 and exon 11 mutations.

Abstract

AIM: To detect the loss of heterozygosity (LOH) and microsatellite instabilities (MSI) of fragile histidine triad (FHIT) gene in gastric carcinoma and to study their association with the clinical pathological characteristics of gastric carcinoma.

METHODS: LOH and MSI of FHIT gene were detected at four microsatellite loci D3Sl3H, D3S4l03, D3Sl48l and D3S1234 using PCR in matched normal and cancerous tissues from 50 patients with primary gastric cancer.

RESULTS: The average frequency of LOH and MSI of FHIT gene in gastric cancer was 32.4% and 26.4% respectively. LOH and MSI of FHIT gene in gastric cancer had no association with histological, Borrmann, and Lauren's classification. LOH of FHIT gene in gastric cancer was related to invasive depth. The frequency of FHIT LOH in gastric cancer with serosa-penetration was obviously higher than that in gastric cancer without serosa-penetration (73.5% *vs* 37.5%, $P < 0.05$). MSI of FHIT gene in gastric cancer was associated with the lymph node metastasis. The frequency of MSI in gastric cancer without lymph node metastasis was significantly higher than that in gastric cancer with lymph node metastasis (66.7% *vs* 34.3%, $P < 0.05$).

CONCLUSION: LOH of FHIT gene is correlated with invasive depth of gastric carcinoma. MSI of FHIT gene is correlated with lymph node metastases. LOH and MSI of FHIT gene play an important role in carcinogenesis of gastric cancer.

INTRODUCTION

Gastric carcinoma is the most frequent malignancy and the leading cause of cancer-related deaths in China[1-4]. The specific oncogenes and tumor suppressor genes correlated with gastric cancer have not been found. In recent years, many genes have been found to be related to gastric carcinogenesis, such as fragile histidine triad gene (FHIT), RUNX3 and PTEN, among which FHIT gene is a tumor suppressor gene[5] which is located in chromatosome 3p14.2, and comprises 10 exons. Exons 1-4 and 10 are non-coding exons, and exons 5-9 are coding exons. Recent studies indicate that FHIT abnormality mostly results from loss of exons 5 and 8[6-9]. Exon 5 contains the start codon (ATG) of opening read frame (ORF), exon 8 contains core unit of coding histidine triplet. Chromosome 3p14.2 containing the common apaphidicolin-induced fragile site (FRA3B)[10-13], is the non-randomly fragmental or fissured site by its spontaneous or induced actions, and susceptible to chromosome loss and rearrangement because of the frequent fragmentation or fissure, which might be related to tumor-genesis. In this study, we detected the loss of heterozygosity (LOH) and microsatellite instabilities (MSI) of microsatellite alleles close to FHIT gene in 50 cases of gastric cancer.

MATERIALS AND METHODS

Specimens

All specimens of gastric cancerous and matched distal normal mucosal tissues were surgically resected at No.1 Hospital of China Medical University without preoperative chemotherapy and radiotherapy. Specimens were put immediately into liquid nitrogen after removal, stored at -70℃, and classified respectively by Borrmann, WHO histological classification, Lauren classification, invasive depth and lymph node metastasis, *etc.*

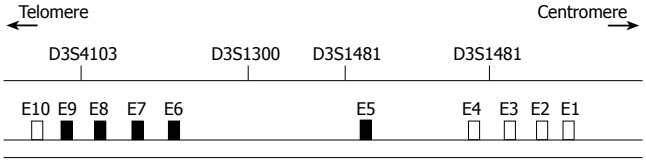

Figure 1 FHIT gene cDNA at different sites.

DNA extraction

DNA was extracted from the frozen gastric cancerous and normal mucosal tissues by standard phenol-chloroform method[3,4], dissolved and stored in TE buffer. Finally, purity and concentration of the extracted DNA were analyzed by gel electrophresis and ultraviolet spectrophotometry.

Microsatellite marker selection and PCR amplification

Four microsatellite marker sites (D3S1300, D3S1234, D3S4103 and D3S1481) in chromosome 3p14.2 were selected to detect LOH and MSI of FHIT gene. PCR primers (sequences in Table 1 and sites in Figure 1) were synthesized by Beijing AoKe Biology Company. PCR amplification was carried out in a final volume of 50 μL containing 50 ng DNA, 0.5 μmol/L of each primer, 200 μmol/L of each dNTP, and 1U Taq DNA polymerase (TaKaRa Ex Taq™). The amplification conditions were an initial denaturation at 94℃ for 3 min, followed by 30 cycles at 94℃ for 30 s, at 57℃ for 1min, at 72℃ for 40 s, and a final extension at 72℃ for 5 min.

Polyacrylamide gel electrophoresis (PAGE)

The amplified PCR products were denatured at 95℃ for 5 min and run on 8% denaturation polyacrylamide gel (1 × TBE buffer, circulatory water) at a voltage 500 V, power 45 W for 3.5 h. Silver staining was performed as previously described [14].

Determination of FHIT LOH and MSI

Genomic allele with heterozygote was considered as target of LOH analysis information. LOH was defined as complete loss or up to 50% decreased relative density of silver staining bands of PCR products in primary gastric cancerous tissues compared to distal normal mucosal tissues, and MSI was defined as the increased or mobile bands of PCR products of gastric cancerous tissues compared to normal tissues.

Table 2 FHIT gene LOH and MSI at different microsatellite sites *n* (%)

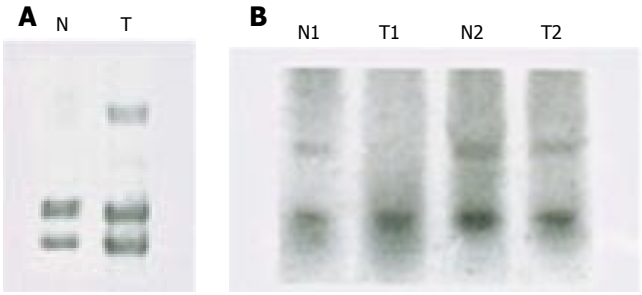

Figure 2 MSI (**A**) and LOH (**B**) at D3S4103. T: Gastric cancer tissues; N: Normal gastric mucosal tissues.

Statistic analysis

Sample rate between different groups was analyzed with chi square test. $P < 0.05$ was considered statistically significant.

RESULTS

Detection of FHIT gene LOH and MSI in gastric cancers

The frequencies of LOH and MSI of FHIT gene in four microsatellite sites are shown in Table 2. The average frequency of FHIT gene LOH in gastric cancer was 32.4%, and the most frequent site was D3S4103, accounting for 43.6% (Figure 2A). All samples had different degrees of LOH at four sites. The average frequency of FHIT gene MSI in gastric cancer was 26.4%, the most frequent site was D3S1300, accounting for 36.8% (Figure 2B), and 11 cases (22.0%) had MSI at two or more microsatellite sites.

Relationship between FHIT gene LOH, MSI and clinicopathological characteristics of gastric cancer

There was no statistical relationship between FHIT gene LOH and Borrmann's, WHO's, Lauren's classification and lymph node metastasis of gastric cancer ($P > 0.05$), while FHIT gene LOH was significantly associated with invasive depth of gastric cancer. LOH frequency in gastric cancers penetrating serosa was significantly higher than that in gastric cancers not penetrating serosa ($P < 0.05$). There was no statistical relationship between FHIT gene MSI and Bormann's, WHO's, Lauren's classification and invasive depth of gastric cancer ($P > 0.05$), while FHIT gene MSI was significantly associated with lymph node metastasis

of gastric cancer. MSI frequency in gastric cancers with lymph node metastasis was significantly higher than that in gastric cancers without lymph node metastasis ($P < 0.05$, Table 3).

DISCUSSION

FHIT gene fragile site containing instable repeated sequence of tris-nucleotide (CGG or CCG) or bi-nucleotide (AT), is subjected to easy breakage because of its susceptibility to external environment carcinogen and mutagen. There are many Alu repeated sequences in proximal telomere of fragile site FRA3B. Susceptible fragile site has highly instable repeated sequence $(TAA)_{15}$[11,12,15-20]. It can be inferred that under the action of external carcinogen, breakage and crevice may occur at FRA3B site, following DNA abnormal repair and rearrangement, thus making complex diversity of FHIT gene[21-24].

Our study showed that the average frequeny of FHIT gene LOH and MSI was 32.4% and 26.4% respectively in gastric cancer. There was no significant discrepancy between different microsatellite sites. The most frequent site of LOH and MSI was D3S4103 (43.6%) and D3S1300 (36.8%) respectively located in the first coding exon 5 near the FHIT gene, suggesting that FHIT gene loss is common in gastric cancer. Moreover, many cases had both LOH and MSI at two or more sites, suggesting that variant range of FHIT gene is broader. We did not discover that FHIT gene LOH was associated with Borrmann, histological and Lauren's classification as well as lymph node metastasis. But significant relationship was found between FHIT LOH and invasive depth of gastri cancer. Huiping *et al*[6] reported that gastric cancer is concomitant with frequent FHIT gene LOH and MSI (84% and 27% respectively), and loss of FHIT protein is closely associated with lymph node metastasis. Cappuzzi *et al*[7] also reported that loss of FHIT protein is positively correlated with clinicopathological stage and histological grade of gastric cancer, but negatively with poor prognosis. Noguchi *et al*[25] showed that LOH of FHIT gene is not related to progression and prognosis of gastric cancer.

There were no significant differences in FHIT gene LOH and MSI among various gastric cancers, suggesting that FHIT gene loss might not be associated with different gastric cancer. FHIT gene LOH was significantly associated with invasive depth of gastric cancer. LOH frequency in gastric cancers penetrating serosa was significantly higher than that in gastric cancer not penetrating serosa, suggesting that FHIT gene LOH is correlated with infiltration and diffusion of gastric cancer. FHIT gene MSI was significantly associated with lymph node metastasis of gastric cancer. MSI frequency in gastric cancers with lymph node metastasis was significantly higher than that in gastric cancers without lymph node metastasis, suggesting that FHIT gene mainly participates in early gastric carcinogenesis. The mechanism of down-regulated expression of FHIT post-transcription needs further study.

In conclusion, FHIT LOH and MSI reflect the genomic instability of gastric cancer and play an important role in gastric carcinogenesis. Abnormal FHIT gene may provide some new clues to malignant biological behavior and molecular mechanism of gastric carcinogenesis.

Abstract

AIM: To purify and characterize α-L-fucosidase from human liver cancer tissue and to detect the localization of α-L-fucosidase in tumor tissue.

METHODS: Cation exchange chromatography on CM-52 and ultrafiltration were used to separate α-L-fucosidase (AFU) from crude extract of liver cancer tissue. 4-methylumbelliferyl-α-L-fucopyranoside was used as a fluorescent substrate to quantify the purified AFU activity in each step. A polyclonal antibody (pAb) against the purified AFU was obtained by anion exchange chromatography on DEAE-52 after ammonium sulfate fractionation and ultrafiltration. Immuohistochemical staining was used to observe the expression of AFU in malignant and adjacent liver tissues.

RESULTS: Human α-L-fucosidase was purified 74–fold to apparent homogeneity with 15% yield. SDS-PAGE indicated the presence of one subunit of molecular weight of 55 Ku. The specific activity of AFU in pooled fraction by chromatography was 10085 IU/mg. Western blot analysis indicated that the pAb could recognize one protein band of molecular weight of 55 Ku. The expression of AFU was observed in cytoplasm membrane of liver cancer tissue but not in that of adjacent tissue.

CONCLUSION: The purified α-L-fucosidase from primary hepatocarcinoma (PHC) is different in its properties from α-L-fucosidase in human other organs. The polyclonal antibody prepared in this experiment can be applied to the diagnosis of PHC.

INTRODUCTION

α-L-fucosidase (AFU) is a glycosidase primarily found in lysosome and involved in the degradation of a variety of fucose-containing fucoglycoconjugates[1,2]. The necessity and importance of AFU (α-L-fucoside fucohydrolase, EC 3.2.1.51) are demonstrated by deficiency of its enzymatic activity leading to fatal neurovisceral storage disorder designated fuocosidosis characterized by mental and motor retardation [3]. The alterations of AFU catalytic activity in human cells, tissues and body fluids have a diagnostic value for human tumors such as primary hepatocarcinoma (PHC)[4-8], colorectal cancer[9-11], ovarian cancer[12].The deficiency of AFU activity in female sera is probably a hereditary condition related to higher risk of ovarian cancer[2,12]. The persistently elevated AFU level in sera of patients with liver cirrhosis contributes to early detection of PHC[5]. In addition, information of the structure and biochemical characteristics of AFU helps to understand the pathogenesis of fuocosidosis on molecular level and to discover therapeutic approaches for the disease[1,13]. In the present investigation, we described an improved purification procedure for AFU by ion exchange chromatography and immunochemical studies using polyclonal antibody against the homogeneous enzyme from human PHC tissue.

MATERIALS AND METHODS

Materials

Liver specimens were obtained from patients with PHC who underwent partial hepatectomy at Tongji Hospital. The procedure conformed to the local ethical guidelines. Informed consents were obtained from the patients or their relatives. The study protocol followed the ethical guidelines of the Helsinki Declaration of 1975. Rabbits used for antiserum production procedure received human care. All procedures were performed at 4℃ unless otherwise specified. Substrate 4–methylumbelliferyl-α–L–fucopyranoside (4-MU-Fuc) and standard product 4–methylumbelliferone (4-MU) were purchased from

Sigma. CM-52 and DEAE-52 cellulose resin were purchased from Whatman, USA.

Enzyme assay

AFU activity was assayed using 4-MU-Fuc as previously described with a minor modification[14-15]. Thirty μL aliquots of enzyme preparation was incubated at 37℃ for 30 min with 150 μL of 0.2 mol/L citrate buffer (pH 5.0) containing 60 nmol/L 4-MU-Fuc. The reaction was terminated by addition of 4 mL of 0.2 mol/L K_2CO_3 (pH 10.0). The fluorescent absorbance was read on a HITACHI F-4500 spectrophotometer with excitation at 365 nm and emission peak at 460 nm. Readings were corrected by subtracting tissue and substrate blanks. One unit of enzyme activity was defined as the amount generating 1 nmol of product 4-MU per min at 37℃. Protein concentration was determined by the traditional method of Bradford[16] using Coomassie brilliant blue G-250, following the standard assay and microassay with a protein concentration assay kit (Nanjing, China) using bovine serum albumin as standard protein. To quantify AFU activity in each purification step, we used a modified procedure to determine enzyme activity which assays the activity of β-galactose and generates a standard curve of known product concentration[17].

Extraction and concentration of enzymes

Crude extract of PHC tissue was prepared as previously described[18] with certain modifications. Portions of human liver from patients with PHC diagnosed by pathological examination were washed in distilled water and cut into small sections, stored in 30% glycerol at -70℃ until use. About 25 g of liver tissue (wet weight) was cut into small blocks within 0.05 mol/L cold sodium acetate pH 5.0 (10 mL per gram of tissue, wet weight). The blocks were then homogenized in a glass homogenizer, heated to 37℃ for 1 h to release the enzyme. The pH was then immediately adjusted to 5.0 with glacial acetic acid. The mixture was heated to 60℃ for 10 min before it was cooled to room temperature on ice and then centrifuged at 0℃ for 30 min at 35 000 r/min. The precipitate was discarded and supernatant pH was adjusted to 5.0 with 15 N NH_4OH. Solid ammonium sulfate was added to the supernatant to 35% saturation. The solution was allowed to stand at 4℃ for 4 h, and then centrifuged at 0℃ for 30 min at 29000 r/min. The precipitate was discarded, and the supernatant was saturated to 50% ammonium sulfate by addition of solid ammonium sulfate and allowed to stand at 4℃ for 20 h, then centrifuged at 0℃ for 30 min at 29000 r/min. The precipitate was dissolved in 4.0 mL of 0.1mol/L sodium citrate (pH 5.0), 0.02% in NaN_3 to yield 35%-50% ammonium sulfate fractions. The supernatant was saturated to 60% of ammonium sulfate by addition of solid ammonium sulfate and allowed to stand at 4℃ for 20 h, then centrifuged at 0℃ for 30 min at 29 000 r/min. The precipitate was dissolved in 2.0 mL of 0.1mol/L sodium citrate (pH 5.0), 0.02% in NaN_3 to yield 50%-60 % ammonium sulfate fractions. The 35%-50% and 50%-60% ammonium sulfate fractions were stored at -20℃ for chromatography.

Chromatographic methods

Further fractionations of the 35%-50% and 50%-60% ammonium sulfate fractions were obtained by chromatography on CM-cellulose (Whatman CM-52). To keep the stability of enzyme activity as possible the whole procedure was performed at 4℃. The chromatography column (2.5 cm × 35 cm) was prepared in 0.011 mol/L citric acid-NaOH (pH 4.5), 0.02 % in NaN_3 as previously described[18]. Details are given in Figure1.

Molecular weight determination of purified AFU

The presence of subunits was determined in 12 % polyacrylamide gels (8 cm × 7.3 cm, 0.75 mm) containing 0.1% SDS as previously described[19]. Briefly, 5% stacking and 12 % running gels were run at room temperature using 25 mmol/L Tris-HCl, 0.2 mol/L glycine buffer (pH 8.3) containing 0.1% SDS for 30-40 min at 80 V and 1-1.5 h at 100 V respectively. AFU samples (20-25 μg/lane) were subjected to electrophoresis after treated with 2% SDS, 5% 2-mercaptoethanol, 25% glycerol, 0.1% bromophenol blue in 60 mmol/L Tris-HCl (pH 6.8) in boiling water bath for 3 min. Prestained molecular mass standards (Fermentas, SM0671) were used and stained at the same condition. The gels were stained as previously described[20] with 0.25% Coomassie brilliant blue R-250 in glacial acetic acid: methanol: distilled water (10:45:45, v/v/v) for 3 h, then distained with the mixture of glacial acetic acid : methanol: distilled water (10:45:45, v/v/v) without Coomassie brilliant blue R-250 for 1 h, 20 min per time.

Immunization of animals

All procedures were performed as previously described[21] unless otherwise specified. Antiserum against AFU was produced by immunizing rabbits with 0.5 mg of purified AFU in equal volume of Freund's complete adjuvant, and 5 mL serum was collected before immunization as a normal control. The emulsion was injected subcutaneously at multiple sites on the rabbit metapodium palm. After 2 wk, the rabbits were injected with 0.5 mg purified AFU in Freund's incomplete adjuvant intramuscularly in each caudal thigh muscle. After 3 wk, the rabbits were given 0.2, 0.2, 0.4 mg of purified AFU respectively in a week at different sites on ear central artery for booster injection. A blood sample from ear central artery was collected for determination of the tilter after the second immunization. One week after the last booster injection, the rabbits were exsanguinated *via* cardiac puncture under general anaesthesia using diethyl ether.

Purification of α-L-fucosidase IgG

Blood was stood at room temperature for 1 h at 4℃ overnight, then centrifuged at 13000 r/min for 30 min at 4℃.The resulting pellet was discarded with the supernatant collected. The whole serum was precipitated with saturated ammonium sulfate to a final saturation of 33%, then desalted with Amicon Ultra-15 PLGC centrifugal filter unit (Millipore, NMWL, 10 KDa) (http://www.millipore.com/catalogue.nsf/docs/C7715).

Anion exchange chromatography

The desalted antiserum was added to anion exchange

Table 1 Purification of AFU from human PHC tissue

Fraction	Protein (mg)	AFU (units)	Specific activity (units/mg protein)	Purification fold	Yield (%)
Homogenate and incubate at 37℃	878.4	120024	137		
35%-50% $(NH_4)_2SO_4$ precipitation	126.55	95352	753	5	79
50%-60% $(NH_4)_2SO_4$ precipitation	46.55	16420	353	3	14
Ultrafiltration fraction

50%-60% $(NH_4)_2SO_4$ precipitation	5.6	6835	1221	9	6
CM-cellulose fraction	1.82	18354	10085	74	15

column (DEAE-52, Whatman) pre-balanced with 0.005mol/L balancing buffer, pH 8.6, Tris-PO_4 and stood at 4℃ for 30 min. Fractionations were eluted using 0.055 mol/L (pH 6.0) and 0.5 mol/L (pH5.1) Tris-PO_4 by a stepwise developing method, and pooled according to their protein content determined by absorbance of optical density at 280 nm. Because of instability of the purified antibody, chromatography should be carried out at 4℃. Pooled fractionations from DEAE-52 were adjusted to pH 6.4 with 10mol/L NaOH and stored at 4℃ to preserve their activity.

Western blot analysis

The proteins from slab gels were electrotransferred to 0.2 μm-pore-size nitrocellulose membrane (Schleicher and Schuell, Keene, NH) in 48 mmol/L Tirs/HCl transferring buffer containing 39 mmol/L glycine, 0.037% SDS, 20% methanol, at 4℃ and 350 mA for 70 min. A portion of nitrocellulose was stained as previously described[22] for 5 min with a working solution of 10-fold dilution of 2% ponceau S, 30% trichloracetic acid (TCA), 30% salicylsulfonic acid, solved in distilled water to 100 mL total volume, then destained vigorously in TBST with shaking until the ponceau S was washed off. The remainder of nitrocellulose was blocked for 2 h under constant shaking at room temperature in 5% non-fat dry milk dissolved in Tris-buffered saline-Tween-20 (TBST) containing 10 mmol/L Tirs/HCl (pH 7.5), 0.15 mol/L NaCl and 0.05% Tween-20. The membrane was incubated overnight at 4℃ in 100-fold dilution of immunoglobulin G (IgG) fraction of anti-AFU polyclonal antibody, and washed three times with TBST under constant shaking for 1 h, 20 min per time. The membrane was incubated with the secondary antibody at room temperature for 2 h under constant shaking, 5000-fold dilution of horseradish peroxide-conjugated immunoPure goat anti-rabbit IgG antibody [IgG (H+L),blotting grade; Pierce]. After three more 20 min washes with shaking (10 mmol/L-Tirs/HCl buffer, pH 7.4), development was accomplished by enhanced chemiluminescence (ECL) for 1 min following the manufacturer's instructions (Pierce), and the membrane was exposed to Kodak X-ray film. Exposure time was determined on the basis of signals generated by the reaction between membrane and mixture solution from ECL kit. The results were obtained through Kodak medical X-ray processor 102 (Eastman Kodak, Rochester, USA).

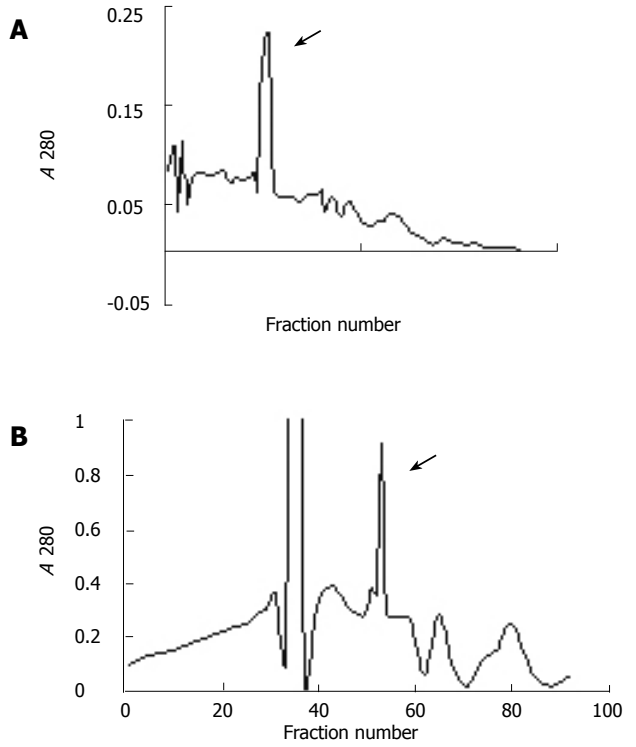
Streptavidin-peroxidase-biotin (SP) immunohistochemistry

The samples were incubated with the primary antibody against AFU (1:50, purified polyclonal, diluted in PBS) at 4℃ overnight. SP-immunohistochemistry (SP-IHC) was performed according to the manufacture's instructions (Zhong Shan Ltd Co, China) for SP kit. Sections were stained with 3, 3'-diaminobenzidine (DAB) and counterstained with haematoxylin for visualization of nuclei. In negative controls, phosphate-buffered saline (PBS) was chosen as the primary antibody instead of anti-human AFU polyclonal antibody.

RESULTS

Purification of AFU

An effective procedure was developed for the purification of AFU from human primary hepatocarcinoma tissue. The process included homogenization, high speed centrifugation, ammonium sulfate precipitation, ultrafiltration and cation exchange chromatography. The results are summarized in Table1. This procedure typically resulted in a purification of 74-fold with a very high specific activity of 10085 (nmol.min/mg) protein in 15% yield.



The stability of purified AFU was evaluated following storage at -20℃, 4℃ and 20℃ (pH 5.0) in the presence of sample buffer respectively. Samples in the frozen condition retained 100% of enzyme activity for at least two months. While samples in refrigerated condition showed slow but progressive decrease of enzyme activity with about 50%-80% of initial activity after two-month storage. Observations also exhibited that 100% enzyme activity remained in aseptic condition at room temperature within two days.

The elution schemes of two fractionations by chromatography are shown in Figure 1.

Standard curve of AFU

To quantify AFU activity in each purification step, we modified a procedure to assay the activity of β-galactose[17]. Using this method, enzyme activity in unknown samples could be compared according to a standard curve.

The absorbance of known concentrations of commercially available products generated at excitation wavelength 365 nm and emission wavelength 460 nm was

Figurge 1 Elution of fractionations on cation exchange. **A:** Chromatography of the ultrafiltration fraction of 35% to 50% $(NH_4)_2SO_4$ ammonium sulfate precipitation (22 mg of protein) on CM-cellulose. The procedure was performed with a column (2.6 cm × 30 cm) at a flow rate of 65 to 75 mL per hour. About 5 mL fractions was pooled. The column was developed initially with 750mL of 0.011 M citric acid-NaOH (pH 4.5), 0.02% NaN_3, and then a stepwise dilution over 400 mL from 0.05, 0.10, 0.15 to 0.25 mol/L NaCl was used to accomplish the development; **B:** Chromatography of the ultrafiltration fraction of 50% to 60% $(NH_4)_2SO_4$ ammonium sulfate precipitation (5.6 mg of protein) on CM-cellulose. The arrows indiente the elution peak of the interest protein.

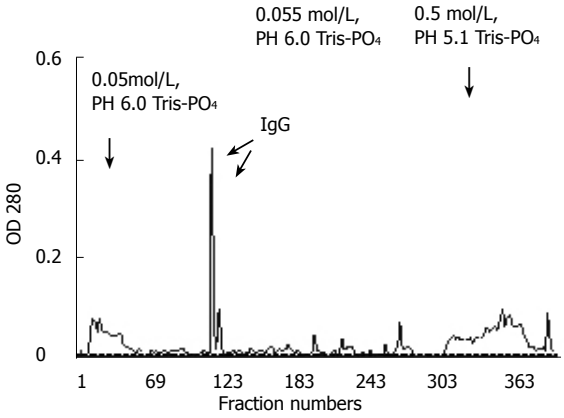

Figure 4 Anion exchange chromatography of crude antiserum against human PHCα-L-fucosidase using a column (2.6 cm × 30 cm) of DEAE-cellulose. The column was eluted as described in Materials and methods. The arrows indicate the applied buffers and the emerged elution peak of IgG.

speed centrifugation, ammonium sulfate precipitation, ultrafiltration and anion exchange chromatography on DEAE-cellulose. The elution profile of anti-serum from anion exchange column is depicted in Figure 4. The curve showed an elution peak of IgG fraction of antiserum against AFU around the 115th collecting tube. SDS-PAGE analysis illustrated the single subunit of 55 kDa of purified IgG and appeared to be highly purified.

Western-blot analysis of human liver AFU

Western blot analysis indicated that purified AFU antiserum recognized the 55 kDa band of the enzyme compared with immunized rabbit serum used as a control. The density of bands seemed to become thicker with prolonged exposure time (Figure 5).

Location and distribution of AFU expression

Immunohistochemistry staining indicated that predominant expression of AFU could be seen primarily in plasma membrane and cytoplasm of primary hepatocarcinoma cells compared with adjacent tissue and negative control. This staining was not found in the negative control treated identically except for primary antibody against human liver AFU.

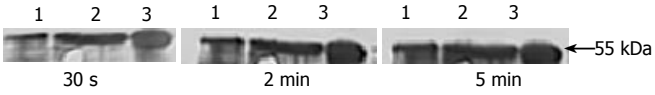

Figure 5 Western blot analysis showing that purified AFU could recognize a single subunit of 5 Ku (transverse arrow of the enzyme at 30s, 2 min, 5 min, respectively. Lane 1: purified AFU (5 μg) detected with a 10^3 dilution of antiserum; lane 2: purified AFU (10 μg) detected with a 5×10^2 dilution of antiserum; lane 3: purified AFU (5 μg) detected with a 5×10^2 dilution of antiserum.

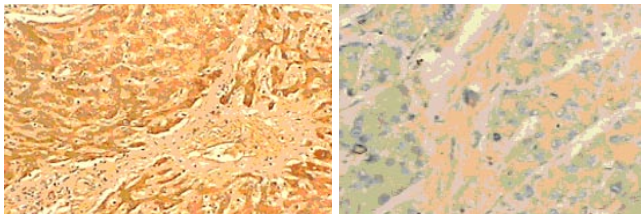

Figure 6 AFU expression in cytoplasm and/or cell membrane of PHC.

DISCUSSION

A number of investigations on α-L-fucosidase (EC 3.2.1.51) in different species have provided evidence for its importance in organism metabolism and diseases[1-3]. Although AFU is of considerable interest in human disease research because of fucosidosis, neurovisceral storage disease lacking of its enzymatic activity, many studies on its role in cancer research have been reported. To our knowledge, this is the first report of purification and characterization of human AFU from primary hepatocarcinoma tissue.

In this study, several criteria were chosen to purify and characterize AFU including ammonium sulfate precipitation, ultrafiltration, ion exchange chromatography, SDS-PAGE, Western blot, immunohistochemsitry staining and production of monospecific antibody against purified AFU. The results showed that this procedure was straightforward and successful for AFU purification. Contaminating glycosidases were removed during the course of each purification step and purified enzyme appeared to be homogeneity.

The molecular weight of purified enzyme determined by SDS-PAGE was a single subunit of 55 Ku, which is different from those reported previously[23-27]. These results may prove that purified AFU from PHC tissue is tetrameric, consisting of four identical subunits.

Western blot analysis showed enzyme of the 55 Ku subunit recognized by anti-AFU polyclonal antibody. None of the bands reacted with a preimmune serum (data not shown). This immunochemical recognition is consistent with previous studies on human colon AFU[11], one band of about 55 Ku was detected when incubated with an immunized serum, which is similar to the report of Johnson *et al*[28].

Immunohistochemistry staining showed predominant expression of AFU in plasma membrane and/or cytoplasm of primary hepatocarcinoma tissue, which is similar to previous results[29](Figure 6). The precise localization of AFU may suggest that expression level and specific site of AFU expression in primary hepatocarcinoma tissue can be a useful marker for early detection of PHC and a prognosis indicator of PHC development. It was reported that serum AFU activity is a useful marker for early detection of PHC particularly in α-fetoprotein -low or negative PHC patients[4-8,30]. However, the mechanism of elevated AFU in serum or tissues of patients with PHC is still obscure. One possible explanation is the increased synthesis and secretion of AFU by tumor cells[31]. Genetic studies suggest that three different phenotypes of AFU are dominated by two alleles exhibiting autosomal inheritance with a gene dosage effect. Individuals with high activity of AFU in serum are considered homozygous. In addition, sialic acid of glycoproteins determines the clearance rate in circulation and its transformation may cause retarded clearance of glycoproteins[32].

In conclusion, purified AFU and corresponding polyclonal antibody can be used as antigen-antibody candidates to detect PHC at early stage.

ACKNOWLEDGEMENTS

The authors thank Hui-Fen Zhu and Xiao-Dan Jiang for their excellent technical assistance, He-Jun Zhou and Wei Yan for preparation of the antiserum.

Abstract

Acute ischemic proctitis is a rare pathological condition. We report here a patient presented with massive rectal haemorrhage from a bleeding vessel superimposed on an underlying pathology of ischemic proctitis. This case report illustrates the difficulties in making the clinical distinction between ischemic proctitis and other pathological entities. We also discussed the beneficial role of arteriogram with embolotherapy as an effective therapeutic measure in the management of lower gastrointestinal bleeding. The literature on the subject is reviewed.

INTRODUCTION

Ischemic proctitis is a rare pathological condition. Bharucha *et al*[1]reviewed all ischemic proctosigmoiditis cases between 1976 and 1991, and only identified 10 cases (6 acute and 4 chronic cases) out of 328 cases of colonic ischemia. Most ischemic proctitis reported was secondary to radiotherapy, previous vascular intervention, aorto-iliac surgery, vasculitis or myointimal hyperplasia of the mesenteric vein[1-5]. These interventions or pathologies can potentially compromise the arterial supply of the rectum, leading to ischemia. It is even less common for the occurrence of spontaneous ischemic proctitis, which accounted for less than 2% of all cases of ischemic colitis.

We present herein a patient with severe rectal haemorrhage from a bleeding vessel and a co-existing pathology of ischemic proctitis.

CASE REPORT

A 62-year-old male, with grade 2 primary hypertension (1999 WHO/ISH classification) and no other past medical history, first presented as an emergency with a 2-wk history of diarrhoea, colicky lower abdominal pain and proctalgia. Vital signs and abdominal examination were unremarkable but rectal examination revealed marked tenderness and fresh rectal bleeding.

Full blood count, CRP, urea and electrolytes were normal. Abdominal radiology and stool culture were negative. Examination under anaesthesia revealed marked inflammation and superficial ulceration in the rectum and distal sigmoid colon. These changes were in keeping with a presumptive diagnosis of inflammatory bowel disease. Whilst histology of rectal biopsy was awaited, the patient was commenced on steroid enemata and discharged with out-patient follow-up.

The patient was readmitted three days later with hypovolaemic shock secondary to profuse rectal bleeding. Following resuscitation and stabilization, an emergency mesenteric arteriogram was performed. Selective examination of the inferior mesenteric artery revealed for the first time vasculature abnormality arising from a branch of the superior rectal artery with early filling of a large vein, consistent with a radiological evidence of arterio-venous fistula (Figure 1). The artery was selectively catheterised and the feeding vessel was embolized with Gel foam pledgets (Figure 2). The rectal blood supply appeared to be intact after the embolization.

The patient rebled two days later and repeated arteriography demonstrated re-canalisation of the venous drainage. In view of the re-canalisation, segment of superior rectal artery was embolized with Gel foam pledgets and metallic coils. There was no radiological evidence of further extravasations following the second embolization (Figure 3). After the second radiological intervention, result of the rectal biopsy from the first admission was then available and demonstrated features consistent of ischemic proctitis.

The patient had another episode of rectal bleeding 48 h later. Flexible sigmoidoscopy showed a grossly ischemic

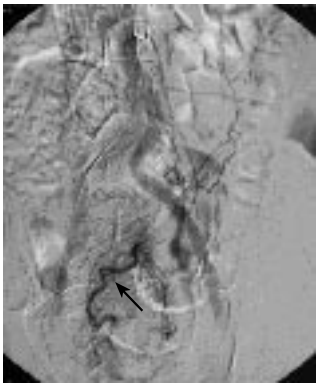

Figure 1 Arteriogram picture taken before the 1st embolization. Arrow demonstrates an abnormal vasculature.

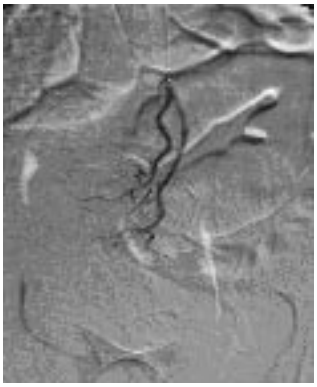

Figure 2 Arteriogram picture taken immediately after the 1st embolization. No abnormal vessels were seen.

Figure 3 Arteriogram picture taken after the 2nd embolization. Arrow demonstrates the Gel foam pledget and metallic coil at the superior rectal artery.

mucosa with numerous vertical linear ulcers. The segment of the affected rectum was well demarcated. A low Hartmann's procedure was successfully carried out with the preservation of the anal sphincter complex. Histology of the resected rectum demonstrated broad areas of necrosis in both mucosal and submucosal layers, confirming the diagnosis of ischemic proctitis.

Patient had a slow recovery. The colostomy was reversed twelve months later with the fashioning of a colo-anal anastomosis.

DISCUSSION

Rectum has an extensive arterial supply network from the inferior mesenteric, internal iliac, internal pudendal arteries, and the marginal artery. This rich collateral supply explain why rectum is normally spared in ischemic colitis and hence the rare occurrence in literatures.

The exact mechanism for acute ischemic proctitis remains unknown. Physiological vasoconstriction secondary to mild central hypovolaemia has been shown to reduce intestinal mucosal perfusion, which might explain in part to the occurrence of acute ischemic proctitis[1,6]. This similar view was also expressed by Bharucha *et al*[1]. The hypovolaemic event in our patient would have therefore further compromised the arterial supply of the rectum, leading to the worsening of the ischemic proctitis.

Clinical presentation of patients with ischemic proctitis may be non-specific and often misleading, since they often present with lower abdominal pain, diarrhoea with bloody discharge, proctalgia, and rectal mucosal erosion on inspection. These presentations are also commonly seen in patients with inflammatory bowel disease, pseudomembranous colitis or neoplasia, and the distinction between these pathological entities can be difficult[7-9]. Histology is often required to confirm the diagnosis.

Conservative management is normally sufficient for majority of the cases of lower gastrointestinal bleeding. When conservative management fails, the aim for the subsequent treatment is to identify the source of bleeding, and coagulate the bleeding point. Emergency arteriography has been shown to be an effective option to locate the bleeding point, with a reported of successful localisation of active bleeding site between 40%-77%[10]. Our treatment was similar to the two-stage embolization approach described by Waugh *et al*[11]. We employed the super-selective technique for the initial embolization, and then a second more proximal embolization when the first attempt failed. Because histological diagnosis of ischemic proctitis from the initial biopsy was not available prior to both arteriogram interventions, rectal ischemia was aggravated by the embolization procedure in our case.

In retrospect, this case presented a clinical dilemma with a visualised extravasation in arteriogram ready for embolization in one hand, but with a co-existing pathology of ischemic proctitis in the other. Nevertheless, arteriogram embolizations offered window opportunities for adequate fluid resuscitation and stabilisation. As with the opinions of Waugh *et al*, arteriogram embolization allows the conversion of an emergency case to a semi-elective case scenario[11]. Due to the ability to localise an active bleeding site, a hemicolectomy can be performed as comparing to a subtotal colectomy, which carried a significantly higher mortality (10% *vs* 22%-37%, respectively)[12-15].

In conclusion, ischemic proctitis is difficult to diagnose clinically because of its rarity and close resemblance in clinical presentation to other pathological conditions. It represents a difficult management problem when there are co-existing clinical scenarios of a massive haemorrhage secondary to a bleeding vessel and an underlying ischemia. Emergency trans-catheterisation embolization can be a beneficial diagnostic and therapeutic tool in the management of similar cases, by providing a window period for optimal resuscitation prior to definitive surgical intervention.

Abstract

Hepatobiliary cystadenomas are rare tumors that are difficult to diagnose preoperatively. They can reach large sizes that make them real intraoperative "surprises". A 63-year-old woman, presented with a symptomatic huge abdominal cystic mass, underwent complete resection of the mass with safety margins. Histopathological report revealed mucinous hepatic cystadenoma with "ovarian-like" stroma and areas of sclerohyalinization. The differential diagnosis of the large cystic tumors which occupy the right hemiabdomen must include the biliary cystadenoma; the complete resection of the tumor with safety margins avoids local recurrence, and therefore represents the optimal therapy because of the malignant potential of the disease. The postoperative follow-up includes abdominal ultrasound or CT scan and CA 19-9 measurement.

http://www.wjgnet.com/1007-9327/12/3779.asp

INTRODUCTION

Biliary cystadenomas are rare epithelial tumors with obvious malignant potential (20% of cases), and are frequently multilocular, predominantly located in the right hepatic lobe. They grow slowly and frequently are discovered accidentally during the medical investigations/surgical interventions performed for other conditions. They are more frequently encountered in women (95%)[1]; the maximum incidence is over the age of 40[2].

Cystadenomas represent less than 5% of the hepatic cystic tumors of biliary origin[3-4], their prevalence being 20 times lower than that of the simple hepatic cyst[3]. Based principally on ultrasound and CT, it has been reported that the prevalence of the biliary cystadenomas is much lower, probably 1000 times lower than that of the simple hepatic cyst[2]. In the speciality literature, there have been reported under 100 cases of biliary cystadenomas[5]. We report herein a case of large hepatic mucinous cystadenoma with mesenchymal stroma and a review of this condition based on the study of the speciality literature.

CASE REPORT

A 63-year-old woman was urgently admitted to the Surgical Clinic with intense abdominal pain located predominantly in the right upper quadrant, which started 5 d before, and was associated with nausea and pressure sensation. Physical examination revealed enlarged abdomen with tenderness in the right hemiabdomen, and a smooth-surfaced large mass (30 cm × 30 cm), without lumbar contact, difficult to mobilize and dull to percussion; as well as an irreducible, painless umbilical hernia with dimensions 4 cm × 4 cm.

Abdominal ultrasound showed a cystic mass with dimensions 24 cm × 18 cm × 24 cm, thin walls, multiple echoes inside and multiple septations posteriorly which delineated other small cysts with dimensions of maximum 5 cm; but homogeneous structure of the liver. Laboratory findings were within normal ranges. Contrast-enhanced abdominal CT scan showed a large abdominopelvic cystic mass that compressed the left hepatic lobe in its superior region, extending caudally to the uterine body and anteriorly to the peritoneal layer (Figure 1); and a septum and a dense mass (5 cm × 3 cm) could be distinguished in the posterior region of the described mass (Figure 2).

Surgery was performed through a supra- and subumbilical incision, which discovered a large cystic mass (25 cm × 25 cm) belonged to the hepatic segments III-IV-V, with the gallbladder lying over the mass (Figures 3 and 4). A total of 2500 mL of brown, mucinous fluid was evacuated by puncturing the cystic mass; and a mass with increased consistency and irregular surface was palpated in the posterior region of the tumor (Figure 5). Retrograde cholecystectomy, complete resection of the tumor and umbilical hernia repair were performed.

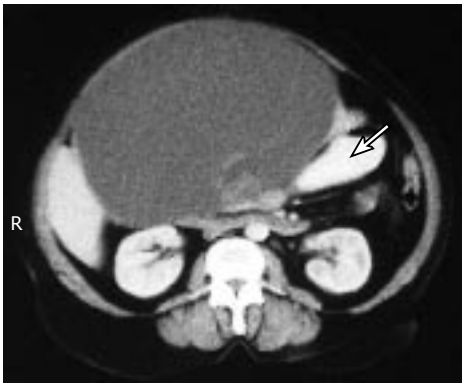

Figure 1 Contrast-enhanced CT scan demonstrates a large liver cyst in the left liver lobe (arrow).

Figure 2 CT scan shows the cyst with contrast-enhanced locules (arrow).

Figure 3 Intra-operative view of the large liver cyst.

Figure 4 Intra-operative aspects after puncture of the tumor. The gallbladder lies over the cyst's wall.

Cross-section of the specimen showed multiple septations in the inner surface and many locules with dimensions between 2-5 cm with mucinous content in the posterior region (Figure 6). Histopathological report revealed mucinous hepatic cystadenoma with "ovarian-like" stroma and areas of sclerohyalinization (Figure 7).

The postoperative course was uneventful ant the patient was discharge at the 10th postoperative day. A clinical check-up was carried out after a month, confirming the favorable evolution.

Figure 5 An area with increased consistency and irregular surface in the posterior region of the tumor.

Figure 6 The surgical specimen with multiple locules and septations.

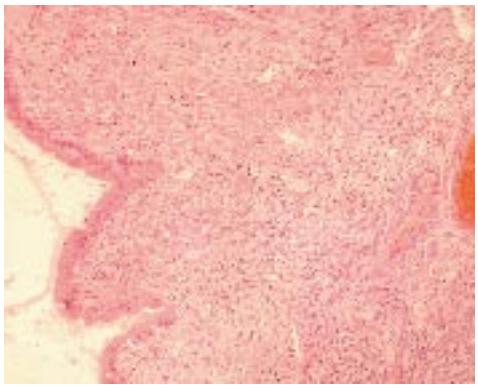

Figure 7 Photomicrograph demonstrates a columnar epithelium and an "ovarian-like" stroma (HE staining, × 200).

DISCUSSION

The problems that occur during the diagnosis of the large hepatic cystic tumors include the determination of the involved organs and differential diagnosis, especially with hepatic malignancies. Pathologically, two types of biliary cystadenomas are described: mucinous and serous[1]. Mucinous cystadenomas appear especially in women (95% of cases, possibly due to hormonal influence) and are located in intrahepatic region (84%), common bile duct (6%), hepatic ducts (4%), cystic duct (4%) and gallbladder

2%[1]. The pathogenesis of the tumor is unknown. It is considered that it has congenital origin from an aberrant intrahepatic biliary duct or from misplaced germ cells[2].

Biliary cystadenoma with mesenchymal stroma represents a tumoral histological variant that only affects women and has a columnar or cuboidal epithelium, an intermediary subepithelial layer of mesenchymal or fusiform cells, resembling ovarian stroma ("ovarian-like" stroma) and an external layer formed by a fibroconjunctive sheath that separates it from adjacent hepatic parenchyma, making a pseudocapsule. Biliary cystadenomas are usually multilocular .

Ultrasonography is the first paraclinical exploration used and shows an anechoic mass with hyperechoic internal septations and possibly mural papillary growths[4]. Abdominal CT demonstrates a single area with thin walls and internal septations; intravenous injection of contrast medium enhances the density of the cystic wall and may visualize the intracystic septations and the mural nodules[2,4]. MRI demonstrates the relationships of the tumor with local vascular structures and may bring informations about the nature of the intracystic fluid[6].Hepatic angiography shows an avascular lesion and possibly displacement of the intrahepatic vascular structures, but scintigraphy has a limited interest[2,4].Intra-operative ultrasound allows an exact identification of the site of the cystic mass and its relations with the adjacent biliovascular structures[7].

The serum CA 19-9 level may be elevated in biliary cystadenoma with mesenchymal stroma. It has been reported normalization of CA 19-9 level after the resection of the tumor, suggesting the possibility of using this investigation during the long-term post-operative follow-up of the patients[2]. The measurement of the CA 19-9 (marked increase but variable) and CEA (moderate increase) levels, originating from the intracystic fluid, differentiate these tumors from the simple and hydatid cysts of the liver, but cannot differentiate the biliary cystadenoma from cystadenocarcinoma[2]. Because of these causes, the differential diagnosis is difficult, especially with simple hepatic cyst, hepatic hydatid cyst and cystadenocarcinoma.

The evolution of biliary cystadenoma is slow with the possibility to occur various complications, out of which malignant transformation is of distinct importance. A study has demonstrated that 1/3 of hepatic cystadenocarcinomas arise from preexisting benign biliary cystadenomas[4].

The treatment of biliary cystadenoma is exclusively surgical. Complete resection of the tumor with intact hepatic resection margin is recommended, sometimes even hemihepatectomy[3]. This therapeutic approach is motivated by the malignant potential of the lesion and by the difficulty of the preoperative differential diagnosis with biliary cystadenocarcinoma. A study emphasizes that biliary cystadenoma with mesenchymal stroma may be enucleated because of the presence of a pseudocapsule which forms a dissection plane[4]. The indication for tumor enucleation is represented by small lesions, with central location, close to the hepatic hilum. Other performed operations, such as drainage through a Roux-en-Y loop, marsupialisation, percutaneous drainage followed by alcoholisation, partial cystectomy, and aspiration followed by partial excision, are associated with certain recurrence[2,5].

Postoperative follow-up is necessary; within the first year of operation, an ultrasound or CT scan of the liver should be performed after 6 mo, and then yearly. It is also useful to measure serum CA 19-9 level after the same time period.

TO THE EDITOR

Angiogenesis consists of the sprouting of capillaries from pre-existing vessels[1]. It is well-known that tumor growth is angiogenesis-dependent. Vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) stimulated vascular endothelial cell proliferation and are involved in the neoplastic angiogenesis of several types of tumors including those of the intestinal tract[1-5]. Authors usually investigated VEGF and bFGF protein expressions using immunohistochemistry or Western blotting and VEGF and bFGF transcripts using reverse transcriptase polymerase chain reaction (RT-PCR). We recently reported in a previous issue of the *World Journal of Gastroenterology* that cirrhotic liver tissue levels of these two angiogenic growth factors can be easily evaluated by an enzyme-linked immunosorbent assay (ELISA)[6]. In order to confirm if this technical approach was suitable for tumors of the intestinal tract, we performed quantitative analysis of VEGF and bFGF in surgically resected tumors of colorectal cancer, liver metastases of colorectal cancer and hepatocellular carcinomas (HCC).

The procedure of the present study followed the rules edited by the French National Ethics. A total of 86 patients were investigated in the Department of Surgery of Limoges' CHU. Among them, 29 patients (18 men and 11 women, mean age 76 years) had a primary colorectal cancer, 30 patients (15 men and 15 women, mean age 64 years) had liver metastasis of colorectal cancer and 27 patients (26 men and 1 woman, mean age 62 years) had an HCC. Specimens for the tumor and the adjacent tissue were obtained during the surgical procedure and frozen at -80℃ until used. Tissue samples were homogenized in potassium phosphate buffer and VEGF and bFGF contents were detected using specific ELISA assays (DuoSet®, R&D Systems, Europe) according to the manufacturer's recommendations. Results in picogram per milligram (pg/mg) of wet weight are reported as mean ± SE. Differences in contents of VEGF and bFGF among tumor and the adjacent non-tumor tissue were analyzed by the Student *t*-test for paired data. A P value less than 0.05 was considered statistically significant.

As shown in Figure 1 (upper panel), VEGF contents were significantly elevated ($P = 0.0001$) in colorectal tumor (43.1 ± 9.0 pg/mg, $n = 29$) than that in the adjacent non-tumor tissue (5.3 ± 0.8 pg/mg, $n = 29$). Similarly, VEGF levels were markedly elevated ($P = 0.0001$) in liver metastasis of colorectal cancer (72.7 ± 9.5 pg/mg, $n = 30$) compared to the control tissue (14.7 ± 1.5 pg/mg, $n = 30$). In contrast, no significant differences were observed in VEGF levels between HCC (19.0 ± 2.3 pg/mg, $n = 27$) and the adjacent non-tumor tissue (18.4 ± 3.4 pg/mg, $n = 27$) ($P = 0.43$). As shown in Figure 1 (lower panel), bFGF contents were significantly reduced ($P = 0.016$) in colorectal tumor (67.0 ± 6.0 pg/mg, $n = 29$) compared to the adjacent non-tumor tissue (85.0 ± 6.0 pg/mg, $n = 29$). Similarly, VEGF levels were obviously lower ($P = 0.0001$) in liver metastasis of colorectal cancer (21.4 ± 3.4 pg/mg, $n = 30$) than that in the control tissue (39.3 ± 3.0 pg/mg, $n = 30$). VEGF levels were also reduced ($P = 0.0009$) in HCC (35.4 ± 7.3 pg/mg, $n = 27$) as compared with the adjacent non-tumor tissue (63.0 ± 4.6 pg/mg, $n = 27$).

The present study highlights that the ELISA method is a valuable method for the quantitative analysis of bFGF and VEGF contents in tumors located in the intestinal tract. We observed that bFGF contents in colorectal tu-

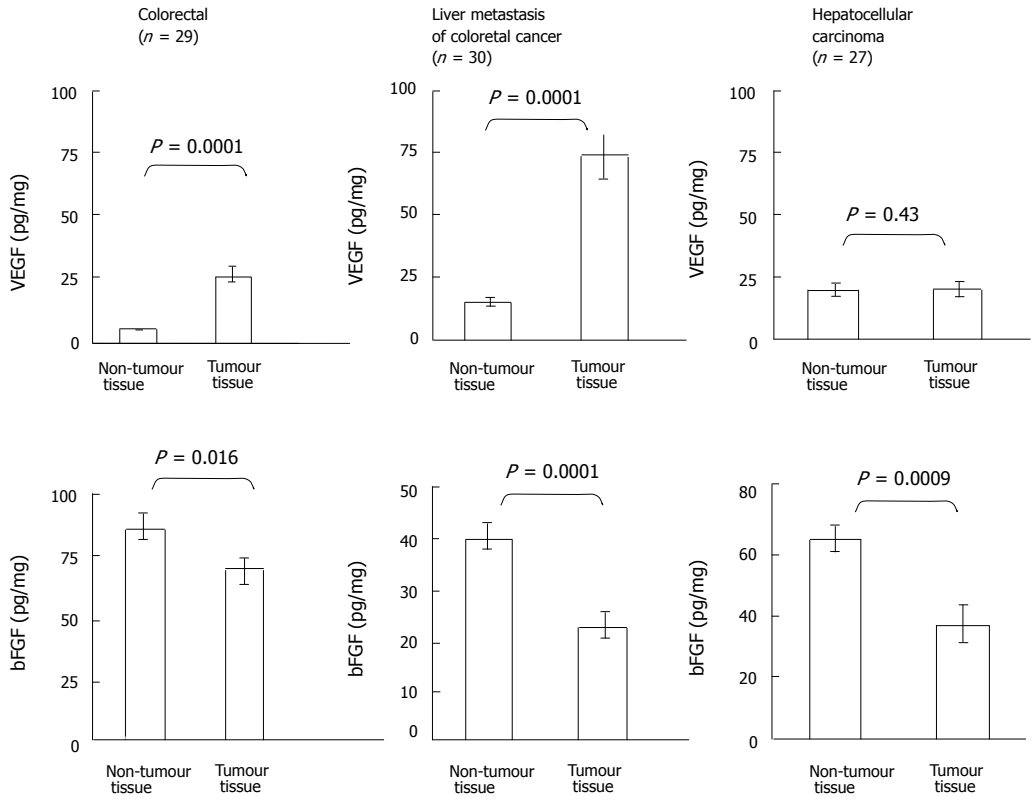

Figure 1 VEGF and bFGF contents in colorectal cancer, liver metastasis of colorectal cancer and HCC determined by ELISA. Specimens of tumors and adjacent non-tumor tissue were obtained during the surgical procedure. VEGF: Upper panel; bFGF: lower panel; *n*: number of patients. Results are expressed as mean ± SE.

mor, liver metastasis and HCC were significantly lower compared to the adjacent non-tumor tissues. This observation confirms a previous report investigating bFGF levels in human colorectal cancer[4]. At first sight, these results might be surprising since studies reported the involvement of bFGF in tumor growth. In fact, even though bFGF lacks a leader sequence for secretion, it is suggested that bFGF (localized to secretory granules) can be secreted by an alternative secretion pathway, accumulates in the extracellular matrix (ECM), from where it can be released by ECM-degrading enzymes. Our observation might, thus, be explained by secretion events inside tumors (leading to low bFGF tumor tissue content) and bFGF accumulation in tumor periphery (leading to high bFGF non-tumor tissue content). VEGF protein levels were markedly elevated in colorectal tumor and in their liver metastasis. These results are in agreement with the well known involvement of VEGF in colorectal tumor growth[7]. In contrast, VEGF protein levels were not elevated in HCC compared with surrounding non-tumor tissue. These results contrast with a previous study[2], but might be explain by the fact that a large number of our patients developed HCC in a cirrhotic liver; VEGF levels being elevated in cirrhotic tissue as compared with HCC ones[3,6].

In conclusion, results obtained with the ELISA procedure corroborate those obtained with other methods. It is, thus, tempting to speculate that the ELISA method would also be valuable for the quantitative analysis of other angiogenic growth factors and cytokines in tumors located in the intestinal tract.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus.*

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included.

Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

COPY EDITOR FOR THIS ISSUE: Dr. Mairi Brittan

World Journal of Gastroenterology (*World J Gastroenterol , WJG*), a leading international journal in gastroenterology and hepatology, has an established reputation for publishing first class research on esophageal cancer, gastric cancer, liver cancer, viral hepatitis, colorectal cancer, and *Helicobacter pylori* infection, providing a forum for both clinicians and scientists, and has been indexed and abstracted in *Index Medicus*, MEDLINE, PubMed, Chemical Abstracts, EMBASE, Abstracts Journals, Nature Clinical Practice Gastroenterology and Hepatology, CAB Abstracts and Global Health. *WJG* is a weekly journal published by The *WJG* Press. The publication date is on 7th, 14th, 21st, and 28th every month. The *WJG* is supported by The National Natural Science Foundation of China, No. 30224801 and No.30424812, which was founded with a name of *China National Journal of New Gastroenterology* on October 1,1995, and renamed as *WJG* on January 25, 1998.

Abstract

According to a meta-analysis, *H pylori* and non-steroidal anti-inflammatory drugs (NSAID) independently and significantly increase the risk of gastroduodenal ulcer and ulcer bleeding. Their coincidence is frequent, demonstration of a possible relationship and consequent attitude is of important implications. But unfortunately, no consensus has been approved in the past years and their interactions are still controversial. *H pylori* and NSAID are known to share a number of pathogenic mechanisms, but there is no evidence for the significant synergic action between these two risk factors. Their relationship is independent, additive, synergistic or antagonistic without considering the influence of other factors because studies on this subject are different in almost all aspects of their methodology, including the definition of a NSAID user as well as the types, doses, duration and their indications for NSAID use, as well as their end-points, definition of dyspepsia and regimes used for eradication of *H pylori*. These might contribute to the conflicting results and opinions. *H pylori* infection in humans does not act synergistically with NSAID on ulcer healing, and there is no need to eradicate it. This notion is supported by the finding that the eradication of *H pylori* does not affect NSAID-induced gastropathy treated with omeprazole and that *H pylori* infection induces a strong cyclooxygenase-2 (COX-2) expression resulting in excessive biosynthesis of gastroprotective prostaglandin which in turn counteracts NSAID-induced gastropathy and heals the existing ulcer. Other investigators claimed that *H pylori* infection acts synergistically with NSAID on ulcer development, and *H pylori* should be eradicated, particularly at the start of long-term NSAID therapy. Eradication of *H pylori* prior to NSAID treatment does not appear to accelerate ulcer healing or to prevent recurrent ulcers in NSAID users. However, some recommendations can be drawn from the results of clinical trails.

H PYLORI AND ASPIRIN

Aspirin has a role in the prevention of cardiovascular and cerebrovascular disease, Alzheimer's dementia and several cancers. The widespread use of aspirin, however, is limited as many older subjects are currently unable to take aspirin because of gastrointestinal (GI) side-effects, such as gastroduodenal mucosal damage and increased risk of upper gastrointestinal bleeding. Cardiovascular patients on long-term low-dose aspirin have a stable risk of major upper GI bleeding, which is higher than that in controlled clinical trials[1]. Many aspirin users should receive prophylactic treatment since they often have several risk factors for upper GI complications. The best therapeutic approach for reducing GI toxicity in low-dose aspirin users is still ill-defined, because the causal relationship between intake of aspirin and *H pylori* appears to be more complex, but there is now wide agreement that *H pylori* infection increases mucosal damage and the risk of upper GI bleeding in low-dose aspirin users. In high-risk patients with a history of ulcer bleeding, curing *H pylori* infection alone without acid suppression has substantially reduced the risk of rebleeding caused by low-dose aspirin. Omeprazole appears to be very effective in reducing both acute gastroduodenal mucosal damage and upper GI bleeding in the high-risk patients taking low-dose aspirin, Thus, it appears that eradication of *H pylori* in patients who presented with GI bleeding and are scheduled to resume low-dose aspirin has the same efficacy as a daily dose of 20 mg of omeprazole for a 6-mo period. It was reported that it is not necessary to shift aspirin to clopidogrel in patients with GI bleeding[2], suggesting eradication of *H pylori* prevents recurrent peptic ulcer or ulcer bleeding in *H pylori*-positive patients, who continue to take low-dose-

aspirin. Maintenance therapy with proton pump inhibitor (PPI) is not generally required. However, it is reasonable to eradicate *H pylori* infection in those with increased risk of gastrointestinal complications (previous history of peptic ulcer, age over 65 years, concomitant use of corticosteroids, anticoagulants or individual non-steroidal anti-inflammatory drugs (NSAID) with higher risk for gastrointestinal complications, serious cardiovascular disease), but it does not guarantee complete protection and therefore a proton pump inhibitor should also be given. Switching from low-dose-aspirin to clopidogrel is not necessary. There are no valid data supporting *H pylori* eradication in low-risk patients on long-term therapy with low-dose-aspirin[3].

H PYLORI AND NSAIDS IN UNCOMPLICATED PUD PATIENTS

Whether *H pylori* eradiation plays a part in the healing and recurrence of ulcers in long term NSAID users remains unknown. It was reported that *H pylori* eradication does not confer any significant advantage on the healing of gastric and duodenal ulcers associated with long term NSAID use in arthritis patients[4], which is supported by a basic study[5] showing that *H pylori* infection is associated with increased cyclooxygenase-2 (COX-2) expression in gastric antral mucosa of both NSAID users and nonusers, but not in gastric ulcer, where the effect of NSAID inhibition plays a major role.

Further more, *H pylori* eradication is associated with significantly slower healing of gastric ulcers than in those not undergoing *H pylori* eradication treatment[6]. However, the effect of *H pylori* eradication on healing of NSAID induced duodenal ulcers does not appear to be so dramatic. There is evidence that it may be possible to prevent *H pylori*-associated duodenal ulcer by eradicating the infection. An evidence-based approach to treatment suggests that NSAID users should undergo *H pylori* eradication therapy if they have a duodenal ulcer, whether they continue NSAID. *H pylori* eradication should not be recommended universally or in high-risk gastric ulcer patients (female, older age and higher NSAID dose) who require management with acid suppression. Because there is evidence that *H pylori* infection does not potentate the risk of ulcer formation or ulcer complications in NSAID users. If such an effect occurs, it is likely to be relatively mild. Some data even indicate that[7] *H pylori* can protect against NSAID-induced gastric ulcers, suggesting that gastric ulcer healing is significantly enhanced in the presence of *H pylori* infection. Routine testing for and eradication of *H pylori* infection are not recommended for current takers of NSAID with no or low risk of peptic ulcers and its complications[8]. But more gastroenterologists believe that use of NSAID increases the risk of peptic ulcer in *H pylori* positive and negative patients and that *H pylori* eradication therapy should be given to all *H pylori*-infected patients with peptic ulcers irrespective of their use of NSAID[10].

Randomized trials comparing *H pylori* eradication to non-eradication in patients receiving NSAID showed that *H pylori* eradication reduces the incidence of peptic ulcer in the overall population receiving NSAID[4]. It appears to be especially effective in non-steroidal anti-inflammatory drug-naive patients. Nonetheless, *H pylori* eradication seems less effective than treatment with a maintenance proton pump inhibitor for preventing NSAID-associated ulcers.

The effect of *H pylori* eradication therapy on the healing of gastric ulcers remains controversial, but more gastroenterologists advise eradication of *H pylori* in this subgroup[9]. We recommend testing for and cure of *H pylori* infection in patients prior to the initiation of NSAID therapy and in those who are currently on NSAID and have a history of dyspepsia, peptic ulcer or ulcer complications. After eradication therapy, acid-suppressant therapy is advised to heal the ulcer. The success of *H pylori* eradication should always be confirmed because of the recurrent risk of peptic ulcer disease and bleeding in *H pylori*-infected patients[10].

The critical review of these studies indicates that the discrepancy arises mainly from heterogeneity in risk factors, patients and outcome measurements[11]. The main confounding factors are the type of treatment, nonaspirin NSAID or low-dose aspirin, different strains of *H pylori*, variable host response and type of ulcer. Therefore, both risks of *H pylori* and NSAID should be removed if possible, because it is not certain which factor is responsible for the ulcer[12].

H PYLORI AND NSAIDS USE IN COMPLICATED PEPTIC ULCERS

It was reported that the frequency of *H pylori* infection is significantly lower in patients with bleeding ulcers than in controls[13]. Interaction term, male multiple ulcers and NSAID use are independent risk factors for bleeding ulcers. There was a negative interaction between *H pylori* and NSAID use. Negative interaction between the two variables suggests that the presence of *H pylori* is associated with a lower risk of bleeding in ulcer patients taking NSAID. *H pylori* and NSAID use are independent risk factors for duodenal ulcer bleeding, whereas NSAID use is the main risk factor for bleeding gastric ulcers[14]. Interaction between these two factors is associated with reduced risk of bleeding gastric ulcers, but not of bleeding duodenal ulcers.

Established risk factors for NSAID-associated ulcer complications include advanced age, female gender, peptic ulcer history , use of non-selective NSAID and anticoagulant drugs or corticosteroids. Probable risk factors comprise *H pylori* infection and heavy consumption of alcohol, use of selective serotonin re-uptake inhibitors and smoking, *etc.* other factors. Knowledge of absolute risk estimates is important for clinical decision making[15].

Relapse of lesions in patients taking NSAID is highly site and type specific, and is not adversely affected by *H pylori* status, indicating that local mucosal factors predispose to ulceration in patients taking NSAID[16]. Identification of the responsible mucosal changes aids understanding and improves treatment. This finding

encourages analyzing the mechanism of relapse of peptic ulcer. After reviewing most of these articles we conclude that it *H pylori* eradication alone is insufficient in preventing recurrent peptic ulcer or ulcer bleeding in *H pylori*-positive patients on NSAID. Maintenance therapy with proton pump inhibitors (PPIs) or switching from nonselective NSAID to COX-2 inhibitors is required after eradication of *H pylori* in primary *H pylori*-negative patients with increased risk for gastrointestinal complications.

Clinically, maintenance treatment should be given after *H pylori* eradication if aspirin and or NSAID therapy is needed in patients with peptic ulcer bleeding. PPI significantly reduces the cumulative relapse of symptomatic and complicated ulcers in patients requiring NSAID after eradication of *H pylori*.

TREATMENT OF NSAIDS - RELATED DYSPEPSIA

NSAID-induced dyspepsia occurs in 10%-30% of patients treated with NSAID, leading to discontinuation of treatment in 5%-15%. Gastrointestinal tolerability of COX-2 selective inhibitors is better than THAT OF non-selective NSAID. *H pylori* infection does not influence gastrointestinal tolerability of NSAID. Therefore, patients should not be tested and treated for *H pylori* infection unless they have a history of peptic ulcer. Symptoms of NSAID-induced dyspepsia are poorly correlated with gastroduodenal mucosal damage. Therefore, upper gastrointestinal endoscopy should be performed only if symptom relief is not achieved with the first line empirical treatment and/or if symptoms suggestive of complications, such as bleeding. Proton pump inhibitors appear to be the treatment of choice for NSAID-induced dyspepsia[17].

H PYLORI AND COX-2

COX-2 inhibitors appear not to be ulcerogenic. The use of COX-2 inhibitors reduces significantly the gastrointestinal side effects of anti-inflammatory treatment. Management of *H pylori* in patients taking these drugs can be based upon the same risk assessment as in patients not taking NSAID. Treatment with celecoxib is as effective in patients with a recent history of ulcer bleeding as treatment with diclofenac plus omeprazole, with respect to the prevention of recurrent bleeding[18]. Selective COX-2 inhibitors (coxibs) can effectively treat pain and inflammation while reducing risk of gastropathy[19]. In case of patients with risk of NSAID-induced gastrointestinal toxicity, treatment with nonspecific NSAID should be selected[20].

SUGGESTIONS

Because the prevalence of *H pylori* infection and its associated diseases such as peptic ulcer and gastric cancer is different in different countries, it is not surprise to see different approvals for treatment. The clinical and cost-effectiveness advantage of *H pylori* screening have improved the patients' ulcer risk or the protective effect of *H pylori* eradication.

Many important issues should be considered when assessing the interaction between *H pylori* and NSAID. A better understanding of the interaction between *H pylori* and NSAID as well as the histological characteristics of *H pylori*-induced or NSAID-related gastropathy, contributes to the eradication of duodenal or gastric ulcer and their complications. Clinical trails should focus on strategies for subgroups of NSAID patients with *H pylori* infection. Multiple centers, big samples, double blind and randomized controlled clinical trails with comparable methodology should be performed to farther elucidate the interaction and relationship between *H pylori* and NSAID.

Abstract

Sphincter of Oddi dysfunction (SOD) is a syndrome of chronic biliary pain or recurrent pancreatitis due to functional obstruction of pancreaticobiliary flow at the level of the sphincter of Oddi. The Milwaukee classification stratifies patients according to their clinical picture based on elevated liver enzymes, dilated common bile duct and presence of abdominal pain. Type I patients have pain as well as abnormal liver enzymes and a dilated common bile duct. Type II SOD consists of pain and only one objective finding, and Type III consists of biliary pain only. This classification is useful to guide diagnosis and management of sphincter of Oddi dysfunction. The current gold standard for diagnosis is manometry to detect elevated sphincter pressure, which correlates with outcome to sphincterotomy. However, manometry is not widely available and is an invasive procedure with a risk of pancreatitis. Non-invasive testing methods, including fatty meal ultrasonography and scintigraphy, have shown limited correlation with manometric findings but may be useful in predicting outcome to sphincterotomy. Endoscopic injection of botulinum toxin appears to predict subsequent outcome to sphincterotomy, and could be useful in selection of patients for therapy, especially in the setting where manometry is unavailable.

INTRODUCTION

Sphincter of Oddi dysfunction (SOD) is characterized by symptoms of pancreaticobiliary obstruction in the absence of other structural causes. Symptoms attributable to SOD can be seen in three clinical scenarios: (1) the post-cholecystectomy syndrome; (2) acalculous biliary pain with an intact gallbladder; and (3) recurrent idiopathic pancreatitis. Its prevalence in the general population is 1.5%[1]. SOD is seen in 1% of patients after cholecystectomy, but in 14%-23% of patients with the post-cholecystectomy syndrome (biliary pain with elevated liver enzymes)[2,3]. This may reflect either disclosure of SO dysfunction after the reservoir function of the gallbladder is removed or that the symptoms leading to cholecystectomy are in fact caused by SO dysfunction. SOD can also be detected in 29% of patients with unexplained right upper quadrant pain and no evidence of gallstone disease[4], although due to symptom overlap many of these patients are not detected until after cholecystectomy. The prevalence of SOD in recurrent "idiopathic" pancreatitis ranges from 14.7%-72%[5-7]. A high index of suspicion is required to make the diagnosis after ruling out structural causes. Diagnosis is further limited by the wide spectrum of presentations (from predominantly structural SO stenosis to predominantly functional SO dyskinesia), as well as by the limited availability of invasive diagnostic techniques, such as manometry. We present herein a review of the literature and propose an approach to management of the SOD patient specifically in the setting where manometry is unavailable.

CLINICAL MANIFESTATIONS

Although SOD can be seen in any age group or gender, it is most commonly seen in women between the ages of 20 and 50 years[1]. Patients with predominantly biliary symptoms present with pain localized to the right upper quadrant or epigastrium lasting 30 min or more and should meet the Rome II diagnostic criteria for biliary-type pain[8]. To meet these criteria, the patients must have episodes of severe, steady pain in the epigastrium and right upper quadrant as well as all of: (1) episodes lasting 30 min or more; (2) symptoms occurring on one or more occasions in the previous 12 mo; (3) steady pain that interrupts daily activities or requires consultation with a

physician; and (4) no evidence of structural abnormalities to explain the symptoms. These patients may also have associated elevated conjugated bilirubin, transaminases or alkaline phosphatase, particularly during episodes of pain. A clinical classification system popularized by Geenen and Hogan separates patients with suspected biliary SOD into three groups based on the presence of objective signs of biliary obstruction[9]. Type I SOD is characterized by biliary pain as well as elevated liver enzymes (alkaline phosphatase and AST more than twice normal) on at least two separate occasions, a dilated common bile duct (> 12 mm at ERCP), and delayed contrast drainage from the bile duct (more than 45 min). Type II SOD is characterized by biliary pain and only one or two of the aforementioned objective criteria, and Type III SOD presents with only biliary pain and no objective criteria. This classification system has subsequently been modified by eliminating the delayed contrast drainage criterion as it is both cumbersome and often unreliable.

Type I patients are thought to have sphincter of Oddi stenosis as a cause for their symptoms and are likely to respond to endoscopic sphincterotomy. Type III patients represent a group of patients with true functional pain who may have sphincter of Oddi dyskinesia either alone or as part of a more diffuse smooth muscle dysmotility disorder. Type II patients represent an overlap between structural SO obstruction and a motility disorder, and the etiology can often be clarified by manometry. This clinical classification system also correlates with manometric findings, with elevated basal sphincter of Oddi pressures in 60%-85% of Type I, 18%-55% of Type II and 7%-28% of Type III patients[3,10].

When the pancreatic sphincter is involved, SOD can present with acute pancreatitis and should be considered in the differential diagnosis of recurrent idiopathic pancreatitis. A set of clinical criteria similar to those used to stratify biliary-type SOD has been utilized for pancreatic-type SOD[10]. Type I consists of recurrent pancreatitis and/or typical pancreatic pain and all of (1) elevated lipase or amylase more than one and a half times normal, (2) dilated pancreatic duct (head > 6 mm, body > 5 mm), and (3) prolonged pancreatic drainage time (> 9 min). Type II consists of typical pancreatic pain and only one or two of the other criteria, and Type III consists of typical pancreatic pain only. As in biliary pain patients, the clinical classification correlates with the likelihood of manometric abnormality with elevated basal pancreatic sphincter pressures in 92% of Type I, 58% of Type II and 35% of Type III patients[10].

PATHOGENESIS

The sphincter of Oddi is a smooth muscle sphincter which impedes biliary flow when contracted. It is composed of three sphincteric regions. First is the biliary sphincter, which is 10 mm long and controls biliary flow from the common bile duct. The pancreatic sphincter is slightly shorter (6 mm) and controls flow of secretions through the pancreatic duct. Finally, a 6-mm long common sphincter encircles the confluence of the pancreatic and bile ducts as they near the duodenal lumen[11]. A component of the sphincter is intraluminal, and it is this portion that is transected during endoscopic sphincterotomy. The etiology of SOD is not entirely clear. Pain is presumed to be due to obstructed biliary or pancreatic flow leading to increased upstream pressure. This is especially evident in the post-cholecystectomy population where removal of the gallbladder may eliminate a reservoir for backflow of bile. Elevated sphincter pressure has also been shown to produce acute pancreatitis in an animal model[12]. In some patients, there may be fixed obstruction at the level of the papilla. Biopsies of the ampullary region show inflammation or fibrosis in 43% of patients with SOD[13]. These patients may correspond to Type I SOD with a fixed "papillary stenosis" picture.

Microlithiasis has been proposed as a possible contributing factor by creating a transient obstruction. However, only 3.5%-5% of patients with symptoms of SOD have microlithiasis detected in bile samples[14,15]. In addition, there is no difference in the frequency of microlithiasis between symptomatic patients with elevated sphincter pressures and those with normal manometry[14,15], so microlithiasis is not likely to explain symptoms in these patients. Another potential cause for SOD symptoms is a motor abnormality of the sphincter of Oddi, or "biliary dyskinesia". In addition to elevated resting basal sphincter pressures, SOD has been associated with increased frequency of phasic contractions, increased retrograde propagation of contractions and a paradoxical response to cholecystokinin (CCK)[16]. A paradoxical response to CCK (failure to completely obliterate phasic contractions) is seen more frequently in SOD patients with concomitant irritable bowel syndrome, indicating the possibility of a global gut motility disorder[17]. Supporting this theory is the presence of increased phase II and III migrating motor complex activity in the small bowel of post-cholecystectomy patients with objective evidence of SOD[18].

SOD patients also exhibit increased non-gastrointestinal symptomatic complaints and increased rates of childhood sexual abuse compared to controls[19], similar to that seen in irritable bowel syndrome. In one series, a formal diagnosis of somatization disorder was made in 30% of women with SOD and none of controls. In patients with Type III SOD (those with no objective signs of biliary obstruction), increased rates of depression, obsessive compulsive traits and anxiety compared to controls are also seen[20]. Visceral hyperalgesia is postulated to cause pain in irritable bowel syndrome, and indeed duodenal hyperalgesia as assessed with duodenal barostat was confirmed in SOD Type III when compared to controls[20]. Interestingly, no evidence of rectal hyperalgesia was detected in Type III SOD patients compared to controls[20], while irritable bowel patients had significantly lower rectal pain thresholds compared to SOD patients and controls[21]. Thus, at least in Type III SOD, visceral hyperalgesia and psychiatric factors may play a role in symptoms, necessitating a multidisciplinary approach to pain control.

DIAGNOSIS

Diagnostic evaluation in patients with pancreaticobiliary

symptoms should begin by ruling out structural causes for pain. Liver biochemistry as well as pancreatic enzymes should be drawn. Radiologic imaging is somewhat site-dependent but may include transabdominal ultrasound, endoscopic ultrasound, CT scan, MRCP, ERCP and analysis of bile for crystals. Up to 4.3% of patients with suspected SOD may have an ampullary tumor as the cause of their symptoms, so biopsies of the ampullary region should be considered[13]. When no other explanation for a patient's symptoms can be found, a variety of diagnostic methods exist to confirm the diagnosis of SOD.

Manometry

Manometry is the accepted gold standard for diagnosis of SOD since symptoms are thought to stem from obstructed biliary or pancreatic flow at the level of the sphincter of Oddi. Manometry findings have been shown to be reproducible[22] with good interobserver variability[23]. Geenen *et al*[24] found manometric findings were stable over time when repeated. However, these results were recently refuted in a group of patients with normal manometry and persistent symptoms[25]. Repeat manometry in this group of 12 patients diagnosed SOD in five patients with eventual symptom relief after endoscopic therapy. In the absence of a pathologic gold standard for comparison, most studies have used elevated basal sphincter pressure when compared to duodenal pressure as diagnostic of SOD[24,26]. An elevated basal sphincter pressure is defined as > 40 mmHg (3 SD greater than that of healthy volunteers)[27]. This SO hypertension is deemed likely to correlate with SO obstruction, and indeed most studies have found a correlation between SO hypertension on manometry and outcome after endoscopic sphincteroto my[24,28-30]. Other motility abnormalities include increased frequency of phasic contractions (> 8/min), increased retrograde propagation of phasic contractions (> 50%), and paradoxical response to cholecystokinin[16], although these findings of "SO dysmotility" have generally not been used to select patients in outcome studies. In fact, the one study that did compare outcome after sphincterotomy in patients with SO hypertension and those with other markers of dysmotility found no difference in outcome between patients with normal manometry and those with SO dysmotility, whereas patients with elevated basal sphincter pressures had a significant benefit after sphincterotomy[31]. Thus, although sphincter dysmotility may be seen in patients with SOD symptoms, it is not successfully treated with sphincterotomy, possibly because it causes pain through mechanisms other than obstruction to biliary flow.

When SO manometry is performed for presumed SOD, it is now generally accepted practice to measure pressures at both the biliary and pancreatic sphincter. Discordant results are obtained from the pancreatic and biliary sphincters in 30%-48% of patients[6,32,33], indicating that manometry should be performed at both sphincters so as not to misdiagnose patients who could ultimately benefit from therapy. Manometry is limited by its availability and the level of technical expertise required for its performance. One must be cautious that the drugs used for sedation do not alter SO motility, as midazolam has been found to reduce basal SO pressure[34] and narcotics to cause SO spasm[35]. Diazepam does not appear to have an effect on SO motility and may be safely used as sedation in this setting[36]. Manometry is also an invasive diagnostic procedure with a potential risk of pancreatitis in 17%-27% of cases[37,38]. Much of the risk of pancreatitis seen after manometry appears to be attributable to concomitant ERCP as a significantly lower rate of pancreatitis is seen in patients who undergo manometry alone compared to manometry with ERCP (9.3% *vs* 26.1%)[37], and there is no significant difference in pancreatitis rates between SOD patients undergoing ERCP alone compared to ERCP plus manometry (*OR* = 0.72)[38]. However, THE 9% pancreatitis risk seen in patients who underwent SO manometry alone is still a significant adverse outcome that must be weighed against the benefits of this diagnostic modality.

Finally, although manometry has been shown to correlate with endoscopic outcome in many studies as previously mentioned, it is not 100% sensitive. In a study by Rolny *et al*[39], 35% of Type I SOD patients had normal manometry but still benefited from endoscopic sphincterotomy. Similarly, in a study by Wehrmann *et al*[40], manometry findings were similar between Type II and Type III SOD patients, but therapeutic response was significantly better in patients with Type II SOD. Because of the imperfect predictive value of manometry as well as its limited availability and potential for adverse effects, much attention has been paid to non-invasive diagnostic techniques.

Quantitative hepatobiliary scintigraphy

Hepatobiliary scintigraphy (HBS) is performed in the fasting state and involves administration of a radionuclide tracer to quantitate biliary flow. In the setting of SOD, obstructed biliary flow is expected which can be quantitated using a number of outcome measures. Intravenous CCK infusion is used to enhance bile flow and aid in the demonstration of obstruction. Although an attractive alternative to manometry due to its non-invasive nature, studies of HBS have been limited by the lack of a standardized protocol and the use of a variety of outcome measures [duodenal appearance time (DAT), hilum-to-duodenum transit time (HDTT), or a composite scintigraphic score]. The variability in study protocol may in part explain the wide range of reported sensitivities (from 25 to 100%) and specificities (from 78% to 100%)[41-43].

An early study by Sostre *et al*[43] reported a sensitivity and specificity of 100% for the diagnosis of SOD using a scintigraphic score composed of (1) time to peak liver activity, (2) time of first visualization of the intrahepatic biliary tree, (3) biliary tree prominence, (4) time of visualization of bowel, (5) percent common bile duct emptying, and (6) CBD to liver ratio. However, these results were from a small series of twelve patients, and only seven of these patients had elevated basal sphincter pressure. These impressive results have not been replicated to date.

Using HDTT, DAT and half time of excretion as outcomes, Madacsy *et al*[44] found a significant difference in scintigraphic parameters between SOD patients with elevated sphincter pressures and asymptomatic controls.

They found HDTT to be the most sensitive measure with a sensitivity of 89%. However, this was a small study with twenty controls and twenty patients, of whom only nine had elevated basal sphincter pressures. Subsequently, a study of 29 patients with persistent post-cholecystectomy pain undergoing both manometry and scintigraphy showed a sensitivity of only 25%-38% and specificity of 86%-89% when using various cut-off values for the previously described scintigraphic score[41]. The sensitivity of HDTT was equally poor at 13%, although the specificity was 95%. No correlation was found between basal SO pressure and HDTT value. Similarly, a prospective series of 304 patients with suspected SOD compared HBS to manometry as the gold standard. Sensitivity and specificity were 49% and 78%, respectively, using hepatic peak, half time and percent CBD clearance as outcome measures[42]. These larger, prospective studies using manometry as a gold standard showed that HBS is not sensitive or specific compared to manometry as a diagnostic modality.

Interobserver variability and reproducibility of the scintigraphic score was examined in a group of asymptomatic post-cholecystectomy patients with normal liver enzymes[45]. Interobserver agreement was good (κ = 0.507), but when two scans for each patient were compared there was poor agreement (κ = 0.062), indicating poor reproducibility. Interestingly, in this asymptomatic population, 40% had at least one of their two HBS studies reported as abnormal, indicating a significantly lower specificity than previously reported for this score. Although correlation between HBS and manometry seems to be poor, one must remember that manometry is not a perfect gold standard. The most important outcome to be considered is response to therapy, and it is possible that a functional test of bile flow may detect patients with normal manometry who may nonetheless respond to endoscopic sphincterotomy. This was demonstrated by Cicala *et al*[46] in a group of Type I and Type II SOD patients where prolonged HDTT predicted a response to endoscopic therapy in 93% of cases, as compared to only 57% of responses predicted by manometry. In this study, all Type I patients had abnormal scintigraphy studies, as did 64% of Type II patients, and all patients with abnormal manometry also had abnormal HBS. In a different study which showed a poor correlation between HBS and manometry, HBS predicted 86% of patients who subsequently had a long-term symptomatic response to sphincterotomy[42]. Thus, although the role of HBS in diagnosing SOD remains undetermined, it may have a place in predicting therapeutic outcomes and determining which patients should undergo endoscopic sphincterotomy. Variations on the HBS technique may also improve its diagnostic ability. Morphine provocation to accentuate sphincter of Oddi spasm during HBS produced a significantly different percent excretion of tracer between patients with normal and abnormal SO motility[47]. Sensitivity was 83% and specificity 81% for this technique compared to manometry as a gold standard. A functional obstruction in SOD patients was demonstrated by the administration of glyceryl trinitrate which reversed the abnormal HBS findings in a group of patients with abnormal SO manometry, while having no effect on patients with mechanical biliary obstruction[48]. It is possible that further refinement of these techniques may aid in diagnosis of SOD and prediction of outcome to therapy, but further trials with response to sphincterotomy as an outcome are needed.

Fatty meal ultrasonography

Fatty meal ultrasonography (FMU) is performed by ingestion of a standardized fatty meal with ultrasound performed before and 45 min after ingestion. The fatty meal stimulates release of CCK which induces bile flow. In the setting of a functional obstruction to bile flow, this causes dilation of the diameter of the common bile duct when compared to baseline. Sensitivity of FMU when compared to manometry in SOD patients is only 21%, although specificity is 97%[42]. Similar to HBS, however, 87% of patients with abnormal FMU results did have a therapeutic response to sphincterotomy, indicating a possible role in selection of patients for therapy. The utility of both FMU and HBS for diagnosis is further limited because their accuracy falls as objective signs of SOD decrease. Ninety percent of SOD Type I patients had abnormal findings in at least one of these non-invasive tests, as compared to only 50% with Type II and 44% with Type III SOD[42]. Type I patients have more objective signs of biliary obstruction and pose less of a diagnostic dilemma than Type II and III patients who are the patients who would most benefit from a non-invasive diagnostic test prior to contemplating invasive therapy such as sphincterotomy. This limitation further restricts the use of non-invasive diagnostic testing at this time.

Non-invasive testing of the pancreatic sphincter

Fatty meal ultrasonography and hepatobiliary scintigraphy assess bile flow, but SOD can also present with pancreatitis due to a hypertensive pancreatic sphincter. Non-invasive testing of the pancreatic portion of the sphincter of Oddi has centered on the use of secretin to stimulate pancreatic flow with subsequent assessment of pancreatic ductal dilatation as a marker of obstructed flow. The secretin test was initially performed with trans-abdominal ultrasound, and was found to have a sensitivity of 88% and a specificity of 82% when compared to manometry in patients with recurrent idiopathic pancreatitis[49]. Not surprisingly, concordance with results from pancreatic manometry was superior to concordance with manometry findings from the biliary sphincter. An endoscopic ultrasound-guided secretin test has also been described[50]. A lower sensitivity of only 57% and specificity of 92% were reported with this technique, although only 20 patients with SOD were examined. Again, the secretin test was less accurate in detecting a hypertensive biliary sphincter as compared to pancreatic sphincter hypertension. A preliminary study of secretin MRCP in 15 patients with recurrent idiopathic pancreatitis showed concordance in 13 (87%) of these patients[51]. The two patients in whom MRCP results were false negatives were patients with normal basal sphincter pressures but some other form of sphincter dysmotility. These results are intriguing, and MRCP could have the added benefit of ruling out structural causes of pancreaticobiliary symptoms in these patients, reducing the need for invasive testing, such as ERCP and SO

manometry, in this high-risk group of patients. Further evidence of the utility of secretin MRCP is necessary at this time.

THERAPY

Medical therapy

Medical therapy for SOD has been disappointing. Calcium channel blockers, such as nicardipine, have been shown to decrease sphincter of Oddi pressure in healthy subjects[52]. In small placebo-controlled, crossover studies, nifedipine also decreased biliary-type pain in patients with Type II sphincter of Oddi dysfunction[53,54], however, these trials were of short duration (twelve to sixteen weeks of active treatment). A more recent attempt at a longer duration of nifedipine therapy for sphincter of Oddi dysfunction (types II and III) was terminated due to unacceptably high rates of side effects, including peripheral edema, headache and dizziness[55] and did not show a reduction in pain episodes compared to placebo. The effect of nitrates on the sphincter of Oddi has also been investigated. Oral nitrates have been shown to reduce sphincter of Oddi pressure[56,57] but no clinical trials have assessed their use in SOD, and therapy is likely to be limited by side effects, such as headache. Overall, medical therapy to date has been limited by medication side effects, the inconvenience of long-term oral therapy, and the possibility of tachyphylaxis, and is not currently standard of care for sphincter of Oddi dysfunction. Other avenues of potential medical treatment remain to be explored. Intravenous octreotide effectively decreases basal and peak sphincter pressures in SOD patients when compared to a placebo infusion[58]. Clinical trials to determine whether this effect translates into improved clinical endpoints would be beneficial, especially with the availability of a long-acting injectable form of octreotide. Preliminary data with the prostaglandin E1 analogue, alprostadil alfadex, as well as the protease inhibitor, gabexate mesilate showed relaxant effects on the sphincter of Oddi[59,60], and their clinical utility also remains to be explored. One small study showed a relaxant effect on sphincter of Oddi motility with the use of electroacupuncture at an acupoint thought to be related to the hepatobiliary system when compared to a control acupoint[61]. A reduction in basal sphincter pressure as well as phasic contraction was seen during electroacupuncture, which was associated with elevation of plasma CCK levels. It remains to be seen whether this novel therapy could present a non-invasive therapeutic option for SOD.

Endoscopic therapy

Since the clinical symptoms of sphincter of Oddi dysfunction are thought to stem from a functional obstruction at the level of the sphincter, sphincterotomy to alleviate this obstruction would seem a promising therapeutic avenue. This is especially true in Type I SOD, where objective features of biliary obstruction (elevated liver enzymes and a dilated common bile duct) are present. Indeed, Rolny *et al*[39] treated a group of seventeen Type I SOD patients with sphincterotomy and found that despite the fact that sphincter of Oddi hypertension was not found in 35% of patients at manometry, all patients experienced pain relief after sphincterotomy for a mean follow-up of 28 mo (Table 1). These results were replicated in a series reported by Sugawa *et al*[62], in which Type I SOD patients underwent sphincterotomy without prior manometry. All patients in this series experienced symptom resolution at 26 mo of follow-up[62]. Based on these outcomes, sphincterotomy is recommended in Type I patients without prior manometry, since these patients are likely to have a clinical improvement regardless of manometric findings.

Type II and III patients have fewer clinical manifestations of high grade biliary obstruction, and correspondingly are less likely to respond to endoscopic sphincterotomy (Table 1). In a landmark trial by Geenen *et al*[24], 47 Type II SOD patients were randomized to sphincterotomy or sham. Manometry was also performed. For patients with elevated sphincter of Oddi pressure, 10 of 11 patients who underwent sphincterotomy had improvement in pain scores at one year, as compared to only 3 of 12 patients who underwent sham. This benefit was also seen when follow-up was extended to four years, with a 94% clinical response rate after sphincterotomy in patients with elevated basal sphincter pressures as compared to clinical improvement in one third of patients with normal baseline pressures regardless of treatment. Since patients with normal manometry had no difference in pain relief between the sphincterotomy and sham groups, SO manometry is recommended in Type II SOD patients prior to subjecting them to the possible adverse effects of a sphincterotomy. Subsequent studies have both confirmed the efficacy of sphincterotomy for patients with elevated basal pressures and shown no response in patients with normal pressures or with sphincter dyskinesia[28-31]. Sphincterotomy is then recommended only in Type II patients with elevated basal sphincter pressures.

Subsequent studies of endoscopic therapy have included patients with Type III SOD, who have no objective findings of biliary obstruction. A retrospective analysis showed no difference in baseline sphincter hypertension between Type II and Type III patients (60% *vs* 55%, respectively), and subsequently showed no difference in the proportion of Type II and Type III patients in response to sphincterotomy (68% *vs* 56%, respectively)[63]. A prospective trial by Wehrmann *et al*[40] confirmed that a similar proportion of Type II and Type III patients had manometric findings of SOD, but found that only 8% of Type III patients had a sustained clinical improvement at 2.5 years of follow-up, as compared to 60% of Type II patients. Based on these findings, manometry in Type III SOD patients should be approached with caution as it both carries procedural risks and does not reliably predict outcome to sphincterotomy.

Risks of sphincterotomy

Sphincter of Oddi manometry is limited by its availability as well as potential complications of the procedure. Indeed, SOD has been shown to carry an increased risk of post-ERCP pancreatitis with frequencies ranging from 12.5% to 27%[58,64,65] as compared to 3%-5% of patients who undergo ERCP for bile duct stones. In patients with

[1]NS= not specified; [2]Man+ve = manometry positive; Man-ve = manometry negative.

SOD, manometry does not appear to independently increase the risk of pancreatitis, but pancreatitis is increased with biliary sphincterotomy (*OR* = 5.13) and pancreatography (*OR* = 11.32)[38]. Since pancreatitis in this setting is thought to result from edema at the level of the sphincter of Oddi, trials of pancreatic stents to improve pancreatic drainage have been performed. Although an early study did not show a significant benefit for pancreatic stenting[66], subsequent trials have shown a significant reduction in pancreatitis in patients who have a pancreatic stent placed at the time of biliary sphincterotomy[67-69]. A subsequent meta-analysis confirms the benefit of pancreatic stenting to decrease pancreatitis in high-risk patients (including sphincter of Oddi dysfunction) with an odds ratio of 0.3 and a number needed to treat of eleven[70]. Preliminary evidence with botulinum toxin injection into the pancreatic sphincter to prevent pancreatitis after biliary sphincterotomy shows a trend towards benefit. Six of fourteen (43%) patients in the sham arm developed pancreatitis compared to three of twelve (25%) patients in the botulinum toxin arm[71]. Until more trials with botulinum toxin become available, the use of prophylactic pancreatic duct stenting in these high risk patients should be strongly considered, especially if additional risk factors such as a small common bile duct are present.

Selecting patients for sphincterotomy

Because of the problems of availability and adverse effects, non-invasive surrogate markers predicting outcome after sphincterotomy have been sought with conflicting results. Retrospective analysis has shown a better outcome after sphincterotomy in patients with greater common bile duct diameter or delayed contrast drainage from the bile duct[29]. Another retrospective series of Type Ⅱ SOD patients did not find common bile duct diameter to be predictive of outcome after sphincterotomy, but did find elevated liver enzymes to predict clinical resolution after endoscopic therapy[72]. Patients in this series did not have SOD confirmed by manometry, and some of the response after sphincterotomy may have been due to microlithiasis, which would also have caused elevated liver enzymes. However, in prospective studies, none of elevated liver enzymes, common bile duct diameter, common bile duct drainage or a morphine-prostigmine test predicted outcome after sphincterotomy[24,31].

Quantitative choledochoscintigraphy has been compared to manometry as a predictor of outcome after sphincterotomy. Scintigraphy has the advantage of providing functional information regarding bile flow, as opposed to the structural information provided by manometry. Scintigraphy showed a prolonged hepatic hilum-duodenum transit time (HHDT) in all eight Type I SOD patients studied as well as 64% of Type Ⅱ SOD patients. HHDT was abnormal in all of the patients with abnormal manometry as well as 46.66% (7/15) patients with normal SO pressure[46]. In 14 patients who subsequently underwent sphincterotomy, symptomatic improvement was accurately predicted by scintigraphy in 13 (93%), while manometry predicted improvement in only eight (57%). Scintigraphy is thus a promising non-invasive method for prediction of outcome after sphincterotomy, even in patients with normal manometry who may have a functional obstruction to

bile flow causing their biliary-type pain. Larger studies are needed to confirm these findings.

Biliary stenting may predict outcome after sphincter ablation. In a small prospective series, 90% of patients who had a symptomatic response 12-14 wk after placement of a biliary stent subsequently responded to sphincterotomy[73]. The stent trial had a positive result in all of the 7 patients with elevated sphincter of Oddi pressure (6 of whom later responded to sphincterotomy) as well as in 16 patients with normal manometry (of whom 5 subsequently responded to sphincterotomy). Although a biliary stent trial may detect some patients with normal manometry who may subsequently benefit from sphincter ablation, it requires a second invasive procedure to be performed in a significant proportion of patients who do not benefit, and thus is not a viable option to select patients for sphincterotomy. In the absence of reproducible non-invasive predictors of response to sphincterotomy, some have suggested performing empirical sphincterotomy in Type II SOD without prior manometry[74]. Manometry-guided therapy was compared to empiric sphincterotomy with a decision analysis model, and the empiric sphincterotomy pathway was shown to cut costs from $2790 per patient to $2244 per patient. Fifty-five percent of the manometry-guided group was predicted to experience symptom resolution, as compared to 60% in the empiric sphincterotomy group. Randomized, controlled trials to compare these two treatment options are necessary, but in centres where manometry is unavailable, empiric sphincterotomy may be justifiable.

Botulinum toxin

Botulinum toxin acts by inhibiting presynaptic release of acetylcholine to inhibit contraction in smooth and striated muscle. Because of this property, it has been used for a variety of gastrointestinal disorders characterized by elevated muscle tone, including achalasia, gastroparesis and anal fissure[75]. Botulinum toxin has been shown to reduce sphincter of Oddi pressure in animals[76], and subsequently in case reports in patients with SOD[77,78]. Two uncontrolled case series have examined the clinical effect of botulinum toxin for both biliary type SOD[79] and for recurrent pancreatitis due to pancreatic SOD[80]. In patients with biliary type pain (type III SOD), endoscopic sphincterotomy is of uncertain benefit[40], and given the high risk of pancreatitis[64] in patients with SOD, a less invasive option such as botulinum toxin injection is attractive. Of 22 type III SOD patients treated with 100-unit botulinum toxin injection, 12 had a resolution of symptoms[79]. Eleven of these patients underwent endoscopic sphincterotomy when they developed recurrent pain, and all of these patients responded to sphincterotomy. In contrast, none of the botulinum toxin non-responders experienced symptom resolution after sphincterotomy despite a significant reduction in sphincter of Oddi pressure, indicating that a hypertensive sphincter of Oddi was not the cause of their abdominal pain. A trial of botox injection had a positive predictive value of 100% and a negative predictive value of 80% in predicting the outcome of sphincterotomy, illustrating the potential utility of using botulinum toxin injection as a diagnostic and

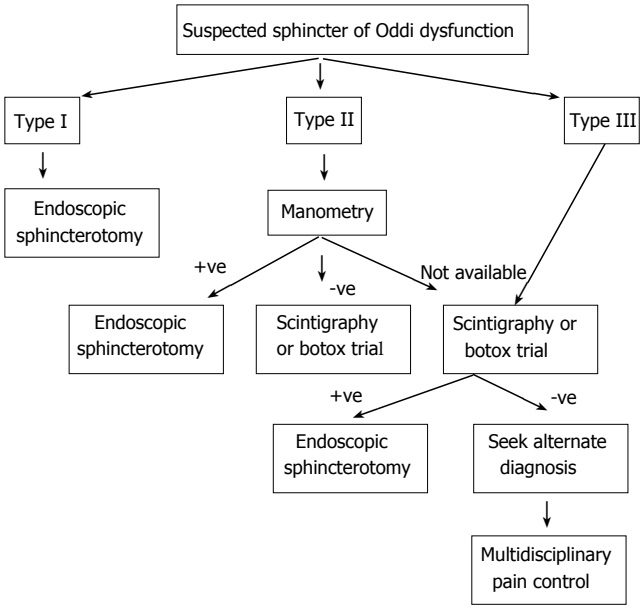

Figure 1 Sphincter of Oddi Dysfunction: Management algorithm.

therapeutic trial before proceeding to the more invasive procedure of sphincterotomy. Similarly, in patients with recurrent pancreatitis and elevated pancreatic sphincter of Oddi pressures, 80% (12/15) patients had no further pancreatitis attacks for a mean of six months after botulinum toxin injection[80]. These patients then experienced long-term remission after sphincterotomy.

In both of these series, botulinum toxin was effective, free of significant side effects and was relatively easy to administer, as cannulation of the papilla was not required. Unfortunately, its role as a therapy is limited by its duration of efficacy. Muscular function usually returns within two to six months after injection[75]. If these results can be replicated and extended at other centers, botulinum toxin can act as a diagnostic trial when manometry is unavailable to predict which patients would subsequently benefit from sphincterotomy.

In conclusion, sphincter of Oddi dysfunction is a disorder that should be suspected in patients with chronic biliary pain or recurrent pancreatitis when other organic causes have been ruled out. Because of the lack of a pathologic gold standard, manometry has been adopted as the *de facto* standard diagnostic test despite the fact that it does not have perfect correlation with outcome to therapy, it is invasive and it is available only at specialized centers. In patients with Type I SOD, a good response to sphincterotomy can be predicted regardless of manometric findings, and these patients should proceed directly to sphincterotomy (Figure 1). Type II SOD patients are the group who can most benefit from manometry to select patients for sphincterotomy. If manometry is not available, hepatobiliary scintigraphy or possibly a botulinum toxin trial can be used instead to predict response to sphincterotomy. Finally, Type III SOD patients pose a particular therapeutic challenge and likely represent a chronic pain disorder or dysmotility syndrome. The risks of manometry in this group outweigh the benefits and here scintigraphic studies

or a botulinum toxin trial may also be effective in predicting response to sphincterotomy. Further research is needed in many areas regarding sphincter of Oddi dysfunction. Larger trials of non-invasive diagnostic modalities are needed, with therapeutic outcome as an endpoint. Clinical trials comparing outcomes to sphincterotomy after selection with manometry compared to empiric sphincterotomy would guide therapy in Type II patients. Finally, there is little information regarding treatment of patients who have an incomplete response to sphincterotomy. Answering these questions will bring us closer to a more evidence-based mode of managing these patients.

Abstract

AIM: To clarify the relations between tumor differentiation phenotype and tumor invasion or genetic alterations in gastric differentiated-type tumors.

METHODS: We examined the tumor differentiation phenotype, the presence of mutations in *APC* and *p53*, and the microsatellite instability (MSI) status in 48 gastric adenomas and 171 differentiated-type carcinomas. The tumor differentiation phenotype was determined by examining the expression of human gastric mucin (HGM), MUC6, MUC2 and CD10. The tumors were then classified into gastric- (G-), gastric and intestinal mixed- (GI-), or intestinal- (I-) phenotypes, according to the immunopositivity of the above markers. The presence of mutations in *APC* and *p53* and the MSI status were also investigated in all the tumors.

RESULTS: Gastric adenomas were significantly associated with CD10 expression, I-phenotype tumors and the presence of *APC* mutations, compared with carcinomas (66.7% *vs* 25.1%, $P < 0.0001$; 56.3% *vs* 14.6%, $P < 0.0001$; 39.6% *vs* 14.0%, $P < 0.0001$, respectively) and inversely associated with expressions of HGM and MUC6 and the presence of *p53* mutations (10.4% *vs* 62.6%, $P < 0.0001$; 39.6% *vs* 64.3%, $P = 0.003$; 2.0% *vs* 26.3%, $P = 0.001$, respectively). The frequency of *APC* mutations was significantly higher in HGM-negative tumors, MUC6-negative tumors, CD10-positive tumors and I-phenotype tumors than in HGM-positive tumors, MUC6-positive tumors, CD10-negative tumors and G-phenotype tumors (32.7% *vs* 7.1%, $P < 0.0001$; 27.8% *vs* 14.0%, $P = 0.0182$; 37.3% *vs* 10.4%, $P < 0.0001$; and 38.5% *vs* 9.5%, $P = 0.0017$, respectively). The frequency of MSI was significantly higher in MUC6-positive tumors, CD10-negative tumors and G-phenotype tumors than in MUC6-negative tumors, CD10-positive tumors and I-phenotype tumors (24.8% *vs* 6.7%, $P = 0.0009$; 22.2% *vs* 8.0%, $P = 0.0143$; and 28.6% *vs* 9.6%, $P = 0.0353$, respectively).

CONCLUSION: The tumor differentiation phenotype is closely related to tumor invasion and genetic alterations in gastric differentiated-type tumors.

INTRODUCTION

Gastric carcinoma is histologically classified into two types, differentiated- and undifferentiated-type or intestinal- and diffuse-type, based on the prevalent gland formation[1,2]. The pathogenesis and genetic alterations leading to these two distinct types of adenocarcinoma are generally considered different. Previous molecular genetic studies have shown that carcinogenesis is a multistep process characterized by accumulating genetic alterations[3,4]. *K-ras* mutations, *c-erbB-2* amplification, *APC* mutations, allelic loss of the *Bcl*-II and *DCC* loci, and microsatellite instability (MSI) are preferentially associated with differentiated-type carcinoma[5,6]. Conversely, the reduced or absent expression of *E-cadherin* and *K-sam* amplification are unique to undifferentiated-type carcinoma. The abnormal expres-

sion and amplification of *Met*, the inactivation of the *p53* tumor suppressor gene, the abnormal transcription of *CD44*, and the loss of telomerase are common events in both types[3,4,7]. Recently, several authors have reported that gastric carcinomas can be classified as having either a gastric- (G-), gastric and intestinal mixed- (GI-) or intestinal- (I-) phenotype, depending on the immunopositivity of human gastric mucin (HGM), MUC6, MUC2 and CD10 stainings[8-10]. HGM, MUC6, MUC2 and CD10 are specifically expressed in gastric surface mucous cells, pyloric gland cells, intestinal goblet cells of the mature gastrointestinal tract, and the brush border of intestinal epithelial cells, respectively. We previously reported that G-phenotype tumors account for 27.7% of differentiated tumors, and are often referred to as intestinal-type tumors according to Lauren, while I-phenotype tumors account for 10.1% of undifferentiated tumors[8]. The phenotypic marker expression of tumors is conventionally thought to imitate that of the tissue of origin[11-13]. Thus, the above data suggest that gastric carcinomas can occur in various types of gastric mucosa, although differentiated tumors are generally thought to arise from gastric mucosa with intestinal metaplasia while undifferentiated tumors are thought to arise from ordinary gastric mucosa without intestinal metaplasia[1,2]. Recently, G-phenotype tumors have been associated with a poorer outcome and greater malignant potential, compared with tumors of other phenotype[8-10,14-17]. Therefore, this phenotypic classification is useful not only for investigating the tumorigenesis of gastric carcinoma, but also for evaluating tumor aggressiveness. Phenotypic expression in gastric neoplasm has also been suggested to depend on genetic changes[18]. However, there are conflicting opinions regarding the relations between tumor differentiation phenotype and tumor invasion or genetic alterations in gastric differentiated-type tumors.

In the present study, we examined the tumor differentiation phenotype, mutations in *APC* and *p53* genes, and the MSI status in 48 gastric adenomas and 171 differentiated-type adenocarcinomas to clarify the relations between tumor differentiation phenotype and tumor invasion or genetic alterations in gastric differentiated-type tumors.

MATERIALS AND METHODS

Patients

The present series consisted of 48 patients with gastric adenoma having undergone an endoscopic biopsy or an endoscopic mucosal resection and 171 patients with differentiated-type gastric adenocarcinoma having undergone surgical resection between 2001 and 2003 at Showa University Hospital. Written informed consent was obtained from all the patients before they were included in the present study.

Histological review

The specimens were fixed with 10% buffered formalin and embedded in paraffin. Consecutive sections (4 μm thick) were stained with hematoxylin and eosin (HE) and immunohistochemical stains for the histopathological examination. The intramucosal neoplastic lesions were histologically classified according to the general rules established by the Vienna classification[19]. Forty-eight adenomas (35 low-grade adenomas and 13 high-grade adenomas), 132 differentiated-type, early-stage carcinomas (80 intramucosal carcinomas and 52 carcinomas with invasion to the submucosal layer), and 39 differentiated-type, advanced-stage carcinomas (13 carcinomas with invasion to the muscularis propria layer, 15 carcinomas with invasion to the subserosa, and 11 carcinomas with invasion to the serosa) were identified.

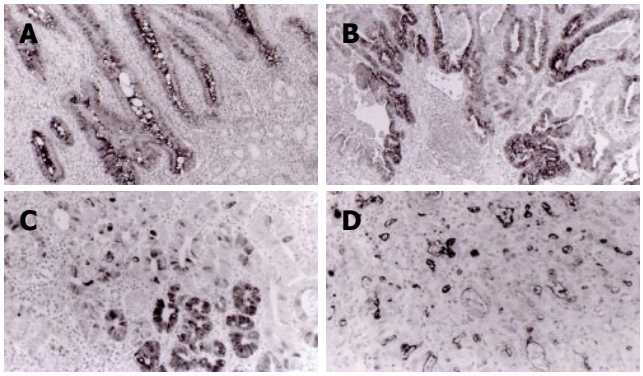

Figure 1 Immunohistochemical analysis of tumor differentiation phenotype in gastric tumor. **A**: Human gastric mucin (HGM) (45M1, × 200); **B**: MUC6 (CLH5, × 100); **C**: MUC2 (Ccp58, × 200); **D**: CD10 (56C6, × 200).

Analysis of tumor differentiation phenotype

The following mouse monoclonal antibodies were used: 45M1 (Novocastra Laboratories Ltd, UK) diluted 1:50 to detect HGM, CLH5 (Novocastra Laboratories Ltd, UK) diluted 1:50 to detect MUC6 glycoprotein, Ccp58 (Novocastra Laboratories Ltd, UK) diluted 1:100 to detect MUC2 glycoprotein, and 56C6 (Novocastra Laboratories Ltd, UK) diluted 1:40 to detect CD10 glycoprotein expression. 45M1 and CLH5 were examined as gastric-phenotype markers, and Ccp58 and 56C6 were examined as intestinal-phenotype markers. 45M1 could recognize the mucin epitope located in the peptide core of HGM, synonymous with MUC5AC. This antibody is known to react with surface foveolar cells in the stomach[20] (Figure 1A). MUC6 glycoprotein is expressed in mucous cells in the neck zone of oxyntic mucosa and in antral glands[21,22] (Figure 1B). MUC2 glycoprotein, also known as the "intestinal-mucin related protein antigen", is an intestinal apomucin that is known to be expressed in the supranuclear area of goblet cells in regions showing intestinal metaplasia in the stomach[22,23] (Figure 1C). CD10 glycoprotein is a 100-kDa cell metalloendopeptidase that inactivates a variety of biologically active peptides and is known to be expressed on the brush border of intestinal epithelial cells as well as in the germinal centers of lymphoid follicles[24] (Figure 1D). The avidin-biotin-peroxidase complex immunohistochemical method was used for all immunohistchemical studies according to a previously described protocol[25].

With regard to the evaluations of HGM, MUC6, MUC2, and CD10 staining, distinct staining in more than 5% of the tumor cells was recorded as positive immunore-

	Gastric-phenotype markers HGM - MUC6 +	
Intestinal-phenotype markers MUC2 -		Gastric-phenotype
Intestinal-phenotype markers CD10 +	Intestinal-phenotype	Gastric and intestinal mixed-phenotype

Figure 2 Classification of tumor differentiation phenotype. The phenotypes were classified into three groups (gastric-phenotype, intestinal-phenotype, gastric and intestinal mixed-phenotype) according to the combination of the expression of human gastric mucin (HGM), MUC6, MUC2 and CD10.

activity for the relevant marker. These immunohistochemical methods were used to classify the tumors into three different phenotypes: tumors with gastric phenotypic cells accounting for more than 5% of their cell population were classified as gastric- (G-) phenotype tumors, those with intestinal phenotypic cells accounting for more than 5% of their cell population were classified as intestinal- (I-) phenotype tumors, and those with both gastric and intestinal phenotypic cells accounting for more than 5% of their cell population were classified as gastric and intestinal mixed- (GI-) phenotype tumors as previously described[8,9,26] (Figure 2).

DNA extraction

Serial sections (10 μm thick) of formalin-fixed, paraffin-embedded tumor and normal mucosa were stained with HE and precisely microdissected under microscopic visualization using a PixCell laser capture microdissection system (Arcus Engineering, Mountain View, CA) to avoid DNA contamination from inflammatory or stromal cell nuclei and the DNA of cancerous cells inconsistent with the overt differentiation phenotype of the tumor. Genomic DNA was extracted from the microdissected tissue as previously described[27].

Mutation analysis of APC and p53

APC mutations in the exon 15, codons 1260-1596 region were detected by fluorescence-based PCR-single-strand conformation polymorphism analysis (PCR-SSCP) using an automated DNA sequencer as previously described[28]. This region was amplified by 4 parts using the following primer sets: 5'-CAGACTTATTGTGTAGAAGA-3' and 5'-CTCCTGAAGAAAATTCAACA-3', 5'-AGGGTTC-TAGTTTATCTTCA-3' and 5'-TCTGCTTGGTGGCAT-GGTTT-3', 5'-AACCATGCAGTGGAATGGTA-3' and 5' -AAATGGCTCATCGAGGCTCA-3', 5'-ACTCCAGAT-GGATTTTCTTG-3' and 5'-GGCTGGCTTTTTTGCTT-TAC-3'. The 5'-terminals of the primers were labeled with Cy5 dye. DNA fragments were amplified by PCR from 2 μL of 50 μL of extracted DNA. PCR was performed at 94℃ for 1 min followed by 40 cycles at 94℃ for 1 min, at 58℃ for 1 min, and at 72℃ for 2 min. Mutations were detected by electrophoresis using the ALFexpress DNA sequencer (Amersham Biosciences, NJ, USA) with TME buffer (30 mmol/L Tris-HCl, 36 mmol/L MES, 1 mmol/L EDTA; pH 6.8) at 20℃, 25℃, and 30℃. The detected peaks were analyzed using the Fragment Manager program (Amersham Biosciences).

p53 mutations in the exon 5-8 region were detected by fluorescence-based PCR-SSCP using capillary electrophoresis[28]. The nucleotide sequences of the forward and reverse primers were as follows: 5'-TTCACTTGT-GCCCTGACTTTC-3' and 5'- CTCTCCAGCCCCAGCT-GCTC-3' for exon 5, 5'-ATTCCTCACTGATT-GCTCTT-3' and 5'-TCCTCCCAGAGACCCCAGTT-3' for exon 6, 5'-ACAGGTCTCCCCAAGGCGCA-3' and 5'-TGCAGGGTGGCAAGTGGCT-3' for exon 7, 5' -GGTAGGACCTGATTTCCTTACTGCC-3' and 5' -CCCTTGGTCTCCTCCACCGCTTCTTG-3' for exon 8. The 5'-terminals of the primers for p53 were labeled with FAM. DNA fragments were amplified by PCR from 2 μL of 50 μL of extracted DNA. Mutations were detected by electrophoresis using a 3100 genetic analyzer (Applied Biosystems, CA, USA) with 2 × TME buffer (60 mmol/L Tris-HCl, 72 mmol/L MES, 2 mmol/L EDTA). The precise electrophoresis conditions have been described elsewhere[29]. The peak pattern was analyzed using QUISCA software, established by Higasa *et al*[30] and kindly provided by Dr. K Hayashi. The nucleotide sequences of DNA fragments with shifted peaks were determined using a genetic analyzer 310 with a BigDye Terminator (Applied Biosystems).

Microsatellite instability analysis

Microsatellite instability was detected using five microsatellite markers: BAT-25, BAT-26, D2S123, D5S346, and D17S250. The primers and PCR conditions have been described elsewhere[31]. The 5'-terminals of the forward primers were labeled with FAM. PCR was performed at 94℃ for 1 min followed by 35 cycles at 95℃ for 30 s, at 50℃ for 1 min, and at 70℃ for 1 min. The samples were capillary electrophoresed on an ABI 3100 genetic analyzer using Genescan analysis software (Applied Biosystems). An allelic shift (MSI) in a microsatellite marker was identified by the presence of at least one additional band in the tumor's DNA that was not present in the control DNA. A specimen was defined as MSI-high (MSI-H) when at least two markers showed instability, MSI-low (MSI-L) when only one marker showed instability, and microsatellite stable (MSS) when none of the markers exhibited MSI[32].

Statistical analysis

The data were analyzed using Student *t*-test or Mann-Whitney *U*-test and chi square test or Fisher' exact test, as appropriate. $P < 0.05$ was considered statistically significant.

RESULTS

HGM, MUC6, MUC2 and CD10 expressions, tumor differentiation phenotype, and genetic alterations in 219 gastric tumors

The expression of HGM, MUC6, MUC2, and CD10 was demonstrated in 112 (51.1%), 129 (58.9%), 163 (74.4%) and 75 (34.2%) of the 219 gastric tumors, respectively. Taking into account the observed combinations of these phenotypic markers, the 219 tumors were classified into 42 G-phenotype tumors (19.2%), 125 GI-phenotype

tumors (57.1%) and 52 I-phenotype tumors (23.7%). *APC* mutations were detected in 43 (19.6%) of the 219 tumors. Of these mutations, 30 (69.8%) were frameshift mutations (20 deletions and 10 insertions) (Figure 3) and 13 (30%) were point mutations (3 missense and 10 nonsense). *p53* mutations were detected in 47 (21.5%) of the 219 tumors. Of these mutations, 38 (80.9%) were point mutations (35 missense and 3 nonsense) and 9 (19.1%) were frameshift mutations (9 deletions). MSI was observed in 38 (17.4%) of the 219 tumors (Figure 4). MSI-L and MSI-H tumors were observed in 22 (10.0%) and 16 (7.3%) of the 219 tumors, respectively.

Tumor differentiation phenotype and genetic alterations in gastric adenoma and carcinoma

The tumor differentiation phenotype, presence of *APC* or *p53* mutations, and the MSI-status in gastric adenomas, early and advanced carcinomas examined in this study are shown in Table 1. Gastric adenomas were significantly associated with CD10 expression, I-phenotype and *APC* mutations compared with carcinomas (66.7% *vs* 25.1%, $P < 0.0001$; 56.3% *vs* 14.6%, $P < 0.0001$; and 39.6% *vs* 14.0%, $P < 0.0001$, respectively), and inversely associated with HGM and MUC6 expression and *p53* mutations (10.4% *vs* 62.6%, $P < 0.0001$; 39.6% *vs* 64.3%, $P = 0.0030$; 4.2% *vs* 26.3%, $P = 0.0010$, respectively). There were no differences in any of the variables listed in Table 1 between early and advanced carcinomas.

Relations between HGM, MUC6, MUC2, or CD10 expressions and genetic alterations

The relations between the expressions of HGM, MUC6, MUC2, or CD10 and *APC* mutations, *p53* mutations, and the MSI status in gastric tumors are shown in Table 2. The frequency of *APC* mutation was significantly higher in HGM-negative, MUC6-negative and CD10-positive tumors than in HGM-positive, MUC6-positive and CD10-negative tumors (32.7% *vs* 7.1 %, $P < 0.0001$; 27.8% *vs* 14.0%, $P = 0.0182$; and 37.3% *vs* 10.4%, $P = 0.0398$, respectively). The frequency of MSI was significantly higher in MUC6-positive and CD10-negative tumors than in MUC6-negative and CD10-positive tumors (24.8% *vs* 6.7%, $P = 0.0009$ and 22.2% *vs* 8.0%, $P = 0.0143$, respectively). There were no significant differences in the frequency of *p53* mutations according to the expressions of HGM, MUC6, MUC2 or CD10.

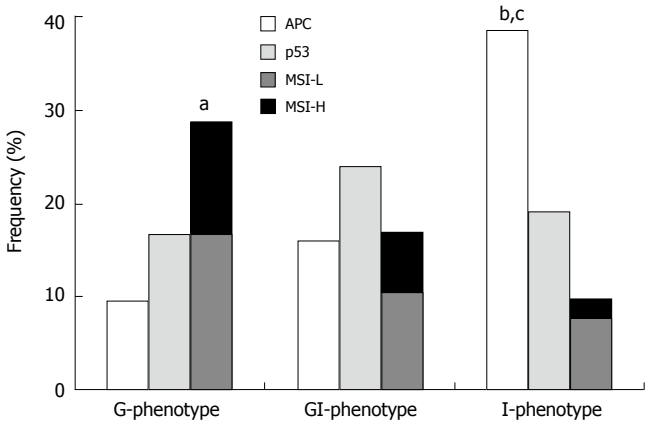

Figure 5 Frequency of *APC*, *p53* mutation and MSI in gastric- (G-), gastric and intestinal mixed- (GI-), and intestinal- (I-) phenotype tumors. [a]$P = 0.0353$ (G-phenotype *vs* I-phenotype, 28.6% *vs* 9.6%), [b]$P = 0.0017$ (I-phenotype *vs* G-phenotype, 38.5% *vs* 9.5%), [c]$P = 0.0022$ (I-phenotype *vs* GI-phenotype, 38.5% *vs* 16.0%).

Relations between tumor differentiation phenotype and genetic alterations

The relations between tumor differentiation phenotype and *APC* mutations, *p53* mutations and the MSI-status in gastric tumors are shown in Figure 5. The frequency of *APC* mutations was significantly higher in I-phenotype tumors than in G- phenotype and GI-phenotype tumors (38.5% *vs* 9.5% and 16.0%, $P = 0.0017$ and $P = 0.0022$, respectively). The frequency of MSI was significantly higher in G-phenotype tumors than in I-phenotype tumors (28.6% *vs* 9.6%, $P = 0.0353$). There were no significant differences in the frequency of *p53* mutations among the G-, GI- and I-phenotypes.

DISCUSSION

Our present results revealed that gastric adenomas were significantly associated with CD10 expression, I-phenotype and *APC* mutation and inversely associated with HGM and MUC6 expression and *p53* mutations, compared with early and advanced carcinomas. Gastric adenomas were also significantly associated with MUC2 expression, compared with advanced carcinomas. Therefore, gastric adenomas are clearly different from early and advanced carcinomas in terms of the tumor differentiation phenotype and genetic alterations.

With respect to the difference in the tumor differentiation phenotype between gastric adenomas and carcinomas, our present results revealed that more than half of gastric adenomas exhibited I-phenotype and the incidence of I-phenotype tumor was significantly higher in gastric adenomas than in early and advanced carcinomas. On the other hand, the majority of early and advanced carcinomas exhibited a G- or GI-phenotype. These findings indicate that the tumor differentiation phenotype is related to tumor invasion in gastric differentiated-type tumors. Recently, several reports have demonstrated distinct differences in the biological behavior of tumors with different phenotypic markers[8-10,14-18,26]. Endoh *et al*[34] reported that low positivity for Ki-67 staining along the mature collagenous stromal reaction in the invasive area can be seen in differentiated-type carcinomas of I-phenotype, reflecting the slow growth of this tumor. We have previously reported that patients with G-phenotype tumors have a significantly poorer prognosis than those with I-phenotype tumors in patients with advanced gastric carcinoma[8].

In the present study, gastric adenomas were significantly associated with *APC* mutations and inversely associated with *p53* mutations, compared with those in early and advanced carcinomas. MSI is a common event in both gastric adenomas and differentiated-type carcinomas. The absence of sequential accumulations of genetic alterations between gastric adenomas and early or advanced carcinomas suggests that gastric differentiated-type tumors with *APC* mutations, especially gastric adenomas, may have a low invasive potential. Lee *et al*[31] suggested that gastric adenomas without *APC* mutations have a different biological behavior from those with *APC* mutations and are precursors of differentiated-type carcinoma. Distinct differences in the tumor differentiation phenotype and genetic alterations between gastric adenomas and differentiated-type carcinomas suggest that the adenoma-carcinoma sequence, typically seen in colorectal carcinoma, is not be a major pathway in tumorigenesis of gastric differentiated-type tumor. Furthermore, our present findings also suggest that the tumor differentiation phenotype and genetic alterations are related to tumor aggressiveness in gastric differentiated-type tumors.

The relations between tumor differentiation phenotype and genetic alterations have not been examined in any large study on gastric adenoma and early differentiated-type carcinoma. Our present results revealed that MSI was

significantly associated with MUC6 expression and G-phenotype, and inversely associated with CD10 expression. On the other hand, *APC* mutation was significantly associated with CD10 expression and I-phenotype, and inversely associated with expressions of HGM and MUC6, suggesting that the tumor differentiation phenotype is closely related to genetic alterations in gastric differentiated-type tumors. Differentiation of gastric epithelial cells, especially pyloric gland cells, may be related to MSI, while differentiation of intestinal epithelial cells, especially absorptive cells, may be related to *APC* mutations. To the best of our knowledge, this is the first report describing associations between genetic alterations, such as *APC* mutations and MSI, and the expressions of HGM, MUC6, MUC2 or CD10 in gastric differentiated-type tumors.

The differences in the biological behavior of tumors with different phenotype as described above suggest that the action of different genetic alterations depends on the tumor differentiation phenotype of gastric tumors. Kabashima *et al*[10] reported that G-phenotype tumors can potentially degrade the extracelluar matrix through the overexpression of matrix metalloproteinases, compared with I-phenotype tumors. Shibata *et al*[17] reported that the apototic index/proliferative index ratio is significantly lower in G-phenotype tumors than in I-phenotype tumors. Endoh *et al*[18] have detected *E-cadherin* mutations in 21% of differentiated-type carcinomas with a G-phenotype, although this mutation is generally considered to be involved in undifferentiated-type but not differentiated-type carcinomas. Our present findings show that the tumor differentiation phenotype is closely related to tumor invasion and genetic alterations in gastric differentiated-type tumors. Previous molecular genetics studies have shown that gastric tumorigenesis is a multistep process with accumulation of genetic alterations[3,4]. Therefore, the previous data and our present findings suggest that different genetic pathways according to the tumor differentiation phenotype might play a role in the tumorigenesis of the gastric differentiated-type tumor, leading to their different biological behavior.

In conclusion, the tumor differentiation phenotype is closely related to tumor invasion and genetic alterations in gastric differentiated-type tumors.

Abstract

AIM: To study effects of recombinant human growth hormone (rhGH) on growth of a human gastric carcinoma cell *in vivo*.

METHODS: Experimental mice were divided into control group, rhGH group, oxaliplatin (L-OHP) group and rhGH+L-OHP group. Cultured human gastric carcinoma cells BGC823 were inoculated into right axilla of nude mice and carcinoma xenograft model was established successfully. Inhibitory rate of xenograft tumor growth was estimated by measuring tumor volume; expression of proliferating cell nuclear antigen (PCNA), Bax and Bcl-2 proteins of xenograft tumor was detected using immunohistochemical S-P method.

RESULTS: Tumor growth inhibitory rate, the positive expression rate of PCNA, Bax and Bcl-2 were 49.3%, 58.2%, 65.2% and 59.2% in rhGH+L-OHP group respectively; 46.6%, 62.5%, 59.7% and 64.7% in L-OHP group; 5.0%, 82.7%, 23.2% and 82.2% in rhGH group and 0, 77.8%, 23.5% and 80.3% in control group. There was significant difference between rhGH+L-OHP group (or L-OHP group) and control group or rhGH group ($P < 0.05$), whereas there were no significant differences ($P > 0.05$) between L-OHP group and rhGH+L-OHP group and between rhGH group and control group.

CONCLUSION: rhGH does not accelerate the proliferation of human gastric cancer cell *in vivo*.

INTRODUCTION

Recombinant human growth hormone (rhGH) can reverse many nutritional and metabolic abnormalities associated with severe catabolic states. In clinical studies rhGH has been shown to promote protein synthesis, improve nitrogen balance, accelerate wound healing[1-6], maintain host immune function and alleviate postoperation fatigue syndrome (POF)[7]. GH has become available for clinical use. It was reported that rhGH enhanced positive nitrogen balance in metabolic recuperation of postoperative patients who suffered from malignant tumor[8,9]. However, it is still controversial[10-12] whether rhGH should be applied in postoperative tumor patients since hGH promoted the proliferation of normal cells, as well as tumor cells. In the present study we investigated the effects of rhGH on human gastric cancer cell line BGC823 *in vivo* by inducing carcinoma xenograft model in nude mice, in an effort to clarify whether rhGH can be applied in postoperative patients with gastric cancer for metabolic intervention.

MATERIALS AND METHODS

Materials

B*ALB/C* nude mice were obtained from Shanghai Pharmaceutical Institute of Chinese Academy of Sciences. The mice were 6 wk old, with weights ranging between 12-22 g. Human gastric cancer cell line BGC823 was supplied by the Cell Bank of Shanghai Cell Biology Institute of Chinese Academy of Sciences. rhGH (Saizen) was supplied by Serono (Switzerland). Oxaliplatin (L-OHP) was purchased from Henrui Pharmaceutical Company, Jiangsu, China. Immuno-histochemical reagents, including proliferating cell nuclear antigen (PCNA), Bax and Bcl-2 were obtained from Maixin Reagents Company, Fujian, China.

Methods

At logarithmic growth phase, the cells of human gastric

Table 1 Volume and inhibitory rate of xenograft tumor growth (n = 6, mean ± SD)

Group	Volume (cm^3)	Inhibitory rate (%)
Control	0.406 ± 0.138	0
rhGH	0.383 ± 0.136	5
L-OHP	0.215 ± 0.087[a]	46.6
rhGH+L-OHP	0.208 ± 0.102[a]	49.3

[a]P < 0.05 *vs* control or rhGH.

cancer cell line BGC823 were digested by trypsin. Then the activity of the cells was examined (*Via* = 98.6%) and the cells were counted in hemocytometer using Trypan blue exclusion. The density of single cell suspension was adjusted to 1×10^{10}/L for further use.

Cell suspension (0.2 mL) was inoculated subcutaneously into right axilla of nude mice and all of carcinoma xenograft models were established within 3-7 d. Then the volume of tumor was measured. The experimental mice were randomly divided into 4 groups: control group, rhGH group, L-OHP group and rhGH+L-OHP group, 6 in each according to the drugs they received. From the 8th day of inoculation, the following drugs were administrated for 6 consecutive days: normal saline(NS) was subcutaneously injected in control group, 0.1 mL/d; rhGH group with rhGH, 2 IU/kg per day; L-OUP group with L-OHP by celiac injection, 1.3 mg/kg per day; and rhGH+L-OHP group with both rhGH and L-OHP of the same dosage as rhGH group and L-OHP group, respectively.

Immunohistochemistry

The mice were killed on the 7 d of drug administration and inhibitory rate of xenograft tumor growth was estimated by measuring tumor volume and expressions of PCNA, Bax and Bcl-2 proteins were detected by using immunohistochemical technique. Definition of positive PCNA cells was that cytoblast was nigger-brown stained and that for positive Bax and Bcl-2 cells was brown yellow stained in cytoplasm and cell membrane.

Statistical analysis

Data were expressed as mean ± SD and analyzed by variance analysis with SPSS11.0. Statistical significance was considered at $\alpha = 0.05$.

RESULTS

Inhibitory rate of xenograft tumor growth

Length(a) and breadth(b) of xenograft tumor were measured and the volume was counted using the formula: $V = ab^2/2$, as Oscieka described[13]. Xenograft tumor grew more slowly and tumor growth inhibitory rate was larger in rhGH+ L-OHP group and L-OHP group compared with control group and rhGH group ($P < 0.05$), whereas there was no significant difference between control group and rhGH group or between L-OHP and rhGH+L-OHP groups (Table 1). Tumor growth inhibitory rate (%) = [(volume in control group-volume in experiment group)/ volume in control group] × 100%

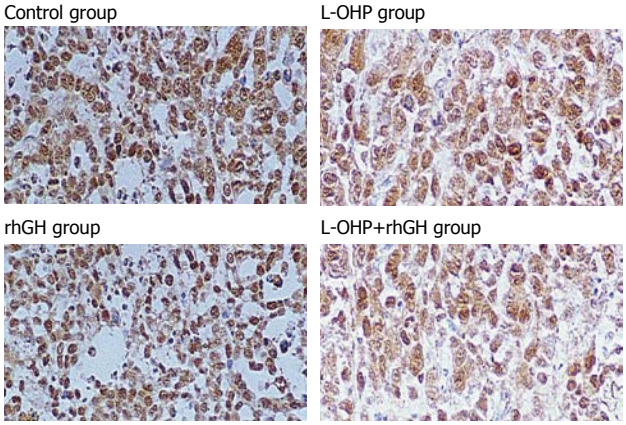

Figure 1 Positive expression of PCNA of human gastric cancer cell (SABC × 100).

Detection of PCNA, bax and Bcl-2 proteins using immunohistochemical technique

Positive expression of PCNA of human gastric cancer: There were more cells whose cytoblasts were nigger-brown stained in control group and rhGH group compared with L-OHP group and rhGH+L-OHP group.

Positive expression of Bcl-2 of human gastric cancer: There were more cells whose cytoplasm and cell membrane were brown yellow stained in control group and rhGH group compared with L-OHP group and rhGH+L-OHP group. In contrast, positive expression of Bax was seen more in L-OHP group and rhGH+L-OHP group (Figures 1, 2, and 3).

PCNA and Bcl-2 expressions were obviously decreased, while Bax distinctly increased in rhGH+L-OHP group and L-OHP group compared with control group and rhGH group ($P < 0.05$), but there was no significant difference between control group and rhGH group or between L-OHP and rhGH+L-OHP group (Table 2).

DISCUSSION

Nude mouse was a mutant mouse found and cultured in 1966. Because it has no thymus and completely lacks lymphocyte function and has no repellent reaction to heterogeneous transplant, it is especially adapted to animal heterogeneous transplant and human tumor heterogeneous transplant. In addition, karyotype, histological form and tumor biological characters of transplant tumor is the same as original tumor. Therefore, tumor model of nude mice is an ideal model for studying human malignant tumor. In our study, tumor xenograft model was successfully established through inoculation of human gastric carcinoma cells BGC823 into right axilla of nude mice. All tumor xenograft grew obviously.

In recent years, many studies reported that rhGH did not promote tumor growth[14-17]. Researchers from home and abroad found that rhGH accelerated improvement of patients by tentatively applying rhGH to patients with gastrointestinal malignant tumor after operation for metabolic intervention. rhGH did not promote tumor

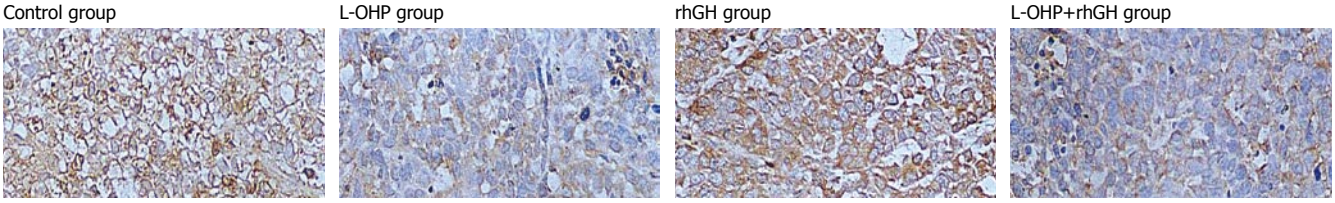

Figure 3 Positive expression of Bcl-2 of human gastric cancer cell (SABC × 100).

Table 2 Percentages of positive cells of PCNA, Bax and Bcl-2 expression

Group	PCNA	Bax	Bcl-2
Control	77.8 ± 6.3	23.5 ± 4.3	80.3 ± 8.9
rhGH	82.7 ± 9.4	23.2 ± 5.7	82.2 ± 7.4
L-OHP	62.5 ± 7.2[a]	59.7 ± 12.8[a]	64.7 ± 6.2[a]
rhGH+L-OHP	58.2 ± 5.2[a]	65.2 ± 11.9[a]	59.2 ± 9.2[a]

[a]$P < 0.05$ *vs* control or rhGH.

growth and metastasis in all their reported cases. Juergen *et al*[18] showed that postoperative treatment with rhGH in short term did not promote recurrence of tumor in 75 patients with gastrointestinal malignant tumor. Others carried out short-term nutritional treatment with rhGH in patients with tumor completely excised or other anticancer therapy[19].

In the present study, in comparison of rhGH+L-OHP and L-OHP groups with control and rhGH groups, PCNA and Bcl-2 apparently decreased and Bax obviously increased ($P<0.05$), while there was no significant difference between control group and rhGH group or between L-OHP and rhGH+L-OHP groups. It suggests that rhGH did not increase gastric cancer cell growth. In addition, tumor grew more slowly and tumor inhibitory rate was higher in L-OHP and rhGH+L-OHP groups, compared with control group and rhGH group, whereas there were no distinct differences between control group and rhGH group or between L-OHP and rhGH+L-OHP groups. These results also indicate that rhGH did not accelerate gastric cancer growth.

This study showed rhGH did not accelerate growth of a human gastric carcinoma xenograft model in nude mice. The results coincide with Fiebig's study that rhGH did not promote tumor (renal cancer and lung cancer) growth in nude mice[20] and also our former experiment *in vitro*[21]. In addition, our former study results showed tumor inhibitory rate did not change correspondingly with increase of the dose of rhGH. On the other hand, Blanck *et al*[22] proved rhGH did not promote liver cancer and renal cancer growth in rat tumor model. The mechanism that rhGH does not promote tumor growth is unknown. The possible mechanisms are (1) rhGH enhanced immunity of body[23]. Some researchers found GH and insulin-like growth factor-1 (IGF-1) increased the activity of natural killer cell (NK)[24,25]; (2) hGH directly or indirectly stimulate cell toxic effect[23]; (3) GH receptor expression reduced in tumor cell[22,26]; (4) IGF-1 and insulin-like growth factor binding protein-3 (IGFBP-3) were increased because of therapy of GH and IGFBP counteracted proliferation effect of IGF-I. Furthermore, IGFBP accelerated apoptosis independently of IGF-1[27]. Moreover, IGFBP-3 has been reported to inhibit the development of colonic tumors in experimental models and may hold promise as an adjuvant therapy for patients with neoplasm[28].

To sum up, our study demonstrates that postoperative treatment with rhGH in short term does not promote gastric cancer growth in patients with gastric cancer and it is safe using rhGH with chemotherapeutics.

GASTRIC CANCER

Single-tube-genotyping of gastric cancer related SNPs by directly using whole blood and paper-dried blood as starting materials

Abstract

AIM: To demonstrate an inexpensive method for typing gastric cancer related single nucleotide polymorphisms (SNPs) using whole blood or paper-dried blood as starting materials.

METHODS: PCR amplification is directly carried out from the whole blood or paper-dried blood sample without any DNA extraction step. Before PCR, a blood sample, four primers, and all of biological reagents necessary for PCR were added at a time; After PCR, the amplified products were directly separated by slab gel electrophoresis or microchip CE without any purification. SNP typing was performed by tetra-primer PCR with two inner primers specific to each allele and two outer primers defining the length of allele-specific amplicons. Genotypes were directly discriminated by the size of amplicons specific to each allele, thereby avoiding any post-PCR process.

RESULTS: Using a special PCR buffer, inhibitory substances in blood (including the anticoagulant in blood) and filter paper were effectively suppressed; a "true" single-tube-genotyping is thus realized. We successfully determined genotypes IL-1B-511 and IL-1B-31 polymorphisms at the gene IL-1B by using whole-blood and paper-dried blood samples as starting materials respectively. The method is so sensitive that 0.5-1.0 μL of blood sample is enough to give a satisfactory typing results. The genotyping results were confirmed by RFLP-PCR using purified genome DNA, indicating that amplification specificity was not affected by inhibitory components (including coagulants) in blood or filter paper.

CONCLUSION: Compared with SNP typing methods based on purified DNA, the proposed method is labor-saving, simple, inexpensive, and less cross-contaminated. It is promising to use this method to type other SNPs.

INTRODUCTION

Gastric cancer is a complex disease with a high mortality rate[1-3], but the recent success of the Human Genome Project[4] as well as the identification of vast numbers of single nucleotide polymorphisms (SNPs)[5] enables us to prevent or alleviate the disease by detecting the potential disease-susceptibility alleles and diallelic markers. It was reported that cytokine IL-1B, a potent proinflammatory cytokine that is also a powerful inhibitor of gastric acid secretion, is up-regulated by *H pylori* infection and is important in initiating and amplifying the inflammatory response to this infection[6]. Genetic analysis from different race's population[6-12] showed that the IL-1B-511 and -31 polymorphisms in the promoter region are associated with the development of gastric cancer. Currently, several different IL-1B genotyping techniques have been described; these include restriction fragment length polymorphisms (RFLP)[7,12-14] analysis and pyrosequencing. Although RFLP is very simple and can be performed without any expensive instrument, post-PCR process and a particular restriction endonuclease are required. Pyrosequencing is a newly developed typing method based on a real-time DNA sequencing[15,16], but an expensive pyrosequencer is needed for the detection.

Up-to-now, various typing techniques based on different principles, e.g., sequence-specific hybridization[17,18], allele-specific extension[19,20] or ligation[21,22], and structure specific cleavage[23,24], have been developed. However, almost all of these methods require purified genome DNA as the

starting material for PCR. The genome DNA extraction is costly and time-consuming. More over, DNA isolation process causes the risk of sample contamination with foreign DNAs. Since a huge number of SNPs should be typed through multiple regions of interest for clarifying the disease-susceptibility SNPs, a simple, inexpensive and labor-saving genotyping method without the DNA extraction procedure is preferable. Here we propose a single-tube genotyping method by combining whole blood PCR (WB-PCR) and tetra-PCR[25,26]. Neither a post-PCR step nor an expensive instrument is required. The type of SNP could be determined by the length of the amplicons from PCR with whole blood or paper-dried blood in a single tube containing four primers: two inner primers specific to each allele and two outer primers defining the length of allele-specific amplicons. To reduce the sample consumption and to increase the typing speed, microchip electrophoresis[27] was used for the detection. As shown in Figure 1, the procedure is very simple, and all of the reagents necessary for PCR as well as blood sample were added in the tube at a time before PCR. Therefore, the aim of the present study is to demonstrate an inexpensive method for typing gastric cancer related SNPs using whole blood or paper-dried blood as starting materials.

MATERIALS AND METHODS

Reagents

Taq DNA polymerase and ethidium bromide were from Promega (Madison, USA). Agarose gel was from Oxoid Limited (Basingstoke Hampshire, England), and dNTP was from Genebase Gene-Tech (Shanghai, China). All solutions were prepared in deionized and sterilized water. DNA 1000 ladder, DNA 1000 Marker15/1500 bp, DNA Dye, and DNA Gel Matrix were purchased from Agilent technologies. The other reagents used in the experiment are analytical pure grade or molecule biology grade. PCR buffer BL-AMP™ was from Bailong Gene Company (Nanjing, China).

Blood samples

Human blood samples were obtained from 40 patients with clinical confirmation and informed consent. Whole-blood samples were venously collected and treated with dipotassium EDTA anticoagulant. The blood sample for condition test was from a volunteer in our laboratory, and directly treated with dipotassium EDTA, sodium citrate, and sodium heparinate respectively. All of the whole blood samples were stored at + 4℃ before use. Paper-dried blood was prepared by dropping a small amount of anticoagulant blood sample on a piece of sterile filter paper, followed by air dry at room temperature, and stored in vacuum desiccator at room temperature before use.

DNA Extraction

Genomic DNA was extracted from blood samples using standard procedures with phenol-chloroform extraction method to separate proteins from nucleic acids[28]. DNA isolation was carried out by suspending whole blood in equal volume of lyses buffer (10 mmol/L Tris-HCl, pH 7.6, 50 mmol/L $MgCl_2$, 320 mmol/L sucrose and 10 g/L Triton-100). After mixing and centrifugation (2 min at micro-centrifuge), the supernatant fluid was removed. This isolation procedure was performed twice. Then the pellet was dissolved with TES buffer (15 mmol/L Tris-HCl, 15 mmol/L EDTA, 15 mmol/L NaCl, 5 mol/L $NaClO_4$, and 100 g/L SDS; pH 8.0), and incubated at 37℃ for 15 min and at 65℃ for 20 min. DNA was extracted twice with 1 volume of phenol-chloroform-isoamyl alcohol (25:24:1). Nucleic acids remained in the aqueous phase; cellular proteins were separated into the organic phase or lay at the phase interface. After centrifugation, the organic phase was discarded and the aqueous phase was precipitated with absolute ethanol. The pellet was washed with 700 mL/L ethanol, dried in the still air and suspended in Tris-EDTA buffer (10 mmol/L Tris base, 1 mmol/L EDTA; pH 8.0). The DNA was quantified spectrophotometrically at 260 nm, and then stored at 4℃ before use.

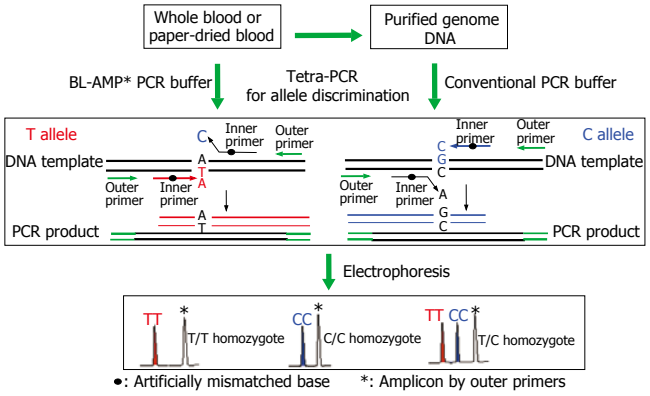

Figure 1 Schematic of a single-tube-genotyping method using tetra-PCR amplification from blood and extracted DNA.

Table 1 Primers for typing polymorphisms IL-1B-31 and IL-1B-511

Polymorphism	Primer sequences
IL-1B-31	P1-1 5′- tcaactgcacaacgattgtca -3′
	P1-2 5′- tcccttagcacctagttgtaa -3′
	S1-1 5′- ttctccctcgctgtttttGta -3′
	S1-2 5′- ctacttctgcttttgaaaCcc -3′
IL-1B-511	P2-1 5′-ggaagggcaaggagtagcaaac-3′
	P2-2 5′-ggcagagctcatctggcattga-3′
	S2-1 5′-ctgcaattgacagagagctGcc-3′
	S2-2 5′-ttgggtgctgttctctgccAca-3′

The capital letters indicated artificial mismatched bases.

PCR primers and target sequences

The nucleotide sequences for the IL-1B gene are available from Genbank (http://www.ncbi.nlm.nih.gov/), and the accession number is AY137079. IL-1B polymorphic sites in the promoter region at position -31 and -511 were genotyped. For typing one SNP, four primers are necessary: two allele-specific primers (S1-1, S1-2 or S2-1, S2-2; Table 1) and two outer primers (P1-1, P1-2 or P2-1, P2-2; Table 1). The sequences of all the primers were listed in the Table 1. A mismatched base was introduced into the third position

upstream from 3' terminal of the allele-specific primer to decrease the probability of spurious extension reaction. Genotypes of IL-1B-31 were determined by a 258-bp PCR fragment (specific to IL-1B-31T) with primers P1-1 and S1-1, and a 162-bp PCR fragment (specific to IL-1B-31C) with primers P1-2 and S1-2. Genotypes of IL-1B-511 were determined by a 356-bp fragment (specific to IL-1B-511C) with primers P2-1 and S2-1, and a 226-bp fragment (specific to IL-1B-511T) with primers P2-2 and S2-2. The software of Primer Premier Version 5.0 (http://www.premierbiosoft.com/) was used to calculate the melting point and to analyze the risk of primer-dimer formation and secondary structures. All the oligonucleotides were synthesized and purified by Invitrogen Biotechnology Co., Ltd (Shanghai, China).

Tetra-primer PCR amplification

Purified DNA template was amplified in a final volume of 15 μL containing 0.2 mmol/L dNTP mixture, 1.67 μmol/L of each of four primers (IL-1B-31), or 2.67 μmol/L of each outer-primer and 0.67 μmol/L of each inner-primer (IL-1B-511), 1 U of Promega *Taq* DNA polymerase, 10 × Buffer, and 1.5 mmol/L $MgCl_2$. Thermocycling was carried out on PTC-225 Peltier Thermal Cycler (MJ RESEARCH, INC.) at an initial denaturation at 96℃ for 3 min, then 35 cycles of 94℃ for 30 s, 52℃ (IL-1B-31) or 58℃ (IL-1B-511) for 1 min, and 72℃ for 1 min, followed by 72℃ for 7 min. Whole blood or paper-dried blood sample was amplified in a 20 μL PCR mixture containing BL-AMP™ buffer instead of the conventional 10 × PCR buffer, 0.2 mmol/L dNTP mixture, 1.5 mmol/L $MgCl_2$, 2 U of Promega *Taq* DNA polymerase, and 1.5 μmol/L of each of four primers (IL-1B-31), or 3 μmol/L of each outer-primer and 0.75 μmol/L of each inner-primer (IL-1B-511). Following the assembly of the PCR mixture, anticoagulant-treated whole blood or filter paper-dried blood was added (commonly 1 μL of blood per 50 μL of PCR mixture) into the bottom of the PCR tube without any agitation. Thermocycling was carried out at an initial denaturation at 96℃ for 3 min, then 40 cycles of 94℃ for 30 s, 52℃ (IL-1B-31) or 58℃ (IL-1B-511) for 1 min, and 72℃ for 1 min, followed by 72℃ for 7 min.

Gel and microchip electrophoresis of PCR products

PCR products were separated by either gel electrophoresis or microchip electrophoresis. The gel electrophoresis was performed on a 20 g/L agarose gel stained with 0.005 g/L EtBr in 1 × TAE buffer at 100 V for 14 min. Gel images were captured on a Bio Imaging System (Syngene, UK). Microchip electrophoresis was carried out on Agilent 2100 bioanalyzer (Agilent technologies, German) according to the manufacture's instructions.

RESULTS

Direct PCR on whole blood and paper-dried blood

To evaluate whether or not target sequences in whole blood or paper-dried blood could be amplified using the "BL-AMP™" buffer, PCR with two sets of primers (P1-1 and P1-2, and P2-1 and P2-2; Table 1), which were used as outer primers for typing IL-1B-31 and -511 polymorphisms, were carried out. Except for PCR buffer, all PCR conditions including *Taq* polymerase, concentration of Mg^{2+} and dNTPs and thermal cycling conditions, are the same as that used in conventional PCR. As shown in Figure 2, the fragments with the expected length of 379 bp and 539 bp were successfully amplified from whole blood with the anticoagulant of dipotassium EDTA, sodium citrate, or sodium heparinate respectively. To check whether paper constitutes suppress PCR or not, a piece of filter paper with 1 mm^2 was added into 50 μL of PCR reaction mixture containing purified genome DNA; and the results showed that "BL-AMP™" buffer could block the PCR inhibition by the chemicals present in filter paper (data not shown). Direct PCR with two sets of primers (P1-1 and P1-2, and P2-1 and P2-2; Table 1) using 0.5, 1, 2 and 4 μL of EDTA-blood dried on filter paper as starting materials were carried out to evaluate the sensitivity (Figure 3); and PCR with 1 μL of fresh blood without an anticoagulant was performed in parallel for the comparison. Successful PCRs were obtained for all samples, and 1 μL of paper-dried blood gave an optimum sensitivity.

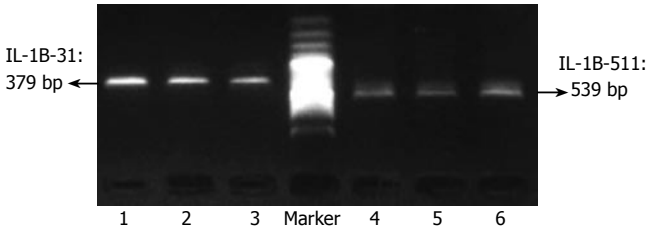

Figure 2 Direct PCR amplification from blood samples with the anticoagulant of dipotassium EDTA (1, 4); Sodium citrate (2, 5); and Sodium heparinate (3, 6).

Genotyping of IL-1B-31 and -511 polymorphisms from various forms of blood samples

By coupling the "BL-AMP™" buffer with tetra-PCR, genotyping of IL-1B-31 and -511 polymorphisms was carried out by using whole blood (with dipotassium EDTA anticoagulant) and dried blood (on a piece of sterile common filter paper) as the starting material respectively. Samples from fifteen different individuals were employed for the evaluation. Amplicons were separated by slab gel electrophoresis that is a simple and inexpensive way in a regular lab. As shown in Figures 4 and 5, it is very easy to get unambiguous SNP types from electrophoretic patterns by using whole-blood samples or paper-dried blood samples as PCR starting materials. As the amplification efficiency of two allele-specific amplicons is different, the concentration ratios of two allele-specific primers were optimized as 8:1 (S1-1:S1-2) to get a relatively equal band-intensities (Figure 6). The bands of 162 bp and 258 bp represent allele C and T respectively. The band of 379 bp was the amplicon by two outer primers P1 and P2; this band was used to be a positive control for checking the sample quality. For a heterozygote sample, both 162- and 258-bp fragments were co-amplified, while either 162- or 258-bp fragment was amplified if the sample was of a homozygote. All of three genotypes were unambiguously determined, indicating that the newly developed method is

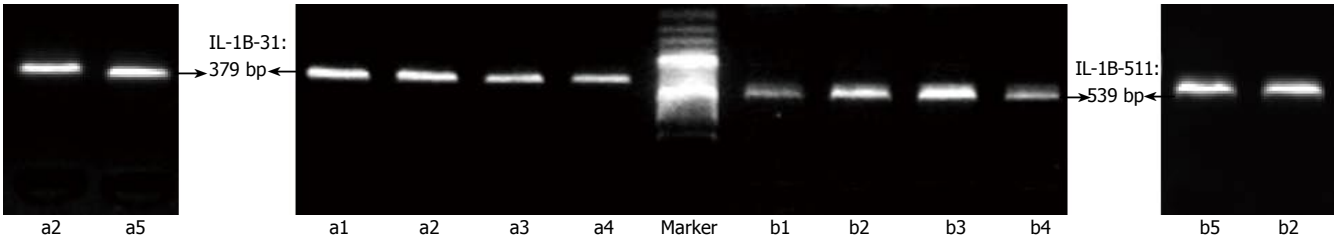

Figure 3 Direct PCR with two sets of primers (P1-1 and P1-2; P2-1 and P2-2) using 0.5 μL (a1, b1), 1 μL (a2, b2), 2 μL (a3, b3) and 4 μL (a4, b4) of EDTA-blood dried on filter paper as starting materials. PCR with 1 μL of fresh blood without an anticoagulant was performed in parallel for the comparison (a5, b5). a1-a5: 379-bp fragment; b1-b5: 539-bp fragment.

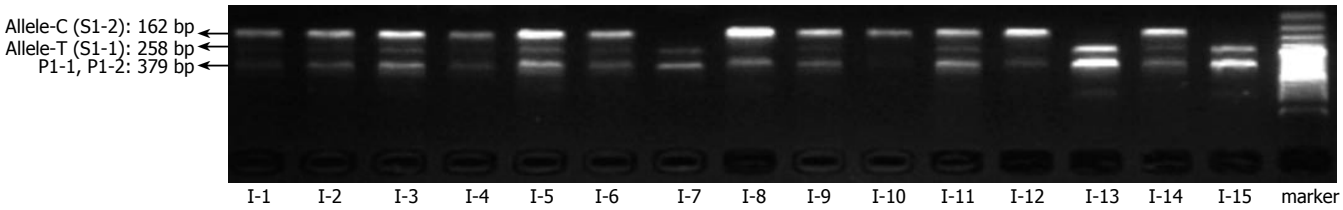

Figure 5 Results of genotyping of IL-1B-31 using paper-dried blood as starting PCR material.

highly specific.

To test the effect of inhibitors in blood or paper tissues on the specificity, genotyping was also performed on the genome DNAs extracted from the same blood samples as those in Figure 4; the results (Figure 7) were in complete agreement with those obtained with whole blood or paper-dried blood samples. Therefore the presence of the inhibitors did not interfere with the specificity of genotyping. By using the same condition, polymorphism of IL-1B-511 was typed directly from fifteen blood samples as shown in Figure 8. The allele-specific PCR fragments are marked by allele-C and allele-T, which correspond to the amplicons with the size of 226 bp and 356 bp respectively. A 539-bp amplicon was from two outer primers (P2-1 and P2-2). The unambiguous typing results of all tested samples were obtained. Also the genotyping results of IL-1B-511 polymorphism from three different starting materials (whole blood, paper-dried blood and purified DNA) are completely consistent (data not shown).

Compared with slab gel electrophoresis, microchip electrophoresis is time-saving, labor-saving, and extremely sensitive. As the separation is in the microchannel, a small amount of DNA sample is enough for getting a reliable result; the typing cost can thus be further decreased. In this report, Agilent 2100 bioanalyzer was employed to analyze the amplified products of the above fifteen blood

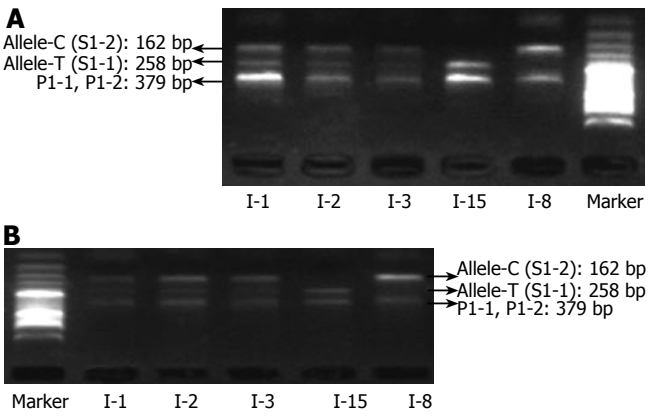

Figure 6 The optimized experiment results of polymorphism IL-1B-31 by changing the concentration ratios of two allele-specific primers from 1:1 to 8:1 (S1-1: S1-2) to get relatively equal band-intensities. **A**: PCR using whole blood as starting PCR materials; **B**: PCR using paper-dried blood as starting PCR materials.

samples. With the DNA markers of different sizes, the length of each amplicon was identified automatically. We found that all blood-based tetra-PCR amplicons gave the expected sizes. Figures 9A and 10A show the typing results of three typical genotypes (two kinds of homozygotes and a heterozygote) of IL-1B-31 and IL-1B-511 respectively.

To evaluate the accuracy of SNP typing, five representative individuals including heterozygotes and

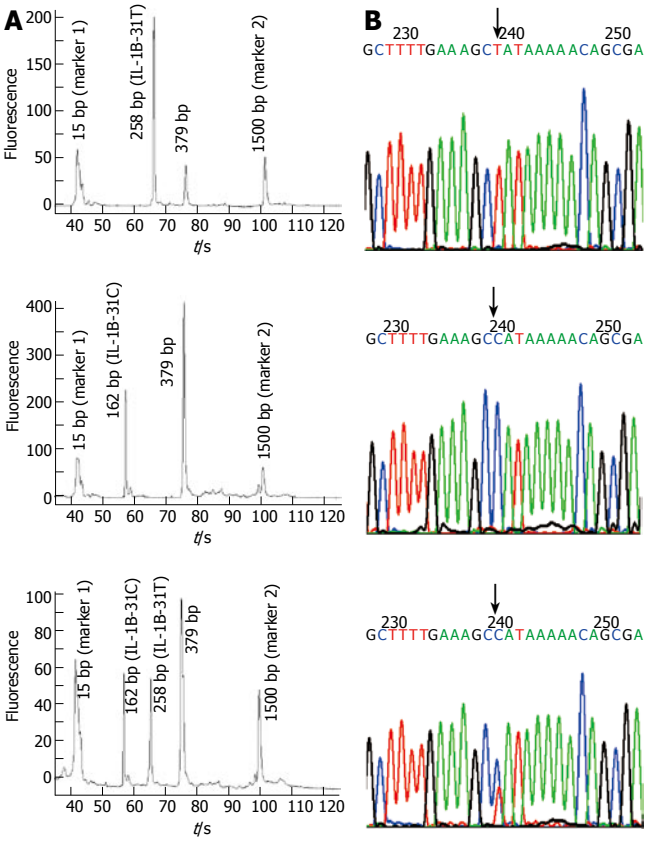

Figure 9 Electrophoresis results of three typical genotypes were obtained, heterozygote (C/T) and both homozygotes (T/T and C/C) of IL-1B-31, by the microchip (**A**) and Sanger's sequencing method (**B**) respectively. The fragment of 379 bp was from two outer primers (P1-1 and P1-2).

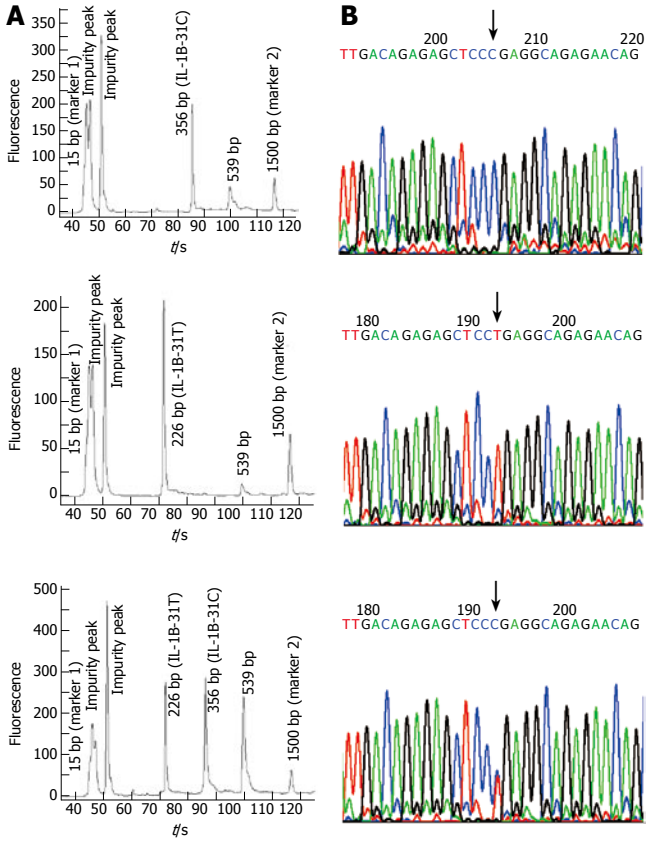

Figure 10 Electrophoresis results of three typical genotypes were obtained, heterozygote (C/T) and both homozygotes (T/T and C/C) of IL-1B-511, by the microchip (**A**) and Sanger's sequencing method (**B**) respectively. The fragment of 539 bp was from two outer primers (P2-1 and P2-2).

both homozygotes were selected and genotyped again by Sanger's sequencing method using purified genomic DNA. The sequencing-based typing results of the five individuals completely coincided with those by the single-tube tetra-PCR. For the comparison, sequencing spectra of the samples used in Figures 9A and 10A were listed as Figure 9B and 10B respectively, indicating that it is very accurate to apply the newly developed single-tube method for genotyping IL-1B-31 and -511 polymorphisms.

To test the robustness of the method, we analyzed three blood samples with typical genotypes for ten times at ten different days. The consistent typing results at both IL-1B-31 and IL-1B-511 polymorphisms were obtained, indicating that the proposed method is reproducible

and reliable. In addition to the blood samples from 15 individuals, we also typed another 25 whole-blood samples by using the proposed single-tube-genotyping method; and unambiguous typing results of both IL-1B-31 and IL-1B-511 polymorphisms were obtained (data not shown).

DISCUSSION

Tetra-PCR is very simple and time-saving[25,26]; but it is not a true single-tube genotyping method as DNA isolation step was still required. Since many substances existing in blood, e.g. polysaccharides, proteins, lipids and haemoglobin, suppress PCR[29], it is very difficult to escape the DNA extraction step and directly use whole blood for PCR amplification. Moreover, anticoagulants, such as EDTA or heparin, which are commonly added to prevent blood samples from the clotting, may interfere with PCR amplification. To effectively suppress the inhibitory substances including the anticoagulant in blood, a novel PCR buffer named "BL-AMP™" was developed.

By coupling tetra-PCR amplification with this buffer, a single-tube-genotyping method using the whole blood and paper-dried blood as the starting material was realized. To type each allele, four primers (two outer primers and two inner primers) were used for amplifying two allele-specific fragments. Two inner primers complementary to sense and non-sense strands respectively were used to discriminate the allele. As one base differing at the 3'-ends of each inner primer is not enough to perfectly switch the allele-specific extension reaction, an artificial mismatch base was introduced into the third base from the 3'-ends. Two outer primers define the length of two allele-specific amplicons. After PCR, amplicons were separated by electrophoresis, e.g., slab gel electrophoresis or microchip electrophoresis. The SNP type is discriminated by the pattern in the electrophoretogram; two bands mean a heterozygote and one band means a homozygote. The length of the band determines the genotype of the homozygote. Unlike Taqman, molecular beacon, or minisequencing, the newly proposed method does not require labeling, and less sample manipulation than RFLP is needed. As the success in avoiding DNA isolation, the genotyping is a true single-tube format by using "BL-AMP™" buffer for PCR.

From the results of our study, it is demonstrated that PCR amplification using "BL-AMP™" buffer is independent of the type of anticoagulant in blood. In terms of transportation and storage of blood samples, it is very convenient to use filter paper as a carrier because no refrigeration is required for paper-dried blood; this is thus very useful to collect blood samples in remote areas. In addition, no significant difference in PCR efficiency between 1-μL fresh blood and dried blood equivalent to 1-μL fresh blood was observed. Compared with conventional PCR using purified DNA, a reddish color in the final PCR products was observed; however, this would not interfere with the detection of PCR products via electrophoresis. Consequently whole blood or paper-dried blood other than purified genome DNA can be employed for the starting materials of PCR.

Although no clean-up process was used after whole-blood PCR, direct microchip electrophoresis of raw PCR products gave a steady baseline. It is straightforward to discriminate genotypes with peaks in the electrophoreic spectra. Based on the peak assignment, genotypes can be accurately determined even if unspecific amplicons occurred in the spectra, so that it becomes easier to design primers for SNP typing by tetra-PCR. On the other hand, it is not necessary to optimize the primer concentration to get an even amplification as the Agilent 2100 bioanalyzer can assign the size to peaks with lower intensities.

In summary, we have successfully proposed a simple, labor-saving, inexpensive and rapid genotyping method that directly uses whole blood or paper-dried-blood as starting materials for SNP typing in a single tube. The successful genotyping of the IL-1B-31 and -511 polymorphisms demonstrated the reliability of the single-tube genotyping using whole blood or paper-dried blood as the starting material. As the DNA extraction step is taken out, the possibility of sample contamination is significantly decreased. By coupling CE-chip for the readout, an automatic and high-throughput genotyping could be achieved. In the post-genome era, a simple and inexpensive method for diagnostic analysis is highly demanded, so we believe that the whole-blood PCR should be very useful for genetic diagnosis in biologic laboratories.

Abstract

AIM: Although increased insulin-like growth factor-I receptor (IGF-IR) gene expression has been reported in hepatocellular carcinoma, studies assessing IGF-IR in chronic hepatitis C (CHC) and cirrhosis are scarce. We therefore aimed to evaluate IGF-IR and IGF-I mRNA expression in liver from patient with CHC.

METHODS: IGF-IR and IGF-I mRNA content were determined by semi-quantitative RT-PCR and IGF-IR protein expression was determined by immunohistochemistry in hepatic tissue obtained from patients with CHC before (34 patients) and after (10 patients) therapy with interferon-α and ribavirin.

RESULTS: An increase of IGF-IR mRNA content was observed in hepatic tissue obtained from all CHC patients as well as from 6 cadaveric liver donors following orthopic transplantation (an attempt to evaluate normal livers) in comparison to normal liver, while no relevant modifications were detected in IGF-I mRNA content. The immunohistochemical results showed that the raise in IGF-IR mRNA content was related both to ductular reaction and to increased IGF-IR expression in hepatocytes. A decrease in IGF-IR mRNA content was observed in patients who achieved sustained virological response after therapy, suggesting an improvement in hepatic damage.

CONCLUSION: The up-regulation of IGF-IR expression in hepatocytes of patients with CHC could constitute an attempt to stimulate hepatocyte regeneration. Considering that liver is the organ with the highest levels of IGF-I, our finding of increased IGF-IR expression after both acute and chronic hepatic damage highlights the need for additional studies to elucidate the role of IGF-I in liver regeneration.

INTRODUCTION

There is a close relationship between the endocrine system and the liver, in which processes such as hormonal inactivation, synthesis of hormonal binding proteins, and growth factors take place. The insulin-like growth factor (IGF) system is an attractive target of study, since it may be modified by liver diseases and, reciprocally, it might play a relevant role in the progression of some hepatic diseases. This system is comprised of two ligands, IGF-I and IGF-II, their specific receptors, IGF-IR and IGF-IIR, and the IGF-binding proteins (IGFBPs)[1-4]. IGFs are peptides involved in proliferation, differentiation and inhibition of apoptosis of several cell types[5]. IGF-IR has been shown to be capable of mediating both IGF-I and IGF-II signalling, whereas IGF-IIR (mannose 6-phosphate) is only able to decrease the bioavailability of IGF-II[6].

Circulating IGF-I is synthesized primarily by the liver in response to growth hormone, but most tissues express

IGF-I, which exerts autocrine and paracrine functions[7]. Within the normal adult liver, IGFs are believed to play relatively little effect, since IGF-II expression is down-regulated and IGF-I, although highly expressed, does not exert its actions due to low IGF-IR expression on hepatocytes[8]. Therefore, liver is the organ with the highest levels of IGF-I expression, while it exhibits almost undetectable levels of IGF-IR mRNA. This pattern of expression may be partially explained by down-regulation of IGF-IR promoted by locally produced IGF-I[9]. In contrast to hepatocytes, it is believed that the presence of IGF-IR in non-parenchymal rat liver cells (Kupffer cells, myofibroblasts and hepatic stellate cells [HSC])[10] and in human HSC[11] makes these cell types susceptible to IGFs mitogenic effects.

The role of IGF-I system in hepatic diseases and in liver regeneration remains uncertain. Although an elevation of IGF-IR expression during progression of preneoplastic hepatic foci to hepatocellular carcinoma (HCC) has been reported[12], studies using cultured HCC cells demonstrated a failure of IGF-I to stimulate mitogenesis[10,13,14]. On the other hand, hepatic over-expression of the IGF-II gene has been observed in animal models of hepatocarcino genesis[15,16] as well as in human HCV-induced cirrhosis and HCC[17-19]. Increased IGF-IR gene expression was observed in HCC and in human hepatoma cell lines[8,12,20], however, there are few studies evaluating different chronic hepatitis C (CHC) staging and cirrhosis concerning IGF-IR expression[11,18]. Therefore, the present study was designed to semi-quantify the hepatic expression of IGF-IR and IGF-I in patients with CHC, searching for possible correlations with histopathological lesions in each compartment of hepatic acini.

MATERIALS AND METHODS

Patients and tissue samples

A series of 34 patients with CHC was evaluated at the Clinical Hospital of the University of Sao Paulo Medical School. The diagnosis of CHC was based on a positive serological test for HCV by at least a second-generation enzyme-linked immunoabsorbent assay, positive HCV-RNA by polymerase chain reaction (PCR) assay, and compatible liver biopsy. All patients received combined treatment with interferon-α (3 million U three times a week) and ribavirin (1000-1200 mg/d, accordingly to body weight) for 48 wk, since genotyping was not available. Hepatic tissue fragments obtained before treatment were divided in two samples: one was formalin-fixed paraffin-embedded for histopathological and for immunohistochemical studies; the other was collected in sterile containers and frozen in liquid nitrogen for RNA extraction. Additionally, in 10 patients, liver biopsy was performed within one month after the end of treatment. Among the 34 treated patients, 14 (41.1%) patients reached sustained virological response, 16 (47.05%) patients were non-responders and 4 (11.76%) patients relapsed in the follow-up period. Among the 10 patients histologically evaluated in the post-treatment period, 5 (50%) patients were sustained virological responders and 5 (50%) patients were non-responders.

In order to obtain normal hepatic tissue, hepatic fragments were collected from six cadaveric liver donors (8-12 h of cold ischemia) following orthopic transplantation. The organs obtained from the six cadaveric donors were non-diseased liver transplanted in patients presenting HCV-related end-stage liver disease. The transplants were performed at Experimental Surgery Division, Clinical Hospital, University of Sao Paulo Medical School.

This study was approved by the Ethical Committee of the University of Sao Paulo Medical School and informed consent was obtained from all patients.

Histological and immunohistochemical analyses

Formalin-fixed paraffin-embedded samples were sectioned at a thickness of 3 μm, stained by hematoxylin and eosin (H&E), Masson's trichrome staining and reticulin impregnation, and evaluated by a single pathologist. Histopathological classification was based on criteria defined by the Brazilian Consensus on Chronic Hepatitis[21], which assesses individual histologic variables from zero (normal) to four (maximal degree of lesion): staging of architectural disturbances/fibrosis, necro-inflammatory lesions in portal tract, interface hepatitis and parenchymal lesions. Steatosis was also graded as follows: 0 = no fat deposition in hepatocytes; 1 = up to 25% of hepatocytes; 2 = 25%-50%; 3 = 51%-75%; and 4 = more than 75% hepatocytes presenting fat vacuoles.

Immunohistochemistry for IGF-IR was performed on sections deparaffinized with xylene, dehydrated with graded ethanol, incubated in 3% H_2O_2 to block endogenous peroxidase activity. To improve the staining pattern, antigen retrieval was obtained by heating in 0.5 mol/L EDTA (pH 8.0). The sections were incubated with Protein Block System and Biotin Blocking System (X0909, DAKOCytomation, USA). The primary antibody, mouse monoclonal IGF-IR (α-subunit) Ab-1 (Clone 24-31) (LAB VISION Corporation, Westinghouse, USA) at a dilution of 1:50 was incubated overnight. Signal amplification was achieved by kit LSAB-HRP (Labelled Streptavidin-Biotin) (DAKOCytomation, USA). Chromogen solution included 3, 3-diaminobenzidine tetrahydrochloride (DAB) (Sigma Chemical Co., USA). A sample from liver with cholangiocarcinoma was considered as a positive control and a normal liver sample as negative control. The staining was graded according to the estimative of fraction of positive cells of the interlobular bile ducts, lymphocytes from portal tracts and lobular areas, Kupffer cells, hepatocytes, endothelial cells and ducts cells from periportal areas (canals of Hering). Scores were predefined as follows: 0 = without staining; 1 = small amount of immuno-positive liver cells; and 2 = large amount of immuno-positive liver cells.

Semi-quantitative RT-PCR

After tissue pulverization with a dismembrator (B. Braun Biotech International, Melsungen, Germany) at liquid nitrogen temperature, total RNA was extracted using TRIzol® reagent (Invitrogen Life Technologies, Carlsbad, USA) according to the manufacturer's instructions. After phenol treatment and drying, RNA was dissolved in RNase-free water and RNA concentration was spectrophotometrically determined. RNA quality was checked on agarose gel electrophoresis. The expressions of IGF-

IR and IGF-I in the tissue series were performed by using semi-quantitative RT-PCR. Total RNA (3 μg) was reverse-transcribed into complementary DNA (cDNA) using the SuperScrip™ II Reverse Transcriptase and random primers (Invitrogen Life Technologies) according to manufacturer's recommendations and diluted with ddH_2O to a final volume of 20 μL. The optimal number of PCR cycles was determined for each primer set so that the amplification process was conducted during the exponential phase of amplification. Concomitant amplification of the break-point control region (BCR) gene transcript was used as the internal control to stringently control for any variability in RNA degradation and RT efficiency. Reactions were carried out in a 45 μL final reaction volume containing 3 μL of cDNA template, 20 mmol/L Tris-HCl (pH 9.0), 50 mmol/L KCl, 1.5 mmol/L $MgCl_2$, 0.22 mmol/L deoxynucleotide triphosphates (dNTPs), 2.0 U *Taq* DNA polymerase (GE Healthcare-Amersham plc, Buckinghamshire, UK) and specific primers for the target genes and for BCR gene. In order to achieve exponential co-amplification for both IGF-IR and IGF-I mRNA expressions in relation to the endogenous internal control (BCR) at the same number of cycles, sense and antisense primer concentrations were appropriately adjusted between 0.22 and 0.44 μmol/L. PCR amplifications for both genes were performed under the following cycling conditions: initial denaturation at 94℃ for 2 min 30 s, denaturation at 94℃ for 30 s, annealing at specific temperature 57℃ for 1 min and extension at 72℃ for 1 min 30 s, followed by a final extension at 72℃ for 1 min 30 s. The number of cycles to achieve the exponential phase was 40. As a positive control for IGF-IR and IGF-I, human placenta was used. For comparison purpose, normal human liver cDNA was commercially acquired (Human Liver QUICK-Clone cDNA [Clontech Laboratories, Inc., Palo Alto, CA, USA]) and, according to the manufacturer's instructions, cDNA was generated from Poly A+ RNA from samples obtained from two normal human livers. The PCR products were submitted to electrophoresis through a 20 g/L agarose gel containing ethidium bromide and visualized under ultraviolet light. The band intensities were analysed by Molecular Analyst Software (Bio-Rad Laboratories, Hercules, USA). The expression levels of IGF-IR and IGF-I were normalized by the BCR housekeeping gene expression and the ratios of gene expression (IGF-IR or IGF-I/BCR) were calculated in all samples as arbitrary units of optical density (AU). The primers were designed with the primer3_www.cgi v 0.2 program[22] as follows: BCR (377-bp product): 5'-GAG AAG AGG GCG AAC AAG-3' (sense) and 5'-CTC TGC TTA AAT CCA GTG GC-3' (antisense); IGF-IR (230-bp product): 5'-ACC CGG AGT ACT TCA GCG CT-3' (sense) and 5'-CAC AGA AGC TTC GTT GAG AA-3' (antisense); IGF-I (303-bp product): 5'-TCT TGA AGG TGA AGA TGC ACA CCA-3' (sense) and 5'-AGC GAG CTG ACT TGG CAG GCT TGA-3' (antisense).

Statistical analysis

Data were tested for statistical significance using the JMP version 5.1 statistical computer program (SAS Institute Inc. Cary, NC, USA). Since assumptions for a parametric test were not valid (Kolmogorov-Sminov, $P < 0.05$), all data were evaluated by Kruskall-Wallis analysis of variance and the Mann-Whitney *U* test as a multiple comparison method. The Spearman test was used to assess the statistical significance of correlations among the different variables tested. Chi-square and Fisher's exact tests were used to establish statistical relationship between groups regarding histopathological and immunohistochemical findings. *P* values less than 0.05 were considered statistically significant.

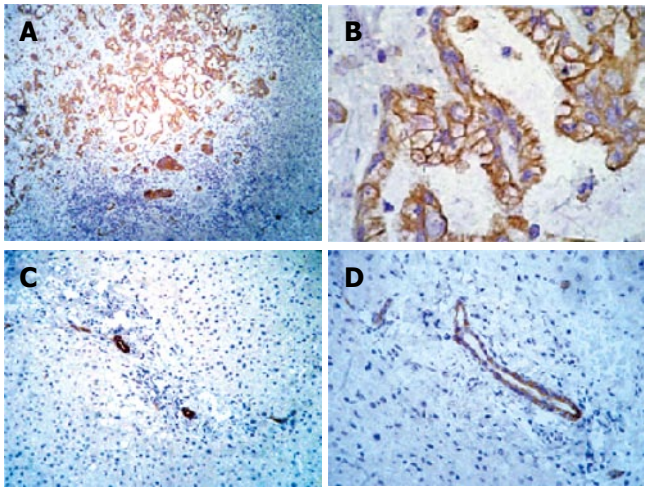

Figure 1 Immunohistochemical analysis of IGF-IR in liver tissue. **A**: Positive control cholangiocarcinoma tissue showing strongly positive staining for IGF-IR in neoplastic ducts (-100 ×); **B**: positive control cholangiocarcinoma tissue showing strongly positive staining for IGF-IR in neoplastic ducts (-200 ×); **C**: normal liver tissue showing IGF-IR immunoreactivity in ductal cells (-100 ×); **D**: normal liver tissue showing IGF-IR immunoreactivity in ductal cells (-200 ×).

RESULTS

Immunohistochemical analysis of IGF-IR

A section of cholangiocarcinoma tissue served as positive control for immunohistochemical analysis of IGF-IR. The positive pattern was observed in cytoplasmic membrane of the neoplastic duct epithelial cells (Figures 1A and 1B). Since positive staining for IGF-IR was detected in ductal cells, they served as internal control, both in normal liver where IGF-IR expression was not detected in hepatocytes (Figures 1C and 1D) and in chronic hepatitis liver samples. In CHC, an expressive increase in IGF-IR immunoreactivity was observed in membrane and in cytoplasm of proliferated bile ducts and in hepatocytes cytoplasm located in all acinar zones (Figures 2A-D). However, nuclear staining was not detected.

Histological and immunohistochemical findings before treatment (samples from 34 patients) and post-treatment (samples from 10 patients) are shown in Figures 3 and 4. Immunohistochemical analyses demonstrated of IGF-IR positivity in hepatocytes in 85% (29/34) samples of CHC before treatment; twenty-three of these 29 samples showed positive immunostaining in hepatocytes located in all regions of the lobe (zones I, II and III of the Rappaport's acinus), while in 6 of these 29 samples revealed positive immunostaining with grade 1 in periportal region, zone 1 (Figure 2E). On contrary, no IGF-IR positivity in

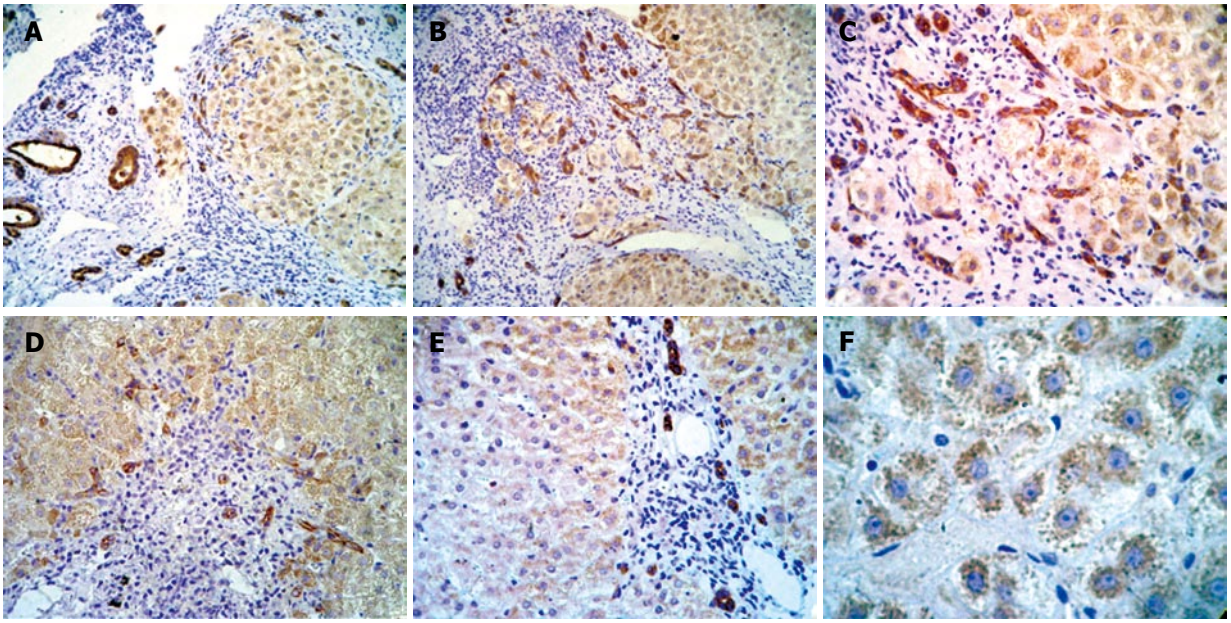

Figure 2 Immunohistochemical analysis of IGF-IR in different samples of liver. **A**: Strong positive staining in cytoplasm of hepatocytes in all acinar zones (-100 ×); **B**: strong positive staining in cytoplasmic membrane and cytoplasm of proliferate bile ducts and in cytoplasm of hepatocytes located in all acinar zones (-100 ×); **C**: strong positive staining in cytoplasmic membrane and cytoplasm of proliferate bile ducts and in cytoplasm of hepatocytes located in all lobular regions (-200 ×); **D**: strong positive staining in cytoplasmic membrane and cytoplasm of proliferate bile ducts and in cytoplasm of hepatocytes located in all acinar zones (-100 ×); **E**: strong positive staining in periportal duct cells (-100x); and **F**: granular pattern of positivity in cytoplasm of hepatocytes in all lobular regions (-400 ×).

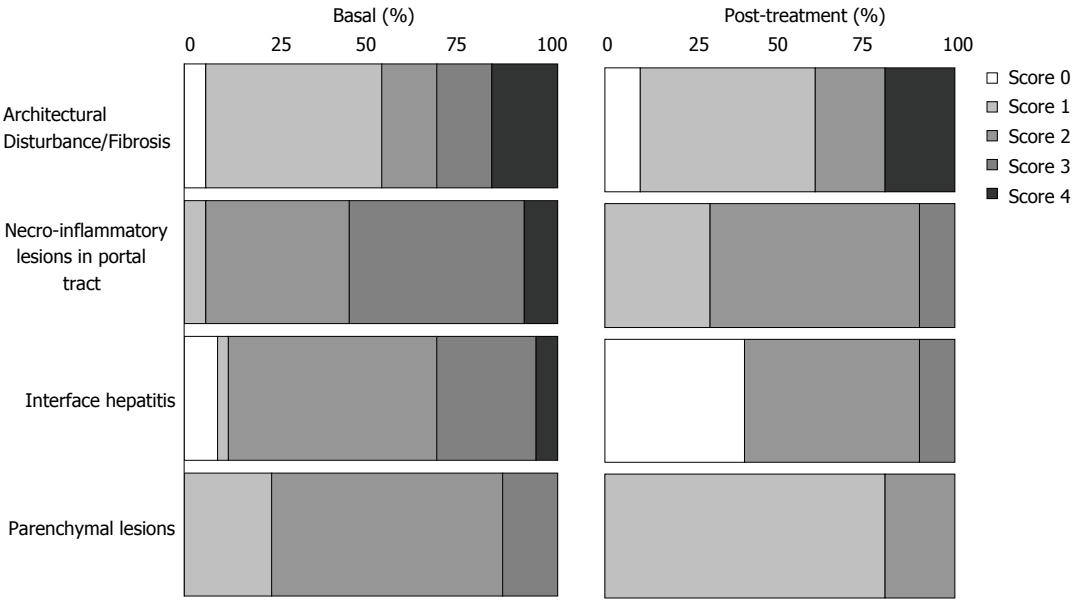

Figure 3 Percentage of score distribution obtained by histological analyses in liver biopsies from pre- (34 cases) and post-treatment (10 cases, 5 sustained virological responders and 5 non-responders) according to Brazilian Consensus on Chronic Hepatitis[21].

hepatocytes was observed in 15% (5/34) samples of CHC before treatment.

Among the patients with fibrosis of degree 0, 1 and 2, 13% (3/23) did not show positivity in hepatocytes, 70% (16/23) showed weak staining and 17% (4/23) showed intense staining. Within the group with fibrosis of degree 3 and 4, 9% (1/11) did not show any staining, 55% (6/11) showed weak staining and 36% (4/11) showed intense staining. In some cases, especially in cirrhotic livers, a granular pattern of positivity in hepatocytes cytoplasm from all lobular regions was visualized (Figure 2F).

All of the pre-treatment samples (34/34) showed IGF-IR positivity in bile ducts, with strong positivity (degree 2) in 91% (31/34) of the positive cases. Twenty-eight of 34 (82%) samples showed IGF-IR positivity in periportal duct cells (canals of Hering), with weak positivity (degree 1) in 25 of 28 samples and strong positivity (degree 2) in 3 of 28 samples.

Only 50% (17/34) and 15% (5/34) of the samples showed positivity in portal lymphocytes and Kupffer cells, respectively, with a weak (degree 1) positivity pattern. No staining in lobular lymphocytes and in endothelial cells was observed.

Histopathological and immunohistochemical variables

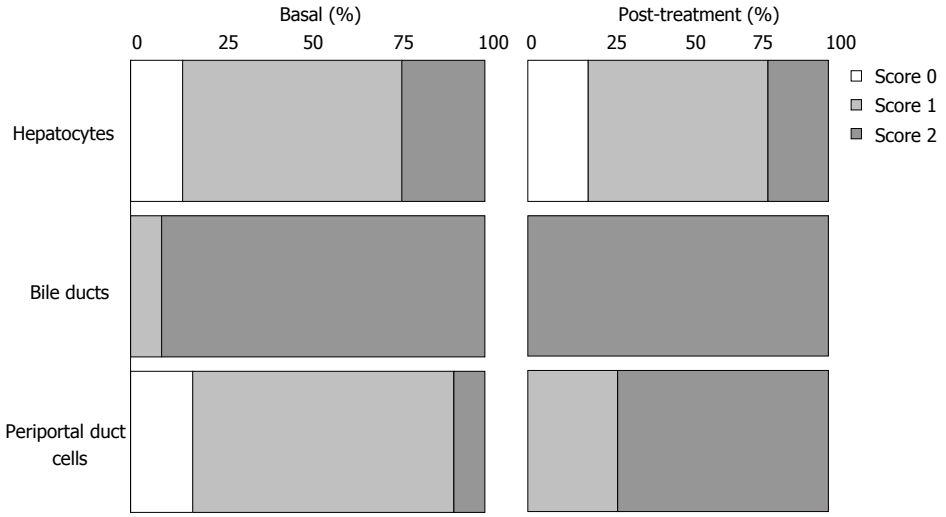

Figure 4 Percentage of score distribution obtained by IGF-IR immunohistochemical analyses in liver biopsies from pre- (34 cases) and post-treatment (10 cases, 5 sustained virological responders and 5 non-responders).

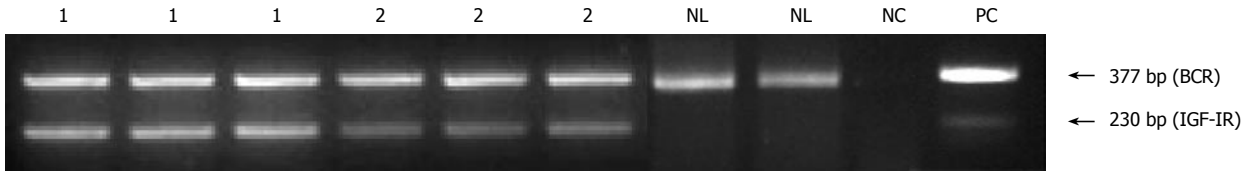

Figure 5 Semi-quantitative RT-PCR analysis of IGF-IR mRNA in hepatic fragments obtained from 2 patients with chronic hepatitis C (lanes 1 and 2) and normal human liver (NL). The experiments for the patients with CHC were carried out in triplicates and for normal human liver (NL) in duplicates. Human placenta was used as a positive control (PC) and no DNA template as negative control (NC).

did not show any statistically significant correlation. There were no statistically significant differences on IGF-IR immunohistochemical pattern in hepatic tissues from patients with and without sustained virological response between pre- and post-treatment periods (Figure 4).

mRNA expression of IGF-IR and IGF-I

An increased IGF-IR mRNA content was detected in hepatic tissue of all 34 patients with CHC before treatment as compared with normal liver (Clontech Laboratories) which did not express IGF-IR mRNA (Figure 5). There were no relevant modifications in IGF-I mRNA content in hepatic tissue from patients with CHC as compared with normal liver, however, since there was only one sample of normal hepatic tissue, it was not possible to perform a statistical evaluation (data not shown).

IGF-IR and IGF-I mRNA contents were evaluated in hepatic tissue obtained within one month of the end of treatment in ten patients. There was a statistically significant decrease ($P = 0.05$) in mean IGF-IR mRNA content in hepatic tissues from patients who achieved sustained virological response in comparison to non-responders (Figure 6), while there was no statistically significant difference in IGF-I mRNA content in hepatic tissues from patients with and without sustained virological response between pre- and post-treatment periods (Figure 7). Furthermore, no statistically significant correlations were observed between IGF-IR and IGF-I mRNA contents and histopathological or immunohistochemical variables.

In an attempt to better characterize the expression pattern of these two genes in normal hepatic tissues, IGF-IR and IGF-I mRNA contents were evaluated in hepatic fragments from six cadaveric liver donors (8-12 h of cold ischemia) following orthopic transplantation. Interestingly, despite being considered as normal livers by histopathological examination, all samples presented an increased IGF-IR mRNA content (Figure 8), regardless the degree of ischemia-reperfusion injury, which ranged from 1 to 3, accordingly to Gayotto & Leitão classification[23]. In addition, there were no relevant modifications in IGF-I mRNA content in hepatic tissue from liver donors following orthopic transplantation in comparison to normal liver (data not shown).

DISCUSSION

Although almost all tissues and cells express IGF-IR during embryogenesis, in the normal adult liver, IGF-IR mRNA is practically undetectable[5] and very low IGF-I binding has been shown in cultured hepatocytes[8], possibly due to IGF-IR down-regulation by the locally produced IGF-I. However, hepatic non-parenchymal cells, such as Kupffer cells, endothelial cells and HSC, express IGF-IR and are susceptible to their mitogenic effects[11,24,25].

In the current investigation, we demonstrated an increase of IGF-IR mRNA content in hepatic tissue from patients with different CHC staging. The immunohistochemical findings suggested this augmented mRNA content might be secondary to ductular proliferation, since these epithelial cells expressed IGF-IR, and to increased IGF-IR expression in hepatocytes. Although IGF-IR im-

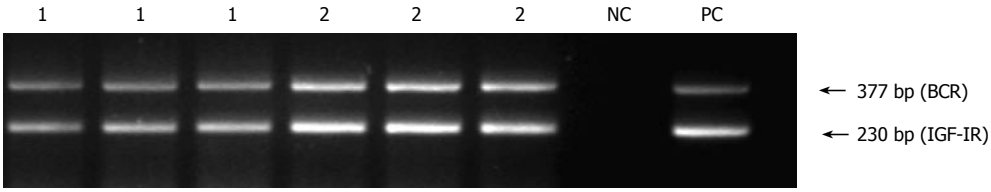

Figure 8 Preservation-reperfusion injury: Representative results of semi- quantitative RT-PCR analysis of IGF-IR mRNA in 2 hepatic fragments from cadaveric liver donor following orthopic transplantation (lanes 1 and 2). The experiment was carried out in triplicates. Human placenta was used as a positive control (PC) and no DNA template as negative control (NC).

munoreactivity was low in Kupffer cells and in portal lymphocytes, we could not rule out that the expression of this receptor in these cell types has also contributed to increase the level of IGF-IR mRNA observed in all cases.

The proliferative response to several types of liver injury in human liver is characterized by an increase in bile duct–like structures, termed "ductular reaction"[26,27]. Ductular reaction located at the limiting plate takes place in hepatitis C[28], where a significant correlation between the extent of ductular proliferation and the severity of inflammation was observed[29]. Eleazar *et al*[30] have also demonstrated a positive correlation between ductular reaction and disease activity in chronic hepatitis, including CHC. Although in the current study, immunohistochemical staining for specific epithelial cell markers such as cytokeratin 19 has not been performed, IGF-IR immunostaining and H&E analysis have clearly shown ductular reaction. Previous findings showing an increase in the number of cells that originate newly proliferated ductal cells, the hepatic progenitor cells ("oval cells"), as hepatitis C severity progresses[31] as well as the recent report of a strong correlation between portal fibrosis and periportal ductular reaction with progenitor cells expansion in CHC[32] illustrate the need for further studies addressing the mechanisms underlying progenitor cells activation and liver remodelling in CHC.

The up-regulation of IGF-IR expression in hepatocytes of patients with CHC could constitute an attempt to stimulate hepatocyte regeneration in response to liver damage. The role of IGF-IR in liver regeneration following subtotal hepatectomy has been demonstrated in animal models. Caro *et al*[8] showed a significant increase in IGF-I binding in freshly isolated hepatocytes from regenerating adult rat liver. In addition, Santos *et al*[33] demonstrated both a transient increase in IGF-I binding to liver membranes and an increase on IGF-IR mRNA concentrations. Up-regulation of IGF-IR as well as IGF-I was also observed in hepatocytes of rats chronically treated with carbon tetrachloride (CCl_4) and immunoreactivity increased proportionally to fibrosis development, which might be a compensatory reaction to the continuous loss of hepatocytes[34]. However, the role of IGF-I system in the injured liver has not been completely understood. While experiments in cultured HSC support the participation of IGF-I in HSC transformation toward a fibrogenic phenotype, promoting HSC proliferation[25,35] and collagen synthesis[11], targeted over-expression of IGF-I in activated HSCs attenuates fibrogenesis and accelerates liver regeneration after acute CCl_4-induced injury. These effects appear to be mediated in part by up-regulation of HGF and down-regulation of TGF-β1, suggesting that IGF-I can modulate the cytokine response to liver injury, facilitating regeneration and reducing fibrosis[36]. Based on our finding of increased IGF-IR expression even after an acute challenge such as ischemia-reperfusion injury, we question if a direct effect of HSC-derived IGF-I on hepatocytes expressing IGF-IR might contribute to the accelerated hepatic regeneration observed in this model. Additionally, Desbois-Mouthon *et al*[37] have recently reported that hepatocyte proliferation

during liver regeneration is impaired in liver-specific IGF-IR knockout mice as evidence that IGF-IR contributes to liver regeneration.

In the liver, it has been shown that ischemia-reperfusion injury occurs as biphasic pattern, with an initial acute phase characterized by hepatocellular damage at 3-6 h and a sub-acute phase characterized by massive neutrophil infiltration at 18-24 h[38]. The ischemia-reperfusion injury also induces the activation of intracellular pathways clearly involved in the hepatocellular regenerative response[39], such as expression of tumor necrosis factor α (TNF-α)[40,41] and IL-6-associated signalling pathways[42], in an attempt to replace cells lost to ischemic and immunologic damage[43]. To our knowledge, augmented IGF-IR expression has never been reported in animal or human livers submitted to ischemia-reperfusion injury, while it was described in a murine model of renal ischemia-reperfusion injury[44]. Considering that liver is the organ with the highest levels of IGF-I expression, our finding of increased IGF-IR expression in an acute model of hepatic damage such as ischemia-reperfusion injury as well as in the condition of chronic hepatitis C highlights the need for additional studies to elucidate the role of IGF-I in the complex events of liver regeneration.

Regarding IGF-IR expression in the post-treatment period, although few patients were available for this analysis, the decrease in IGF-IR mRNA content observed in the patients who achieved sustained virological response suggests an improvement in hepatic injury without returning to the expression pattern observed in normal liver, which exhibits undetectable levels of IGF-IR mRNA. We hypothesized that the change on IGF-IR mRNA content in the absence of modifications on the immunostaining pattern, as well as the positivity of IGF-IR mRNA in all studied samples even in the absence of IGF-IR immunostaining may be explained by the higher sensibility of RT-PCR in comparison to immunohistochemical analysis. It remains to be clarified if, as observed for histopathological changes, longer periods following sustained virological response are require for detecting additional reduction in IGF-IR mRNA content.

Because of the important role of the IGF system in mediating not only normal growth and tissue repair but also carcinogenesis, the expression and function of all components of this system must be strictly controlled. Although we speculate that up-regulation of IGF-IR might participate in hepatocyte regeneration, the suggestion that HCV replication might mediate expression of the IGF-IR ligand IGF-Ⅱ in cirrhotic livers[45] rise concerns that these two simultaneous changes could act as possible factors for HCV-associated hepatocarcinogenesis in cases of advanced hepatic lesion, since an autocrine and/or paracrine activation of the IGF-Ⅱ/IGF-IR axis has been implicated in the development of HCC[46]. This hypothesis is corroborated by the finding that hepatitis B virus (HBV) X protein (HBx), which participates in the process of HBV-associated liver carcinogenesis, activates the IGF-IR gene expression[47,48]. It remains to be elucidated if a direct activation of IGF-IR gene by HCV could contribute to the increased IGF-IR expression in hepatocytes in CHC.

Abstract

AIM: To assess the defensive nature of *Sargassum polycystum* (*S. polycystum*) (Brown alga) against acetaminophen (AAP)-induced changes in drug metabolizing microsomal enzyme system, tumor necrosis factor (TNF-α) and fine structural features of the liver during toxic hepatitis in rats.

METHODS: Male albino Wistar strain rats used for the study were randomly categorized into 4 groups. Group I consisted of normal control rats fed with standard diet. Group II rats were administered with acetaminophen (800 mg/kg body weight, intraperitoneally). Group III rats were pre-treated with *S. polycystum* extract alone. Group IV rats were orally pre-treated with *S. polycystum* extract (200 mg/kg body weight for 21 d) prior to acetaminophen induction (800 mg/kg body weight, intraperitoneally). Serum separated and liver was excised and microsomal fraction was isolated for assaying cytochrome P450, NADPH Cyt P450 reductase and b_5. Serum TNF-α was detected using ELISA. Fine structural features of liver were examined by transmission electron microscopy.

RESULTS: Rats intoxicated with acetaminophen showed considerable impairment in the activities of drug metabolizing microsomal enzymes, such as cytochrome P450, NADPH Cyt P450 reductase and b_5 when compared with the control rats. The rats intoxicated with acetaminophen also significantly triggered serum TNF-α when compared with the control rats. These severe alterations in the drug metabolizing enzymes were appreciably prevented in the rats pretreated with *S. polycystum*. The rats pretreated with *S. polycystum* showed considerable inhibition in the elevation of TNF-α compared to the rats intoxicated with acetaminophen. The electron microscopic observation showed considerable loss of structural integrity of the endoplasmic reticulum, lipid infiltration and ballooning of mitochondria in the acetaminophen-intoxicated rats, whereas the rats treated with *S. polycystum* showed considerable protection against acetaminophen-induced alterations in structural integrity.

CONCLUSION: These observations suggest that the animals treated with *S. polycystum* extract may have the ability to protect the drug metabolizing enzyme system and mitochondrial functional status from free radical attack, thereby showing its defense mechanism in protecting hepatic cells from acetaminophen toxic metabolite N-acetyl-para-benzoquinone-imine (NAPQI).

INTRODUCTION

Our modern lifestyle has drastically changed the chemistry of the environment in which we live. There is ample documentation of increased toxicity in our food, air and water. In addition, chronic illnesses often are connected to the production of toxic chemicals that inflame and cause oxidative stress. Moreover, many medications are metabolized in the liver, and in effect, can function as toxins. Unfortunately, many of us promote an increase of our own toxin levels with excessive alcohol intake, smoking and over counter drug use[1]. Drug detoxification is an important function of the liver. It is a complex

process that occurs in the endoplasmic reticulum of the hepatocyte, which involves several phases. Its main role in detoxification involves neutralizing harmful compounds, such as drugs, pesticides, hormones and bacterial toxins from the intestines.

The seaweeds are considered the most nutritious plants on earth. Their nutritive values greatly exceed those found in other food sources that humans can readily utilize. From the time immemorial the macroscopic marine algae have been closely associated with human life and are being commonly used in numerous ways as a source of food/feed and medicine. In folk medicine, seaweeds have been used for a variety of remedial purposes, such as in eczema, gallstone, renal trouble, scabies, psoriasis, asthma, arteriosclerosis, heart disease, ulcers and cancer. The cell walls of marine algae characteristically contain polysaccharides, which are not found in land plants and which may have specific functions in ionic regulation and wide spectrum of pharmacological importance. Sulphated polysaccharide (e.g. fucoidan) is structurally unique that is found only in the cell walls of several types of brown seaweed. Brown algae substantially differ from algae of other divisions and terrestrial plants in their composition[2,3]. A perusal of literature study has shown that the brown algae contain essential minerals, vitamins, free amino acids, mannitol, glucitols, sulphated polysaccharides and phlorotannins. These compounds in brown algae are found to have wide spectrum of biological properties[4-7].

Based on the previous studies regarding free radical scavenging property of *Sargassum polycystum* (*S. polycystum*) extract against acetaminophen-induced toxic hepatitis in rats, the present study was attempted to assess the defensive nature of *S. polycystum* (Brown alga) extract against acetaminophen-induced alterations in drug metabolizing microsomal enzyme system, TNF-α during toxic hepatitis and cellular structural integrity during toxic hepatitis.

MATERIALS AND METHODS

Sample collection and extraction

S. polycystum was collected from Gulf of Mannar, Rameswaram, India. The species authentication was done by Prof. V. Krishnamurthy (Krishnamurthy Institute of Algology, Chennai, India). The seaweed sample was washed in seawater and then fresh water to remove the epiphytes and other contamination. The coarsely powdered seaweed material was extracted with ethanol in cold for a period of 72 h with occasional shaking. The crude extract was filtered, concentrated on a water bath, and then dried in vacuum. The resulting dried powder was used for the animal experimentation. The extract was subjected to thin layer chromatography (TLC) and phytochemical analysis, which showed positive result for the presence of terpenoids and flavonoids[8].

Animals

Male Wistar strain albino rats, weighing about 100-130, were procured from Fredrick Institute for Plant Protection and Toxicology, Padappai, Chennai, India. The animals were housed in cages under proper environmental conditions and fed with a commercial pelleted diet (M/s Hindustan Foods Ltd, Bangalore, India). The animals had free access to water throughout the experimental period.

Experimental protocol

The experimental animals were divided into four groups, each group comprising six animals. Group I consisted of normal control rats fed with standard diet. Group II rats were intoxicated with acetaminophen (800 mg/kg body weight, intraperitoneally in saline solution in a boiling water bath and used after cooling at 37℃). Group III rats were orally pre-treated with *S. polycystum* extract alone (200 mg/kg body weight for 21 d). Group IV rats were orally pre-treated with *S. polycystum* extract (200 mg/kg body weight for 21 d) prior to acetaminophen induction (800 mg/kg body weight, intraperitoneally).

At the end of the experimental period the animals were deprived of standard diet for 20 h and then anesthetized with diethyl ether, followed by cervical decapitation. Blood collected without anticoagulant for serum. The liver was excised and immersed in ice-cold 0.01 mol/L tris (hydroxymethyl) aminomethane (Tris)-1.15 mol/L KCL buffer (pH 7.4). After rinsing twice in buffer, the liver was weighed and homogenized with a Teflon potter-Elvehjem homogenizer in ice-cold measured volumes of Tris-KCL buffer. The homogenate was then centrifuged at 9000 g for 15 min at 0℃. The microsomal pellet was then layered with 1 mL of Tris-KCl buffer and recentrifuged for an hour at 105 000 g at 0℃.

Microsomal enzyme profile

The microsomal pellets were layered and stored frozen prior to performing enzyme assays. Cytochrome p450 and b_5 assay was performed as previously described by Omura and Sato[9]. NADPH-cytochrome p450 reductase assay performed as previously described by Phillips and Langdon[10].

Tumor necrosis factor-α (TNF-α)

One hundred microgram of the protein sample in carbonate buffer (pH 9.4) was coated on the 96-well polyvinyl chloride ELISA plates and kept overnight at 4℃. The coated wells were washed twice with phosphate-buffered saline (pH 7.4) containing 0.5 mL/L Tween 20, blocked with 10 g/L bovine serum albumin (BSA) in phosphate-buffered saline (100 μL/well) and incubated at 37℃ for 1 h. The coated wells were washed thrice with phosphate-buffered saline containing 0.5 mL/L Tween 20. Then 50 μL of anti-TNF-α was added and incubated at 37℃ for 1 h or overnight at 4℃. After incubation, the ELISA plates were washed as above and 50 μL of anti-mouse goat anti-rabbit-IgG-HRP (1:5000) diluted with phosphate-buffered saline was added and incubated for 1 h. The wells were washed with PBS-Tween 20 thrice and with PBS thrice. Fifty microliter of substrate solution (1 μL of H_2O_2, 0.5 mg OPD in 1 mL citrate-phosphate buffer, pH 5.0) was added. Fifty microliter of 1.5 mol/L H_2SO_4 was added after 30 min to stop the reaction. The intensity of the color was recorded on an ELISA reader at 490 nm[11].

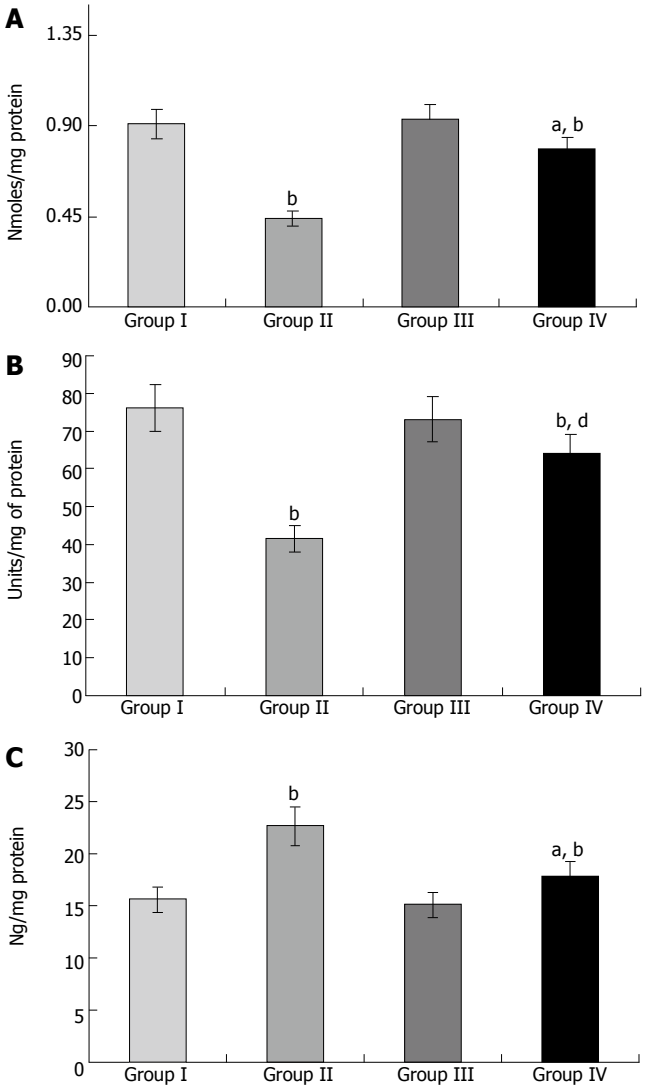

Figure 1 Various effects of *S. polycystum* against acetaminophen-induced toxic hepatitis in rats. **A**: Effect of *S. polycystum* on cytochrome P450 during acetaminophen-induced toxic hepatitis; **B**: Efficacy of *S. polycystum* on cytochrome b_5 against acetaminophen-induced toxic hepatitis; **C**: Effect of *S. polycystum* on the status of microsomal cytochrome P450 reductase. Values are expressed as mean ± SD for six rats. $^{b}P < 0.01$ *vs* group I, $^{d}P < 0.001$ *vs* group II, $^{a}P < 0.05$ *vs* group I.

Transmission electron microscopy

A portion of the liver tissue was instantaneously immersed in 25 g/L of glutaraldehyde solution, buffered with 0.1 mol/L sodium cacodylate (pH 7.4). The specimen was then placed in the buffer fixative medium, followed by washing with sodium cacodylate and fixation in 20 g/L osmium tetroxide buffered with 0.1 mol/L sodium cacodylate. After dehydration in a graded series of alcohol and propylene oxide, the tissues were transferred to the propylene oxide: ethanol mixture (1:1) and embedded in resin. The specimens were mounted on epoxy resin blocks and left in the oven at 65℃ for 72 h. Thin sections were cut with an ultramicrotome, stained with uranyl acetate and lead citrate, and then examined under an EM-9A electron microscope.

Statistical analysis

Values were expressed as mean ± SD for six rats in each group and significance of the differences between mean values were determined by one-way analysis of variance (ANOVA), followed by the Duncan test for multiple comparison. A *P* value less than 0.05 was considered statistically significant.

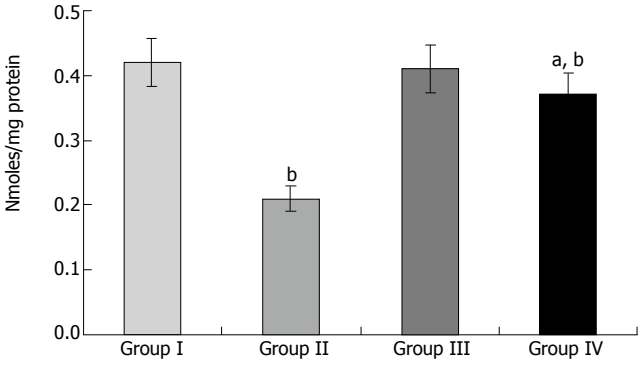

Figure 2 Effect of *S. polycystum* on TNF-α in serum of control and experimental group of rats. Values are expressed as mean ± SD for six rats. $^{a}P < 0.05$ *vs* group I, $^{b}P < 0.01$ *vs* group I, $^{d}P < 0.001$ *vs* group II.

RESULTS

Effect of S. polycystum on microsomal enzymes and TNF-α

Figure 1 shows the activities of microsomal enzymes in the control and experimental group of rats. The group II rats intoxicated with acetaminophen showed considerable impairment in the activities of drug metabolizing microsomal enzymes, such as cytochrome P450, NADPH Cyt P450 reductase and b_5 when compared with group I control rats. Figure 2 shows the serum TNF-α of control and experimental rats. The group II rats intoxicated with acetaminophen also significantly triggered serum TNF-α when compared with group I control rats. However, these severe alterations in the drug metabolizing enzymes were appreciably prevented in group IV rats pretreated with *S. polycystum* when compared with group II intoxicated rats. A considerable inhibition in the elevation of TNF-α was observed in the rats pretreated with *S. polycystum* compared to group II rats intoxicated with acetaminophen.

Effect of S. polycystum on liver cell structural integrity

Figure 3A shows the hepatic transmission electron microscope of the control rat liver. Figure 3B, Figure 3C and Figure 3D show acetaminophen-induced alterations in the structural integrity and lipid membrane of group II rats when compared with group I control animals. Group IV rats pretreated with S. polycystum showed considerable protection against acetaminophen-induced alterations in structural integrity when compared with toxicant group (Figure 3E, Figure 3F, Figure 3G, Figure 3H).

DISCUSSION

Puntarulo and Cederbaum[12] have found a close parallelism between formation of malondialdehyde and loss of microsomal enzyme activities. Cyt P450 and NADPH cytochrome P450 reductase are not rapidly

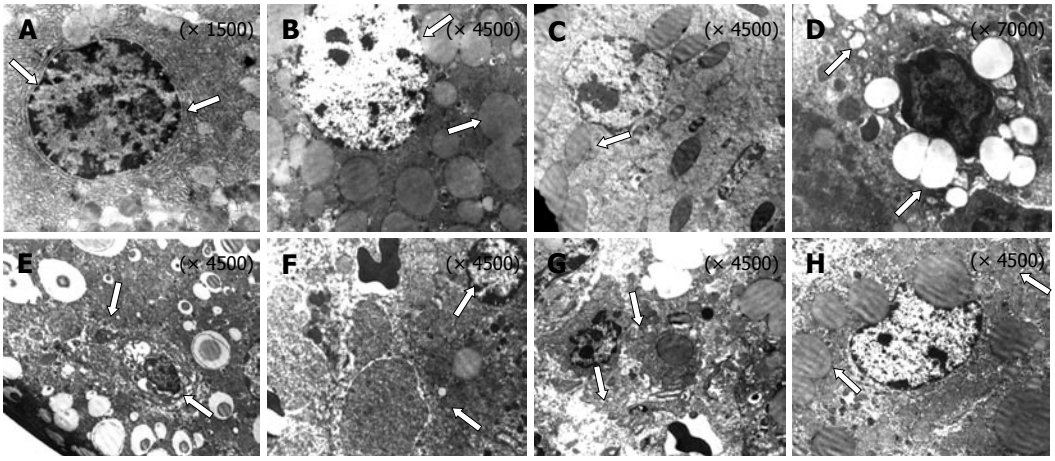

Figure 3 Structural features of liver examined by transmission electron microscopy. **A**: Normal cellular structure of rat liver without any destruction; **B**, **C** and **D**: Effect of acetaminophen on fine ultrastructural changes during toxic hepatitis in rats; **E**, **F**, **G** and **H**: Effect of *S. polycystum* against acetaminophen-induced alterations in structural integrity during toxic hepatitis.

organized in the microsomal membrane and they possess lateral mobility, which largely depends on fluidity of the membrane[13]. Peroxidation of membrane lipids has been shown to repress the membrane fluidity[14]. Therefore, the observed impairment in the activities of xenobiotic metabolizing enzymes in acetaminophen-intoxicated rats could account for the alteration in membrane fluidity.

In the liver, exogenous and endogenous compounds are metabolized by the cytochrome P450-dependent monoxygenase system. The enzymes involved in this process are located in the endoplasmic reticulum of the liver, and their activities are dependent on many environmental factors[15,16]. When considering biotransformation processes, it is important to analyze them together with other cellular processes taking place in the hepatocyte. Impairment of these processes may disturb cellular nutritional status, thus affecting the detoxication reactions[17-19]. This enzyme system, therefore, provides our primary defense against xenobiotics and is a major determinant in the therapeutic efficacy of pharmacological agents[20].

The catalytic cycle of cytochrome P450 (Cyt p450) is complex and involves two single electron transfer process. Electrons are relayed from NADPH to Cyt P450 via the flavoprotein called NADPH Cyt P450 reductase[21]. Cyt b_5 is a small hemoprotein that influences the rate of some Cyt P450 catalyzed reactions[22]. The altered levels of Cyt P450 and Cyt b_5 during acetaminophen administration have also been attributed to the increase in the degradation of heme by acetaminophen-induced heme oxygenase activity. Acetaminophen also affects thiol groups in cytochrome apoproteins and thus prevents heme incorporation[23]. The activity of NADPH Cyt P450 reductase depends upon the concentration of its substrate Cyt P450. Low availability of Cyt P450 might have been responsible for the reduction in the activity of NADPH Cyt P450 reductase. It has also been suggested that, once exposed acutely to xenobiotics such as acetaminophen, hepatic cytochrome P450 can undergo oxidative destruction through its active intermediates and can induce carbon monoxide (CO) overproduction mediated by hemeoxygenase 2 (HO-2), even when the inducible enzyme is not over-expressed[24,25].

The rats pretreated with *S. polycystum* extract showed appreciable prevention in the acute impairment of microsomal enzyme activities when compared with acetaminophen-intoxicated rats. Thus, it is evident in this study that near normal activity of NADPH Cyt P450 reductase indirectly lends support to the hypothesis that NADPH Cyt P450 reductase may be the locus within the cytochrome P450 electron transport chain, which is most susceptible to peroxidative attack by free radicals[26]. A hypothesis states that bioactive compounds that are able to optimize the microsomal enzyme function can provide protection against the hepatotoxicity only when they are given before the metabolic activation of the hepatotoxin and fail to afford any protection after the generation of reactive metabolites[27]. These observations contemplate that the seaweed extract probably acted against acetaminophen-induced microsomal lipid peroxidation triggered during toxic hepatitis.

Covalent protein modification, and free radical damage due to acetaminophen metabolism have been identified as pathways leading to hepatocyte damage; however, evidence has also been published that TNF-α may participate in the processes causing liver failure, because the administration of anti-TNF-α antibodies to acetaminophen-treated animals ameliorated the enzyme leakage during the early phase of the intoxication[28,29].

Overdoses of acetaminophen depleted glutathione stores, leading to accumulation of NAPQI, mitochondrial dysfunction[30] and the development of acute hepatic necrosis. The depletion of glutathione enhances the expression of TNF-α[31]. TNFQ primes phagocytic NADPH oxidase to the enhanced production of oxygen-free radicals and contributes to liver damage[32]. Acetaminophen caused a moderate sinusoidal perfusion failure (-15%) and infiltration of neutrophils along with activation of nuclear factor-kappaB (NF-κB) and intercellular adhesion molecule-1 and cytokine-induced neutrophil chemoattractant-1 mRNAs.

Reactive oxygen species (ROS) activate NF-κB by releasing the inhibitory subunit from NF-κB complex[33]. Increase in the production of ROS during acetaminophen metabolism leads to activation of NF-κB and increase in the synthesis of TNF-α. The animals pretreated with *S. polycystum* extract showed considerable inhibition in the elevation of TNF-α, which may be attributed to the inhibition of excessive reactive metabolite by their

antioxidant nature.

The electron microscopic observation demonstrated the contribution of multiple factors toward the development of toxic hepatitis, and showed the damage in nuclear membrane with swelling of mitochondria in acetaminophen-intoxicated rats. The increase in lipid peroxides observed in microsomal membrane might be viewed as an additional index of alteration of membrane permeability, suggesting that oxidative modifications of unsaturated lipids are also detectable *in vivo* after AAP administration. The respiratory enzyme NADH dehydrogenase is located in the mitochondrial membrane[34]. NAPQI, the toxic metabolite of acetaminophen, arylates and oxidizes essential protein sulfhydryls in the mitochondrial respiratory chain, thereby limiting the ability of the mitochondria to meet the energy demand of the cell and affecting cellular energy homeostasis[35], which is consistent with our electron microscopic observation which depicts remarkable morphological alterations of mitochondria. The appearance of lipid droplets and sinusoids, concurrent with the evolution of hepatic necrosis in acetaminophen-induced rats, represents the adaptive response to the disturbance of phospholipid metabolism induced by potentially toxic stimuli. In addition, the acetaminophen-induced secondary lipidosis as reflected by the accentuated lamellated dense bodies is likely to result from the binding of the toxic metabolite with membrane phospholipids. The exact mechanism of the aforementioned relationship is still elusive. The rats pretreated with *S. polycsytum* considerably prevented the alterations in liver cell structural integrity triggered by acetaminophen, thereby showing that the extract contain bioactive compounds which may have a role in modulating the mitochondrial functional status and lipid metabolizing enzymes[36,37]

In conclusion, the defensive action of the seaweed extract may be due to their anti-hepatotoxic and antioxidant property against the acetaminophen-induced severe impairment in the drug metabolizing microsomal enzyme system and inhibitory action on TNF-α. The extract also possesses promising protection against acetaminophen-induced alterations in liver cell structural integrity during toxic hepatitis. Even though the extract possesses a promising preventive mode of efficacy against acetaminophen toxicity, the mechanism of its action is still elusive. Presently, we have isolated 8 fractions from the *S. polycystum* extract and their structural identification using nuclear magnetic resonance (NMR) and high performance liquid chromatography (HPLC), and the mechanism of action in liver protection is under way.

Abstract

AIM: To investigate the effects of experimental partial hepatectomy and normothermic ischemia-reperfusion damage on the time course of the expression of four different growth factor receptors in liver regeneration. This is relevant due to the potential therapeutic use of growth factors in stimulating liver regeneration.

METHODS: For partial hepatectomy (PH) 80% of the liver mass was resected in Sprague Dawley rats. Ischemia and reperfusion (I/R) were induced by occlusion of the portal vein and the hepatic artery for 15 min. The epidermal growth factor receptor, hepatic growth factor receptor, fibroblast growth factor receptor and tumour necrosis factor receptor-1 were analysed by immunohistochemistry up to 72 h after injury. Quantitative RT-PCR was performed at the time point of minimal receptor expression (24 h).

RESULTS: In immunohistochemistry, EGFR, HGFR, FGFR and TNFR1 showed biphasic kinetics after partial hepatectomy with a peak up to 12 h, a nadir after 24 h and another weak increase up to 72 h. During liver regeneration, after ischemia and reperfusion, the receptor expression was lower; the nadir at 24 h after reperfusion was the same. To evaluate whether this nadir was caused by a lack of mRNA transcription, or due to a posttranslational regulation, RT-PCR was performed at 24 h and compared to resting liver. In every probe there was specific mRNA for the receptors. EGFR, FGFR and TNFR1 mRNA expression was equal or lower than in resting liver, HGFR expression after I/R was stronger than in the control.

CONCLUSION: At least partially due to a post-transcriptional process, there is a nadir in the expression of the analysed receptors 24 h after liver injury. Therefore, a therapeutic use of growth factors to stimulate liver regeneration 24 h after the damage might be not successful.

INTRODUCTION

Cytokines, hormones and growth factors are known to be involved in the liver's regeneration. Until now, therapeutic use of growth factors, or anything else capable of stimulating regeneration *in vivo,* has not been successful[1]. Since not only ligands like cytokines, hormones and growth factors but also receptors could limit the influence of these factors, the aim of our research was the kinetics of growth factor receptors in liver regeneration. Epidermal growth factor receptors (EGFR) and hepatocyte growth factor receptors /c-Met (HGFR) are activated immediately after partial hepatectomy (PH)[2,3]. Research with c-met knockout mice demonstrates impaired liver regeneration after PH or toxic injury[4,5]. However, it seems that other signal transduction pathways could compensate for the lack of HGFR and induce liver growth. Furthermore, impaired liver regeneration in complicated situations seems to be more the consequence of alterations of the receptor site of the signalling pathway rather than a result of a decreased amount of ligands. In a model of fulminant hepatic failure due to a combination of PH and right liver lobe necrosis, Mizuguchi *et al*[6] found lower c-met expression compared to PH alone, but elevated levels of cytokines. The same is true after hepatectomy in rats with CCL(4)-induced cirrhosis[7,8]. HGF over-expression when c-Met is not altered leads to tumour formation in transgenic mice but could not promote liver regeneration[8]. From these references we hypothesised, that growth factor receptors, more than their ligands, are limiting in liver

regeneration and therefore, it is more reasonable to look for the expression of the receptors.

There are several growth factor receptors, other than HGFR/c-Met, like EGFR, fibroblast growth factor receptor (FGFR) and tumour necrosis factor alpha receptor 1 (TNFR1) involved in liver regeneration about which, even less is known.As we know from recent experiments with transgenic animals, these receptors are required in liver regeneration[9,10]. Their kinetics during liver regeneration were unknown until now. Therefore, we analysed the kinetics of EGFR, HGFR, FGFR and TNFR1 in two models of liver regeneration: PH and reperfusion after warm 15 min ischemia (I/R).

MATERIALS AND METHODS

Models

The experiments were performed in male Sprague-Dawley rats weighing 350-500 g (Charles River, Sulzfeld, Germany) in accordance with the local regulation for animal experiments. All procedures were performed under isoflurane (Abbott, Wiesbaden, Germany) inhalation anaesthesia 2.5%-4%.

Partial hepatectomy (PH) was conducted after midline laparotomy. About 80% of the liver mass was resected, following ligation with a 3-0 polyglycolic acid ligature (Dexon,Braun, Melsungen, Germany). Then, the incision was closed by using a continuous two-layer suture technique.

Ischemia and reperfusion (I/R) were induced after midline laparotomy, by occlusion of the portal vein and the hepatic artery near the liver, by a vessel loop (Ethicon, Norderstedt, Germany). Care was taken not to occlude the bile duct. After 15 min, the loop was removed and the incision closed.

In each of the two models, regeneration after the injury was analysed at the following time points 0 h, 5 h, 2 h, 6 h, 12 h, 24 h, and 72 h. Each group consisted of five animals.

After regeneration, euthanasia was performed under general anaesthesia by blood collection and hepatectomy.

Immunohistochemistry

Receptors were identified by immunohistochemistry using 4 μm paraffin sections cleared with Rotihistol (Roth, Karlsruhe, Germany), passed through a graduated series of alcohol, and incubated for 5 min in room temperature water to rehydrate. Antigen retrieval for EGFR was accomplished using a microwave at 750 watts in target retrieval solution (pH 9.9) (vectastain, vectorlab, Burlingame, USA) and for TNFR1, HGFR, FGFR by incubation in 0.05% proteinase K for 15 min. Endogenous peroxidase activity was halted using 3% peroxide in methanol for 30 min, followed by endogenous biotin bound to avidine for 10 min and finally, in biotin for 10 min; non-specific binding was blocked by 1% BSA (Sigma, Munich, Germany). The antibodies for staining receptors were anti-TNFR1 (H-5, Santa Cruz Biotechnology, Santa Cruz, USA), anti-EGFR (1161-1186,Calbiochem, San Diego, USA), anti-Met (B-2; Santa Cruz Biotechnology, Santa Cruz, USA), and anti-FGFR (Ab-1, Oncogene, Boston, USA). Antibodies were used at a dilution of 1:50-1:100 in PBS. Detection was performed using an avidine -biotin peroxidase system (vectastain, vectorlab, Burlingame, USA) with anti-mouse or anti-rabbit antibodies, and stained with 3-amino-9-rthyl-carbazole (Carbazol, Sigma, Munich, Germany).

Cell preparations for PCR

Zone-selective cell isolation was performed after periportal or perivenous cell damage by ante- or retrograde perfusion with digitonin as described by Lindros[11].The portal vein and vena cava superioris were canulated under anaesthesia and washed out with approx. 300 mL oxygenated buffer I (5.36 mmol/L KCl, 1.17 mmol/L $MgSO_4$, 0.79 mmol/L Na_2HPO_4, 0.15 mmol/L KH_2HPO_4, 10 mmol/L Hepes, 145 mmol/L NaCl, 0.1% glucose, and 1 mmol/L $CaCl_2$, at pH 7.4). Afterwards, the liver was perfused via the portal vein or vena cava with 4 mM digitonin in oxygenated buffer I for 1-1.5 min. In a third step, the liver was washed out with 900 mL buffer II (5.36 mmol/L KCl, 0.77 mmol/L $MgSO_4$, 0.93 mmol/L $MgCl_2$, 0.34 mmol/L Na_2HPO, 0.44 mmol/L KH_2HPO, 0.2 mmol/L EDTA, 10 mmol/L Hepes, and 145 mmol/L NaCl, at pH 7.4). Afterwards, the liver was perfused with collagenase (0.025%) in buffer III (5.36 mmol/L KCl, 0.77 mmol/L $MgSO_4$, 0.93 mmol/L $MgCl_2$, 0.34 mmol/L Na_2HPO_4, 0.44 mmol/L KH_2HPO_4, 10 mmol/L Hepes, 145 mmol/L NaCl, 0.2% glucose, 0.003% penicillin, 0.005% streptomycin, and 0.2% BSA, at pH 7.4), and one minute later, 4.3 mL of 200 mmol/L $CaCl_2$ was added.

After mincing the liver into small particles in oxygenated buffer I, the liver cell-buffer mixture was pressed through a gauze and then through a 100 μm nylon filter. The cells were washed twice with 50 mL oxygenated buffer and centrifuged at 500 rpm for 5 min at 4℃. The pellet was brought to a Percoll gradient (Percoll, Amersham Biosciences d = 1.065) and centrifuged at 500 rpm for 15 min at 20℃ . Hepatocytes were collected in the pellet and washed twice with 50 mL oxygenated buffer.

Gluminsynthetase (GS) assay

The correct discrimination between PP and PC hepatocytes was checked by performing the GS assay, as GS is located strictly pericentrally[12,13] . 250 000 hepatocytes were homogenized in oxygenated buffer I. A 100 μL sample was added to 400 μL test mix (2 × 250 mmol/L imidazole buffer, 2 × 250 mmol/L l-glutamic acid, 1 × 250 mmol/L hydroxylamine hydrochloride, 1 × 1.6 mmol/L adenosine-5-diphosphate, 1 × 250 mmol/L disodiumhydrogen arsenate, 1 × 10 mmol/L manganese chloride) and incubated 16-60 min at 37℃. The reaction was stopped by 100 μL stop-mix (2.42% iron III chloride, 1.45% trichloric acid in 5.4% HCl). The mixture was centrifuged (15 min, 3300 g) and analyzed in a photometer at 540 nm. GS activity was calculated as follows:

GS activity $= \Delta E \times V \times 1000 \times (\varepsilon \times d \times \Delta t \times v \times c)^{-1}$ U/g with E = extinction, V = 1.5 mL

$\varepsilon = 0.04395\ l^* mmol^{-1^*} mm^{-1}$, d = 10 mm , t = time, v = 0.1 mL, c = protein concentration.

PC hepatocytes were used with a GS activity above 300 U/g, PP hepatocytes were used with a GS activity below 30 U/g.

RT-PCR

RNA was isolated using the RNeasy kit (QIAGEN, Hilden, D) and quantitative PCR was performed using

Table 1 Expression of growth factor receptors in immunohistochemistry after partial hepatectomy

	Resting liver	PH						I/R					
Time (h)	0	0.5	2	6	12	24	72	0.5	2	6	12	24	72
EGFR	-	+	+[1]	++	+	-	+	-	-	-	+	-	-
FGFR	(+)	(+)	+[2]	++	++	(+)	+	(+)	(+)	-	-	-	-
HGFR	-	-	+	++	++	-	++	-	+	+	+	-	-
TNFR1	(+)	(+)	+	+	(+)	(+)	++	(+)	(+)	(+)	(+)	-	+

(PH), 15-min warm ischemia (I/R). -: negative, (+): positive but not more than in the resting liver, +: positive, ++: strong positive; [1]: mainly portal; [2]: mainly centre of the hepatic acinus.

the SYBER-Green technique (QuantiTect, QIAGEN, Hilden, D), according to the instructions given by the manufacturer. PCR was carried out by a one-step RT-PCR with the following cycle conditions: cycle 1: Temp.: 50℃ 30:00 min, cycle 2: Temp.: 95℃ for 15:00 min, cycle 3: Temp.: 94℃ for 0:15 min, cycle 4: Temp.: 52℃ for 0:30 min, cycle 5: Temp.: 72℃ for 0:30 min, cycles 3-5 were repeated 45 times. Primer design was performed by Primer 3 (primer3_www.results.cgi) with sequences from NCBI:
HGFR (NM-031517): gtcttcaagtagccaagggc and aacatgcagtttcttgcagc
FGFR (NM-024146): gaagagcgacttccatagcc and acactgttacctgtctgcgg
TNFR1 (BC 086413): ctttgagcctttctaacccg and agtaagacgatcggaccagg
EGFR (M37394): tggacaaccctcatgtatgc and acatagtccaggaggcaacc

As an internal standard, we used 18 s rRNA: cgt agt tcc cga cat aaa cg and cag ctt tgc aac cat act cc. The difference between the threshold cycle C_T of 18 s rRNA and the mRNA of interest is shown as ΔC_T. A high ΔC_T represents a low amount of specific RNA and vice versa.

Statistics

Data management and *t*-test for unpaired data were carried out using PRISM® software. In case of semi-quantitative analysis in immunohistochemistry, a statistical analysis was omitted.

Unless otherwise stated, the chemicals used were from Sigma, Munich, Germany.

RESULTS

Using immunohistochemistry, we analysed the expression of EGFR, FGFR, HGFR and TNFR1 in the resting liver (tissue not influenced by proliferative stimuli) as control, during liver regeneration after partial hepatectomy, and during reperfusion after 15-min normothermic ischemia. Receptor expression was analysed semi-quantitatively with results shown in Table 1. For exemplary immunohistochemistry see Figures 1 and 2. There is weak expression of FGFR but a strong one by TNFR1 in resting liver. Following PH, there is a strong expression of all receptors after 6 h and 12 h, and again after 72 h. Yet, there is no, or in case of FGFR and TNFR1, only weak expression of the receptors after 24 h. During regeneration after I/R, there is only a short and weak expression of EGFR, HGFR and TNFR1 in the first 12 h. TNFR is expressed strongly after 72 h again. After PH, as after I/R, there was no expression of any receptor, stronger than in the control after 24 h.

As there was a gap with no expression of any receptor, at 24 h after the liver injury, even when there was positive immunohistology at 72 h, we performed a quantitative PCR comparing the receptor mRNA in the resting liver and at 24 h. Each PCR was separately conducted for periportal and pericentral hepatocytes. As

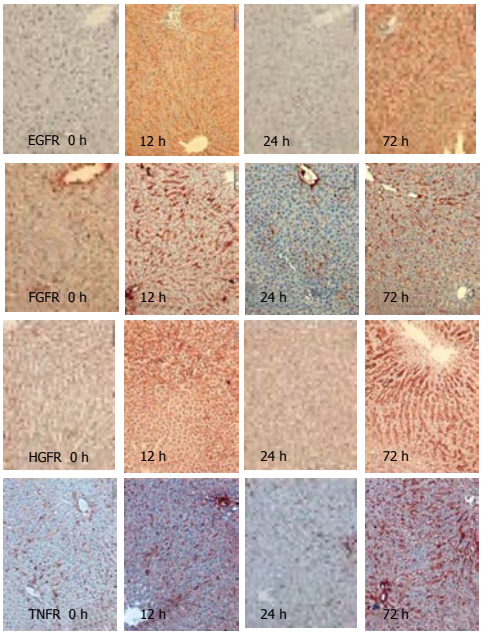

Figure 1 Sample immunohistochemistry of EGFR, FGFR, HGFR and TNFR in regenerating liver 12 h, 24 h, and 72 h after partial hepatectomy. (0 h: control).

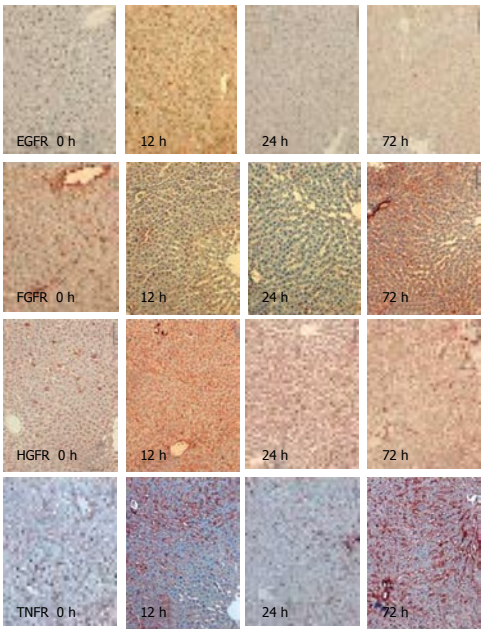

Figure 2 Sample immunohistochemistry of EGFR, FGFR, HGFR and TNFR in regenerating liver 12 h, 24 h, and 72 h after ischemia and reperfusion. (0 h: control).

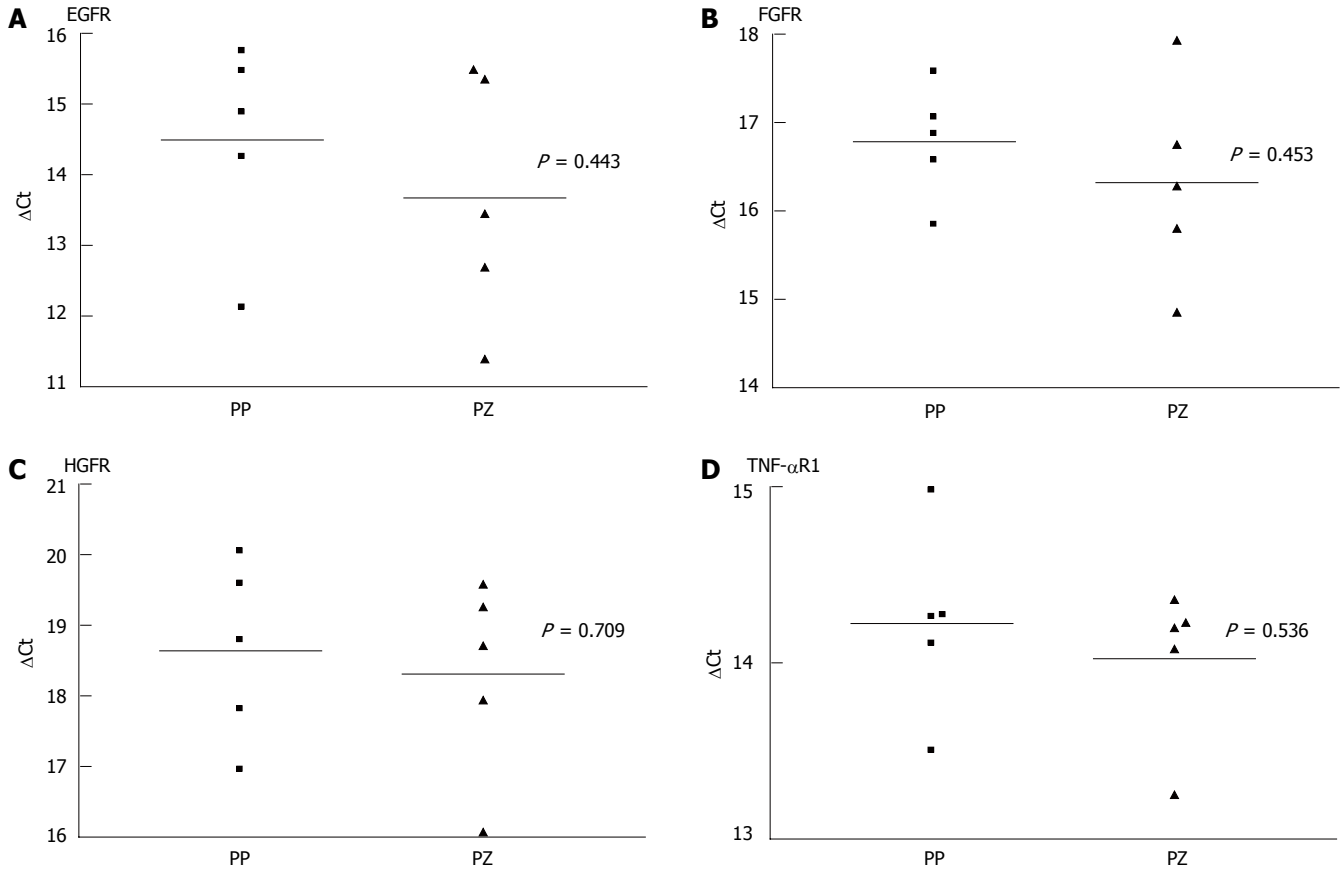

Figure 3 Results of quantitative PCR comparing receptor expression in periportal (PP) and pericentral (PC) hepatocytes in resting liver.

shown in Figures 3 and 4, there was no difference in the expression of the analysed mRNA between periportal and pericentral hepatocytes in the resting liver or in regenerating liver after PH. In I/R there was a stronger pericentral expression of receptors. In case of EGFR and TNFR1 mRNA, this difference was significant (Figure 5).

Comparing receptor mRNA between resting liver and in regenerating liver, there was a significantly reduced expression of EGFR after PH and I/R, FGFR after I/R and TNFR1 after PH, represented by a greater ΔC_T. Only HGFR was expressed more strongly 24 h after I/R than in resting liver. At every time point, there was a positive expression of receptor mRNA, even if immunohistochemically no receptor could be detected .

DISCUSSION

We analysed the expression of several growth factor receptors in two different models of liver injury and found a marked expression after 6 and 12 h with a nadir at 24 h and an increased expression after 72 h.

With no receptors to interact with, external growth factors might therefore not be able to promote the course of liver regeneration *in vivo*[1] when administered at the time of the nadir, at 24 h. It furthermore should be discussed, whether external growth factors influence receptor expression by negative feedback mechanisms. At 72 h, when the hepatocyte proliferation reaches its maximum, there is, once again, a (weak) expression of receptors. During this period, external growth factors do not promote regeneration, probably because proliferation is already at its maximum. Further research, investigating the meaningful application of growth factors in liver regeneration, is clearly warranted and should consider these two hypotheses.

The results demonstrated here correlate to previously published data of EGF binding studies. There, the observation was made that the EGF binding capacity of hepatocytes was reduced after PH, compared to control[14]. It is not yet clear why receptor kinetics during liver regeneration, after PH, are a biphasic process. Based on immohistochemical findings at 6 h after injury, we assume that there is an immediate expression of preformed receptors. It appears unlikely that *de novo* receptor synthesis can take place within 6 h. Later, after the injury, a *de novo* rebuilding of receptors might occur which correlates to the increase after 72 h.

After I/R, the expression of receptors is only very weak, only slightly more intensive than in the resting liver. Interestingly, the biphasic kinetics of TNFR1 after I/R are comparable to PH. In fact, the expression of FGFR and TNFR1 could be suppressed beyond the baseline using I/R.

The reason for the lack of receptor expression at 24 h after injury could be reduced mRNA expression, a posttranscriptional mechanism or shedding of the receptors. All of these mechanisms have been described in the context of receptor regulation processes[15,16]. In all samples, there is mRNA expression, yet at a reduced level. Therefore, a negative posttranscriptional effect may

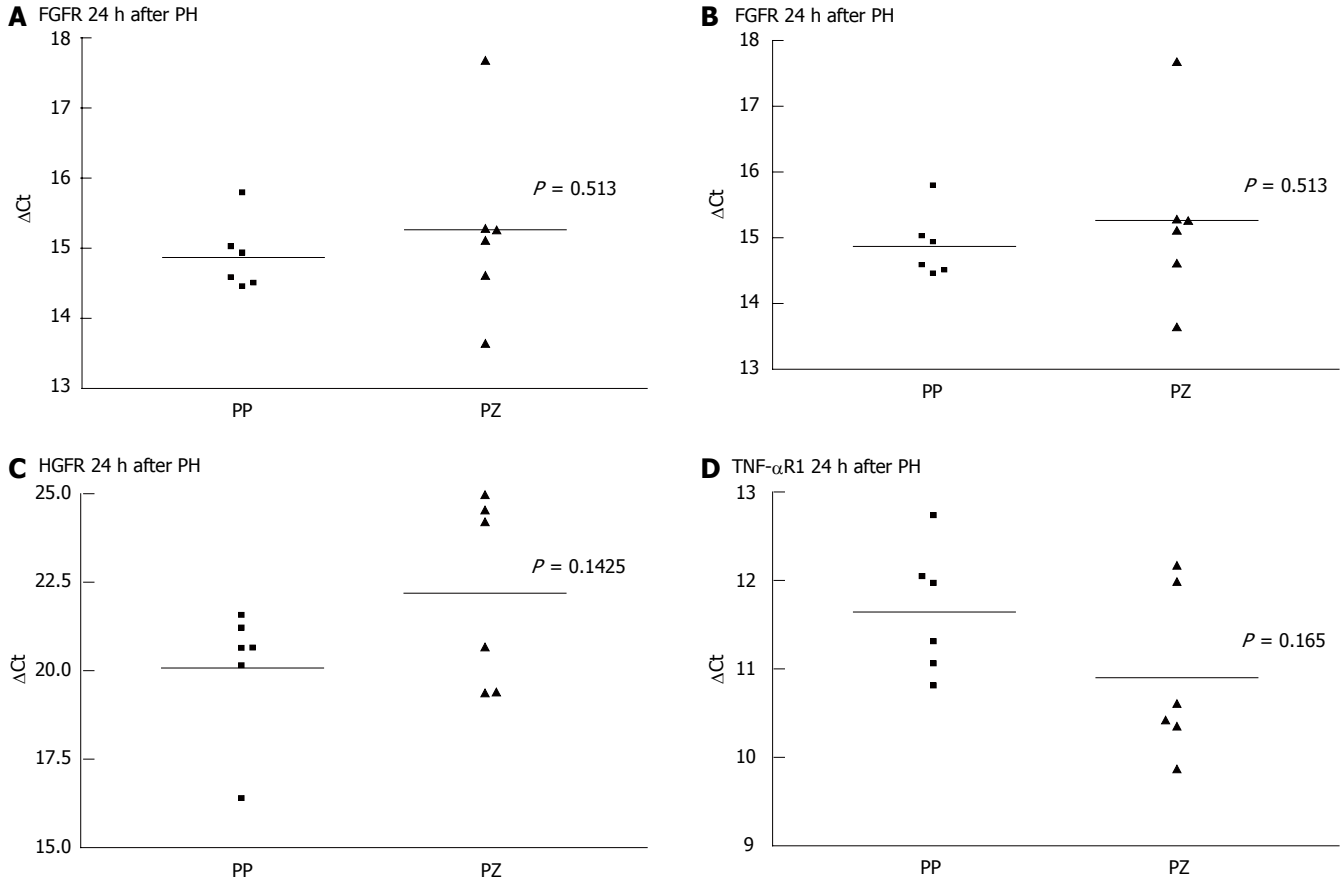

Figure 4 Results of quantitative PCR comparing receptor expression in periportal (PP)and pericentral (PC) hepatocytes 24 h after liver injury.

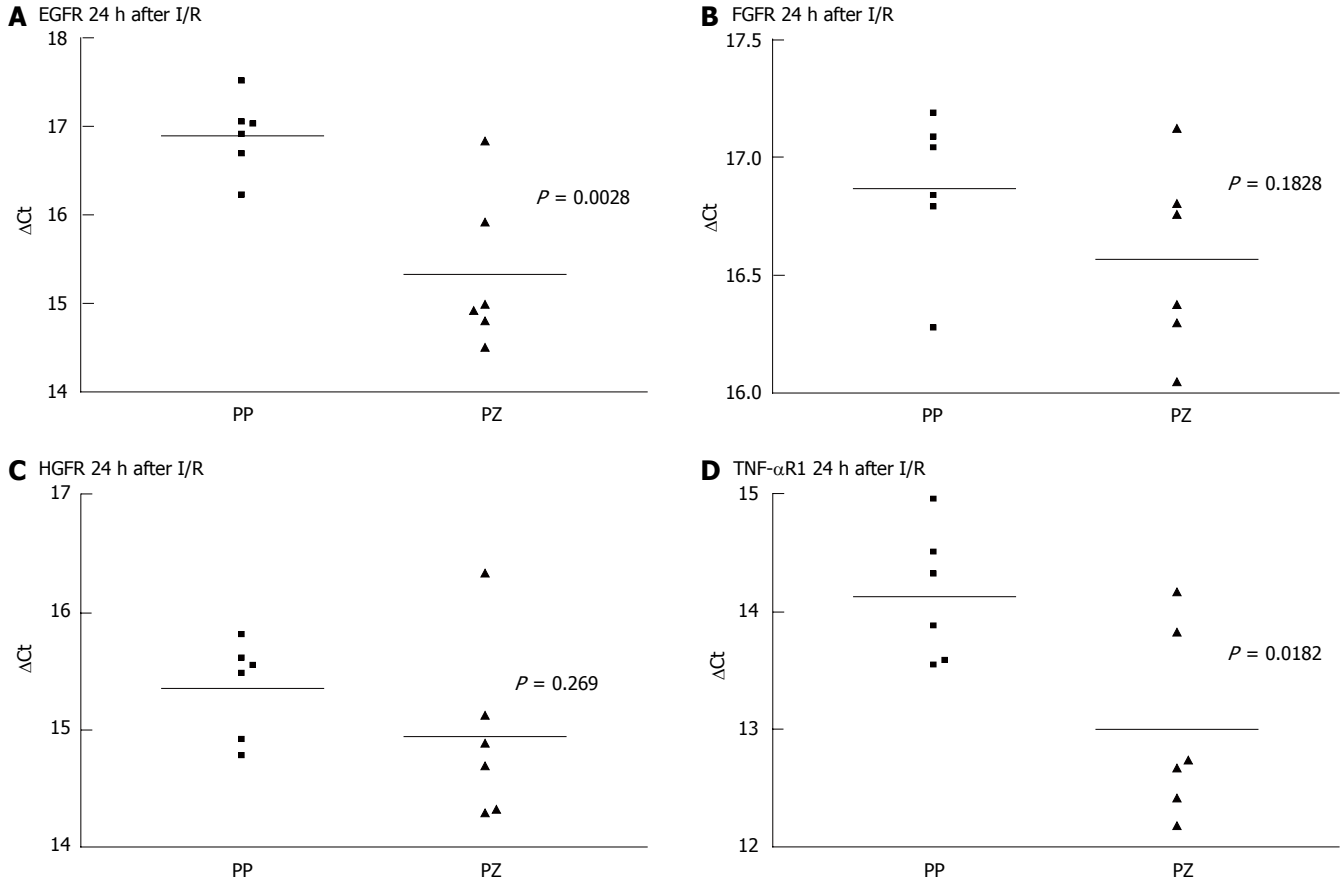

Figure 5 Results of quantitative PCR comparing receptor expression in periportal and pericentral hepatocytes 24 h after reperfusion.

take place as well as a reduced translation of mRNA. In case of HGFR after I/R, this posttranscriptional effect is demonstrated, as more specific mRNA is detectable in regenerating liver tissue than in control.

In I/R model, we did not find the same increase in receptor expression as after PH. This is of particular interest because in myocardial and neuronal tissue, an up-regulation of growth factor receptors seems to be involved in ischemic preconditioning[17,18]. We could not find a similarly strong receptor expression after ischemic stimuli in liver regeneration. Although ischemic preconditioning is effective in the clinical setting of partial hepatectomy, it might not be due to a strong expression of growth factor receptors. As opposed to the resting liver and to the regenerating liver after PH, there is a zone-specific difference in the receptor mRNA expression after I/R. There is stronger expression in pericentral than in periportal hepatocytes. In immunohistochemistry, this difference is not found since there are no receptors at all. The observed variations in mRNA expression reflect the different impact of ischemia on the various parts of the liver acinus. The pericentral part is more sensitive than the periportal. In regeneration after I/R, there is stronger receptor mRNA expression in pericentral hepatocytes. Contrary to mRNA expression in I/R, there is no obvious predilection to any part of the liver acinus in the PH model, neither concerning the trauma nor the receptor expression (immunohistochemically and mRNA) during regeneration. This is of interest, as we know[19] that the proliferation after PH is stronger in periportal than in pericentral areas.

At 24 h after partial hepatectomy, many regulatory processes take place in the regenerating liver. As Xu *et al*[20] demonstrated by microarray, there are more genes expressed at 24 h than at any other time during liver regeneration. The receptors analysed here are not up-regulated at this time point, maybe they are part of the 135 genes Xu *et al* found to be down-regulated. As there should be a posttranscriptional regulation in case of the receptors, the approach of Liu *et al*[21], for analysing proteomics of regenerating liver, should be even more interesting than microarrays.

CONCLUSION

Concerning the expression of growth factor receptors, liver regeneration is a biphasic process with a nadir at 24 h. As a result, we hypothesise that the expression of receptors is an essential regulative factor in this process. This will have to be validated in subsequent studies.

Further research must focus on the mechanisms responsible for the decrease in receptor expression after 24 h. It should also be promising to analyse the expression of growth factor receptors in other models like sepsis or combined injuries such as, resection plus reperfusion or resection plus sepsis, since these are combinations correlated to complicated courses of liver regeneration in the clinical setting. In order to use therapeutic growth factors in liver regeneration, detailed knowledge about the kinetics of their corresponding receptors is of elementary importance.

Abstract

AIM: To investigate whether Thy1 recognizes oval cells in the fetal liver and to characterize the cultured Thy1-selected cells from E14 rat livers.

METHODS: Thy1 populations were analyzed by fluorescence activated cell sorter analysis. Thy1 positive cells were isolated using magnetic beads. Hepatic markers were detected by Western blotting, immunocytochemistry and RT-PCR.

RESULTS: The percentage of Thy1-positive cells decreased during early development of fetal rat liver (E13-E16). E14 fetal livers contained 7.8% Thy1 positive cells, of which 61% were positive for α-fetoprotein (AFP) and 25% expressed albumin. The Thy1+ population expressed oval cell markers c-Kit and CXCR4, liver enriched-transcription factors HNF1α and HNF6, hepatocytic markers albumin, AFP and cytokeratin 18, and biliary marker cytokeratin 19. Thy1- selected cells formed only mesenchymal colonies when plated on collagen and in serum-containing media. Thy1 selected cells were able to form hepatic colonies positive for HNF1α, HNF6, albumin, AFP, cytokeratin 18, cytokeratin 19 and glycogen, when grown on STO feeder layers in serum free-media.

CONCLUSION: Oval cells positive for Thy1 are present in early liver embryonic stages.

INTRODUCTION

Bipotential hepatic stem cells are found in murine and rat embryonic livers at stages E13 and E14, although at these embryonic stages a large majority of cells are already committed to the hepatocytic and bile duct lineage. Bipotential liver cells or hepatoblasts express an array of genes, such as α-fetoprotein (AFP), albumin, gamma-glutamyl transpeptidase (GGT), glutathione-S-transferase p and HNF6[1-3]. With maturation towards the hepatocytic lineage, fetal liver parenchymal cells have lower levels of AFP and higher levels of albumin, start expressing cytokeratin 18 (CK18) and break loose of GGT expression. Cells that differentiate towards biliary epithelial lineage retain GGT expression, express cytokeratins 7 and 19, c-kit and CD34 and stop expressing AFP and albumin[1-5]. Some liver-specific genes, such as glutamine synthetase, tyrosine aminotransferase (TAT), phosphoenolpyruvate carboxykinase and α2-microglobulin appear later in hepatocytes, at birth or even after birth. Recently, several groups have isolated bipotential fetal progenitor cells from murine and rat origin, which form colonies of both hepatocytes and bile duct cells, identified by albumin and cytokeratin 19 (CK19) expression, respectively[6,7].

There is controversy over the identity of adult liver stem cells, and whether they exist in the adult liver. One of the candidates is the oval cells. However, oval cells are only detected after certain protocols, such as carcinogenic insults to the liver, followed by partial hepatectomy[8]. There are suggestions that oval cells are bone marrow cells that migrate to the liver and become hepatocytes. Reconstitution of sublethally-irradiated male mice with female bone marrow, followed by a protocol that results in oval cell proliferation, showed that oval cell-derived hepatocytes are of donor origin[9]. Moreover, the homing molecule for hematopoietic stem cells to the bone marrow, stroma-derived factor 1 (SDF-1), is induced on hepatocyte surface in livers treated with oval cell proliferation-inducing protocols, and the oval cells express the CXCR4, the receptor for SDF-1[10]. If indeed oval cells are of bone marrow origin, it may explain the expression of common markers in both oval cells and hematopoietic cells, such as

Thy1, CD34 and c-kit. Several current studies have shown that bone marrow cells that arrive at the liver do not differentiate into hepatocytes, but undergo fusion with hepatocytes[11].

Recently, one group has investigated the presence of oval cells in the fetal liver, since expression of Thy1 is never determined in fetal liver hepatoblasts[12,13]. This group isolated Thy1 positive cells from E16-E20 livers, and stained these cells with hepatocytic marker CK18[12]. They found that 0.5%-1% of the cells are positive for both Thy1 and CK18 and speculated that these double-positive cells may be hepatic progenitor cells[12]. Other markers for oval cells are c-kit, oncostatin M receptor β and CXCR4 and dlk[10,14,15]. Dlk is a marker for both murine hepatoblsts and murine oval cells, and its expression is the strongest at E10.5 and down regulated after E16.5[16].

The purpose of the present study was to determine whether oval cells are present in early embryonic fetal liver, and to characterize the cultured Thy1- positive cells from E14 fetal livers.

MATERIALS AND METHODS

Animals

Fischer 344 rats with known durations of pregnancy were maintained in the animal facility of the Tel Aviv Sourasky Medical Center on a standard rat chow diet in a 12 h light and dark cycle. By convention, the first day of gestation was defined as d 0. Use of animals was in accordance with the NIH policy on the care and use of laboratory animals and approved by the Animal Care and Use Committee of the Tel Aviv Sourasky Medical Center.

Isolation of fetal rat hepatocytes

Cell suspensions enriched for liver parenchymal cells were isolated as described previously with minor modifications[17]. Livers from E13, E14 and E16 embryos were removed and placed into ice cold, Ca^{2+}-free Hank' s balanced salt solution (HBSS) containing 0.8 mmol/L $MgCl_2$ and 20 mmol/L HEPES (Sigma Chemical Company, Israel), pH 7.3 (modHBSS). After all tissues were collected and non-hepatic tissue was removed, HBSS-5 mol/L EGTA was added to a final EGTA concentration of 1 mmol/L. The livers were gently triturated 6-8 times to partially disaggregate the tissue and then centrifuged at 400 r/min for 5 min at 4℃ (all subsequent centrifugation steps were done at the same settings). The pellet of cells and tissue were resuspended in 35 mL modHBSS containing 0.08 g collagenase type 1 (Worthington Biochemical Corporation, NJ, USA) and 1 mmol/L $MgCl_2$, gently triturated and stirred at 37℃ for 15 min in an Erlenmeyer flask. The dispersed cells were pooled, centrifuged and resuspended in modHBSS. Cell number and viability were determined by hemacytometer and trypan blue exclusion.

Fluorescence activated cell sorter analysis

The freshly isolated liver cells from fetal livers were stained for 1 h on ice with Thy1-fluorescein isothiocyonate (FITC) (Serotec, Oxford, United Kingdom) diluted in DMEM + 100 mL/L fetal calf serum (FCS) (Biological Industries, Bet Haemek, Israel). At the end of the incubation, the cells were washed and fixed in 5 g/L paraformaldehyde in phosphate buffered saline (PBS). Thy1-positive cells were analyzed using a Becton-Dickson fluorescence activated cell sorter (FACS) and the results were analyzed using the WinMDI software. For double staining of Thy1 and α-fetoprotein, the cells were stained with Thy1-phycoerythrin (PE)(1:100), fixed with solution A of Intrastain kit (Dako, Glostrup, Denmark), permeabilized with solution B, and stained for intracellular expression with antibodies to rat α-fetoprotein-FITC (1:80) (Nordic, Tilburg, The Netherlands). Thy1 and α-fetoprotein were analyzed using a Becton-Dickson FACS and the results were analyzed using CellQuest software. For double labeling of cell surface with dlk and oncostatin receptor β, and intracellular staining of AFP, we used antibodies to dlk (Santa Cruz Biotechnologies, Santa Cruz, CA) and to mouse OSMRβ (R&D Systems, Minneapolis, MN), followed by anti-goat-PE conjugated antibody (Jackson Laboratories, Bar Harbor, ME) and staining with AFP-FITC.

Thy1 selection

The freshly isolated fetal liver cells were selected using an EasySep kit from StemCell Technologies, Vancouver, Canada. Briefly, cells were incubated for 15 min at room temperature with 3 mg/L Thy1-FITC (Serotec, Oxford, United Kingdom) in PBS containing 20 mL/L FCS and 1 mmol/L EDTA. Cells were washed once with excess buffer, then incubated with EasySep FITC selection cocktail for another 15 min, and then with the EasySep magnetic nanoparticles for 10 min. Buffer was added to cells at total volume of 2.5 mL, and the labeled cells were placed for 5 min inside the Violet Magnet (StemCell Technologies, UK). Unlabeled cells were poured off from the tube. The procedure was repeated two more times. The selected cells were resuspended in buffer and counted, and used for further characterization or for plating.

Clonal assays

Thy1-selected cells were plated at two densities per well in 6- well plates (approximately 1000 and 2000 cells/cm^2). The plates were coated with collagen type I. The media used to culture the cells were as follows. Medium 1: DMEM supplemented with 100 mL/L FCS (Biological Industries, Bet Haemek, Israel), 50 μg/L EGF (PeproTech Asia/CytoLab, Rehovot, Israel) and 10 mg/L insulin (Sigma, St. Louis, MI)[18]; medium 2: DMEM supplemented with 10 μg/L oncostatin M and 10 μg/L flt-3 ligand (PeproTech Asia/CytoLab, Rehovot, Israel)[19]; medium 3: DMEM supplemented with 100 mL/L FCS, 1mg/L insulin, 10^{-7} mol/L dexamethasone, 10 mmol/L nicotinamide, 50 μmole/L β-mercaptoethanol, 50 μg/L HGF (PeproTech Asia/CytoLab, Rehovot, Israel), 20 μg/L EGF[6]; medium 4: DMEM supplemented with 100 mL/L FCS.

The cells were allowed to grow for 2 wk with the medium changed every three days. The colonies were stained with 2.5 g/L crystal violet solution and counted. The experiments were done at least three times.

STO feeder layers

STO cells were a kind gift of Professor Lola Reid (UNC, Chapel Hill, NC). The cells were cultured in DMEM (F12 media 1: 1) supplemented with 100 mL/L FCS, 10 mL/L dimethylsulfoxide (DMSO), 100 mg/L penicillin and 100 mg/L streptomycin.

The STO cells were growth arrested for 3 h with 10 mg/L mitomycin C (Sigma, St. Louis, MI), then plated on 1 g/L gelatin-coated plates at a density of 60×10^3 cells/cm^2 in the medium described above and cultured for 2 d prior to seeding Thy1- selected cells on them.

Culture of Thy1- selected cells on STO feeders

Thy1-selected cells from e14 fetal livers were plated on STO feeder layers at a density of 4000 cells/cm^2 and cultured for 2 wk in hormonally defined medium (HDM)[20] consisting of DMEM supplemented with 100 mg/L penicillin/streptomycin, 2 g/L bovine serum albumin, 610 mg/L nicotinamide, 740 μg/L $ZnSO_4 \times 7H_2O$, 20 μg/L $CuSO_4 \times 5H_2O$, 5 mmol/L glutamine, 5 mg/L insulin, 5 mg/L iron-saturated transferrin, 5 μg/L selenous acid and 10^{-7} mole/L dexamethasone. All the medium additives were obtained from Sigma, St. Louis, MI.

Western blots

Total protein was extracted by incubation for 30 min on ice in lysis buffer (250 mmol/L sucrose, 5 mmol/L $MgCl_2$, 10 mmol/L Tris pH 8.0, 5 g/L Triton X-100 and 1 mmol/L PMSF), and insoluble material pelleted at 17 000 g. The extracts were normalized to total protein content, determined using Bradford reagent (Sigma, St. Louis, MI) and boiled for 5 min in sample buffer containing SDS and β-mercaptoethanol. Protein (10-20 μg per lane) was separated by SDS-PAGE (BioRad Protean II minigel) in 100 g/L acrylamide gels and blotted onto Hybond C extra (Amersham, Arlington Heights, IL) for 1 h at 250 mA constant current. The blots were blocked overnight in Tris-saline buffer pH 7.5, containing 0.5 g/L Tween-20 and 50 g/L milk, and incubated with antibodies to rat albumin (Sigma, St. Louis, MI) and AFP (Santa Cruz Laboratories, Santa Cruz, CA), washed and incubated for 1 h with the appropriate horseradish peroxidase-conjugated secondary antibody (Jackson Laboratories, Bar Harbor, ME). The blots were then subjected to chemiluminescent detection and flurorography using X-ray film (NEN Life Science Products, Boston, MA).

Immunocytochemistry

Cells were fixed with 95 mL/L ethanol for 10 min at 4℃, and incubated with a blocking solution containing 100 mL/L FCS for 30 min at room temperature. Cells were then incubated with primary antibodies to rat albumin (1:400) (Sigma, St. Louis, MI), mouse AFP (1:200), CK19 (Novacastra) for 1 h at room temperature, washed three times, followed by addition of anti-rabbit second antibody conjugated to Cy3 (1:100) (Jackson Laboratories, Bar Harbor, ME) for another hour at room temperature. Cells were washed three times and stained cells were visualized under Axiovert 25 microscope (Zeiss, Germany) with fluorescent attachments.

Glycogen detection

Glycogen granules in the cultured cells were detected using a periodic acid-Schiff (PAS) staining kit according to the manufacturer's instructions (Sigma, St. Louis, MI).

RT-PCR for liver specific markers

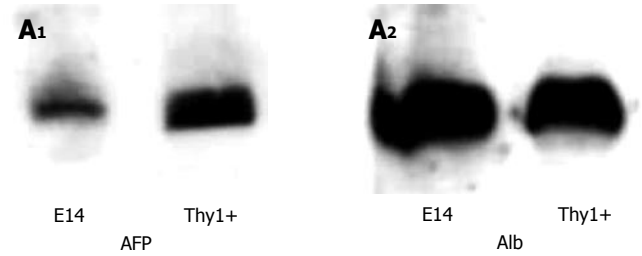
Total RNA was extracted from freshly isolated E14 and Thy1+ selected cells using EZ RNA kit (Biological Industries, Bet Haemek, Israel), treated with DNAse and cDNA was reverse-transcribed. For reverse transcription, 1-2 μg of total RNA was used. The cDNA obtained was used for PCR, using the following oligonucleotide primers[21]: HNF-1α: the 5' primer is 5' -AGCTGCTCCTCCATCATCAGA -3', the 3' primer is 5'-TGTTCCAAGCATTAAGTTTTCTATTCTAA -3'; HNF4α: the 5' primer is 5'-CTTCCTTCTTCA-TGCCAG -3', the 3' primer is 5'-ACACGTCCCCAT-CTGAAG -3'; HNF6: the 5' primer is 5' -AACTCCCAGCAAG-GACTTCCCCACT-3' , the 3' primer is 5'-CCATCTGCCCTGAAT-TACTTCCATTGC-3'; cytokeratin 18 (CK18): the 5' primer is 5'-GCCCTGGACTCCAGCAACT -3' and the 3' primer is 5'-ACTTTGCCATCCACGACCTT -3'; cytokeratin 19 (CK19): the 5' primer is 5' -ACCATGCAGAACCTGAACGAT- 3' and the 3' primer is 5'- CACCTCCAGCTCGCCATTAG-3' ; albumin: the 5' primer is 5'-CTGGGAGTGTGCA-GATATCAGAGT- 3' and the 3' primer is 5' -GAGAAG-GTCACCAAGTGCTGTAGT-3' ; alpha-fetoprotein: the 5' primer is 5' -GTCCTTTCTTCCTCCTGGAGAT- 3' and the 3' primer is 5'-CTGTCACTGCTGATTTCTCTGG-3'; oncostatin M receptor: the 5' primer is 5'-CCCCTGTGAG-GCCGAGGACCGGC-3' and the 3' primer is 5' -TGGCTTTACAATTGATGTTTGTCCCTG-3' ; stroma-derived factor 1(SDF1): the 5' primer is 5' –ATTCTTTGAGAGCCATGTCGC-3' and the 3' primer is 5'-CCTTGAGCTGAGTGACTCTCG-3' ; C-kit: the 5' primer is 5'-AGCAAGAGTTAAC-GATTCCGGAG-3' and the 3' primer is 5' -CCAGAAAGGTGTAAGTGCCTCCT-3'; CXCR4: the 5' primer is 5'-CCCTCGAGATGGAA-ATATACAC-3' and the 3' primer is 5'-GCTCTAGATTAGC-TGGAGTGAAA-3'. For glyceraldehydehyde-3-phosphate-dehydrogenase (GAPDH), the 5' primer is 5' -ACCACAGTCCATGCCATCAC-3' and the 3‘ primer is 5'-TCCACCACCCTGTTGCTGTA-3'. For PCR, 1.5 μL of the reverse transcription reaction was used, and the reaction mixture also contained 0.4 μmol/L of each primer, 200 μmol/L dNTP, 10 mmol/L Tris-HCl (pH = 8.3), 50 mmol/L KCl, 1.1 mmol/L $MgCl_2$, 0.1 g/L gelatin and 2.5 U RED Taq DNA polymerase (Sigma, St. Louis, MI). The mixture was denatured for 1 min at 94℃. The PCR was started at 94℃ for 10 s for the denaturation step, at 53℃ for 30 s for the annealing step and at 72℃ for 1 min for the elongation step. Thirty-five cycles were used to amplify the hepatic markers. The PCR products were finally separated in a 20 g/L agarose gel containing ethidium bromide.

Table 1 FACS analysis of cell surface markers in various rat fetal liver developmental stages

Embryonal stage	Thy1 positive cells (%)	Dlk positive cells (%)	OSM receptor β positive cells (%)
E13	10.5 ± 2.0	10.8	5.3
E14	7.8 ± 0.5	5.3 ± 1.1	3.6 ± 1.5
E16	2.3 ± 0.6	Not done	Not done

RESULTS

Expression of Thy1, dlk and oncostatin receptor M β in fetal livers



We assessed the expression of oval cell markers, Thy1 and oncostatin receptor M β (OSMRβ), and fetal hepatoblast marker dlk in E13, E14 and E16 fetal livers (Table 1). The expression of all three markers decreased with liver development (Table 1). The largest percentage of Thy1 positive cells was in E13 rat livers (10%), and the percentage of Thy1-positive cells decreased with liver development, so that there were 7.8% Thy1 positive cells in E14 livers, and only 2.3% Thy1 positive cells in E16 livers (Table 1). We did not continue to test the percentages of Thy1 positive cells in later stages, since the peak of hematopoiesis in fetal rat liver was at E17 and E18, and Thy1- positive cells at those stages might be hematopoietic cells rather than hepatoblasts.

We defined the positive populations for both Thy1 and α-fetoprotein in E14 fetal livers. In the E14 total liver population, 4.8% of the cells were positive for both Thy1 and α-fetoprotein, while 3 % were positive for Thy1 only (Table 1). There 2.7% of cells positive for dlk and AFP and 1.6% of cells positive for OSMRβ and AFP in the E14 livers.

Characterization of Thy1- positive cells from E14 fetal livers

We obtained 11 × 10^6 single cell suspension cells from per E14 liver, with a viability > 95% determined by trypan blue exclusion. We selected Thy1- positive cells from the single cell suspensions of E14 liver cells using nanoparticles and magnet selection of Thy1-FITC labeled cells. We determined AFP and albumin expression by Western blots using freshly isolated E14 liver cells and Thy1- selected cells. Thy1-positive cells expressed slightly more AFP than E14 cells, while albumin expression was similar in the two cell populations (Figure 1A). We next determined the percentages of albumin positive cells in the Thy1- selected cells from E14 and E16 livers, using immunocytochemistry staining on cytospun cells. Albumin expression in E14 Thy1- selected cells is shown in Figure 1B. We counted albumin positive cells in 20 fields and found that 25% ± 8% of Thy1+ from E14 livers were albumin positive and 18% ± 9% of Thy1+ cells from E16 livers expressed albumin.

We also determined the expression of oval cell markers c-kit, OSMRβ and CXCR4, liver- enriched transcription factors HNF1α, HNF4α and HNF6, hepatocytic markers AFP, albumin, CK18, and biliary epithelial marker CK19

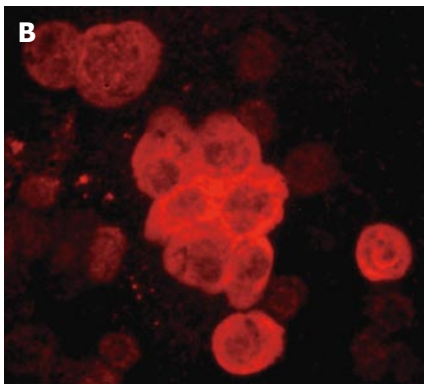


Figure 1 Western blot showing albumin and AFP expression in E14 livers and Thy1 selected cells from rat E14 fetal livers (**A**) and albumin staining on cytospins of Thy1 selected cells from E14 livers (**B**).

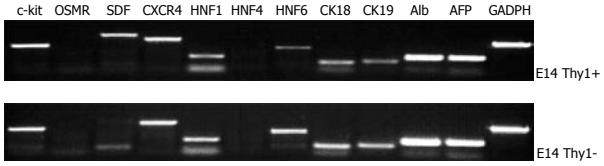

Figure 2 Expression of various oval cell markers, liver-enriched transcription factors and hepatic or bile duct specific markers in Thy1 positive and Thy negative cells from rat E14 fetal livers (RT-PCR).

in Thy1+ and Thy1- cells from E14 livers. We observed that both cell populations were positive for c-kit, CXCR4, HNF1 and HNF6, albumin, AFP, CK18 and CK19, while only the Thy1+ cells were positive for SDF1α, and we could not detect OSMRβ and HNF4 in either cell population (Figure 2).

Culture of Thy1- positive cells isolated from E14 fetal livers

We plated the Thy1-selected cells at clonal densities on collagen type I-coated dishes and in four different media, as described in Materials and Methods. After two weeks, colonies were stained with crystal violet solution and counted. Both medium 2 and medium 3 were beneficial for development of colonies (Table 2). However, the morphology of the cells was not typical of hepatoblasts, but rather of fibroblasts (data not shown). We isolated four clones from two separate experiments of cells grown in medium 3 and on collagen I, and tested them by RT-PCR for hepatic markers. The only hepatic marker detected was CK18 (data not shown).

Since 25% of the Thy1- selected cells expressed albumin, we thought that in the above conditions, the

albumin-positive cells probably did not survive. Therefore, we plated Thy1-selected cells on collagen type I-coated plates and in DMEM with 100 mL/L FCS, at a density of 500 000 cells/well in 6-well plates. After one and two days in culture, typical fetal hepatoblast colonies were observed and stained positive for albumin (data not shown). However, the colonies did not survive for longer periods, but peeled off the plates. Since hepatic fetal cells could grow on feeder layers[7], we plated Thy1- selected cells on STO feeders and in serum free-medium. The cells survived very well under these conditions for two weeks, and formed typical fetal hepatoblast colonies (Figure 3). These colonies were positive for albumin, AFP, CK18 and glycogen (Figure 4). We determined that 0.6% ± 0.17% of the total Thy1 positively-plated cells formed albumin-positive colonies. However, there were numerous other colonies on the plates, with fibroblast morphology similar to the colonies obtained when the cells were cultured on collagen I and in media 1-4 (data not shown).

We examined the expression of mRNA for hepatocytic markers in two weeks- old cultures of Thy1-selected cells grown on STO feeders. We found that there was expression of liver enriched-transcription factors HNF1α and HNF6, as well as hepatic markers albumin, AFP, CK18 and biliary marker CK19 (Figure 5). The expression

of OSMRβ was very weak in the colonies derived from Thy1 positive cells, while transcription factor HNF4α was not detected (data not shown).

DISCUSSION

In the present study, early rat fetal livers contained Thy1-positive cells, and the percentage of Thy1- positive cells decreased between E13 and E16. E14 fetal livers contained about 8% Thy1-positive cells, of which 61% were positive for AFP and 25% were positive for albumin. The Thy1-positive cells expressed oval cell markers c-kit and CXCR4, liver enriched-transcription factors HNF1α and HNF6, hepatocytic markers albumin, α fetoprotein and CK18, and biliary marker CK19. We were able to culture Thy1-selected cells from E14 livers for two weeks on STO feeder layers, and observed several types of colonies, both mesenchymal and hepatic colonies.

In the last few years, hepatic stem cells from various sources, both fetal and adult livers, have been studied extensively. Methods used to isolate the cells from murine and rat fetal livers include FACS sorting using several positive and negative markers[6,7]. When the isolated cells are cultured, they form colonies that contain both hepatocytes and bile duct epithelial cells.

We hypothesized that in addition to the fetal hepatoblasts, which could differentiate into hepatocytes and bile duct epithelial cells during fetal liver development, fetal liver might contain additional stem cells, the "oval" cells. We may surmise that cells positive for oval cell markers Thy1 and AFP might be more numerous in the early stages of fetal liver development and decrease in later stages, so that the oval cell numbers in the adult livers are very few, and in fact difficult to detect unless oval cells proliferate due to carcinogenic injuries.

Thy1 has been shown to be present on rat oval cells, one kind of the putative liver stem cells in the adult liver[9]. Thy1 (CD90) is a cell surface molecule, present on hematopoietic stem cells, subsets of T cells, bone marrow cells, fibroblasts and cells in the brain[22,23]. Thy1 may be a receptor for an unknown ligand, and may play a role in cellular recognition and adhesion [20,21].

Adult rat liver oval cells, in addition to Thy1, expressing AFP, cytokeratin 19 and GGT, are negative for hepatic stellate cell marker, desmin[9]. Other markers for oval cells are c-kit, oncostatin M receptor β and CXCR4[10,14]. Recent studies have shown that Thy1 is present not only on adult rat oval cells, but also in rat E16 fetal liver, and a small percent of Thy1 positive cells also express hepatocytic marker CK18[12], suggesting that the Thy1 + CK18 + are hepatic stem cells. The same group isolated Thy1 positive cells from E16, E18, E20 and E22, and found that the cells are also positive for albumin, AFP and CK18[13]. Long-term cultures (one month) of human fetal hepatocytes also express Thy1, as well as other oval cell and hematopoietic markers such as CD34 and OV-6. In addition, these cells assume a blast-like morphology and express hepatoblast markers AFP, CK19 and CK18[24].

Rat fetal liver rudiment appears at E10, E13 and E14, there are still numerous bipotential hepatic stem cells, though there are also cells committed towards the hepatocyte and biliary epithelial cell lineage[25]. Since the rat fetal liver is both a hepatic and a hematopoietic organ, we tested the expression of Thy1, a hematopoietic marker, before the peak of hematopoiesis in fetal liver, which occurred at E17 and lasted until birth. We found that there were Thy1 positive cells in E13 livers, and the percentage of Thy1 positive cells decreased between E13 and E16.

We chose E14 fetal livers as the ideal stage for isolating oval cells, since the livers contain a large number of cells, and there are many Thy1+ AFP+ cells. Moreover, we observed that Thy1 cells selected from E14 livers expressed numerous hepatic and biliary epithelial markers and liver-enriched transcription factors, as well as oval cell markers c-kit and CXCR4, and OSMRβ detected by FACS analysis, but not by RT-PCR[10]. However, we did detect OSMRβ in colonies of Thy1 positive cells, suggesting that its expression is very weak in the original cells. The Thy1-selected cells were not homogenous and contained both oval cells (Thy1+ AFP+) and mesenchymal cells, (Thy1+ AFP-). When we cultured the cells on collagen I and in various media containing serum, we observed only mesenchymal cell colonies and some epithelial colonies that were positive for CK18. However, when we cultured the Thy1 positive cells on STO feeder layers, we detected formation of hepatic colonies expressing albumin and AFP. The original Thy1+ cells and colonies derived from Thy positive cells were negative for HNF4. It was reported that oval cells are negative for HNF4, and only start expressing this transcription factor when they differentiate into hepatocytes[26], suggesting that fetal oval cells may not undergo complete differentiation into hepatocytes under our culture conditions.

In mice, contrary to rat and human livers, Thy1 appears to identify only mesenchymal cells both in adult and in fetal liver[27,28]. Thy1 positive cells isolated from murine fetal livers have been shown to support differentiation of CD49f positive cells to hepatocytes[28]. The Thy1 positive cells comprise three different populations, one positive for α-smooth muscle actin, another positive for desmin, both markers of hepatic stellate cells, and a third population negative for both[28]. The murine Thy1 positive cells are negative for AFP, cytokeratin 19 and albumin[28].

In conclusion, Thy1 identifies putative oval cells during early fetal liver development, but is also present on other cells such as mesenchymal cells.

Abstract

AIM: To explore the possible mechanisms of curcumin in rat colitis induced by trinitrobenzene sulfonic (TNBS) acid.

METHODS: Rats with TNBS acid-induced colitis were treated with curcumin (30 mg/kg or 60 mg/kg per day ip). Changes of body weight and histological scores as well as survival rate were evaluated. Leukocyte infiltration was detected by myeloperoxidase (MPO) activity assay. The expression of cyclooxygenase-2 (COX-2) was detected by RT-PCR and Western blot. Inflammation cytokines were determined by RT-PCR. Local concentration of prostaglandin E_2 (PGE_2) in colon mucosa was determined by ELISA.

RESULTS: Curcumin improved survival rate and histological image, decreased the macroscopic scores and MPO activity. Also curcumin reduced the expression of COX-2 and inflammation cytokines. In addition, treatment with curcumin increased the PGE_2 level.

CONCLUSION: Curcumin has therapeutic effects on TNBS acid-induced colitis, the mechanisms seem to be related to COX-2 inhibition and PGE_2 improvement.

INTRODUCTION

Inflammatory bowel disease (IBD) is characterized by chronic recurrent ulceration of the bowel. Frontline drugs that are currently used for the treatment of IBD include derivatives of 5-aminosalicylic acid (5-ASA), glucocorticoid and immunosuppressives. Novel agents such as monoclonal antibodies against tumor necrosis factor alpha (TNF-α) are now commercially available[1,2]. However, these agents have varying efficacy and are expensive. Consequently, there is a need for alternative agents that may be equally or more effective and cheaper. Curcumin is the prominent yellow pigment in turmeric, a widely used spice and food colouring agent with anti-inflammatory and anti-cancer properties[3]. Mechanisms by which curcumin exerts its pharmacological effects are thought to involve antioxidation[4], inhibition of kinases, interference with the activity of transcription factors such as NF-κB and AP-1[5]. Cyclooxygenase-2 (COX-2) and lipoxygenase (LOX) are inhibited by curcumin through NF-κB dependent or independent pathway[6,7].

In IBD, increased COX-2 mRNA and protein have been found in inflamed areas, and most of the PGs are produced by the COX-2 pathway. Hence, inhibition of excessive COX-2 activity and PGE_2 production may result in suppression of the inflammatory response. Preventive and therapeutic mechanisms of curcumin are to inhibit the activation of NF-κB and reduce the activity of p38 MAPK[8-11]. But whether treatment of colitis with curcumin reduces COX-2 and PGE_2 remains unknown. In the present study, we investigated the effect of curcumin on body weight changes, the expression of COX-2, the local concentration of PGE_2 in colon mucosa and the changes of inflammatory genes in rats with colitis induced by trinitrobenzene sulphonic (TNBS) acid.

MATERIALS AND METHODS

Experimental animals

Specific pathogen-free Sprague-Dawley rats weighing 200-220 g were obtained from Laboratory Animal Center of Wuhan University (Wuhan, China) and kept at constant temperature (23 ± 2℃) and humidity (50%-70%) in a 12 h light and dark cycle. The rats were allowed to adapt to our laboratory environment for one week before experiment with free access to standard rodent chow and tap water.

Induction of colitis

Colitis was induced by TNBS acid using the modified method described by Morris *et al*[12]. Briefly, rats were fasted the day before colitis induction. Each rat was anesthetized with ether, and 100 mg/kg of TNBS acid (Sigma, St. Louis, MO, 100 g/L TNBS acid in 500 mL/L ethanol, total volume 1.0 mL) was then instilled via a rubber catheter inserted 8 cm into the colon *via* the anus. The rubber catheter was modified with numerous holes in the last 4 cm of its length. The instillation procedure required only a few seconds and the rats were maintained in a vertical position for 3 min to prevent solution leakage. Control mice received 500 mL/L ethanol of the same volume using the same technique. All the rats were checked daily for behavior and body mass. The experiments were approved by the Institution's Animal Care and Use Committee.

Treatment protocols

To investigate the therapeutic and dosage effects of curcumin(≥ 95%, Sigma), rats were randomly divided into four groups: control group(n = 15, receiving ethanol only and no treatment), TNBS acid group(n = 15, receiving TNBS acid and no treatment), curL group(n = 15, receiving 30 mg/kg curcumin per day ip) and curH group(n = 15, receiving curcumin 60 mg/kg per day ip). On d 1, the rats were fasted, colitis was induced and treatment was begun on d 2. Con and TNBS acid groups received the same volume of 5% ethanol (vehicle of curcumin) everyday until the end of the experiment. Treated groups received curcumin just after colitis was induced for two weeks until the rats were sacrificed.

Assessment of severity of colitis

After rapid removal of the colon, specimens were flushed with ice cold PBS, cut open and photographed. The photographs of the colonic specimens were then scored by a blinded observer unaware of the treatment. Scores were assessed by using the following damage scoring system[12]: 0: no damage; 1: localized hyperaemia without ulcers; 2: linear ulcers with no significant inflammation; 3: linear ulcer with inflammation at one site; 4: two or more sites of ulceration and/or inflammation; 5: two or more major sites of inflammation and ulceration or one major site of inflammation and ulceration extending more than 1 cm along the colon. For histological analysis, tissues were fixed in 100 g/L paraformaldehyde in phosphate-buffered saline, and paraffin-embedded tissue sections were stained with hematoxylin and eosin (HE) using the standard techniques.

Assessment of leukocyte infiltration

Myeloperoxidase (MPO) activity was assessed as a marker of neutrophil infiltration. Rat colon samples were snap-frozen in liquid nitrogen and stored at -80℃ before MPO activity assessment. The tissue was thawed, weighed and homogenized in PBS, the homogenate was centrifuged and the pellet was again homogenized in PBS containing 5 g/L hexadecyl-trimethylammonium bromide (HETAB) and 10 mmol/L EDTA. This homogenate was subjected to three cycles of freezing/thawing and brief sonication. A sample of homogenates was added to reaction volume (containing 80 mmol/L PBS, pH 5.4, 5 g/L HETAB and 1.6 mmol/L 3, 3', 5, 5'-tetramethylbenzidine). The mixture was incubated at 37℃ for 5 min and the reaction was started by the addition of H_2O_2. The complete reaction mixture was incubated for exactly 3 min at 37℃ and terminated by the sequential addition of catalase and sodium acetate. The changes in absorbance at 655 nm were measured with a spectrophotometer.

Semi-quantitative RT-PCR

For RT-PCR, rat colon samples were snap-frozen in liquid nitrogen and stored at -80℃ before ribonucleic acid (RNA) preparation. Total RNA was isolated using the TRIzol method (Life Technologies, Canada). Concentration of the RNA was detected from A_{260}, and the integrity of the RNA was verified by electrophoresis on formaldehyde gels. Total RNA was reverse-transcribed into complementary deoxyribonucleic acids (cDNAs) using a first strand cDNA synthesis kit (Fermentas, Life Sciences).The resultant cDNAs were subjected to PCR for measurement of messenger RNAs (mRNAs). The PCR products were subjected to agarose gel electrophoresis and the abundance of each mRNA was normalized to that of GAPDH. The sequences of all primers used in this project are as flowing:

GAPDH: sense: 5'ATGGGTGTGAACCACGAGAAA-3',
anti-sense: 5'GGATACATTGGGGGTAGGAA-3'(330 bp);

COX-2: sense: 5'-TACAAGCAGTGGCAAAGGC-3',
anti-sense: 5'-CAGTATTGAGGAGAACAGATGGG-3'(304 bp);

TNF-α: sense: 5'-TACTGAACTTCGGGGTGATTGGTCC-3',
anti-sense: 5'-CAGCCTTGTCCCTTGAAGAGAACC-3'(295 bp);

IFN- sense:5'AGCCTAGAAAGTCTGAAGAAC-3',
anti-sense:5'ACCGACTCCTTTTCCGCTTCCT-3'(387 bp)

iNOS: sense:5'-TGAAGCACATGCAGAAATGAGTACCG-3',
anti-sense: 5'-CCGTCAGAGGTAACTGTTTACACG-3' (464 bp)

Western blot analysis

Western blot analysis was performed by standard methods. Briefly, frozen tissue samples were homogenized in Tris-HCl buffer containing a cocktail of protease inhibitors and insoluble materials removed by centrifugation at 4℃. The solubilized lysates were resolved by sodium dodecyl sulfate (SDS)-PAGE electrophoresis under reducing conditions at a concentration of 50 μg protein of each sample per lane. Nitrocellulose membranes were incubated overnight with rabbit anti-serum directed against COX-2 (Santa Cruz Biotechnology). Immunodetection with secondary peroxidase-conjugated antibody and chemiluminescence was performed according to the manufacturer's protocol (Santa Cruz Biotechnology). Density of the products was quantified.

Enzyme-link immunosorbent analysis

Colonic mucosal samples kept at -80℃ were weighed and homogenized on ice in 1 mL Tris-HCl buffer containing 5.6 mmol/L indomethacin (pH 7.4), the homogenization

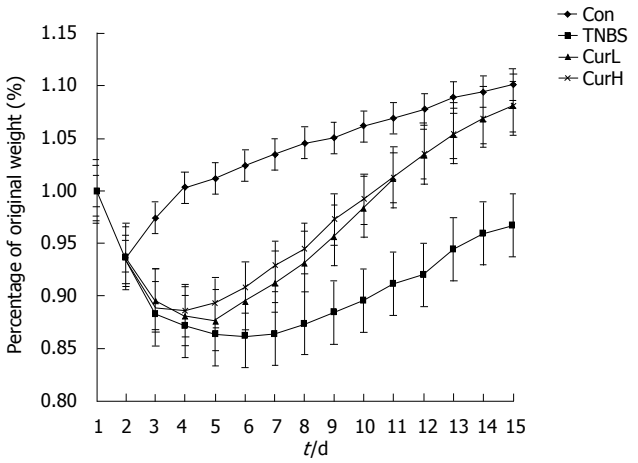

Figure 1 Body mass changes in rats with TNBS acid-induced colitis. Each bar represents mean ± SE. $P < 0.05$ *vs* TNBS acid.

was vortexed thoroughly for at least 2 min. After centrifugation, the concentration of PGE_2 in supernatants was immediately determined with competitive ELISA kits (R&D), according to the manufacturer's instructions. PGE_2 levels were normalized to microgram of protein. The detection limit of PGE_2 was 39 ng/L.

Statistical analysis

Data were expressed as mean ± SE. The statistical significance was evaluated by one-way analysis of variance (ANOVA) followed by Dunnett's test. $P < 0.05$ was considered statistically significant. In the experiment involving histology, the figures shown are representative of at least three experiments performed on different days.

RESULTS

Body mass

Administration of TNBS acid caused a dramatically decrease in body mass of all groups. Most of them decreased more than 30 g after 2 d (data not shown). Con group showed transient and slight loss of body weight (less than 10 g, data not shown) and recovered quickly. From d 3 it began to show significant difference from TNBS acid group ($P < 0.05$, Figure 1). At the end of the experiment, except for TNBS acid group, body weight of the other groups all reached the initial level. No difference was observed among control, curL and curH groups at the end of the experiment.

Macroscopic scores and histological images

TNBS acid-induced colitis was characterized by thick and stiff colonic wall due to edema, chemical erosion or fibriform-proliferation. Ulcers were scattered along the colon or linked with each other, bleeding or redness was observed in whole or partial colon. Necrosis of epithelium, distortion of crypts, destruction of glands and infiltration of inflammatory cells were observed. The macroscopic scores in curL and curH groups were significantly lower than those in TNBS acid group ($P < 0.01$ Figure 2). Treatment with curcumin decreased edema. Ulcers in curcumin-

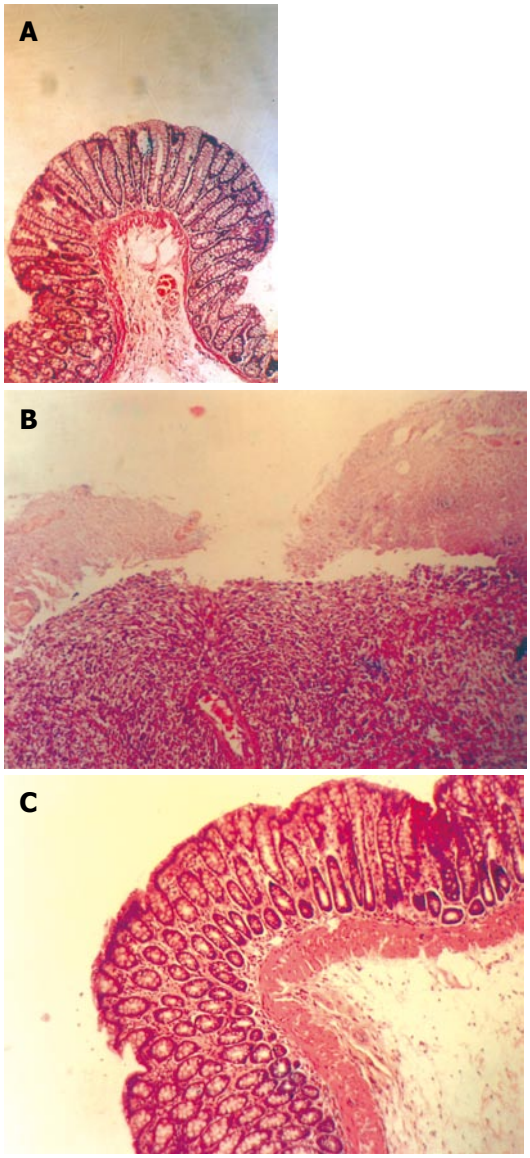

Figure 2 Effects of curcumin on histological scores of rats with TNBS acid-induced colitis in control group (**A**), TNBS acid group (**B**), and cur group (**C**). (HE staining, original magnification: × 200).

treated groups were much smaller and superficial, most of the ulcers were healed and granulation or fibroplasias could be seen. Histological analysis showed that curcumin treatment decreased necrosis of epithelium and the infiltration of inflammatory cells and granulation can be seen.

Leukocyte involvements

Myeloperoxidase activity was significantly ($P < 0.01$) increased in TNBS acid-treated animals compared with control group (101 020 ± 17 170 nkat/g and 249 382 ±43 342 nkat/g tissue protein, respectively, Table 1), which was consistent with the histological findings. Treatment with curcumin (30 mg/kg or 60 mg/kg per day) significantly reduced the degree of polymorphonuclear and neutrophil infiltration in rats with TNBS acid-induced colitis.

COX-2 and PGE_2 expression

Weak expression of COX-2 mRNA could be detected in normal colon (Figure 3). After colitis was induced by

Table 1 Concentrations of PGE_2 , activities of MPO in colon tissue and mRNA in inflammatory response genes (mean ± SE)

	Tissue	Protein	mRNA

CurH 13	215.5 ± 20.4[ac]	122 191 ± 21 171[ad]	0.1727 ± 0.0348[bd]	0.0518 ± 0.0057[d]	1.7250 ± 0.3026[bd]

[a]$P < 0.05$, [b]$P < 0.01$ *vs* control; [c]$P < 0.05$, [d]$P < 0.01$ *vs* TNBS acid (Dunnett's *t* test)

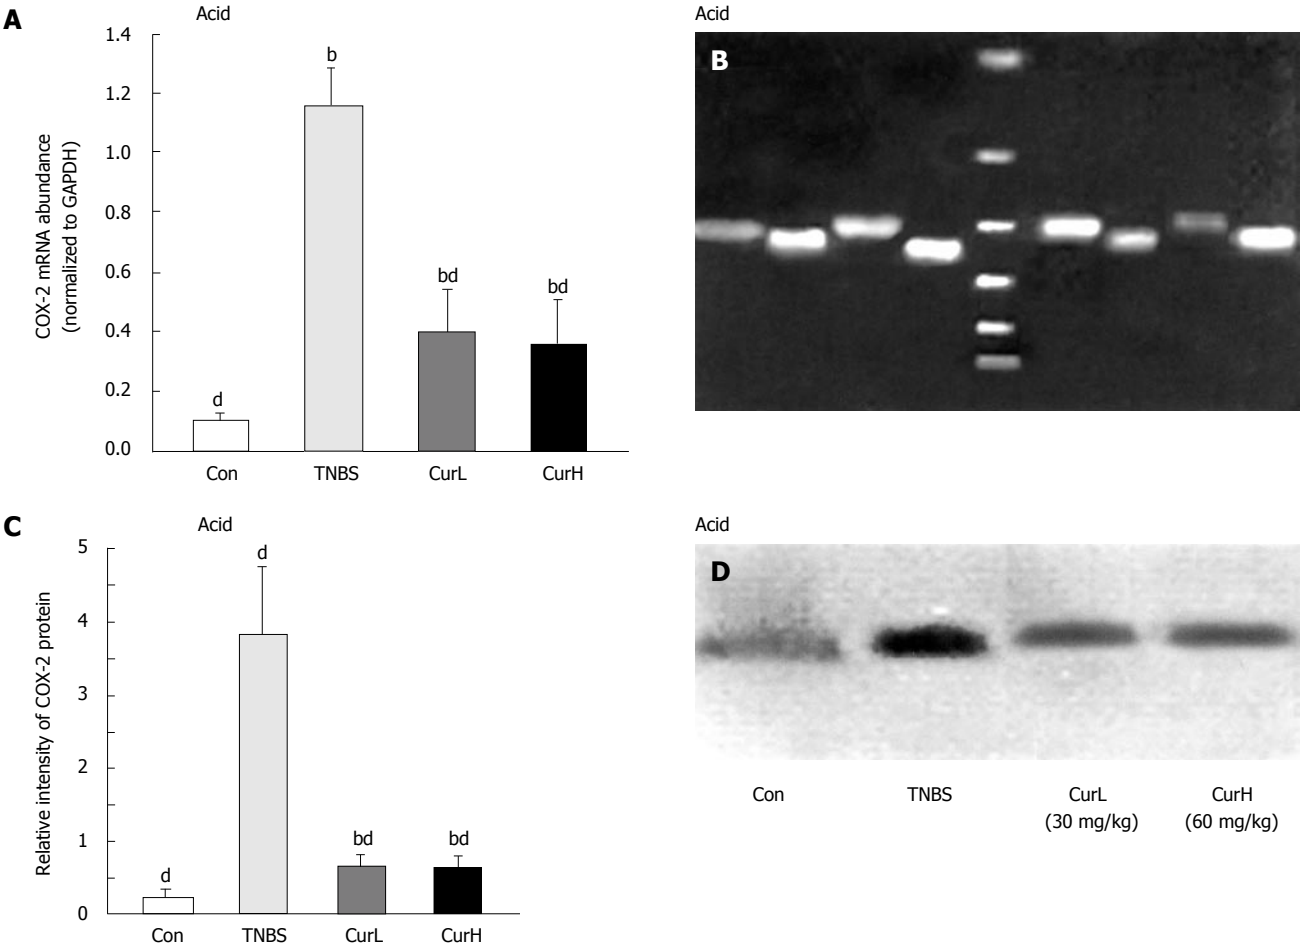

Figure 3 COX-2 expression in rats with TNBS acid-induced colitis. **A**: COX-2 mRNA; **B**: COX-2 products; **C** and **D**: COX-2 protein (M_r72 000) (mean ± SE, Dunnett's *t* test). [b]$P < 0.01$ *vs* control; [d]$P < 0.01$ *vs* TNBS acid.

TNBS acid, its expression increased by more than 10-fold. Treatment with curcumin decreased its expression by 70%, but was still higher than normal ($P < 0.05$). Western blot analysis showed the similar changes of protein in colon mucosa (Figure 3). After colitis was induced, PGE_2 decreased and its expression was increased after curcumin treatment.

Expression of inflammatory mediator genes

Abundance of IFN-γ, TNF-α and iNOS mRNA in TNBS acid group was significantly elevated compared with control group. Curcumin treatment suppressed the increased mRNA efficiently, but its level was still higher than normal (Table 1).

DISCUSSION

Treatment with curcumin (30 mg/kg or 60 mg/kg per day) reduced the severity and extension of damage induced by TNBS acid, decreased the extent of colitis and increased the survival rate and the incidence of adhesions. The rats treated with curcumin had improved histological image and less neutrophil infiltration in colon mucosa. The expression of COX-2 increased in acute and chronic colitis, suggesting that over-expression of COX-2 may result in neoplasia[13-17]. Curcumin exerts its antitumor and anti-inflammation effects by down-regulating COX-2 directly or indirectly[18]. Some reports indicate that selective COX-2 inhibitors exacerbate colitis[19-21], but others indicate that

they have therapeutic effects on colitis[22-26]. In our experiment, the expression of COX-2 increased in colon following the induction of colitis, suggesting that high expression of COX-2 in the colon is associated with high MPO activity and cytokine production. Curcumin decreased the level of COX-2, indicating that decreasing the expression of COX-2 may benefit to colitis.

PGE_2, an inflammatory mediator, participates in epithelium repairing and exerts anti-inflammation effects including suppression of neutrophil function or prevention of mast cell degranulation. Recently, PGE_2 has been implicated in the inhibition of the production of IFN-γ, IL-2 and IL-12[27]. It was reported that in early or acute inflammation phase the expression of PGE_2 is usually upregulated, resulting in inflammatory manifestations, such as redness, edema, pyrexia and ache[15,28]. Treatment with curcumin increased the expression of PGE_2 though its limiting enzyme COX-2 decreased, indicating that curcumin can change the expression spectrum of PGs in colitis.

TNBS acid-induced chronic intestinal inflammation mimics human Crohn's disease, showing high IFN-γ, TNF-α and iNOS, but low levels of IL-4 and IL-5[19,29]. Treatment with curcumin decreased IFN-γ, TNF-α and iNOS distinctly in our study, which is consistent with the reports of Ukil *et al*[11] and Sugimoto *et al*[9]. Since PGE_2 is capable of inhibiting Th1 cytokines, the decreased IFN-γ, TNF-α and iNOS in this study maybe due to PGE_2. Although curcumin decreased the expression of inflammatory response genes, but not decrease it to the normal level, suggesting that curcumin is not able to completely eliminate colitis.

Curcumin (30 mg/kg or 60 mg/kg per day) did not show any difference in the treatment of colitis induced by TNBS acid. Curcumin is also a chemopreventive drug for many tumors[18]. IBD patients are at risk of developing dysplasia and neoplasia. Phase I clinical trial of curcumin indicated that 8 g/d for 3 mo does not show any toxicity[30], suggesting that long-term administration of curcumin in IBD patients is not only safe but also improves colitis and prevents development of colorectal cancer.

In conclusion, curcumin attenuates TNBS acid-induced chronic colitis by decreasing the expression of COX-2 and increasing PGE_2. Curcumin can down regulate the expression of inflammatory genes in colitis induced by TNBS acid and is a safe and therapeutic agent for IBD patients

Abstract

AIM: To explore the expression of macrophage inflammatory protein-1α (MIP-1α) in Kupffer cells (KCs) following liver ischemia/reperfusion injury IRI in rats.

METHODS: Forty male SD rats were divided randomly into five groups. A model of partial warm ischemia/reperfusion injury in the rat liver was established. KCs were isolated and incubated one hour, six hours, 12 h, and 24 h after the reperfusion. Tumor necrosis factor alpha (TNF-α) and interleukin-1beta (IL-1β) in the supernatants were measured by ELISA. MIP-1α in KCs was detected by immunocytochemical and RT-PCR.

RESULTS: No or few MIP-1α protein and mRNA were expressed in the KCs of the control group. Its expression in the IRI group had a significant increase after the reperfusion ($P < 0.05$), which was contrary to the control group.

CONCLUSION: The active behavior of the MIP-1α gene in KCs following liver ischemia/reperfusion injury is assumed to be one of the major causes for the hepatic ischemia/reperfusion injury.

INTRODUCTION

Hepatic ischemia/reperfusion injury (IRI) is a common pathological process of traumatic surgical diseases in the liver, such as severe liver trauma, extensive hepatic lobus excision, liver transplantation, shock and infection[1]. It can cause a series of injuries on metabolism, structure, and function in hepatic tissues and cells, and even liver function failure. It is also one of the major factors influencing the prognosis, operative success and survival of patients. The mechanisms of liver injury caused by ischemia/reperfusion resemble those observed in other organs that are transiently deprived of oxygen. These mechanisms involve a series of events, including Kupffer cell (KCs) activation, cytokine release, neutrophil activation, increased expression of adhesion molecules, sinusoidal endothelial cell death, and hepatocyte injury[2]. Among these, the activation and the release of the excessive quantities of cytokine in the Kupffer cells play a major role.

Chemokines are members of a large and expanding family of proteins that interfere with normal (leukocyte homing, hematopoiesis, angiogenesis) and pathological (inflammation, HIV-1 infection, atherosclerosis) processes[3-7]. Depending on the positioning of the cysteine residues, chemokines are classified as C, CC, CXC and CX_3C chemokines. MIP-1α is from the CC (cysteinecysteine) chemokine subfamily. These soluble factors are chemotactic for specific types of leukocyte populations and are involved in the regulation of cell-mediated immunity[8]. MIP-1α is produced by monocytes, macrophages, lymphocytes, and other cell types[9]. CCR1, CCR4, and CCR5 are the known receptors that bind to MIP-1α[10]. In addition, it has been demonstrated that these CC chemokines can induce mononuclear macrophage to secrete TNF-α and IL-1β[11]. For all the significant roles that these CC chemokines play in immune and inflammatory responses, their role in the mechanism of hepatic ischemia/reperfusion injury is not well understood. Therefore, we established a model of rat hepatic ischemia/reperfusion injury at the room temperature, isolated the Kupffer cells at different times, that is, 0 h, 1 h, 6 h, 12 h and 24 h after the onset of reperfusion, to explore the expressions of MIP-1α protein and mRNA in the Kupffer cells following liver ischemia/reperfusion injury.

MATERIALS AND METHODS

Materials

Type Ⅳ collagenas and percoll were purchased from

Sigma, Inc, (USA). Triozol was from Invitrogen, Inc, (USA). RNA PCR Kit and DNA Maker were purchased from TaKaRa Biotechnology (Dalian) Co., Ltd. (China). Lysozyme, MIP-1α polyclonal antibody and SABC kit were purchased from Wuhan Borsd Biological Engineering Co., Ltd. (China). TNF-α and IL-1β ELISA kit were obtained from Shanghai Sengxiong Biotech Industry Co., Ltd. (China).

Animals

Male Sprague Dawley (SD) rats weighing 250-300 g were used in the study. They were obtained from the Experimental Animal Center of the Xi'an Jiaotong University. All animals were housed in a macroion cage in rooms maintained at a temperature of 22-24℃ using a 12/12-h light/dark cycle. The animals were given a standard rat chow and fasted overnight before the experiment with water allowed ad libitum. Care was provided in accordance with the procedure outlined in the "Guide for the Care and Use of Laboratory Animals" (NIH publication No.85-23, revised 1996). The study was approved by the subcommittee on research animal care at our institution.

Hepatic ischemia/reperfusion injury model in rats

Forty-eight SD rats were divided randomly into six groups: the sham operation group (control group) and the ischemia/reperfusion injury Ⅰ-Ⅴ group (IRI Ⅰ-Ⅴ group). The trial rats were starved for 12 h but were allowed to drink water. A model of the partial warm hepatic ischemia/reperfusion injury was established at room temperature by the Nauta *et al* method[12]. In the experiment, the rats were anesthetized with aether. The liver was exposed by a midline incision before operation. The left lateral and median hepatic lobes were occluded with a microvascular clamp for 45 min. After 45 min of ischemia, reperfusion was induced by removing the vascular clamp. 0 h, 1 h, 6 h, 12 h and 24 h after the reperfusion, the rats were killed to isolate the Kupffer cells at the same time. The sham control rats underwent the same treatment, but without vascular occlusion.

Kupffer cells isolation

With the reference to the collagenase perfusion technique described by Knittel *et al*[13], the Kupffer cells were isolated by an improved method. In the experiment, the liver was perfused for 30 min with D-Hank's containing 0.01% EDTA and removed to be smashed by scissors. The resulted stuff was digested for 45 min in a solution of 0.5 g/L type Ⅳ collagenase and was filtered through 200-mesh strainer. The filtrate was washed thoroughly and suspended in 3mL PBS, layered on 3 mL 25% percoll solution and 3 mL 50% percoll solution, centrifuged at 2500 r/min for 25 min to separate the cells. The cells between the layers of 25% percoll solution and 50% percoll solution were carefully extracted. The freshly isolated cells were suspended in DMEM medium supplemented with 25 mM HEPES, 10% fetal bovine serum, penicillin (100 U/mL), streptomycin (100 μg/mL), and L-glutamine (2 mmol/L). Cell suspensions (4 mL, 8×10^6 cells) were plated on 60-mm culture dishes and maintained in an incubator at 37℃ in a humidified atmosphere of 90% air-100 mL/L CO_2 for 1 h. The supernatants were discarded and the adherent cells were incubated for 4 h. The cellular components of adherent cells were examined by Lysozyme immunohistochemical staining to determine the percentage of Kupffer cells. The percentage of Kupffer cells in the adherent cells was over 90% (Figure 1). The cells were counted after the trypan blue exclusion. The viability of the cells was over 90% in the adherent cells. The Kupffer cells and supernatants were collected in all the groups and stored in refrigeration at -70℃ for subsequent analysis.

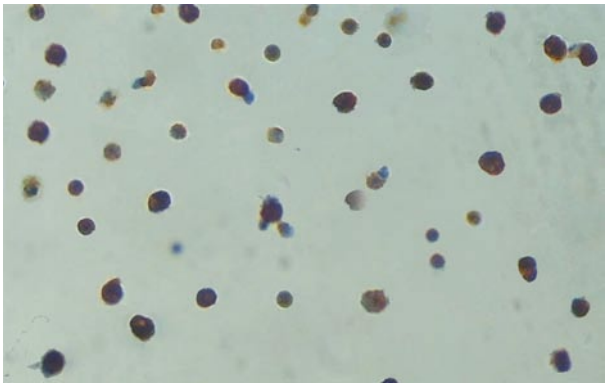

Figure 1 Lysozyme immunohistochemical staining of the Kupffer cells. The cytoplasms of the Kupffer cells were stained brown. The percentage of Kupffer cells in the adherent cells was over 90%.

Expression of TNF-α and IL-1β in supernatants

TNF-α and IL-1β in the supernatants of primary cultures of rat Kupffer cells were measured by TNF-α and IL-1β ELISA kits. The concentrations of TNF-α and IL-1 were estimated based on the absorbance read by an ELISA reader (EL800) at 450 nm.

Immunocytochemiscal detection of MIP-1α protein

Immunocytochemiscal staining of Kupffer cells was performed with the strept-avidin-biotin-peroxidase complex (SABC) method.[14] Kupffer cells adhered to glass slides were fixed with aether and ethanol. They were soaked in 30% hydrogen and pure methanol (1:50) for 30 min at room temperature. After incubation in normal goat serum blocking solution, the glass slides were incubated in rabbit anti-rat MIP-1α polyclonal antibody (1:200) at 4℃ overnight. PBS takes the place of MIP-1α antibody as the negative staining. Then the glass slides were incubated in biotined goat anti-rabbit IgG for 20 min at 20℃. Finally, the values of the mean optical density were measured under the same magnification using an image analysis system (original magnification × 400).

Determination of MIP-1α mRNA by semiquantitative RT-PCR

Total RNA was isolated from rat Kupffer cells using Trizol reagent. One microgram of RNA was reverse-transcribed to complement DNA using RNA PCR Kit according to the manufacturer's instructions. The PCR primers were synthesized on the basis of Gen-Bank data. The primers were chemically synthesized using DNA

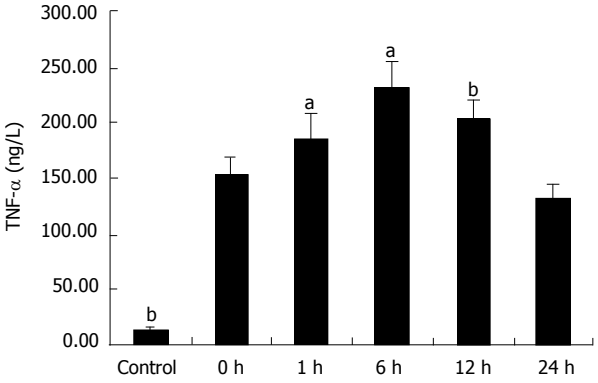

Figure 2 Comparison of TNF-α production in supernatant of Kupffer cells. (n = 8, mean ± SE, $^aP < 0.05$ compared with the next group, $^bP < 0.01$ compared with the next group.)

synthesizer (Tiangen Biotech Co., Ltd, Beijing China). Their sequences were 5'-TTTGAGACCAGCAGCCTTTG-3', 5'-GAAGAGTCCCTGGATGTGGC-3' for MIP-1α and 5'- CATAGACAAGATGGTGAAGG -3', 5'-TCCACAGTCTTCTGAGTGGC -3' for GAPDH. All the PCR reactions had an initial denaturation step at 94℃ for 3 min, and a final extension at 72℃ for 5 min using PTC-100 (MJ Research, Inc. USA.). The PCR amplification cycling conditions were 94℃ 30 s, 52℃ 30 s, 72℃ 30 s, 40 cycles for MIP-1α; 94℃ 30 s, 53℃ 30 s, 72℃ 30 s, 35 cycles for GAPDH. Following RT-PCR, 5 μL samples of amplified products were resolved by electrophoresis in 1.5% agarose gel, and stained with ethidium bromide. The intensity of each PCR product was semiquantitatively evaluated using the labworks analysis software (UVP, Inc, Upland, CA, USA.).

Statistical analysis

Results were expressed as mean ± SE. Statistical calculations were made using the SPSS10.0 software package. One-factor analysis of variance was applied to determine whether the differences among the three groups were statistically significant. In all the cases, P values lower than 0.05 were considered to be statistically significant.

RESULTS

Measurement of levels of TNF-α, IL-1β in supernatants

The cytokines released from the Kupffer cell were studied by ELISA. As shown in Figure 2, the concentration of TNF-α in the supernatant of primary cultures of rat Kupffer cells in the control group was 13.89 ± 2.04 ng/L and it increased at least ten times in IRI group I ($P < 0.01$). Following reperfusion injury stimulation, the TNF-α level was increased with time, and reached the maximum (230.6 ± 26.3 ng/L) 6 h after the stimulation ($P < 0.01$). Even 24 h after the reperfusion, the concentration of TNF-α (133.68 ± 12.15 ng/L) was still significantly high compared with that in the control group ($P < 0.01$). A comparison of IL-1β production in supernatant of Kupffer cells is shown in Figure 3. The concentration of IL-1β in the control group was 64.65 ± 4.63 ng/L and significantly increased with time, reaching its maximum (189.8 ± 13.13 ng/L) 6 h after the reperfusion ($P < 0.01$), and slightly declined (146.30 ± 11.90 ng/L) 24 h after the following reperfusion.

Measurement of the levels of MIP-1α protein in Kupffer cells

Figure 4 shows the immunohistochemical staining of the Kupffer cells that were isolated 12 h after the reperfusion of rat liver. The cytoplasms of these Kupffer cells were stained brown. On the contrary, in the control group, IRI group I and II, the Kupffer cells were not or weakly brown stained. We used an image analysis system to measure the values of the mean optical density of the Kupffer cells in all the groups and found the levels of MIP-1α protein in Kupffer cells had a significant increase at 6 h, 12 h and 24 h intervals ($P < 0.01$), which was contrary to the control group (Figure 5).

Expression of MIP-1α mRNA in Kupffer cells

PCR products were electrophoresed on agarosegels and photographed (Figure 6). The track numbered 1 is for the control group and the tracks numbered 2-6 are for the ischemia/reperfusion injury I-V group. The track marked M is for DNA maker. Quantitative data of MIP-1α mRNA levels in Kupffer cells were represented by the ratio of relative absorbance and expressed as mean ± SD (Figure 7). It showed that the Kupffer cells in the control group had low but detectable levels of MIP-1α mRNA. There was no statistical significance between the control group and the ischemia/reperfusion injury I group ($P > 0.05$). The MIP-1α mRNA level in Kupffer cells significantly increased with time, reaching its maximum 6 h after the reperfusion injury ($P < 0.01$), and slightly declined at 24 h interval but was still much higher than that in the control group ($P < 0.01$).

DISCUSSION

Hepatic ischemia/reperfusion injury is one of the major complications of liver resection surgery, transplantation, and hypovolemic shock[1,15]. The detailed biochemical mechanisms of liver injury caused by ischemia/reperfusion are complex and not well known till now. Several animal

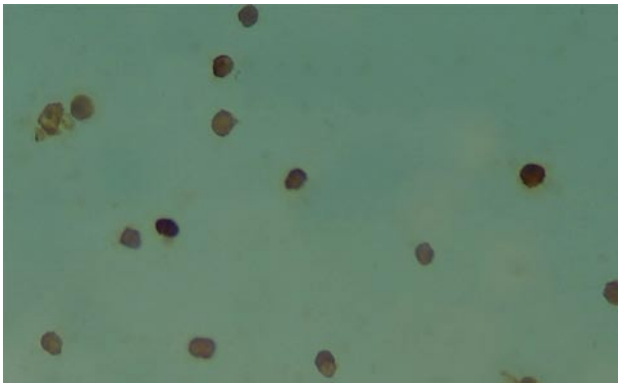

Figure 4 Immunohistochemical staining of MIP-1α in Kupffer cells in IRI group at 12 h's interval SP × 400.

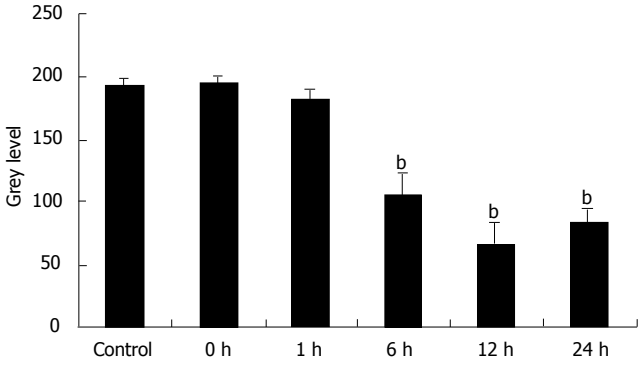

Figure 5 The synthesis of MIP-1α protein in Kupffer cells tested by immunohistochemical (n = 8, mean ± SE, $^bP < 0.01$ compared with control group).

modles were used to establish the pathological process of hepatic ischemia/reperfusion injury, such as the liver transplantation model, the partial warm or cold ischemia/reperfusion injury model and the total hepatic ischemia/reperfusion injury model[16-18]. In this study, the model of rat liver ischemia-reperfusion injury is established by the clamping and unclamping of the vessels to the left lateral and median hepatic lobes, which account for 70% of the rat's liver mass. This hepatic insult is similar to the clinical situation where the whole liver is rendered ischemic during total vascular exclusion (which is not tolerated in the rat) for liver resections. We determine the outcomes 0 h, 1 h, 6 h, 12 h and 24 h respectively after the onset of reperfusion, when a number of mechanisms began to function, such as the increase in the cytokine production, the enhanced oxidative metabolism, and the increase in phagocytotic activity, which contribute to the hepatic injury[1,2]. Therefore, the findings of the present research reveal the pathological process of both 'early and late' phase ischemia/reperfusion injury.

Kupffer cells play an important part in mediating ischemia and reperfusion injury. When activated during the ischemia and subsequent reperfusion, they generate excessive inflammatory cytokines and oxygen-derived free radicals, which play a particularly important role in the pathogenesis of hepatic ischemia and reperfusion injury[19]. In this study, low levels of TNF-α and IL-1β were detected in the supernatant of primary cultures of rat Kupffer cells

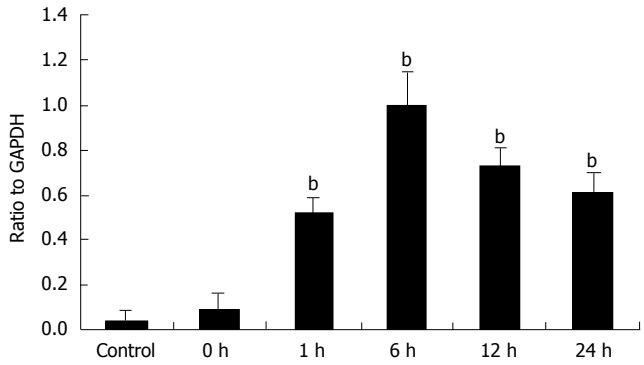

Figure 7 Quantitative data of MIP-1α mRNA levels (n = 8, mean ± SE, $^bP < 0.01$ compared with control group).

in the control group. At the early phase of the ischemia/reperfusion injury, they significantly increased and nearly reached its maximum. Twenty-four h after the reperfusion, these inflammatory cytokines were still significantly high compared with that in the control group. The mechanism of induction of TNF-α and IL-1β bioactivity after hepatic ischemia/reperfusion is complex. As a survival factor in hepatocytes under certain physiological conditions, for example, liver regeneration, Kupffer cells secrete low levels of TNF-α and IL-1β. During the very early phase of the

hepatic ischemia/reperfusion injury, the activated Kupffer cells produce high concentrations of TNF-α and IL-1β that represents the results obtained 0 h and 1 h after the reperfusion. The secretions of these toxic inflammatory cytokines precedes the activation of adhesion factors, chemotactic agents, and the sequestration of neutrophils in the liver and appear to be a key mediator of the inflammatory response to promote the release of other cytokines.

Kupffer cells are both a target and a source of chemokines. Therefore, we also examine the expression of MIP-1α, an important member of CC chemokine subfamily, in Kupffer cells in an ischemia/reperfusion injury. The MIP-1α proteins are not detected by immunocytochemiscal staining in the cells of the control group and IRI group I and II. Likewise, the synthesis of MIP-1α mRNA in the cells of the control group and IRI group I are not active. After the reperfusion injury, the expression of MIP-1α protein and mRNA significantly increase. This may indicate that the genes MIP-1α are inactive in normal Kupffer cells. Some inflammatory factors stimulate MIP-1α gene in Kupffer cells during the reperfusion injury. These findings are in agreement with those in the research by Bukara M *et al*[20]. The role of MIP-1α in the pathological process of hepatic ischemia/reperfusion injury is not well known. However, previous studies have proved that MIP-1α can induce mononuclear macrophage to secrete TNF-α and IL-1β[11]. Therefore, we suppose the active behavior of the MIP-1α gene in the Kupffer cell following liver ischemia/reperfusion injury is assumed to be one of the major causes for the hepatic ischemia/reperfusion injury.

In conclusion, our study focuses on the immediate, innate immune response of the Kupffer cells and demonstrates the prominent expression of MIP-1α in the Kupffer cells in the hepatic ischemia/reperfusion injury. These theories may provide a better understanding of the mechanisms of hepatic ischemia/reperfusion injury and will be useful for the therapies of hepatic ischemia/reperfusion injury in the fields of hepatic surgery, preservation, and rejection.

Abstract

AIM: To construct and produce a recombinant bispecific humanized single-chain Fv (sFv) /Interleukin-2 (IL-2) fusion protein by using mammalian cells.

METHODS: The sFv/IL-2 protein was genetically engineered, and transfected to mammalian cells to determine whether the mammalian protein folding machinery can produce and secrete active sFv/IL-2 with high efficiency.

RESULTS: The fusion protein was constructed and high efficiently expressed with yields up to 102 ± 4.2 mg/L in culture supernatant of the stably transfected 293 cell line. This recombinant fusion protein consisted of humanized variable heavy (V_H) and light (V_L) domains of monoclonal antibody (mAb) 520C9 directed against the human HER-2/neu (c-erbB2) proto-oncogene product p185, and human IL-2 connected by polypeptide linker. The fusion protein was shown to retain the immunostimulatory activities of IL-2 as measured by IL-2-dependent cell proliferation and cytotoxicity assays. In addition to its IL-2 activities, this fusion protein also possessed antigen-binding specificity against p185, as determined by indirect ELISA using p185 positive SKOV 3ip1 cells.

CONCLUSION: The large-scale preparation of the recombinant humanized sFv antibody/IL-2 fusion protein is performed with 293 cells. The recombinant humanized sFv antibody/IL-2 fusion protein may provide an effective means of targeting therapeutic doses of IL-2 to p185 positive tumors without increasing systemic toxicity or immunogenicity.

INTRODUCTION

Interleukin-2 (IL-2) is a 15 kD cytokine synthesized and secreted primarily by activated T cells[1,2]. IL-2 plays a central role in the augmentation of cell-mediated immune responses by stimulating and supporting a broad range of immune cells, including T and B cells, macrophages, and natural killer (NK) cells[3]. Furthermore, IL-2 can also stimulate the production of lymphokine-activated killer (LAK) cells, which are derived from NK cells and can effectively mediate antibody-dependent cellular toxicity. The administration of recombinant human IL-2 (rhIL-2), in combination with LAK cells, has been shown to be of value in the treatment of patients with advanced melanoma or renal cell carcinoma[4]. However, the *in vivo* efficacy of rhIL-2 treatment has been limited by its associated severe systemic toxicity and difficulties in maintaining prolonged high concentration of the cytokine in the tumor microenvironment, which is likely necessary to induce local anti-tumor immune responses[5,6]. To circumvent these problems, several approaches to selectively target IL-2 to tumor sites have been employed, particularly the use of immunoconjugates[7-9].

Murine monoclonal antibodies (mAbs) have been extensively used as carriers to target therapeutic agents to tumor sites for diagnostic and therapeutic modalities over the past decade. Despite some highly encouraging diagnostic data obtained with this approach, the general therapeutic efficacy has been rather disappointing[10-13]. Several major obstacles related to the mAb approach

have been identified, including relatively long half-life of the immunocomplex, human anti-mouse antibody (HAMA) response and inability of the immunoconjugate to penetrate large tumor masses[14,15]. To date, several approaches of engineering conventional murine mAbs have been developed for more effective cancer targeting therapy. One approach is the development of Fv portion of an antibody consisting of the VH and VL domains. This version of antibody is the smallest antibody fragment to bear the antigen binding site. Furthermore, the reports showed that a genetically engineered single-chain Fv(sFv) with binding activity could be produced by connecting the carboxyl terminus of one V domain to the amino terminus of the other with a flexible peptide linker[16]. Advantages of this small antibody fragment include improved clearance of immunocomplex from the circulation, better penetration in solid tumors and lower immunogenicity[17-20]. Other approaches include the development of recombinant immunotoxins and antibody-immunostimulatory molecule conjugates[21-24].

In this study we constructed genetically a recombinant bispecific fusion protein, sFv/IL-2 consisting of sFv and IL-2 portions. We hoped that this protein could target IL-2 to tumor sites to overcome those obstacles mentioned above. The kind of recombinant proteins could be generated in bacteria. But protein from bacteria is not active and must be solubilized, oxidized, and renatured *in vitro*. Even so it is impossible to avoid the loss of its bioactivities. A different approach to produce active fusion protein would be to use the more sophisticated refolding machinery that is located in the endoplasmic reticulum (ER) of mammalian cells. But, fusion proteins were usually expressed at very low level in mammalian cells thus it was not efficient for large-scale preparation[25-27]. For these reasons, we tried to find out an efficient mammalian expression system for the large-scale preparation of the recombinant humanized sFv antibody/hIL- 2 fusion protein[28], and an effective method for preparing the therapeutic doses of the fusion protein.

MATERIALS AND METHODS

Construction of expression plasmids

Mammalian expression plasmids encoding the humanized sFv antibody/IL-2 fusion proteins were constructed. Baculovirus expression plasmid pAcHCs-520C9sFv containing a humanized 816-bp 520C9 sFv cDNA fragment, and the plasmids pLW46 and plasmid pLW42 containing either wild type or mutant human IL-2 cDNA fragments, respectively, were kindly provided by Chiron Corporation (Emeryville, CA). The mutant human IL-2 cDNA contains a single base substitution at position 173 (G→C) which converts amino acid Cys 58 of the wild type protein to Ser, thus eliminating a disulphide bond critical to the biological function of IL-2. Primers used for the amplification of 520C9 sFv and human IL-2 cDNA fragments from the above plasmids were synthesized at the Institute for Molecular Biology (MOBIX), McMaster University (Hamilton, ON). The forward primer AB9883 (5'-CTT AAG CTT GCC ACC ATG GAC ATG AGG GTC CCC GCT-3') was used to amplify the sFv cDNA containing a Kozak consensus sequence prior to the initiating ATG and a terminal *Hin*dIII restriction site. The reverse primer AB7824 (5'-CC GAA TTC TTT AAT CTC CAG TTT TGT CCC TTG GGC-3') contained an *Eco*RI site 3' to the sFv cDNA fragment. The 440-bp mutant human IL-2 and wild type human IL-2 cDNA fragments derived from pLW42 and pLW46 were subjected to PCR amplification using the forward primer AB7822 (5' -GGG GAA TTC GGT GGC GGT GGC TCG GGC GGT GGT GGG TCG GGT GGC GGC GGA TCT ATG CCT ACT TCA AGT TCT ACA AAG AAA ACA CAG-3'), which contained a terminal *Eco*RI site and a coding sequence for a 15 amino acid, glycine rich linker peptide (NH_2-GGGGSGGGGSGGGGS-COOH) 5' to the human IL-2 cDNA fragment. The reverse primer AB4749 (5'-GAC CTC GAG TCA GTG TTG AGA TGA T-3') contained a terminal *Xho*I site adjacent to the termination codon of the human IL-2 cDNA fragment. PCR products were purified from 0.8% agarose gels and ligated into T-ended pBluescript using T4 DNA ligase (Gibco/BRL, Burlington, ON). The ligation mixture was then used to transform competent DH5α cells (Gibco/BRL). Plasmids with inserts were digested with *Hin*dIII and *Eco*RI for the sFv, or *Eco*RI and *Xho*I for the human IL-2 cDNA fragments. These cDNA fragments were purified from agarose gels using QIAGEN Gel purification kit (Qiagen, Chatsworth, CA) and ligated into the *Hin*dIII/*Xho*I site of the mammalian expression vector pcDNA3.1(+) (Invitrogen, San Diego, CA) to produce the recombinant plasmids pcDNA-H520C9sFv-hIL-2 and pcDNA-H520C9sFv-mhIL-2. Fidelity of the PCR-amplified constructs was confirmed by fluorescence-based double-stranded DNA sequencing (MOBIX). The ligation mixture was then used to transform competent DH5α cells. Transformants containing both the humanized 520C9 sFv and IL-2 cDNA fragments were confirmed by restriction enzyme analysis. The constructs were subsequently purified using QIAGEN plasmid Midi kits and dissolved in Tris-EDTA buffer (pH 7.4) to a concentration of 0.4 mg/mL.

Establishment of stable cell lines

The 293 cells used for stable expression of the cDNAs encoding H520C9sFv-hIL-2 or H520C9sFv-mhIL-2 were maintained in Dulbecco's modified Eagle's medium (DMEM) (Gibco/BRL) containing 10% fetal calf serum (FCS; HyClone Laboratories, Logan, UT) at 37℃ in a 50 mL/L CO_2 incubator. Cells grown to 20% confluency were transfected with 5 μg of the plasmid constructs using 30 μL of SuperFect transfection reagent (Qiagen) as described by the manufacturer. As a negative control, pcDNA3.1 (+) was used to transfect 293 cells under the same conditions. Stable transfectants were selected in DMEM containing 10% FCS and 600 μg/mL G418 (Gibco/BRL) for two weeks, after which the concentration of G418 was increased to 1.2 mg/mL. Clones secreting the H520C9sFv-hIL-2 fusion protein were identified by ELISA using either a mouse anti-human IL-2 mAb MAB202 (R&D Systems, Minneapolis, MN) or a rabbit anti-human IL-2 polyclonal antibody EP100 (Genzyme, Cambridge, MA). In brief, 100 μL of supernatant from different clones was

added to a 96-well plate coated with MAB202 (1:250 dilution), and incubated at 37℃ for 2 h. After three washes with PBST, the plate was incubated with EP100 (1:200 dilution) at 37℃ for 1 h, washed and then incubated with horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG polyclonal antibody (Gibco/BRL) (1:1000 dilution) for 1 h at 37℃. After three additional washes with PBST, colour development was performed with peroxidase substrate (Bio-Rad, Hercules, CA) and the resulting OD determined at 405 nm in a microplate reader (Bio-Tek Instrument Inc., Winooski, VT). Clones producing the highest amount of fusion protein were selected and grown in DMEM containing 10% FCS for 72 h. The conditioned medium was collected for subsequent precipitation and analysis.

Determination of concentration of fusion protein

The quantitative indirect ELISA was performed to determine the concentration of fusion protein of conditioned medium. A 96-well microtiter plate was coated with MAB202 (1:250 dilution), and incubated at 37℃ for 2 h overnight at 4℃. The 100 μL of serial diluted standard rhIL-2 and diluted conditioned medium were then added to each well, and incubated at room temperature for 2 h. After three washes with PBST, the plate was incubated with EP100 (1:200 dilution) at 37℃ for 1 h, washed and then incubated with horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG polyclonal antibody (Gibco/BRL) (1:1000 dilution) for 1 h at 37℃. After three additional washes with PBST, colour development was performed with peroxidase substrate and the resulting OD determined at 405 nm in a microplate reader as above.

Immunoprecipitation and purification of fusion proteins

H520C9sFv-hIL-2 and H520C9sFv-mhIL-2 fusion proteins were immunoprecipitated using MAB202 coupled with CNBr-activated Sepharose CL-4B (Pharmacia Biotech, Baie d'Urf, QC). Twenty-five microliters of a 1:1 (v/v) slurry of the absorbent suspended in 20 mmol/L Tris-HCl buffer (pH 7.8) were added to 1.5 mL of the conditioned medium with gentle shaking at 4℃ for 4 h. The Sepharose beads were washed three times using Tris-HCl buffer, then 50 μL of 1 × SDS-PAGE sample buffer containing β-mercaptoethanol was added to the beads. After heating at 100℃ for 3 min, the beads were pelleted by centrifugation and the supernatant collected for immunoblot analysis.

For affinity purification of the fusion protein, the conditioned medium was applied to an MAB202-Sepharose CL-4B affinity column at a flow rate of 5 column volume per h. The column was then washed three times with 20 mmol/L Tris-HCl buffer (pH 7.8) and the fusion protein was eluted with Pierce Gentle Ag/Ab Elution Buffer (Rockford, IL) as described by the manufacturer.

Immunoblot analysis

Twenty microliters of the above supernants were separated on a 15% SDS-polyacrylamide gel under reducing conditions. Proteins were electroblotted onto nitrocellulose membranes (Bio-Rad, Richmond, CA) and the efficiency of protein transfer was determined by staining the blots with Ponceau S (Sigma, St. Louis, MO). Membranes were washed briefly in TBST to remove the Ponceau S stain, blocked in TBST containing 5% skimmed milk at 4℃ overnight and incubated at room temperature for 2 h with EP100 (1:1000 dilution). Following three 20 min washes in TBST, the membranes were incubated for 2 h with an HRP-conjugated goat anti-rabbit IgG polyclonal antibody (1:2000 dilution). After washing in TBST, membranes were developed with the Renaissance Chemiluminescence Reagent kit (DuPont, Boston, MA) as described by the manufacturer.

IL-2 bioactivity assay

Biological activity of the fusion proteins was determined by standard IL-2-dependent CTLL-2 cell proliferation[2] and cytotoxicity assays[29]. CTLL-2 cells deprived of rhIL-2 (Chiron, Emeryville, CA) for 3 d were seeded into a 96-well plate at 1×10^4 cells per well and incubated with either serially diluted rhIL-2 standard or fusion protein at 37℃ in a 50 mL/L CO_2 incubator. After 24 h, 1 μCi of [^{3}H]-thymidine (DuPont, Boston, MA) was added to each well and the cells incubated for an additional 12 h. Cells were harvested onto glass fibre filters (Whittaker Corp., Walkersville, MD), dried and the incorporated radioactivity was counted in a Beckman scintillation counter (Fullerton, CA).

For bioactivity neutralization experiments, 2 ng/mL of rhIL-2 and the same concentration of IL-2 in H520C9sFv-hIL-2 were incubated with increasing concentrations of the anti-rhIL-2 neutralizing mAb MAB202 for 2 h at 37℃ in a 96-well microtiter plate. As a control, mouse IgG was added to H520C9sFv-hIL-2 instead of MAB202. Following this incubation period, 1×10^4 CTLL-2 cells were added to each well. The assay mixture, in a total volume of 100 μL/well, was incubated for 24 h at 37℃ in a 50 mL/L incubator and pulsed with 1 μCi/well [^{3}H]-thymidine for the final 12 h. The cells were then harvested onto glass fiber filters and [^{3}H]-thymidine incorporation was determined.

In the cytotoxicity assay, peripheral blood mononuclear cells (PBMCs) from healthy individuals were separated on a Histopaque 1077 density gradient (Sigma, St. Louis, MO). The PBMCs were cultured in RPMI 1640 medium (Gibco/BRL) supplemented with 10% FCS containing either 1000 IU/mL rhIL-2 or same dose of the H520sFv-hIL-2 fusion protein as determined by the above CTLL-2 assay for 3 d to produce LAK cells. Cytotoxicity of the resulting LAK cells was assessed by a 4 h Calcein AM (Molecular Probe, Eugene, OR) release assay with NK-resistant Daudi cells (ATCC, Rockville, MD) used as target cells. Each well of a 96-well plate contained 1×10^4 Daudi cells which had been pre-labelled with fluorescent Calcein AM. To achieve different effector/target cell ratios, an increasing number of LAK cells was added to each well. The total volume of culture medium per well was 0.1 mL. Following co-incubation of LAK and Daudi cells at 37℃ for 4 h, the cells were pelleted and the fluorescent intensity value ($Value_{sample}$) of 50 μL of cell supernatant from each well containing both types of cells was measured with a Cytofluor 2300 fluorescence reader system (Millipore,

Bedford, MA). The maximal release value ($Value_{maximal}$) of the fluorescent tag was determined by adding an equal volume of 1% (v/v) Triton X-100 to the wells with only target cells. The spontaneous release value ($Value_{spontaneous}$) of the tag was given by the fluorescent intensity of 50 μL of cell supernatant from the wells without any LAK cells. The percentage of specific lysis for each sample of LAK cells was calculated by the formula ($Value_{sample}$-$Value_{spontaneous}$)/($Value_{maximal}$-$Value_{spontaneous}$) × 100.

Determination and specificity of antigen-binding activity of H520C9sFv-hIL-2

Antigen-binding activity was measured by indirect ELISA using cultured SKOV3ip1. Human ovarian carcinoma SKOV3ip1 cells which express high levels of p185[30] were maintained in DMEM containing 10% FCS and used for determination of antigen-binding activity of the H520C9s-Fv-hIL-2 fusion protein. Cells (1×10^4) were added to individual wells of a 96-well microtiter plate one day before the assay. Serially diluted samples of the H520C9sFv-hIL-2 or a chemically-conjugated control mAb 520C9-rhIL-2 were added to each well of the plate and incubated at 37℃ for 2 h[31]. After three washes with PBST, EP100 (1:250 dilution) was added to the cells and incubated for 2 h. Following three washes with PBST, HRP-conjugated goat anti-rabbit IgG polyclonal antibodies (Gibco/BRL) (1:1000 dilution) were added to the cells. After 2 h incubation, the cells were washed three times with PBST, colour was developed with the addition of peroxidase substrate (Bio-Rad, Hercules, CA) and the OD of the solution was determined at 405 nm in a microplate reader as described.

To demonstrate specificity for p185 binding, SKOV 3ip1 cells (1×10^4) grown in 96-well plates were treated with either serially diluted intact 520C9 mAb or normal mouse IgG (0.001 to 10 nmol/L) at 37℃ for 2 h prior to the addition of 10 nmol/L H520C9sFv-hIL-2 fusion protein. Indirect ELISA was then performed as described above.

Statistical analysis

Data are presented as mean ± SD. Statistical differences between groups were determined by using Student's *t*-test. For all analyses, $P < 0.05$ was considered statistically significant.

RESULTS

Determination of concentration of the fusion protein

The concentration of conditioned media from 293 cells stably transfected with either pcDNA-H520C9sFv-hIL-2 or pcDNA-H520C9sFv-mhIL-2 were at 102.0 ± 4.2 or 101.0 ± 5.6 mg/L, respectively.

Detection of the IL-2 moiety in the fusion protein

To confirm the presence of the IL-2 moiety in the fusion protein, the MAB202 immunoprecipitates of conditioned media from 293 cells stably transfected with either pcDNA3.1(+), pcDNA-H520C9sFv-hIL-2 or pcDNA-H520C9sFv-mhIL-2 were analysed by Western blotting using EP100. As shown in Figure 1, a single band of

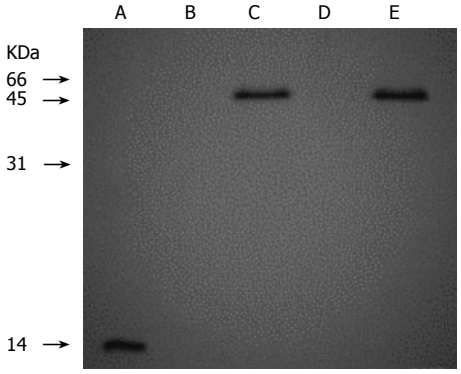

Figure 1 Western blot analysis of recombinant humanized sFv antibody/IL-2 fusion proteins stably expressed in 293 cells. Lane A: 0.5 μg of rhIL 2; Lanes B, C, D and E: The supernants from conditioned medium of 293 cells, 293 cells transfected with pcDNA-H520C9sFv-hIL-2, pcDNA3.1 (+) and pcDNA-H520C9sFv-mhIL-2, respectively. Samples were separated on a 15% SDS-polyacrylamide gel under reducing conditions, transferred to nitrocellulose membranes and immunoblotted using the anti-human IL-2 polyclonal antibody, EP100. The fusion proteins, H520C9sFv-hIL-2 and H520C9sFv-mhIL-2 were shown to migrate as single bands of 45 kD.

45 kD was observed in the conditioned media from 293 cells transfected with either pcDNA-H520C9sFv-hIL-2 (lane C), or pcDNA-H520C9sFv-mhIL-2 (lane E), but not in the culture supernatant of 293 cells (lane B) or the conditioned medium from 293 cells transfected with pcDNA3.1(+) (lane D). Furthermore, the migration positions of these fusion proteins on SDS-PAGE were consistent with their predicted molecular mass. As a positive control, EP100 also recognized rhIL-2 (lane A).

Cell proliferation and cytotoxicity assays

The activity of the H520C9sFv-hIL-2 fusion protein to support the proliferation of IL-2-dependent CTLL-2 cells and to generate LAK cells was compared to those of rhIL-2. As shown in Figure 2, conditioned medium from 293 cells transfected with pcDNA-H520C9sFv-hIL-2, but not pcDNA-H520C9sFv-mhIL2, possessed similar IL-2 bioactivity to rhIL-2 standard. These results indicated that the bioactivity of the IL-2 moiety in terms of its ability to support the growth of CTLL-2 cells was maintained in the H520C9sFv-hIL-2 fusion protein.

In the cytotoxicity assay directed against target Daudi cells, LAK cells generated by 1000 IU/mL of IL-2 of the H520C9sFv-hIL-2 fusion protein, as determined by the above CTLL-2 assay, demonstrated similar effect in the killing of Daudi cells compared to LAK cells activated by 1000 IU/ml of rhIL-2 (Figure 3). The specific lyses of Daudi cells by LAK cells stimulated by the H520C9sFv-hIL-2 and rhIL-2 were 79% and 77%, respectively, at an effector : target ratio of 125:1. No cytotoxic effect was observed when conditioned medium from control 293 cells transfected with pcDNA3.1(+) was used.

Neutralization of IL-2 activity in H520C9sFv-hIL-2

To determine if the proliferation effects of the H520C9sFv-hIL-2 fusion protein were strictly IL-2-dependent, inhibition studies using IL-2 neutralizing antibodies were performed. As shown in Figure 4A, the

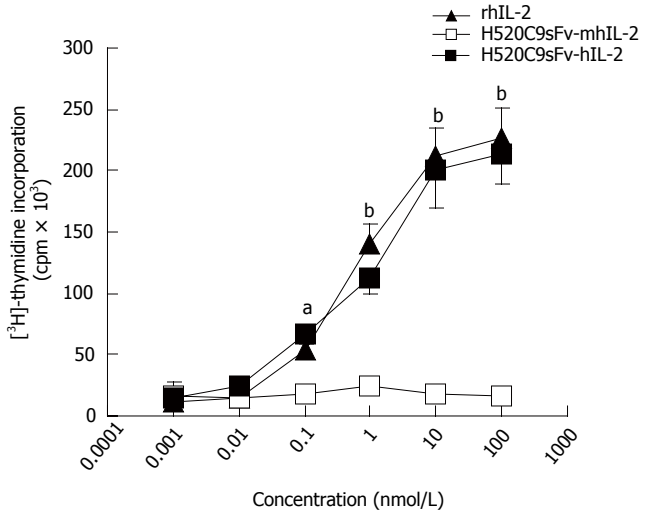

Figure 2 IL 2 activity of recombinant humanized sFv antibody/IL-2 fusion proteins. IL 2 activity of rhIL-2, or conditioned medium from 293 cells transfected with either pcDNA-H520C9sFv hIL 2 or pcDNA-H520C9sFv mhIL 2 was measured by [^{3}H] thymidine incorporation in CTLL 2 cells. The data are the mean ± SD from three separate experiments. $^bP < 0.01$ for rhIL-2 *vs* H520C9sFv mhIL 2, and $P > 0.05$ *vs* H520C9sFv hIL 2; $^aP < 0.05$ for rhIL-2 *vs* H520C9sFv mhIL 2, and $P > 0.05$ *vs* H520C9sFv hIL 2.

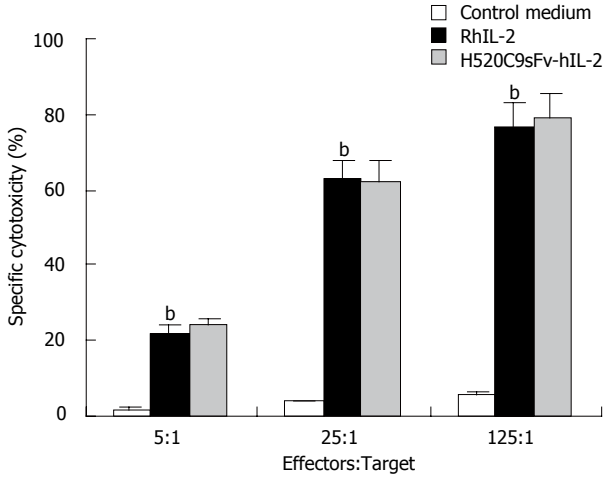

Figure 3 LAK cell-mediated cytotoxicity induced by H520C9sFv-hIL-2 fusion protein. Human LAK cells (effector) were generated by incubation of fresh PBMCs with either conditioned medium from control 293 cells transfected with pcDNA 3.1 (+), rhIL 2 or equivalent dose of H520C9sFv hIL 2. Lysis of Daudi cells (target) was determined using a 4 h Calcein AM release assay. The data are the mean ± SD from three separate experiments. $^bP < 0.01$ for rhIL-2 *vs* control medium, and $P > 0.05$ *vs* H520C9sFv hIL 2.

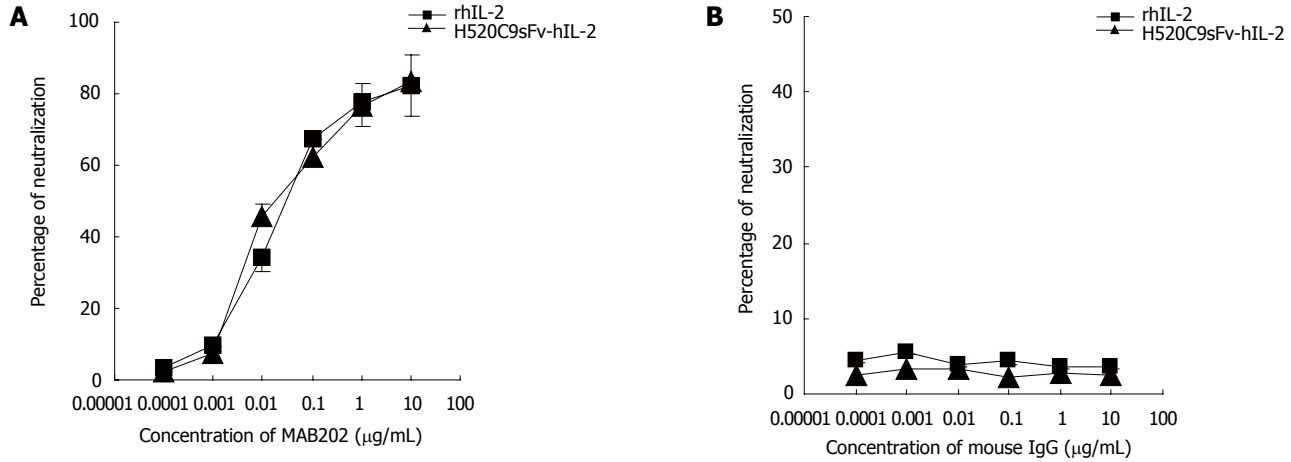

Figure 4 Inhibition of stimulatory effects of rhIL 2 or H520C9sFv hIL 2 on CTLL 2 cells by the anti human IL 2 neutralizing antibody, MAB202. Based on the molecular mass of either IL-2 or H520C9sFv-hIL-2 fusion protein, the neutralization dose 50 for 2 ng/ml rhIL 2 or the same dose of H520C9sFv hIL 2 was determined to be approximately 0.0176 and 0.022 μg/mL MAB202, respectively (**A**). No inhibitory effect was observed using control mouse IgG (**B**). The data are the mean ± SD from three separate experiments (**B**). **A**: $P > 0.05$ for rhIL-2 *vs* H520C9sFv hIL 2; **B**: $P > 0.05$ for rhIL-2 *vs* H520C9sFv hIL 2.

proliferative effects of both rhIL-2 and H520C9sFv-hIL-2 on CTLL-2 cells, as measured by [^{3}H]-thymidine incorporation of the CTLL-2 cells were inhibited by MAB202. Approximately 50% inhibition of [^{3}H]-thymidine incorporation for 2 ng/mL rhIL-2 or same dose of H520C9sFv-hIL-2 was achieved at an MAB202 concentration of approximately 0.0176 and 0.022 μg/mL, respectively. No inhibitory effect was observed when control mouse IgG was added (Figure 4B).

Antigen-binding assays

The antigen-binding specificity of the H520C9sFv-hIL-2 fusion protein was determined by indirect ELISA using SKOV 3ip1 cells, which overexpressed p185. As shown in Figure 5, the conditioned medium from 293 cells transfected with either pcDNA-H520C9sFv-hIL-2 or pcDNA-H520C9sFv-mhIL-2 displayed binding activity for p185 on the cell surface of SKOV 3ip1 cells. As a positive control, the parental 520C9 mAb chemically conjugated to rhIL-2 was shown to bind SKOV 3ip1 cells.

To confirm that the binding of H520C9sFv-hIL-2 fusion protein was specific for p185, SKOV 3ip1 cells were exposed to either the parental 520C9 mAb or normal mouse IgG prior to indirect ELISA. As shown in Figure 6, 520C9 mAb was able to inhibit the binding of the fusion protein to cells in a dose-dependent manner. In contrast, normal mouse IgG did not inhibit the binding of the fusion protein.

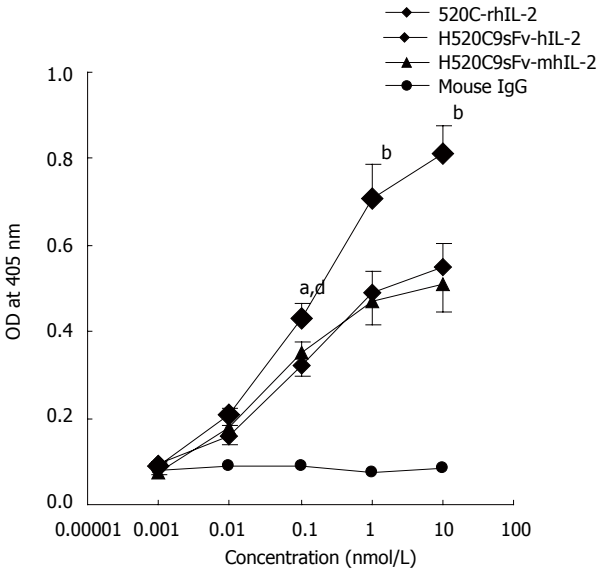

Figure 5 Determination of antigen-binding activity of H520C9sFv-hIL-2 fusion protein. Antigen binding activity was measured by indirect ELISA using cultured SKOV 3ip1. Bound fusion protein was recognised with the anti-human IL2 polyclonal antibody EP100. The fusion proteins, H520C9sFv-hIL-2 and H520C9sFv-mhIL-2 were shown to bind to p185 positive cells SKOV 3ip1. A chemically-conjugated molecule containing the intact parental 520C9 mAb and rhIL-2(520C9-rhIL-2) was used as a positive control. As a negative control, mouse IgG failed to show any binding activity. The data are the mean ± SD from three separate experiments. $^{b}P < 0.01$ *vs* mouse IgG; $^{b}P < 0.01$ for 520C9-rhIL-2 *vs* H520C9sFv-hIL-2 and H520C9sFv-mhIL-2; $^{d}P < 0.01$ *vs* mouse IgG; $^{a}P < 0.05$ for 520C9-rhIL-2 *vs* H520C9sFv-hIL-2 and H520C9sFv-mhIL-2.

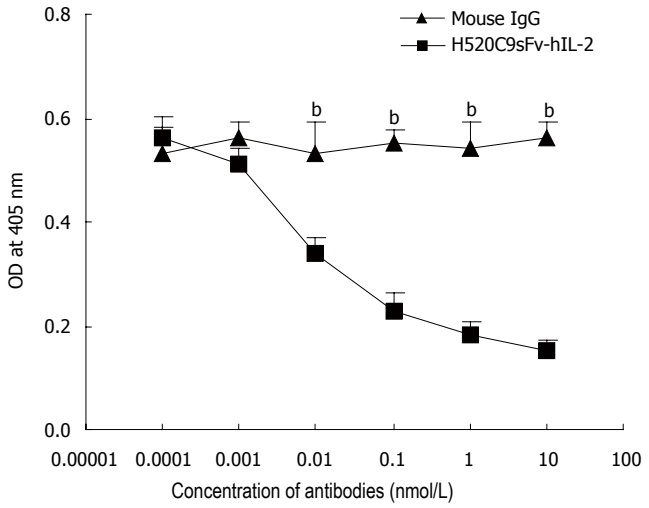

Figure 6 Anti-p185 mAb, 520C9, specifically blocks the binding of H520C9sFv hIL 2 fusion protein to SKOV 3ip1 cells. SKOV 3ip1 cells, pre-exposed to serially diluted intact 520C9 monoclonal antibody or to mouse IgG (0.0001 to 10 nmol/L), then incubated with 10 nmol/L H520C9sFv hIL 2 fusion protein. Bound fusion protein was measured by indirect ELISA using the anti human IL 2 polyclonal antibody, EP100. 520C9 mAb caused a dose-dependent decrease in the binding of the fusion protein to SKOV 3ip1 cells. Control mouse IgG had no effect on the binding of the fusion protein. The data are the mean ± SD from three separate experiments. $^{b}P < 0.01$ *vs* mouse IgG, $P > 0.05$ *vs* mouse IgG.

DISCUSSION

In this study, we report the construction, high efficient expression and characterisation of a recombinant humanized sFv antibody/hIL-2 fusion protein, H520C9sFv-hIL-2. The humanized sFv of 520C9 was constructed by introducing into a human sFv the amino acids from the complementarity-determining regions of mouse mAb 520C9, that recognize the HER/neu (c-erbB2) proto-oncogene product, p185[32]. Human IL-2 was then fused to the C-terminus of H520C9sFv by a flexible glycine linker. Following stable expression in 293 cells, this fusion protein was shown to retain both the immuno-stimulatory activities of IL-2 and the p185 binding characteristics of the parental 520C9 mAb. In the supernatant from stably transfected 293, the concentration of fusion protein cells was demonstrated to be at 102.0 ± 4.2 mg/L. This milligram scale expression makes it possible to prepare a large-scale fusion protein from mammalian cells, which is usually beneficial for keeping the bioactivities of fusion protein.

Our experiments demonstrated no loss of activity of IL-2 in the H520C9sFv-hIL-2 fusion protein as measured by IL-2-dependent cell proliferation and cytotoxicity assays, compared to rhIL-2 standard. This suggests that the fusion of IL-2 to the C-terminus of the humanized 520C9 sFv does not affect the biological activity of IL-2 and is consistent with previous studies describing the preparation of Fab'-IL-2 and SCA-IL-2 fusion proteins[33,34]. Retention of the IL-2 activity in H520C9sFv-hIL-2 may be partially due to the flexible glycine-rich linker between the C-terminus of sFv and the N-terminus of IL-2 which allows for proper folding of the IL-2 moiety, thereby enabling it to interact with its receptor. This is supported by previous findings with diphtheria toxin-IL-2 fusion proteins demonstrating the importance of the mobility of IL-2 in allowing its interaction to occur effectively[35].

We have developed a humanized sFv antibody/human IL-2 fusion protein, which was generated in mammalian cells with high efficacy and shown to retain both IL-2 activity and p185 binding affinity. The use of a humanized sFv as the fusion partner over other antibody-based molecules has the potential to reduce the immunogenicity of the fusion protein. In addition, the small size of the sFv fragment could likely improve its pharmacokinetic properties with respect to penetration of solid tumors and clearance. This bifunctional H520C9sFv-hIL-2 fusion protein may thus provide an effective method of targeting therapeutic doses of IL-2 to tumors or other targeted cells with significantly decreased side-effects of IL-2 and its immunogenicity.

Abstract

AIM: To evaluate the effect of three interventional treatments involving transvenous obliteration for the treatment of gastric varices, and to compare the efficacy and adverse effects of these methods.

METHODS: From 1995 to 2004, 93 patients with gastric fundal varices underwent interventional radiologic embolotherapy at our hospital. Of the 93 patients, 75 were treated with the balloon-occluded retrograde transvenous obliteration (BRTO) procedure; 8 were with the percutaneous transhepatic obliteration (PTO) procedure; and 10 were with the combined BRTO and PTO therapy. A follow-up evaluation examined the rates of survival, recurrence and rebleeding of the gastric varices, worsening of esophageal varices and complications in each group.

RESULTS: The BRTO, PTO, and combined therapy were technically successful in 81% (75/93), 44% (8/18), and 100% (10/10) patients, respectively. Recurrence of gastric varices was found in 3 patients in the BRTO group and in 3 patients in the PTO group. Rebleeding was observed in 1 patient in the BRTO group and in 1 patient in the PTO group. The 1- and 3-year survival rates were 98% and 87% in the patients without hepatocellular carcinoma (HCC) in the BRTO group, 100% and 100% in the PTO group, and 90% and 75% in the combined therapy group, respectively.

CONCLUSION: Combined BRTO and PTO therapy may rescue cases with uncontrollable gastric fundal varices that remained even after treatment with BRTO and/or PTO, though there were limitations of our study, including retrospective nature and discrepancy in sample size between the BRTO, PTO and combined therapy groups.

INTRODUCTION

Currently, various types of therapeutic procedures, including surgery, endoscopic procedures, and direct therapeutic intervention, are available for the treatment of gastric varices. Interventional therapy for gastric varices is classified as transjugular intrahepatic portosystemic shunt (TIPS) and transcatheter embolotherapy. Many studies have reported the use of TIPS in patients with gastric varices[1-5]. Although interventional embolotherapy has been applied for the treatment of gastric varices and a recent study has shown that embolotherapy may control gastric varices better than TIPS, treatment indications and a recommended embolotherapeutic strategy for the eradication of gastric fundal varices have not yet been strictly established[5-10]. In this study, we evaluated the effect of three interventional treatments involving transvenous obliteration for the treatment of gastric varices; the efficacy and adverse effects of these methods were compared. The present study involved 93 patients in whom interventional embolotherapy was performed as a treatment for gastric fundal varices. In addition, 10 of the 93 patients were treated with a combined balloon-occluded retrograde

transvenous obliteration (BRTO) and percutaneous transhepatic obliteration (PTO) therapy, and the clinical efficacy, the complications and outcomes of this therapy were investigated. The aim of this retrospective study was to evaluate the effect of interventional embolotherapy, in particular the clinical efficacy of combined therapy, for the treatment of patients with gastric fundal varices.

MATERIALS AND METHODS

Patients

From 1995 to 2004, 93 patients with gastric fundal varices underwent interventional radiologic embolotherapy at our hospital. The algorithmic strategy used for the treatment of gastric fundal varices in our hospital is shown in Figure 1. According to the treatment algorithm, all the patients were first treated with the BRTO procedure. When the BRTO procedure could not obliterate the gastric varices because of collateral venous drainage, the PTO procedure was chosen as the second line of treatment. When neither the BRTO nor the PTO procedure could obliterate the gastric varices, the patients were treated with a combination of BRTO and PTO as the third line of treatment. Of the 93 patients, 75 were treated with the BRTO procedure; 8 were with the PTO procedure; and 10 were with the combined therapy. The characteristics of the 93 patients are shown in Table 1. The study included 47 men and 46 women with a mean age of 63 years. Table 1 shows the underlying cause of portal hypertension, the presence of serum hepatitis virus markers, and modified Child's classification of the patients[11]. Left-side portal hypertension due to splenic vein obstruction after traumatic pancreatitis was observed in 1 patient. Patients with Child's class C cirrhosis with ascites were excluded from this study because interventional radiologic embolotherapy may increase the portal pressure[12]. Of the 93 patients, 37 (40%) underwent treatment of esophageal varices prior to treatment of gastric varices. 21 (23%) had complications due to hepatocellular carcinoma (HCC). Computed tomography (CT) or ultrasonography could be used to exclude the presence of portal tumor thrombus in all patients who had HCC. Patients with portal vein thrombus were excluded.

According to the classification system originally proposed by Sarin *et al*[13,14], gastric fundal varices are classified as type 2 gastroesophageal varices (GOV2; often long and tortuous, extending from the esophagus below the gastroesophageal junction toward the fundus) or type 1 isolated gastric varices (IGV1; varices located in the fundus that are often tortuous and complex in shape). In our study, 67(72%) patients showed IGV1 and 26 (28%) showed GOV2. The form of fundal varices was massively tumorous in 29 (31%) patients and nodular in 64 (69%).

Gastric fundal varices with active bleeding (spurting or oozing) or signs of recent bleeding or those that were in danger of rupturing were identified for treatment. Variceal bleeding was endoscopically confirmed in all patients immediately after their hematemesis. The bleeding episodes were attributed to ruptured gastric varices based on one of the following criteria: actively bleeding varices at the time of endoscopic examination, presence of adherent clots on varices, or presence of blood in the stomach with gastric varices as the only possible cause of the bleeding. The indications for gastric varices embolization in patients who have not previously had gastric variceal bleeding are as follows: gastric varices with red spots observed during upper intestinal endoscopy or growing gastric varices were considered to be in danger of rupturing.

Bleeding gastric varices were observed in 42 patients, and the remaining 51 patients were prophylactic nonbleeding cases that were in danger of rupturing. An emergency procedure was performed in 14 patients who had active bleeding during urgent endoscopy. To achieve temporary hemostasis, gastric variceal bleeding was treated in the following manner: endoscopic variceal ligation (EVL) in 6 patients, endoscopic injection sclerotherapy (EIS) using cyanoacrylate with lipiodol in 4 patients, clipping treatment in 6 patients, and balloon tamponade in 2 patients. Spontaneous hemostasis was achieved in the remaining 24 patients. Written informed consent was obtained from all patients.

BRTO procedure

Under local anesthesia, a 6.5-French occlusive balloon catheter with a diameter of 20 mm (Create Medic, Yokohama, Japan) was inserted through the femoral or internal jugular vein into the gastrorenal shunt, gastrocaval shunt, or both. Results of balloon-occluded retrograde transvenous varicerography (BRTV) were obtained in advance. Following identification of the gastric varices and their associated feeding and draining veins, the balloon was inflated with CO_2. When the gastric varices were visualized and retention of the contrast medium in the gastric varices was identified, a 50 g/L ethanolamine oleate (EO) solution with iopamidol (50 g/L EOI), which contained equal amounts of 100 g/L EO (Grelan, Tokyo, Japan) and iopamidol 300 (Schering, Berlin, Germany), was used as a sclerosant; the solution was slowly infused through the catheter into the gastric varices and their feeding veins in a retrograde manner during balloon occlusion under fluoroscopy. When varices and feeding veins could be shown in their entirety, injection was suspended. If draining minor collaterals were visualized by retrograde transvenous varicerography, microcoils were used in addition to 50 g/L EOI to embolize the collateral veins in order to prevent leakage of the sclerosing agent into the systemic circulation. After the sclerosant had remained in place for 1 h to allow thrombi formation, hemolyzed blood and excess uncoagulated sclerosant were collected through the catheter; subsequently, the balloon was deflated. Immediately prior to the treatment, 4000 U of haptoglobin (Welfide, Osaka, Japan) was administered by drop infusion to prevent renal damage induced by hemolysis due to the use of EO. The PTO procedure was chosen another day later on when retrograde venography showed that retention of the contrast medium was insufficient even though the collateral vessels had been embolized using metallic coils. (Figure 2A)

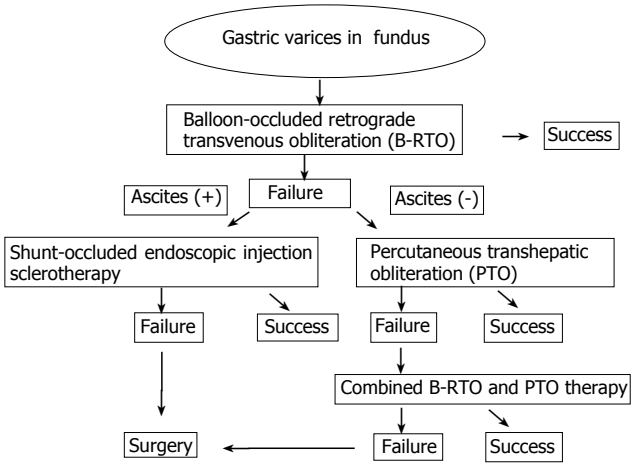

Figure 1 The algorithmic strategy for the treatment of gastric varices.

PTO procedure

We believe that the basic goal of embolotherapy in the treatment of gastric varices is to obliterate the variceal lumen and induce submucosal sclerosis. Therefore, in our hospital, PTO is used to obliterate gastric varices by using a sclerosing agent (50 g/L EOI); this procedure differs from the PTO procedure used previously[15]. Percutaneous transhepatic portography (PTP) using a 5-French catheter with a diameter of 11 mm was performed to determine the hemodynamics of the feeding and draining veins of the gastric varices. Due to the presence of multiple feeding veins, a coaxial catheter was inserted into these feeding veins. Some metallic coils were placed in these feeding veins with the exception of one feeding vein. The balloon catheter was selectively inserted into the remaining feeding vein. Through the balloon catheter, antegrade venography was performed with the balloon inflated. When the gastric varices were visualized and retention of the contrast medium in the gastric varices was identified, 50 g/L EOI, as a sclerosant, was slowly injected in the antegrade direction into the gastric varices under fluoroscopy. When varices could be shown in their entirety, injection was suspended. After the sclerosant had remained in place for 1 h to allow thrombi formation, the hemolyzed blood and excess uncoagulated sclerosant were collected through the catheter. Then, the microcoils were used to embolize the remaining feeding vein and to stabilize the thrombus

in the gastric varices. Portography was repeated to assess obliteration of the feeding veins and the absence of flow to the gastric varices. Immediately prior to the treatment, 4000 U of haptoglobin was administered by drop infusion. When antegrade venography showed that retention of the contrast medium in the gastric varices was insufficient, combined therapy was chosen (Figure 2B).

Combined BRTO and PTO therapy

The BRTO and PTO procedures were performed simultaneously. In other words, the feeding and the draining veins of gastric varices were simultaneously obliterated by the balloon catheters. Through the balloon catheter in the feeding vein, antegrade venography was performed with the double balloon inflated. When the gastric varices were visualized and retention of the contrast medium in the gastric varices was identified, 50 g/L EOI, as a sclerosant, was slowly injected in the antegrade direction into the gastric varices under fluoroscopy. When varices could be shown in their entirety, injection was suspended. After the sclerosant had remained in place for 1 h to allow thrombi formation, the hemolyzed blood and excess uncoagulated sclerosant were collected through the catheter. Immediately prior to the treatment, 4000 U of haptoglobin was administered by drop infusion (Figure 2C).

Evaluation of efficacy of the procedure and follow-up

A follow-up evaluation was performed to check for recurrence and rebleeding of the gastric varices, the aggravation of esophageal varices, complications, and rates of survival in each procedure group. CT was performed 1 wk after the procedure to evaluate obliteration of the gastric varices. Technical success was defined as complete clotting of the gastric varices that were observed during contrast-enhanced CT scanning 1 wk after the treatment. For patients in whom considerable blood flow remained, interventional embolotherapy was repeated until disappearance of blood flow within the gastric varices was confirmed. Initially, endoscopic examination was performed after 1 wk, 3 and 6 mo of the procedure to evaluate the obliteration of the gastric varices. Later, the examination was performed after every 6 mo or whenever clinically required. The laboratory data, including hepatic and renal function tests, were analyzed after 1 d, 1 wk, 1 and 6 mo of the procedure. When red spots on the esophageal varices were detected during endoscopy, the varices were considered to have aggravated and were treated endoscopically as soon as possible. The survival follow-up period was measured as the number of days from the date when interventional embolotherapy was performed until the date of the patient's death or the most recent clinical visit.

Statistical analysis

The cumulative survival rate and the nontreatment rate of esophageal varices were calculated using the Kaplan-Meier method, and the values were compared by means of the Wilcoxon signed rank test. Statistical software (Statview version 5.0; SAS Institute, North Carolina, USA) was used for statistical analysis. $P < 0.05$ was considered statistically significant.

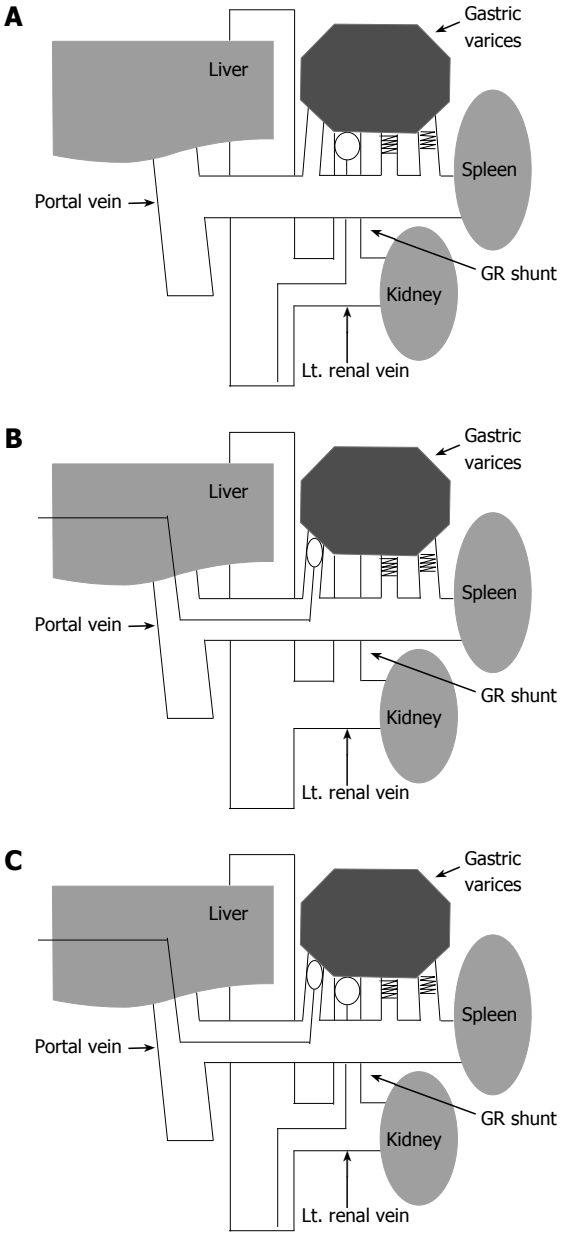

Figure 2 Illustration of radiologic embolotherapy for gastric varices. **A**: Balloon-occluded retrograde transvenous obliteration (BRTO); **B**: percutaneous transhepatic obliteration (PTO); **C**: combined BRTO and PTO therapy; GR = gastrorenal.

RESULTS

The mean observation period was 966 ± 677 d. The mean duration of hospitalization for the treatment of the gastric varices was 17 d. According to the treatment algorithm, the BRTO, PTO, and combined therapy were angiographically successful in 81% (75/93), 44% (8/18), and 100% (10/10) patients, respectively. The three-tiered treatment strategy used in this study enabled successful treatment of all the gastric fundal varices. In 68 of the 75 (91%) patients in the BRTO group, the gastric varices were completely thrombosed; this was shown by the CT that was performed 1 wk after the initial BRTO. The remaining

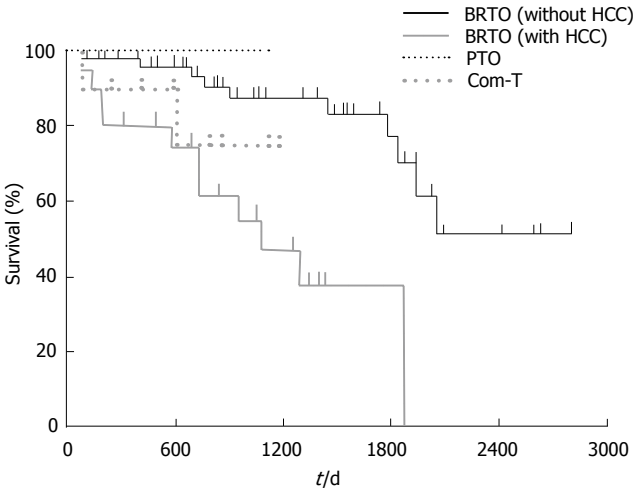

Figure 3 Cumulative survivals after radiologic embolotherapy for gastric varices.

7 (9%) patients who showed no improvement in the gastric varices, as indicated by CT, underwent an additional BRTO procedure. The BRTO procedure was performed twice on 5 patients, and three times on 2 patients with large gastric varices and dilated collateral veins. The overall BRTO technical success rate was 89% (68/75 + 5/7 + 2/2 = 75/84). In 18 patients who underwent variceal embolization by PTO alone or combined with BRTO, CT examination revealed that total obliteration of the gastric varices was achieved in all patients 1 wk after the initial procedure. According to the definition of technical success, the success rate was 91%, 100% and 100% in the BRTO, PTO and combined therapy.

During the follow-up period, recurrence of gastric varices was found in 3 patients (4%) in the BRTO group (1939, 1067, and 723 d after the BRTO procedure) and in 3 patients (38%) in the PTO group (1123, 574, and 150 d after the PTO procedure). In 3 patients in the BRTO group, the GOV2 type of recurrent gastric varices occurred after treatment of IGV1 with the BRTO procedure. Among the 3 patients in the PTO group, 2 had gastric varices of the GOV2 type, while 1 had gastric varices of the IGV1 type before the PTO procedure. In these 3 patients, the type of recurrent gastric varices was identical to those found prior to the PTO treatment. These recurrent gastric varices were strictly followed up without additional treatment. No variceal recurrence was found in the combined therapy group (Table 2).

Rebleeding was observed in 2 patients after treatment (1 patient had received the BRTO procedure and the other had received the PTO treatment). In 1 patient in the BRTO group, rebleeding from gastric varices was observed before the additional BRTO procedure because of incomplete obliteration of the varices by the initial treatment. The gastric varices of the patient were obliterated by the second BRTO procedure. In 1 of the 3 patients who had been noted to have recurrent gastric varices in the PTO group, the rebleeding occurred due to the recurrence. The patient refused additional interventional embolotherapy and underwent Hassab's devascularization after initial hemostasis by an endoscopic procedure[16]. In the combined group, no rebleeding was found.

After the BRTO procedure, the 1- and 3-year survival rates were 92% and 75%, respectively. The 1- and 3-year survival rates were 98% and 87% in the patients without HCC in the BRTO group, 100% and 100% in the PTO group, and 90% and 75% in the combined therapy group, respectively. There was no significant difference across the three groups. On the other hand, the 1- and 3-year survival rates were 80% and 47% in the patients with HCC in the BRTO group. The survival rate after the BRTO procedure was significantly higher in the patients without HCC than in those with HCC ($P < 0.01$, Figure 3).

During the follow-up period, 21 patients in the BRTO group and 2 patients in the combined therapy group died; however, no patients in the PTO group died. Death due to hepatic failure occurred in the case of 8 (11%) patients in the BRTO group (range, 91-2056 d; median, 743 d) and 1 (10%) patient in the combined therapy group (605 d after the procedure). No significant difference was observed among the three procedures. The other causes of death in the BRTO group were hepatocellular carcinoma, cerebral hemorrhage, renal failure (due to diabetes mellitus), and pneumonia. In the combined therapy group, 1 patient died from psychosis 83 d after the procedure (Table 2).

All three procedures caused adverse effects, such as fever (> 38.0℃), hemoglobinuria, abdominal pain, chest pain, nausea, and blood pressure elevation. On the other hand, ascites, pleural effusion, headache, and hepatic encephalopathy were detected in the BRTO group. No fatal complications were observed (Table 3). We have reported the change in the hepatic and renal function tests in patients treated with the BRTO procedure[17]. In terms of laboratory data, there was no difference in the three procedures. The esophageal varices aggravated in 27 (36%) patients in the BRTO group and in 3 patients

Table 3 Complication of treatment *n* (%)

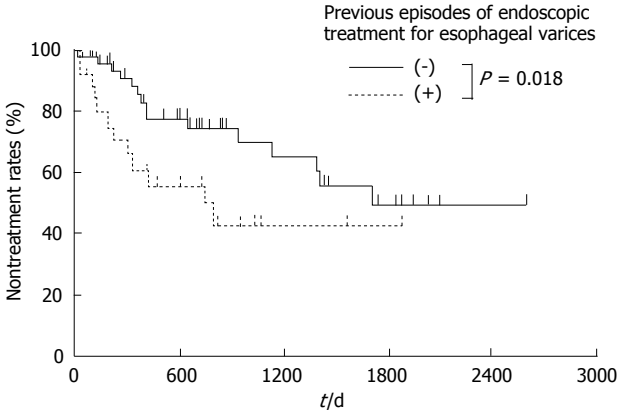

Figure 5 Cumulative non-treatment rates for esophageal varices after balloon-occluded retrograde transvenous obliteration.

in each of the PTO (38%) and combined therapy groups (33%). These were treated using the usual methods of EVL and EIS. During the course after the procedures, the cumulative nontreatment rates of esophageal varices at 1 year were 79%, 73%, and 77% in the BRTO, PTO, and combined therapy groups, respectively. There was no significant difference in the three procedures (Figure 4). The nontreatment rates of esophageal varices in the BRTO group at 1 and 3 year were 61% and 42% in the patients with esophageal varices and 86% and 70% in the patients without them prior to BRTO, respectively. The cumulative nontreatment rates of esophageal varices in the BRTO group were significantly lower in the patients with esophageal varices than in the patients without them prior to BRTO ($P < 0.01$, Figure 5).

DISCUSSION

Since Kanagawa *et al*[18] reported the treatment of gastric varices by BRTO with 50 g/L EOI, BRTO has been widely accepted as an interventional embolotherapy for gastric varices in Japan. Subsequently, many reports demonstrated the clinical efficacy and safety of this treatment[6-9]. According to several reports, the therapeutic result obtained by this treatment is satisfactory and the recurrence rate is very low. In our study, the BRTO procedure was angiographically successful in 81% (75/93) patients; hence, our results are consistent with those reported previously[9,10,19]. Recurrence of gastric varices was found in only 3 of the 75 patients who had undergone the BRTO procedure. In all 3 patients, the GOV2 type of recurrent gastric varices occurred after treatment of IGV1 with the BRTO procedure. Gastric varices that are classified as GOV2 have a direct connection with the coronary vein and esophageal varices. The aggravation of esophageal varices caused by damage of portal hemodynamics after the BRTO procedure has been well documented. It appeared that the mechanism of these recurrent gastric varices was similar to that observed in the aggravation of esophageal varices.

The BRTO procedure is applied to gastric varices that have a portosystemic shunt route to the inferior vena cava. Some gastric varices without a major shunt or those with many small collateral circulations are difficult to treat by the BRTO procedure. Reports of the refractory varices treated with the BRTO procedure are rare[10,20,21]. Thus, an adequate treatment strategy for refractory gastric varices has not yet been established. We performed the PTO procedure for uncontrollable gastric varices treated by the BRTO procedure. The first report on the treatment of gastric varices by the PTO procedure was described by Scott *et al* in 1976[15]. Since the previously used PTO procedure could obliterate inflow vessels but could not easily obliterate gastric varices completely, it was associated with a high incidence of rebleeding and recurrences. Our PTO procedure would fill the lumen of the gastric varices with the sclerotic agent in an antegrade manner by stopping the inflow into varices using coils and a balloon catheter that is wedged in an antegrade manner. EO, an anionic surfactant, infiltrates and destroys the cell membrane of venous endothelial cells. Damage to the venous endothelium caused by EO is greater than that caused by a 50% glucose solution. Therefore, EO causes thrombus formation in gastric varices, and gastric varices thrombosed by EO have been reported to be completely disappeared[6-9]. The PTO procedure that we used is the same as BRTO in that the gastric varices are thrombosed.

In this study, the PTO procedure rescued only 44%

(8/18) patients who had uncontrollable gastric varices treated by the BRTO procedure. To block the gastric variceal blood flow, the PTO procedure, which involves the catheterization of the only feeding vein, may be less effective than the combined therapy. It is probable that the antegrade procedure could obliterate the feeding vein but could not completely and easily obliterate the varices with a large draining vein. The patients in the PTO group had more minor collateral circulation, such as pericardial or hemiazygous veins, as compared with the patients in the BRTO group.

The indication for the PTO procedure with 50 g/dL EOI was the presence of gastric varices without large draining veins and varices untreated by BRTO because of many small collateral veins. In the PTO group, the gastric varices recurred in 3 patients with incomplete eradication; bleeding occurred in 1 of these patients. It appeared that the therapeutic efficacy of the PTO procedure was incomplete for uncontrollable gastric varices treated by the BRTO procedure.

Some of the patients who underwent attempted BRTO had no embolization performed at all *via* antegrade route because of unfavorable anatomy whilst others had some embolization with coils and/or sclerosant. We performed the combined BRTO and PTO therapy on patients in whom uncontrollable gastric varices had been treated by the BRTO procedure and the PTO procedure. Reports on the varices that had been treated with combined therapy, which obstructs both the feeding and the draining veins of the varices, are rare. Kimura *et al*[22] reported a case of rectal varices that was treated with double balloon-occluded embolotherapy in 1997. Similarly, Ota *et al*[23] reported the results of combined therapy comprising BRTO and transileocolic vein obliteration (TIO) in a patient with duodenal varices. Kiyosue *et al*[24] suggested that the indication for combined therapy was the presence of gastric varices that are supplied by single or multiple gastric veins with coexistent gastric veins that are directly contiguous with the shunt but do not contribute to the varices. However, to the best of our knowledge, there have been no studies on the treatment of gastric varices by combined BRTO and PTO therapy. In our study, the therapeutic result of the combined therapy was satisfactory. No bleeding or variceal recurrence was found in the combined therapy group.

Combined therapy, which can obstruct both the feeding and the draining veins of gastric varices to retain the sclerosing agent completely in the varices, may provide a better control of the gastric variceal blood flow than that provided by the only BRTO or PTO procedure. Our study demonstrates that combined therapy is very effective in the treatment of gastric varices, irrespective of whether patients have had a large gastrorenal shunt and/or collateral circulation. Since the combined therapy may eliminate the hemodynamics of gastric varices, this procedure may be more effective than other procedures. In fact, the obliteration of the gastric varices by this method was successful in all 10 patients in whom the BRTO or PTO procedure was unsuccessfully performed.

Although only the femoral or internal jugular vein is punctured in the BRTO procedure, the combined therapy or the PTO procedure requires a puncture in the liver. Therefore, the BRTO procedure is less invasive than the other procedures. Since the combined therapy appears to be similar to the BRTO procedure in terms of safety and efficacy, we propose that the BRTO procedure should be the first choice of the treatment for gastric varices. The combined therapy should only be performed in the case of highly selected patients. We believe that the indication for combined therapy is refractory gastric varices that remain untreated despite being subjected to the BRTO and PTO procedures. In addition, the PTO procedure is less invasive than the combined therapy, because the femoral or internal jugular vein is not punctured in this procedure. Thus, the results presented here indicate that the algorithmic strategy for treating gastric varices using the BRTO and PTO procedures and the combined therapy is feasible (Figure 1).

These three procedures for obliterating the gastric varices may increase the portal pressure. Aggravation of the esophageal by these treatments varices was recognized to be a result of elevated portal pressure. From the viewpoint of aggravation of esophageal varices, no statistical differences were demonstrated among the three procedures. However, non-treatment rate of esophageal varices after the BRTO was significantly lower in those who were treated esophageal varices before BRTO than those not treated. Our results are consistent with those reported earlier[19]. Periodic endoscopic follow-up is recommended after the eradication of gastric varices, particularly in patients with esophageal varices prior to the BRTO procedure. The mortality rate for gastric variceal bleeding is much higher than that for esophageal variceal bleeding[25]. Therefore, we believe that these changes in the portal hemodynamics were preferable because esophageal varices can be easily controlled by endoscopic therapy.

In conclusion, combined BRTO and PTO therapy may rescue cases with uncontrollable gastric fundal varices that remained even after treatment with BRTO and/or PTO. Our study could establish the algorithmic strategy for treating gastric fundal varices using interventional embolotherapy. However, there were limitations of our study, including retrospective nature and discrepancy in sample size between the BRTO, PTO and combined therapy groups. Further, long-term prospective studies would assist in clarifying the effect of combined BRTO and PTO therapy.

Abstract

AIM: To assess the late outcome of teen-agers with a previous history of recurrent abdominal pain (RAP) or irritable bowel syndrome (IBS).

METHODS: A group of 67 children with RAP referred to the department from January 1986 to December 1995 was followed up between 5 and 13 years after the initial diagnosis by means of a structured telephone interview. We hypothesized that those patients with persistent adult IBS-like symptoms would be significantly more likely to report a family history of IBS in comparison with adults with no persistent abdominal complaint.

RESULTS: Out of the 52 trackable subjects, 15 were found to present IBS-like symptoms at follow-up (29%) whereas the majority (37 subjects) did not. Subjects with IBS-like symptoms were almost three times more likely to present at least one sibling with similar symptoms compared to subjects not complaining (40.0% *vs* 16.0%), respectively ($P < 0.05$ at Student t test). Subjects with IBS-like symptoms also reported a higher prevalence of extra-intestinal symptoms, such as back pain, fibromyalgia, headache, fatigue and sleep disturbances.

CONCLUSION: The study confirms previous observations indicating that pediatric RAP can predict later development of IBS. The latter appears to be greatly influenced by intrafamilial aggregation of symptoms, possibly through the learning of a specific illness behavior.

INTRODUCTION

Recurrent abdominal pain (RAP) is characterized by three or more episodes of abdominal pain that occur over at least three months and are severe enough to interfere with activities, such as school attendance and performance, social activities, and participation in sports and extracurricular activities[1].

RAP is common, affecting between 7% to 25% of school-aged children and adolescents[2,3], and may be responsible for 2% to 4% of pediatric office visits[4]. RAP becomes more prevalent with increasing age into adolescence[1,5-7] and is more common in girls[2,8] with an equal gender ratio in early childhood[3,9], but greater female symptom reporting in late childhood and adolescence[1,7,10]. Specific structural, infectious, inflammatory, or laboratory abnormalities are unusual in RAP, particularly in the absence of "red flags" such as weight loss, gastrointestinal bleeding, pain awakening the child at night, systemic symptoms such as fever, or laboratory evidence of anemia or inflammation[11].

Medically unexplained RAP is often considered to be a functional gastrointestinal disorder (FGD), a condition defined as a variable combination of chronic or recurrent gastrointestinal symptoms in the absence of explanatory structural or biochemical abnormalities[12]. Irritable bowel syndrome (IBS) is a FGD characterized by recurrent abdominal pain or discomfort occurring over a 3-mo period, where the symptoms are relieved by defecation and/or are associated with changes in stool frequency or consistency[13].

Implications of pediatric RAP across the lifespan are not well understood. Early follow-up studies have reported

persistence of recurrent abdominal pain into adulthood for one third to one half of affected children[14-16], but are limited by the lack of standardized assessments and formal diagnostic criteria. In more recent studies using standardized assessments and control groups, former RAP patients reported significantly greater abdominal pain, other somatic symptoms, functional impairment, health service use, and internalizing psychiatric symptoms in comparison to controls at 5-year follow-up, and females with a history of RAP are significantly more likely to meet diagnostic criteria for IBS[17,18]. A large, population-based cohort study of adults born in 1946 in the United Kingdom compared the 2% of the sample who consistently reported medically unexplained abdominal pain at ages 7, 11, and 15 years with study participants without a history of chronic abdominal pain on the basis of standardized assessments when participants were 36 years old. Persistent abdominal pain in childhood is significantly associated with an increased risk of psychiatric disorder in adulthood, but not with abdominal pain or headache once psychiatric disorder is controlled for in the regression[19].

In this study, a group of children with RAP or IBS was followed up between 5 and 13 years after the initial diagnosis. We hypothesized that those patients with persistent adult IBS-like symptoms would be significantly more likely to report a family history of IBS in comparison with adults with no persistent abdominal complaint.

MATERIALS AND METHODS

Case identification and recruitment

Potential patients were identified from clinical records of the Pediatric Department at the "L. Sacco" University Hospital of Milan. Charts of children referred to the department from January 1986 to December 1995 were retrieved, searching those children aging between 4 and 14 years at the time of index visit and referred because at least three episodes of medically unexplained abdominal pain occurred and they had an established a diagnosis of RAP or IBS. Criteria for inclusion included: Those proposed for RAP by Apley & Naish in 1958 and revised by Hyams JS *et al*[6], e.g. at least 3 episodes of medically unexplained abdominal pain occurring during a period of at least 3 months that were severe enough to affect the activities of the child or those proposed for IBS by the Rome II Working Party[13], e.g. in children old enough to provide an accurate pain history, at least 12 wk, even not consecutive, in the preceding 12 mo of abdominal discomfort or pain with two out of the following three features: relieved with defecation, and/or onset associated with a change in frequency of stool, and/or a change in form (appearance) of stool, and no structural or metabolic abnormalities[13].

Criteria for exclusion included: abdominal pain with atypical features, symptoms, or findings suggestive of physical disease (e.g. abnormal physical examination or laboratory findings, persistent vomiting, gastrointestinal bleeding, constitutional symptoms such as fever or weight loss), acute or chronic physical disease, and development disability. There were 67 patients identified who fulfilled the diagnostic criteria for either RAP or IBS.

An effort to contact by telephone the potential participants to the study was made, at an interval between 5 and 13 years after the index visit. However, 13 patients could not be tracked, because of change of address or available number incorrect, 1 because already deceased, and 1 because of interview refusal. Thus, data were available for 52 subjects (contact rate: 88%), with only 1 subject declining to participate (refusal rate: 1.5%).

Table 1 Demographic and other clinical features of individuals with or without IBS at follow-up

	IBS symptoms ($n = 15$)	No IBS ($n = 37$)	*P* value
Mean age (yrs) at index diagnosis	7.7	6.2	> 0.05
Female/male	9/6	19/18	> 0.05
Mean duration of follow-up (yr)	8.4	8.6	> 0.05
Siblings with IBS (%)	40	16	< 0.05
Extra-intestinal symptoms (%)	47	13.5	< 0.05
Body mass index	19.9	18.9	> 0.05

The telephone interview was done by two of us (*ZG* and *DGS*) unaware of the index diagnosis of the subjects. A structured questionnaire was used, developed for the purpose of the study, asking very simple questions, as for example actual weight and height, presence or absence of abdominal complaints, presence or absence of siblings with similar complaints, *etc*. In case of affirmative answer to the question regarding presence of abdominal complaints, the interviewer specifically asked the questions 20 to 27 from the Rome II Modular Questionnaire[20], relating to a better characterization of bowel and abdominal pain symptoms, respectively, translated and linguistically adjusted for Italian people. Finally, the severity of dominant abdominal symptom as well as the impact on work/school/sport activities were assessed by using an 1-100 analogue scale. If one sibling was identified as suffering from abdominal complaints as well, then an effort was made to verify this information by a subsequent direct telephone to him or her, and the same questions were asked in case of confirmation.

No payment or other revenge was offered to subjects who agreed to participate in the study.

RESULTS

Fifteen subjects were found to present IBS-like symptoms at follow-up (29%) whereas the majority (37 subjects) did not. The demographics and other clinical features of IBS patients and non-patients at follow-up are presented in Table 1.

Subjects with IBS-like symptoms were almost three times more likely to present at least one sibling with similar symptoms compared to subjects not complaining (40.0% *vs* 16.0%), respectively ($P < 0.05$ at Student *t* test). Not surprisingly, subjects with IBS-like symptoms reported a higher prevalence of extra-intestinal symptoms, such as back pain, fibromyalgia, headache, fatigue and sleep disturbances.

Table 2 shows the features of the 15 subjects with IBS-like symptoms in more detail. Two thirds of the patients reported abdominal pain as opposed by one third only re-

Table 2 Clinical features of the15 subjects with IBS-like symptoms at follow-up

Symptoms	%
Predominant abdominal pain	67
Predominant abdominal discomfort	33
Alternating diarrhea/constipation	15
Severity of dominant symptom (1-100)	50
Limitation in school/sport/play (1-100)	48
Sleep disturbances	19
Headache	15

porting abdominal discomfort. Approximately half of the patients (53%) reported diarrhea as the main bowel habit abnormality, 32% constipation and 15% an alternating habit, respectively.

The predominant symptom was scored by the subjects as moderate severity (50% severity at the analogue scale) and judged to be the cause of significant limitation in daily activities (48% at the analogue scale). Finally, the more frequent extra-intestinal symptom reported was the presence of sleep disturbances (19%), followed by headache (15%).

DISCUSSION

The major finding of our study is the observation that a considerable proportion of young adults (29%), who suffered from a RAP (or IBS) during their childhood severe enough to be referred to the pediatric department of our hospital, still continue to suffer from abdominal complaints who fulfill the diagnostic criteria for IBS. This finding is in agreement with previous published works, in particular the recent papers by Hotopf *et al*[19], Walker *et al*[18], and Campo *et al*[21]. Hotopf *et al*[19] did a population-based birth cohort study, assessing the cohort of 3637 individuals born in UK in one week of 1946. These subjects were prospectively evaluated by means of several "waves" of data gathering, in particular at the ages of 7, 11, and 15 years the information was sought concerning abdominal pain. By doing so, the authors were able to diagnose "persistent" abdominal pain as abdominal pain reported at each of these three time-points, suggesting that pain is chronic. They showed that at the age of seven, 20% of survey members were suffering from abdominal pain, at the age of eleven they were 19% and at the age of fifteen they were 17%, whereas at the age of 36 years, only 7% of the subjects still had persistent abdominal pain. Abdominal symptoms in childhood appear to be weakly associated with persistent abdominal pain or headache in adulthood, but are associated with increasing numbers of physical symptoms at this age[19].

In the study by Walker *et al*[18], 76 patients with RAP and 49 control age- and sex-matched subjects, suffering from acute minor illness or injury, were compared 5 years after their initial evaluation by a structured telephone interview. The subjects constituted a higher proportion of the initial samples, e.g. 84% and 94%, respectively. It turned out that at follow-up frequent (weekly or more often) abdominal pain was significantly more likely to be reported by patients with a history of RAP (45%) than by control subjects (20%) ($P < 0.01$). Patients with a history of RAP were also more likely to report having received a diagnosis of IBS in the 5 years since study entry (5% *vs* 0%). Finally, the former subjects had significantly more school absences and clinical visits because of abdominal pain than the control subjects, while similar levels of school absence and clinical visits for non abdominal symptoms were reported.

Finally, the recent paper by Campo *et al*[21] compared two small samples of young adults, i.e. 28 subjects were evaluated for RAP between the age of 6 and 17 and 28 matched controls participating at the same age in a study about tonsillectomy and adenoidectomy, an average of 11.1 years after the index visit. In this follow-up study, although approximately one third of the RAP group met the criteria for IBS, patients and controls did not differ significantly on interview measures of IBS (33.3% *vs* 22.2%, NS). One third of RAP patients endorsed a history of migraine, over twice as many as controls, with a trend toward statistical significance (35.7% *vs* 14.3%, $P = 0.07$). The second interesting feature is the familial aggregation of symptoms. In our study, the presence of at least one sibling with IBS was identified in the group developing adult IBS symptoms in a proportion greater than twice that observed in the group not developing adult IBS (40% *vs* 16%, $P < 0.01$). This observation is in keeping with the more recent literature, suggesting the importance of parental reinforcement and modeling in the development of gastrointestinal illness behavior in children and adults. Whitehead *et al*[22] demonstrated that people with a functional bowel disorder are more likely to report being given gifts or treat foods when they had minor illnesses (cold or influenza) as a child. Levy *et al*[23] in a case-control study conducted on 631 children of parents with a recent diagnosis of IBS and 646 children matched by parental age, gender and number of children in the family without this diagnosis, found that case children have significantly more yearly visits than controls for gastrointestinal symptoms (0.35 *vs* 0.18, $P < 0.001$) as well as for all causes (mean 12.26 *vs* 9.81, $P = 0.0001$), suggesting an intergenerational transmission of gastrointestinal illness behavior. Finally, Levy *et al*[24] further explored the relative contribution of genetic and environmental (social learning) influences to the development of IBS by comparing concordance rates in monozygotic and dizygotic twins to concordance between mothers and their children. They found that concordance for IBS is significantly greater in monozygotic than in dizygotic twins (17.2% *vs* 8.4%, $P = 0.03$), supporting a genetic contribution to IBS. In addition, they also found that the proportion of dizygotic twins with IBS who have mothers with IBS is greater than the proportion of dizygotic twins with IBS who have co-twins with IBS (15.2% *vs* 6.7%, $P < 0.001$), suggesting that social learning has an equal or greater influence than heredity.

In our study we did not individually assess the relative contribution of these two factors to abdominal illness behavior, nor measured the influence of this abnormal learned sick role on school or work absenteism, but were able to explore the subjective impact of IBS complaints on one aspect of health-related quality of life, i.e. the limitation in school/sport or playing activities. We found

that, on a scale from 0 to 100 it weighted 49.2. The last finding we would like to emphasize is the relatively low rate (less than 20%) of extra-intestinal symptoms, such as sleep disturbances or headache, in the group of subjects developing IBS. This finding points toward a very specific type of learned illness behavior in our group of patients, again in keeping with the observation of others, in particular the group of Chapel Hill[25], who demonstrated that reinforcement of menstrual illness behavior *or* cold illness behavior in parents significantly predicts adult menstrual *vs* cold symptoms and disability days, independent of stress and neuroticism.

Our study has a number of potential limitations. Like most studies of RAP, this was a referred sample from a specialized care setting, which can limit the generalization of our findings. We did not assess the psychopathology of the subjects nor the history of maltreatment, since this was not formally done at the time the subjects were visited the outpatient department because of RAP. Finally, our study was not a case-control one, but merely a follow-up investigation of a cohort of children. We cannot exclude therefore that the rate of adult IBS development observed in our sample is different from that expected in a matched control population. However, to measure the risk of IBS was not our primary aim, which was in fact to compare the individual and family findings of young adults developing or not developing IBS 5 to 13 years after the original diagnosis of RAP or children IBS. On the other hand, valuable features of our study are the large sample investigated (52 subjects tracked compared to 28 in the study by Campo *et al*[21], the average 8.5 years of follow-up compared to 5 years in the study by Walker *et al*[18], and the use of validated diagnostic criteria for the diagnosis of RAP and IBS).

In conclusion, a large proportion, roughly one third of children referred to the hospital because of RAP or IBS, still presents significant abdominal complaints and can be diagnosed as suffering from IBS 5 to 13 years after this diagnosis, confirming that although RAP is a functional disorder, it should not be dismissed as a completely benign condition or a transient reaction to stress. Furthermore, by comparing young adults presenting or not presenting IBS, the presence of one sibling with IBS is the most important factor associated with IBS development, confirming that functional bowel disorders tend to run in families due to heredity factors and social learning influences.

Abstract

AIM: To investigate *c-met* expression during early pancreatic carcinogenesis.

METHODS: We used 46 bulk tissues and 36 microdissected samples, including normal pancreas, chronic pancreatitis, and pancreatic cancer, for quantitative real-time reverse transcription-polymerase chain reaction.

RESULTS: In bulk tissue analyses, pancreatic cancer tissues expressed significantly higher levels of *c-met* than did chronic pancreatitis and normal pancreas tissues. *c-met* levels did not differ between chronic pancreatitis and normal pancreas tissues. In microdissection-based analyses, *c-met* was expressed at higher levels in microdissected pancreatic cancer cells and pancreatitis-affected epithelial cells than in normal ductal epithelial cells (both, $P < 0.01$). Interestingly, pancreatitis-affected epithelial cells expressed levels of *c-met* similar to those of pancreatic cancer cells.

CONCLUSION: Overexpression of *c-met* occurs during the early stage of pancreatic carcinogenesis, and a single alteration of *c-met* expression is not sufficient for progression of chronic pancreatitis-affected epithelial cells to pancreatic cancer cells.

INTRODUCTION

Pancreatic cancer is the fourth and fifth leading cause of cancer death in the United States and Japan, respectively, and has the lowest survival rate of any solid cancer[1-3]. Because the lack of specific symptoms in patients with pancreatic cancer makes early diagnosis difficult, initial diagnosis typically occurs when the tumor has reached an advanced stage[4]. Therefore, we need a better understanding of the early carcinogenesis of pancreatic cancer to facilitate early detection.

The protooncogene *c-met* encodes a member of the family of receptor tyrosine kinases that is a 190-ku glycoprotein comprised of a transmembrane 145-ku β subunit and an extracellular 50-ku α subunit[5,6]. The met receptor binds to and is activated by hepatocyte growth factor/scatter factor (HGF/SF)[7], leading to increased proliferation, altered motility, and enhanced invasion[8]. The wild-type *c-met* gene is amplified or overexpressed in many types of human cancer, including cancers of the breast, stomach, liver, endometrium, nasopharynx, and pancreas[9-14].

Pancreatic ductal cells, which give rise to the most common type of human pancreatic carcinoma, are particularly sensitive to inflammatory and carcinogenic processes[15]. There are reports that pancreatic inflammation may play a key role in early pancreatic carcinogenesis[16]. Rivera *et al* found that *k-ras* mutations that lead to uncontrolled cell growth and may be the principal molecular event in the pathogenesis of pancreatic cancer are present in chronic pancreatitis, providing a genetic basis for the potential progression of chronic pancreatitis to pancreatic cancer[15]. Taken together, the data indicate that the molecular changes associated with chronic pancreatitis

should be studied as a part of a comprehensive strategy to understand pancreatic carcinogenesis. It was reported that *c-met* mRNA expression was increased during development of chronic pancreatitis in dibutyltin-treated mice[17]. Furukawa *et al* also reported that strong immunostaining of c-Met was present in 58% of specimens demonstrating pancreatic hyperplastic epithelia and in 78% of specimens demonstrating ductal adenocarcinoma, respectively[18]. To understand the clinical significance of *c-met* expression in pancreatic carcinogenesis, we need to examine *c-met* expression during early pancreatic carcinogenesis. Therefore, we need accurate measurements of the levels of *c-met* expression in specific cells, such as normal epithelial cells, pancreatitis-affected epithelial cells, and invasive ductal carcinoma (IDC) cells.

The microdissection method, which can isolate specific cells from a frozen section, is used for genetic analysis of specific lesions[19]. Because tumor cells typically represent only 60%-70% of the cells in pancreatic cancer bulk tissues and because the percentage of chronic pancreatitis-affected epithelial cells is very low in bulk chronic pancreatitis tissues[19], cell microdissection is necessary and useful for reliable molecular analyses related to pancreatic carcinogenesis.

In the current study, we examined *c-met* mRNA levels in 46 human pancreatic bulk tissue samples and cells microdissected from 36 samples of pancreas, including normal pancreas, chronic pancreatitis, and pancreatic cancer by quantitative real-time reverse transcription-polymerase chain reaction (RT-PCR). Our goals were to quantify *c-met* expression in chronic pancreatitis, which is an early stage of pancreatic carcinogenesis, and to clarify when overexpression of c-met occurs during pancreatic carcinogenesis.

MATERIALS AND METHODS

Pancreatic tissues

Tissue samples were obtained at the time of surgery at Kyushu University Hospital (Fukuoka, Japan) as described previously[20]. In brief, tissue samples were removed as soon as possible after resection and divided into at least three bulk tissue specimens. The first sample was embedded in OCT compound (Sakura Findek, Tokyo, Japan), snap-frozen for microdissection, and stored at -80℃ until use. The second sample was fixed in formalin, embedded in paraffin, and cut into 4-μm-thick sections for hematoxylin and eosin (H&E) staining. The third sample was snap-frozen for bulk tissue analysis and stored at -80℃ until use. Tissues adjacent to the specimens were examined histologically, and the diagnosis was confirmed by pathologists. Thirteen pancreatic cancer tissue specimens were obtained from tumoral lesions of resected pancreas with primary pancreatic cancer. Twelve normal pancreatic and 11 pancreatitis-affected pancreatic tissue specimens were taken from peripheral tissues away from the tumor or pancreas resected due to mass-forming pancreatitis. Written informed consent was obtained from all patients, and the study was approved by our institution's surveillance committee and conducted according to the Helsinki Declaration.

Table 1 *c-met* and *β-actin* primer sequences and product size

Primer	Forward	Reverse	Product size
	Sequence 5′-3′	Sequence 5′-3′	
c-met	tgatgatgaggtggacaca	ctatggcaaggagcaaaga	149
β-actin	aaatctggcaccacaccttc	ggggtgttgaaggtctcaaa	139

Pancreatic cancer cell lines

Fourteen pancreatic cancer cell lines, ASPC-1, BxPC-3, KP-1N, KP-2, Panc-1, Suit-2 (provided by Dr. H. Iguchi, National Shikoku Cancer Center, Matsuyama, Japan), MIA PaCa-2, NOR-P1 (established in our laboratory), Capan-1, Capan-2, CFPAC-1, H48N, HS766T, and SW1990 (American Type Culture Collection, Manassas, Virginia), and four primary cultured pancreatic fibroblasts derived from resected pancreatic tumors were used. Cells were maintained as described previously[21].

RNA Isolation

Total RNA was extracted from bulk tissues with an RNeasy Mini Kit (Qiagen, Tokyo, Japan) per the manufacturer's protocol. Total RNA was extracted from cells isolated by microdissection with the standard acid guanidinium thiocyanate-phenol-chloroform protocol[22] with or without glycogen (Funakoshi, Tokyo, Japan).

Quantitative analysis of c-met mRNA expression by real-time RT-PCR

Quantitative real-time RT-PCR was performed with a QuantiTect SYBR Green RT-PCR Kit (Qiagen) with a LightCycler Quick System 350S (Roche Applied Science, Mannheim, Germany) as described previously[23]. In brief, the reaction mixture was first incubated at 50℃ for 15 min to allow for reverse transcription. PCR was initiated with one cycle of 95℃ for 10 min to activate modified Taq polymerase followed by 45 cycles of 94℃ for 15 s, 55℃ for 20 s, and 72℃ for 10 s, and one cycle of 95℃ for 0 s, 65℃ for 15 s, and + 0.1℃/s to 95℃ for melting analysis. Each sample was run twice. In addition, any sample showing more than 10% deviation in the values was tested a third time. The 10% deviation was calculated from the concentrations determined from the calibration curve. The level of *c-met* mRNA expression was calculated from a standard curve constructed with total RNA from the Capan-1 pancreatic cancer cell line. The range of threshold cycles was from 20-35 cycles for *c-met* primers[24] and from 5-30 cycles for *β-actin* primers[25] (Table 1). Expression of *c-met* mRNA was normalized to that of *β-actin* mRNA.

Microdissection-based quantitative analysis of c-met mRNA

Frozen tissues were cut into 8-μm-thick sections. One section was stained with H&E for histologic examination. IDC cells from 13 sections, pancreatitis-affected epithelial cells from 12 sections, and normal ductal epithelial cells from 11 sections were selectively isolated with a laser microdissection and pressure catapulting system (P.A.L.M. Microlaser Technologies, Bernried, Germany) in accordance with the manufacturer's protocols. After microdis-

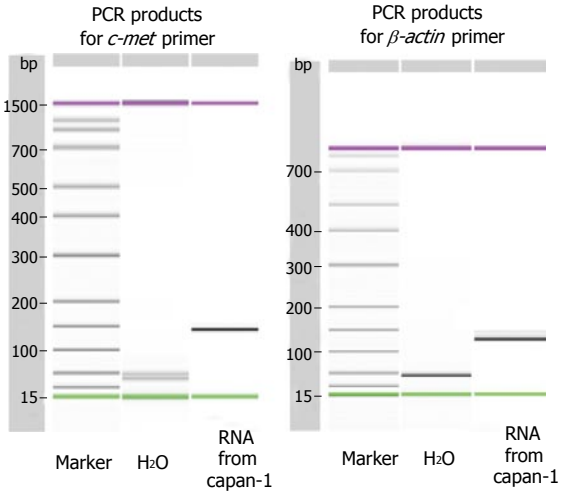

Figure 1 PCR products were analyzed with an Agilent Bioanalyzer 2001. A single 149-bp band was observed for *c-met* primer pairs (left panel). A single 138-bp band was observed for *β-actin* primer pairs (right panel). Each primer pair used in the present study produced a single melting peak on real-time RT-PCR and a single prominent band of the expected size on microchip electrophoresis.

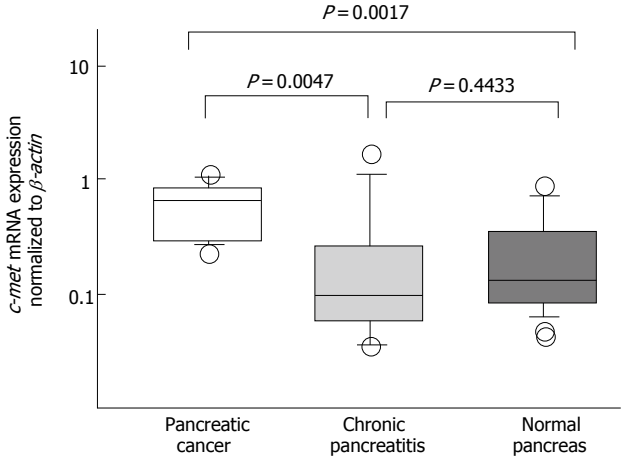

Figure 2 We performed quantitative real-time RT-PCR to quantify *c-met* expression in pancreatic cancer tissues (n = 11), normal pancreatic tissues (n = 20), and chronic pancreatitis tissues (n = 15). *c-met* was overexpressed in pancreatic cancer tissues in comparison to expression in normal pancreatic (P = 0.0017) and chronic pancreatitis tissues (P = 0.0047). Levels of *c-met* did not differ between normal pancreatic and chronic pancreatitis tissues (P = 0.4433).

section, total RNA was extracted from the selected cells and subjected to real-time RT-PCR for quantitative measurement of *c-met* as described previously[19].

PCR products sized by the Agilent 2100 Bioanalyzer

Microchip electrophoresis was performed on an Agilent 2100 Bioanalyzer (Agilent Technologies, Waldbronn, Germany). A DNA 1000 Assay Kit was purchased from Agilent Technologies. As shown in Figure 1, each PCR product was analyzed with DNA 1000 Lab Chips (Agilent Technologies) per the manufacturer's protocol[26].

Statistical analysis

Data were analyzed with the Kruskal-Wallis test for comparison of three groups and Mann-Whitney U test for comparison of two groups because normal distribution was not obtained after logarithmic transformation. Statistical significance was defined as $P < 0.05$. Because we performed multiple comparisons of our real-time RT-PCR data, we conservatively used the Bonferroni correction, and therefore, the adjusted significance level was $P < 0.017$.

RESULTS

Quantitative analyses of c-met expression in bulk pancreatic tissues

In the bulk tissue analyses, we measured *c-met* expression in pancreatic cancer tissues (n = 11), normal pancreatic tissues (n = 20), and chronic pancreatitis tissues (n = 15). As shown in Figure 2, the level of *c-met* expression in normal pancreatic tissues was similar to that in chronic pancreatitis tissues. The median values were 0.130 for normal pancreatic tissues and 0.107 for chronic pancreatitis tissues (P = 0.44). The median value of *c-met* expression in pancreatic cancer tissues was 0.678, which was approximately 5-fold greater than that in normal pancreatic tissues (P = 0.0017) and 6-fold greater than that in chronic pancreatitis tissues (P = 0.0047). All data from bulk tissue analyses indicated that *c-met* was overexpressed in pancreatic cancer, but not chronic pancreatitis tissues.

Quantitative Analysis of c-met expression in 14 pancreatic cancer cell lines and 4 primary pancreatic fibroblast cultures

To confirm expression of *c-met* mRNA in pancreatic cancer cell lines, total RNA was isolated from 14 pancreatic cancer cell lines. As shown in Figure 3, *c-met* was expressed in all 14 pancreatic cancer cell lines with median value of 0.742. The 4 primary cultures of normal pancreatic fibroblast1, 2, 3 and 4 (Panc-f1, Panc-f2, Panc-f3, and Panc-f4) expressed low levels of *c-met* mRNA with a median value of 0.023. Pancreatic cancer and chronic pancreatitis tissues usually contain abundant stromal cells, such as fibroblasts. Most of the bulk pancreatic cancer tissues in the present study also contained many desmoplastic changes and the chronic pancreatitis tissues contained stromal components. Therefore, the level of *c-met* expression detected in bulk tissue analyses may not represent the true levels of expression by specific cells due to dilution of these specific cells by contaminating cells such as stromal fibroblasts.

Quantitative analysis of c-met in microdissected pancreatic cancer cells, pancreatitis-related epithelial cells, and normal pancreatic epithelial cells

In general, bulk pancreatic tissue is complex, containing ductal epithelial cells, acinar cells, fibroblasts, islet cells, and mesenchymal cells. Tumor cells comprise only 60%-70% of the cells in bulk tissue specimens of pancreatic cancer[19]. Therefore, data from bulk tissue analyses may not accurately reflect *c-met* levels in specific cells, such as pancreatic cancer cells, pancreatitis-affected epithelial cells, and normal ductal epithelial cells. It has been reported that *c-met* is expressed in acini and pancreatic islets in normal human pancreas[27]. To avoid the influence of contami-

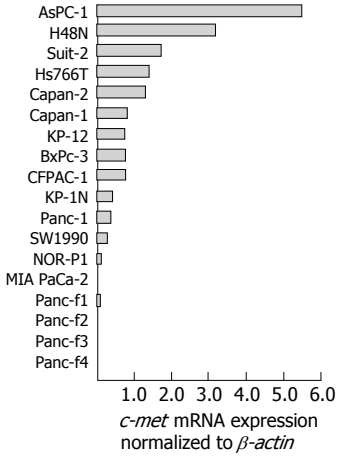

Figure 3 *c-met* expression in pancreatic cancer cell lines and primary pancreatic fibroblasts. The median value of *c-met* expression from pancreatic cancer cell lines was 0.742. In contrast, the median value of *c-met* expression in 4 primary cultures of pancreatic fibroblasts (Panc-f1, Panc-f2, Panc-f3, and Panc-f4) was 0.023.

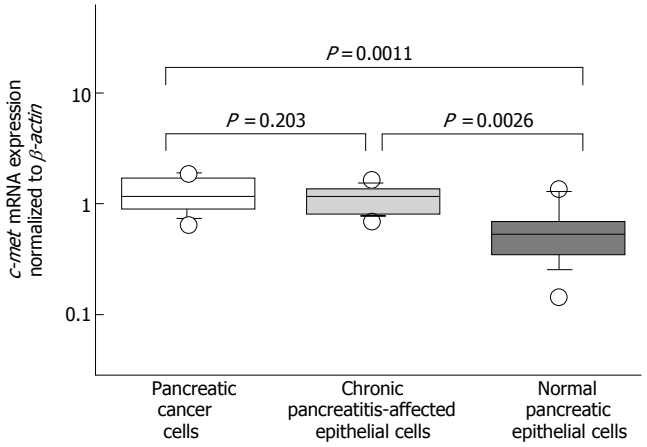

Figure 4 Quantitative analysis of *c-met* mRNA levels in microdissected pancreatic cancer cells (n = 13), pancreatitis-affected epithelial cells (n = 11), and normal pancreatic ductal epithelial cells (n = 12). *c-met* levels in pancreatic cancer cells (median, 1.208) were 2.21-fold higher than those in normal ductal epithelial cells (median, 0.546; P = 0.0011). *c-met* levels in pancreatitis-affected epithelial cells (median, 1.211) were 2.22-fold higher than those in normal ductal epithelial cells (median, 0.546; P = 0.005). *c-met* levels in microdissected normal ductal epithelial cells were the lowest with a median value of 0.546. Interestingly, pancreatitis-affected epithelial cells expressed levels of *c-met* that approached those in pancreatic cancer cells.

nating non-ductal cells, we used a laser-microdissection method to select specific cells for analysis. For microdissection analyses, we isolated pancreatic cancer cells from 13 sections, normal pancreatic ductal epithelial cells from 12 sections, and pancreatitis-affected epithelial cells from 11 sections. As shown in Figure 4, *c-met* expression in pancreatic cancer cells (median, 1.208) was 2.21-fold higher than that in normal pancreatic duct epithelial cells (median, 0.546; P = 0.0011). *c-met* level in normal pancreatic ductal epithelial cells was the lowest. Interestingly, the *c-met* level in pancreatitis-affected epithelial cells (median, 1.211) was significantly higher than that in normal pancreatic duct epithelial cells (median, 0.546; P = 0.005). These data suggested that *c-met* was overexpressed in chronic pancreatitis-affected epithelial cells at levels close to those in pancreatic cancer cells.

DISCUSSION

We performed quantitative real-time RT-PCR to measure *c-met* expression in pancreatitis-affected epithelial cells, which may progress to pancreatic cancer[28-30], to clarify the significance of *c-met* expression in an early stage of pancreatic carcinogenesis. Bulk tissue analyses revealed that *c-met* was overexpressed in pancreatic cancer, but *c-met* expression did not differ between chronic pancreatitis and normal pancreatic tissues. In microdissection-based analyses, we found that pancreatitis-affected epithelial cells expressed high levels of *c-met* that approached those of pancreatic cancer cells. Although it may be difficult to make comparison because microdissection data are based on c-met mRNA levels in single cell, our findings appear to be inconsistent with those of previous immunohistochemical studies in which the positive rates of c-Met were 58%, 80%, and 78% of specimens demonstrating hyperplastic epithelia, severely dysplastic epithelia, and pancreatic ductal adenocarcinoma, respectively[18]. However, Furukawa *et al*[18] also reported that pancreatic cancer patients with diffuse c-Met immunostaining survived longer than c-Met-negative patients. Welm *et al* reported that overexpression of c-*Met* alone did not result in development of tumors, although c-Met acted cooperatively with other genetic alterations, such as overexpression of *MYC*, to induce mammary tumorigenesis[31]. In addition, there have been several reports that the cumulative risk of pancreatic cancer among patients with chronic pancreatitis is only 1% to 4%[28-30]. Taken together, these data suggest that overexpression of *c-met* occurs in the early stage of pancreatic carcinogenesis but is not sufficient for progression of chronic pancreatitis-affected epithelial cells to pancreatic cancer cells. However, these data also suggest that pancreatitis-affected epithelial cells expressing high levels of *c-met* in conjunction with other genetic or epigenetic changes may have the potential to progress to pancreatic cancer. Therefore, *c-met* may be a useful marker for identifying persons with high-risk lesions that may progress to pancreatic cancer.

Abstract

AIM: To investigate the influence of a positive proximal margin in total gastrectomy patients with gastric adenocarcinoma of the cardia.

METHODS: Medical records of 191 patients with total gastrectomies for adenocarcinoma of the cardia between 1995 and 2000 were reviewed. The clinicopathologic features associated with a positive margin were determined, and the predictors for survival were analyzed.

RESULTS: The incidence of positive proximal margin was 8.4% (16/191). The positive margins were associated with advanced diseases. The tumor size and the depth of tumor invasion were independent risk factors for a positive margin. The mean survival in the positive margin group was 33.9 mo as compared with 62.4 mo in the negative group ($P < 0.001$). However, the difference in survival lost significance in subgroup analysis according to stage. Multivariate analysis identified that a positive margin was not an independent prognostic factor for survival.

CONCLUSION: A positive margin is more of an indication of advanced disease in patients with gastric adenocarcinoma of the cardia rather than an independent prognostic factor for survival.

INTRODUCTION

A curative resection is the only treatment offering hope for cure in patients with gastric cancer. This suggests removing the primary lesion with an adequate tumor-free margin[1,2]. Several reports have looked into the detrimental effect of a positive margin on survival in gastric cancer patients[3-5]. However, these studies have included heterogeneous groups with respect to the resection margins. Patients with various tumor locations of gastric cancer or with proximal and distal margins of various types of gastrectomies are grouped together.

Gastric cancer of the cardia has been regarded as a separate neoplasm because of its distinct prognostic and pathological features[6]. A positive proximal resection margin poses a management dilemma for surgeons. To our knowledge, there are few reports on the influence of a positive proximal margin in total gastrectomy for adenocarcinoma of the cardia, and there is some controversy as to whether a positive margin is an independent prognostic factor for survival or not.

The aim of this retrospective study was to investigate the risk factors associated with a positive proximal margin in gastric adenocarcinoma of the cardia, and to assess the influence of a positive margin on the patient's long-term survival, as well as its independent impact on prognosis.

MATERIALS AND METHODS

Medical records were reviewed of 202 patients with adenocarcinoma of the cardia undergone surgery between September 1995 and December 2000 at the Department of Surgery, Yonsei University College of Medicine. Two patients with recurrent gastric cancer, 2 with preoperative metastatic findings and 7 with incomplete data were excluded from the analysis. Therefore, 191 patients who underwent total gastrectomy with curative intent for gastric adenocarcinoma of the cardia, were enrolled in the study. One hundred and twenty-nine patients (67.5%) were males and 62 patients were females. The median age was 57 years ranging from 29 to 85 years.

Table 1 Comparison of demographic and pathologic data between patients with positive and negative margins *n* (%)

Variable	Positive margins (*n* = 16)	Negative margins (*n* = 175)	*P* value
Age (years)	49.3 ± 12.7	57.5 ± 11.2	0.006

Table 3 Logistic regression analysis of risk factors for a positive margin

Variable	Regression coefficient	Standard error	Odds ratio	95% CI for odds ratio	*P* value
Serosal invasion	2.300	0.782	9.970	2.152 - 46.196	0.003
Tumor size	1.875	0.787	6.524	1.395 - 30.512	0.017

The location of tumor and preoperative staging were determined by esophagoduodenogastroscopy, upper gastrointestinal barium examination and abdominal CT scan. All patients had either a type II or III tumor according to the Siewert classifications[7]. A total gastrectomy with transhiatal resection of the distal esophagus and esophagojejunostomy were performed and a macroscopically tumor free proximal resection margin was achieved on all patients. Intraoperative frozen section margin evaluation was not routinely carried out except in patients with suspicion of obtaining a positive margin and thus was not analyzed. During the operation, one hundred and twenty-five of these patients (65.4%) underwent splenectomy for the purpose of lymph node dissection or suspicion of direct tumor invasion to the spleen. A D2 lymphadenectomy was regularly performed. In our institute, postoperative fluorouracil-based adjuvant chemotherapy was usually given in advanced cancer patients except for those with T2N0M0 stage.

A resection margin was considered positive if the permanent section examination revealed cancer infiltration at the line of the transection. The length of the resection margin was defined as the distance from the proximal limit of the lesion to the site of the resection. Collected data included patient demographics, clinicopathologic features and survivals. Stage was reported according to the fifth version of the UICC/AJCC guidelines. Survival was measured from the date of operation to death or to the last follow-up date of June 30, 2003. Of the 191 patients, 88 (46.1%) died during the follow-up period.

Statistical analyses were performed using SPSS version 10.0 (SPSS, Chicago, IL, USA). Univariate analysis was done using two-tailed χ^2 test or unpaired Student's *t*-test. The risk factors associated with a positive margin were identified using a logistic regression model. Survival probability was estimated using the Kaplan-Meier method. The survival curves were compared using the log-rank test. The prognostic factors for survival were analyzed using the Cox proportional hazards regression model with forward stepwise method. $P < 0.05$ was considered statistically significant.

RESULTS

Sixteen out of the 191 patients (8.4%) had a positive margin. The incidence of this event was 26.5% (9/34) in patients with stage IV gastric cancer, while 10.5% (6/57) in stage III and 2.3% (1/43) in stage II. None of the 57 patients with stage I disease had a positive margin. The mean length of the proximal resection margin was 2.5 ± 1.1 cm (range, 0.8-7.0 cm). It was 2.6 ± 1.4 cm (range, 0.8-6.5 cm) in the positive group as compared with 2.5 ± 1.2 cm (range, 0.8-7.0 cm) in the negative margin group (P = 0.703). A positive margin was significantly associated with Borrmann III and IV gross type, large size of the primary tumor, serosal invasion, node involvement and advanced stage disease (Table 1, Table 2). Logistic regression analysis revealed that the size of the primary tumor and the depth of tumor invasion were independent risk factors for a positive margin (Table 3).

The mean follow-up time and survival time after surgery were 44.3 mo (range, 0.5-93.5 mo) and 59.9 mo (95% confidence interval, 54.6-65.1 mo), respectively.

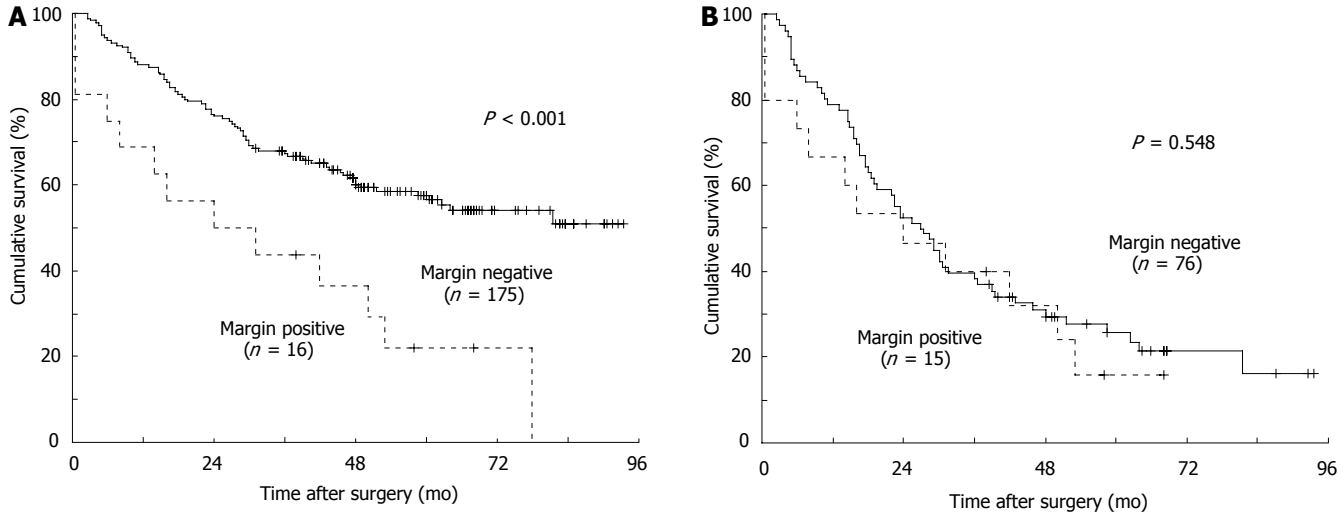

Figure 1 Cumulative survival curves according to the margin status in a total of 191 patients (**A**) and 91 stage III and IV (**B**) patients with gastric cancer of the cardia. The mean survival time of patients with positive margins was 33.9 mo compared to 62.4 mo of patients with negative margins in total 191 patients, and 29.2 mo compared to 38.2 mo in 91 patients with stage III and IV diseases

On univariate analysis, the gross type, size of the primary tumor, serosal invasion, lymph node involvement, stage, resection margin status and splenectomy were significantly associated with the long-term survival. The mean survival time in patients with positive margins was 33.9 mo as compared with 62.4 mo in patients with negative margins ($P < 0.001$, Figure 1A). Since fifteen out of 16 patients (93.8%) with positive margins had stage III and IV gastric cancer in the present study, we then analyzed the subgroup patients stratified by stage, the difference in survival between both groups did not reach significance in stage III and IV gastric cancer (Figure 1B).

On multivariate analysis, seven variables with a significance level of < 0.05 in univariate analysis were included in the model. Positive margin was not identified to be an independent predictor for survival (Table 4).

Table 4 Multivariate analysis of prognostic factors for survival

Variable	Regression coefficient	Standard error	Odds ratio	95% CI for odds ratio	*P* value
Gross type	-0.174	0.258	0.840	0.507 - 1.392	0.500
Tumor size	0.209	0.248	1.232	0.758 - 2.001	0.399
Serosal invasion	-0.125	0.264	0.883	0.526 - 1.481	0.637
Node involvement	0.838	0.431	2.311	0.994 - 5.374	0.052
Stage	1.469	0.389	4.344	2.028 - 9.304	< 0.001
Margin status	0.397	0.330	1.488	0.779 - 2.843	0.229
Splenectomy	0.276	0.292	1.318	0.744 - 2.337	0.344

DISCUSSION

The incidence of positive resection margin has been reported to vary from 5% to 35%[8-10]. In this study, the incidence of this event was 8.4%. However, it was significantly higher in patients with stage III and IV gastric cancer (16.5%) than in patients with stage I and II gastric cancer (1.0%). There are several factors accounting for such a high incidence of positive margin in advanced gastric cancer patients. First, it has been reported that the incidence of positive margin increases with deeper invasion of the tumor into the gastric wall and advanced disease stage[11,12]. Secondly, patients with stage III and IV disease have more Borrmann III and IV gross type of tumors and/or more undifferentiated tumors (data not shown), and these patients may have a higher risk of sub-clinical intramural tumor infiltration to the esophagus[10]. Finally, intraoperative frozen section margin evaluation is not routinely performed in advanced disease patients, which may possibly increase the incidence of a positive margin in those patients[13].

The risk factors for a positive margin in the present study were identified based on the same length of the proximal resection margin between margin positive and negative groups. Logistic regression analysis showed that the risk mainly depended on the depth of cancer invasion and the size of the primary tumor.

The depth of invasion into the gastric wall is significantly related to a higher rate of esophageal infiltration. Bozzetti *et al*[14] reported that the risk of proximal infiltration is significantly higher when the tumor infiltrates the serosa or beyond it. Songun *et al*[14] demonstrated that the depth of tumor invasion is one of the independent prognostic factors for a positive margin in gastric cancer at various tumor locations. Our results are similar to the aforementioned reports. The size of the primary tumor was also identified as an independent predictor for a positive margin, which is in agreement with that reported by Yokoda *et al*[16], who found that a lesion exceeding 5 cm in maximum diameter is predisposed to a positive margin in gastric cancer.

Although frozen section has a high sensitivity and specificity, it is not routinely used to assess the resection margin[3,17,18]. It is advisable that this technique should be used selectively for patients who may benefit from it since frozen sections are costly and time-consuming[19]. Our study observed that patients with advanced stage disease had a higher risk of obtaining a positive margin. In addition, a

positive margin was associated with deeper tumor invasion to the gastric wall and larger tumor size. These findings may provide some evidence for helping the surgeons select patients to perform intraoperative frozen section margin evaluation.

The influence of a positive margin on prognosis of gastric cancer of the cardia remains controversial. Chan *et al*[20] reviewed 137 total or proximal gastrectomies for gastric cancer with various lesion sites and observed that a positive oesophageal margin is an independent poor prognostic factor for long-term survival. A similar result has been reported by Mariette *et al*[21], who reviewed 94 adenocarcinomas of the esophagogastric junction, but different surgical approaches were involved in their work. In addition, there are no difference in the clinicopathologic features between the positive margin group and the negative margin group in the study[21]. These aforementioned studies are not in accordance with the results we observed that a positive margin was not associated with the long-term survival in gastric adenocarcinoma of the cardia. This discrepancy, although has to be interpreted with caution, may be explained by the following reasons. First, it was a retrospective study and the analyses were based on relatively few patients with or without positive margins in our single institution. Second, a positive margin is often associated with advanced disease. Gall *et al*[22] investigated 87 patients who underwent esophagectomy for cancer and found that the positive margin is involved mainly in late stage disease which does not influence the long-term survival in those patients. Kim *et al*[23] reported that a positive margin loses its predictive value for survival in patients with T3 or T4 lesions and stage III or IV disease. Finally, because the relationship between margin status and treatment failure patterns were not addressed in our study with the limited data, our results may possibly due to the uncertainty in advanced disease, the patients may usually succumb to metastatic disease before the effect of the positive margin is observed[24].

Our results suggest that a positive margin is more of an indication of advanced disease rather than an independent prognostic factor for survival in patients with gastric cancer of the cardia. However, more definitive conclusions would be based on multi-center studies with the results of large-scale analyses.

Abstract

AIM: To review and evaluate our experience in laparoscopic cholecystectomy.

METHODS: A retrospective analysis was performed on data collected during a 13-year period (1992-2005) from 1220 patients who underwent laparoscopic cholecystectomy.

RESULTS: Mortality rate was 0%. The overall morbidity rate was 5.08% (n = 62), with the most serious complications arising from injuries to the biliary tree and the cystic artery. In 23 (1.88%) cases, cholecystectomy could not be completed laparoscopically and the operation was converted to an open procedure. Though the patients were scheduled as day-surgery cases, the average duration of hospital stay was 2.29 d, as the complicated cases with prolonged hospital stay were included in the calculation.

CONCLUSION: Laparoscopic cholecystectomy is a safe, minimally invasive technique with favorable results for the patient.

INTRODUCTION

Laparoscopic cholecystectomy was first introduced by Muhe in 1986[1], and has now evolved to the point where it has replaced the open technique in many medical centers around the world. Today, laparoscopic cholecystectomy, rather than the open technique, is considered as the treatment of choice for gallstone disease[2-5].

Perceived advantages of laparoscopic cholecystectomy, compared with the open technique, include earlier return of bowel motility, less post-operative pain, better cosmetic result and shorter hospital stay resulting in equal or lower hospital costs, as documented by various randomized control trials[6-9].

At the university hospital of Patras, we performed our first laparoscopic cholecystectomy on September 1992. Since then, a total of 1220 laparoscopic cholecystectomies have been performed. As our surgeons are increasingly familiar with it, laparoscopic cholecystectomy has become the most common operation in our daily practice.

MATERIALS AND METHODS

Subjects

This is a retrospective study that involves data collection from medical records of patients undergoing laparoscopic cholecystectomy. Data collection for this research project was approved by the Ethics Committee. The Department of Surgery at the University Hospital of Patras maintains medical records for all patients who have an operation in this institution since the hospital opened in 1988. Our records include paper-only charts up to 1999, and electronic records since then. The records of all patients who underwent laparoscopic cholecystectomy between September 1992 and September 2005 in our institution were retrieved. During this period, a total of 1220 patients underwent laparoscopic cholecystectomy. The female to male ratio was 3:1 (907 *vs* 313) and the mean patient age was 53.3 (range 16-86) years.

Data collection

Data recorded included demographic information, past medical history, diagnosis and indication for the operation, name of surgeon and anesthesiologist, duration of the operation, peri-operative and post-operative complications, time to return of bowel function, oral intake and ambulation, postoperative pain and hence further need for analgesics and length of hospital stay. The recorded perioperative complications included subcutaneous

emphysema, pneumothorax, bleeding, hemodynamic instability, myocardial ischemia, injury to the biliary tree or the cystic artery.

Postoperative complications included re-operation, ileus, fever, atelectasis, pneumonia, wound infection, incisional hernia, myocardial ischemia or infarction, unplanned ICU admission or death. Data were entered into a computerized database for further analysis. Most patients (86.3%) presented uncomplicated biliary colic. The remainder had symptoms of acute cholecystitis, pancreatitis and cholangitis. All patients had an ultrasound of the upper right abdominal quadrant and, in selected cases, an ERCP was performed before the operation.

All patients scheduled for elective cholecystectomy were admitted the day before, and were allowed to have food and liquids until 6 h before the operation.

Surgical technique

The operation was performed with the standard four-port technique, using carbon dioxide for peritoneal cavity insufflation. For the first 283 cases, the Veres technique was used to obtain pneumoperitoneum. Thereafter and for the subsequent cases, we preferred the Hasson technique. Following gallbladder removal, drains were placed selectively in difficult cases where there was a risk of postoperative bleeding. All patients wore anti-embolic stockings and received low molecular heparin subcutaneously. Antibiotic prophylaxis was ensured with 3 peri-operative doses of first generation cephalosporin intravenously. The administration of heparin continued postoperatively, until the discharge of the patient from the hospital. The average time of the operation was 72 (range 50-102) min.

Anesthetic management

All procedures were performed under general endotracheal anesthesia. The anesthetic regimen was not standardized, but was tailored to the needs of each patient, as determined by the attending anesthesiologist. All patients were NPO (nil per os) after midnight, or, for cases done later in the day, for at least 6 h before the operation. All medications, except anti-platelet agents or anticoagulants, were continued until the morning of surgery. Before induction of anesthesia, patients were premedicated with intravenous ranitidine 50 mg, and midazolam 2-5 mg, depending on age, gender and preoperative anxiety. Most patients received an antiemetic (metoclopramide or ondansentron) to prevent post-operative nausea and/or vomiting. Anesthesia was induced with intravenous administration of 50-100 μg of fentanyl, followed by intravenous propofol (2 mg/kg) or thiopental (3-5 mg/kg). Muscle relaxation was accomplished with a non-depolarizing relaxant (vecuronium 0.1 mg/kg or rocuronium 0.5 mg/kg). After intubation, anesthesia was maintained, in most cases, with inhaled agents (isoflurane, sevoflurane or desflurane in an air/oxygen mixture), although TIVA with opioids and propofol infusion at 100-200 μg/kg per min was occasionally used. After its introduction to the market, remifentanil was widely used, combined with propofol or an inhaled agent, to provide intra-operative analgesia. Analgesia was accomplished with intravenous fentanyl in the early part of the procedure, followed by intravenous or intramuscular meperidine (25-50 mg) towards the end. In addition, patients who exhibited severe pain also received NSAID as an adjuvant analgesic. At the end of the procedure, all port sites were injected with 5 g/L bupivacaine (total of 10 mL). Additional meperidine or morphine was given in the recovery room if required, based on patient VAS pain score. All patients received an intravenous infusion of 1-2 L of crystalloid solution during the operation. Patients who could not tolerate pneumoperitoneum, or in cases where urine output was less than 0.5 mL/kg per hour, additional colloid (60 g/L hetastarch 500 mL) was administered, to ensure adequate patient hydration.

Post-operative analgesia was achieved with acetaminophen (*po*, 500 mg 4 times a day), and oral codeine/acetaminophen combinations (30-60 mg 4 times daily). Additional metoclopramide or ondansentron was administered if nausea or vomiting persisted postoperatively. All patients had oral liquids and were encouraged to proceed with food in the evening after the operation, provided there was no nausea or vomiting.

RESULTS

Today laparoscopic cholecystectomy has become the golden rule for the treatment of gallstone disease. In our clinic, the laparoscopic approach was initially reserved for the uncomplicated cases. However, as experience was accumulated and our surgeons became more familiar with the technique, even more complicated cases were treated laparoscopically. In 1994, 18.1% of all cholecystectomy procedures (53 cases) in our institutions were performed laparoscopically. This percentage kept increasing every year, to the point where in 2004, 60% (148 patients) of all cholecystectomies were performed laparoscopically (Figure 1). Prior to operation, 72 patients underwent preoperative ERCP due to ultrasonographic suspicion of

Table 1 Conversion to open cholecystectomy

Reason	*n* (%)
Bleeding	6 (0.49)
Bile leakage	3 (0.24)
Duodenal injury	1 (0.08)
Technical Problem	1 (0.08)
Anatomic Variation (gallbladder aplasia)	1 (0.08)
Inadequate exposure (dense adhesions- inflammation)	11 (0.9)

choledocholithiasis, elevated titer of bilirubin and liver function enzymes, recent history of jaundice and/or pancreatitis. Patients with stones in the common bile duct were treated with endoscopic sphincterotomy.

Mortality rate was 0%, but complications did occur, especially early in our series, when surgical experience was still limited. Concerning major complications, bile leak from the cystic duct occurred in 3 (0.24%) patients. In two cases, the leak resulted from failure to clip the cystic duct due to unsatisfactory application of the endoscopic clips. The problem was recognized before the conclusion of the operation in both cases. However, in one of these cases, ligation was impossible, and conversion to the open procedure was necessary. In a third case, the cystic duct injury went undiagnosed intraoperatively, and was only suspected when a significant amount of bile accumulated in the drain on the 1st postoperative day. In this case ERCP confirmed the diagnosis. Endoscopic sphincterotomy was performed and a naso-biliary drainage tube was placed. The leak eventually resolved without any further therapy after 7 d. In 2 (0.16%) patients, a common bile duct injury occurred. In the first occasion, the common bile duct was clipped as it was falsely believed to be the cystic duct. Unfortunately, that mistake went unrecognized intraoperatively and it was only suspected the next postoperative day when the patient developed obstructive jaundice. Eventually, the diagnosis was confirmed with an ERCP and the patient was operated immediately for end-to-end repair of the duct and T-tube placement. In the second case the patient was released from the hospital after a 24 h stay only to return after 2 d with fever, leucocytosis and signs of peritonitis. After an abdominal CT the diagnosis of choloperitoneum was made and the patient was operated on the same afternoon. Intraoperatively, a leak was identified in the common bile duct and it was attributed to the diathermy. After proper cleaning of the peritoneal cavity, the defect was restored with a T-tube placement. In both patients the end result was favorable and no further manipulation was needed.

In 3 (0.24%) cases, bile leak from the gallbladder bed occurred after removing the gallbladder. One case, in whom the leak was identified intra-operatively, was converted to the open procedure. However, in two other cases, the diagnosis was made post-operatively and the patients required ERCP with sphincterotomy.

Thermal injury of the duodenum (2nd segment) occurred in 1 (0.08%) patient. The injury was handled with conversion to open cholecystectomy and suturing of the traumatic lesion.

Bleeding from injury of the cystic artery occurred in 5 (0.4%) patients, 3 of which were admitted and had surgery emergently for acute cholecystitis. The procedure was converted to open cholecystectomy, and bleeding was controlled successfully in all cases. In 10 (0.81%) cases, the bleeding originated from minor accessory vessels of the gallbladder fossa. In 4 of these patients (2 with history of hepatic cirrhosis and 2 with preexisting coagulation abnormalities), conversion to an open procedure was necessary to control bleeding. In 4 (0.32%) cases, bleeding occurred from the port site, and in 1 of them conversion to open procedure was necessary to achieve homeostasis.

Four (0.32%) patients developed a surgical site infection. In 3 of them, gram (+) bacteria were isolated (*S. aureus* in 2, *Enterococcus spp* in 1), whereas in 1 case *E. coli* was the underlying pathogen. All cases were treated successfully with intravenous antibiotics. However, in one case surgical drainage of the wound was necessary. Twenty-seven (2.21%) patients developed moderate post-operative fever. All cases of fever were considered of respiratory origin and treated as such with good outcome.

Two (0.16%) patients developed subcutaneous emphysema, but this was a transient phenomenon and did not cause any morbidity. Hernias at the trocar sites occurred as late complications in 2 (0.16%) patients.

The reported rate of conversion to open cholecystectomy ranges between 3 and 7%[10,11]. In our series, 23 (1.88%) of all procedures were converted to the open technique (Table 1). In most cases, uncontrollable bleeding and bile leakage, as well as previous abdominal operation associated with dense adhesions were the main reasons for conversion to the open procedure.

Finally, 2 (0.16%) patients returned to the hospital 1 wk after hospital discharge with signs of choledocholithiasis. This was attributed to stones in the biliary tree that went undiagnosed at the time of the operation. Both patients were treated with ERCP and sphincterotomy, resulting in a good outcome.

DISCUSSION

Today, laparoscopic cholecystectomy is considered as the treatment of choice for gallstone disease. In our department, laparoscopic cholecystectomy was initially reserved for otherwise healthy patients with uncomplicated disease. However, as experience was gained, laparoscopic cholecystectomy was also offered for patients with more complicated biliary disease, such as acute cholecystitis, former pancreatitis and choledocholithiasis.

Laparoscopic cholecystectomy confers definite advantages compared to the open procedure, but carries its own risks. Consequently, some complications occurred in our series, especially in our early cases when surgeons were less experienced.

In our series, 8 (0.65%) patients suffered injury at various levels of the biliary tree (3 in the cystic duct, 2 in the CBD and 3 in the intrahepatic ducts). The frequency of this complication is 0%-0.8% in laparoscopic chol ecystectomy[10,12-14], whereas it is very rare in the open procedure. The relatively high incidence of bile duct injury

in laparoscopic cholecystectomy is perceived by many surgeons as the main drawback of the technique. However, as surgeons obtain more experience, the frequency of this complication should decrease.

Bleeding is one of the most frequent and dangerous complications of laparoscopic cholecystectomy. Clinically significant bleeding occurs in 0.5% of laparoscopic cholecystectomy[15]. In our series, bleeding was observed in 19 (1.55%) patients, but in most cases, it was minor and easily controlled. Only 6 (0.49%) patients had bleeding that necessitated conversion to the open procedure. Factors contributing to operative site bleeding may include inadequate exposure, acute inflammation, portal hypertension, adhesions, coagulopathy and rough technique[16]. This was the case in our series, as 5 of the 6 patients who needed conversion to the open procedure were acute admissions. In these patients, inflammatory reaction in the gallbladder fossa prevented adequate exposure of the cystic artery, and transection of the vessel was the end result. In another patient, bleeding occurred from the trocar port in the abdominal wall. Though not significant in amount, its origin could not be revealed and conversion to open was inevitable. Though bleeding is a potentially catastrophic complication, inherent to the laparoscopic technique, it is also the most preventable one, as it is largely related to operator technique.

Wound infection, usually involving the umbilical cannulation site through which the gallbladder is extracted, occurs in 0.3%-1% of cases[4,5,17,18]. Surgical site infection was seen in 4 (0.32%) of our patients, and were all treated successfully with intravenous antibiotics. Postoperative fever occurred in 27 patients. In all cases, the fever was of respiratory origin and resolved with antibiotics and chest physiotherapy.

The average hospital stay was 2.29 d. Recent studies have demonstrated that laparoscopic cholecystectomy can be performed as one day-surgery[19]. In our series, this was true in most uncomplicated, otherwise healthy patients. However, our mean hospital stay was longer, because, when calculating the average length of hospital stay, we included all cases with complications, which required prolonged hospitalization.

In conclusion, in the past few years, much attention has been given to the learning curve of laparoscopic cholecystectomy. Our study adds to and is consistent with the growing body of literature, demonstrating that laparoscopic cholecystectomy is a safe, minimally invasive technique, with favorable results for the patients, provided that the surgeon is meticulous, well-trained and experienced.

Abstract

AIM: To evaluate the efficacy of postoperative serial assay of carcinoembryonic antigen (CEA) and cytokeratins for the detection of recurrent disease in patients with colorectal adenocarcinoma after radical surgery.

METHODS: Between 1993 and 2000, 120 patients with colorectal adenocarcinoma underwent radical surgery in the Department of Surgical Gastroenterology, Federal University of São Paulo-Escola Paulista de Medicina, São Paulo, Brazil. Periodic postoperative evaluation was performed by assaying markers in peripheral serum, colonoscopy and imaging examination. Presence of CEA was detected using the Delfia® method with 5 μg/L threshold, and cytokeratins using the LIA-mat® TPA-M Prolifigen® method with 72 U/L threshold.

RESULTS: In the first postoperative year, patients without recurrent disease had normal levels of CEA (1.5 ± 0.9 μg/L) and monoclonal tissue polypeptide antigen-M (TPA-M, 64.4 ± 47.8 U/L), while patients with recurrences had high levels of CEA (6.9 ± 9.8 μg/L, $P < 0.01$) and TPA-M (192.2 ± 328.8 U/L, $P < 0.05$). During the second postoperative year, patients without tumor recurrence had normal levels of CEA (2.0 ± 1.8 μg/L) and TPA-M (50.8 ± 38.4 U/L), while patients with recurrence had high levels of CEA (66.3 ± 130.8 μg/L, $P < 0.01$) and TPA-M (442.7 ± 652.8 U/L, $P < 0.05$). The mean follow-up time was 22.3 mo. There was recurrence in 23 cases. Five reoperations were performed without achieving radical excision. Rises in tumor marker levels preceded identification of recurrences: CEA in seven (30%) and TPA-M in eleven individuals (48%).

CONCLUSION: Intensive follow-up by serial assay of CEA and cytokeratins allows early detection of colorectal neoplasm recurrence.

INTRODUCTION

Serum tumor markers are substances that can be assayed in peripheral blood. Raised levels of these markers indicate the possible existence of neoplasia in the organism, and thus they form an important instrument in the therapeutic management of such patients[1]. In colorectal adenocarcinoma, carcinoembryonic antigen (CEA) discovered by Gold *et al*[2] in 1965, has been distinguished as a tumor marker with the best characteristics. It is an antigen with high serum levels at the embryonic stage and low levels in adult individuals, and forms the standard for different instances of evaluation[3,4]. Its diagnostic capacity oscillates around 40%[4]. It has a correlation with staging especially among patients with lesions at stage IV[4] of the TNM classification[5] and validity for determining prognostic indices[6]. It can be used as an instrument for determining tumor recurrence[7].

A variety of markers have been developed for better assessing patients with colorectal malignant neoplastic processes, such as CA 19-9[8], CA 242[9], CA 72-4[10], cytokeratins[11], vascular endothelial growth factor (VEGF)[12] and p53[13]. Of these, cytokeratins deserve special attention because of their characteristics. The first method developed for detecting cytokeratins was the tissue polypeptide antigen (TPA) method in 1978[11], evolving into the tissue polypeptide-specific antigen (TPS) method in 1992, using a reagent to identify the M3 epitope of the TPA molecule[14]. Subsequently, in 1994, monoclonal tissue polypeptide antigen (TPA-M) was developed with monoclonal antibodies directed against various epitopes of three different cytokeratins: 8, 18 and 19[15,16]. It has

been studied to evaluate whether it can be utilized for identifying patients with colorectal adenocarcinoma[15,16] and neoplasias in various other organs, such as prostate[17], ovary[18], lung[19], bladder[20] and breast[21].

The objective of the present study was to investigate the value of postoperative serial assay of cytokeratins and CEA, for detecting recurrences of tumors of the colon and rectum, with the aim of determining their possible clinical advantages.

MATERIALS AND METHODS

Patients

Between December 1993 and March 2000, 120 patients with colorectal adenocarcinoma underwent curative surgical treatment in the Department of Surgical Gastroenterology, Federal University of São Paulo-Escola Paulista de Medicina (UNIFESP-EPM), São Paulo, Brazil. Among the patients 69.2% were white, 20.1% brown, 7.7% yellow and 3% black, and 43.2% were male. At the time of diagnosis, their mean age was 62.16 years, ranging from 19 to 89 years. The location of the lesion was the rectum (54.4%), left colon (18.9%), transverse colon (3.6%) and right colon (23.1%). The mean diameter of the tumor was 6.1 cm, ranging from 1 to 17 cm.

The patients were treated according to a protocol approved by the Research Ethics Committee of the institution. The patients were made aware of the study, and signed a statement of consent to their participation in the investigation. Patients with other neoplasias on earlier occasions or those who received previous anti-neoplastic therapy were excluded from the investigation. The operation was considered curative or palliative in accordance with evaluation of the preoperative staging tests, intraoperative evaluation of whether there was residual macroscopic lesion, and verification of the anatomopathological report.

Methods

Staging of the neoplasias was done according to the TNM scheme. Stage I was found in 29, stage II in 21, stage III in 29, stage IV in 41 patients respectively[5]. It was proposed to the patients that evaluations should be made 6, 12, 18, 24, 36, 48 and 60 mo after the operation. Follow-up was performed by clinical assessment, laboratory tests and supplementary examinations such as colonoscopy, computerized tomography (CT) of the abdomen and pelvis, and radiography (X-ray) of the chest using posteroanterior (PA) and lateral views. Opaque enema, nuclear magnetic resonance (NMR) and bone scintigraphy were requested in accordance with the clinical indication in each case.

The CEA and TPA-M markers were evaluated for all patients in the study following the operation, and calculated by patient category (with or without recurrence of neoplasia) for each collection time. The initial collection of blood for assaying the tumor markers was performed while inducing anesthesia prior to the surgical operation. The blood samples were centrifuged with collection of peripheral serum, and stored at -20℃. The serum assays of tumor markers were performed in the Clinical Analysis Laboratory of Hospital São Paulo, UNIFESP-EPM. The CEA concentration was determined using the Delfia® method, taking 5 μg/L as the limit for normalcity[4,7]. Cytokeratins were quantified using the LIA-mat® TPA-M Prolifigen® method, taking 72 U/L as the limit for normality.

Statistical analysis

Statistical analysis was performed using receiver operator characteristic (ROC) curves[22], quantitative analysis of the variables and repeated-measurement variance analysis[23].

RESULTS

In the first postoperative year, patients without tumor recurrence had normal levels of CEA (1.5 ± 0.9 μg/L) and TPA-M (64.4 ± 47.8 U/L), while patients with recurrences had high levels of CEA (6.9 ± 9.8 μg/L, $P < 0.01$) and TPA-M (192.2 ± 328.8 U/L, $P < 0.05$) (Table 1). The serum levels of the tumor markers CEA and TPA-M were measured during the first postoperative year. These parameters could predict recurrences of neoplasia during the second postoperative year. The accuracy was 0.59 (0.43-0.76) for CEA and 0.76 (0.63-0.89) for TPA-M (Figure 1A).

The second postoperative year was the principal period for identifying tumor recurrence. During this year, the CEA levels were normal (2.0 ± 1.8 μg/L) in patients without tumor recurrence, and high (66.3 ± 130.8 μg/L, $P < 0.01$) in patients with recurrences (Table 1), with an accuracy of 0.68 (0.43 - 0.93) (Figure 1B). The circulating TPA-M levels remained normal (50.8 ± 38.4 U/L) in patients without tumor recurrence and high (442.7 ± 652.8 U/L, $P < 0.05$) in patients with recurrences (Table 1), with an accuracy of 0.78 (0.62-0.94) (Figure 1B).

Three (2.5%) out of the 120 patients were lost their follow-up after surgery. The mean time of follow-up was 22.3 mo, ranging 0.2-75 mo. Recurrence of neoplasia was observed in 23 patients (19.2%) during the study period, which was found by clinical, radiological and endoscopic examinations at an average of 18 mo after the initial operation, ranging from 6 to 48 mo. This was preceded by a rise in CEA in 7 patients (30%) and TPA-M in 11 patients (48%).

Among the 23 patients with recurrence of neoplasia, 18 (78.3%) presented multiple tumor recurrences, while 5 (21.7%) who were considered operable underwent surgery for the new lesions. They continued to present residual disease after surgery. Four of these patients died during the postoperative follow-up.

DISCUSSION

One year after the operation, the CEA level was around 1.5 μg/L in the patients without tumor recurrence and around 6.9 μg/L in those with tumor recurrence with an accuracy of 76%. The mean level of TPA-M was around 64.4 U/L in the patients without tumor recurrence and around 192.2 U/L in those with recurrence with an accuracy of 59.1%. In the second postoperative year, the mean CEA level was around 2.0 μg/L in patients without tumor

Table 1 Serum CEA and TPA-M levels by postoperative year (mean ± SD)

	Recurrence of neoplasia	1st yr	2nd yr	3rd yr	4th yr	*P*
CEA (μg/L)	-	1.5 ± 0.9	2.0 ± 1.8	1.4 ± 1.1	1.9 ± 1.0	< 0.01
	+[b]	6.9 ± 9.8	66.3 ± 130.8	19.9 ± 32.0	1.2 ± 0.7	
TPA-M (U/L)	-	64.4 ± 47.8	50.8 ± 38.4	54.0 ± 19.5	43.6 ± 29.0	< 0.05
	+[a]	192.2 ± 328.8	442.7 ± 652.8	93.3 ± 82.0	343.5 ± 437.6	

[a]$P < 0.05$, [b]$P < 0.01$, *vs* no recurrence.

recurrence and around 66.3 μg/L in those with recurrence with a sensitivity of 50% and a specificity of 76.9% and an accuracy of 67.9%. The mean level of circulating TPA-M was around 50.8 U/L in the patients without tumor recurrence and around 442.7 U/L in those with a recurrence, with sensitivity of 75%, a specificity of 71.8% and an accuracy of 78.2%.

Various investigations have suggested that raised level of serum CEA is an important indicator for the recurrence of colorectal neoplasia[4,7]. However, it is not unanimous because of the lack of practical results obtained through clinical follow-up of patients[24]. Nonetheless, periodic postoperative assay of CEA is considered an effective low-cost measure for identifying tumor recurrence[25]. No studies have been undertaken to analyze the efficiency of cytokeratins in detecting recurrences originating from colorectal adenocarcinoma. The present study demonstrated that TPA-M and CEA were comparable in terms of sensitivity, specificity and accuracy in the detection of recurrences. Further studies are needed for evaluating and confirming the importance of TPA-M in following up patients with colon or rectum cancer after surgery.

According to the 2000 consensus of the American Society of Clinical Oncology[25], a postoperative finding of raised CEA concentration in peripheral blood indicates that closer endoscopic and radiological follow-up should be undertaken until such possible tumor recurrences are located. It is certain that patients with colorectal rumor recurrence are never completely cured. Such patients still carry neoplastic cells that are capable of developing when conditions are suitable.

The question is therefore whether intensive follow-up is effective. The medical literature presents conflicting opinions in this respect. One option is to follow up with assay of tumor markers in patients and additional tests if higher than normal concentrations are found[4]. Another alternative is to undergo periodic tests, such as radiological examinations and endoscopic procedures, for rapid identification of reoccurrences of neoplasia and prompt reintervention[6]. Nonetheless, no significant improvements have been achieved in patient survival obtained through close medical follow-up for recurrences of colorectal neoplasia. Minton *et al*[26] showed that reoperation can achieve a five-year disease-free survival. Moertel *et al*[24] carried out interventions in 417 patients with recurrence, and found that 2.3% of them have no relapse in more than one year. Lucha Jr. *et al*[7] achieved a five-year survival in three reoperated patients (1.1%) out of 285 who were

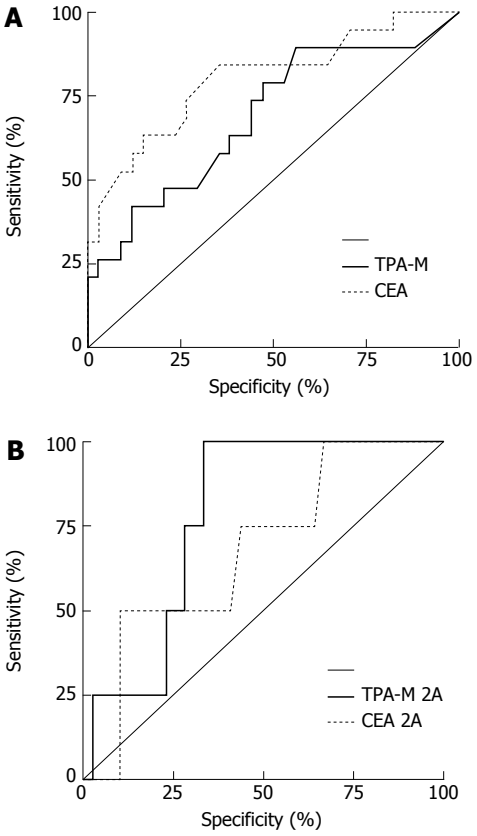

Figure 1 ROC curve for CEA and TPA-M in the first (**A**) and second (**B**) postoperative year among patients with colorectal cancer.

given radical treatment. None of the patients in the present study with recurrence of colorectal neoplasia after the initial resection could be cured. The tumor marker levels are increased in peripheral blood before recurrence of the neoplasia can be identified, which has been confirmed by a recent study[7]. Early surgical intervention at the site of tumor recurrence might become possible through improvements in the imaging methods available[4].

There are some possible explanations why the rates of curative resection of tumor recurrence are low. Sometimes, when resection of a metastasis in a given organ is carried out, the patient may still have micrometastases in other organs, and thus the surgery must be classified as non-radical. Institutional delays cause patients for reintervention with disease that is more advanced than it is when the recurrence is discovered, thereby always obtaining worse results. Moreover, metastases are often multiple, making it difficult to obtain complete resection

and thus compromise the cure for the patient.

Whether intensive follow-up prolongs patient survival is unclear. Ohlsson *et al*[27] evaluated 107 patients in Sweden who were divided into intensive and non-intensive follow-up groups after curative surgery for colorectal neoplasia, and found that there is no statistical difference in the two groups. Secco *et al*[28] followed up 216 patients with colon or rectum cancer undergoing curative surgery for lesion resection (127 of them had intensive follow-up), and found that adherence to a strict medical follow-up program can prolong survival of colorectal cancer patients. There is a consensus that the ideal marker for colorectal neoplasia does not yet exist[29].

Intensive follow-up in the present study enabled early detection of recurrences of colorectal neoplasia, through levels of the tumor markers CEA and TPA-M were increased, which even occurred before the recurrence site was located. Increased CEA and TPA-M levels prior to locating the recurrences occurred in 30% and 48% of the patients with recurrences. However, although reoperation was performed, no cure was obtained.

In conclusion, intensive follow-up by serial assay of CEA and cytokeratins allows early detection of colorectal neoplasm recurrence.

Abstract

AIM: To investigate the effect of interaction between enteric epithelial cells and lymphocytes of Peyer's patch on the release of nitric oxide (NO) and IL-6 in response to *Shigella* lipopolysaccharide (LPS).

METHODS: Human colonic epithelial cells (Caco-2) were mixed cocultured with lymphocytes of Peyer's patch from wild-type (C57 mice) and inducible NO synthase knockout mice, and challenged with *Shigella* F2a-12 LPS. Release of NO and mIL-6 was measured by Griess colorimetric assay and enzyme-linked immunosorbent assay (ELISA), respectively.

RESULTS: In the absence of LPS challenge, NO was detected in the culture medium of Caco-2 epithelial cells but not in lymphocytes of Peyer's patch, and the NO release was further up-regulated in both cocultures with lymphocytes from either the wild-type or iNOS knockout mice, with a significantly higher level observed in the coculture with iNOS knockout lymphocytes. After *Shigella* F2a-12 LPS challenge for 24-h, NO production was significantly increased in both Caco-2 alone and the coculture with lymphocytes of Peyer's patch from the wild-type mice but not from iNOS knockout mice. LPS was found to stimulate the release of mIL-6 from lymphocytes, which was suppressed by coculture with Caco-2 epithelial cells. The LPS-induced mIL-6 production in lymphocytes from iNOS knockout mice was significantly greater than that from the wild-type mice.

CONCLUSION: Lymphocytes of Peyer's patch maintain a constitutive basal level of NO production from the enteric epithelial cell Caco-2. LPS-induced mIL-6 release from lymphocytes of Peyer's patch is suppressed by the cocultured epithelial cells. While no changes are detectable in NO production in lymphocytes from both wild-type and iNOS knockout mice before and after LPS challenge, NO from lymphocytes appears to play an inhibitory role in epithelial NO release and their own mIL-6 release in response to LPS.

INTRODUCTION

The intestinal mucosa is an important route of entry for microbial pathogens. The single layer of enteric epithelial cells that lines the intestinal mucosa is the initial site of interaction between the host and entero-invasive microbial pathogens. Following bacterial entry, intestinal epithelial cells rapidly initiate the innate and acquired immune response. Within the first few hours after bacterial invasion, the intestinal mucosa produces mediators that orchestrate the onset of an early inflammatory response. Characteristics of this program include the increased production and release of chemokine[1], cytokines[2,3] and nitric oxide (NO)[4]. These molecules can act as early signals to activate an acute mucosal inflammatory response and enhance the ability of epithelial cells to produce cytokines that regulate mucosal immune responses.

NO is generated by the conversion of L-arginine to L-citrulline by NO synthase (NOS), which exists in three

isoforms, encoded by a separate gene. The expression of inducible NOS (iNOS, encoded by NOS2, one of the isoforms) is regulated in various cell types and can be upregulated by stimulation with several cytokines or with bacterial lipopolysaccharide (LPS). iNOS can also be expressed constitutively, in some specialized cells, such as human lung epithelial cells[5]. In human colon epithelial cell lines, the iNOS expression and production of NO are upregulated following stimulation with a combination of interferon-γ (IFN-γ) and interleukin-1 (IL-1) or tumor necrosis factor-α (TNF-α)[6]. NO can mediate a wide array of physiological effects in the intestine that are relevant to neuronal regulation of vascular function, and epithelial barrier integrity[7]. Moreover, NO produced by intestinal epithelial cells could play a protective role in the host response to enteric microbial pathogens[8,9]. Entero-invasive bacteria directly activate expression of iNOS and NO production in intestinal epithelial cells[10]. The NO in the intestine has been implicated in the suppression of microbial entry into epithelial cells by increasing the protective barrier through the release of epithelial mucus[11] and the induction of intestinal fluid secretion[12]. In addition to direct innate immune action, NO has immuno-regulatory effects relevant to the control of infection on modulating the subsequent acquired immune response[13].

Interleukin 6 (IL-6) is a pleiotropic cytokine that is produced by many different cell types and mediates several physiological responses, such as humoral immune response, acute-phase reactions, and hematopoiesis. In the intestine, IL-6 enhances IgA production in murine Peyer's patch B cells[14] and human appendix B cells that express the IL-6 receptor[15]. Intestinal epithelial cells may also secrete IL-6 and TGF-β to enhance IgA secretion and suppress IgM production by mucosal B cells, whose function is highly dependent upon local production of T cell cytokines[16,17]. These facts indicate that IL-6 plays an important role in the mucosal immune response.

We have previously established a coculture system of human colonic epithelial cells (Caco-2) with murine lymphocytes of Peyer's patch and demonstrated that the cell-cell contact between epithelial and immune cells is important in modulating the epithelial barrier and transport function in response to challenge of *Shigella* LPS[18]. Although accumulating evidence suggests that the interaction or "cross-talk" between epithelial cells and lymphocytes of the intestine is crucial in the immune response to bacterial invasion, no report has clearly demonstrated how the interaction between epithelial cells and lymphocytes, particularly from the Peyer's patch, affects the release of important immuno-regulatory mediators, such as NO and IL-6, at rest and in response to bacterial infection. The present study was undertaken using the established coculture system of Caco-2 epithelial cells with lymphocytes of Peyer's patch to investigate NO and IL-6 release in response to *Shigella* LPS challenge. We also cocultured Caco-2 epithelial cells with lymphocytes from iNOS knockout mice to investigate the involvement of NO in regulation of IL-6 release in response to *Shigella* LPS.

MATERIALS AND METHODS

Isolation of Peyer's patch lymphocytes

Wild-type (C57) mice and iNOS knockout mice of C57 background (SPF, 6-8 wk-old) were obtained from the Animal House of Chinese University of Hong Kong. The lymphoid follicles of the mouse Peyer's patch were excised from the intestinal serosal side and placed in 10 mL PBS, supplemented with 20 mL/L FBS (Invitrogen Co., Grand Island, NY) and 2% penicillin-streptomycin (Invitrogen Co.). The collected patches were triturated by pipetting up and down a few times and smashing through a metallic grid (mesh: 100). Individual lymphocytes were released in the medium below the metallic grid. The lymphocytes were washed with PBS, in which the distribution of Peyer's patch T and B cell populations was consistent with previous data when they were checked by flow cytometry[19], and diluted to a concentration of 1×10^7 cells/mL prior to mixed culture with Caco-2.

Enteric epithelial cell culture

Human colonic cell line Caco-2 was purchased from American Type Culture Collection (Rockville, MD). The cells were grown in Dulbecco modified Eagle's minimal essential medium (DMEM; Invitrogen Co.) with 100 mL/L FBS, 2 mmol/L L-glutamine (Invitrogen Co.), 100 μmL/L non-essential amino acid (Invitrogen Co.), 200 units/mL penicillin and 200 μg/ml streptomycin, at 37℃, 50 mL/L CO_2. To maintain the growth of an uniform polarized epithelial monolayer, Caco-2 cells were seeded at a density of 3×10^5 cells on a floating permeable support, which was made of a membrane filter (Millipore, 0.45 μm pore size) with a silicone rubber ring attached on top of it for confining the cells (0.45 cm^2 growth area).

Coculture configurations

Three types of culture configurations were established in this study: (1) Caco-2 culture alone: Caco-2 cells were cultured as a homogenous polarized monolayer according to the epithelial cell culture method mentioned above and they served as the epithelial cell control; (2) Coculture: Caco-2 cells (3×10^5) completely mixed with Peyer's patch lymphocytes (1×10^6), and then were seeded on a permeable support described above and maintained up to the 5th d at 37℃ in a 50 mL/L CO_2 atmosphere; (3) Lymphocytes of Peyer's patch alone: lymphocytes were cultured in an equal volume of the coculture (1×10^6/well in 96-well plate) at 37℃ in a 50 mL/L CO_2 atmosphere as the lymphocyte control.

Shigella F2a-12 LPS pretreatment

When the cells cultured on the membrane filter reached confluence on the 4th d, *Shigella F2a-12* LPS (5 μg/mL, obtained from the Immunology Department of Institute of Microbiology & Epidemiology, Academy of Military Medical Sciences) was added on the apical side of the epithelium monolayer growing on the membrane filters and treated for 24 h at 37℃ in a 50 mL/L CO_2 atmosphere.

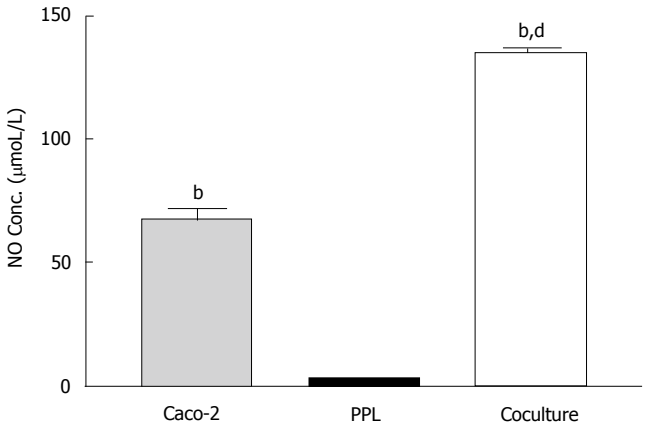

Figure 1 Enhancement of the constitutive NO release in the Caco-2 cocultured with lymphocytes of Peyer's patch. The level of NO in different culture conditions (Caco-2 alone: gray bar; PPL alone: black bar; coculture: white bar) was measured by Griess reagent system and the bar values were derived based on a standard curve. The values represent the means ± SE for 6-12 different samples; $^{b}P < 0.001$ *vs* PPL; $^{d}P < 0.001$ *vs* Caco-2.

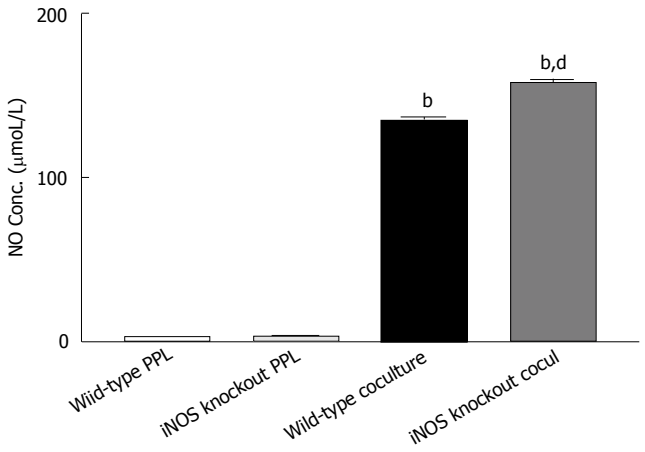

Figure 2 Release of NO is upregulated to the epithelial source Caco-2 cocultured with PPL from iNOS knockout mice. Two sets of cocultures were established (Caco-2 cocultured with PPL of wild-type mice; and Caco-2 cocultured with PPL of iNOS knockout mice). The data are indicated by the following bars (white bar: PPL only from wild-type control mice; light gray bar: PPL only from iNOS knockout mice; black bar: coculture of Caco-2 and PPL from wild-type control mice; dark gray bar: coculture of Caco-2 and PPL from iNOS knockout mice). The level of NO production was measured by Griess colorimetric assay and the bar values were derived based on a standard curve. The values present the means ± SE for 6-8 different samples; $^{b}P < 0.001$ *vs* its own PPL; $^{d}P < 0.001$ *vs* wild-type coculture.

Detection of NO release (Griess colorimetric assay)

After confluent Caco-2 monolayers on the Millipore filter were challenged by *Shigella F2a-12* LPS pretreatment for 24 h, cell culture supernatants were collected and kept at -20℃ until evaluation of NO level in the medium by Griess reagent system (Promega, USA). Briefly, nitrite accumulation was determined by mixing equal volumes of cell culture medium and the Griess reagent (10 mL/L sulfanilamide in 50 mL/L phosphoric acid, and 1 mL/L *N*-1-napthylenediamine dihydrochloride in water). The absorbance (A_{520}-A_{550}) was read on a 96-well microplate reader. Standard curves were constructed with known concentrations of sodium nitrite. The values for the amount of NO were converted from the absorbance values based on the standard curve constructed for each assay.

Enzyme-linked immunosorbent assay (ELISA)

After confluent Caco-2 monolayers on the Millipore filter were challenged by *Shigella F2a-12* LPS pretreatment for 24 h, the culture supernatants were collected and kept at -20℃ until evaluation of mIL-6 level in the culture medium. The IL-6 was measured using a mouse IL-6 quantitative colorimetric sandwich ELISA from Biosource (USA) according to the manufacturer's instructions. The values were calculated on the basis of a standard curve constructed for each assay.

Statistical analysis

All data are expressed as means ± SE. The number of experiments represents independent measurements on separate monolayers. Statistical analysis was performed by repeated measure analysis of variance (ANOVA), and "*P*" values less than 0.05 were considered statistically significant.

RESULTS

Constitutive release of NO from Caco-2 epithelial cells was potentiated by the cocultured lymphocytes of Peyer's patch

In the absence of LPS stimulation, measurements of NO from the culture medium showed a moderate level of NO release from Caco-2 cells (67.64 ± 13.79 μmoL/L) but almost negligible amount (3.15 ± 0.46 μmol/L) in lymphocytes of Peyer's patch from wild-type mice; however coculture of both produced over 2-fold ($P < 0.001$) increase in NO release (Figure 1).

The increase in NO production in the coculture could be due to either potentiation of epithelial release by the cocultured lymphocytes or induction of NO release from lymphocytes by coculturing with epithelial cells. To distinguish this, lymphocytes from iNOS knockout mice were used. If coculture induced NO production in lymphocytes, this would not be observed with iNOS knockout lymphocytes. However, as shown in Figure 2, high level of NO (158.29 ± 2.62 μmoL/L) was still observed in the coculture of Caco-2 with iNOS knockout lymphocytes, confirming the epithelial origin of NO. Moreover, coculure with iNOS knockout lymphocytes produced a level of NO significantly greater than that produced by coculture with lymphocytes of intact iNOS ($P < 0.001$), indicating an inhibitory role of iNOS from lymphocytes in regulating NO release from epithelial cells.

Shigella LPS induced NO release from Caco-2 epithelial cells but with little effect on either lymphocytes of Peyer's patch or the coculture with lymphocytes of iNOS knockout mice

As shown in Figure 3, the level of NO in the culture me-

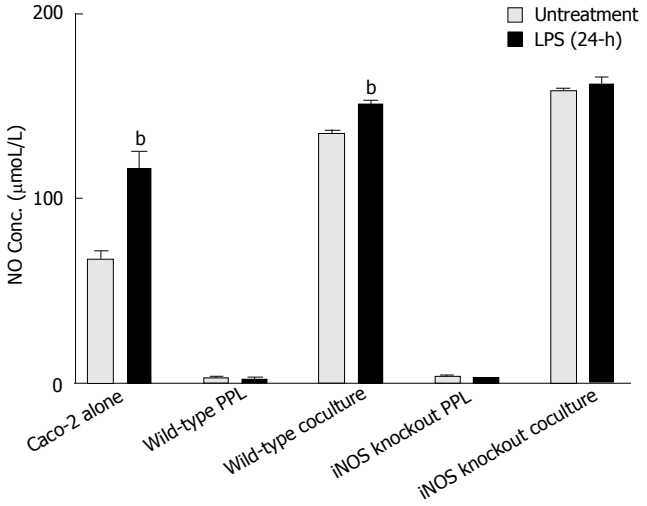

Figure 3 Comparison of NO release induced by *Shigella* LPS in various Caco-2 and PPL culture configurations. *Shigella* LPS was added to five different cultures (set 1: Caco-2 alone; set 2: wild-type PPL only; set 3: Caco-2 and wild-type PPL coculture; set 4: iNOS knockout PPL alone; set 5: Caco-2 and iNOS knockout PPL coculture) and the level of NO release was measured by Griess colorimetric assay and derived based on a standard curve. The black bar and the gray bar represent 24 h treatment with and without LPS, respectively. The values represent the means ± SE for 6-14 different samples. Statistical significance relative to its own un-treatment group was indicated by $^{b}P < 0.001$.

dium of Caco-2 alone and the coculture with lymphocytes of wild-type mice was significantly increased 24 h after LPS treatment as compared to its untreated control (from 67.64 ± 13.80 μmol/L to 116.44 ± 34.57 μmol/L, $P < 0.001$; from 135 ± 4.4 μmol/L to 151.35 ± 4.84 μmoL/L, $P < 0.001$); however, no changes in NO levels were observed in the lymphocytes after LPS treatment (from 3.15 ± 0.46 μmol/L to 2.46 ± 0.52 μmol/L, $P > 0.05$). LPS treatment for 24 h did not significantly produce further increase in the already-high levels of NO release from the coculture of epithelial cells with lymphocytes from iNOS knockout mice (Figure 3).

Suppression of mIL-6 release from lymphocytes of Peyer's patch by cocultured epithelial cells

The release of mIL-6 from different cultures was measured using a mouse ELISA kit. The results showed that mIL-6 release was detected from the lymphocytes of Peyer's patch alone (55.23 ± 2.98 pg/mL) but not from Caco-2 cells, indicating no cross-reactivity of the mouse antibody with human IL-6. When the lymphocytes were cocultured with Caco-2 cells, mIL-6 release was significantly reduced (Figure 4).

LPS triggered mIL-6 release from both lymphocytes of Peyer's patch and cocultures, which was further enhanced with iNOS knockout lymphocytes

As shown in Figure 5, mIL-6 levels in either lymphocytes alone or in cocultured with Caco-2 cells were significantly increased 24 h after *Shigella* F2a-12 LPS treatment. Furthermore, the levels of LPS-induced increases in mIL-6 release were significantly higher in groups with lymphocytes from iNOS knockout mice (Figure 5), indicating an inhibitory role of iNOS from lymphocytes in regulating mIL-6 release.

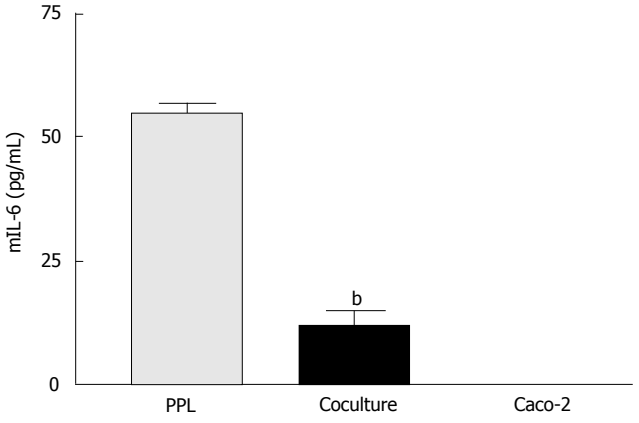

Figure 4 Suppression of mIL-6 release from PPL by cocultured Caco-2 epithelial cells. The bars (gray: wild-type PPL only; black: coculture of Caco-2 and PPL; white: Caco-2 only control) indicate the level of mIL-6 release 4 d after culture. The level of mIL-6 was measured by mIL-6 ELISA and the values were derived based on a standard curve. The values represent means ± SE; $n = 4$; $^{b}P < 0.001$ *vs* PPL.

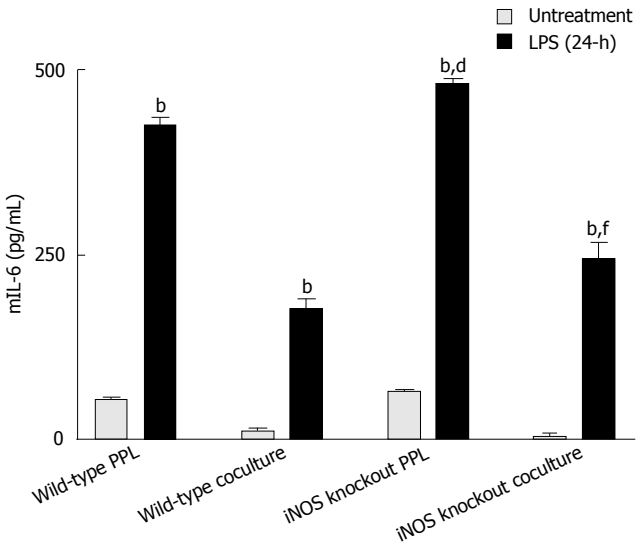

Figure 5 Comparison of mIL-6 release induced by *Shigella* LPS in various Caco-2 and PPL culture configurations. *Shigella* LPS was added to four different cultures (set 1: wild-type PPL only; set 2: Caco-2 and wild-type PPL coculture; set 3: iNOS knockout PPL only; set 4: Caco-2 and iNOS knockout PPL coculture) and the level of mIL-6 release was measured by mIL-6 ELISA and the values were derived based on a standard curve. The black bar and the gray bar represent 24 h treatment with and without LPS, respectively. The values represent the mean ± SE for 4 different samples; $^{b}P < 0.001$ *vs* its own untreatment group, $^{d}P < 0.001$ *vs* wild-type PPL 24-h after challenge *Shigella* LPS and $^{f}P < 0.001$ *vs* wild-type coculture 24-h after *Shigella* LPS challenge.

DISCUSSION

Kerneis S and colleagues[19] have demonstrated that murine Peyer's patch lymphocytes cocultured with human differentiated Caco-2 cell monolayers are able to induce a phenotypic conversion of enterocytes into cells sharing structural and functional properties with M cells. This phenomenon reveals the profound influence of Peyer's patch lymphocytes on intestinal epithelial phenotypes[20,21]. And our previous study indicated that Peyer's patch lymphocytes may modulate intestinal epithelial barrier and ion transport

function in homeostasis and host defense via cell-cell contact and cytokine signaling[18]. The present study has further demonstrated the importance of the interaction between intestinal epithelial cells and lymphocytes of Peyer's patch in regulating the release of NO and IL-6 from Caco-2 epithelial cells and lymphocytes of Peyer's patch, respectively, at rest and in response to *Shigella* LPS challenge.

The present study has demonstrated constitutive release of NO from enteric epithelial cells but not from lymphocytes of Peyer's patch. We also firstly found that the cocultured Peyer's patch lymphocytes potentiated NO release from the enteric epithelial cells. It is known that the constitutive and iNOS activity has the highest level in intestinal villus cells, which is resembled by Caco-2 cells, and the lowest is in crypt cells[22]. Further studies have also demonstrated that the enterocytes regulate their own ion transport processes, either in basal condition or in the presence of active secretion, through the activation of a constitutive NOS-NO pathway, functioning as a braking force of cAMP-induced ion secretion[23]. It has also been reported that iNOS-derived NO is a key mediator of early villous re-epithelialization following acute mucosal injury[24]. These facts indicate that constitutive NO production may have a physiological role in intestinal epithelial cells. It has been proposed that NO synthesis in intestinal epithelial cells is up-regulated through some molecules or cytokines including T-lymphocytes derived cytokines[25] during cell-cell contact with lymphocytes[26]. The observed potentiation of NO release from epithelial cells by Peyer's patch lymphocytes is consistent with the above notion. Our data also suggest that NO from the lymphocytes, although almost negligible, may be involved in negatively regulating NO release from enteric epithelial cells since lymphocytes from iNOS knockout mice further enhance NO release from the epithelial cells. This also rules out the possibility of coculture-induced NO release from the lymphocytes, confirming epithelial release of NO potentiated by the lymphocytes.

Upon *Shigella* F2a-12 LPS challenge, the present results showed that NO from epithelial cell Caco-2 significantly increased but not from lymphocytes of Peyer's patch alone groups. Witthoft[10] has indicated that entero-invasive bacteria directly activate expression of iNOS and NO production in human colon epithelial cells. NO is involved in the protective mechanisms in the gastrointestinal tract. Enterocyte-derived NO changes intestinal monolayer permeability and ion channel *via* iNOS and COX-2[27-30]. In the acute phase response, *shigellosis* inflammation is characterized by increased cell turnover in the lamina propria (LP) and the epithelium, increased iNOS expression in the surface epithelium, and apoptosis, which seems to be associated with LP macrophages[31]. However, NO production in the coculture with C57 wild type lymphocytes further up-regulated by the LPS treatment, yet there was almost no increase in NO production in the coculture with iNOS knockout lymphocytes following LPS challenge. This observation suggests that the coculture of Caco2 and iNOS knockout lymphocytes has become insensitive to the LPS challenge. The iNOS knockout lymphocytes might lack the additional factors that are crucial for LPS-induced NO release. This is a likely scenario since recent studies demonstrated that host defense function of NO in intestinal mucosal immune response is regulated by IL-12 and/or IFN-γ[32], which are deficient in the iNOS knockout mice[33].

Another interesting finding from the present study is that epithelial cells could also suppress mIL-6 secretion by lymphocytes of Peyer's patch with cell-cell contact. The mIL-6 level in both coculture groups was significantly reduced as compared to that of lymphocytes of Peyer's patch alone. It is clear that IL-6 is produced by a number of cell types including antigen-presenting cells, lymphocytes and even epithelial cells *via* stimulating of endotoxin and a number of other stimuli (TGF-β, IL-1β, etc). However, the mIL-6 in the coculture system is only detectable from mouse lymphocytes of Peyer's patch in our previous study[18]. It should be noted that there is evidence that epithelial cells could inhibit IL-6 secretion from lymphocytes by the interaction between epithelial cells and lymphocytes of Peyer's patch in homeostasis. After *shigella* LPS treatment for 24 h, mIL-6 level was obviously increased in all groups. More interestingly, the LPS-induced mIL-6 release was significantly greater in groups with lymphocytes from iNOS knockout mice, indicating an inhibitory role of iNOS in regulating mIL-6 release from lymphocytes their own. Mucosal production of IL-6 is important because this cytokine may regulate a number of local and systemic immune responses, including IgA secretion[16], macrophage differentiation, T cell proliferation, and acute phage protein synthesis[34] in liver and intestine as well as active transcription of a variety of cytokines and receptors[35]. Accumulating evidence[36] suggests that NO inhibits the LPS-induced IL-6 production and this effect may be a direct effect or caused by inhibited PGE2 production, or both PGE2 and NO may act in an autocrine or in a paracrine manner. NO from epithelial cells is easy to reconcile NF-γB activity with the needs of host defense through autocrine pathway to produce a rapid response to a pathogenic stimulus that is shut down promptly so as to minimize host damage[37]. This study only investigated NO release and mIL-6 secretion from different sources to illustrate the cross-interaction between epithelial cells and lymphocytes in homeostasis and host defense. Further studies are required to identify their regulatory mechanism of NO from intestinal epithelial cells to reduce LPS-induced IL-6 production of Peyer's patch lymphocytes.

In summary, the cross-interaction between intestinal epithelial cells and lymphocytes of Peyer's patch regulates host defense mechanism. Lymphocytes of Peyer's patch can induce a basal constitutive production of NO from epithelial cells. This basal level NO may play an important physiological role in the enteric epithelium in the absence of infection. During infection, NO release from epithelial cells is further upregulated. Conversely, epithelial cells can downregulate IL-6 secretion of Peyer's patch lymphocytes, while LPS can upregulate IL-6 release. Furthermore, NO from lymphocytes appears to play an inhibitory role in the epithelial NO release and their own IL-6 release in response to LPS. Taken together, NO and IL-6 are important immuno-regulatory mediators in response to bacterial infection through the interaction between epithelial cells and Peyer's patch lymphocytes.

Abstract

AIM: To evaluate the frequency of the loss of the Adenomatous Polyposis Coli (APC) protein and to compare the APC status with the characteristics of colorectal adenomas.

METHODS: Immunohistochemical analysis of the APC protein was performed on 118 adenomas and the results were compared with parameters of malignant potential, location of adenomas, macroscopic appearance and age of the patients.

RESULTS: A complete loss of the APC protein was found in 28 (24%) adenomas, while 90 (76%) were APC positive. The mean size of adenomas was 13.5 ± 14.2 mm (95% CI 10.5-16.5) in APC-positive, and 13.8 ± 15.5 mm (95% CI 7.8-19.8) in APC-negative adenomas (P = 0.364). Statistical analysis revealed no difference between APC-positive and negative adenomas as to the histological type (P = 0.327) and grade of dysplasia (P =0.494). We found that even advanced adenomas did not differ in their APC status from the non-advanced tumors (P = 0.414). Finally, no difference was found when the location (P = 0.157), macroscopic appearance (P = 0.571) and age of patients (P = 0.438) were analysed and compared between both APC positive and negative adenomas.

CONCLUSION: Most adenomas expressed full-length APC protein, suggesting that protein expression is not a reliable marker for assessment of *APC* gene mutation. Complete loss of APC protein did not influence morphology, location, or appearance of adenomas, nor was it affected by the patient's age.

INTRODUCTION

Adenomatous polyposis coli (APC) gene is thought to play a key role in the pathogenesis of colorectal cancer not only in patients with familial adenomatous polyposis syndrome (FAP), but also in the majority of patients with sporadic colorectal neoplasia[1]. About 60%-80% of sporadic carcinomas of the large bowel carry at least one mutation in the *APC* gene and a similar frequency was reported in colorectal adenomas[2-4]. Hence, a mutation in the *APC* gene is suspected to be an early event in the process of colorectal carcinogenesis[5].

There are numerous known, functionally important mutations in the *APC* gene. Almost all of the mutations implicated in the process of the neoplastic conversion lead to a stop codon with subsequent synthesis of a truncated APC protein, which lacks the carboxyl-terminal part[5,6]. Loss of this part of the APC protein results in the absence of almost all binding sites for β-catenin, which, if not bound in a multiprotein complex with APC, translocates into the nucleus, where it promotes the process of malignant transformation[6]. The absence of the full-length and functional APC protein can be detected by immunohistochemistry using the rabbit or mouse polyclonal antibodies[7,8]. Iwamoto *et al* reported the results of an immunohistochemical analysis, where the frequency of the complete loss of the APC protein was substantially lower

in colorectal adenomas than that detected in carcinomas[9]. Another authors also studied the relationship between the APC protein expression and morphological features of colorectal neoplasms, but results are still conflicting[10-12]. Therefore, in our study we investigated the relationship between the loss of the full-length APC protein assessed by immunohistochemistry and some characteristics of colorectal adenomas with special attention to the malignant potential of adenomas.

MATERIALS AND METHODS

Subjects

One hundred and eighteen consecutive patients with endoscopically-removed colorectal adenomas were involved in this study. Patients with known diagnosis of the familial adenomatous polyposis were excluded. In patients with more than one adenoma, only the largest one was used for further assessment. The size of each adenoma was measured, either using the biopsy forceps, having their tips separated in close proximity to the adenoma within the bowel, or after removal of the polyp from the colon. In large, piecemeal, resected tumors, the size was assessed before the adenoma was removed from the bowel. Adenomas arising in the cecum, ascending colon, or transverse colon were defined as right-sided tumors, whereas those arising distally to the splenic flexure were labeled as left-sided adenomas. Appearance of adenomas was defined either as pedunculated, when a visible stalk was present, or sessile, in the absence of a stalk.

All adenomas were evaluated histologically after staining with hematoxylin-eosin by an experienced pathologist (I.V.). An immunohistochemical examination of the APC protein was then performed on all adenomas and evaluated for size, histology and grade of dysplasia, as parameters of the malignant potential. We also included the adenoma's location, its macroscopic appearance and the patient's age in the statistical analysis. An informed consent was obtained from all patients and the study was approved by the Ethics Committee of the General Teaching Hospital, Prague.

Immunohistochemistry of the APC protein

In general, APC immunohistochemistry was performed using the anti-APC antibodies and their dilution as described by Iwamoto *et al*[9,13]. Paraffin-embedded tissue blocks were cut to obtain sections 4 μm thick, deparaffinized in xylen and rehydrated in a series of graded alcohol + water solutions. Endogenous peroxidase activity was then blocked using a 3% solution of hydrogen peroxide in methanol. Subsequently, tissues were incubated in non-immune serum for 30 min. Next, samples were incubated with anti-APC antibodies (C-terminus, Santa Cruz Biotechnology, Santa Cruz, USA) diluted 1:200 for 60 min. Streptavidin peroxidase (detection kit) with diaminobenzidine (DAB) as a substrate was used for detection at room temperature. Sections were stained with hematoxylin, dehydrated and assembled into the xylen-soluble medium. A definite APC immune reaction in the adjacent normal mucosa of each adenoma served as a control of the normal APC protein reaction.

Table 1 Demographics of patients and characteristics of adenomas

Patients	*n*		118
Adenomas	Sex	Male/Female	71 (60%)/47 (40%)
	Age (yr)	Mean (range), Median	63 (25-86), 65
	Size (mm)	Mean (range), Median	14 (3-55), 6
	Location	Left/Right	83 (70%)/35 (30%)
	Histology	Tubular/ Tubulo-villous/ Villous	82 (70%)/32 (27%)/4 (3%)
	Dysplasia	Low/High-grade	103 (87%)/15 (13%)
	Appearance	Pedunculated/ Sessile	31 (26%)/87 (74%)

Statistical analysis

Normality was tested by Shapiro-Wilk's W test, as the data did not show a normal distribution, non-parametrical statistical methods were used. The APC status was compared with characteristics of adenomas using the Fisher´s exact test and χ^2 (Chi-square) test for categorical variables and the Mann-Whitney test for continuous variables. All tests were bilateral and the significance level was set at 5% for each analysis. We used the statistical software Statistica, version 7, StatSoft, Inc. (2004).

RESULTS

Patients' demographics and the adenomas' characteristics are shown in Table 1.

Results of immunohistochemistry

Of 118 adenomas evaluated, 90 (76%) expressed full-length APC protein, whereas 28 (24%) were APC protein-negative (Figures 1 and 2). APC status was then compared with the parameters defininig the malignant potential of the adenoma (size, histology and grade of dysplasia) (Table 2).

Comparison of the APC status and characteristics of adenomas

The mean size of APC-positive and negative adenomas was 13.5 mm (SD ± 14.2; 95% CI 10.5-16.5) and 13.8 mm (SD ± 15.5; 95% CI 7.8-19.8), respectively. Using the Mann-Whitney test, no statistically significant difference was found between the two groups ($P = 0.364$). Histological assessment revealed that among 82 tubular adenomas, 20 (24%) were APC-negative, and 62 (76%) were positive for APC by immunostaining. Similarly, of 32 tubulovillous adenomas, eight (25%) were negative, while 24 (75%) were positive for the APC protein. All four villous adenomas expressed the APC protein. No statistically significant relationship was found between the histology and the APC status of adenomas (χ^2 test, $P = 0.327$). Majority of adenomas harboured low-grade dysplasia ($n = 103$). Twenty five (24%) of them were APC-negative, while the remaining 78 (76%) were positive. Three (20%) adenomas with high-grade dysplasia did not show APC positivity, whereas

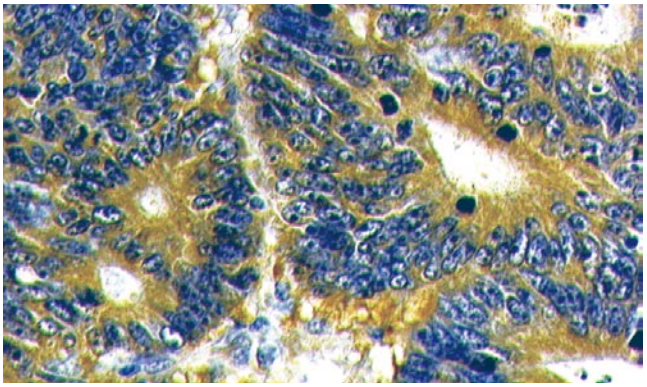

Figure 1 APC immunohistochemistry in colonic adenoma. Difuse positivity (brown color) in the cytoplasma of epithelial cells of the adenoma – presence of the full-lenghth APC protein. Counterstained with hematoxylin. Magnification × 20.

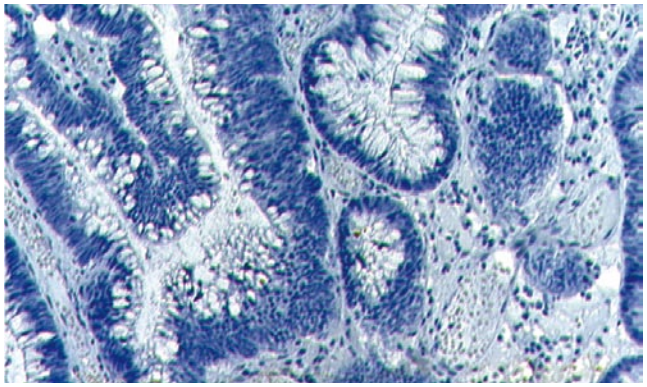

Figure 2 Absence of the immunoreactivity in the cytoplasma of epithelial cells of the adenoma due to the complete loss of the full-lenghth APC protein. Counterstained with hematoxylin. Magnification × 10.

12 (80%) were positive. Again, no significant relationship between the APC presence/absence and the grade of dysplasia was observed in our group (Fisher`s exact test, P = 0.494).

We identified a substantial number of advanced adenomas (n = 46, 39% of entire group). Of them, ten (22%) were APC-negative. Similar results were obtained among non-advanced adenomas, where 18 out of 72 (25%) did not express the APC protein. Using the Fisher's exact test, no significant difference was found between the APC groups (P = 0.414).

Further assessment was performed to look for a relationship between the APC status and the location of adenomas, their macroscopic appearance and the patient's age (Table 2). More than 2/3 of all adenomas were located distally to the splenic flexure. Seventeen left-sided adenomas (20%) were APC-negative, compared with 11 (31%) APC-negative right-sided tumors (Fisher`s exact test, $P$ = 0.157). Comparison between the APC status and the macroscopic appearance of the adenomas revealed 21 (24%) APC-negative, sessile adenomas. Similarly, seven (23%) APC-negative, pedunculated polyps were observed (Fisher`s exact test, P = 0.571). To evaluate the relationship between the age and APC immunoreactivity, patients were divided into groups according to their age: < 41, 41-50, 51-60, and > 60 years of age. Corresponding numbers of APC-negative adenomas were 3 (37%), 4 (36%), 5 (16%), and 16 (24%), respectively. No significant difference was found among the groups (χ^2 test, P = 0.438).

Table 2 Comparison of characteristics of adenomas with APC

Parameter		APC+	APC-	P
Size (SD)		13.5 (± 14.2)	13.8 (±15.5)	0.364[1]
Histology	Tubular	62 (76%)	20 (24%)	
	Tubulovillous	24 (75%)	8 (25%)	0.327[2]
	Villous	4 (100%)	0 (0%)	
Dysplasia	Low-grade	78 (76%)	25 (24%)	0.494[3]
	High-grade	12 (80%)	3 (20%)	
Advancement	Advanced	36 (78%)	10 (22%)	0.414[3]
	Non-advanced	54 (75%)	18 (25%)	
Location	Left	66 (80%)	17 (20%)	0.157[3]
	Right	24 (69%)	11 (31%)	
Appearance	Sessile	66 (76%)	21 (24%)	0.571[3]
	Pedunculated	24(77%)	7 (23%)	
Age (yr)	< 41	5 (63%)	3 (37%)	
	41-50	7 (64%)	4 (36%)	0.438[2]
	51-60	27 (84%)	5 (16%)	
	> 60	51 (76%)	16 (24%)

DISCUSSION

We attempted to verify the hypothesis that the absence of the full-length APC protein resulting from a bi-allelic mutation of the *APC* gene (or a mutation in one allele and the loss of the other) might be associated with a higher degree of malignant potential or with an advanced type of adenoma. We found a complete loss of the APC immunoreactivity in a relatively small proportion of adenomas (24%), whereas more than 3/4 of them displayed either complete, or partial positive results in APC immunostaining. This result is, to some degree, inconsistent with the hypothesis that complete inactivation of both alleles of the APC gene occurs early during the process of colorectal tumorigenesis. These data were derived from studies demonstrating a similar frequency of *APC* mutation, about 60%-80%, in both carcinomas and adenomas[2,3-5]. Contrary to this, our results might indicate that the large number of adenomas contain the mutation of only one allele of the *APC* gene. Whereas 45%-60% of all sporadic adenomas and 60%-80% of carcinomas harbour one inactivated allele, a bi-allelic defect could be found in approximately 30% of adenomas[5,8]. One possible explanation for this finding is that the carcinogenesis of the sporadic colorectal tumors differs from that in patients with familial adenomatous polyposis syndrome, where the vast majority of adenomas harbour a bi-allelic mutation of the *APC* gene[14,15].

However, it is necessary to emphasize that immu-

nohistochemistry detects the presence of the full-length APC protein instead of the actual mutation of the gene. It is the current assumption that almost all of the *APC* gene's mutations result in the production of a truncated protein that has lost its tumor suppressor function[6]. The absence of the full-length APC protein thus indicates a bi-allelic loss of the gene, caused by two mutations or by the combination of one allele's mutation with another type of genetic or epigenetic event (allelic loss or promoter hypermethylation). No clear relationship between the APC protein expression and adenomas' morphology was observed in our study. While some authors found higher frequency of the *APC* gene mutations in tubulovillous and villous adenomas[16], others refuted this observation[9]. The lack of significant difference between adenomas with different malignant potential is contrasted by an abrupt increase in the APC protein loss in carcinomas, which harbour a complete (bi-allelic) *APC* defect much more frequently. Such results were published by Iwamoto *et al*, who found completely negative response for APC immunostaining in 83% of carcinomas, but in only 29% of adenomas[7]. Moreover, even when the exact proportion of *APC* gene mutations or other epigenetic changes were assessed, results were different for adenomas compared with carcinomas[5,8]. On the other hand, Chen *et al* demonstrated positivity of the APC protein detected immunohistochemically and by western blot analysis in the majority of colon cancers[17]. In this study, the APC protein levels were not different among tissues with unchanged or mutated *APC* gene. Even hypermethylation of the *APC* gene, which seems to be a relatively frequent mechanism of APC silencing[18], did not result in APC protein negativity.

Sporadic adenomas may grow with only one allele inactivated[19] as a result of, for example, dominant-negative effect of APC protein homodimers formed by a truncated protein together with the full-length APC protein[20]. These homodimers prevent normal function of APC protein but not its immunoreactivity. This theory is supported by the finding of the nuclear, so that abnormal accumulation of β-catenin in adenomas with a definite positive immunohistochemical result of the APC protein[7]. Therefore, the presence of the APC immunostaining does not necessarily mean the presence of functioning APC protein. Furthermore, mutations of APC may have direct oncogenic effect. Tighe *et al* suggested that the initial APC mutation acts as a "double whammy", destabilising the genome and setting the stage for deregulated proliferation upon loss of the second APC allele[21].

A key question is whether the presence, or absence, of the full-length APC protein affects the prognosis of adenomas as to their future malignant transformation. Theoretically, the lack of the APC protein should stimulate adenomas to grow and undergo malignant transformation. While some reports, including our results, showed no different morphology of APC-negative and positive adenomas[7,9], others found that the prevalence of *APC* mutation continuously increased in the transformation from normal mucosa to carcinoma[8], or that the frequency of *APC* mutations in tubulovillous or villous adenomas was higher than in tubular adenomas[10]. Among our adenoma specimens, a lack of APC protein was observed even in some polyps smaller than 5 mm, which are generally thought to be of minimal clinical importance. On the other hand, several investigators have observed that there are many other genes involved in colorectal carcinogenesis and that a significant number of adenomas, as well as carcinomas, do not harbor any *APC* gene mutations at all[8,16,22]. It should also be noted that colorectal cancers are genetically heterogeneous, multiple genes and mutation may be involved in the tumorigenesis simultaneously as well as the key mechanism may be different in different parts of the colon.

In conclusion, we have not observed a relationship between the presence, or absence, of the full-length APC protein and histology as well as clinical phenotype of sporadic colorectal adenomas. Moreover, only a small part of adenomas did not express the APC protein as assessed by immunohistochemistry. Both these results may indicate that adenomas either harbour genetically heterogenous background, or that one allele remains unchanged and still allows production of normal, full-length APC protein. Hence, immunohistochemistry seems to be an unreliable marker for assessment of *APC* gene changes in colorectal adenomas.

Abstract

AIM: To assess the practically usefulness and diagnostic yield of this new method in a group of patients with suspected small bowel lesions.

METHODS: Capsule endoscopic (CE) examination by using M2A capsule endoscope TM (Given Imaging, Yoqneam, Israel) was performed in thirty nine patients (26 males, 13 females) with suspected small intestinal lesions. The composing of the patients was as follows: obscure gastrointestinal bleeding in twenty three patients, known Crohn's disease in 6 patients, in whom CE was used to evaluate the severity and extension of the diseases, chronic diarrhea in 8 patients, abdominal pain in one patient and malignancy in one patient with unknown origin.

RESULTS: In two patients CE failed. Different abnormalities were revealed in 26 patients overall. Detection rate of abnormalities was highest among patients with obscure gastrointestinal bleeding and the source of bleeding was demonstrated in 17 of 23 patients with obscure bleeding (73.9%). Entero-Behcet was diagnosed in two patients by CE as a source of obscure gastrointestinal bleeding. In 6 patients with known Crohn's disease, CE revealed better evaluation of the disease extension. In 3 of 8 (37.5%) patients with chronic diarrhea; CE revealed some mucosal abnormalities as the cause of chronic diarrhea. In a patient with unexplained abdominal pain and in a cancer patient with unknown origin, CE examination was normal.

CONCLUSION: In our relatively small series, we found that capsule endoscopy is a useful diagnostic tool particularly in diagnosis of obscure gastrointestinal bleeding, chronic diarrhea and in estimating the extension of Crohn's disease.

INTRODUCTION

Demonstration of small bowel lesions was always difficult due to its inaccessibility in conventional modalities. Currently available diagnostic methods such as enteroclysis or push enteroscopy are far from satisfactory results regarding diagnostic yields, patients comfort and technical ease. The technology used in present study permits us to demonstrate the whole small bowel, which was relatively not possible by using conventional modalities. When the diseased area is located to the small bowel, endoscopic evaluation can be extremely difficult. Push enteroscopy has the ability to demonstrate only the proximal to mid-jejunal lesions[1,2]. Endoscopic imaging of the entire small bowel can only be carried out by sonde enteroscopy or surgically assisted enteroscopy which are invasive and uncomfortable techniques[3-6]. On the other hand, capsule endoscopy (CE) allows painless, non-invasive and to get physiologic imaging of the small bowel lesions. Many studies have demonstrated that this technique is superior to the conventional investigations.

In this study, our aim was to investigate the diagnostic capability of CE in different small bowel pathologies in which conventional modalities failed to demonstrate the organic lesions.

MATERIALS AND METHODS

All patients undergoing CE were from February, 2002 to February, 2005 at the Department of Gastroenterology of Hacettepe Medical Center. Thirty nine patients (26 males, 13 females) were evaluated (Table 1). The mean age of the patients was 43 ± 17 years (range, 13-83 years). The indications for the study were obscure gastrointestinal bleeding (23 patients), evaluation of Crohn's disease (6 patients), chronic diarrhea (8 patients), chronic abdominal

Table 1 Indications and findings of capsule endoscopy in thirty nine patients

No	Age (yr)	Sex (F/M)	Indication	Diagnosis/Finding	Comp

OGB: Obscure gastrointestinal bleeding, CD: Crohn's Disease, AP: Abdominal pain, BLH: Benign lymphoid hyperplasia.

pain (one patient), and malignancy with unknown origin (one patient) (Table 2). All patients were undergone by upper gastrointestinal endoscopy and colonoscopy, as well as small bowel follow-through barium studies to exclude any structuring lesions. Some patients were undergone by these endoscopic procedures more than two times when bloody mucosa exists during first examination.

Table 2 Indications for capsule endoscopy

Indication of patient for CE	Number of patients
Obscure gastrointestinal bleeding	23
Crohn's disease	6
Chronic diarrhea	8
Abdominal pain	1
Cancer of unknown origin	1
Total patients	39

Technique used

All patients swallowed Given M2A video capsule (Given Imaging Yoqneam, Israel) after a 10-12 h fasting period. Laxative preparations were not used. The sensors were attached to eight locations on the anterior abdominal wall. A belt containing data recorder was positioned outside the anterior abdominal wall. Patients then swallowed the M2A Capsule with a mouthful of water. The patients remained nil orally for 2 h. Then they allowed to drink clear fluid and after an additional 2 h were allowed to resume their daily diet and activity if their conditions were good enough to do so. After completion of the examination, the recorder was removed and data were transferred to a com-

puter workstation through a high capacity digital link. The images were reviewed by 2 gastroenterologists.

RESULTS

CE examinations were unsuccessful in two patients. In one elderly patient with obscure gastrointestinal bleeding, the capsule failed to pass the pyloric channel since the patient was in supine position because of his medical condition. In another patient with chronic diarrhea, CE examination was unsuccessful after recording about 3 h.

Two patients with obscure gastrointestinal bleeding had undergone surgery for complicated peptic ulcer and one patient with chronic diarrhea for gastric lymphoma in the past (Table 1).

The average gastric emptying time (based on 35 patients) was 37 ± 30 min. (range 3 to 113 min.). In 28 of the 39 patients, the capsule passed the ileocecal valve within the duration of the examination. The mean small bowel transit time (based on 26 patients) was 280 ± 101 min. (range 149 to 484 min.). Neither had symptoms of intestinal hurrying, nor were on prokinetic drugs and encountered complain related to the capsule used. Potentially bleeding sites were identified in 17 patients (73.9%) including active bleeding area (three patients), ulcer (seven patients), angiodysplasia (six patients) and vegetative mass (one patient) (Figure 1).

In three of twenty-three patients with obscure gastrointestinal bleeding; active bleeding (fresh blood) sites were noted as in proximal small intestine, but the source of the bleeding was not clearly seen. In two of the three, the bleeding sources were identified as angiodysplasia located at proximal small intestine related to operation. Six patients had angiodysplasia noted (3 proximal intestine, 1 proximal and distal intestine, 1 distal intestine, 1 colon) without evidence of active bleeding (Figure 2). These lesions were thought to be the cause of the bleeding. Colonic angiodysplasia missed during colonoscopy. In one patient, a vegetative mass was demonstrated in the proximal jejunum which was missed during abdominal CT scan small bowel series. This patient was operated and diagnosed as a jejunal invasion of recurrent renal cell carcinoma (Figure 3). Very interestingly, in two patients with obscure gastrointestinal bleeding, CE demonstrated ulcerations and/or angiodysplasia in terminal ileum which are specific lesions for Behcet's disease (Figure 4). In five patients with obscure gastrointestinal bleeding single or multiple ulcers were

found. In the three of five patients, typical ulcers in distal intestine have been identified in which abdominal CT scan small bowel series were negative for typical findings of Crohn's disease. In one patient with vasculitis, CE found multiple ulcers in proximal intestine. Leiomyosarcoma was demonstrated in one of those patients through the histopathologic examination of the surgical specimen. In those five patients neither active bleeding nor a positive source of bleeding was demonstrated.

Of the six patients with known Crohn's disease, all had obvious ileal ulcer (Figure 5).

As seen in Table 1, in 2 of the eight patients with chronic diarrhea typical benign lymphoid nodular hyperplasia was demonstrated on entire small bowel (Figure 6). Many parasites looks-like *Hymenolepsis nana* were demonstrated throughout the small intestine of one patient with benign lymphoid hyperplasia. His feces were examined carefully and cystic forms of giardia and eggs of *Hymenolepsis nana* were demonstrated. In one patient with Billroth II because of stomach lymphoma, CE found multiple ulcers in small intestine.

In a patient with unexplained abdominal pain and in another cancer patient with unknown origin, CE didn't reveal any abnormalities.

DISCUSSION

In daily practice, available imaging techniques of the small intestine consists of push-endoscopy and X-Ray studies such as small bowel series and enteroclysis. In most cases upper endoscopy can easily reach to the second part of the duodenum. Enteroscopy can demonstrate more extent sites of intestine, but maximally only reach to the mid-jejunum[1,2]. Biopsy is also possible during enteroscopy. Push and sonde enteroscopies have been used for revealing the small intestinal lesions, but these techniques are not easy to neither carry out nor give a high diagnostic yield. In radiological studies, diagnostic accuracy of any small bowel pathology is often low as well as being very uncomfortable. Overall visualization of the mid and distal portion of small bowel is unsatisfactory. Regarding the difficulty for evaluation of occult GI bleeding, which has often been attributed to a source in the small intestine, the many patients finally undergo surgery without knowing the actual source of bleeding.

CE has shown a good diagnostic tool in patients with obscure gastrointestinal bleeding[7-14]. In several clinical studies, it has been shown that this modality may be superior to push enteroscopy[15-21] , small bowel series[7,22], enteroclysis[23] and CT scan[24] in identifying small bowel lesions in obscure gastrointestinal bleeding. Currently, obscure GI bleeding is very common[25]. The diagnostic yield of CE for the suspected bleeding source in obscure GI bleeding has been reported up to from 38% to 93%[9]. In this study, this modality demonstrated the source of bleeding in 17 of the 23 patients (73.9%) with obscure GI bleeding. In our two cases diagnosed as Behcet's disease with obscure GI bleeding, CE revealed multiple punched-out ulcers in which some are bleeding located at terminal ileum. The punched-out ulcer was first time demonstrated in the literatures by using CE.

Definitive diagnoses included angiodysplasia 53%, malignancy 6.3% and inflammatory disease 6.3%[15]. In our study the most important finding is that CE clearly demonstrated angiodysplasia in 6 patients (26%).

Intestinal metastases from renal cell carcinoma are rare. The most common clinical presentation of intestinal metastases of renal cell carcinoma is intestinal bleeding[26]. In the literature, one patient with a history of renal-cell carcinoma had a mass in the proximal small bowel found by using CE[27]. In our study, we diagnosed metastatic tumors originating from renal cell carcinoma in one patient who had severe gastrointestinal bleeding and required 25 units blood transfusion. Small bowel follow-through barium series and abdominal CT scan didn't reveal any abnormalities but CE demonstrated the tumor mass and bleeding area. Only in five patients with obscure GI bleeding, CE did not find any abnormalities.

CE is a superior and more sensitive diagnostic tool than barium follow-through and entero-computerised tomography in patients with suspected Crohn's disease[24,28]. CE is effective in diagnosing patients with suspected Crohn's disease undetected by using conventional diagnostic methods[29-33]. In six cases with known Crohn's disease who underwent CE as a part of routine evaluation of the effectiveness of the treatment, we found obvious ileal ulcers that were missed during small bowel series. Additionally, in three patients with obscure gastrointestinal bleeding, there were typical ileal ulcers and pseudopolyps for Crohn's disease. It is clear that in these three patients CE was very helpful for diagnosis of such abnormalities. On the other hand, this modality took the images out is only lasting 2 to 4 h.

CE did not play an important role in the evaluation of patients with chronic abdominal pain of unknown origin[34]. In patients with undiagnosed abdominal pain the yield of CE appears to be low[35]. In our patients with unexplained abdominal pain CE did not find any abnormalities.

In conclusion, this modality is an exiting new diagnostic technique allowing us to visualize an important section of the gut, which previously has been considered an inaccessible area. When compared with push enteroscopy and small bowel radiography, CE is superior in diagnostic accuracy. In particular for Crohn's disease, CE was is very useful for making the diagnosis and determining the extent and severity of involvement.

In our relatively small series, we found that CE is a useful endoscopic technique particularly in diagnosing obscure gastrointestinal bleeding, chronic diarrhea and Crohn's disease.

Abstract

AIM: To quantify the circulating DNA in plasma from patients with hepatocellular carcinoma (HCC) and to evaluate its prognostic value.

METHODS: Blood samples were collected from 79 patients with HCC before operation, 20 patients with liver cirrhosis, and 20 healthy volunteers. Circulating DNA was extracted from plasma and quantified. The association between circulating DNA level and prognosis of HCC patients was evaluated.

RESULTS: Compared with the healthy volunteers (17.6 ± 9.5 ng/mL), a significant higher circulating DNA level was found in the patients with HCC (47.1 ± 43.7 ng/mL, P = 0.000) or with liver cirrhosis (30.0 ± 13.3 ng/mL, P = 0.002). The circulating DNA level was closely associated with tumor size (P = 0.008) and TNM stage (P = 0.040), negatively associated with the 3-year disease-free survival (DFS) (P = 0.017) and overall survival (OS) (P = 0.001).

CONCLUSION: Large or invasive tumor may release more circulating DNA, and higher level of circulating DNA may be associated with poor prognosis of HCC patients.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common and aggressive malignancies worldwide, and has been ranked the 2nd cancer killer in China since 1990s. The age-standardized mortality rate in China is as high as 34.7/100 000, accounting for 53% of all liver cancer deaths worldwide[1]. Although encouraging long-term survival of HCC patients has been obtained in some clinical centers, recurrence after surgical resection remains one of the major obstacles to further prolonging survival of HCC patients and the overall dismal outcome of patients with HCC has not been completely changed[2,3]. The extremely poor prognosis of HCC is largely due to a high rate of recurrence after surgery or intra-hepatic metastases that develop through invasion of the portal vein or spread to other parts of the liver[4,5].

Identifying biomarker with prognostic significance, especially for predicting recurrence has become an important aspect in HCC study[6]. Since patients with cancers, particularly with high metastatic potential, tend to have higher levels of DNA in plasma, and the molecular biologic findings of circulating DNA in cancer patients are mimicked to those of cancer cells, plasma DNA may be a candidate because of its less invasiveness, simple manipulation, and prognostic information available before operation[7,8]. Few reports have shown the existence of circulating DNA in HCC patients[9-11]. However, the association between circulating DNA level and prognosis of HCC patients is still unclear. In this study, we quantified the circulating DNA in plasma from patients with HCC and evaluated its prognostic value.

MATERIALS AND METHODS

Patients and their clinicopathological characteristics

Seventy-nine patients who received surgical treatment for HCC at Liver Cancer Institute (Zhongshan Hospital) of Fudan University during August-December 2001 were enrolled in this study. The mean age of the patients was 51 years (range 21-83 years). All the patients had a normal liver function preoperatively. All tumors were histopathologically diagnosed as HCC (Table 1). TNM stages of the patients were classified according to the UICC TNM classification of primary liver cancer (6th

edition)[12]. All the 79 patients were given informed consent and followed up till January 2005.

Sample collection

Peripheral blood samples (5 mL) were collected from the HCC patients before surgical operation and put into an EDTA tube. Blood samples from 20 patients with compensated liver cirrhosis (histopathologically diagnosed by biopsy) and 20 healthy volunteers were collected as control. The blood samples were centrifuged at 3000 r/min for 10 min to separate buff coats and plasma. An additional centrifugation for 10 min was performed to produce cell-free plasma. Blood samples were then stored at -80℃ prior to DNA extraction.

Plasma DNA quantification

Plasma and control lymphocyte DNAs were extracted with QIAamp® DNA Blood Midi Kit (Qiagen, Hilden, Germany) according to the blood and body fluid protocol of the manufacturer. Two milliliters of plasma was used, a DNA elution volume of 300 μL was obtained after extraction, and 10 μL of plasma DNA was mixed with equivalence 1:3000 SYBR green I (fluorescence dye). The mixture was analyzed by ultraviolet transilluminator system and photographed under stimulating wave of 345 nm and absorbing wave of 500 nm. The diagram was analyzed by software system to read its intensity[13]. The quantity of plasma DNA was calculated by regression equation which was established by intensity of standard DNA content.

Statistical analysis

Results were expressed as mean ± SD. Fisher's exact test was used to compare qualitative data. $P < 0.05$ was considered statistically significant. Continuous variables were transformed into dichotomous variables before survival analysis. Student's *t*-test was used for mean comparisons. Patients' survival was calculated from the data of operation to the data of death or to the data of point. Survival curves were estimated according to the method of Kaplan-Meier and compared with a log-rank test. To identify the factors that might be of independent significance in influencing the disease-free survival (DFS) or overall survival (OS), a Cox stepwise proportional risk regression model was fitted. All statistical analyses were performed with Stata (version 7) statistical software.

RESULTS

Compared with the healthy volunteers (17.6 ± 9.5 ng/mL), a significant higher circulating plasma DNA level was found in the patients with HCC (47.1 ± 43.7 ng/mL, $P = 0.000$) or with liver cirrhosis (30.0 ± 13.3 ng/mL, $P = 0.002$). However, no significant difference was found in the circulating plasma DNA levels between the patients with HCC and liver cirrhosis ($P = 0.191$).

When we used 36.6ng/mL (mean healthy volunteers +2*SD)[14] as cutoff point of circulating DNA level, the 79 HCC patients were divided into high plasma DNA level group (HDNA) (≥ 36.6 ng/mL) and low plasma DNA level group (LDNA) (< 36.6 ng/mL). Significant differences were found in tumor size ($P = 0.008$) and TNM stage ($P = 0.040$) between the two groups of HCC patients (Table 1).

Table 1 Circulating DNA level and clinicopathological features of HCC patients

Variable	*n*	Circulating DNA level		
		HDNA	LDNA	*P*
Tumor number				0.26

HDNA: High plasma DNA level (≥ 36.6 ng/mL); LDNA: Low plasma DNA level (< 36.6 ng/mL); DFS: Disease-free survival; OS: Overall survival.

The 3-year DFS rates for HDNA group and LDNA group were 22% and 47% respectively ($P = 0.008$), while the 3-year OS rates were 24% and 61% respectively ($P = 0.000$) (Table 1). High circulating DNA level was independently associated with a poorer DFS and OS ($P = 0.004$, $P = 0.000$) (Figure 1A and Figure 1B).

DISCUSSION

The first discovery of extracellular nucleic acids in the circulation was reported in 1948 by Mandel and Métais[15], who demonstrated the presence of both DNA and RNA in the plasma of healthy and sick individuals. This work was particularly remarkable as it was reported only 4 years after the demonstration of DNA as the material of inheritance[16], and it even preceded the landmark paper by Watson and Crick[17] on the double helical structure of DNA. However, their work did not attract much attention, and further development of the field had to wait some

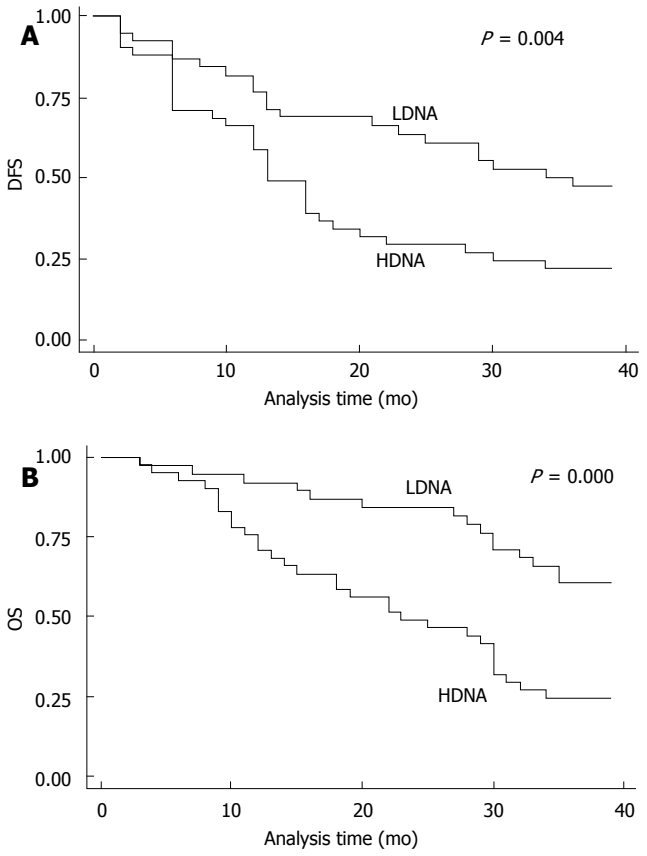

Figure 1 Disease-free (**A**) and overall survival (**B**) curves for HCC patients evaluated according to circulating DNA level. HDNA: High plasma DNA level (⩾ 36.6 ng/mL); LDNA: Low plasma DNA level (< 36.6 ng/mL); DFS: Disease-free survival; OS: Overall survival.

30 years until Leon[18] showed that cancer patients have much higher concentration of circulating DNA than those with non-malignant disease, which is decreased in some cases after anti-cancer therapy. Since then, several follow-up studies have been done to establish the possible value of free circulating DNA as a prognostic factor in patients with pancreatic carcinoma[19], esophageal adenocarcinoma[20], lung cancer[21], melanoma[22] and nasopharyngeal carcinoma[23].

Both plasma and serum samples have frequently been used in the analysis of cell-free DNA. Of particular interest is that the concentrations in serum samples are significantly higher than those in matched plasma samples, which is mainly generated *in vitro* by lysis of white blood cells, suggesting that serum is not suitable for monitoring the concentration of cell-free DNA[24]. A recent work performed a quantitative comparison of matched serum and plasma DNA in patients with colorectal liver metastases and found that serum and plasma DNA level is not correlated with colorectal liver metastases. Furthermore, while serum DNA is significantly associated with the presence of metastases, only plasma DNA is predictive of recurrence, indicating that serum DNA might represent an indirect but tumor-related process, and that plasma DNA better reflects the *in vivo* levels of circulating DNA[14]. Different blood processing protocol may also influence the level of circulating DNA[25]. The plasma obtained by centrifugation alone at various speeds, without subsequent microcentrifugation, has been shown to have substantial amounts of cellular components which may led to the detection of aberrantly high total concentrations of plasma DNA[26]. Therefore, in our study, an additional centrifuge for 10 min was performed to produce cell-free plasma. In order to exclude interference of cell death caused by hepatitis or liver resection, normal liver function test is required for patients' blood sample collection before operation.

In our study, according to the cutoff point of circulating DNA level, the 79 HCC patients were divided into high plasma DNA level group (HDNA) and low plasma DNA level group (LDNA). In HDNA group, 59% (24 of 41) patients had tumor size larger than 5cm while there were only 29% (11 of 38) patients had tumor size larger than 5cm in LDNA group ($P = 0.008$). We also observed that there were 49% (20 of 41) patients with TNM stage III/IV in HDNA group, while there were only 26% (10 of 38) patients with TNM stage III/IV in LDNA group ($P = 0.040$). The mean circulating plasma DNA level was significantly associated with tumor size and TNM stage, indicating that large or invasive tumor may release more circulating DNA and higher level of plasma circulating DNA may be associated with poor prognosis.

Multivariate analysis further confirmed that high circulating DNA level was an independent predictor for poorer 3-year DFS and OS. Furthermore, among patients with TNM stage III or IV, there was no remarkable difference in the 3-year DFS and 3-year OS between HDNA group and LDNA group ($P = 1.000$, $P = 0.448$), while among patients with TNM stage I or II, the 3-year DFS and 3-year OS of patients with HDNA were 24% (5/21) and 38% (8/21), which were much lower than those of patients with LDNA, the 3-year DFS was 57% (16/28) ($P = 0.020$), the 3-year OS was 75% (21/28) ($P = 0.009$). These data suggest that circulating DNA level is negatively associated with the long-term survival of hepatocellular carcinoma patients and might be supplementary to traditional TNM staging.

In conclusion, circulating DNA in liver cancers opens a new research area and eventually be comes a suitable source for development of noninvasive diagnostic methods for HCC.

Abstract

AIM: To compare the one-day quadruple therapy with a standard 7-d triple therapy for *H pylori* eradication in a rural population of China.

METHODS: A total of 396 patients with ^{13}C-urea breath test positive for *H pylori* were assigned into two groups: 239 patients received one-day quadruple therapy (amoxicillin 2000 mg qid; metronidazole 500 mg qid; bismuth citrate 900 mg qid and lansoprazole 60 mg once daily) and 157 patients received 7-d standard triple therapy (amoxicillin 1000 mg bid; clarithromycin 500 mg bid and lansoprazole 30 mg bid). All the patients underwent a ^{13}C-UBT to assess the eradication of *H pylori* infection six weeks after treatment.

RESULTS: Two hundred and twenty-nine patients completed the one-day therapy (95.8%) and 148 patients completed the 7-d therapy (94.2%). The one-day therapy eradicated *H pylori* infection in 64 patients (27.95%). In contrast, 103 patients (69.59%) were *H pylori* negative after the 7-d therapy ($P < 0.01$).

CONCLUSION: This pilot study suggests there is no beneficial effect of the one-day therapy in treatment of *H pylori* infection compared with the 7-d standard therapy.

INTRODUCTION

H pylori infection is the most common cause of gastritis, gastric ulcer, duodenal ulcer, and primary gastric MALT-lymphoma, and plays an important role in the development of gastric cancer[1-5].

Linqu County is a rural area with a high risk of gastric cancer in northern part of China, where 72% of adults and 52% of children aged 3-4 years are infected with *H pylori*[6]. Our previous studies carried out in this region suggested that *H pylori* infection is associated with an increased risk of gastric cancer[7,8] and a random trial in Linqu has demonstrated that one-time eradication of *H pylori* infection can yieldcan a significant benefit on precancerous gastric lesions and a favorable trend on gastric cancer development[9].

Multiple therapies against *H pylori* infection are available at present with a higher cure rate than the single-antibiotic regimens. A triple-drug regimen, consisting of a proton-pump inhibitor, clarithromycin and amoxicillin for over a period of 7 d, has been recommended as a first-line therapy in *H pylori* management[10,11].

In 2003, Lara reported an efficacy of 95% with one-day quadruple therapy for the eradication of *H pylori* in comparison with 90% of 7-d triple therapy[12]. The advantages of the one-day therapy are low costs, low antibiotic resistance and a higher compliance, which motivated us to conduct a similar trial in Linqu County, Shandong Province, China. Herein, we report the results of a random trial of one-day quadruple therapy *vs* standard 7-d triple therapy in a rural population at high-risk of gastric cancer in China.

MATERIALS AND METHODS

Study design

This was a prospective, open, standard controlled therapeutic trial. Subjects with positive ^{13}C-urea breath test (^{13}C-UBT) were allocated to receive one-day therapy and 7-d standard therapy respectively. The efficacy of the treatment was assessed six weeks after the therapy.

Clinical characteristics of the groups

A total of 654 healthy residents aged 25-49 years from 3 villages were invited to participate in this study. All participants received a ^{13}C-UBT to determine *H pylori* infection status. Trained field staff from the Peking University School of Oncology interviewed all the participants using a structured questionnaire containing age, sex, address, occupation, and previous histories of peptic ulcers, use of antibiotics and any allergic reaction to antibiotics. Exclusion criteria for the trial included negative *H pylori* infection, age younger than 25 years or older than 49 years, pregnant or breast-feeding women and people with allergic reaction or severe concomitant illness (e.g. cardiac, respiratory, renal, hepatic diseases and bleeding ulcer). Finally, 396 subjects from 3 villages qualified for entering this trial as illustrated in Figure 1. Among them, 239 patients from two villages (Xinzhuang and Zhujiagou) received a one-day quadruple therapy, and 157 patients from another village (Shiyazuei) received a 7-d triple therapy. The project was approved by the Institutional Review Board of the Peking University School of Oncology and an informed written consent was obtained from all the patients.

Assessment of H pylori status

Details of the assay of ^{13}C-UBT were described previously[13,14]. All participants were fasted overnight before baseline samples of exhaled CO_2 were collected the following morning. Each patient was then requested to drink 20 mL of water with a pill of 80 mg ^{13}C-urea (> 99%). Exhaled CO_2 was collected in sampling tubes 30 min later. $^{13}CO_2$ values were determined using a gas isotopic ratio mass spectrometer, and any concentration of $^{13}CO_2$ at 30 min that exceeded the baseline concentration more than 4 parts per 1000 (> 0.4%) was regarded as a positive result. Samples of duplication were tested with an agreement of 97.2%. The sensitivity and specificity of the test were 94% and 83%, respectively[15].

All the ^{13}C-UBT assays were blinded to the treatment aims. The end point of the study was the proportion of the patients with negative results of the ^{13}C-UBT 6 wk after treatment in each aim.

Treatment

In the one-day treatment group, a quadruple regimen consisted of amoxicillin 2000 mg qid; metronidazole 500 mg qid; bismuth citrate 900 mg qid and lansoprazole 60 mg once daily. And in the 7-d treatment group, the triple regimens consisted of amoxicillin 1000 mg bid, clarithromycin 500 mg bid and lansoprazole 30 mg bid.

To maintain a high compliance, all the patients in each village were organized into 4-5 groups and each group took medications in one household. The staff from the Peking University School of Oncology visited each household and monitored the medications for each patient at 8:00 and 20:00 everyday for the 7-d therapy and at 7:00, 13:00, 19:00 and 1:00 for the one-day therapy.

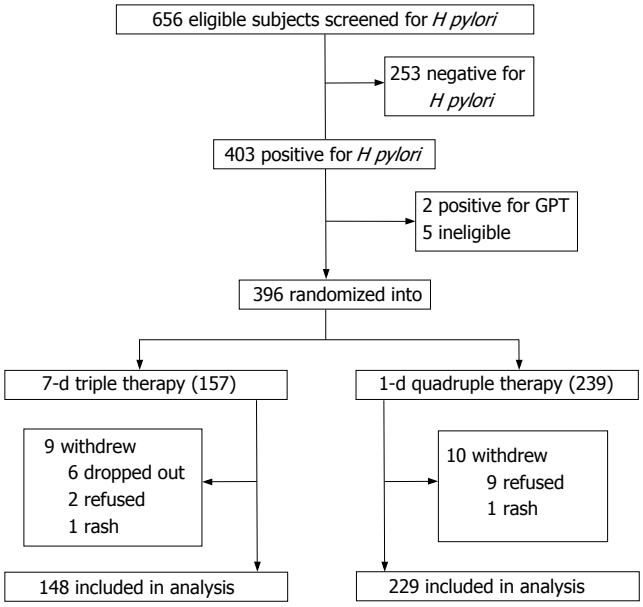

Figure 1 Trial profile.

Table 1 Demographic data and patient compliance in two groups

Treatment	*H pylori* (+)	Age	Completed	Compliance (%)
1-d	239	39.3 ± 6.9	229 (M105, F124)	95.8
7-d	157	39.5 ± 7.3	148 (M78, F70)	94.3
Overall	396	39.4 ± 7.1	377 (M183, F194)	95.2

Monitoring of adverse events

To monitor the adverse reaction related to the anti-*H pylori* therapies, each patient was interviewed using a questionnaire at six days after the treatment. Since metronidazole may injure the hepatic function, 2 mL blood was collected from each fasted patient before, 6 d and 6 wk after the treatment to test glutamic-pyruvic transaminase (GPT) in the laboratory of Linqu County Hospital.

Statistical analysis

For the efficacy analysis, the differences between the two eradication rates were assessed by the chi-square testing. A two-sided 95% confidence interval for the difference between success rates was calculated. All tests were two-sided and values of $P < 0.05$ were considered to indicate statistical significance.

RESULTS

Two hundred and twenty-nine patients (95.8%) completed the one-day therapy and 148 patients (94.3%) completed the 7-d therapy (Table 1). The treatment was unsuccessful for 10 patients in the one-day therapy group and 9 patients

Table 2 Eradication of *H pylori* in two groups

Treatment	*n*	*H pylori* (-)	Eradication (95% CI)	*P*
1-d	229	64	27.95% (22.13-33.76)	
				< 0.01
7-d	148	103	69.59% (62.18-77.00)	

in the 7-d therapy group. In the one-day therapy group, 9 refused the treatment and 1 had to withdraw because of severe rash. Of the 9 patients in the 7-d therapy group, 2 refused the treatment, 6 dropped out and 1 had to withdraw because of severe rash also.

H pylori infection was eradicated in 64 of 229 patients (27.95%) in the one-day therapy compared with 103 of 148 patients (69.59%) in the 7-d therapy six weeks after the treatment (Table 2).

As it shows in Table 3, the proportions of skin rash (5.4%) and abdominal bloating (12.8%) in the 7-d therapy group were significantly higher than that of the one-day therapy group ($P = 0.013$ and $P = 0.035$). In the one-day therapy group, the proportion of stool discoloration (33.2%) was significantly increased ($P < 0.001$).

All 377 patients had a normal hepatic function before the treatment. Six days after the treatment, 91 patients (24.1%) showed abnormal GPT (> 40 IU), and in 9 patients (2.4%) GPT exceeded 100 IU, including 3 from the one-day therapy group and 6 from the 7-d therapy group. In the one-day therapy group, 26.6% of the patients (61/229) had a temporarily abnormal hepatic function (GPT > 40 IU) compared with 24.3% of the patients (36/148) in the 7-d therapy group. However, 36 d later, GPT level of most patients declined to below 40 IU.

Table 3 Incidence of side effects in each group

	Treatment group			
Side effects	7-d	*n* (%)	1-d	*n*(%)
Total		148		229
Rash		8 (5.4)[1]		2 (0.01)
Diarrhea		12 (8.1)		10 (4.4)
Abdominal pain		3 (2.0)		10 (4.4)
Abdominal bloating		19 (12.8)[1]		15 (6.6)
Stool discoloration		14 (9.5)		76 (33.2)[1]
Headache		5 (3.4)		4 (1.75)
Dizziness		4 (2.7)		8 (3.5)
Nausea		15 (10.1)		17 (7.4)
Metallic taste		0		4 (1.75)
Loss of appetite		5 (3.4)		7 (3.1)
Increase of appetite		14 (9.5)		13 (5.7)
Disappearance of abdominal pain		1 (0.007)		1 (0.004)
Stools becoming normal		8 (5.4)[1]		3 (1.3)
Feeling better		3 (2.0)		17 (7.4)[1]

[1]There was significant difference between the two groups ($P < 0.05$).

DISCUSSION

The rates of *H pylori* eradication were 27.95% by one-day therapy and 69.59% by 7-d therapy in this pilot study. It was similar to one of our previous studies (64%)[9,16], in which 3411 patients received 14-d therapy with amoxicillin 1000 mg bid and omeprazole 20 mg bid. Wong *et al* reported 76.4% of eradication of *H pylori* by 7-d triple therapy in a trial in Changle County, China[17]. The result of the one-day anti-*H pylori* therapy in Linqu does not support Lara's report[12]. The eradication rate of *H pylori* is lower (27.95%) than that reported by Lara (95%).

In our study, quality control was enforced throughout the trial. The patients in the one-day therapy group were confined to the village throughout the medication day and monitored by our staff according to the schedule. Although a few patients were out of the village during the 7 d treatment, they were allowed to take the medicine during away and required to contact our staff by cell phone immediately after medicine was taken on schedule.

The reason for the poor eradication rate of *H pylori* in one-day therapy is unclear. The antibiotics are widely used in China and all over the world. As a result, antibiotic resistance is a growing and severe problem worldwide. Kato *et al* reported the prevalence of *H pylori* resistance to clarithromycin, metronidazole and amoxicillin is 29%, 24% and 0% (51 of *H pylori* isolated strains) among Japanese children[18]. Kim *et al* studied 652 *H pylori* isolated strains from Korea residents, and the resistance rates were 40.6% (metronidazole), 5.9% (clarithromycin), 5.3% (tetracycline), and the resistance to metronidazole increased from 1994 to 1999 (from 33.3 to 47.7%)[19]. Li reported the *H pylori* resistance to metronidazole in Chinese is between 28% and 80%, and to clarithromycin is < 5%, respectively[20]. Although the relatively high-dosages of antibiotics are used in the one-day therapy, it is worth investigating the time frame associated with the effectiveness of proton-pump inhibitors and antibiotics. If the proton-pump inhibitor plays a more effective role in the middle or late stage of the treatment in combination with antibiotics, one-day therapy may result in low efficacy in eradication of *H pylori*. In general, the efficiency of *H pylori* eradication in general population is lower than that in clinical patients. The clinical patients with active inflammation seem to be more sensitive to anti-*H pylori* therapy than those with long-term infection and with severe precancerous lesions.

In conclusion, our trial confirms a high efficacy rate of eradication of *H pylori* infection by a standard 7-d triple therapy; whereas, one-day quadruple therapy with high dosage of amoxicillin, metronidazole, bismuth citrate and lansoprazole produces a low eradication rate of *H pylori*. Because the efficacy of *H pylori* eradication reported by Lara *et al* can not be confirmed, the one-day quadruple therapy could not be recommended to use in a large scale study in future.

Abstract

AIM: To study the significance of serum anti-hepatitis E virus (HEV) IgA in patients with hepatitis E.

METHODS: A new method was established to assay anti-HEV IgA, which could be detected in the middle phase of the infection. We compared anti-HEV IgA assay with anti-HEV IgM and anti-HEV IgG assay in sera from 60 patients with positive HEV-RNA.

RESULTS: The 60 patients with positive HEV-RNA had both anti-HEV IgA and anti-HEV IgM and 410 patients with negative HEV-RNA were used as control. Periodic serum samples obtained from 60 patients with hepatitis E were tested for HEV RNA, anti-HEV IgM, anti-HEV IgA and anti-HEV IgG. Their HEV-RNA was detectable in the serum until 20 ± 11 d. We used anti-HEV IgM and anti-HEV IgA assay to detect HEV infection and positive results were found in 90 ± 15 d and 120 ± 23 d respectively, the positive rate of anti-HEV IgA was higher than that of anti-HEV IgM and HEV-RNA (P <0.05).

CONCLUSION: The duration of anti-HEV IgA in serum is longer than that of anti-HEV IgM, and anti-HEV IgA assay is a good method to detect HEV infection.

INTRODUCTION

Hepatitis E is caused by infection with hepatitis E virus (HEV), which is a non-enveloped single-stranded RNA virus. Just like hepatitis A virus (HAV), HEV is usually transmitted from person-to-person via the fecal-oral route. Epidemic of hepatitis E has been found in Central and South-East Asia, North and West Africa, and Mexico, where fecal contamination of drinking water is common. However, recent reports showed that HEV occurs in individuals without traveling in HEV epidemic areas in developed countries like the United States of America and Japan[1-5]. The application of recently developed serologic tests has revealed anti-HEV in almost all countries, including developed countries, in which the disease virtually does not occur[6-8]. Possible reservoirs of HEV in the developed countries may be found in animals like monkeys, pigs, cows, rodents, sheep or goats, suggesting that HEV may be zoonotic[9-12]. Xia *et al*[13] reported that acute hepatitis E occurs in rhesus monkeys, indicating that transfusion transmits hepatitis E. Hepatitis-E is a self-limited disease. But a current research indicates that there are cis-reactive elements in HEV ORF3[14]. Surjit M *et al*[15] found that enhanced alpha microglobulin secretion from Hepatitis E virus ORF3-expressing human hepatoma cells is mediated by the tumor susceptible gene 101. HEV is highly epidemic in China and it is very important for us to find a reliable assay for diagnosing its acute, sub-clinical and chronic infection.

Immunoglobulin M (IgM) against HEV (anti-HEV IgM) is used as a reliable and sensitive marker for recent HEV infection[16-19]. However, the specificity of solid-phase assay for anti-HEV IgM has been questioned in patients with IgM-rheumatoid factors in serum. It was reported that anti-HEV IgA can be utilized as an additional complementary antibody for detecting recent HEV infection[20-23]. But the clinical and epidemiological implications of anti-HEV IgA in finding HEV infection remain to be clarified.

In this study, we used the solid-phase assay to detect HEV-specific IgA. The kinetics of anti-HEV IgM, anti-HEV IgA and anti-HEV IgG responses in serum from patients with hepatitis E demonstrated that anti-HEV IgA assay could identify HEV infection.

MATERIALS AND METHODS

Serum samples

This study enrolled 100 patients (77 males and 23 females,

mean age 52 ± 11 years) with acute hepatitis E admitted to the Department of Infectious Diseases of Tongji Hospital in Wuhan, China, during the period of August 2003 - August 2004. Sera were collected from 60 HEV-RNA positive patients on d 15, 30, 60, 90 and 120 after the onset of symptoms. In addition, 410 serum samples obtained from HEV-RNA negative patients (304 males and 106 females, mean age 42 ± 9 years) were used as controls, including 100 samples from voluntary blood donors with normal alanine aminotransferase (ALT) level, 218 samples from patients with hepatitis A, B or C, 52 samples from patients with autoimmune hepatitis, 40 samples from patients with rheumatoid arthritis. Liver function tests included total serum bilirubin (T-Bil) and direct bilirubin (D-Bil, aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, total protein, γ-glutamyltranspeptidase, prothrombin time, and total cholesterol levels. The serum samples were stored at -70℃ until HEV RNA test.

The presence of anti-HAV IgM, hepatitis B surface antigen (HbsAg), hepatitis B e antigen (HbeAg), antibodies to HBV core (anti-Hbc), and anti-HCV was determined with commercially available kits.

RNA extraction and RT-PCR

Total RNA was extracted with guanidinium isothiocyanate. RT-PCR was carried out in a 50 μL reaction volume containing 10 μL purified RNA, 25 pmol each primer, 1 μL AMV reverse transcriptase and 0.5 μL Taq polymerase. Thirty-five cycles of PCR amplification were performed at 94℃ for 1 min, at 52℃ for 45 s, at 72℃ for 1 min, and a final extension at 72℃ for 7 min. Second-round reactions were carried out in a volume of 50 μL containing 10 μL first-round product, 25 pmol each primer and 0.5 μL Taq polymerase. Thirty PCR omplification cycles were performed at 94℃ for 1 min, at 52℃ for 45 s, at 72℃ for 1 min, and a final extension at 72℃ for 7 min.

Consensus oligonucleotide primers for ORF2 were designed within regions of conserved sequences in the full-length sequences from Asia, Mexico, USA and China strains. The ORF2 primers, at positions 5681nt-6486nt, produced a product of 805 bp nucleotide: EP1 (5´-GCTTCAAATTATGCCCAGTA-3') and EP2 (5' -TGTTGGTTGTCATAATCCTG-3'). Second round internal primers amplified 345 bp products for ORF2: EP3 (5´-GTTATGCTTTGCATA(T)CATGG-3') and EP4 (5' -CCGACGAAATCAATTCTGTC- 3').

Sequence analysis

Second-round PCR products were purified and ligated into pMD 18-T vectors. Twenty-five clones were sequenced automatically with an ABI model - 3730 DNA sequencer and the ABI sequencing ready reaction kit (Perkin - Elmer) according to the manufacturer's instructions. Sequences used for phylogenetic analysis were obtained from Mexico (GenBank accession no. M74506), Burma (D10330), USA (AF060669), China (C1, AJ272108; C2, AF103940; C3, AF151963).

Phylogenetic analysis

Nucleotide sequences were aligned using Clustalx 1.81 (http://downloads.scalableinformatics.com/downloads/clustalx/). These alignments were analyzed with Mega 2.0 (http://evolution.genetics.washington.edu/phylip/software.html) to evaluate the evolutionary distances between sequences using 1000 bootstraps of the data. Bootstrap values greater than 70% could provide significant evidence for phylogenetic analysis grouping.

ELISA for anti-HEV-IgM and anti-HEV-IgG

Anti-HEV-IgM and anti-HEV-IgG were detected by using commercially available kits (BeiJing Wantai Biological Pharmacy Enterprise Co., LTD.). Absorbance (*A*) value was measured at 450 nm. Anti-HEV-IgM cut off = 0.26 + negative control mean *A* value, Anti-HEV-IgG cut off = 0.16 + negative control mean *A* value. Samples with *A* values > cut off were considered positive, Samples with *A* values ≤ cut off were considered negative.

ELISA for anti-HEV-IgA

ELISA for detection of IgG using purified recombinant ORF2/ORF3 protein (WanTai biological pharmacy enterprise co. LTD.) was performed with HRP-labeled coat monoclonal anti-human IgA (Wuhan Lingfei Science and Technology Limited Company) in stead of HRP-labeled coat monoclonal anti-human IgG. In order to detect the titers of goat anti-human IgA-HRP, ELISA was performed with 6 diluted concentrations: 1:500, 1:1000, 1:2000, 1:4000, 1:8000, 1:16000. Results demonstrated that P/N (ratio of sample *A* to negative *A*) of 1:4000-1:8000 of diluted antibodies was ≥ 2.0. In order to obtain the stably detectable results, the diluted concentration of 1:4000 was adopted as standard one and 410 sera with negative HEV-IgM and HEV–IgG were detected for HEV-IgA.

Statistical analysis

Chi square test was used for statistical analysis.

RESULTS

Among the 100 acute phase sera with hepatitis E, 60 (60%) were positive for HEV RNA by reverse transcription- nested polymerase chain reaction (RT- nPCR) using the degenerated primers. Among which 25 partial ORF2 sequences (5972-6317 nt) belonging to HEV genotype Ⅳ were analyzed.

HEV RNA in serum samples from 100 donors negative for anti-HEV-IgM and anti-HEV-IgG was detected by anti-HEV-IgA assay. The absorbance (A) was set at 0.128, standard deviation (SD) at 0.053. When critical value was set at A + 2SD, the IgA assay results were all negative in 410 HEV-IgM and -IgG negative sera. When the A value of positive HEV-IgA assay was set as the mean value of negative control plus 0.18, the specificity of anti-HEV IgA was verified by absorption with the same recombinant ORF2 protein (50 mg/L at the final concentration for anti-HEV IgA assay). Briefly, prior to assay, 10 serum samples were diluted at 1:100, 1:500, 1:1000, 1:5000 to make its A value < 1.5. The microwells were incubated at 37℃ for 0.5 h, then at 4℃ overnight. When the ten serum samples were diluted at 1:500, the A value of the tested samples

Table 1 Prevalence of anti-HEV IgM and anti-HEV IgA in different groups of subjects

Group	*n*	Age (mean ± SD)	Anti-HEV IgA, *n* (%)	Anti-HE IgM, *n* (%)	Anti-HEV IgG, *n* (%)	HEV RNA, *n* (%)

[a]$P < 0.05$, [b]$P < 0.01$ compared with anti-HEV IgM positive results.

was reduced by ⩾ 75% in the anti-HEV IgA assay with the recombinant ORF2 protein, the sample was considered positive for anti-HEV.

Among the serum samples obtained from 100 blood donors, only one sample was positive for anti-HEV IgM, and two samples were positive for anti-HEV IgA. The same samples were positive for anti-HEV IgG and HEV RNA. Using the cutoff values, among remaining 310 serum samples obtained from 62 patients with hepatitis A, 100 patients with hepatitis B, 56 patients with hepatitis C, 52 patients with autoimmune hepatitis, 40 patients with rheumatoid arthritis, were tested for anti-HEV IgA, anti-HEV IgM and anti-HEV IgG (Table 1). Among the 410 patients who were not infected with HEV, including the 100 blood donors, anti-HEV IgM was positive in 7 serum samples, including 2 from patients with hepatitis, 4 from patients with autoimmune disorders. Anti-HEV IgA was detected in 6 serum samples including 4 from patients with hepatitis. The positivity for HEV antibodies could not be confirmed by the absorption test in any of the 10 samples. Serum samples obtained from 100 patients with sporadic acute hepatitis E were tested for the presence of IgM and IgA anti-HEV antibodies. All the 100 patients were positive for anti-HEV IgM and anti-HEV IgA. The presence of anti-HEV IgM and anti-HEV IgA was confirmed by the absorption test in the serum samples from all 100 patients. HEV IgA assay was highly specific and false- positive results in HEV-IgG and IgM assay could also be found in the IgA assay (Table 1).

Anti-HEV IgA, IgM and HEV-RNA were positive in patients with early HEV infection. HEV RNA remained detectable in the serum for one month, anti-HEV IgA for four months (> 50%, anti-HEV IgM for three months (> 50%), ALT and T-Bil for four months (Table 2).

DISCUSSION

Although the incidence of acute hepatitis especially acute hepatitis E has been gradually increased, the correct diagnosis of HEV infection largely depends on the sensitivity and specificity of HEV assay kits. The golden diagnosis standard for acute hepatitis E is based on detection of the HEV genome in serum or feces by RT-PCR, but it can only be used for earlier diagnosis. A solid-phase (sandwich or indirect) ELISA for detecting anti-HEV IgM and IgG is simple and has been currently used in diagnosis of HEV infection[24]. One of its disadvantages is the reduced sensitivity due to competition among virus-specific IgM, IgA and IgG for antigen-binding sites. Another potential disadvantage of the solid-phase test for IgM antibody is that IgM-rheumatoid factor in sera from patients with rheumatoid arthritis may produce a false-positive result. Although the existence of anti-HEV IgG in serum is very long, we cannot distinguish current acute infection from the last infection. It is important to find a new diagnosis assay. It has been reported that anti-HEV IgA can be utilized as an additional confirmatory antibody for recent HEV infection[25]. Although the presence of a specific antibody of IgA can show recent infection in several viral or nonviral diseases, including hepatitis A and B as well as cholera[26], the clinical and epidemiological significance of positivity for anti-HEV IgA remains to be fully verified.

In the present study, we used ELISA to detect IgA using HRP-labeled coat monoclonal anti-human IgA in stead of HRP-labeled coat monoclonal anti-human IgG. The results showed both anti-HEV IgM and anti-HEV IgA were detectable in serum samples obtained from all 60 patients tested who were subsequently diagnosed with HEV infection. The sensitivity was 100%. Among the 410 serum samples from subjects not recently infected with HEV, 6 were falsely positive for anti-HEV IgM and 5 were falsely positive for anti-HEV IgA, indicating that the false-positive rate is low both in anti-HEV IgM and in anti-HEV IgA. Except for one occult HEV infection, none was positive for both anti-HEV IgM and anti-HEV IgA. The specificity of anti-HEV IgA was verified in the absorbant and inhibitory assay.

HEV RNA, anti-HEV IgA, anti-HEV IgM, ALT and TBiL were defected in serum samples from 60 infected patients during follow-up. From these 60 patients, the serum samples obtained on d 15, 30, 60, 90 and 120 after the disease onset. The period of apparent manifestations was 40 d, liver disfunction usually lasted 5 mo, the peak of alanine aminotransferase and total bilirubin was 246 ± 53 U/L and 506 ± 123 μmol/L respectly. The positive number of HEV RNAs in serum was 60 (100%), 36 (60%), 3 (5%) and 0 in wk 2, mo 1-3 respectly. The positive number of anti-HEV IgA was 60 (100%), 60 (100%), 58 (97%), 56 (93%), 38 (63%), 18 (30%) in the second week, the first

1-5 mo after the disease onset, respectively. The positive number of anti-HEV IgM was 60 (100%), 60 (100%), 46 (77%), 34 (57%), 12 (20%), 2 (3%) in the second week, the first 1-3 mo, respectively. The positive rate of anti-HEV IgM and anti-HEV IgA was not significantly different in the first month after the disease onset. From the second month, the positive rate of anti-HEV IgM decreased sharply. The positive rate of anti-HEV IgA maintained at a high level. There were significant changes in them ($P < 0.05$). Since the duration of sero-positivity for HEV RNA, anti-HEV IgM and anti-HEV IgA lasted 1, 3 and 4 mo respectively, hepatic dysfunction lasted 4 mo, the diagnosis of HEV infection could be made by assay of anti-HEV IgM and anti-HEV IgA. Anti-HEV IgA and anti-HEV IgG can be used as a diagnostic indicator of HEV without anti-HEV IgM.

We have previously reported that indirect ELISA can detect anti-HEV IgG and anti-HEV IgA. The performance of IgA test has been extensively evaluated[27,28]. The assay specificity, sensitivity, and consistency are carefully documented. Based on the results obtained in the study, we conclude that anti-HEV IgA assay is as specific as the anti-HEV IgM assay in diagnosis of hepatitis E. IgM and IgA anti-HEV tests can be used together to characterize serum specimens with non-acute hepatitis E. Detecting both IgM anti-HEV and IgA anti-HEV at the same time help to minimize the false positive rate, thus improving diagnosis of HEV infection.

Abstract

AIM: To study the effects of extract from Ginkgo biloba (EGb) containing 22% flavonoid and 5% terpenoid on chronic liver injury and liver fibrosis of rats induced by carbon tetrachloride (CCl_4).

METHODS: All rats were randomly divided into control group, CCl_4-treated group, colchicine-treated group and EGb-protected group. Chronic liver injury was induced in experimental groups by subcutaneous injection of CCl_4 and fed with chows premixed with 79.5% corn powder, 20% lard and 0.5% cholesterol (v/v). EGb-protected group was treated with EGb (0.5 g/kg body weight per day) for 7 wk. At the end of wk 8, all the rats were killed. Liver function, liver fibrosis, oxidative stress and expression of transforming growth factor β_1 (TGF-β_1), a-smooth muscle actin (α-SMA) and type I collagens in liver were determined. In addition, pathology changes of liver tissue were observed under light microscope.

RESULTS: The levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST) and albumin (Alb) in EGb-protected group were notably improved as compared with the CCL_4-treated group ($P < 0.01$). The contents of serum hyaluronic acid (HA), type III procollagen (PCIII), type IV collagen (CIV) and the expression of hepatic tissue TGF-β_1, α-SMA and type I collagen in EGb-protected group were significantly lower than those in CCL_4-treated groups ($P < 0.05$, $P < 0.01$). The degrees of liver fibrosis in EGb-protected groups were lower than those in CCL_4-treated groups (6.58 ± 1.25 *vs* 9.52 ± 2.06, $P < 0.05$). Compared to the CCL_4-treated group, the levels of plasma glutathoine peroxidase (Se-GSH-Px), superoxide dismutase (SOD) and malondialdehyde (MDA) were strikingly improved also in EGb-protected group ($P < 0.05$, $P < 0.01$).

CONCLUSION: EGb resists oxidative stress and thereby reduces chronic liver injury and liver fibrosis in rats with liver injury induced by CCl_4.

INTRODUCTION

Chronic liver diseases commonly result in liver fibrosis and eventually liver cirrhosis. It has been demonstrated that oxygen-derived free radicals (ODFR) and lipid peroxidation play a critical role in the pathogenesis of various liver diseases including hepatic fibrosis[1-3]. Thereby it has become the key to prevent and cure hepatic damage by eliminating free radicals and preventing lipid peroxidation[4-8], and are applied in clinical medicine[9-11].

Extract from Ginkgo biloba (EGb) is an extract from dried ginkgo leaves. EGb could be used in the treatment of asthma and bronchitis. Recent studies have shown that flavonoid (ginkgo-flavone glycosides) and terpenoid (ginkgolides and bilobalides) are the most important active substances in the extract[12]. EGb is well known for its antioxidant property due to its ability to scavenge free radicals and to neutralize ferryl ion-induced peroxidation[13]. Furthermore, EGb can antagonize platelet-activating factor (PAF)[14]. Studies have shown that the antioxidant activity of EGb contributes to the prevention and treatment of diseases associated with oxidative stress[15-19]. These properties of the EGb are thought to provide many beneficial effects against chronic liver damage and liver fibrosis. Therefore, the purpose of this study was to investigate the protective effect of EGb on chronic liver damage and liver fibrosis induced by carbon tetrachloride (CCl_4) in rats.

MATERIALS AND METHODS

Animals and reagents

Male Spratgue-Dawley rats weighing 180 to 220 g were purchased from the Experimental Animal Center, Xi'an Jiaotong University Medical School (certification number: Shaanxi 8-005). Fifty-five animals were treated humanely according to the national guideline for the care of animals and divided randomly into four groups. The rats in control group were given common chows, while the rats in the other three groups were fed with chows premixed with 79.5% corn powder, 20% lard and 0.5% cholesterol (v/v). Meanwhile, 3 mL/kg body weight CCl_4 (analytically pure, Xi'an Chemical Factory, China) as a solution 40% (v/v) in peanut oil was injected subcutaneously twice a week into the rats of CCl_4-treated group, and the first dosage was 5 mL/kg body weight CCl_4. The EGb-treated group and colchicine-treated group received EGb (Tianbao Yinxingpian, 19.2 mg flavonoid glycoside in 80 mg EGb of each tablet, Guizhou Xinbang Drug Design Co. Ltd, China) 0.5 mg/kg per day and colchicine (Xi'an Chemical Factory, China), 0.5 g/kg body weight per day. The control group and CCl_4-treated group were fed with distilled water.

Rats were sacrificed 7 wk later. Serum or plasma was collected and stored at -20℃ for determination. Specimens of isolated rat livers were fixed in formaldehyde and stored in liquid nitrogen.

Detection of serum markers

Activities of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) and concentration of album (Alb) were assayed by a 7170-A automatic analyzer (Hitachi, Japan). Meanwhile, serum hyaluronic acid (HA), type III procollgen (PCIII) and type IV collagen (CIV) concentrations were measured radioimmunologically using commercial kits (Peking Northern Biotech Institute, China).

Parameters of plasma antioxidation

The activity of glutathoine peroxidase (GSH-Px) and superoxide dismutase (SOD) in plasma was quantified, and the concentration of malondialdehyde (MDA) in plasma was determined as previously described[20].

Liver histopathology

For histopathological analysis, thin liver slices were cut, fixed in formaldehyde and embedded in paraffin. Five-μm thick sections were then stained with hematoxylin-eosin (HE) and masons trichrome before observed under light microscope. The degree of hepatic fibrosis was determined by a semi-quantitative method[21].

Immunohistochemical examination

Liver tissue sections were mounted onto slides, deparaffinized in xylene, and rehydrated in alcohol. The levels of transforming growth factor β_1 (TGF-β_1) (Dako, USA), α-smooth muscle actin (α-SMA) (Neomarkers, USA) and type I collagen (Sigma, USA) were determined by immunohistochemical methods using S-P immunohistochemical test kits (Maixing Bio-technological Co., Ltd, Fujian, China). Based on the histological staging, α-SMA, type I collagen and TGF-β_1 positive cells were expressed as percentage of the total area of the specimen.

Table 1 Effect of EGb on liver function in rats with CCl_4-induced injuries (mean ± SD)

Group	*n*	ALT (nkat•L^{-1})	AST (nkat•L^{-1})	Alb (g•L^{-1})
Control	10	42.8 ± 12.5	112.5 ± 36.5	35.3 ± 3.8
CCl_4 treated	11	286.9 ± 52.6^b	250.4 ± 22.5^b	25.5 ± 4.8^b
Colchicines	12	165.2 ± 36.5^d	193.6 ± 20.8	29.5 ± 4.1
EGb	12	92.5 ± 27.5^d	118.2 ± 18.2^d	32.3 ± 6.2^d

$^bP < 0.01$ *vs* control group; $^dP < 0.01$ *vs* CCl_4-treated group.

Table 2 Effect of EGb on liver antioxidation in rats with CCl_4-induced injuries (mean ± SD)

Group	*n*	SOD (nkat•mg^{-1})	GSH-Px (nkat•g protein^{-1})	MDA (nmol•g^{-1})
Control	10	336.9 ± 82.4	482.4 ± 119.3	62.5 ± 15.6

$^bP < 0.01$ *vs* control group; $^dP < 0.01$, $^aP < 0.05$ *vs* CCl_4-treated group.

Statistical analysis

Data were expressed as mean ± SD unless indicated specially, and analyzed by software package SPSS. The Mann-Whitney *u* test for nonparametric and unpaired values, Student's *t*-test or Fisher's exact test was used as appropriate. $P < 0.05$ was considered statistically significant.

RESULTS

Changes of serum indicators

Table 1 gives the values for the activities of serum indicator enzymes and Alb. CCl_4 produced a marked increase in the activities of serum ALT and AST and a significant decrease in Alb level. CCl_4 plus EGb-protected group showed a significant decrease in enzyme levels and a significant increase in Alb level.

Effects of EGb on plasma antioxidation in rats

The activities of plasma SOD and GSH-Px were markedly reduced in CCl_4-treated group compared with control group, while the content of MDA was significantly increased ($P < 0.01$). Markers in EGb-protected group were dramatically recovered compared with model group ($P < 0.01$, Table 2).

Effects of EGb on serum fibrosis

The contents of HA, PCIII and CIV were significantly increased in CCl_4-treated group compared with control group ($P < 0.01$). EGb could reduce the three ECM markers ($P < 0.05$, $P < 0.01$, Table 3).

Influence of EGb on degree of liver fibrosis in rats

HE and mason's trichrome-stained liver sections were observed. The normal control livers showed normal lobular architecture with central veins and radiating hepatic cords

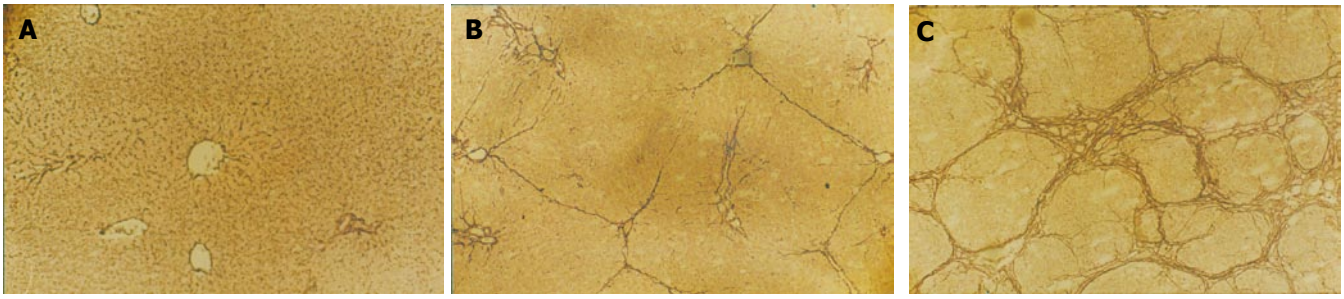

Figure 1 Effects of EGb on histology of CCL_4-induced fibrotic rat liver. Masson trichome staining, scale bar = 40 μm, original magnification × 100. **A**: Normal rat liver; **B**: Fibrosis in CCL_4-treated group; **C**: Fibrosis in EGb-protected group.

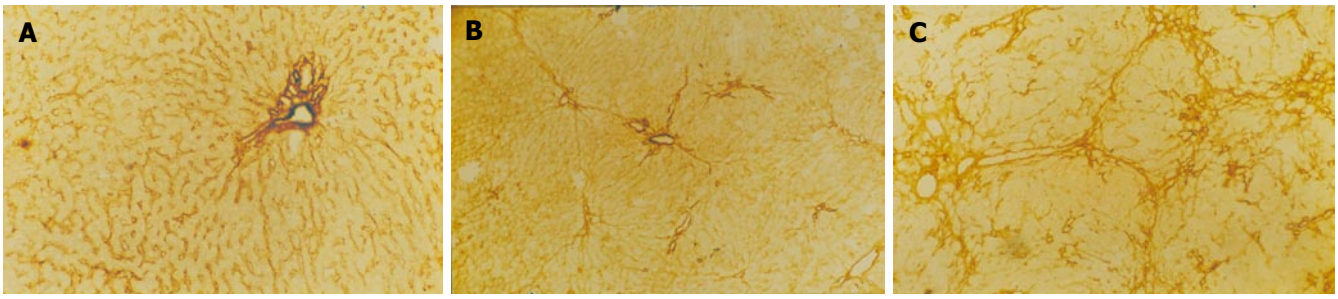

Figure 2 Effects of EGb on type I collagen expression in CCl_4-induced fibrotic rat liver. Immunohistochemistry staining, scale bar = 40 μm, original magnification × 100. **A**: Normal rat liver; **B**: Strong expression of type I collagen in CCL_4-treated group; **C**: Expression of type I collagen in EGb-protected group.

Table 3 Effect of EGb on serum levels of HA, PCIII and CIV (mean ± SD)

Group	*n*	HA (μg•L^{-1})	PCIII (μg•L^{-1})	CIV (μg•L^{-1})
Control	10	40.5 ± 7.8	15.3 ± 3.2	18.5 ± 4.0
CCl_4 treated	11	126.9 ± 12.8[a]	36.5 ± 7.2[a]	56.2 ± 7.8[b]
Colchicines	12	79.2 ± 16.5[b]	23.5 ± 5.6[b]	33.6 ± 5.5[d]
EGb	12	91.5 ± 11.6[b]	28.5 ± 6.0[a]	38.4 ± 5.8[a]

[b]$P < 0.01$ *vs* control group; [d]$P < 0.01$, [a]$P < 0.05$ *vs* CCl_4-treated group.

Table 4 Effect of EGb on degree of liver fibrosis in rats (mean ± SD)

Group	*n*	Degree of liver fibrosis			
		0	I	II	III
Control	10	10	0	0	0
CCL_4 treated[b]	11	0	1	2	8
EGb[a]	12	0	6	4	2

[b]$P < 0.01$ *vs* control group; [a]$P < 0.05$ *vs* CCl_4-treated group.

(Figure 1A). Histological examination of livers from CCL_4-treated group rats revealed hepatocyte denaturation, necrosis, connective tissue hyperplasia, hepatic lobule disorganization and pseudo-lobule formation, degree III fibrosis and hyperplasia (Figure 1B). However, in EGb-protected group, the hepatocyte denaturation and necrosis were not obvious. Hyperplasia of connective tissue was decreased. Liver fibrosis belonged to degree I or II (Figure 1C), but pseudo-lobule formation was not found.

The fibrosis degrees of all groups are shown in Table 4. In addition, detection of hepatic fibrosis markers in serum (6.58 ± 1.25) was also lower than that in CCL_4-treated group (9.52 ± 2.06) compared with control group ($P < 0.05$).

Effects of EGb on TGF-β$_1$, α-SMA, type I collagen expression in rats with CCl_4-induced injuries

Immunohistochemistry revealed that type I collagen was stained in vascular smooth muscle cells and sinusoids of control group rat livers only (Figure 2A). While in CCl_4-treated group, type I collagen was strongly expressed within centrilobular and periportal fibrotic bands (Figure 2B). The percentage of type I collagen expressing area in EGb-protected group was obviously lower than that in CCl_4-treated group ($P < 0.05$, Figure 2C).

The percentage areas of type I collagen, TGF-β$_1$ and α-SMA staining in the rat liver are shown in Figure 3. The results suggested that administration of CCl_4 significantly increased the percentage areas of all the three-marker staining. However, this condition could be significantly suppressed by use of EGb.

DISCUSSION

Carbon tetrachloride (CCl_4) is widely used to experimentally induce liver damage. Peroxidation of membrane lipids secondary to the formation of trichloromethyl ($CCl_{3\ 1/2}$ and /or $CCl_3OO_{1/2}$) radicals is believed to be the basis for the toxic effect of CCl_4[22]. These radicals are capable of initiating a chain of lipid peroxidation reactions by abstracting hydrogen from polyunsaturated fatty acids (PUFA). Peroxidation of lipids, particularly those containing PUFA, can dramatically change the properties of biological membranes, resulting in severe cell damage and play a significant role in pathogenesis of diseases. Membrane lipid peroxidation induces crosslinking in proteins. This can be provoked by the MDA generated

during PUFA degradation. The two-aldehyde functions of MDA can covalently bind to the free amine functions of proteins and lead to an irreversible polymerization. Oxidative damage can also produce reversible disulfide-bonded polymers resulting from the oxidation of protein tiols. These substances lead to CCl_4 hepatoxicity by starting lipid peroxidation in the membranes[23-24].

Standard Ginkgo biloba extract, EGb 761 (commercial name), contains 22%-27% flavonoids (ginkgo-flavone glycosides) and 5%-7% terpenoids (ginkgolides and bilobalides), which are the most important active substances in the extract. The most important flavonoids are glycosides of kaempferol, quercetin, and isorhamnetin with glucose or rhamnose. Ginkgolides, not found in any other living species and only presented in Ginkgo biloba extract, can be divided into types A, B, C, and a very small quantity of J, which are only different in the number and position of hydroxyl groups[12,13,25]. Several mechanisms of action of EGb have been described: vasoregulatory activity and rheological effects, such as decreased iscosity, anti-platelet activating factor activity, and metabolic changes, such as increase neuron tolerance to anoxia, as well as gene- regulatory effects, such as suggesting anticancer activity, and prevention of damage to cell membranes caused by free radicals[13-16, 26].

Recent studies have provided considerable support for the *in vitro* and *in vivo* protective effects of EGb 761 on ischemia/reperfusion injury or oxidative stress[13,15,19,27]. These effects are closely related to the ability of ginkgo-flavone glycosides, the main component of EGb. It has been reported that flavonoids origin nuclear can reduce hydroxy function group, which could capture oxygen-derived free radicals, such as superoxide anion, hydroxyl and peroxyl radicals, and nitric oxide, act as a donator of hydrogen atom to terminate pathological aggravation of free radical chain reaction and lipid peroxidation, and relieve the injury caused by oxygen-derived free radicals and lipid peroxidation[12,13]. Consequently, it reduces lipid peroxidation. Thus EGb has wide antioxidant effects and can be used in disease treatment[16-19,25,28].

Recent studies indicate that oxidative stress is relevant to the formation of fibrosis in most chronic liver diseases, frequently accompanying decline of anti-oxidation abilities, such as accumulation of lipid peroxidation, descent of anti-oxidase capability, decline of reduced glutathione, which plays an important role in pathologenesis of various liver diseases. Therefore, lipid peroxidation is an important factor, which connects inflammatory injury with hepatic fibrosis. Under the circumstances, we suppose that antioxidant therapy could protect hepatocytes from lipid peroxidation, and prevent or relieve chronic liver damage processes[1-3,22]. Daba *et al*[22] demonstrated that EGb is a protective agent against lung toxicity induced by BLM treatment. This study showed that the levels of hepatic enzyme indicator MDA were decreased while the serum levels of ALB and the activity of SOD and GSH-Px in the CCl_4 plus EGb-protected group were decreased when compared with CCl_4-treated group. The findings are similar to the results of Daba *et al*[22], which further confirmed that EGb can inhibit CCl_4-induced lipid peroxidation in plasma and liver tissue and has protective effect on experimental chronic liver damage induced by CCl_4.

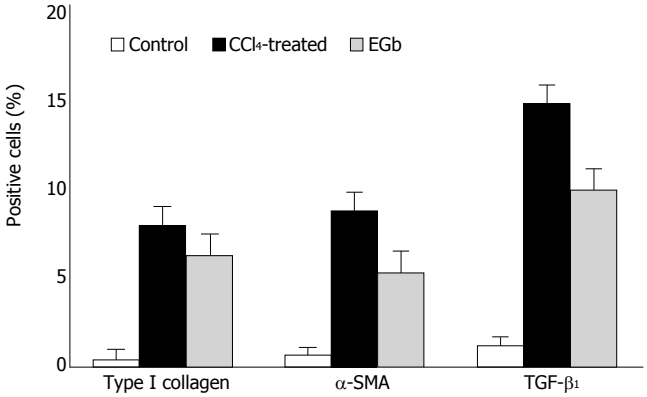

Figure 3 Percentage areas (%) of type I collagen, α-SMA, and TGF-β1 in rat liver.

Hepatic fibrosis is usually initiated by hepatocyte damage, leading to recruitment of inflammatory cells and platelets, activation of kupffer cells and subsequent release of cytokines and growth factors[29,30]. These factors probably link the inflammatory and repair phase of liver cirrhosis by activating hepatic stellate cells (HSC)[31,32]. Recently, HSC have been identified as an important cellular source of extracellular matrix (ECM) in liver fibrosis[33]. These cells reside in the perisinusoidal space of Disse that separates hepatocytes from the sinusoidal endothelium. Upon injury (e.g. by toxins or chronic hepatitis), the normally quiescent HSC are activated and start to proliferate. The activated HSC undergo a phenotypic transdifferentiation to contract myofibroblasts (MFB) expressing α-SMA, and produce an excess of ECM molecules. TGF-β1 is one of the most fibrogenetic cytokines on HSC, and initiates HSC activation characterized by proliferation and expression of α-SMA and ECM[34-36]. It has been shown that lipid peroxidation, free-radical-mediated process, and certain lipid peroxidation products induce genetic overexpression of fibrogenic cytokines (e.g. TGF-β1 and platelet-derived growth factor) and increase the synthesis of collagen. Free radicals and MDA can stimulate the synthesis of collagen and initiate the activation of HSC[37,38]. Our results showed that the expression of TGF-β1, α-SMA and type I collagen in liver, the level of hepatic fibrosis markers in serum and the degrees of fibrosis in liver tissue in EGb-protected group were obviously lower than those in model group, accompanying the decreasing MDA content. These findings suggest that EGb can suppress TGF-β1 expression and TGF-β1-initiated HSC activation, inhibit HSC proliferation and down-regulate α-SMA protein. The antifibrotic effect of EGb may be in part due to its radical scavenging action or antioxidant activity.

In conclusion, EGb is effective against oxidative liver damage and liver fibrosis induced by CCl_4, the protective effect may be due to its radical scavenging action or antioxidant activity. Therefore, EGb can be used to prevent and treat hepatic fibrosis. Further investigations on this matter are needed.

Abstract

AIM: To investigate the role of transglutaminase 3 (TGM3) gene in human esophageal squamous cell carcinoma (ESCC), and analyze its relationship with clinicopathological parameters.

METHODS: Gene expression of TGM3 in fresh esophageal cancer tissues and their corresponding normal mucosas was detected immunohistochemically(IHC) by means of tissue microarray(TMA). Its correlation with clinical characteristics was evaluated and analyzed by univariate analysis. All statistical analyses were performed by SPSS version 10.0.

RESULTS: Expression rate of TGM3 was reduced to 81.8% in ESCC. Expression of TGM3 was significantly inversely correlated with histological grade of esophageal carcinoma (in grade I, II and III tumors, the reduced expression was 4/7, 57/71, and 20/21, respectively, $P < 0.05$), whereas it had no obvious correlations with lymph node metastasis and depth of invasion.

CONCLUSION: Reduced expression of TGM3 may play an important role in esophageal carcinogenesis.

INTRODUCTION

Esophageal cancer ranks among the 10 most frequent cancers in the world, with a predominant distribution in developing countries. Our previous study showed that genetic susceptibility to esophageal cancer was one of the important causes for the high prevalence and familial aggregation of this disease in some areas of northern China[1]. Chen *et al* observed the down-regulation of TGM3 gene in human ESCC using polymerase chain reaction (RT-PCR) and Northern blot techniques[2]. To our best knowledge, this is the first time to investigate the protein expression of TGM3 in ESCC. The expression levels of TGM3 gene decreased in ESCC tissues compared with their normal counterparts. The results are consistent with that from RT-PCR and Northern blot. Therefore, TGM3 gene might be related to human ESCC and further study may provide insight into the mechanisms of carcinogenesis of esophagus. TGM3 is a member of a family of Ca^{2+}-dependent enzymes, which can catalyze the substrates to form a complex that is related to the differentiation of the stratified squamous epithelia[3]. The gene is localized on chromosome 20q11.2[4]. The full-length cDNA of TGM3 is about 2.6 kb, encoding 692 amino acids. TGM3 as a proenzyme, whose molecular weight is about 77 ku, becomes highly active upon proteolytic cleavage into 50 ku (amino-terminal) and 27 ku species[2].

Tissue microarray was first introduced in 1998[5], which allows simultaneous analysis of many tumors using small-diameter cores sampled from larger blocks of tissue, but may be limited by tumor heterogeneity[6]. This study used TMA for the study of four molecules of interest as prognostic factors in ESCC, including methods for assessing immunocytochemical scoring of microarrays. TMA blocks were constructed from 99 cases of ESCC with corresponding normal tissues, taking four cores from different areas of each tumor and adjacent esophageal epithelia. Immunocytochemical labelling was performed for TGM3. The extent and intensity of scoring was determined for each core and the degree of agreement was determined for results from the assessment of two, three or four cores for each carcinoma. In a subset of 99 representative cases, the labelling in the TMA was compared with that in whole-tissue sections of the

same carcinomas. An adequate sample of carcinoma was obtained in more than 90% of the 396 cores. TMA is a reliable tool to demonstrate cellular and molecular alterations in ESCC. We recommend using the mean results from four cores for biological studies, with analysis of categorical data based on quartile groups.

MATERIALS AND METHODS

Materials

Specimens of cancer tissues and matched adjacent normal mucosa were taken from 99 consecutive patients with squamous cell carcinoma of the thoracic esophagus who had undergone esophagectomy with regional lymph node dissected from Oct 2004 to Sept 2005 at the Department of Thoracic Surgery, the First Affiliated Hospital of Anhui Medical University. None of them received irradiation or chemotherapy preoperatively. The patients included 87 men and 12 women with a mean age of 54 (range 36-79) years. Six tumors were located in the upper thorax, 61 in the middle thorax and 32 in the lower thorax (Table 1). The removed specimens were examined histologically with hematoxylin and eosin staining, and then the clinicopathologic stage was determined according to TNM classification.

Table 1 Clinical and histopathological characteristics of patients

Characteristics	*n* = 99 (%)
Sex	
Male	87 (87.9)
Female	12 (12.1)
Location of tumor	
Upper thoracic	6 (6.1)
Middle thoracic	61 (61.6)
Lower thoracic	32 (32.3)
Histological grade	
Ⅰ	7 (7.1)
Ⅱ	71 (71.7)
Ⅲ	21 (21.2)
Depth of invasion	
T1	5 (5.1)
T2	35 (35.4)
T3	59 (59.6)
T4	0 (0)
Lymph node metastasis	
Positive	32 (32.3)
Negative	67 (67.7)

Construction of TMA

Archival paraffin-embedded, formalin-fixed tissues are collected. Two pathologists selected representative areas from each donor tumor block, and then punched cores 0.6 mm in diameter, from the donor block. Sections of the resultant tissue microarray were sliced and transferred to glass slides for processing of TGM3 by immunohistochemistry (Pictured is a 120-specimen TMA with 0.6 mm spots).

Immunohistochemical staining

Immunohistochemical analysis was done retrospectively. Resected esophageal specimens, including both tumor and normal mucosae, were fixed in a 40 g/L formaldehyde solution and embedded in paraffin. The following antibody was used in this study: goat polyclonal anti-human TGM3 antibody (Santa Cruz Biotech Co, USA) diluted 1:100 in PBS. Four μm thick sections of formalin-fixed paraffin-embedded tissue blocks of esophageal tumors were sliced. TMAs were deparaffinized, dehydrated and blocked to remove endogenous peroxidase activity by 3 mL/L H_2O_2 in methanol for 30 min. TMAs were treated with microwave in 0.1 mol/L citrate buffer pH 6.0 at 96℃ for 15 min. After incubation with 100 mL/L normal goat serum to block non-specific binding, they were then incubated with the primary antibodies overnight at 4℃. After antibody was washed with PBS, TMAs were incubated with the secondary antibody and the third antibody (Streptavidin/HRP) according to the manufacturer's instructions, and finally DAB was visualized. Tissues were counterstained with hematoxylin. Negative control was designed by using PBS instead of primary antibody.

Evaluation of staining

The cytoplasmic expression of TGM3 in the ESCC was evaluated as described previously and scored as follows: (a) 0, < 5% of the epithelial cells in the respective lesions; (b) 1, 5%-25% of the epithelial cells in the respective lesions; (c) 2, 26%-50% of the epithelial cells in the respective lesions; (d) 3, 51%-75% of the epithelial cells in the respective lesions; and (e) 4, >75% of the epithelial cells in the respective lesions. The intensity was graded as follows: (a) 0, negative; (b) 1+, weak; (c) 2+, moderate; and (d) 3+, strong (as intense as normal mucosa). A final score between 0 and 12 was achieved by multiplication of the extent of positivity and intensity[7,8]. Scores of 8-12 were defined as "strong expression", scores of 3-7 were defined as "reduced expression", and scores of 0-3 were defined as "markedly reduced expression". Positive staining more than 5% in cell cytoplasm was defined as positive staining; less than 50% in cell cytoplasm was defined as reduced expression; more than 50% in cell cytoplasm was defined as preserved expression[9].

Statistical analysis

χ^2 test or Fisher's exact probability test and Spearman rank correlation coefficient analysis were used to assess the association between immunohistochemical features and clinicopathological characteristics. A P value less than 0.05 was considered statistically significant. All the statistical analyses were performed using the SPSS 10.0 V for Windows.

RESULTS

Expression of TGM3 in esophageal squamous cell carcinoma

TGM3 positive expression showed brown stained signals in the normal mucosa cytoplasm and reduced or positive expression in ESCC, with only a small number of expressions in cell membranes. No nuclear expression of TGM3 was observed in cells. The positive expression rate of TGM3 in 99 esophageal cancer patients was 60.6% (60/99). Significant positive correlation was found in TGM3 expression of the cases between paired normal

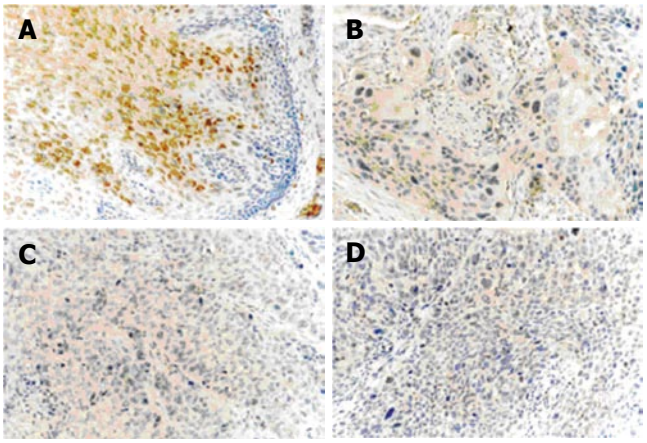

Figure 1 Immunohistochemical analysis of TGM3 in paired ESCC tissue samples using anti- TGM3 antibody (1:100). Diffuse and strong staining was detected in the cytoplasm of the normal epithelial cells (**A**), while sporadic and weak staining was observed in the cytoplasm of matched esophageal cancer epithelial cells (**B**: well-differentiated, **C**: moderately-differentiated, **D**: poorly-differentiated) (original magnification × 200).

and cancerous tissue of esophageal carcinoma ($P < 0.05$). The reduced expression rate of TGM3 was 81.8% (81/99) (Figure 1).

Relationship between TGM3 expression and clinicopathologic variables in esophageal squamous cell carcinoma

Expression of TGM3 correlated significantly only with histological grade of esophageal squamous cell carcinoma. Significant inverse correlation existed between the intensity of TGM3 expression and histological grade ($P < 0.05$). No significant correlation was found between abnormal expression of TGM3 and lymph node metastasis and depth of invasion (Table 2).

Table 2 Relationship between clinicopathological parameters and expression of TGM3

Type	Cases	TGM3		*P*
		Preserved	Reduced	
Histological grade				
Ⅰ	7	3	4	< 0.05
Ⅱ	71	14	57	
Ⅲ	21	1	20	
Depth of invasion

Muscular layer	35	5	30	
Full-thickness	59	13	46	
Lymph node metastases				
Positive	32	6	26	> 0.05
Negative	67	12	55	

DISCUSSION

Transglutaminase(TGM) enzymes are widespread in both plants and animals[10,11]. They catalyze the formation of anisodipeptide cross-linking between the ε-NH2 side chain of a protein-bound lysine residue and the γ-amide side chain of aprotein-bound glutamine residue, thereby forming an insoluble macromolecular aggregate that is used for a variety of cellular functions. To date, there are nine known TGM enzymes encoded in the human genome[12], and interestingly, three of them are active in the epidermis and its appendages. These include: the TGM1 enzyme[13] which can function as membrane-associated[14], soluble full-length, and soluble proteolytically activated processed forms in the epidermis[15]; the soluble, "tissue" TGM2 enzyme[16], and the soluble TGM3 proenzyme, which also requires proteolytic activation[17,18]. The TGM3 enzyme is expressed during the late stages of the terminal differentiation of the epidermis and in certain cell types of the hair follicle[19]. The enzyme is thought to be critically involved in the cross-linking of structural proteins and in the formation of the cornified cell envelope, thereby contributing to rigid structures that play vital roles in shape determination and/or barrier functions[20-22]. Although TGM3 mRNA represents less than 2% of the TGM transcripts, the activated TGM3 accounts for up to 75% of the total TGM activity in mammalian epidermis[15].

The understanding of the molecular basis of tumor development has progressed dramatically in the last two decades. It is well known that tumor is essentially a genetic disease. Therefore it is important to demonstrate what these oncogenes are and how they work in carcinogenesis. Identifying the genetic differences between normal and tumor cells or tissues will help discover the genes that directly cause tumor or are associated with tumorigenesis and provide novel markers for early detection and appropriate therapy.

Although the role of TGM3 has been well established in skin keratinocytes, little information is available concerning its involvement in esophageal epithelia. In previous study, TGM3 gene showed down-regulation in human ESCC tissues[2,23]. To verify this differential expression, we first investigated immunohistochemically the expression of TGM3 protein in paired ESCC by means of TMA. The results of IHC revealed that TGM3 reduced expression in 81.8% (81/99) examined tumor tissues relative to the corresponding normal tissues. Among 99 esophageal tumors examined, which were histologically squamous-cell carcinomas, seven tumors were in grade I, 71 were in grade II and 21 were in grade III. Our data showed that decreased TGM3 expression was uncommon in 3 phases of primary esophageal cancer. This is in agreement with previous studies on a variety of cancers, such as laryngeal carcinoma[24], head and neck squamous cell carcinoma[25], oral squamous cell carcinoma from leukoplakia[26]. In all these studies, reduction or loss of TGM3 expression was significantly associated with dedifferentiation, increased invasiveness, and high incidence of lymph node metastasis, hematogenous recurrence and poor prognosis in a number of human carcinomas. In our investigation, 81.8% of ESCC showed reduced expression of TGM3. As a marker associated with squamous cell histological grade, the level of TGM3 expression had an inverse correlation with histological grade, but not with lymphatic metastases and depth of tumor invasion. TGM3, therefore, is one of the most important adhesion molecules expressed by epithelial cells and is regarded as an invasion suppressor molecule. Further investigations are needed to predict the prognostic value of TGM3 for esophageal tumor patients.

Abstract

Although the association between inflammatory bowel disease and gastrointestinal infections has been suggested, the mechanisms involved in the pathogenesis of Crohn's disease (CD) are still undetermined. We report the case of a man, who presented with mesenteric adenitis initially due to a *Yersinia pseudotubercolosis* infection, who was later diagnosed with Crohn's disease. This case is in keeping with recent evidence in the literature which suggests that CD is a disease linked to abnormal immune responses to enteric bacteria in genetically susceptible individuals.

INTRODUCTION

Infection by *Yersinia pseudotubercolosis* is of increasing pathological importance. Yersinial subspecies should be considered as etiological agents in gatrointestinal infections. Patients with mesenteric adenitis normally present with symptoms similar to those of appendicitis. Such non complicated infections are, at present, successfully managed with systemic antimicrobial agents[1].

We report the case of a young man with terminal ileitis due to *Yersinia pseudotubercolosis* infection, in whom Crohn's disease (CD) was subsequently diagnosed.

CASE REPORT

A 29 year old man was admitted to our GI unit with abdominal pain and diffuse arthralgies. He had demonstrated 5 kg weight loss in the last 7 months, which was probably due to a reduction in food intake because of abdominal symptoms. There was no family history of inflammatory bowel disease or cancer and no previous abdominal surgery. In the preceeding few months the patient had suffered from episodes of severe abdominal pain, emesis, fever (38-40℃), articular and back pain and demonstrated elevated inflammatory markers. The clinical condition of the patient remained poor despite antimicrobial treatment (ceftriaxone) and one month later he developed pleuropericardic effusion and active synovitis of the right knee.

An ultrasound examination revealed thickening of the last 20 cm of the terminal ileum (5-6 mm) with light retrodilatation and pathologically enlarged lymph nodes (1-2 cm). An abdominal MRI confirmed the wall thickening and the wall post iv contrast material enhancement, expression of active inflammation, and the presence of round and excavated mesenteric lymph nodes (Figure 1). Due to persistent abdominal pain, a laparoscopy was performed and biopsies of two mesenteric lymphnodes (transvers mesocolon) were collected. These revealed no histologic evidence of lymphoma. The diagnosis of *Yersinia pseudotubercolosis* infection was confirmed by serology and bacterial culture of the biopsied material. On the basis of suspected ileitis due to Yersinia pseudotubercolosis, cotrimoxazole and cefazime therapy was started. However, despite the antimicrobial treatment, intestinal and arthralgies were still present. Physical examination of the patient revealed poor condition. The abdomen was tender, with pain at palpation of the right iliac region. The tympanites was enhanced. Peristalsis was reduced with metallic sound.

There were no signs of immunodeficiency and most laboratory tests were normal, but indexes of inflammation were present (increased white blood cell count :14, 8/mm^3;

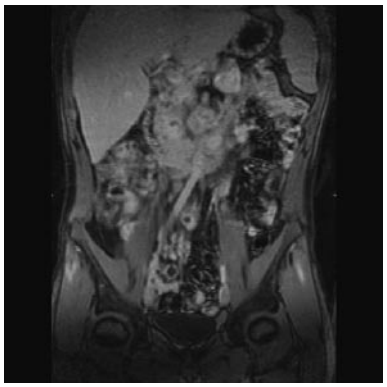

Figure 1 MRI coronal view, T1-weighted post oral administration of superparamagnetic contrast agent. Image illustrates marked wall thickening and enhancement at the level of terminal ileum and enlarged mesenteric lymph nodes.

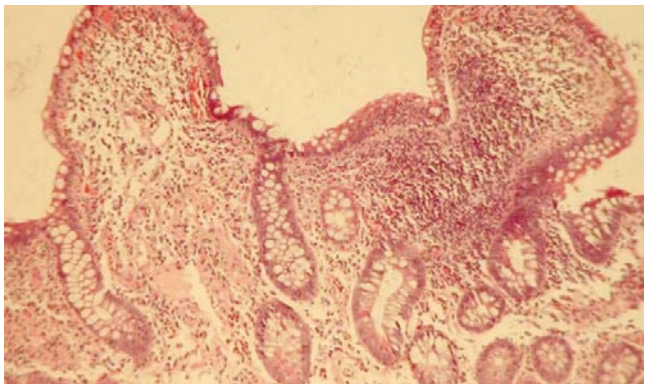

Figure 2 Biopsy of the terminal ileum showing histopathological findings of Crohn's disease.

neutrophils 74%, ESR 60 mm/1 h; CRP 8,14 mg/dL) with associated anemia (HB 118 g/L; ferraemia 21,3 mcg/dL).

The presence of mesenteric lymphoadenitis and anemia suggested Coeliac disease as a possible diagnosis. However, upper gastrointestinal endoscopy and serological screening (EMA IgA, EMA IgG, antibodies anti-transglutaminase IgA) were all negative. Finally, a total colonoscopy with retrograde ileoscopy was performed. It showed erythema, edema, multiple erosions and ulcerations in the ileum. Random biopsies of the ileum were taken and the histopathological findings showed epithelial damage, distorsions of villous architecture and increased inflammatory infiltrate (lymphocytes and eosinophils) in the lamina propria and submucosa (Figure 2). These findings suggested a diagnosis of Crohn's disease, treatment with oral mesalazine 2, 4 g/d was started and clinical improvement ensued. This improvement may also have related to a delayed effect of previous administration of systemic antibiotics. After one year of follow-up the patient was still in remission, and repeated endoscopy and ileal biopsies confirmed the diagnosis.

DISCUSSION

This case report describes the development of Crohn's disease in a patient with a previous *Yersinia pseudotubercolosis* infection. In recent years, very little has been published on the relationship between Yersinia infections and Crohn's disease[2,3], although microorganisms have long been suspected of causing CD. *Yersinia pseudotubercolosis* is a Gram-negative coccobacillus and a primary pathogen of wild and domestic animals and birds. It is an enteric pathogen that causes a variety of clinical symptoms in the human. These include diarrhoea, abdominal pain and post-bacteremia systemic symptoms such as fever, scarlattiniform skin rash, conjunctivitis, erythema nodosum and lymphadenophathy. Additional complications in the form of reactive arthritis, acute uveitis, coronary aneurysm and acute renal failure have also been reported[4].

When refrigerated, this organism survives while others do not. As a result, in a recent paper Hugot et al., have suggested the refrigerator as a new contributing factor in the development of CD[5]. In relation to the observation that CD is linked to a familial environmental risk factor related to modern lifestyle, the authors show temporal and geographical coincidences between the development of the refrigerator and the outbreak of CD.

This bacterium exhibits a marked tropism for lymphatic tissue and the characteristic histopathological findings in mesenteric lymph nodes suggest that the stimulation of T cells play a central role in the pathogenesis of this infection[6]. A key factor in the etiology of IBD is the chronic inflammatory process. Much evidence suggest that the transcription factor nuclear factor-kappa B (NFkB) plays an essential role in developing inflammation through the regulation of genes encoding pro-inflammatory cytokines, adhesion molecules, chemokines, growth factors, and inducible enzymes such as cyclooxigenase 2 (COX2) and inducible nitric oxide synthase (iNOS)[7]. Evidence has shown that Gram negative bacteria such as Yersinia pseudotubercolosis, target the eukaryotic signal transduction pathways that lead to NFkB activation[8]. NOD2 (renamed CARD15 by the International Nomenclature Committee) a gene involved in innate immunity, is an activator of the NFkB pathway[9]. The link between bacterial components, including lipopolysaccharide (LPS) and CD is strongly supported by the discovery that mutations in CARD15 predispose people to the disease[10]. Recent studies have demonstrated that a frameshift mutation in CARD15 may result in innate hyporesponsiveness to bacterial components, inducing an altered adaptive response to enteric bacteria[11].

This report supports previous evidence that CD is a disease of an abnormal immune response to enteric bacteria in genetically susceptible individuals. In common with previous studies associating infectious organism with CD, much work remains to elucidate whether the presence of the microorganisms is an epiphenomenon or actually a factor in the pathogenesis of CD.

Abstract

Dieulafoy's lesion is an unusual cause of recurrent GI bleeding. This report describes a case of actively bleeding Dieulafoy's lesion of the small bowel in which the diagnosis was made by capsule endoscopy, followed by treatment with the use of push enteroscopy. The case illustrates that capsule endoscopy and enteroscopy are highly complementary in patients with small bowel diseases.

http://www.wjgnet.com/1007-9327/12/3936.asp

INTRODUCTION

Dieulafoy's lesion (DL) is an unusual cause of recurrent gastrointestinal (GI) bleeding[1-3]. It consists of a large-caliber, tortuous artery, 1-3 mm in diameter, that lies in the submucosa in close contact with the mucosa over a variable distance. Massive bleeding can occur with erosion of the mucosa and arterial wall[4] .

Because of the small size of the lesion and the normal surrounding mucosa, the diagnosis of a Dieulafoy's lesion can be made with confidence only during active bleeding. A variety of endoscopic modalities have been used, either alone or in combination, with high success rates. This report describes a case of actively bleeding Dieulafoy's lesion of the small bowel in which the diagnosis was made by capsule endoscopy (CE), followed by treatment with the use of push enteroscopy.

CASE REPORT

A 50-year-old man was admitted to our hospital with chief complain of melena. He had a 1-year history of prosthetic heart valves implantation and was taking coumadin. At admission, Hb level was 83 g/L, hematocrit 21.5%, red blood cell count 2.15×10^{12}/L, a platelet count 249×10^{9}/L and international normalized ratio (INR) 3.35. However, the patient was hemodynamically stable. Esophagogastroduodenoscopy (EGD) and colonoscopy, performed on emergent basis, were negative for a source of bleeding. Hence, capsule endoscopy was performed because it was necessary to rule out other possible sources of bleeding, which revealed a single active bleeding vascular lesion of the small bowel (Figure 1). Peroral push enteroscopy disclosed a single oozing vessel with normal surrounding mucosa and no evidence of ulceration (Figure 2).

A hemostatic clip (Quick-Clip; Olympus Optical Co. Ltd., Tokyo, Japan) was applied to the vessel (Figure 3). The course of the patient after endoscopic treatment was uneventful and the patient was discharged 5 d later. Hemoglobin was 108 g/L on the day of discharge. At 6 mo after the endoscopic treatment, there had been no recurrence of upper GI bleeding.

DISCUSSION

Dieulafoy's lesion accounts for 2% to 5% of all cases of acute GI bleeding, but it can be the cause of recurrent and often potentially life-threatening hemorrhage[1-4]. Previous descriptions of the Dieulafoy's lesion emphasized a predilection for the proximal stomach. However, it is increasingly apparent that these lesions, although usually gastric, may develop throughout the GI tract (esophagus 2%, jejunum 2%, colon 10%)[5,6]. A variety of endoscopic modalities, including monopolar and bipolar electrocoagulation, heat probe coagulation, injection sclerotherapy, hemoclip placement, endoscopic band ligation, and laser photocoagulation, have been used, either alone or in combination, with a success rates of 90%-95% and a rate of recurrent bleeding of 5%-10%[7-16]. Because of the small size of the lesion, the

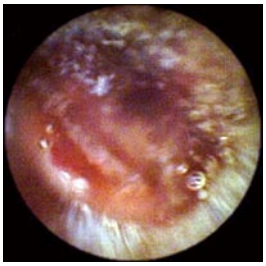

Figure 1 Capsule endoscopy showing a single active bleeding vascular lesion of the small bowel.

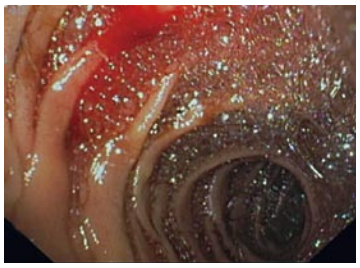

Figure 2 Enteroscopy showing a single oozing vessel with normal surrounding mucosa and no evidence of ulceration.

Figure 3 Application of a hemostatic clip to the vessel.

normal surrounding mucosa and the intermittent nature of the bleeding, endoscopic diagnosis is challenging and may require multiple and combined procedures.

This report describes a case of actively bleeding Dieulafoy's lesion of the small bowel in which the diagnosis was made by capsule endoscopy, followed by treatment with the use of push enteroscopy. Capsule endoscopy is a technically simple procedure that is extremely well tolerated by patients. However, possibility for therapeutic maneuvers cannot be performed with the capsule. By contrast, push enteroscopy is more labor intensive, but it enables various endoscopic therapeutic procedures. Thus, capsule endoscopy is suitable as an initial imaging study for small bowel disorders, whereas enteroscopy is desirable for the confirmation of small-bowel diseases, tissue sampling, and therapeutic applications. The combination of capsule endoscopy and enteroscopy provides a powerful strategy for the diagnosis, as well as treatment of small bowel diseases. As illustrated by the case presented, these procedures are highly complementary.

Abstract

Inflammatory myofibroblastic tumors (IMTs) or inflammatory pseudotumors (IPs) have been extensively discussed in the literature. They are usually found in the lung and upper respiratory tract. However, reporting of cases involving the biliopancreatic region has increased over recent years. Immunohistochemical study of these lesions limited to the pancreatic head or distal bile duct seems to be compatible with those observed in a new entity called autoimmune pancreatitis, but usually intense fibrotic reaction (zonation) predominates producing a mass. When this condition is limited to the pancreatic head, the common bile duct might be involved by the inflammatory process and jaundice may occur often resembling adenocarcinoma of the pancreas. We have previously reported a case of IMT arising from the bile duct associated with autoimmune pancreatitis which is an extremely rare entity. Four years after Kaush-Whipple resection, radiological examination on routine follow-up revealed a tumor mass, suggesting local recurrence. Ultrasound-guided FNA confirmed our suspicious diagnosis. This present case, as others, suggests that persistent follow-up is necessary in order to prevent irreversible liver damage at this specific location.

INTRODUCTION

Histologically, inflammatory myofibroblastic tumor (IMT) is characterized by a proliferation of spindle cells admixed with variable amounts of a lymphoplasmacytic infiltrate. These changes in the pancreatic head produce a mass effect in the biliopancreatic region mimicking a malignant tumor. Thus, surgical resection has been often necessary in order to obtain a definitive diagnosis as well as to relieve symptoms[1]. IMT has been shown to possess potentiality for local infiltration and recurrence with persistent local growth at any organ. Hence, a strict follow-up after surgery is necessary because local recurrence may occur many years later. We report herein a case of local IMT recurrence four years after Kausch-Whipple resection with tumor-free margins in a 55-year-old woman. Primary tumor was located in the distal common bile duct accompanied with lymphoplasmacytic reaction in the pancreatic head. To our best of knowledge, this is the first case reporting a local reappearance of inflammatory pseudotumor in the distal bile duct associated with benign lymphoplasmacytic sclerosing pancreatitis that responded successfully to corticosteroid therapy. Further follow-up in the present case is necessary to elucidate if it behaves as a reactive progressive lesion or tumor.

CASE REPORT

A 55-year-old woman with a past history of IMT affecting the biliopancreatic region [myofibroblastic inflammatory tumor of the distal bile duct (OCD-O code C-24.O M-8825/1) associated with lymphoplasmacytic sclerosing pancreatitis, chronic cholecystitis and reactive lymphadenitis of the isolated nodes] was on routine follow-up after Kaush-Whipple resection.

Four years later, routine surveillance CT scans detected a well defined mass in close relation to the portal vein without apparent infiltration of surrounded structures. At this time, weight loss, malaise or anemia were not present. The tumor mass was well circumscribed, measuring 5 cm × 5 cm, had solid pattern and did not enhance with contrast (Figure 1). An abdominal MRI further delineated that the

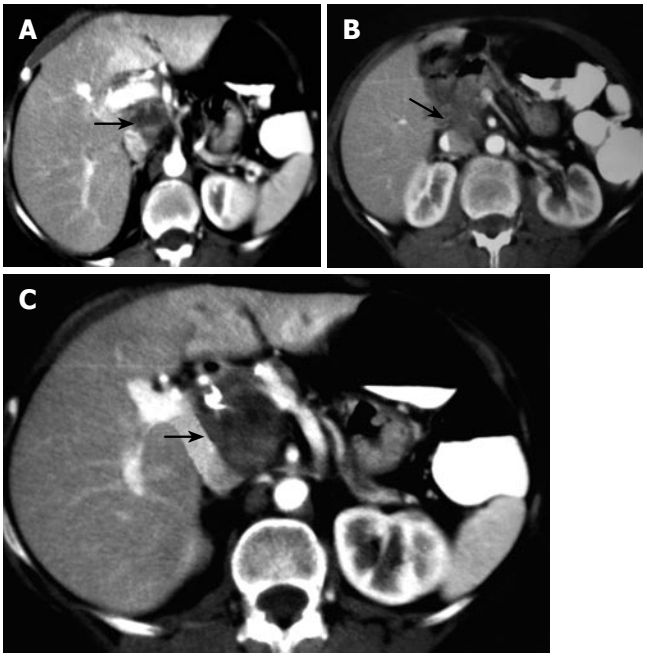

Figure 1 CT scan revealing a well delimited solid mass (arrow), without enlarged regional or para aortic lymph nodes and any evidence of invasion of other organs.

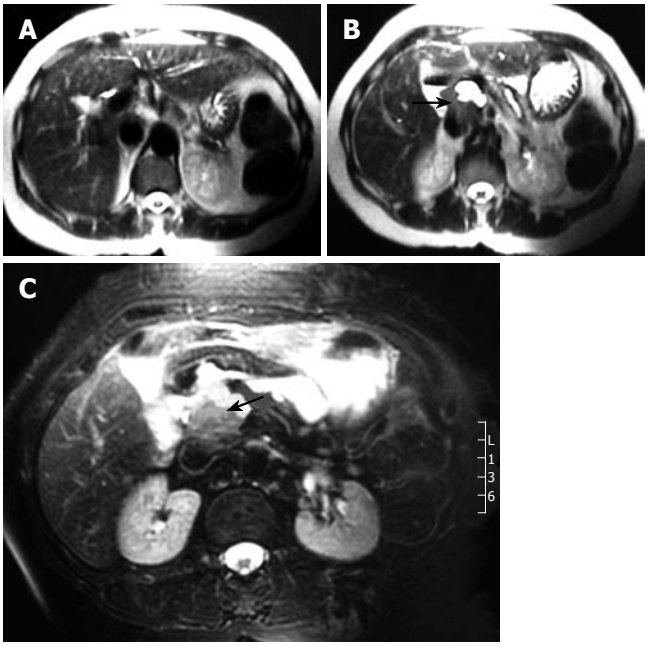

Figure 2 CT scan showing a clear relationship between tumor and inferior cava vein (arrow).

mass was located between the portal vein and inferior vena cava with no signs of widespread infiltration of organs, thereby strongly suggesting the diagnosis of local recurrence (Figure 2). It did not reveal intrahepatic bile duct dilatation but did show chronic changes in pancreatic tissue (Figure 3). Ultrasound-guided fine-needle aspiration (FNA) was performed for cytological examination, which revealed prominent infiltrate of lymphocytes, plasma cells, and acute inflammatory cells without cytologic atypia. These findings were compatible with IMT. Therefore,

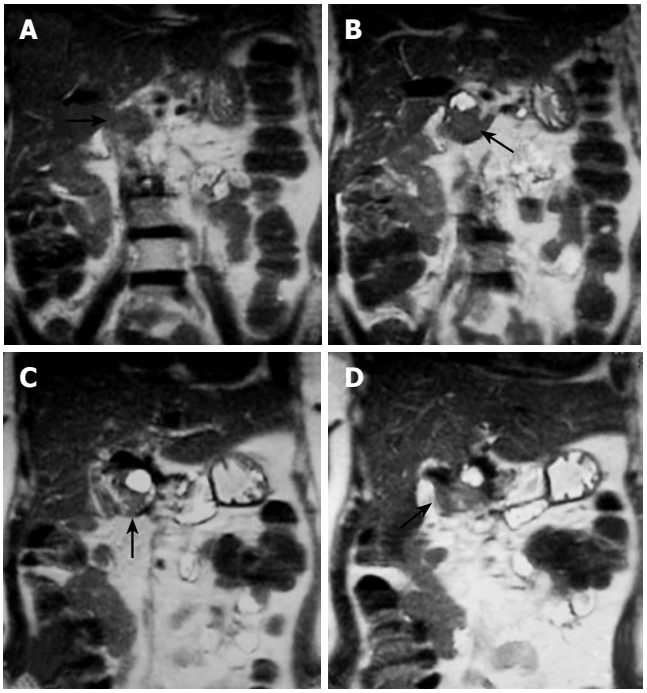

Figure 3 Serial magnetic resonance imaging of the abdomen (coronal plane) showing the tumor mass in the porta hepatis in close relation with the portal vein and biliary tract.

local recurrence showing benign behaviour was suspected. Then, without evidence of systemic disease, corticosteroid therapy was started. A repeat ultrasound revealed complete remission of the tumor at the 3rd mo. The steroid dose is being tapered downward gradually, and we might expect complete remission 6 mo later on low-dose steroid maintenance treatment. On the 5th mo of therapy, the patient remains well and liver function tests were within normal limits.

DISCUSSION

Although IMTs generally behave as benign lesions that are usually cured by radical excision, some cases demonstrate an aggressive growth behaviour. In a study conducted by Coffin *et al*[2], a significant recurrence rate of 25% was demonstrated, likely related to factors precluding complete surgical resection of the pseudotumor. There is a tendency to believe that IMT occurring in the abdomen or retroperitoneum has a propensity for more aggressive behavior with multiple recurrences, invasion into adjacent structures and metastases as shown by DiFiore *et al*[3] and Meis *et al*[4]. However, other recent reports showed that aggressive behaviour, rapid infiltration and multiple recurrences of IMTs are not limited to abdominal location[5-7]. Nowadays, limited evidences exist on the outcomes of patients with a local recurrence of IMT from the biliopancreatic region.

A recent review[1] mentioned reported cases of IMT at the biliopancreatic region, describing locoregional recurrences of four cases at the biliopancreatic region[8,9] after primary resection of the tumor. Further study of these cases showed that just only one of the four cases represented a true local recurrence of pseudotumor arising

from the bile duct. The other three cases were much different from ours because primary tumor mass was located in the pancreas or because the recurrence was found at a distant site (lung) or the recurrence occurred after a long time interval (17 years) from resection and at a different site from primary tumor. The case reported by Johnson *et al*[9] in a 29-year-old black woman recurred after Kaush-Whipple procedure 8 mo later at original site, although the tumor mass was primarily located in the pancreas tissue. Walsh *et al*[8] reported three cases of IMT affecting the biliopancreatic region with long-term follow-up. In one of them, recurrence was found at a distant site (lung). In other case, there was a long interval from resection to recurrence in the pancreatic tail, reason why is not considered a true recurrence. If these recurrences represent a second tumor, multicentricity or metastasis is unknown. In the third case, the tumor recurred at the original site (right main hepatic duct) 14 years later, extending into the liver and showed a benign behaviour. This latter case requires further attention as it is similar to ours but has some interesting differences.

It is widely believed today that IMT at the biliopancreatic region, specially distal bile duct, are usually associated with a new entity called autoimmune pancreatitis which is believed to be an initial activation process. There are clear evidences in literature that most of the reported cases of IMT from the distal bile duct showed association with sclerosing lymphoplasmacytic pancreatitis or autoimmune pancreatitis[1,10-13] and indicates that the fibroblastic cells in both lesions may be induced at the same site and are usually the same inflammatory and fibrosing process with different histological appearances. However, Walsh *et al*[8] did not mention whether the primary tumor at the common bile duct was associated with any form of pancreatitis. Pancreatic tissue was not studied, even they did not mention whether the distal margin was free of inflammatory process. Whether this case represents a form of cholangitis associated with lymphoplasmacytic sclerosing pancreatitis is unknown.

Thus, the case reported by Walsh *et al*[8] that did not show any association with autoimmune process is different from ours in which the distal bile duct and pancreatic head was involved by the same inflammatory process. Other important point is that final post-mortem study of the specimen from the case of Walsh *et al*[8] showed involvement of the liver which suggests and reinforces previous theories that there is possibly an idiopathic pancreatobiliary inflammatory disease complex involving various processes such as autoimmune pancreatitis, although this was not demonstrated.

Apart from this reported cases, our case represent a true local recurrence of pseudotumor of the distal bile duct associated with autoimmune process in the pancreas head. The present case confirms that IMTs have a tendency to recur with time even after radical excision of primary tumor with free margins. These findings support the theory that IMTs are considered as a systemic disease with different pattern of behaviour in which persistent autoimmune reaction process and multicentricity might be involved[13,14].

Our case seem to accord with the theories previously developed by Kawaguchi[15], Zen[13,16] and Klöppel[17] which associates autoimmune pancreatitis with variable involvement of the pancreas and the biliary tract. Fibrosis and zonation[2] may occur as a consequence of persitent inflammatory autoimmune process and biliary stenosis might developed in two different ways: due to external compression from fibrotic changes in the pancreatic head and secondary to zonation of the inflammatory process in the biliary tract which represents our case.

This report provides many important messages. First, local recurrence of IMT at biliopancreatic region has been rarely described. To our knowledge, no cases have been reported in the modern era, which usually associate pseudotumor formation in the distal bile duct with a new entity called autoimmune pancreatitis representing zonation of the same inflammatory process. Second, the biologic potential of inflammatory pseudotumors is highly variable (depending on its location and likely related to factors precluding complete surgical resection, such as adherence to vital structures and multifocality), but it generally has an innocuous course, with more local recurrences than distant metastasis as in our case.

Recurrence is common and the use of corticosteroids is permitted. In these cases, as shown by Voss *et al*[18] and our present case, local recurrences and systemic disease might not require surgery. However, surgery cannot be excluded and long-term follow-up is necessary in order to prevent irreversible liver damage in this specific location. Usually, acute lesions typically respond to high doses of corticosteroid[10], but chronic lesions such as recurrences, which tend to have more fibrosis, might not respond to medical therapy. Third, our case seems to reinforce the hypothesis that inflammatory myofibroblastic tumors from the bile duct might represent zonation by proximity of an autoimmune process affecting the pancreas. This might be explained by pattern of recurrence: our patient presented 4 years ago with indolent jaundice accompanied by biliary dilatation by inflammatory pseudotumor of the distal bile duct. She underwent Whipple procedure with tumor-free margins and negative isolated nodes. However, 4 years later, remaining asymptomatic, radiologic examinations revealed a tumor mass close to the primary lesion without bile duct compression. Moreover, MRI, liver function test and bilirrubin levels were normal. As Whipple procedure separates bile duct from pancreas tissue by interposed bowel loop, where did this recurrence come from? What does the recurrence signify? Perhaps this might be explained by new pseudotumor formation mediated by autoimmune process against remaining pancreatic tissue. Obviously, multicentricity or a new second tumor cannot be excluded.

Many questions still arise about the increasing appearance of inflammatory pseudotumors at different sites: What does really represent inflammatory myofibroblastic tumor? High concentrations of serum Ig subtype, such as IgG4, in IMTs suggest that immunoglobulins may have a pathological role in the fibrosing process mediated by an autoimmune process. Broad pattern of presentation and its ample relation with other autoimmune diseases reinforce this theory[13,16,19-21].

Among other hypothesis, this theory is being increas-

ingly recognized and reflects that inflammatory pseudotumors might represent an advanced stage of an autoimmune process in which intense fibrotic reaction (zonation) predominates[2,17]. What evidences exist in favour of the theory that IMTs at the biliopancreatic region are secondary to autoimmune process in the pancreas? Possible evidences are the frequent occurrence of various autoimmune antibodies, such as antibodies against carboanhydrase II and nuclear antigens[22], the elevated IgG4 serum levels and IgG4 positive plasma cells[13,16,20,23], the oligoclonal pattern of T cell receptor gamma gene rearrangements[24], its association with reactive hyperplastic lymphadenopathy[1,8,25,26], and the responsiveness to steroid therapy of the reported cases[10,27-29]. More importantly, immunohistochemical results of these tumors are compatible with those of other autoimmune diseases. Is it a systemic disease when found at the biliopancreatic region whose course is determined by its biological activity? Strong association between these tumors and other autoimmune processes suggest that IMTs are advanced reactive lesions secondary to an unidentified agent. High concentrations of serum IgG4 found in reported cases at various sites supports that IMTs represent a systemic condition. Hence, it may be localized, multicentric or systemic at the time of presentation and has a strong tendency to reccur. When found at the biliopancreatic region it may represent more than just a biliopancreatic disease.

Some evidences exist about its different biological behaviours that may represent a premalignant state[2,4,5,29-31]. What is the pattern of behaviour of inflammatory pseudotumors at the biliopancreatic region? Limited evidence exists to respond this question, but usually behaves as a benign lesion as reported in the literature to date. Our case represents a local recurrence or multicentricity of IMT at the biliopancreatic region that responds well to conservative treatment. A series of four patients previously described by Walsh *et al*[8] and Voss *et al*[18] demonstrated that IMT from the biliopancreatic region showed a tendency to progressive involvement of multiple organ systems by the same histopathologic process at follow-up.

Is it possible to diagnose preoperatively an inflammatory myofibroblastic tumor presenting with jaundice at the biliopancreatic region and then avoid a complex surgical procedure? A high index of suspicion is necessary to diagnose preoperatively this kind of tumor and exclude malignancy. Medical past history relating other autoinmmune process or previously diagnosed inflammatory pseudotumors at any site should be investigated. FNA with inmmunohistochemical study, and a good response to steroid therapy is necessary to avoid a surgical procedure. Distinguishing inflammatory pseudotumors from malignancy is extremely difficult to do on the basis of radiographic, ultrasound and MRI findings[1,33], specially at the biliopancreatic region as shown by Venkataraman *et al*[34]. Agrons *et al*[35] agreed with them but referring to extra-abdominal sites (lung). The heightened awareness should prompt more extensive non-invasive and minimally invasive radiologic, histopathologic, and inmmunohistochemical evaluations before directing patients toward complicated and potentially high-risk surgical procedures.

Further investigation will improve our understanding

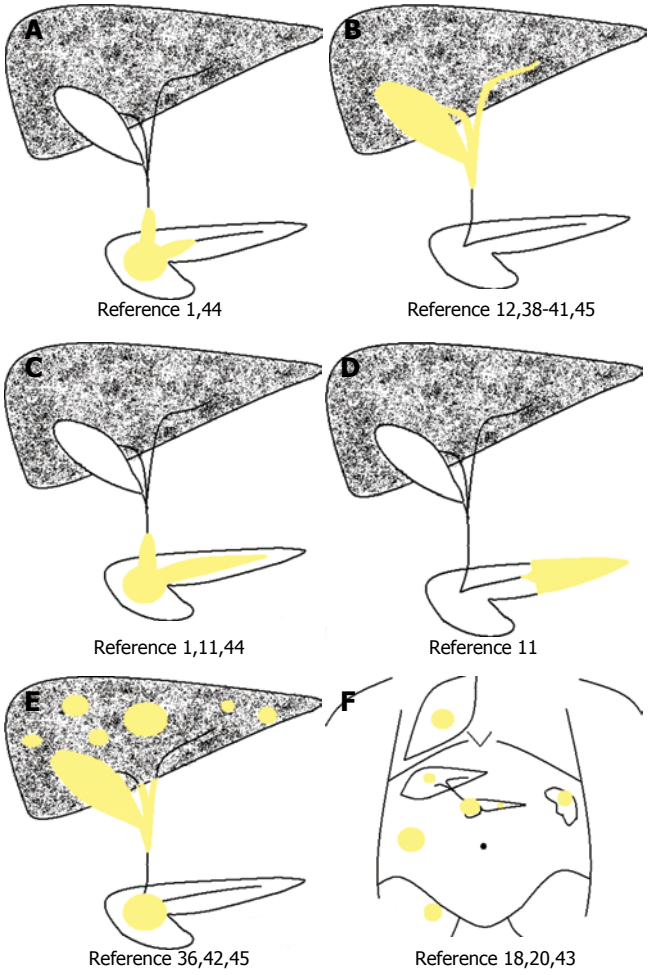

Figure 4 Dynamic classifications for autoimmune pancreatitis. **A-E**: Classification of the variable involvement of the hepatobiliopancreatic system which may be observed in patients with autoimmune pancreatitis. In yellow color is shown the affected zone. [Ref] References of the most relevant and reliable studies that identify this specific pattern of disease. **F**: Multisystemic organ involvement by inflammatory pseudotumor at the biliopancreatic region. of pathophysiology and etiology of these lesions and such data will help us better recognize this entity preoperatively and differentiate it from carcinomas in order to avoid a surgical procedure. A well illustrated case was the one described by Sasahira *et al*[36].

How should we follow-up these patients? Most organ systems may be involved by primary inflammatory pseudotumors; but also progressive multisystemic organ at follow-up has been described (Figure 4F)[18]. It also has been demonstrated that these chronic process may represent an indolent premalignant state[5,30,31]. Therefore, it is important to follow-up these patients to rapidly diagnose local or multisystemic recurrences in order to avoid complications specifically at the the biliopancreatic region where these compressing lesions might cause liver damage, cholangitis or pancreatitis. Follow-up must not be limited to the biliopancreatic region but also to other systemic organs. Increase rate in specific IgG4 might indicate reappearance of the autoimmune disease and become a useful marker to detect pseudotumor recurrence[37], but this issue remains

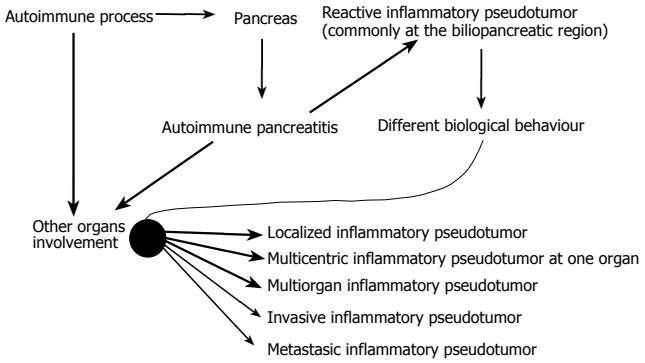

Figure 5 Autoimmune pancreatitis process.

unresolved and controversial[36].

The recurrence in our case is, in fact, represented by multicentricity of the primary tumor, a local recurrence or even systemic disease mediated by an autoimmune process. Overall, we must emphasize that such lesions respond well to corticosteroid therapy and high index of suspicion avoids a surgical procedure.

In conclusion, it seems to be only a question of time until inflammatory pseudotumor will reappear at any site once diagnosed. These lesions most likely will not appear until the etiology is more clearly defined and thus further studies should make a greater emphasis on etiologic factors rather than its presentation form, as virtually any organ may be involved.

Steroid therapy should be the treatment of choice in recurrent cases as good responses have been found in the present and other cases. Follow-up is necessary to avoid complications from recurrences at the biliopancreatic region, especially to avoid liver damage as interval from silent cirrhosis to the development of complication may vary widely. We proposed a new dynamic classification for autoimmune pancreatic-related IMTs[17], with special attention at the biliopancreatic region (Figure 4)[1,11,12,18,20,36,38-44]. Among other theories[45-51], the most widely accepted theory today is that IMT is an auto-immune disorder (Figure 5). IgG4 can be useful as a serological marker of autoimmune pancreatitis and seems also to be useful for the follow-up of patients treated with steroids.

Abstract

Poorly differentiated gastric neuroendocrine carcinomas, although rare, deserve particular attention, as they are aggressive and have an extremely poor prognosis. In this report we describe a gastric neuroendocrine carcinoma with rapidly fatal outcome. Immunohistological staining of the resected specimens revealed that the tumor was an endocrine carcinoma. The tumor disclosed intense immunoreactivity to pan-neuroendocrine markers and diffuse somatostatin immunoreactivity. There were no psammoma bodies and no demonstrable association with von Recklinghausen's neurofibromatosis. In the gastrointestinal tract, neuroendocrine tumors producing predominantly somatostatin have been described only in the duodenum. To the best of our knowledge, the present report is the second case report of a neuroendocrine gastric carcinoma expressing diffusely somatostatin as the only neuroendocrine regulatory peptide.

INTRODUCTION

Neuroendocrine [NE] carcinoma of the stomach is a rare, highly malignant tumor with an extremely poor prognosis[1-6].

A subset of NE carcinoma is associated with inherited syndromes, such as multiple endocrine neoplasia [MEN1] and von Hippel-Lindau syndrome[7]. However, the vast majority of NE carcinomas occur sporadically[2,8,9,10].

Poorly differentiated NE carcinomas of the stomach are a separated entity in respect to well-differentiated carcinoids. There is little evidence to support the origin of neuroendocrine carcinomas from malignant evolution of well-differentiated tumors. Rather, it is conceivable that they derive from endocrine-committed immature stem cells, as suggested by the studies of mixed exocrine-endocrine tumors[11,12]. Like type III sporadic carcinoids, NE gastric carcinomas develop independently from hypergastrinemia, thus recognizing a substantially different pathogenetic feature with respect to type I and II enterochromaffin-like (ECL) cell tumors[4,9,13].

The first report of a NE carcinoma of the stomach with diffuse somatostatin immunoreactivity was done by Chejfec *et al*[14]. They reported a neuroendocrine gastric tumor with a rapid fatal outcome, displaying neurosecretory granules by electron microscopy and immunoreactivity to pan-neurosecretory markers, i.e., chromogranin and neuron-specific enolase. The only neuroendocrine regulatory peptide detected in the tumor was somatostatin, identified by immunohistochemistry in the majority of neoplastic cells. In contrast with duodenal somatostatinomas, there were no psammoma bodies and no demonstrable association with von Recklinghausen's neurofibromatosis. Rindi[4] described two gastric neuroendocrine carcinomas in which immunohistochemical staining revealed that 5% to 30% of tumor cells were positive for somatostatin[4]. Yu *et al*[3] reported a case of NE gastric carcinoma expressing somatostatin, but they did not describe the intensity of the staining. To the best of our knowledge, the present report is the second case report of NE gastric carcinoma expressing somatostatin in the majority of the neoplastic cells.

METHODS

Paraffin-embedded specimens containing a representative sample of the tumor were sliced into 3 μm thick sections and mounted on silanized slides. These underwent immunohistochemical analysis using avidin-biotin immunoperoxidase complex technique.

First, the tissue was deparaffinized and hydrated in alcohol. The next step was antigen recovery in a dampness cooker with a steam solution of 10 mmol/L citrate pH 6.0 at 95-100℃ for 35 minutes. Blockage of the endogenous peroxidases was done with a hydrogen-peroxide wash 10V (3%), and following that, non-specific sites were bound with skim milk 2%. Then, the primary antibodies (Dako A/S®, Copenhagen, Denmark) were diluted in this proportion: 1:50 for serotonin, 1:200 for somatostatin, 1:1000 for specific neuronal enolase, 1:800 for synaptophysin, 1:1000 for chromogranin, 1:320 for cytokeratins AE1/AE3, 1:100 for insulin, 1:50 for glucagons and 1:200 for gastrin, in bovine serum albumin (Sigma Diagnostics®, St. Louis, MO). 100 μL of the resulting solution was poured onto the tissue sections and incubated for 18 hours at 4℃.

The slides were washed in sodium phosphate buffer 0.05 M, pH 7.2-7.4 and incubated with the secondary antibody (Large Streptavidin-Avidin-Biotin–Peroxidase System; Dako A/S®, Copenhagen, Denmark). Following this, the slides were developed with chromogene (3-3'-diaminobenzamidine; Sigma Diagnostics®, St. Louis, MO), and counter-stained with Harris' hematoxylin (Sigma Diagnostics®, St. Louis, MO).

The brownish-color was considered evidence of a positive expression of the respective antibodies in the tumor cells. As a positive and negative control of the reactions, histological cuts of human pancreas were used for serotonin, somatostatin, specific neuronal enolase, chromogranin, insulin and glucagon; human colon for synaptophysin and cytokeratins AE1/AE3; and human stomach for gastrin. Uncolored red blood cells were used as negative internal control.

CASE REPORT

A white man, 73 years old was admitted with a 2-mo history of intense epigastric pain, weight loss of 10 kg, loss of appetite and asthenia. Physical examination revealed only discolored mucosa. Laboratory exams were normal except for a hemoglobin level of 9.8 g%. Gastroduodenoscopy showed gastric lesion in the gastric body, with a Bormann III macroscopic aspect, whilst endoscopic biopsies revealed undifferentiated carcinoma. Pre-operatory tomography showed a mass in the gastric region and hepatomegaly with multiple heterogenous nodules suggesting metastasis. Radiographs of the thorax and colonoscopy was normal. On laparotomy a gastric mass was found measuring 6.5 cm in length, located in the gastric fundus and body invading the body and tail of the pancreas and the spleen. Palliative total gastrectomy, omentectomy, splenectomy and distal pancreatectomy were performed to control the patient's pain. Histology revealed a neuroendocrine carcinoma which was poorly differentiated, having medium-sized, polygonal cells, with trabecular or acinar, cytoplasm

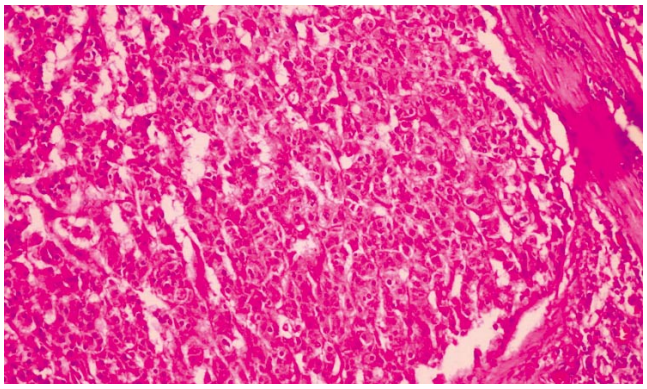

Figure 1 Micrograph of histological section of the neuroendocrine gastric carcinoma showing a proeminent trabecular architecture, organoid pattern with pseudoglandular structure, uniform cells and abundant mitoses. (Hematoxilin & Eosin staining; original magnification, × 200).

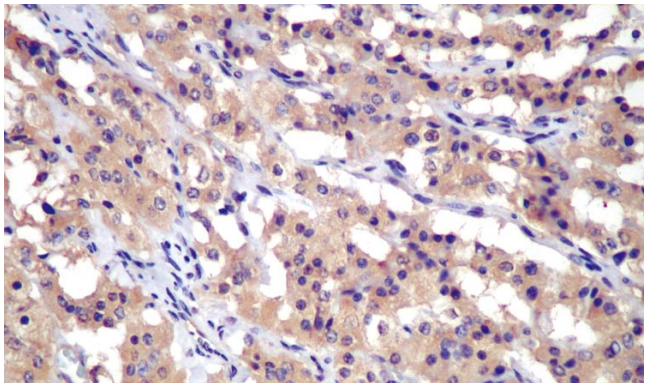

Figure 2 Immunohistochemistry of the neuroendocrine gastric carcinoma showing intense and diffuse somatostatin-positive imunoreactivity in the neoplastic cells (Immunoperoxidase, primary antibody anti-human somatostatin-code A0566-Dako A/S®, Copenhagen, Denmark, original magnification, × 400).

eosinophilic or clear appearance with low pleomorphism (Figure 1). The neoplasia had infiltrated the wall as far as the serosa and there was evidence of vascular and perineural infiltration. The surgical margins were free of any neoplastic infiltration. From a total of 14 perigastric lymph nodes one showed neoplastic involvement. The spleen and pancreas were also infiltrated by neoplasia. Immunohistochemical neoplasia analysis showed immunoexpression for chromogranin, specific neuronal enolase, synaptophysin, cytokeratines AE1/AE3, CAM 5.2 and was strongly positive for somatostatin in the majority of the neoplastic cells (Figure 2). There was no immunoexpression for insulin, glucagon, serotonin, or gastrin. These immunohistochemical investigations of the neoplastic cells confirmed the tumor as a neuroendocrine carcinoma. Post-operatively, abdominal and pelvic tomography showed intra-abdominal collections and the patient was reoperated on the 21st post-operative to drain intracavitary abscesses. An esophageal-jejunal anastomosis fistula appeared and despite parenteral and enteral nutritional support, the patient presented with progressive cachexia and died five months after gastric resection.

DISCUSSION

Gastric neuroendocrine tumor disease embraces a group of tumors that exhibit a spectrum of histopathologic variations ranging from the clearly benign tumors to those characterized by marked cytological atypia and high mitotic activity, which clinically, behave in a highly malignant fashion. In general, the majority of these tumors are well-differentiated, benign ECL tumors, whose courses are indolent and not life-threatening. A relatively small percentage of well-differentiated ECL tumors may have a low-grade malignant potential and deserve an adequate cancer treatment and follow-up. Poorly differentiated gastric neuroendocrine carcinoma tumors are the most aggressive of the group. They have an extremely poor diagnosis, which justifies an aggressive therapeutic approach[4].

Different endocrine cell types have been identified and characterized in the human gastric mucosa[15]. Besides ECL cell producing histamine, enterochromaffin (EC) cell producing serotonin, and G cell producing gastrin, there is the D cell producing somatostatin. Although in theory any one of these endocrine cell types could undergo neoplastic transformation, only the ECL and gastrin [G] cells are found as the exclusive or dominant tumor cell type in oxyntic and antral neuroendocrine tumors, respectively. Conversely, any one or more of the remaining endocrine cell types can be found as minor subpopulation in gastric neuroendocrine tumors[4]. Somatostatin-producing cells were subsequently identified by immunofluorescence in the stomach and in the first portion of the duodenum[16]. Gastric carcinomas display focal somatostatin immunoreactivity infrequently[17] although it is very frequently observed in metaplastic gastric mucosa associated with peptic ulcer or gastric carcinoma[18]. In this present case, none of the peptides generally associated with gastric neuroendocrine tumors were demonstrable by immunohistochemistry except for somatostatin. The diffuse, strong, and very predominant immunoreactivity for somatostatin noted in the majority of neoplastic cells differed from the focal somatostatin reactivity and the coexpression with other hormones reported in neuroendocrine gastric carcinomas[19].

NE gastric carcinomas are in general not associated with an overt endocrine syndrome, even when hormone-like immunoreactivities were detected in tumor tissue, possibly because of the scarce amount of hormone produced or because inactive prohormones, rather than active molecular species, were produced[12,20,21]. Although pancreatic endocrine tumors have commonly been associated with somatostatinoma syndrome, extrapancreatic somatostatinomas are not usually accompanied by a complete scenario of diabetes mellitus, biliary tract disease, diarrhea, steatorrhea, hypochlorhydria, weight loss, or anemia. These gastrointestinal tumors appear to be hormonally inactive and abdominal pain is the main clinical feature[22]. This also occurred with the patient of the present report.

Neuroendocrine tumors of the upper gastrointestinal tract displaying predominantly somatostatin immunoreactivity have thus far only been described in the duodenum[14].

In this case, neoplastic cells expressed immunoreactivity to pan-neurosecretory markers chromogranin A, synaptophysin, and neuron-specific enolase. As in the case described by Chejfec *et al*[14], the predominant neuroendocrine regulatory peptide detected in the tumor was somatostatin, identified by immunohistochemistry in the majority of neoplastic cells. There were no psammoma bodies and no demonstrable association with von Recklinghausen's neurofibromatosis, as is frequently in duodenal somatostatinomas.

NE tumors in non-NE organs are neoplasms that consist of relatively uniform NE cells. These tumors are classified as carcinoid tumors or NE carcinoma based on the combination of NE cell differentiation and cellular atypia. Histologically, NE carcinomas are solid, organoid, trabecular, pseudoglandular, spindle cell, or rosettelike[2]. The tumor of the patient related in this report was composed of malignant neoplasia with cells having a monotome aspect, and exhibiting vascular and perineural invasion as detected in practically all NE carcinomas[21].

Based on both cell size and morphologic features, Matsui *et al*[2] subdivided NE carcinomas into two variants, namely, small and large cell NE carcinoma. Comparing with small cell NE carcinomas, large cell NE carcinomas had a higher mitotic index, larger polygonal cells, a decreased nuclear-cytoplasmic ratio, coarser nuclear chromatin, and more frequently conspicuous nucleoli. Large cell NE carcinoma was an aggressive tumor with a very poor prognosis that approached that small cell NE carcinoma.

There have been many cases of a poorly differentiated adenocarcinoma that show a minor component with histology similar to that of NE carcinoma[1]. It is generally true that NE carcinoma shows the organoid structure of NE tumor despite cellular atypism, but such histological features can be difficult to evaluate in a small biopsy specimen. Thus, it is considered that a diagnosis of NE carcinoma can be made only after histological evaluation of the resected material[23].

In the present patient, the gastric tumor showed a so-called organoid pattern with diffuse immunoreactivity observed for general NE markers. Therefore, the diagnosis of NE carcinoma was considered to be appropriate, although the initial diagnosis based on the biopsy specimen was undifferentiated carcinoma.

The mean age at presentation of these tumors is in the seventh decade, with no significant sex prevalence. NE gastric carcinomas are generally large [mean size 4.2 cm], fungating or annular lesions, found most frequently in the body/fundus. At the time of diagnosis, most of the tumors are already in advanced stage, particularly the lesions with tumor diameter more than 4 cm, and show extensive metastases[2-4,21,24,25]. This clinical picture was also observed in our case.

Although rare, poorly differentiated gastric NE carcinomas deserve particular attention, as they are aggressive and have an extremely poor prognosis. The surgical resection is the most appropriate form of treatment for this type. The usefulness of multi-drug chemotherapy remains to be evaluated in larger clinical studies[2,3,26].

Mean survival rates of 6.5-14.9 mo have been reported with a 1-year survival rate of 58%[3,10,25,26]. As the patient reported in this study, the majority of the patients die due to extensive metastatic disease[1,27].

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus.*

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included.

Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.
