Abstract

AIM: To observe the effect of solanine on the membrane potential of mitochondria in HepG2 cells and $[Ca^{2+}]_i$ in the cells, and to uncover the mechanism by which solanine induces apoptosis.

METHODS: HepG2 cells were double stained with AO/EB, and morphological changes of the cells were observed using laser confocal scanning microscopy (LCSM). HepG2 cells were stained with TMRE, and change in the membrane potential of mitochondria in the cells were observed using LCSM. HepG2 cells were double stained with Fluo-3/AM, and change of $[Ca^{2+}]_i$ in the cells were observed using LCSM. HepG2 cells were double stained with TMRE and Fluo-3/AM, and both the change in membrane potential of mitochondria and that of $[Ca^{2+}]_i$ in the cells were observed using LCSM.

RESULTS: Cells in treated groups showed typical signs of apoptosis. Staining with TMRE showed that solanine could lower membrane potential; staining with Fluo-3/AM showed that solanine could increase the concentration of Ca^{2+} in tumor cells; and those of double staining with TMRE and Fluo-3/AM showed that solanine could increase the concentration of Ca^{2+} in the cells at the same time as it lowered the membrane potential of mitochondria.

CONCLUSION: Solanine opens up the PT channels in the membrane by lowering the membrane potential, leading to Ca^{2+} being transported down its concentration gradient, which in turn leads to the rise of the concentration of Ca^{2+} in the cell, turning on the mechanism for apoptosis.

INTRODUCTION

Solanine is found mainly in the tuber of the potato (Solanum tuberosum L.)[1-5] and in the whole plant of the nightshade (Solanum nigrum Linn) of the family Solanaceae. The content of this substance is rather high in the green peel and the sprouts of potato and is the main toxic substance[6]. The whole plant of the nightshade contains many steroid alkaloids, including solamargine, solasonine, and solanine, as well as saponin and other substances. It can be used for anti-tumor purposes, with a strong inhibitory effect on tumors in animals and a clearly toxic effect on tumor cells[7]. Its ethanol extract is capable of inhibiting the growth of breast cancer and induce apoptosis in tumor cells[8]. The extract from the nightshade also has a strong anti-inflammatory effect because it can facilitate the formation of antibodies[9]. The anti-tumor effect of solamargine has been reported[10], but there is as yet no report about any anti-tumor effect of solanine. From our past experience in both in vivo and in vitro experiments, we have found that solanine is cytotoxic to cells, especially for the hepatocarcinomatic cell HepG2. Through morphological observation, as well as DNA ladder and flow cytometry, we discovered that solanine exerted its anti-tumor effect by inducing apoptosis in HepG2.

The concept "apoptosis" was officially proposed by Kerr in 1972[11]. In the three decades since it was proposed, it has always been the focus of biological researches. Especially since 1990s, the study of apoptosis has suddenly been propelled to the frontier of life science, leading to an upsurge of research activities involving almost all the fields of biomedical studies. As a result, a great deal of literature accumulated in a few years about the

morphological characteristics of apoptosis, biochemical changes in apoptotic cells, genes regulating apoptosis, and various factors that can lead to apoptosis, as well as the relationship between apoptosis and health conditions. Membrane potential of mitochondria[12,13] and $[Ca^{2+}]_i$ in the cells[14,15], two factors closely associated with apoptosis, are themselves supplementary to and closely related with each other.

Rapid and continuous increase in the concentration of calcium ion is the earliest detectable biochemical change in cells undergoing apoptosis. The fact that the use of calcium-free culture medium and other methods capable of inhibiting the rise in the concentration of Ca^{2+} in cells can help to inhibit apoptosis[16] also shows that the rise in the concentration of Ca^{2+} in cells is an important condition for apoptosis to take place. A typical sign of apoptosis is the appearance of apoptotic bodies, but it is only when the concentration of Ca^{2+} has been raised that endogenous nuclease is activated, cutting the DNA chain between nucleosomes into discontinuous fragments (or apoptotic bodies), the basic unit of which is 180-200 bp long.

The mitochondrion is the storehouse for calcium in the cell, and change in its membrane potential can lead to Ca^{2+} and other ions being released from the mitochondrion or flowing into it, and the release and influx of Ca^{2+} and other ions are also the direct causes for changes in the membrane potential of mitochondrion. The essence of membrane potential change is the opening of the PT channels in the membrane. The opening of these channels precedes the release of Ca^{2+}, which is followed by changes in the membrane potential.

There are many approaches to studying apoptosis. In the present study, we tried to explicate the mechanism by which solanine induced apoptosis of tumor cells by focusing on the mitochondria and by observing the effect of solanine on the membrane potential of $HepG_2$ and $[Ca^{2+}]_i$ in the cell(Figure 1).

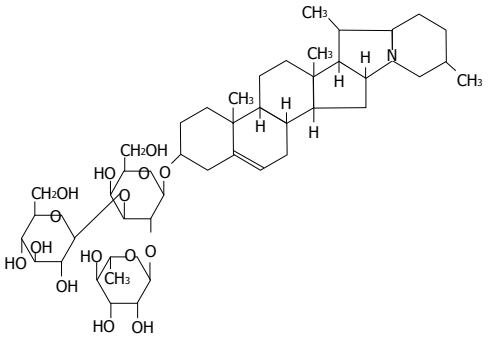

Figure 1 Molecular structure of solanine.

MATERIALS AND METHODS

Materials

The cell line: $HepG_2$ human hepatocarcinomatic cell lines were purchased from the Institute for Cancer Research, Heilongjiang Cancer Hospital.

Test drugs: Solanine with a purity of 99% was provided by Heilongjiang Institute For Drug Control.

Chemical reagents: RPMI 1640 culture medium was supplied from HyClone Laboratories; fetal bovine serum from Hangzhou Sijiqing Biological Engineering Materials Co.,Ltd; pancreatin from Gibio; ethidium bromide (EB) from AMRESCO; acridine orange (AO) from AMRESCO; Fluo-3/AM from Biotium, US; TMRE(molecular probe) from Biotium, US; HEPES from AMRESCO.

Preparation of the reagents: Fluo-3/AM 0.1 mg/stick was diluted to suitable concentration with DMSO, and then separately loaded and stored in the dark. TMRE 25 mg/stick was made into 1 mg/mL mother solution using anhydrous alcohol, separately loaded and stored in the dark. These were diluted with buffer solution for laboratory use and added to achieve the needed final concentrations before they were used in experiments.

Apparatuses: CO_2 incubator (CO-150, NBS, US); inverted microscope (CKX-41-32, Olympus, Japan); superclean bench (SW-CJ-2F, Suzhou Purification Equipments of the Sujing Group, Suzhou); laser confocal scanning microscope (SP2, Leica, Germany) were used.

Methods

Cell culture and treatment: $HepG_2$ cell culture was incubated in RPMI 1640 medium containing 10% fetal bovine serum at 50 mL/L CO_2 and 37℃, and transfer of culture was performed once every 3-4 d. When the cells grew steadily in the phase of logarithmic growth, 0.25% pancreatin was used to digest the cells. Digested cells were re-suspended using RPMI 1640 medium containing 10% fetal bovine serum and counted, and the concentration of cells was adjusted to 1×10^4 /mL. Cell suspension was added to the round troughs of 35 mm Petri dishes at 200 μL/dish, and the dishes were divided into 2, 0.4, 0.08, 0.016, and 0.0032 μg/mL treatment groups, the control, and the positive control (to be treated with camptothecine). After being incubated for 24 h at 50 mL/L CO_2 and 37℃, the treatment groups were treated with solanine of different concentrations so that their final concentrations were 2, 0.4, 0.08, 0.016, and 0.0032 μg/mL, respectively; an equal volume of RPMI 1640 was added to the control, while the positive control was treated with camptothecine, with a final concentration of 0.08 μg/mL. The dishes were then incubated for another 48 h at 50 mL/L CO_2 and 37℃ in CO_2 incubator.

Observation of Solanine-induced morphological changes of $HepG_2$ nuclei using LCSM: After 48 h, the cells were taken out of the incubator. The culture solution in the Petri dishes was sucked out, and the cells were rinsed 3 times with PBS at 5 min/time, double stained with 200 μL of acridine orange (AO)/ethidium brumide (EB) so that the final concentration was 5 μg/mL, incubated for 5-10 min at 37℃, and rinsed 3 times with PBS, 5 min/time. Then 200 μL of PBS was added, and LCSM was used to observe the morphology of the cells. Dual-channel activation was used, with an excitation wavelength of 488 nm and emission wavelength of 500-520 nm for PMT1(AO) and an excitation wavelength of 543 nm and emission wavelength of 600-700 nm for PMT2(EB)[17]. Other devices included Objective APO CS40 × /1.25 oil, zoom > 1, pinhole 1.5 Airy, mode XYZ, format 512 × 512.

Observation of Solanine-induced change in $[Ca^{2+}]_i$

in $HepG_2$ cells using LCSM: After 48 h, the cells were taken out of the incubator. The culture solution in the Petri dishes was sucked out, and the cells were rinsed 3 times with HEPES, and 4 μg/mL Fluo-3/AM (Molecular Probes) was added, 200 μL/dish. After the cells were incubated at 37℃ for 50 min and rinsed with HEPES for 3 times, 200 μL of HEPES culture medium was used to cover all the cells in the troughs, and then LCSM was used to observe the fluorescence intensity (FI) of the cells, with an excitation wavelength of 488 nm and emission wavelength of 555 ± 15 nm. Other devices included objective APO CS40 ×/1.25 oil, zoom > 1, pinhole 1.5 Airy, mode XYZ, format 512 × 512.

Observation of Solanine-induced change in the membrane potential of the mitochondria in the cells using LCSM: After 48 h, the cells were taken out of the incubator. The culture solution in the Petri dishes was sucked out, the cells were rinsed 2-3 times with PBS, and 200 μL of tetramethyl rhodamine ethyl ester (TMRE, Molecular Probes) was gently added to the dishes, so that the final concentration was 2 μmol/L (1.03 μg/mL). The cells were then incubated for 30 min and, after the staining solution was sucked out, gently rinsed 3 times with PBS. 200 μL PBS was used to cover all the cells in the troughs, and then LCSM was used to observe the fluorescence intensity of the cells, with an excitation wavelength of 543 nm and emission wavelength of 570 ± 20 nm. Other devices included objective APO CS40 ×/1.25 oil, zoom > 1, pinhole 1.5 Airy, mode XYZ, format 512 × 512.

Simultaneous observation of changes in the morphology of cells, membrane potential, and the concentration of calcium in the cells: Experiment was performed on 2 groups of $HepG_2$ cells simultaneously. Cell incubation, treatment, and operation procedures were all the same as above, with the same amount of time and conditions for cell incubation. One group was marked with AO/EB and the effect of solanine on its $HepG_2$ cells was observed using LCSM; while $HepG_2$ cells in the other group were marked with TMRE and Fluo-3/AM, and changes in membrane potential of the mitochondria and $[Ca^{2+}]_i$ in the cells were observed using LCSM. Methods for AO/EB double staining and measurement were as before, while the procedures for double staining with Fluo-3/AM and TMRE and measurement are as follows: (1) Staining after 48 h, the cells were taken out of the incubator. The culture solution in the Petri dishes was sucked out, the cells were rinsed 3 times with RPMI1640, and 150 μL of tetramethyl rhodamine ethyl ester (TMRE, Molecular Probes) working fluid with a concentration of 2 μmol/L (1.03 μg/mL) was pipetted onto the dishes. The cells were then incubated for 30 min at 37℃, and after the staining solution was sucked out, rinsed 3 times with RPMI1640. Finally 150 μL of Fluo-3/AM (Molecular Probes) with a concentration of 4 μg/mL was added. The cells were then incubated for 50 min at 37℃ and rinsed 3 times with RPMI1640, and 200 μL of RPMI1640 was added to cover all the cells in the troughs, whereupon the Petri dishes were mounted for measurement. (2) Observation LCSM was used to examine the fluorescence intensity (FI) of the cells. Dual-wavelength excitation was used, with excitation wavelengths of 488 nm and 543 nm, respectively. The emission wavelength used for PMT1 was 555 ± 15 nm, while that for PMT2 was 570 ± 20 nm. Other devices included Objective APO CS40 × /1.25 oil, zoom > 1, pinhole 1.5 Airy, mode XYZ, format 512 × 512. Sequential scanning was used to eliminate interference due to spectral overlap.

Statistical analysis

t test was performed on data obtained from the experiments, with the results expressed in the format mean ± SD. $P < 0.05$ was taken as significant.

RESULTS

Effect of Solanine on the morphology of $HepG_2$ cells

After the DNA-specific fluorochromes AO and EB were used to stain $HepG_2$ cells, LCSM was used to observe the morphological changes of $HepG_2$ cells treated with solanine. From Figure 2A, it can be seen that the control was morphologically normal. The nuclei of different cells were of similar sizes, regularly shaped, and evenly stained. The more deeply colored parts of the nuclei represented heterochromatin which did not take part in transcription under normal circumstances. With solanine treatment, however, the cells showed marked morphological changes. In the groups treated with 0.0032 μg/mL and 0.016 μg/mL of solanine (Figures 2B and 2C, respectively), the cells were wrinkled, and the chromatin was concentrated and marginalized. In the group treated with 0.08 μg/mL of solanine (Figure 2D), cells with fragments and apoptotic bodies appeared, a typical sign for apoptosis. In the groups treated with 0.4 μg/mL and 2 μg/mL of solanine (Figures 2E and 2F, respectively), the number of cells containing apoptotic bodies was significantly increased. At the same time, it could be seen that high dosage of solanine was lethal to tumor cells, because with increasing dosage, the number of viable cells decreased significantly. Apoptotic bodies also appeared clearly in the positive control treated with camptothecin with the final concentration of 0.08 μg/mL.

Change induced by Solanine in $[Ca^{2+}]_i$ in $HepG_2$ cells in the process of apoptosis

As shown in Figure 3 the effect of different dosages of solanine (0.0032, 0.016, 0.08, 0.4, and 2 μg/mL) on $[Ca^{2+}]_i$ in $HepG_2$ cells was observed using LCSM with staining with the fluorescent probe Fluo-3/AM. On the left side of each group is the photograph (green) showing $[Ca^{2+}]_i$ taken under the confocal microscope, with the depth of the color representing the fluorescence intensity (FI). On the right is the 3D configuration reconstructed using LCSM for the group, with different colors reflecting different FI values, which indirectly reflect the concentrations of $[Ca^{2+}]_i$ for the test group in question. It is shown from these photographs that the $[Ca^{2+}]_i$ for the control in Figure 3A was very low, while those for the groups treated with solanine (Figures 3B-F) were all increased, in a concentration dependent manner. The positive control camptothecin did not increase $[Ca^{2+}]_i$. Statistics on FI obtained through LCSM for the various groups in Table 1 showed the same results.

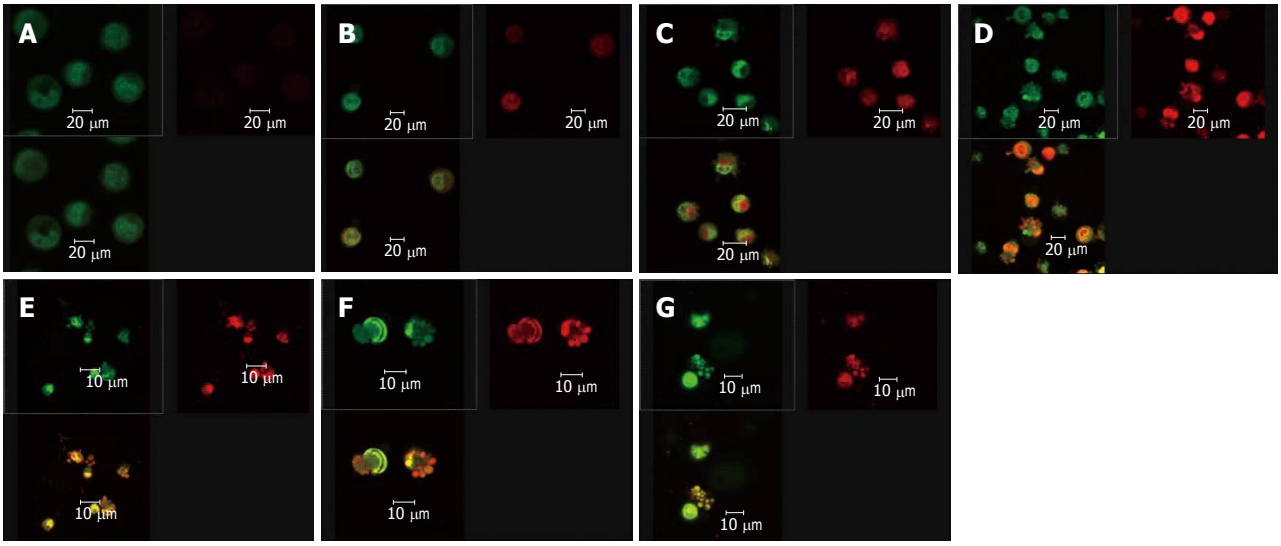

Figure 2 Effect of solanine on the morphology of HepG2. **A**: Control group, PMT1 nuclear chromatin was stained green and showed normal structure, while PMT2 showed no or only weak red fluorescence; **B**: Group treated with Solanine with final concentration of 0.0032 μg/mL: The cells show slightly pyknotic and crumb-shaped structures. Permeability of cell membrane has increased, so that AO and EB can enter the cells, resulting in the cells showing both green and red fluorescence; **C**: Group treated with Solanine with final concentration of 0.016 μg/mL: The cells show slightly pyknotic and crumb-shaped structure. Fragments or apoptotic bodies appear in the nuclei of some of the cells; **D**: Group treated with solanine with final concentration of 0.08 μg/mL: Cell structure is further damaged. The cells are not only stained with AO and EB, but morphologically the nuclei have become deeply stained fragments or apoptotic bodies; **E**: Group treated with solanine with final concentration of 0.4 μg/mL: Cell structure is damaged even further. Apoptotic bodies have definitely appeared; **F**: Group treated with solanine with final concentration of 2 μg/mL: Definite apoptotic bodies can be seen, while the number of cells in sight has decreased; **G**: Group treated with camptothecin with final concentration of 2 μg/mL: The appearance of apoptotic bodies is obvious in HepG2 cells.

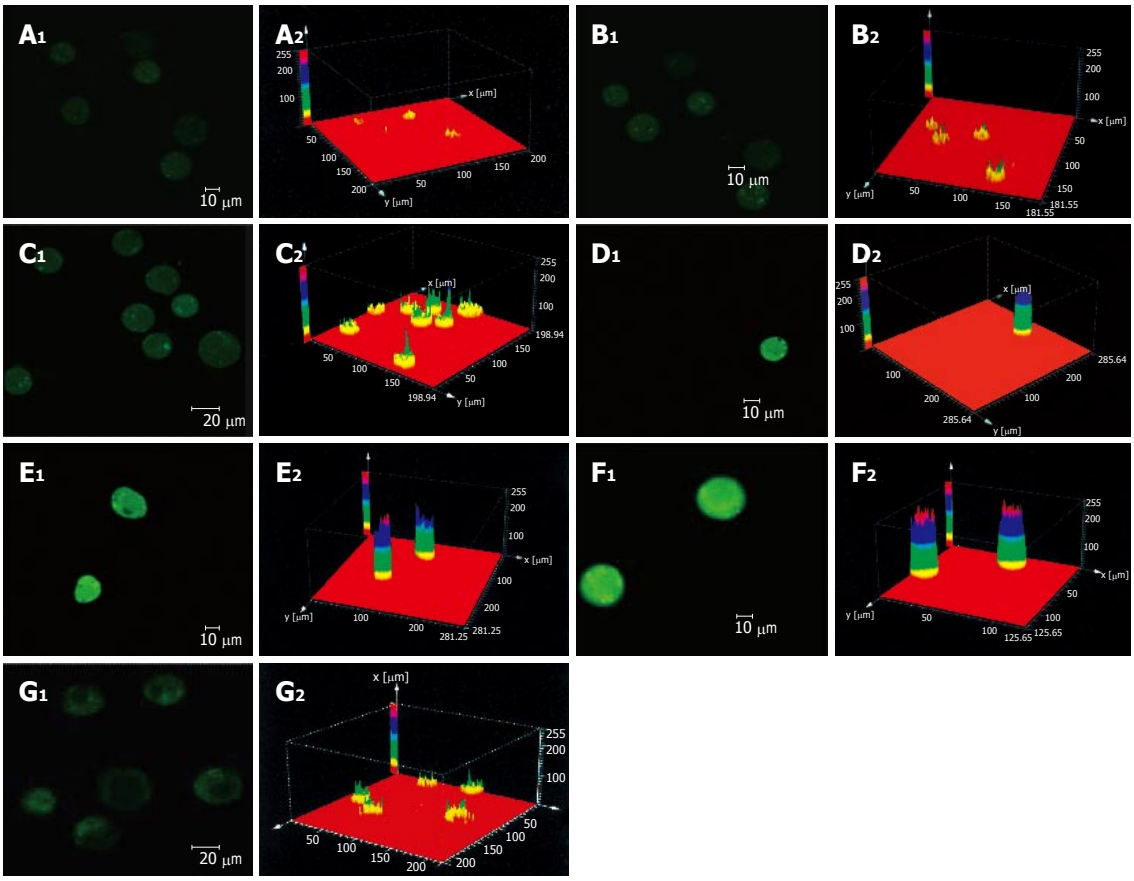

Figure 3 Effect of Solanine on $[Ca^{2+}]_i$ in HepG2 cells. **A**: Control; **B**: 0.0032 μg/mL solanine; **C**: 0.016 μg/mL solanine; **D**: 0.08 μg/mL solanine; **E**: 0.4 μg/mL solanine; **F**: 2 μg/mL solanine; **G**: 0.08 μg/mL camptothecin.

Change induced by Solanine in the membrane potential of mitochondria in HepG2 cells in the process of apoptosis

The effect of different dosages of solanine (0.0032, 0.016, 0.08, 0.4, and 2 μg/mL) on the membrane potential of mitochondria in HepG2 cells was observed using LCSM with staining by the fluorescent probe TMRE (Figure 4). The brightness of the coloration reflected different values of FI, thus indirectly indicating the membrane potential of mitochondria in the cells for these different groups. From those photographs, it could be seen that the membrane

potential of mitochondria in the cells was relatively high for the control in Figure 4A, while those for the groups treated with solanine (Figures 4B-F) were all increased, in a dosage dependent manner. Statistics on FI obtained through LCSM for the various groups in Table 2 showed that the membrane potential of mitochondria in the cells was significantly lowered ($P < 0.01$) in groups treated with 0.016, 0.08, 0.4, and 2 μg/mL of solanine. The membrane potential in the 0.0032 μg/mL group was also lowered, but the difference from the control was not significant. The membrane potential of mitochondria in $HepG_2$ cells of the group treated with 0.08 μg/mL of camptothecin was also significantly lowered.

Simultaneous observation of changes induced by solanine in cell morphology, $[Ca^{2+}]_i$ in cells, and mitochondrial membrane potential in $HepG_2$ cells in the process of apoptosis

Double staining with AO/BE and with Fluo-3/AM and TMRE were simultaneously used in this experiment (Figure 5). Changes in cell morphology, $[Ca^{2+}]_i$ in cells, and membrane potential of mitochondria in the same cell were simultaneously observed using LCSM for groups treated with different concentrations of solanine, so as to examine simultaneous changes in cell morphology, $[Ca^{2+}]_i$ in cells, and membrane potential of mitochondria in cells at the same time points in the apoptosis process induced by solanine of different concentrations and, moreover, to explore the physiological mechanisms of $[Ca^{2+}]_i$ and membrane potential of mitochondria in the cells and the relationship between them. As shown in Figure 5A for the control group, the cells were normal morphologically, and the $[Ca^{2+}]_i$ in the cells was relatively low, while the corresponding mitochondrial membrane potential was relatively high. Results for the groups treated with solanine (with final concentration of 0.0032, 0.016, 0.08, 0.4, and 2 μg/mL, respectively) are shown in Figures 5B-F. It could be seen that with the dosage increased, the shape of the cells gradually became more and more irregular, and typical apoptotic cells such as irregularly shaped cells and apoptotic bodies appeared, with apoptotic bodies, characteristic of apoptosis appearing first in the group treated with 0.08 μg/mL of solanine (Figure 5D). As the dosage increased, the percentage of apoptotic bodies gradually increased, and $[Ca^{2+}]_i$ in the cells also gradually increased, while the membrane potential of mitochondria in the cells gradually decreased for the corresponding groups. The group treated with camptothecin showed no change in $[Ca^{2+}]_i$ but it did show a significantly decreased membrane potential of mitochondria, results consistent with those obtained with single staining. It also showed that solanine induced apoptosis in $HepG_2$ cells by a

different mechanism from camptothecin. Detailed changes of different groups are shown in Table 3.

Solanine-induced changes in $[Ca^{2+}]_i$ and membrane potential of mitochondria in $HepG_2$ cells in the process of apoptosis and their distribution in the cells

When the images for the double staining with Fluo-3/AM and TMRE were recombined using the image analyzing capacity of the laser confocal scanning microscope, it could be seen that Ca^{2+} was widely distributed in the whole cell, but with different concentrations in different regions of the cell. In contrast, membrane potential of mitochondria was distributed only in certain parts of the cell (Figure 6). Superimposing the two images, it can be seen that regions where Ca^{2+} was more concentrated were basically also those where membrane potential was distributed.

DISCUSSION

The mitochondrion is an important organelle of the eukaryotic cell and the main site for the production of ATPs in animal cells[18,19]. NADH is produced from the tricarboxylic cyclophorase series in mitochondrial matrix through the dehydroxidization of the substrate, and then oxidized through the electron transport chain on the inner membrane of the mitochondrion. This leads to the transmembrane transfer of protons, resulting in a transmembrane proton gradient (or transmembrane potential). The ATP synthetase on the inner membrane of the mitochondrion synthesizes ATPs using the energy derived from the proton gradient. Through the ADP/ATP carriers on the inner membrane of mitochondria, ATPs synthesized this way are exchanged for ADPs from the cytoplasm, thus entering the cytoplasm to take part in various processes requiring energy.

In recent years, reports have been made that the dissipation of the membrane potential of mitochondria precedes the activation of nuclease[20], and that it precedes the exposure of phosphatidylserine on the surface of the cell. When the transmembrane potential of mitochondria is dissipated, the cell would enter the irreversible apoptotic process. The uncoupled respiratory chain of the mitochondrion would produce a large amount of active oxygen, oxidizing the cardiolipin on the inner membrane of the mitochondrion. Experiments have shown that the decoupling reagent mClCCP can lead to the apoptosis of

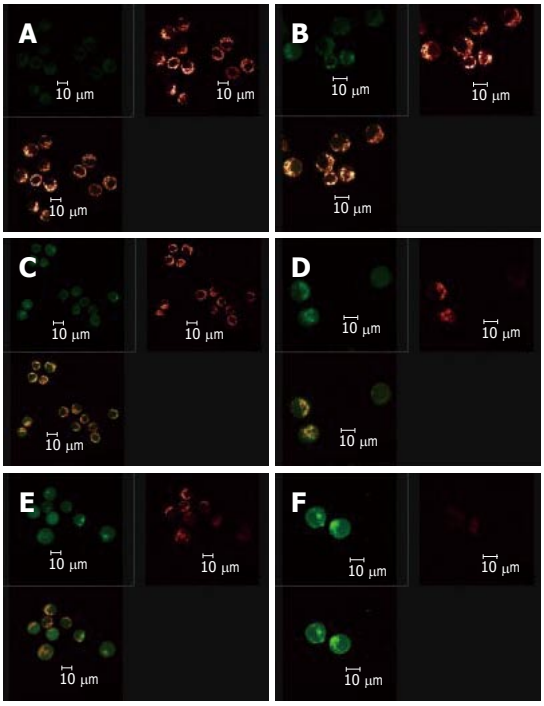

Figure 6 Distribution of solanine-induced changes in $[Ca^{2+}]_i$ and membrane potential of mitochondria in the $HepG_2$ cells in the process of apoptosis. **A**: Blank; **B**: 0.0032 μg/mL solanine; **C**: 0.016 μg/mL solanine; **D**: 0.08 μg/mL solanine; **E**: 0.4 μg/mL solanine; **F**: 2 μg/mL solanine.

lymphocytes[21,22], whereas if the transmembrane potential of mitochondria can be stabilized, apoptosis would be prevented. Therefore, the dissipation of transmembrane potential of mitochondria is closely related to apoptosis.

The dissipation of transmembrane potential of mitochondria in the process of apoptosis is mainly caused by changes in the permeability of the inner membrane of mitochondria, which is due to the formation of dynamic pores for permeability transition (PT) (each composed of several proteins) at points of contact between the outer and inner membranes of the mitochondrion[23]. PT channels are made up of proteins from various parts of the mitochondrion and those from the cytoplasm[24,25]. They include a protein in the cytochylema (hexokinase)[25], proteins on the outer membrane of the mitochondrion (peripheral benzodiazepine receptors and voltage-dependent anion channels), a protein in the interstice between the inner and outer membranes of the mitochondrion (creatine kinase)[26], a protein on the inner membrane of the mitochondrion (the ADP-ATP carrier)[27], and a protein in the mitochondrial matrix (cyclophilin D)[28]. Any substance, such as protoporphyria IX, the ligand for benzodiazepine receptors, that can specifically induce the formation of PT channels in mitochondria could cause apoptosis[29-32]. PT channels are a kind of channels with high electric conductivity. The lowering or even disappearance of membrane potential would suggest that PT channels are open.

Results from earlier experiments show that solanine can induce the apoptosis of $HepG_2$ cells. In the present study, double staining with AO/EB and solanine (0.0032, 0.016, 0.08, 0.4, and 2 μg/mL) carried by TMRE were used to treat $HepG_2$ cells, and LCSM was used to observe changes in the membrane potential of mitochondria as solanine induced the appearance of apoptotic bodies[33]. As solanine induced the appearance of apoptotic bodies and caused the apoptosis of cells, the membrane potentials of mitochondria in cells in groups treated with different dosages of solanine (0.0032, 0.016, 0.08, 0.4, and 2 μg/mL) were all decreased in comparison with the control (Figures 2 and 4, and Table 2). The amount of decrease was dosage-dependent, and the difference from that of the control was significant for the groups treated with 0.016, 0.08, 0.4, and 2 μg/mL of solanine, respectively, suggesting that solanine can lead to the lowering of the membrane potential of mitochondria in $HepG_2$ cells. However, the lowering of the membrane potential of mitochondria is a manifestation of the opening of the PT pores of the mitochondria[34], so solanine can lead to the opening of the PT pores of the mitochondria.

The opening of PT pores can lead to the occurrence of two events[35]: (1) the intra-membrane and extra-membrane ion concentrations tend toward equilibrium, the transmembrane H^+ gradient disappears, and the respiratory chain is uncoupled; (2) the flow of intra- and extra-membrane ions toward equilibrium leads to a hypertonic mitochondrial matrix, resulting in change in the volume of the mitochondrion. Since the surface area of the folded inner membrane of mitochondrion is larger than that of the outer membrane, this would lead to the rupture of the outer membrane.

These two events lead respectively to two consequences. Since a large number of Ca^{2+} have accumulated in mitochondria, the concentration of Ca^{2+} in mitochondria is much higher than that in the cytoplasm. The occurrence of the first event would lead directly to the flow of Ca^{2+} from the mitochondria to the cytoplasm, resulting in rapid increase in the concentration of Ca^{2+} in the cytoplasm. In the present study, the Ca^{2+}-specific molecular probe Fluo-3/AM was used to carry solanine at different concentrations to treat $HepG_2$ cells, and LCSM was used to observe changes in $[Ca^{2+}]_i$ in the cells after the treatment. In groups treated with different dosages of solanine (0.0032, 0.016, 0.08, 0.4, and 2 μg/mL), the concentrations of Ca^{2+} in $HepG_2$ cells were all increased in a dosage-dependent way (Figure 3 and Table 1). This verifies the inference we have drawn, namely, by opening up PT channels, solanine leads to the release of Ca^{2+} from the mitochondria, resulting in the increase of $[Ca^{2+}]_i$ in the cell. In order to obtain more powerful evidence for our inference, LCSM with double staining with Fluo-3/AM and TMRE was used to observe simultaneously the change in membrane potential and the change in $[Ca^{2+}]_i$ in the cell after the treatment. The results showed that as the dosage increased, the rate of apoptosis gradually increased, the membrane potential gradually decreased, and $[Ca^{2+}]_i$ in the cell gradually increased (Figure 5 and Table 3). These results were consistent with that obtained with single staining.

At the same time, the data collected using LCSM was analyzed and observation was made on the distribution of $[Ca^{2+}]_i$ and the membrane potential of mitochondria in the cells in the apoptotic process of $HepG_2$ induced by solanine. The image overlay function of LCSM was used

to superimpose and compare the images of $[Ca^{2+}]_i$ and the membrane potential of mitochondria in the cells. Results showed that membrane potential was mainly distributed on the inner membrane of the cells, with no distribution in the center of the cells; but the inner membrane was precisely where mitochondria were concentrated (Figure 6). $[Ca^{2+}]_i$ was distributed throughout the whole cell, but the distribution was uneven. This can be observed in the photograph with green fluorescence in Figure 6, where the brightness of the fluorescence depends on the region of the cell. When the image for $[Ca^{2+}]_i$ distribution (green) was superimposed on that for membrane potential (red), it can be seen that regions where Ca^{2+} was concentrated overlaps with where membrane potential was concentrated (as shown by the yellow regions in the third photograph in each group in Figure 6), suggesting that the distribution of Ca^{2+} in the mitochondria was high. In addition, the concentration of Ca^{2+} in both the mitochondria and the cytoplasm continued to rise in the different groups, suggesting that as $[Ca^{2+}]_i$ increased in the cytoplasm, Ca^{2+} flew out not only from the mitochondria, but also from some other source(s) as well, e.g., an inflow of Ca^{2+} from outside the cell.

In conclusion, solanine can facilitate the opening of the PT channels in mitochondria, leading to release of Ca^{2+} from these organelles. This results in an increase in the concentration of Ca^{2+} in the cell, thus triggering the mechanism for apoptosis and the occurrence of apoptosis. However, to uncover how the PT channels are opened and which enzymes and genes are involved in this process, further research is needed.

Abstract

AIM: To investigate the dynamic functional and ultrastructural changes of gastric parietal cells induced by water immersion-restraint stress (WRS) in rats.

METHODS: WRS model of Sprague-Dawley (SD) rats was established. Fifty-six male SD rats were randomly divided into control group, stress group and post-stress group. The stress group was divided into 1, 2 and 4 h stress subgroups. The post-stress group was divided into 24, 48 and 72 h subgroups. The pH value of gastric juice, ulcer index (UI) of gastric mucosa and H^+, K^+-ATPase activity of gastric parietal cells were measured. Ultrastructural change of parietal cells was observed under transmission electron microscope (TEM).

RESULTS: The pH value of gastric juice decreased time-dependently in stress group and increased in post-stress group. The H^+, K^+-ATPase activity of gastric parietal cells and the UI of gastric mucosa increased time-dependently in stress group and decreased in post-stress group. Compared to control group, the pH value decreased remarkably (P = 0.0001), the UI and H^+, K^+-ATPase activity increased significantly (P = 0.0001, P = 0.0174) in 4 h stress subgroup. UI was positively related with stress time (r = 0.9876, P < 0.01) but negatively with pH value (r = -0.8724, P < 0.05). The parietal cells became active in stress group, especially in 4 h stress subgroup, in which plenty of intracellular canalicular and mitochondria were observed under TEM. In post-stress group, the parietal cells recovered to resting state.

CONCOUSION: The acid secretion of parietal cells is consistent with their ultrastructural changes during the development and healing of stress ulcer induced by WRS and the degree of gastric mucosal lesions, suggesting gastric acid play an important role in the development of stress ulcer and is closely related with the recovery of gastric mucosal lesions induced by WRS.

INTRODUCTION

Stress ulcer is a common complication of severe brain trauma and psychosis in clinical practice. Critically ill patients are at increased risk of developing stress-related gastric mucosal lesions and gastrointestinal bleeding[1,2]. But the pathogenesis of stress-related gastric mucosal lesions is not fully elucidated. The development and healing of stress ulceration are a complex process affected by many factors. It had been shown that gastric acid plays an important role in the development of stress-induced ulcer and is the most common endogenous destructive factor[3-5].

It is reported that water immersion-restraint stress (WRS) may lead to changes of gastric acid secretion. Some studies indicate that WRS increases acid secretion[6,7], while other studies showed that gastric acid secretion decrease during WRS[8,9]. Gastric acid secretion is intimately related with the ultrastructure of parietal cells, but the dynamic ultrastructure change of parietal cells during WRS has not been reported yet.

Moreover, changes of parietal cells ultrastructure and gastric acid secretion during the healing of stress-induced ulceration are poorly understood so far. The purpose of the present study was to investigate the dynamic ultrastructural and functional of gastric parietal

cells induced by WRS in order to demonstrate the role of gastric acid in the development of stress ulcer and in the healing of gastric mucosal lesions.

MATERIALS AND METHODS

Animals and water immersion-restraint stress model

Fifty-six male SD rats, weighing 180-220 g were purchased from Xipuer-Bikai Experimental Animal Co. LTD, Shanghai, China. The animals were fasted for 24 h with free access to water and deprived of water 1 h before the experiment. Animals were randomly divided into control group (n = 8), stress group (n = 24) and post-stress group (n = 24), and exposed to various periods of stress and immersed in 19 ± 1℃ water as previously described[10]. Rat in control group were sacrified after lightly anesthetized with ether. Rats in stress group were killed after 1, 2 and 4 h of WRS respectively. Rats in post-stress group were killed after 24, 48 and 72 h of WRS respectively[11].

Measurement of gastric juice pH

All rats were anesthetized with pentobarbital sodium (30 mg/kg *ip*). A midline laparotomy was performed and the stomach was exposed. The pylorus and cardia were ligated, and the pH electrode of pH/mV meter (59 002-00, Cole-Parmer Instrument Company, USA) was inserted into stomach lumen to measure the pH value of gastric juice[12].

Evaluation of gastric mucosal ulcer index (UI)

The ulcer index (UI) of gastric mucosal lesions was evaluated by the score system reported by Nie SN *et al*[13]. Briefly, after measurement of the pH value of gastric juice, the stomach was opened along the greater curvature and rinsed with 0.1 mol/L ice-cold phosphate-buffered saline (PBS). The stomach was then examined with a 10 × magnifier to observe erosions and make scores as 1-5: 1: small round hemorrhagic erosion, 2: hemorrhagic erosion < 1 mm, Grade 3: hemorrhagic erosion = 1-2 mm, 4: hemorrhagic erosion = 2-3 mm, 5: hemorrhagic erosion > 4 mm. The score was multiplied by 2 when the width of erosion was larger than 1 mm.

H+, K+-ATPase assay

The oxyntic mucosa was scraped with glass slides, immediately frozen in liquid nitrogen and stored at -80 ℃ for H^+, K^+-ATPase assay, at which time they were thawed at 4℃. Microsomal gastric H^+, K^+-ATPase was prepared after homogenization of gastric mucosa and sucrose-Ficoll gradient centrifugation[14,15]. H^+, K^+-ATPase was assessed with a kit (Nanjing Jiancheng Biotechnology Company), and protein was quantified using a UV/spectrophotometer (PE)[16]. The gastric mucosal H^+, K^+-ATPase activity was expressed as μmol Pi/mg protein/h (U/mg prot).

Electron microscopy

Tissue specimens of the oxyntic mucosa for electron microscopy, were immediately fixed in a solution containing 1% glutaraldehyde and 3% formaldehyde buffered at pH 7.4 with 0.1 mol/L sodium PBS for 2 h at 4℃. Secondary fixation was carried out in 1% osmium tetroxide solution buffered at pH 7.4 with 0.1 mol/L sodium phosphate buffer for 1 h at 4℃. The specimens were then dehydrated in graded acetone solutions and embedded in epoxy resin (Epon 812). Ultrathin sections (60-80 nm) were made for double staining with aqueous uranyl acetate and lead citrate, and observed under transmission electron microscope[17]. Parietal cells were recognized by the presence of secretory canaliculi and/or tubulovesicles. Secreting parietal cells were defined as cells having secretory canaliculi. Non-secreting cells had tubulovesicles but no secretory canaliculi[18].

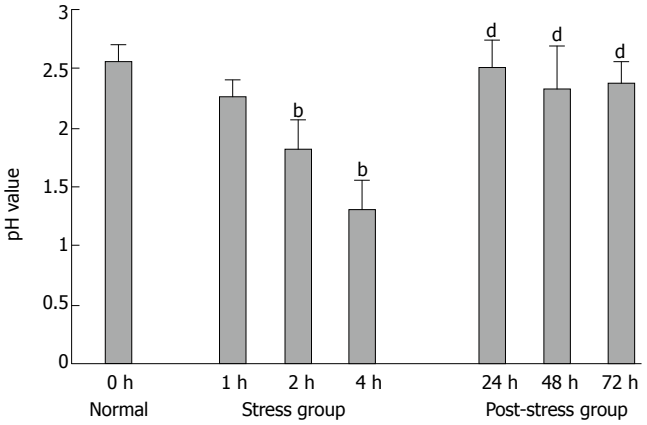

Figure 1 pH value of gastric juice in all groups. $^bP < 0.01$ *vs* normal group; $^dP < 0.01$ *vs* stress 4 h group.

Statistical analysis

All data were expressed as mean ± SD. The statistical differences between different groups were analyzed by Student's *t*-test. The relationship between two variants was analyzed by linearly relevant analysis. $P < 0.05$ was considered significant.

RESULTS

Change of gastric juice pH value

The pH value of gastric juice was 2.56 ± 0.14 in normal group and gradually declined after 1, 2 and 4 h of WRS in rats (2.26 ± 0.04, 1.81 ± 0.25 and 1.31 ± 0.24, respectively) (Figure 1). The pH value was significantly lower (2.0-fold) in stress 4 h group than that in normal group ($P < 0.001$). The pH values of gastric juice after 24, 48, 72 h of WRS in post-stress groups was significantly higher (1.9-fold, 1.8-fold and 1.8-fold, respectively) than that in stress group ($P < 0.001$), but there was no statistical significance compared to normal group ($P > 0.05$, Figure 1). These data demonstrated that the pH value of gastric juice decreased time-dependently in stress group and increased in post-stress group.

Change of gastric mucosal ulcer index (UI)

There was no gastric mucosal lesion in normal group. Scattered spot or lineal erosions, hemorrhage and ulcers were observed in oxyntic mucosa in stress group. The gastric mucosal UI gradually increased after 1, 2 and 4 h of WRS in rats (9.5 ± 2.98, 22.5 ± 3.16 and 35.0 ± 3.93) (Figure 2). The UI decreased significantly (2.0-fold and 4.7-fold) after

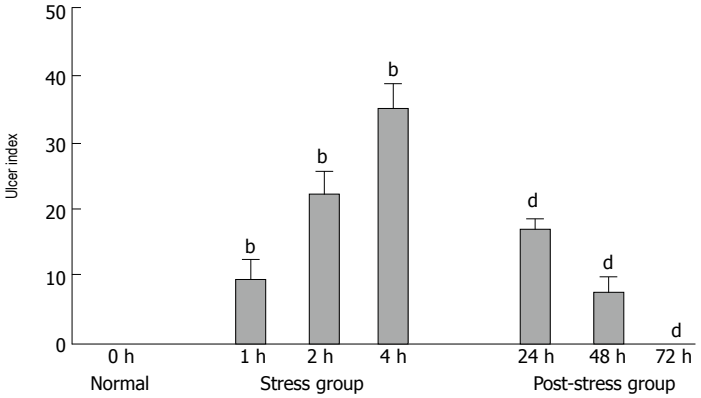

Figure 2 Ulcer index (UI) of gastric mucosa in all groups. [b]$P < 0.01$ *vs* normal group; [d]$P < 0.01$ *vs* stress 4 h group.

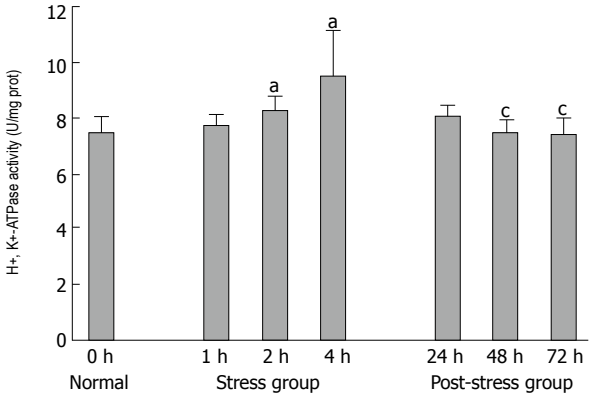

Figure 3 H^+, K^+-ATPase activity of parietal cells in all groups. [a]$P < 0.05$ *vs* normal group; [c]$P < 0.05$ *vs* stress 4 h group.

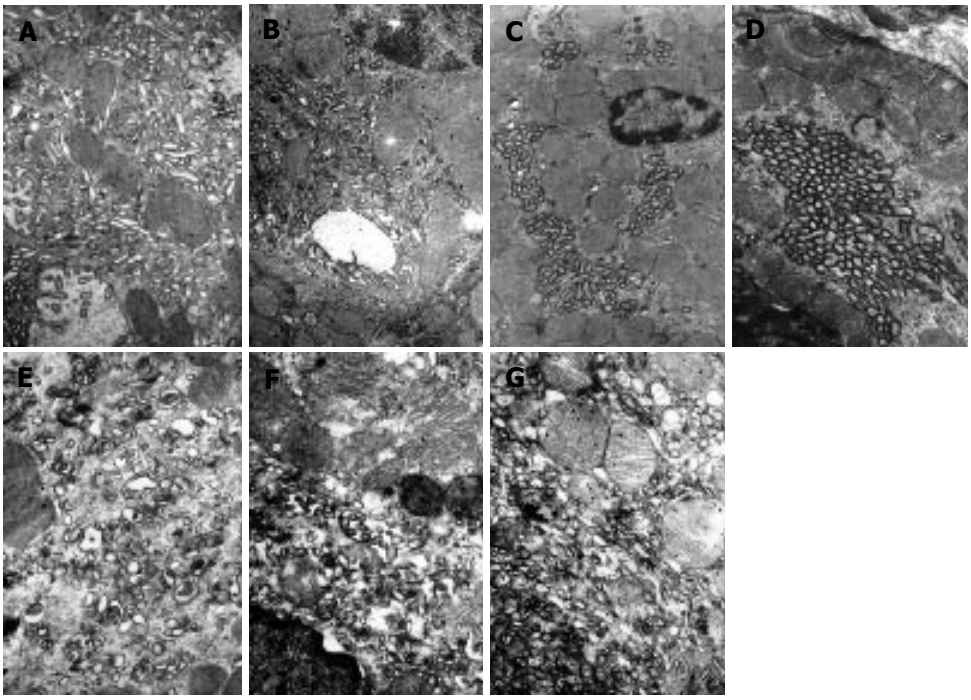

Figure 4 Ultrastructural change of parietal cells. **A:** Gastric parietal cells presented resting state, abundant tubulovesicles and few intracellular canaliculi lined with rare microvilli could be found in the cytoplasm in normal group (×12 000); **B**: Parietal cells presented pre-secreting state, intracellular canaliculi lined with short microvilli were observed, plenty of vesicles were located around the canaliculi and accumulated on the apical plasma membrane in 1 h WRS group (×12 000); **C:** Parietal cells presented secreting state with decreased vesicles and increased intracellular canaliculi lined with elongated microvilli in 2 h WRS group; **D:** Parietal cells presented active secreting state and cytoplasm was almost devoid of vesicles and intracellular canalicular lumen contained numerous elongated microvilli in 4 h WRS group (×12 000); **E - G:** at 24, 48 and 72 h at the end of WRS for 4 h, Parietal cells returned to resting state with abundant tubulovesicles and few canaliculi in cytoplasm in post-stress group swollen mitochondria, vacuolar degeneration, crista-fragmentation, concentrated karyotin, roughness of nuclear envelopes and dilated perinuclear space were observed (×15 000).

24 and 48 h of WRS in post-stress group compared to that in stress group ($P < 0.001$). No lesion occurred in the oxyntic mucosa of rats 72 h after WRS (Figure 2). These data demonstrated that the UI of gastric mucosa increased time-dependently in stress group and decreased in post-stress group. UI was positively related with stress time ($r = 0.9876$, $P < 0.01$) but negatively with pH value ($r = -0.8724$, $P < 0.05$).

H+, K+-ATPase activity

The H^+, K^+-ATPase activity of gastric parietal cells was 7.48 ± 0.59 U/mg prot in normal group and gradually increased after 1, 2 and 4 h of WRS in rats (7.72 ± 0.41, 8.28 ± 0.52 and 9.50 ± 1.63 U/mg prot, respectively) (Figure 3). The H^+, K^+-ATPase activity was significantly higher (1.1-fold and 1.3-fold) in stress group than in normal group ($P < 0.05$). The H^+, K^+-ATPase activity decreased in post-stress group, but there was no statistical significance ($P > 0.05$). The H^+, K^+-ATPase activity was significantly lower (1.3-fold, respectively) after 48 and 72 h of WRS in post stress group than in stress group ($P < 0.05$, Figure 3). These data demonstrated that the H^+, K^+-ATPase activity of gastric parietal cells increased time-dependently in stress group and decreased in post-stress group.

Ultrastructural change of parietal cells

As shown in Figure 4A, gastric parietal cells in normal group presented resting state, a large number of tubulovesicles and few intracellular canaliculi lined with rare microvilli could be found in cytoplasm. As shown in Figure 4B, parietal cells in 1 h WRS subgroup presented pre-secreting state, intracellular canaliculi lined with short microvilli were observed, and plenty of vesicles in the cytoplasm were located around the canaliculi and accumulated on the apical plasma membrane, and the secretory surface was more elaborate than that of the non-secreting cells. As shown in Figure 4C, parietal cells in 2 h WRS subgroup presented secreting state, where decreased vesicles and increased

intracellular canaliculi lined with elongated microvilli were observed. The remaining vesicles were in the region adjacent to the surface and frequently fused with the plasma membrane. In addition, there were abundant mitochondria in the cytoplasm. As shown in Figure 4D, parietal cells in 4 h WRS subgroup presented active secreting state. The cytoplasm was almost devoid of vesicles, whereas the intracellular canalicular lumen contained numerous elongated microvilli. The cytoplasm in these secreting cells was extremely dense owing to the close packing of mitochondria. As shown in Figure 4E-G, in 24, 48 and 72 h WRS subgroups, the parietal cells returned to resting state, abundant tubulovesicles and few canaliculi were observed in the cytoplasm in post-stress group after 24, 48 and 72 h WRS. Besides, Swollen mitochondria, vacuolar degeneration and crista-fragmentation were observed in some parietal cells. Concentrated karyotin, roughness of nuclear envelopes and dilated perinuclear space were observed in other cells, which might be due to the damaged parietal cells induced by stress.

DISCUSSION

Stress ulcers are the superficial mucosal lesions located predominantly in fundus of the stomach. They occur mainly in severe trauma and sepsis as well as in acute severe psychological stress. It has become apparent that the physiological stress of critical illness increases the risk of developing stress-related mucosal injury and gastrointestinal bleeding. The pathogenesis of stress ulcers is not completely understood. however, recent studies indicate that the origin may be multifactorial, and there is an imbalance between protective and destructive factors[19-21]. Major destructive factors include acid, pepsin, bile, reperfusion injury and free oxygen radicals[22-24]. Protective factors include adequate mucosal blood flow, mucus-bicarbonate layer, epithelial cell renewal and prostaglandins[25-27]. It is generally agreed that mucosal ischemia is the major inciting event in the pathogenesis of acute stress ulceration of the stomach and that the presence of luminal acid and pepsin is required in the development of overt ulceration[28]. Back-diffusion of acid occurs in the absence of overt disruption of the mucosal barrier, and is closely related to the formation of ulcers.

In this study, we found that gastric mucosal lesions gradually aggravated after 1, 2 and 4 h of WRS in rats. Gastric mucosa lesions progressed to apparent erosions and hemorrhage in 4 h WRS group. There positive relevance between the ulcer index UI was significantly related with the exposure time to WRS. We also found that gastric juice pH value decreased and H^+, K^+-ATPase activity of parietal cells gradually increased after 1, 2 and 4 h of WRS, indicating that gastric acid secretion increases with the exposure time to WRS. The pH value was significantly lower (2.0-fold) and the H^+, K^+-ATPase activity was significantly higher (1.3-fold) in stress group than in normal group. UI was negatively related with pH value. These results strongly suggest that gastric acid can mediate acute gastric mucosal lesions induced by WRS.

The present study assessed the dynamic ultrastructural change of gastric parietal cells in rats induced by WRS. Gastric parietal cells also known as oxyntic cells, have two systems in the cytoplasm under transmission electron microscope: intracellular secretory canaliculus system and tubulovesicular system[29]. In normal group, abundant tubulovesicles and few intracellular canaliculi lined with rare microvilli were found in cytoplasm and the gastric parietal cells presented resting state. Tubulovesicles gradually decreased while intracellular canaliculi lined with elongated microvilli gradually increased after exposed to WRS for 1, 2 and 4 h. In 4 h WRS group, parietal cell cytoplasm was almost devoid of vesicles and the intracellular canalicular lumen contained numerous elongated microvilli. Our observation showed that parietal cells presented a series of states from resting, pre-secreting, secreting to active secreting after 0, 1, 2 and 4 h of WRS. Our study also showed that gastric mucosal lesions induced by WRS paralleled to time-course changes of ultrastructure of gastric parietal cells. These results indicate that WRS can time-dependently activate parietal cells and induce gastric acid secretion.

The mechanism of the recovery of gastric mucosa after stress is not fully understood. the healing of stress ulcer is a very complex process affected by multi-factors. It has been reported that the mucosal integrity and repair involved enhancement of gastric mucosal blood flow and increased mucosal cell proliferation mediated by epidermal growth factor (EGF) and transforming growth factor alpha (TGFα)[30,31]. The importance of gastric acid in the process of restructuring gastric mucosa after WRS has not yet been evaluated. In present study, we found that the injured gastric mucosa was gradually restructured after the stress was removed and no lesion was observed after 72 h at the end of WRS for 4 h. We also found the pH value increased significantly at 24, 48 and 72 h of WRS. These results strongly demonstrate that the decrease of gastric acid is beneficial for restructuring injured gastric mucosa.

In the present study, we found that the parietal cells returned to resting state while swollen mitochondria, vacuolar degeneration, crista-fragmentation, concentrated karyotin, roughness of nuclear envelopes and dilated perinuclear space were observed after 24, 48 and 72 h of WRS, suggesting that damaged parietal cells induced by WRS.

The major founding of our study is that the ultrastructural changes of parietal cells is consisitent with the change of H^+, K^+-ATPase activity in the development and healing of stress ulceration induced by WRS. Moreover, the recovery of ultrastructural and functional changes of parietal cells was earlier than the restructuring of damaged gastric mucosa after WRS, suggesting that the ultrastructural and functional changes of parietal cells may be an important pathophysiologic mechanism in restructuring stress ulceration.

In conclusion, ultrastructural and functional changes of gastric parietal cells are induced by WRS in rats. Increased gastric acid secretion induced by WRS is consistent with the ultrastructural changes of parietal cells and is significantly correlated with the degree of gastric mucosa lesions. Gastric acid not only plays an important role in the development of stress ulcer, but also is closely related to the recovery of gastric mucosal lesions induced by WRS.

Abstract

AIM: To clone Δ^{12} -fatty acid desaturase gene of *Mortierella isabellina* and to functionally characterize this gene *in vitro* and *in vivo*.

METHODS: Reverse transcriptional polymerase chain reaction (RT-PCR) was used to clone the open reading frame of Δ^{12}-fatty acid desaturase gene (D12D) of *Mortierella isabellina*. Plasmids pEMICL12 and pYMICL12 were constructed with it. pEMICL12 was transformed into *Escherichia coli* (*E.coli*) strain BL21 using $CaCl_2$ method for expression after induction with IPTG. pTMICL12 was transformed into *Saccharomyces cerevisiae* strain INVSc1 using lithium acetate method for expression under the induction of galactose. Northern blotting method was used to investigate the effect of temperature on the transcriptional level of this gene in *S.cerevisiae* strain INVSc1.

RESULTS: Recombinant plasmids pEMICL12 and pTMICL12 were successfully constructed and transformed into *E.coli* and *S.cerevisiae* separately with appropriate method. After induction with IPTG and galactose, it was found that expression of Δ^{12}-fatty acid desaturase genes in *E.coli* and *S. cerevisiae* under appropriate conditions led to the production of active Δ^{12}-fatty acid desaturase, which could convert 17.876% and 17.604% of oleic acid respectively to linoleic acid by GC-MS detection *in vitro* and *in vivo*.

CONCLUSION: Cloning and expression of *M.isabellina* D12D gene in *E.coli* and *S.cerevisiae* is successfully completed.

INTRODUCTION

As an economically important filamentous fungi, *M isabellina* which belongs to *Mucor sp.* can produce linolenic acid(GLA) that plays very important roles in regulating the hormone level and fatty acid metabolism in human. In addition, recent study indicated that GLA can alleviate the symptoms of many kinds of diseases such as neurodegeneration[1,2] , adipogenesis[3], cancer[4,5] , Protofibrils[6-8] , cardiovascular disease[9-11], diabetes[12] and psoriasis[13]. Being a kind of nutritionally and pharmaceutically important substance, GLA has become the hotspot both in academic and applied fields. *M isabellina* has been a widely used strain in industry to produce GLA by fermentation, in which GLA accounts for 8 percent of total fatty acids. Further efforts to enhance the percentage of the GLA by traditional mutation or by changing fermentation conditions such as medium and temperature have been made, but the extent is relatively small. Therefore, we attempted to reconstruct this strain with genetic engineering.

In most eukaryotic cells, GLA is biosynthesized by two desaturation processes, using stearic acid C18:1 as initial substrate[14-17] . Linoleic acid (LA) C18:2 is synthesized from C18:1 by the reaction catalyzed by Δ^{12}-fatty acid desaturase and then LA can be converted to GLA by Δ^{6}-fatty acid desaturase. LA can also be converted to α-linolenic acid (ALA) by ω3 fatty acid desaturase. LA and ALA are so-called essential fatty acids (EFAs)[18,19] to human bodies because of their inability to synthesize these compounds *de novo*. Linoleic acid is the precursor of polyunsaturated fatty acids (PUFAs) in both routes of n-6 and n-3[20]. Therefore, Δ^{12}-fatty acid desaturase is the key enzyme for producing LA and is also the speed-limiting enzyme for routes of n-6 and n-3. Cloning and characterization of Δ^{12}-fatty acid desaturase gene will help understand the biosynthetic pathway of GLA and further enhance the percentage of GLA in total fatty acids.

Our research interest focuses on PUFAs having 18

carbon atoms or more such as linoleic acid and linolenic acid in fungus. In this paper, we report the isolation of cDNA of D12D from *M isabellina*. The cDNA was expressed in a classical system, *S.cerevisiae* and *E.coli*.

MATERIALS AND METHODS

Materials and culture conditions

Mortierella isabellina M_{6-22} was grown at 28℃ for 2 d in liquid medium containing 2% glucose, 1% bacto-yeast extract, 0.2% KH_2PO4 and 0.1% $MgSO_4$, with pH adjusted to 6.0. *S. cerevisae* strain INVScI was used as recipient strain in transformation experiments and was grown at 30℃ in complex medium containing 1% bacto-yeast extract, 2% bacto-peptone and 2% glucose. *E.coli* strain DH5a was grown at 37℃ in Luria–Bertani medium (LB) supplemented with 100 mg/L of ampicillin. *E.coli* strain BL21 and the expression vector pET21a were purchased from Novegon(Novegen Inc., Madison, WI).

Restriction endonucleases, and the other DNA-modifying enzymes were obtained from TaKaRa Bio. Dalian, China Co. Ltd. Other chemicals were purchased from Sangon Bio. Shanghai, China Co. Ltd.

RNA extraction

Mycelia were harvested by filtration and washed with phosphate buffer. The extraction of total RNA was done according to the guanidinium thiocyanate method as described by Chomczynski and Sacchi[21] and extracts were stored at -70℃ for future use.

Cloning of Δ^{12}-fatty acid desaturase gene by RT-PCR

A pair of primers was designed according to the reported sequence of Δ^{12}-fatty acid desaturase gene from *Mortierella alpine*[22] to clone the open reading frame (ORF) of the *M isabellina* D12D gene, P1: 5'-TAC CTC ***GAA TCC*** **ATG** GCA CCT CCC AAC ACT ATC GAT GCC-3'; P2: 5'-AAC CGT ***CTC GAG*** **TTA** CTT CTT GAA AAA GAC CAC GTC TCC-3', which corresponded to the nucleotide sequences of start and stop codons (in boldface) of the Δ^{12}-fatty acid desaturase gene, respectively. The 5'-end of both primers contained an *Eco*R Ⅰ and an *Xho* Ⅰ site(underlined and in boldface), respectively that were underlined to facilitate subsequent manipulation. PCR was performed in a Biometra T-gradient thermal cycler using the following program: at 94℃ for 1 min, 53℃ for 1 min, 72℃ for 2 min for 30 cycles, followed by extension for 10 min at 72℃. PCR fragments were subcloned into pGEM-T vector (Promega, Madison, WI) to produce recombinant plasmid pTMICL12, which was then transformed into *E.coli* DH5a. Subsequently, nucleotide sequences were determined (TaKaRa Bio, Dalian, China). Analysis of the sequences was done with DNAMAN software (version 4.0, Lynnon BioSoft, Quebec).

Plasmid construction

The ORF of Δ^{12}-fatty acid desaturase from *M isabellina* was digested from pTMICL12 with *Eco*R Ⅰ and *Xho* Ⅰ and subcloned respectively into *S.cerevisiae* expression vector pYES2.0 and *E.coli* expression vector pET21a. Positive transformants were screened on the LB plate with ampicillin resistance. The resultant positive plasmid was validated by PCR and restriction enzyme digestion. The construction sketch of pYMICL12 is shown in Figure 1. The resultant plasmids, pYMICL12 and pEMICL12 were stored and propagated in *E.coli* strain DH5a.

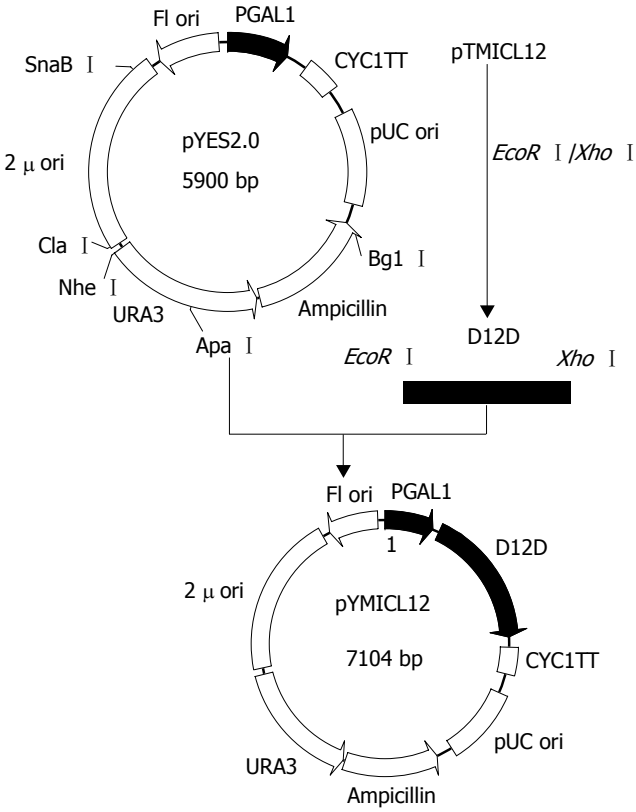

Figure 1 Construction sketch of pYMICL12.

Yeast transformation and inducement of transgenic yeast

The recombinant plasmid pYMICL12 was transformed into *S.cerevisiae* INVSc1 using the lithium acetate method [23]. Positive transformants were selected by plating on complex synthetic minimal medium agar lacking uracil (SC-Ura) and grown at 30℃ for 2-3 d. The putative Δ^{12}-desaturase gene was heterologously expressed in yeast, which was induced under transcriptional control of the GAL1 promoter. Yeast cultures were grown to logarithmic phase at 30℃ in synthetic minimal medium containing different concentrations of galactose(1%, 2%, 3%, 4% respectively), and 0.67% yeast nitrogen. Subsequently, cells were harvested by centrifugation followed by washing in sterile water for three times. The cells were dried and ground into fine powders for determination of fatty acid composition by gas chromatography and for gas chromatography–mass spectrometry (GC-MS) analysis.

Inducement of the transgenic E.coli cells

Transformant containing plasmid pETMICL12 was cultured in M9 medium at 37℃ overnight. Five hundred milliliter M9 medium was inoculated into 2.8 L Fernbach flask with aliquot from the overnight culture until the light density reached 0.5. IPTG was added until the final concentration reached 0.4 mmol/L. After 4 hours' induction,

cells were pelleted by centrifugation at 5000 r/min for 10 min at 4℃ and stored at -70℃ for future use.

Preparation of cell membrane

Cells defrosted at room temperature were suspended in 30 mL buffer A (containing 10 mmol/L $MgCl_2$, 50 mmol/L MOPS-NaOH, 1 mmol/L EGTA, 10 μg/mL DNase) and then were treated with supersonic 450 Hz for 40 cycles, 4 s per cycle. Intact cells and cell debris were pelleted by centrifugation at 5000 r/min for 10 min at 4℃. Supernatants containing cell membrane were pelleted by super-centrifugation at 150 000 r/min for 30 min at 4℃ and then were re-suspended in 200 μL buffer A.

SDS-PAGE

Ten percent of the gel was used to separate the protein bands, and stained by Coomassie Blue R-250[24].

In vitro assay of activity of Δ^{12}-fatty acid desaturase

Sodium salt was added into the membrane suspension in buffer A to reach the final concentration of 150 μmol/L and then the mixture was incubated at 25℃ in water bath for 30 min after oleic acid was added. Soon after that, the mixture was extracted with chloroform methanol and water (volume ratio 2:1:2). The extraction was methyl-esterified with 5% HCl/methanol at 85℃ for 150 min. Fatty acid methyl ester was solubilized with hexane[25,26].

Detection of desaturase activity expressed in transgenic yeast

Total fatty acid was extracted from the cells by treating 100 mg yeast powder with 5 mL 5% KOH in methanol for saponification at 70℃ for 5 h. pH of the product was adjusted to 2.0 with HCl (6 mol/L) before the fatty acid was methyl-esterified with 4 mL 14% boron trifluoride in methanol at 70℃ for 1.5 h. Then, fatty acid methyl esters (FAME) were solubilized with hexane after addition of saturated sodium chloride solution. FAMEs were analyzed by gas chromatography (GC; GC-9A, Shimadzu, Kyoto, Japan) and identified by the comparison of their peaks with that of standards (Sigma). Qualitative analysis of FAME was performed by GCMS using an HP G1800A GCD system (Hewlett–Packard, Palo Alto, CA, USA). Both analyses were carried out with the same polar capillary column (HP, 5.30 mU, 0.25 mm in internal diameter). The mass spectrum of a new peak was compared with that of the standard for identification of fatty acid.

Analysis of mRNA level in transgenic yeast after induction at different temperature

Northern blotting was used to investigate the effect of temperature on the transcriptional level of MID12. Total RNA of transgenic yeast after induction at different temperatures was extracted by UNIQ-10 column (Sangon Corp.) and digoxingenin (Roche Diagnostics Corp.) was used to label the DNA probe (PCR of MID12)

RESULTS

Target gene obtained

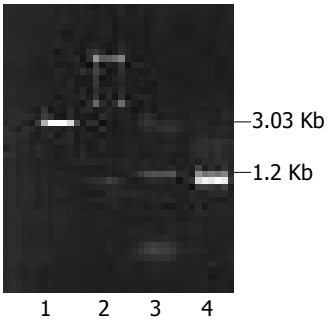

Figure 2 Identification of the recombinant plasmid, pTMICL12 by restriction enzyme. 1: pGEM-T/*Eco*R Ⅰ/*Xho* Ⅰ; 2: DNA size marker λ DNA/*Bst* Ⅱ; 3: pTMICL12/*Eco*R Ⅰ/*Xho* Ⅰ; 4: PCR product of D12D DNA.

PCR product about 1.2 kb long was gel-purified by electrophoresis and cloned into pGEM-T vector. Positive clones were selected on LB plate by color reaction. PCR and enzyme restriction were used to analyze the resultant transformant named pTMICL12. After digestion with *Sac*Ⅱ and *Pst* Ⅰ, a 3.03 kb fragment and a 1.2 kb target gene were obtained as shown in Figure 2. Subsequently, nucleotide sequences were determined (TaKaRa Bio, Dalian, China)

Nucleic acid sequence of Δ^{12} -fatty acid desaturase in *M. isabellina* has been deposited in Genbank database and assigned the accession No. AF417245. Comparison of the DNA sequence with other Δ^{12}-fatty acid desaturase gene showed that it has the highest identity with Δ^{12}-fatty acid desaturase gene from *M. alpina* (about 99.92%) and higher identity with other D12D from fungi[27-30] (more than 40%). Therefore, this sequence encoded a putative Δ^{12}-fatty acid desaturase gene.

Expression vector construction for S. cerevisiae and E coli

In order to investigate the function of this sequence, target gene was subcloned into YES2.0 and pET21a to construct two recombinant plasmids pYMICL12 and pEMICL12 which were transformed into *E.coli* DH5a for propagation. After digested by *Eco*R Ⅰ and *Xho* Ⅰ, both of the plasmids released a 1.2 kb fragment (Figure 3), indicating that the recombinant plasmids were successfully reconstructed.

Detection of desaturase activity in transgenic yeast

After inducement, the total fatty acid in transgenic yeast

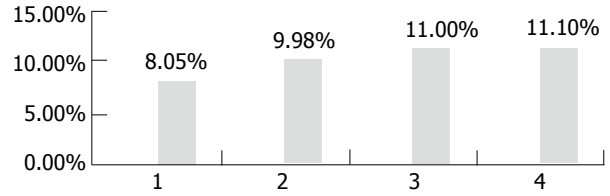

Figure 4 Percentage of linoleic acid in transgenic yeast induced by different concentration of galactose. 1: 1% galactose; 2: 2% galactose; 3: 3% galactose; 4: 4% galactose.

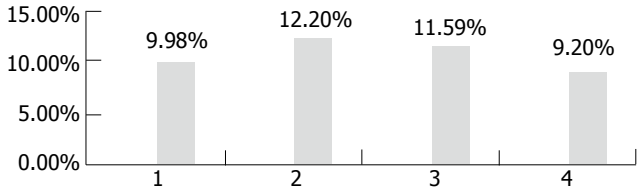

Figure 5 Percentage of linoleic acid in transgenic yeast induced for different durations. 1.12 h; 2. 24 h; 3.36 h; 4. 48 h.

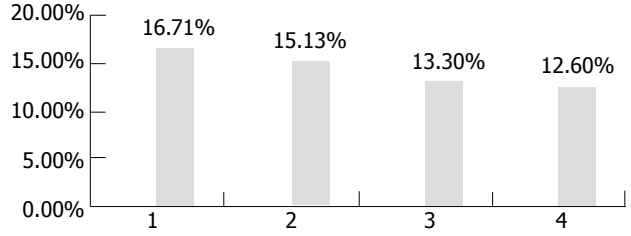

Figure 6 Percentage of linoleic acid in transgenic yeast induced at different temperature. 1: 15℃; 2: 20℃; 3: 25℃; 4: 30℃.

harboring plasmid pYMICL12 was extracted and analyzed by GC. It was found that under different conditions, the expressed desaturase showed different activities.

First, the transgenic yeast was induced at 30℃ for 36 h, with different concentrations of galactose: 1%, 2%, 3%, 4%. The result of GC showed that percentage of LA in transgenic yeast was the highest when it was induced with 3% galactose (Figure 4).

Then, different duration times were used to induce the transgenic yeast by 3% galactose at 30℃ for 12, 24, 36, and 48 h respectively. The result of GC showed that the optimal induction time was 24 h as shown in Figure 5.

Thirdly, the transgenic yeasts were induced by 3% galactose for 24 h at different temperatures of 15℃, 20℃, 25℃, and 30℃ respectively. It was found that the lower the temperature, the higher the activity of the expressed enzyme. The highest percentage of LA reached 16.706% of total fatty acid in induced yeast harboring plasmid pYMICL12 when the temperature was 15℃ (Figure 6).

Therefore, the optimal condition for expressing D12D from *M isabellina* was: 3% galactose induction for 24 h at 15℃. GC analysis of the fatty acid composition of the transgenic yeast containing plasmid pYMICL12 indicated that a novel peak that had the same retention time with that of LA standard appeared. That specific peak was absent from the control transformant (Figure 7).

Northern blot

Northern blot was performed to check if there was an increase of mRNA after induction by low temperature which resulted in the higher activity of Δ^{12}-fatty acid desaturase in transgenic yeast, INVSc1(pYMICL12).

After induction at different temperatures, total RNA was extracted. In the formaldehyde-denaturalization electrophoresis, 30 mg RNA was used for each sample. The result of the Northern blot is shown in Figure 8.

Any visible change of the level of RNA could not be found on the photo of Northern blot. Analysis by VDS-scan also showed no obvious difference between the samples, implying there were no changes of the mRNA level of D12D in the transgenic yeast at different temperature. The level of transcription was not the key cause for the change of LA level in INVSc1 (pYMICL12) under cold condition. The increasing activity of Δ^{12}-fatty acid desaturase might come from the protection of the enzyme activity by low temperature, which even prolonged the half life of Δ^{12}-fatty acid desaturase mRNA.

Detection of Δ^{12}-fatty acid desaturase expressed in E coli by SDS-PAGE

Transformants harboring plasmid pEMICL12 were cultured in M9 medium and induced by IPTG to express Δ^{12}-fatty acid desaturase from *M isabellina*. Cell membranes were pelleted by super-centrifugation. Analysis with SDS-PAGE showed that a specific protein band that had the molecular weight of approximately 43 kd existed on the gel, whereas cell membrane from control transformant harboring the plasmid pET21a did not express the specific protein. In addition, the molecular weight of the specific protein band was nearly identical to other reported Δ^{12}-fatty acid desaturase. These results suggested that this specific band putatively was Δ^{12}-fatty acid desaturase (Figure 9).

In vitro assay of activity of Δ^{12}-fatty acid desaturase

In order to test whether this protein band could convert OA to LA, *in vitro* assay with membrane protein was done. *E coli* can not produce OA that is the most commonly used substrate of Δ^{12}-fatty acid desaturase. Therefore, OA must be added into the reaction mixture to be converted to LA by Δ^{12}-fatty acid desaturase. GC analysis of the mixture after reaction indicated that transformant containing plasmid pETMICL12 exhibited Δ^{12}-fatty acid desaturase activity and that the membrane protein could convert 17.604% of the OA to LA(indicated by arrow), whereas cell membrane protein from transformant containing empty plasmid pET21a did exhibit Δ^{12}-fatty acid desaturase activity. Also, the retention time of the specific peak in Figure 10 was identical to standard LA from Sigma. These results indicated that the specific band had Δ^{12}-fatty acid desaturase activity.

DISCUSSION

M isabellina strain $M_{6\text{-}22}$ is a mutant strain in which total fatty acids account for 60 percent of the dry weight of the mycelium. Also, it synthesizes PUFAs only up to 18-carbon with c isomer of linolenic acid (GLA), which make the subsequent purification relatively easy. Thus, *M isabellina*

strain $M_{6\text{-}22}$ is a promising producer of GLA and also a potential strain to be used to produce other nutritionally and pharmaceutically important PUFAs. However, increasing the percentage of GLA meets great challenges, which made us to turn to other methods including genetic engineering. As we all know, cloning the genes encoding corresponding enzymes is the first thing we should do. In our previous work, we have successfully cloned and characterized Δ^6-fatty acid desaturase gene from *M isabellina*[31]. In order to further elucidate the biosynthetic pathway of polyunsaturated fatty acid, we decided to clone the enzyme genes that are ahead of the Δ^6-fatty acid desaturase gene in reaction chains.

As *M isabellina* is very near to *M alpine* in phylogeny, we adopted the strategy of direct cloning the gene by designing the primer identical to the reported *M alpine* Δ^{12}-fatty acid desaturase gene. Using this method, a fragment of proximately 1.2 kb was obtained. Sequence comparison indicated it has the highest identity with *M alpine* Δ^{12}-fatty acid desaturase gene. In order to functionally identify this nucleic acid sequence, two expression systems were applied: yeast and *E.coli*. In both systems, the heterologously expressed proteins exhibited Δ^{12}-fatty acid desaturase activity, indicating that this sequence encoded a functional desaturase. The high identity between the two sequences suggests that *M alpine* and *M isabellina* belong to the same species. But there indeed exist great differences between the two species. *M alpine* can produce many kinds of PUFAs, but *M isabellina* can only synthesize PUFAs up to 18-carbon. This indicates that other factors may contribute to the difference.

Protein expression in yeast is influenced by many factors such as temperature, induction time. In this work, different temperatures were used. In a certain extent (15-30℃), the higher the temperature, the lower the desaturase activity. At even lower temperature, the yeast INVSc1 (pYMICL12) could achieve more LA. However, a temperature lower than 15℃ would hinder the growth of the mycelium, which reduced the total activity of Δ^{12}-fatty acid desaturase.

Although desaturase activity increased as the temperature decreased, northern blotting analysis indicated that the increasing of desaturase activity was not due to the corresponding increase of the mRNA level. In our study, no significant difference existed among the mRNA level at different temperatures. Other researchers also have reported the same result[28]. This indicates that under certain conditions, mRNA level can not be influenced by temperature. The most important factor that can change it may be the promoter activity. Does the increased activity of Δ^{12}-fatty acid desaturase, however, come from the influence of coldness on mRNA level or protein level? Or does longer half life of Δ^{12}-fatty acid desaturase even directly influence activity of protein? There are different opinions about this in academia.

In conclusion, this report about cloning and character-

ization of the *M isabellina* Δ^{12}-fatty acid desaturase gene will be helpful for us to utilize the industrially used strains.

Abstract

AIM: To investigate the association between malnutrition and quality of life in patients with benign gastrointestinal disease.

METHODS: Two hundred patients (104 wellnourished and 96 malnourished) were assessed according to the Subjective Global Assessment, anthropometric measurements and bioelectrical impedance analysis. Quality of life was determined with the validated Medical Outcomes Study 36-item Short-Form General Health Survey (SF 36). Muscle function was assessed by hand grip strength and peak flow.

RESULTS: Body mass index, body cell mass, arm muscle area and hand grip strength were significantly lower in the malnourished patients. Quality of life was generally lower when compared to norm values. Seven out of eight quality of life scales (excluding *bodily pain*) were significantly reduced in the malnourished patients. Comparing patients with liver cirrhosis and inflammatory bowel disease (IBD), patients with IBD experienced significantly lower values in the perception of *bodily pain,social functioning* and *mental health*. Malnourished liver cirrhotics suffered reductions in more scales (six out of eight) than malnourished IBD patients did (four out of eight).

CONCLUSION: Quality of life is generally low in benign gastrointestinal disease and is further reduced in patients who are classified as malnourished. It appears that liver cirrhosis patients experience a higher quality of life than IBD patients do, but the impact of malnutrition seems to be greater in liver cirrhosis than in IBD.

INTRODUCTION

Malnutrition is common in chronic and acute gastrointestinal disease affecting both morbidity and mortality. Impairment of nutritional status frequently also decreases muscle function[1,2], which lastly results in an impaired functional status.

Studies have shown a close relationship between malnutrition and decreased quality of life in some populations such as elderly institutionalized patients[3,4], patients with cancer[5-7] and patients on haemodialysis[8-10]. Quality of life is a subjective multidimensional construct reflecting functional status, emotional and social well being as well as general health. Its measurement is based on the patient's perception of well being.

In order to evaluate patients' situation or benefits of new treatment strategies, quality of life has become a new clinically relevant outcome parameter[11-13]. In chronic disease in particular, where recovery from disease is not always achievable, quality of life is essential and its measurement should be integrated as one main intervention target. It is therefore crucial to better understand the relationship between more objective measures such as disease parameters, nutritional status and subjective quality of life.

Studies investigating factors influencing quality of life in benign gastrointestinal (GI) disease have not looked at the impact of nutritional deficiency[14-17]. Hitherto, there are no data on quality of life in relation to nutritional status in patients with benign gastrointestinal disease. Since malnutrition frequently occurs in gastroenterological disease, we explored the impact of malnutrition as identified by the Subjective Global Assessment in patients with benign gastroenterological disease. We also focused the evaluation on subgroups of our study patients with chronic gastrointestinal disease like liver cirrhosis or chronic inflammatory bowel disease (Crohn's disease or ulcerative colitis).

MATERIALS AND METHODS

Patients

A total of 200 patients with benign gastroenterological disease admitted to a gastroenterology ward at our university hospital were recruited for the study. Sixty one patients with liver cirrhosis (n = 33 men and n = 28 women), 69

patients with inflammatory bowel disease (n = 29 men and n = 40 women) as well as 70 patients with various acute and chronic gastroenterological diagnoses (n = 32 men, n = 38 women) were included in the study (Table 1). All patients were considered for inclusion if they had a non-neoplastic disease regardless of disease severity. Exclusion criteria were malignant comorbidity and terminal disease (life expectancy < 3 mo) in order not to bias interpretation of quality of life. Patients with neuro-muscular disease, hemiplegia or rheumatoid arthritis were excluded in order to avoid potential confounders on muscle strength. Furthermore, patients with implanted defibrillator were excluded from the bioelectrical impedance analysis. All measurements were performed within 36 h of admission. Patient recruitment was consecutive until at least 100 well nourished patients with benign gastrointestinal disease were included. Then, only malnourished patients were consecutively included in order to obtain comparable patient groups.

All patients signed written informed consent and this study was approved by the local ethics committee.

Ulcerative colitis	23			**Total**	**200**

Quality of life

Quality of life was assessed employing the validated Medical Outcomes Study 36-item Short-Form General Health Survey described in detail elsewhere[18,19]. The questionnaire consists of 36 questions forming 8 multi item scales and is self administered [18,19]. These scales range from 0-100 percent (absolute values), but norm values differ substantially across the scales. In order to facilitate interpretation and to compare the results with norm values obtained in 1998 (1998 SF-36 US population norms), all scales were therefore not only expressed as absolute values but also norm based scored, i.e. each scale was scored to have the same average and the same standard deviation. We employed the standard (US) scoring algorithms, as has been recommended by Ware *et al*[19]. Results for the eight scales can then easily be compared directly since they are all standardized in relation to population norms.

Classification of malnutrition

The Subjective Global Assessment (SGA) was carried out using the protocol developed by Detsky *et al*[20]. It relies on the patient's history regarding weight loss, dietary intake, gastrointestinal symptoms, functional capacity, and physical signs of malnutrition (loss of subcutaneous fat or muscle mass, edema, ascites). Patients were classified as well nourished (A), moderately or suspected of being malnourished (B) or severely malnourished (C). Since subgroups of patients classified as SGA C were too small, comparative analyses were performed between well-nourished patients classified as SGA A and malnourished patients classified as either SGA B or C.

Anthropometry

Body weight was measured on light clothes with a portable electronic scale (seca 910, Hamburg Germany) to the nearest 0.1 kg and height was measured with a portable stadiometer (seca 220 telescopic measuring rod) to the nearest 0.1 cm. Weight and height were used to calculate BMI (weight (kg)/height (m)^2). Mid upper arm circumference (of the nondominant arm) was measured to the nearest 0.1 cm with a nonelastic tape measure and triceps skinfold was measured to the nearest 0.1 mm with a Holtain caliper (Crymych, UK) on the non dominant relaxed arm midway between the tip of the acromion and the olecranon process. Arm muscle area (AMA) and arm fat area (AFA) were calculated applying the formula by Gurney[21].

Body composition

BIA was performed using a BIA 2000M (Data Input GmbH, Darmstadt, Germany) applying alternating electric currents of 800 μA at 50 kHz. Patients were measured in the morning after an overnight fast, in the supine position with arms and legs abducted from the body. Source and sensor electrodes were placed on the dorsum of both hand and foot of the dominant side of the body. Total body water and fat free mass (FFM) were then calculated according to the formula by Kushner and Schoeller, body cell mass (BCM) and extracellular mass (ECM) were calculated as described previously[22]. BCM was also expressed corrected for height (BCM/m^2). ECM/BCM ratio was calculated to detect shifts between BCM and ECM.

Phase angle is a bioimpedance parameter that reflects the contribution between resistance, the pure opposition of a biological conductor to alternating electric current, and capacitance, which is the resisting effect produced by the tissue interfaces (arc tangent of this ratio transformed to degrees). It has been shown to be of clinical relevance in a number of disease settings[23,24].

Muscle function

Hand grip strength was measured both in the nondominant and in the dominant hand with a Digimax electronic dynamometer (Mechatronic GmbH, Germany). The patients performed the test while sitting comfortably with shoulder adducted and neutrally rotated, the elbow supported on a table and flexed to 90 degrees, forearm and wrist in neutral position. The patients were instructed to perform a maximal isometric contraction.

Table 2 Study population and differences between well and malnourished patients

Characteristics	Overall study population (n = 200)	Well nourished (SGA A) (n = 104)	Malnourished (SGA B C) (n = 96)	P

Table 3 Study population and differences between liver cirrhosis and IBD patients

Differences	Liver cirrhosis	Inflammatory bowel disease	P
SGA A *vs* BC	34/27	33/36	NS
Gender (M/F)	33/28	29/40	NS
Age (yr)	56.8 ± 12.2	38.5 ± 13.4	< 0.000
Albumin (g/Ll)	33.0 ± 6.0	38.0 ± 7.0	< 0.000
Body mass index (kg/m²)	26.1 ± 4.9	21.2 ± 3.6	< 0.000
Phase angle (°)	4.7 ± 1.0	5.4 ± 1.2	< 0.000
BCM/height (kg/m²)	8.4 ± 1.9	7.9 ± 1.8	NS
ECM/BCM	1.4 ± .5	1.2 ± .8	< 0.000
Arm muscle area (mm²)	4606.3 ± 1485.9	3921.9 ± 1069.8	0.009
Hand grip strength (kg)	30.9 ± 11.6	31.5 ± 11.4	NS
Peak flow (L/min)	328.2 ± 116.9	375.8 ± 112.5	0.048

The test was repeated within 30 s and the highest value was recorded.

Peak expiratory flow was investigated by the Vitalograph© Peak Flow Meter. Patients were instructed to exhale as fast and as forcefully as possible. The test was repeated within 30 seconds and the highest value was recorded.

Statistical analysis

Statistical analysis was carried out using the software package SPSS© (version 11, SPSS Inc. Chicago, IL, USA). All data are given as mean ± SD. The Mann–Whitney U Test was used for comparison between groups. An acceptable level of statistical significance was established a priori at $P < 0.05$.

RESULTS

Patients' characteristics are given in Table 2. Patients classified moderately or severely malnourished (n = 96) by the Subjective Global Assessment were not significantly older than well nourished patients were. As anticipated however, they exhibited lower blood albumin levels, a significantly reduced body cell mass corrected for height and a significantly increased ECM/BCM ratio when compared to the well nourished patients. Body mass index and arm muscle area were also reduced. Moreover, muscle function as assessed by hand grip strength was significantly lower in the malnourished patients (Table 2). Peak flow was not different between well and malnourished patients.

All patients suffered impaired quality of life in all scales when compared with norm values from the US adult population (Figure 1). Characteristics of the liver cirrhosis and IBD patients are given in Table 3. IBD patients were significantly younger than liver cirrhosis patients and had higher serum albumin level. BCM did not differ between the two groups. IBD patients exhibited lower body

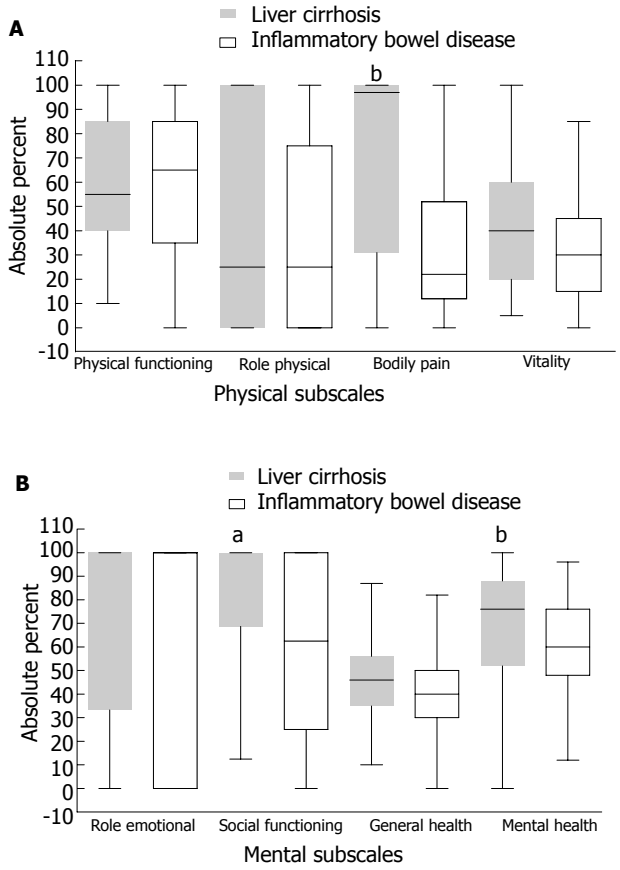

Figure 2 Quality of life ($^{a}P < 0.05$, $^{b}P < 0.01$).

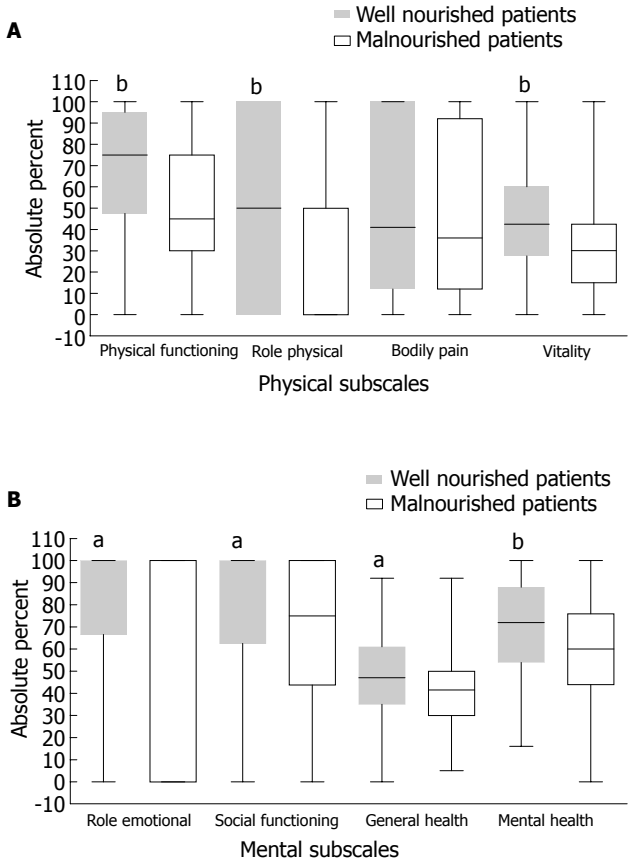

Figure 3 Quality of life in malnourished *vs* well nourished patients ($^{a}P < 0.05$, $^{b}P < 0.01$).

mass index, higher phase angle but reduced arm muscle area. ECM/BCM ratio was significantly also lower in IBD patients than liver cirrhosis patients. Hand grip strength was not different between the two groups but peak flow was higher in IBD patients. When evaluating their quality of life, IBD patients exhibited slightly lower quality of life values than liver cirrhosis patients did. This was significant in the scales concerning bodily pain ($P < 0.00001$), general health ($P < 0.00001$), mental health ($P = 0.031$) and social functioning ($P = 0.016$) (Figure 2).

Impact of malnutrition on parameters of quality of life

Malnourished patients from the overall study group suffered significantly impaired quality of life in both the mental and physical dimension of the quality of life. All subscales except bodily pain were reduced (Figure 3).

Evaluating the two chronic disease groups, malnourished liver cirrhosis patients experienced significantly lower quality of life in six out of the eight scales compared to well nourished liver cirrhosis patients. Malnourished IBD patients showed reduced quality of life in four out of the eight scales (Table 4).

DISCUSSION

In this study we investigated the quality of life of 200 patients with benign acute and chronic gastrointestinal disease in relation to their nutritional status. Quality of life in relation to nutritional status has been investigated in patients on haemodialysis, in institutionalized elderly and in patients with cancer[3-9,25,26]. At present however, there is not sufficient information on quality of life in relation to nutritional status in chronic benign gastroenterological disease, although malnutrition is frequently observed in these patients[27,28] and has well known adverse effects on clinical outcome[29-31]. In order to use quality of life as a clinical outcome parameter in these patients, it is therefore essential to enhance the understanding of quality of life and its association with nutritional status. We employed the SF 36 questionnaire which has been validated in various settings[32-34] and has the advantage of being disease unspecific. We moreover compared the results with values gathered in the 1998 US National Survey of Functional Status. Quality of life was generally impaired in our study population when compared to the norm values. Similar to the findings in other disease settings we also found that quality of life appeared to be compromised in malnutrition. Patients from the overall study group classified as malnourished experienced a significantly lower quality of life than the well nourished patients in all scales except in the perception of pain, leading to impairment of both the mental and the physical dimension of quality of life.

Among our study patients, the largest subgroups were patients with liver cirrhosis or IBD. Since health related quality of life obviously depends on underlying disease we also focused the evaluation on these patients.

Malnourished liver cirrhosis patients suffered statistically significant reductions in all scales except the

perception of social functioning and bodily pain whereas malnourished IBD patients were compromised in social functioning but mainly in the physical scales such as physical functioning, role physical and vitality.

One difficulty in evaluating our study results was to reliably differentiate between the effects of disease and the effects of malnutrition on quality of life, since they obviously are closely interrelated. Severity of disease is likely to trigger a worsening of nutritional status and malnutrition has well known adverse effects on the clinical outcome. Studies investigating health related quality of life in relation to disease severity do not show consistent findings. Kalantar-Zadeh *et al*[8] observed that quality of life assessed by the SF 36 had a strong association with disease severity judged by prospective hospitalization and mortality in patients on haemodialysis. Bianchi *et al*[10] showed a relationship between the disease severity index Child Pugh Score and the Psychological General Wellbeing Index. In patients with hepatocellular carcinoma however, quality of life was not primarily related to tumour mass or hepatocellular failure, but sleep disorders were shown to be strongly associated with quality of life. Similarly, in primary biliary cirrhosis, no associations between scales of the Nottingham health profile and biochemical liver tests, histological stages or duration of the disease were found[17]. Moreover, Hauser *et al* found psychiatric or active medical comorbidity to be of a larger influence than disease severity in a population with various liver diseases[35].

In this study, reliable data on disease severity were only available in liver cirrhosis and Crohn's Disease. In these groups, malnourished patients also experienced greater disease severity classified by the Child Pugh Score or the Crohn´s Disease Activity Index (data not shown). This clearly makes interpretation of the results more difficult and we consider it a limitation of the study. We cannot reliably conclude whether the observed impairments of quality of life in malnutrition are due exclusively to nutritional deprivation.

Malnutrition however is known to be associated with impaired functional status[1,2], worsened immune system[36], delayed recovery, higher mortality and morbidity[31]. The malnourished patients in our study population exhibited both lower muscle mass (as measured by body cell mass and arm muscle area) and muscle function and these changes were not attributable to age. It is therefore highly probable that malnutrition per se-defined mainly by weight loss in the preceding 6 months-has a measurable impact at least on the physical aspect of quality of life, which in the end is likely to affect the mental dimension as well.

Interestingly, overall quality of life was lower in the patients suffering from IBD than in liver cirrhosis patients, which was due to the perception of general health, mental health, vitality, social functioning and bodily pain. The physical scales physical functioning, role physical and vitality were not significantly higher in the IBD patients despite their younger age. There were no significant differences between patients with ulcerative colitis or Crohn's disease (data not shown). Considering that IBD in general is associated with a better prognosis and longer survival time than liver cirrhosis, these results are somewhat alarming. Our findings indicate that acute disease specific aspects such as diarrhoea and abdominal pain occurring in IBD rather than survival associated disease severity lead to a greater impairment of health-related quality of life. Marchesini *et al*[14] who studied quality of life in an Italian cohort of liver cirrhotics found similar associations between non life threatening symptoms such as muscle cramps and quality of life.

It is evident that subjective perception of quality of life depends on more than nutritional status or disease severity. Cancer patients currently on remission might e.g. experience a better quality of life than their healthy but overworked physician. When deciding on optimal therapy, it must also be taken into account that patients with impaired quality of life must be considered in need of intensified attention and care.

In conclusion, quality of life is impaired in benign gastrointestinal disease and becomes further compromised in malnutrition. It appears that liver cirrhosis patients experience a higher quality of life than IBD patients do, but the impact of malnutrition seems to be greater in liver cirrhosis than in IBD. Further studies are required to investi-

gate and identify therapy strategies that improve quality of life in chronic benign gastroenterological disease. Whether nutritional intervention is successful in enhancing quality of life in these patients remains to be studied.

Abstract

AIM: To explore rectal nitric oxide (NO) as biomarker of treatment response in ulcerative colitis (UC) and Crohn's disease (CD), and examine relationships between rectal NO, mucosal expression of NO synthases (NOS), and pro-inflammatory cytokines.

METHODS: Twenty-two patients with UC and 24 with CD were monitored during steroid treatment. Rectal NO levels were measured and clinical activities were assessed on days 1, 3, 7 and 28. Mucosal presence of NOS and pro-inflammatory cytokines were analyzed by immunohistochemistry and RT-PCR.

RESULTS: Active UC and CD displayed markedly increased rectal NO levels (10950 ± 7610 and 5 040 ± 1 280 parts per billion (ppb), respectively) as compared with the controls (154 ± 71 ppb, $P < 0.001$). Rectal NO correlated weakly with disease activity in both UC and CD ($r = 0.34$ for UC and $r = 0.48$ for CD, $P < 0.01$). In 12 patients, a steroid-refractory course led to colectomy. These patients had only slightly increased NO levels (UC: 620 ± 270 ppb; CD: 1260 ± 550 ppb) compared to those with a therapeutic response (UC: 18860 ± 530 ppb, $P < 0.001$; CD: 10060 ± 3200 ppb, $P < 0.05$).

CONCLUSION: Rectal NO level is a useful biomarker of treatment response in IBD as low NO levels predicts a poor clinical response to steroid treatment.

INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease (CD) are chronic inflammatory diseases sharing a clinical course with flares of disease, characterized by an increase of symptoms due to increased inflammatory activity of the intestinal mucosa. Symptom-based clinical activity indices are today's standard methods applied to monitor disease activity in clinical trials, but rarely used in clinical practice. Available indices have been criticized for depending almost exclusively on clinical features that are often subjective. The use of systemic markers of inflammation, such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), platelet count and white blood cell (WBC) count are commonly used in clinical practice, but correlation to ongoing intestinal inflammation is poor[1,2]. An approach of direct assessment of mucosal inflammation has been promising, such as measurements of tumor necrosis factor (TNF)-α and interleukin (IL)-1β[3] and intestinal permeability tests[4]. The implementation of these tests is, however, restricted by a complicated analysis. The development of a more feasible objective marker of mucosal inflammation is, therefore, warranted. Data on local measurements of inflammatory products such as calprotectin, lactoferrin and nitric oxide (NO) in UC and CD have been promising[5].

We use a minimally invasive method employing chemiluminescence to measure rectal NO levels in conditions with inflamed intestinal mucosa[6,7]. Increased NO generation has been demonstrated in both UC and CD[6,8,9]. The excessive formation of NO is elaborated by inducible nitric oxide synthase (iNOS)[10,11]. Some groups have also reported increased endothelial NOS (eNOS) activity in inflamed mucosa in patients with UC[12] and iNOS expression restricted to epithelial cells[13,14]. Other groups have demonstrated iNOS expression also in

macrophages and granulocytes of the lamina propria[10,11].

The activation of iNOS is dependent on the transcription factor nuclear factor (NF)-κB, which is activated by bacterial products (e.g., endotoxins) and pro-inflammatory cytokines, such as TNF-α, IL-1β and interferon (INF)-γ. These pro-inflammatory cytokines act in synergy to stimulate NO production[15]. The aim of the present study was to investigate rectal NO levels as a biomarker of response in UC and CD during glucocorticosteroid (GCS) treatment, using established clinical indices as gold standard for clinical activity. We also assessed mucosal immunoreactivity to the cytokines TNF-α, IL-1β and INF-γ as well as activation of eNOS, iNOS and neuronal NOS (nNOS).

MATERIALS AND METHODS

Patients

Patients treated with prednisolone (0.5-1 mg/kg orally) at the Karolinska University Hospital for active UC or CD were eligible to enter this study. Forty-six consecutive patients, 22 with UC and 24 with CD, diagnosed by conventional endoscopic, radiological and histological criteria of IBD[16] were recruited to this study. Diagnosis of UC or CD was confirmed for all included patients at follow-up one-year after completion of the study. The majority of patients had concomitant medication with aminosalicylates, whereas no patient was on immunomodulators at baseline (Table 1).

The patients were studied at four different occasions during the first month of treatment, before onset of prednisolone treatment (d 1), and at follow-up during ongoing treatment on days 3, 7 and 28. A flexible sigmoidoscopy was performed at baseline, and at all follow-up visits. Disease activity was assessed using the Disease Activity Index (DAI)[17] for the patients with UC. The Harvey-Bradshaw Index (HBI)[18] was used for the patients with CD. The endoscopic classification was done according to the DAI score also for the CD patients.

At the last visit (d 28), the patients were divided into responders (remission) and non-responders (no remission) for further subgroup analysis. Remission was defined as DAI $\leqslant$ 2 in UC, and HBI $\leqslant$ 4 in CD, whereas non-responders were defined as DAI $\geqslant$ 3 in UC and HBI $\geqslant$ 5 in CD, respectively.

Two different control groups were used: the control for immunohistochemistry analyses consisted of six individuals undergone control colonoscopy after prior polypectomy, and the control for rectal NO consisted of 25 healthy volunteers with no history of gastrointestinal symptoms or abdominal surgery.

The study was approved by the Karolinska Institutet Ethics Committee. Written informed consent was taken from all patients.

Determination of rectal NO levels

NO was measured with a chemiluminescence analyzer (CLD 700, *Eco* Physics, Dürnten, Switzerland). The detection limit for NO was 1 part per billion (ppb). The analyzer was calibrated at known concentrations (100-10000 ppb) of NO in nitrogen gas (AGA, Lidingö, Sweden), administered through an electromagnetic flow controller (Environics, Middletown, CT, USA). The chemiluminescence assay is highly specific for NO without interference from other nitrogen oxides[19]. For sampling of rectal gas, we applied an all-silicon catheter (Argyle®, Sherwood Medical, Tullamore, Ireland) inserted into the rectum, using lubrication gel, free of local anesthetics, to a level 10 cm above the anal sphincter[7]. The balloon of the catheter was then inflated with 10 mL of ambient air containing less than 5 ppb of NO, and left for 10 min to equilibrate with gases in the rectum. Thereafter, the gas was withdrawn from the catheter balloon and diluted to a final volume of 50 mL before chemiluminescence analysis with correction for dilution. Analyses were performed within 15 min of sampling[7]. In cases where measurements exceeded the upper detection limit, further dilution steps were made in order to measure NO within the calibrated range.

Table 1 Patient characteristics

	Ulcerative colitis (n = 22)	Crohn's disease (n = 24)
Sex (M/F)	13/9	14/10
Age (yr) (mean and range)	41 (18 – 78)	42 (20 – 69)
Duration (yr) (mean and range)	7.4 (0 – 30)	9 (0 – 28)

Disease activity index (mean and range)	9.4 (5 – 12)	
Harvey-Bradshaw index (mean and range)		14.9 (4 – 29)
Endoscopic score (mean and range)	2.2 (1-3)	2.1 (0-3)

Immunohistochemistry

Mucosal biopsies were sampled at sigmoidoscopy. Biopsy specimens were always taken in the vicinity of lesions or ulcerations. In case of colectomy (n =12), the surgical specimens were additionally used for analyses. Biopsies were kept in Histocon (Histolab, Gothenburg, Sweden) on ice and snap-frozen in liquid nitrogen within 30 min. Approximately 6 μm thick cryostat sections were mounted on gelatin-coated glass slides, and stored at -80 ℃. Before staining, the slides were thawed at room temperature and subsequently fixed in cold 20 g/L formaldehyde in phosphate-buffered saline (PBS). All following incubation and washing steps were performed in PBS supplemented with 1 g/L saponin (Sigma Chemicals, St Louis, MO, USA) to permeabilize cellular membranes[20]. Peroxidase activity was blocked with 3 g/L hydrogen peroxidase and 1 g/L sodium azide in PBS-saponin[21]. Human and goat serum

(Vector Laboratories Inc, Burlingame, CA, USA) and avidin/biotin blocking kit (Vector Laboratories) were used to block unspecific bindings. The sections were incubated overnight at 4℃ with mouse monoclonal antibodies to iNOS (NOS-IN 20 mg/L, Sigma), nNOS (NOS-BI 73 mg/L, Sigma), eNOS (NOS-EI 17 mg/L, Sigma), IL-1β (2D8 1.4 mg/L, ImmunoKontact, Abingdon, Oxon, UK), TNF-α (Mab I 10 mg/L + Mab II 14 mg/L, Pharmigen, San Diego, CA, USA), and to INF-γ (7-B6- 10 mg/L + 1-DIK 10 mg/L, Mabtech AB, Nacka, Sweden). Mouse IgG_1 (28 mg/L, Dako, Glostrup, Denmark) served as an isotype-matched negative control. Biotinylated goat anti-mouse IgG_1 (4 mg/L, Caltag laboratories, Burlingame, CA, USA) was used as secondary antibody, except for the eNOS staining (an IgA antibody) where it was substituted with biotinylated goat anti-mouse immunoglobulin (11 mg/L, Dako). The biotinylated secondary antibodies were followed by horse-radish peroxidase-conjugated avidin/biotin-complex (Vectastain, ABC-elite, Vector Laboratories). Positive peroxidase staining was developed with 3, 3´-diaminobenzidine (DAB peroxidase substrate kit, Vector Laboratories) and counterstained with haematoxylin (Histolab).

Quantification of immunohistochemical staining

All microscopic evaluations were performed by one investigator (T.L.) who was blinded to the clinical data as well as analyzed parameters (eNOS, nNOS, iNOS, TNF-α, IL-1β, INF-γ and IgG_1). To validate the observer's quantification, eight randomly chosen sections were additionally analyzed by a second observer (C. J.). Absolute correlation was seen between the two observers. Sections were analyzed using light microscope (Nikon Ltd, Tokyo, Japan). For each section, three different grid areas rich in positive cells of satisfactory technical quality were chosen for quantitative analysis of NOS and cytokine immunohistochemistry. Due to some background staining of the epithelial cells, we restricted our quantitative analysis to the lamina propria. For each area, the number of positive cells was counted at high-power magnification (× 400), thereafter the total number of positive cells was divided with the total grid area. For each section, the result was expressed as the mean number of positive cells per one grid area. For comparison, the percentage of positive cells in the lamina propria was also calculated. A high correlation between immunohistochemistry quantification expressed as positive cells per grid area and percentage positive cells of total cell number in lamina propria was observed ($r = 0.98$, $P < 0.001$).

Measurement of iNOS gene expression

Colonic biopsies were taken from four patients with CD and two with UC. The biopsies were collected from both normal and inflamed parts of the colon in each patient. Tissue samples were immediately placed in RNAlater (Qiagen, Hilden, Germany), stored for 24 h at 2-8℃ and then at -80℃.

After thawing, total RNA was isolated from the biopsies using the RNeasy mini kit (Qiagen). cDNA was synthesized using oligo $(dT)_{20}$ primers and SuperScript III enzyme (Invitrogen, Carlsbad, CA, USA). Semi-quantitative RT-PCR was performed using cDNA normalized against the house-keeping gene glyceraldehyde-3-phosphate dehydrogenase (GAPDH). PCR products obtained with primers specific for the human iNOS gene (sense 5´-CCAAAAGGGTCATCATCTCT-3´; antisense 5´-CCTGCTTCACCACCTTCTTG-3´) (GenBank accession number AF049656) in the linear amplification range (39 to 45 cycles) were electrophoresed on a 15 g/L agarose gel, photographed and bands quantified (Kodak Gel Logic 100 Imaging System, Rochester, NY, USA).

Table 2 Disease activity index, UC patients

t/d	All (n = 22)	Responder (n = 10)	Non-responder (n = 12)	Operated (n = 5)
1	9.4 (5-12)	9.5 (5-12)	9.4 (5-12)	11.2 (10-12)
3	7.4 (2-12)	7.1 (2-10)	7.6 (5-12)	12
7	5.7 (2-9)	4.8 (2-7)	7.2 (5-9)	NA
28	2.5 (0-8)	0.8 (0-2)	5 (3-8)	NA

Responder (DAI 2); non-responder (DAI ⩾ 3).

Table 3 Harvey-Bradshaw index, CD patients

t/d	All (n = 24)	Responder (n = 8)	Non responder (n = 16)	Operated (n = 7)
1	14.9 (4 - 29)	12.8 (4 - 26)	15.9 (9 - 29)	16.9 (11 - 29)
3	11.2 (2 - 22)	7.9 (2 - 13)	12.9 (2 - 22)	16.2 (11 - 22)
7	7.7 (1 - 19)	5.8 (1 - 19)	9.6 (2 - 13)	11.5 (10 - 13)
28	4.2 (1 - 9)	1.9 (1 - 3)	6.9 (4 - 9)	NA

Responder (HBI ⩽ 4); non-responder (HBI ⩾ 5).

Statistical analysis

For statistical analysis and graph plotting, GraphPad Prism (GraphPad Software, San Diego, CA, USA) was used. Data were expressed as mean ± SE, and range where appropriate. Groups of independent data were compared using the Mann-Whitney U test. Intra-group variation was analyzed with the paired Wilcoxon test. Correlation coefficients between different analyses were calculated using the Spearman rank-test. $P < 0.05$ was considered statistically significant.

RESULTS

Clinical activity

Baseline DAI or HBI scores did not differ significantly between steroid responding *versus* non-responding patients and did not predict clinical outcome. On d 28, 45% (10/22) patients with UC and 33% (8/24) patients with CD were in remission (DAI ⩽ 2 and HBI ⩽ 4, respectively) (Table 2, Table 3). In 26.08% (12/46) patients (5 UC, 7 CD), colectomy was carried out on d 2-26 due to steroid-refractory severe disease. The DAI and HBI scores in this subgroup did not differ significantly on d 1 between subsequently operated patients and those responding to treatment (DAI: 9.5 ± 0.7 *vs* 11.2 ± 0.5 for responding and operated UC patients; and HBI: 12.8 ± 2.3 *vs* 16.9 ± 2.3

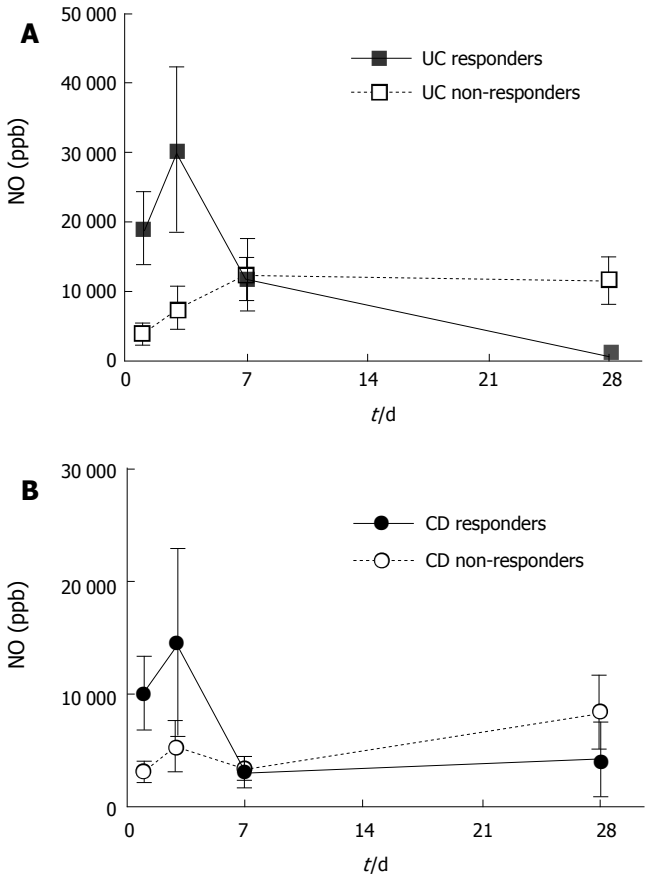

Figure 1 **A**: Rectal NO levels in UC; **B**: Rectal NO levels in CD.

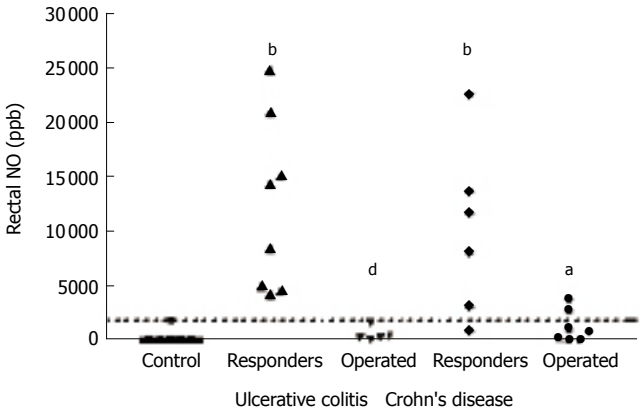

Figure 2 Rectal NO levels in the treatment of UC and CD patients on d 1. $^{b}P < 0.001$ *vs* Control; $^{d}P < 0.01$, $^{a}P < 0.05$ *vs* patients responding to treatment.

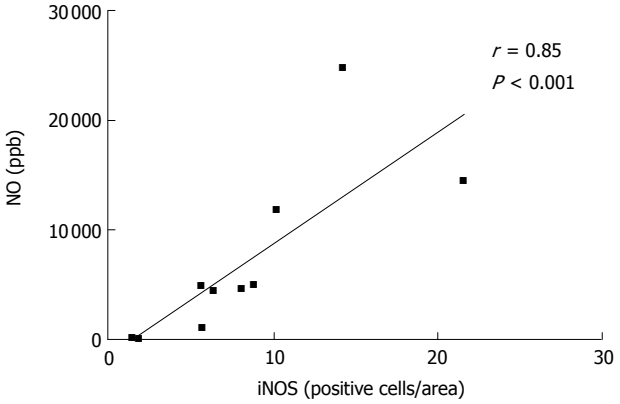

Figure 3 Correlation between mucosal iNOS-expressing cells and rectal NO levels in patients with UC.

for responding and operated CD patients) (Table 2, Table 3).

Rectal NO levels

On d 1, patients with active UC and CD had greatly increased rectal NO levels (10 950 ± 7610 and 5040 ± 1280 ppb, respectively) as compared with the controls (154 ± 71 ppb, all $P < 0.001$). Repeat measurements of rectal NO showed a numerical increase on d 3 compared to d 1, after which a decrease was seen (Figure 1). This pattern of NO release was mainly attributed to the patients responding to steroid treatment, whereas non-responders displayed a less prominent increase on day 3, and showed no subsequent decrease (Figure 1). For steroid-responding patients, rectal NO levels decreased significantly between d 1 and 28 (from 18 860 ± 5390 to 850 ± 450 ppb in UC, and 10 060 ± 3200 to 4130 ± 3380 ppb in CD, $P < 0.001$ and $P < 0.05$, respectively).

Rectal NO levels were correlated weakly with clinical activity scores of the whole study population, DAI for UC ($r = 0.34$, $P < 0.01$), and HBI for CD ($r = 0.48$, $P < 0.01$). However, the association was clear-cut in the group of responders to treatment ($r = 0.72$ for UC and $r = 0.64$ for CD, all $P < 0.001$).

A different rectal NO pattern was seen in the subgroup of patients in whom colectomy was carried out. The rectal NO levels of these patients were significantly lower at baseline (620 ± 270 ppb in UC, and 1260 ± 550 ppb in CD) than corresponding values in the patients with a treatment response ($P < 0.001$ for UC and $P < 0.05$ for CD) (Figure 2). Applying a cut-off level of rectal NO at 2000 ppb in combination with DAI ⩾ 10 for patients with UC identified all five patients with a steroid-refractory disease, leading to colectomy within 7 d, Whereas none of the UC patients responding to treatment combined rectal NO ⩽ 2000 ppb and DAI ⩾ 10. For CD patients, the same cut-off of NO ⩽ 2000 ppb in combination with HBI ⩾ 10 detected 5 of 7 patients subsequently operated, and was seen in 3 CD patients not leading to surgery.

Expression of NO synthases and pro-inflammatory cytokines

The number of iNOS-expressing cells, as judged by immunohistochemistry, was significantly higher in patients with UC and CD on d 1 as compared with the healthy controls (all $P < 0.001$). Furthermore, the number of iNOS-positive cells decreased between d 1 and 28 (Figure 4), reaching a borderline significance by pooling UC and CD patients ($P = 0.064$). The number of iNOS-positive cells was obviously correlated with rectal NO levels in patients with UC ($r = 0.53$, $P < 0.01$). This association was strengthened by analyzing the patients responding to treatment ($r = 0.85$, $P < 0.01$) (Figure 3).

However, no correlation was found between number of iNOS-positive cells and rectal NO levels in patients with CD. The majority of iNOS-positive cells in lamina

propria had the morphology of polymorphonuclear leukocytes (Figure 4).

Semi-quantitative RT-PCR showed over-expression of iNOS mRNA in the inflamed compared to normal parts of the mucosa ($P < 0.05$) (Figure 5). Presence of eNOS-positive cells was abundant in all sections and localized to the epithelium, but showed no temporal relationship with rectal NO levels. Recovery of nNOS staining was slight and, when occurring, mostly seen in the submucosa in nerve cells and randomly in mononuclear cells of the lamina propria.

TNF-α, IL-1β and INF-γ expressions, as judged by immunohistochemistry, were restricted to mononuclear cells in the lamina propria. IL-1β expression was significantly increased on d 1 compared to healthy controls ($P < 0.05$), whereas TNF-α and INF-γ were not. However, both TNF-α and IL-1β decreased numerically between d 1 and 28 for UC and CD (Figure 4). By pooling data from UC and CD patients, a significant reduction was seen ($P < 0.05$ for both TNF-α and IL-1β immunoreactivity). INF-γ did not change between d 1 and 28. A marked increase of iNOS-expressing cells was correlated with TNF-α expression in both UC ($r = 0.46$, $P < 0.05$) and CD ($r = 0.44$, $P < 0.05$). By pooling data for UC and CD, a weak correlation was detected for IL-1β ($r = 0.33$, $P < 0.05$). No correlation was seen between the numbers of iNOS and INF-γ-expressing cells.

DISCUSSION

This study provide evidence suggesting that the greatly increased rectal NO levels seen in active UC and CD are elaborated by high iNOS activity. In our study, a strong correlation was seen between rectal NO levels and clinical

activity indices in patients responding to steroid treatment. A relationship between ongoing inflammatory activity and increased NO production in the gut is well established[6,8]. In agreement with this, we found a correlation with clinical disease activity indices in both UC and CD.

Taking into account the relatively low number of patients recruited, the subgroup analysis have to be interpretated with caution. In the non-responding group, no correlation was seen between rectal NO and clinical activity indices. This is in part explained by the aberrant rectal NO pattern in the 12 patients who subsequently underwent colectomy due to severe disease. The finding that baseline rectal NO $\leqslant$ 2000 ppb in severe UC detected all patients in need of surgery within 7 d due to steroid-refractory disease makes it tempting to suggest rectal NO measurement as a predictive marker of the need of colectomy in active UC. In CD patients, rectal NO seems to be a less strong marker for steroid-response, which is in agreement with previous studies demonstrating a 70% endoscopic remission post-treatment in UC as compared with only 13% endoscopic remission in CD[22,23], as well as a recent study by Costa *et al*[24] showing that fecal calprotectin is a stronger marker for relapse in UC than in CD[24].

Due to the high affinity of NO to hemoglobin[25], one may argue that luminal NO is scavenged by blood in the colon, which should cause falsely low rectal NO levels in the most severe UC and CD cases. This is however unlikely since other severe cases in our group displayed high rectal NO levels in the presence of overt rectal bleeding.

The role of NO in intestinal inflammation is unclear, as both pro-inflammatory and tissue-protective properties have been demonstrated[26]. Our observation that high rectal NO levels at the first visit was associated with a favorable clinical outcome is consistent with the idea that NO may act as an endogenous inhibitor of an aggregated immune response. Tissue-protective properties of NO have been shown in animal models of colitis[27]. The finding that NO production in collagenous colitis, a chronic inflammatory bowel disease without mucosal cell damage[28], might be even greater than in active IBD supports the concept of NO acting as a modulator of inflammatory activity in the gut. An uncontrolled chronic inflammation could, however, lead to an intracellular depletion of L-arginine, during which NOS will produce O_2^- instead of NO, O_2^- will then immediately react with NO to form $ONOO^-$, considered to be highly cytotoxic[29].

Genetic polymorphisms of iNOS might be a plausible explanation for the different rectal NO patterns seen in the group of responding *versus* non-responding patients. iNOS polymorphism has previously been associated with outcome variables in different diagnoses[30-32].

There is substantial evidence pointing towards iNOS-expressing epithelial cells lining the mucosa as a major site of NO production in intestinal inflammation[13-15]. We could not confirm this finding in our present study as we encountered unspecific staining of the epithelial cells, but we consider the correlation between the number of iNOS-positive cells in lamina propria and the production of NO, measured as rectal NO levels, as circumstantial evidence, suggesting the importance of these cells in the production of the increased NO levels seen in active UC and CD. This is supported not only by earlier studies showing iNOS-positive macrophages and granulocytes in the mucosa in IBD[11], but also by our present finding of a molecular activation of iNOS within the tissue. Our morphological examination of iNOS-positive cells ascribes polymorphonuclear leukocytes as a plausible cellular source of NO production.

Whether the constitutive forms of NOS contribute to the increased NO production in IBD is unclear. For eNOS or nNOS, we could not detect any differences in staining between healthy controls, active IBD or IBD in remission. Little information is available on possible changes in eNOS and nNOS in IBD in literature. One previous study reports findings in line with our results[14], i.e. activation of mainly iNOS, whereas another group claims specific changes in eNOS and nNOS expression in UC[12].

Determination of tissue cytokine levels in IBD has resulted in disparate results. In general, pro-inflammatory cytokines (TNF-α, IL-1β and INF-γ) are believed to have a regulatory function in the activated immune response in IBD. Clearly the last years' development has pin-pointed the key role of TNF-α in CD[3,21,33]. In line with some previous studies, we failed to show increased TNF-α expression in IBD compared to controls[34,35]. However, we found a decrease in TNF-α expression as a response to treatment, supporting data demonstrating an association between TNF-α expression and active IBD[3,36,37]. Our data showing increased IL-1β expression in active IBD compared to healthy controls are consistent with earlier studies providing evidence that IL-1β has a central role in the mucosal inflammation as seen in IBD[34,36,37]. In our study, we found no support for INF-γ as a marker of disease activity in IBD.

We found a correlation between TNF-α and IL-1β expression and iNOS expression, supporting the concept that these cytokines may have a role in inducing NO production[15].

In summary, our study shows that active UC and CD are associated with highly increased rectal NO levels. Rectal NO levels decreases in response to steroid treatment, hence offering a plausible and feasible objective method to monitor disease activity in IBD. Low rectal NO levels $\leqslant$ 2000 ppb might be a predictive marker for steroid-refractory IBD requiring acute colectomy. Furthermore, our data suggest that the major part of the increased NO production seen in active IBD is elaborated by the inducible form of NOS.

Abstract

AIM: To investigate the relationship between ulcerative colitis (UC) clinical activity index (CAI) and circulating levels of IL-1ra, IL-10, IL-6 and IL-18.

METHODS: Blood levels of IL-1ra, IL-10, IL-6 and IL-18 were measured in 31 patients with active UC, the mean CAI was 11.1, ranging from 5-25; and 12 healthy individuals as controls. Patients were given granulocyte and monocyte adsorptive apheresis (GMA) with Adacolumn. Leucocytes which bear the FcγR and complement receptors were adsorbed to the column leucocytapheresis carriers. Each patient could receive up to 11 GMA sessions over 8 wk.

RESULTS: We found strong correlations between CAI and IL-10 (r = 0.827, P < 0.001), IL-6 (r = 0.785, P < 0.001) and IL-18 (r = 0.791, P < 0.001). IL-1ra was not correlated with CAI. Following GMA therapy, 24 of the 31 patients achieved remission and the levels of all 4 cytokines fell to the levels in healthy controls. Further, blood levels of IL-1ra and IL-10 increased at the column outflow and inflow at 60 min suggesting release from leucocytes that adhered to the carriers.

CONCLUSION: Elevated blood levels of IL-6 and IL-18 together with peripheral blood granulocytes and monocytes/macrophages in patients with active UC show activative behaviour and increased survival time can be pro-inflammatory and the targets of GMA therapy.

INTRODUCTION

Factors which initiate and perpetuate ulcerative colitis (UC) are not well understood. However, the condition is often associated with elevated circulating granulocytes and monocytes/macrophages[1-5] that show activative behaviour and increased survival time[6-10]. Another feature of active UC is the increased generation and activities of inflammatory cytokines which can initiate and perpetuate the disease[11-15]. Furthermore, recent clinical and basic research data indicate that the clinical relapse of UC is mediated by an unchecked influx of granulocytes and monocytes/macrophages into the mucosal tissue[16-19]. The level of neutrophils in the mucosa was quantitatively related to the severity of intestinal inflammation and relapse both in UC and Crohn's disease[16].

Granulocytes and monocytes/macrophages are major sources of inflammatory cytokines[20-24] and therefore, it is assumed that high and activated peripheral blood lev-

els of these leucocytes can be a major pro-inflammatory condition. Factors believed to contribute to the elevated neutrophil counts and increased survival time include inflammatory cytokines[8] and paradoxically corticosteroids[9] that are given to most patients with severe active UC. The circulating levels of anti- and pro-inflammatory cytokines are likely to follow leucocyte levels or activities and are potentially related to disease activity.

However, leucocytes produce proinflammatory as well as anti-inflammatory cytokines. Thus, interleukin-6 (IL-6) produced by neutrophils and monocytes/macrophages (as well as other cell types including endothelial cells) is reported to play a major role in neutrophil and monocyte recruitment during inflammation[15]. Similarly, IL-18 produced by monocytes/macrophages is thought to be a potent inducer of interferon-γ (IFN-γ) production, hence contributing to the induction of Th1 responses[23, 24] A similar scenario may be described for anti-inflammatory cytokines. Thus, elevated level of IL-1 receptor antagonist (IL-1ra) is considered to reflect a natural compensatory mechanism to counter the activities of the pro-inflammatory cytokine IL-1β in inflammatory diseases[25-26]. Similarly, during inflammation, production of IL-10 increases and potentially can switch off the production of pro-inflammatory cytokines including IFN-γ, IL-1β, IL-6, IL-8, IL-12 and tissue necrosis factor (TNF-α).

Therefore, there are cytokines which can initiate and perpetuate inflammation and others which mitigate the inflammation. Accordingly, cytokines currently represent the best validated therapeutic targets[25-30]. With this in mind, we studied the circulating levels of 2 major anti-inflammatory and 2 major pro-inflammatory cytokines during active UC and during remission. IL-10 and IL-1ra were chosen as two known anti-inflammatory cytokines while IL-6 and IL-18 were considered to represent two typical pro-inflammatory cytokines. Since peripheral blood granulocytes and monocytes/macrophages are thought to represent major sources of both pro- and anti-inflammatory cytokines[1-6], we targeted these cells using granulocyte and monocyte/macrophage adsorptive apheresis (GMA) with Adacolumn[4,5].

MATERIALS AND METHODS

Study objectives

First, to see the relationship between CAI and circulating levels of the two major anti-inflammatory cytokines IL-10, IL-1ra and two pro-inflammatory cytokines IL-6 and IL-18 during active UC. Second, to investigate the effects of adsorptive granulocytes and monocyte/macrophage apheresis (GMA) on the levels of these cytokines and CAI. This was to provide an insight into the mechanisms of clinical efficacy of GMA with Adacolumn presently and hitherto reported[4,5,31]. Third, to identify predictors of response to GMA.

Patients

The demography of the 31 patients included in this study is presented in the Table 1. There were 17 males and 14 females, mean age 34.3 years, range 14-58 years.

Table 1 Demography of 31 patients with active ulcerative colitis who were investigated in this study

Backgroung	Measurement	
Male/Female	17/14	
Age, yr (range)	34.5-15.3	(14-58)
Age at first attack (yr)	29.1-11.9	(12-54)
Duration of UC (yr)	5.9-7.2	(0.5-26)
Number of relapses	4.3-3.9	(1-15)
Classification of severity		
Mild		4
Moderate		16
Severe		11
Mean (range) clinical activity index (CAI)[33]		11.1(5-25)
Total colitis		24
Left sided colitis		7

CAI was determined according to Rachmilewitz[32]. UC was severe in 11, moderate in 16 and mild in 4. All patients had been treated with conventional medications including 5-aminosalicylic acid (5-ASA) and prednisolone prior to entry. Eighteen of the 31 patients were steroid dependent , 9 were steroid refractory and 4 were steroid naive. The conventional medication was continued and the steroid dose was tapered when CAI score decreased to remission level (4 or less). Twelve healthy individuals of the same age range served as a control group.

Granulocyte and monocyte adsorptive apheresis

GMA was performed with Adacolumn precisely as described previously[4,5,20,31,33]. In Japan, GMA with Adacolumn has been approved by the Ministry of Health for public funding to treat patients with active UC. Adacolumns were purchased from Japan Immunoresearch Laboratories (Takasaki, Japan). Each patient could receive up to 11 GMA sessions. Patients with CAI > 12 received 2 sessions/wk in the first 3 wk and then one session/wk. During wk 6, CAI scores were determined and GMA was continued until patients had received up to 11 sessions. This therapy was added to the patients' ongoing treatment following a relapse or worsening UC symptoms. No additional conventional medication was given during this study.

Assessment of response to therapy

CAI equal or greater than 5 was the entry criteria. Clinical remission was defined as a CAI decrease to 4 or less and mucosal vascular patterns had become visible (at least partly). When CAI had fallen, but was still above 4, the patient was considered to have improved.

Measurement of cytokines

Peripheral blood was sampled directly via a venepuncture in the antecubital vein and also from the Adacolumn inflow at the start of GMA and then at the end of the 60 minutes GMA session from the column inflow and outflow (blood which was returning to patients). IL-1ra, IL-10, IL-6 and IL-18 were measured using enzyme linked immuno-sorbent assays (ELISA). Human IL-1ra ELISA

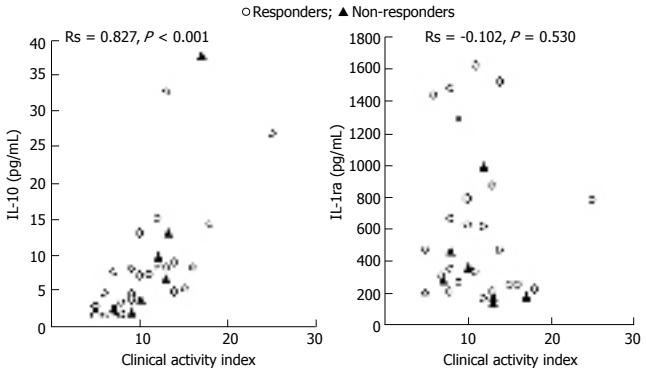

Figure 1 The relationship between blood levels of IL-10 and IL-1ra as measured in serum samples and the ulcerative colitis CAI in 31 patients with UC.

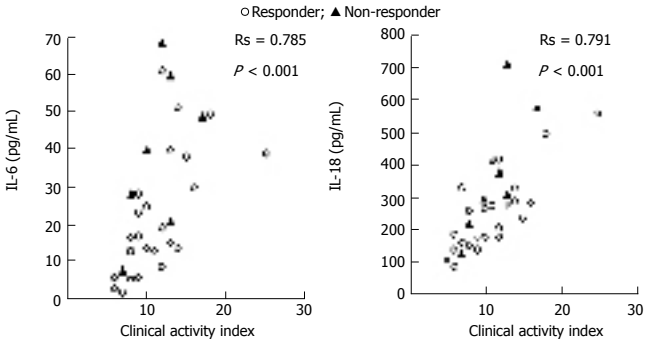

Figure 2 The relationship between blood levels of IL-6 and IL-18 and CAI in 31 patients with UC.

kit was from R&D systems (Minneapolis, USA); the ELISA kit for IL-10 was from Biosource Europe SA (Nivelles, Belgium); human IL-18 ELISA Kit was from MBL (Medical and Biological Laboratories, Nagoya Japan) and the ELISA kit for IL-6 was from FUJIREBIO Inc. (Tokyo). All assays were done at an special research laboratory (SRL) in blind manner and the data were processed by an individual who was unaware of the subjects' clinical conditions or the purpose of the study.

Ethics

As indicated above, Adacolumn is officially approved in Japan for the treatment of patients with active UC. However, when blood samples were required for research other than for routine clinical laboratory, patients were informed of the extra volume of blood to be taken and the purpose of the blood sample. All patients we consulted agreed to donate blood samples for assaying cytokines. They were advised that refusal to donate blood will not jeopardize their future treatment and care.

Statistical analysis

The amounts of IL-1ra, IL-10, IL-6 and IL-18 are presented as individual observations and comparisons are made using the Stat View Software. Statistical tests were the Mann-Whitney U test, Scheffe's test, the Turkey-Kramer test or the Spearman's rank correlation test, indicated in the figure legends. A significance level of 0.05 was used for all statistical tests, and two-tailed tests were applied when appropriate.

RESULTS

Blood levels of anti- and pro-inflammatory cytokines during active UC

The relationship between CAI and blood levels of IL-10 and IL-1ra in 31 patients is presented in Figure 1. The Spearman's rank correlation coefficient (Rs) showed a strong positive relationship between blood levels of IL-10 and CAI, while no correlation was found between blood levels of IL-1ra and CAI. Similarly, the majority of non-responders to GMA (albeit a few) had low blood levels of IL-1ra, while no obvious difference between responders and non-responders to GMA was seen for circulating IL-10 levels. Likewise, Figure 2 shows the relationship between blood levels of IL-6, IL-18 and CAI in the 31 patients. Also for these two pro-inflammatory cytokines, Rs shows a strong positive correlation with CAI. Most of the few non-responders to GMA had high blood levels of IL-6 and IL-18.

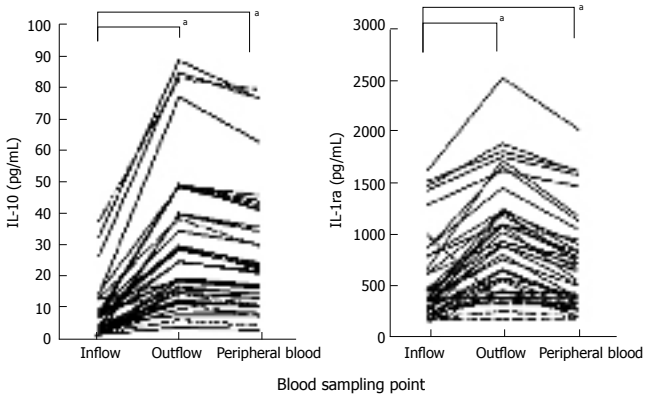

Figure 3 Blood levels of IL-10 and IL-1ra at the Adacolumn inflow (peripheral blood) at the start of GMA therapy and outflow at the end of the 60 min GMA and again peripheral blood just after the completion of 60 minutes GMA therapy in 31 patients with active UC. [a]$P < 0.05$ *vs* inflow by Turkey-Kramer test.

Blood levels of anti- and pro-inflammatory cytokines during GMA

Figure 3 shows the changes in blood levels of IL-10 and IL-1ra at the Adacolumn inflow (peripheral blood) at the start of GMA therapy and outflow at the end of the 60-min GMA and again peripheral blood just after the completion of GMA in the 31 patients. The dotted lines represent patients who did not respond to GMA during the observation period. This figure shows that blood levels of both IL-10 and IL-1ra are significantly higher in the column outflow relative to inflow and this accounts for the elevated levels of these cytokines in the peripheral blood during the GMA procedure. We found strong correlations between ulcerative clinical activity index (CAI) and circulating levels of IL-10, IL-6 and IL-18. In contrast, IL-1ra was high in most patients during active UC, but did not show correlation with CAI. However, the circulating levels of all 4 cytokines were low during remission, similar to the levels in healthy controls. It is inferred that the increments in IL-1ra and IL-10 in the column outflow are due to release from monocytes/macrophages and neutrophils

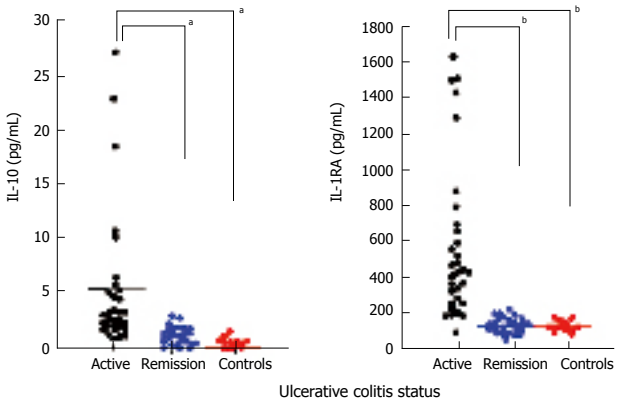

Figure 4 Blood levels of IL-10 and IL-1ra in patients with UC during active disease (n = 31), when in remission (n = 24) and in age matched controls (n = 12). [a]$P < 0.05$, [b]$P < 0.01$ *vs* active by Scheffe's test.

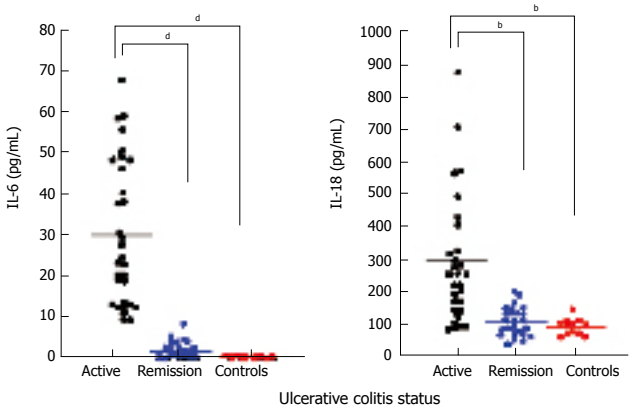

Figure 5 Blood levels of IL-6 and IL-18 (measured in serum samples) in patients with UC during active disease (n = 31), when in remission (n = 24) and in age matched controls (n = 12). [b]$P < 0.01$, [d]$P < 0.001$ *vs* active by Scheffe's test.

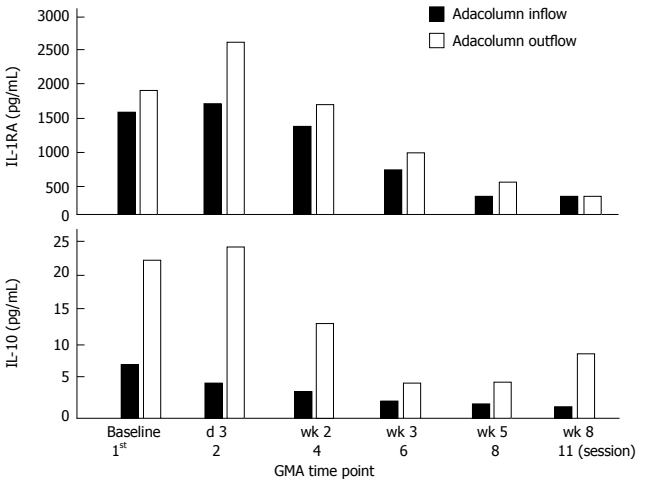

Figure 6 Changes in blood levels of IL-10 and IL-1ra in one typical case during an 8 wk GMA course (up to 11 GMA sessions).

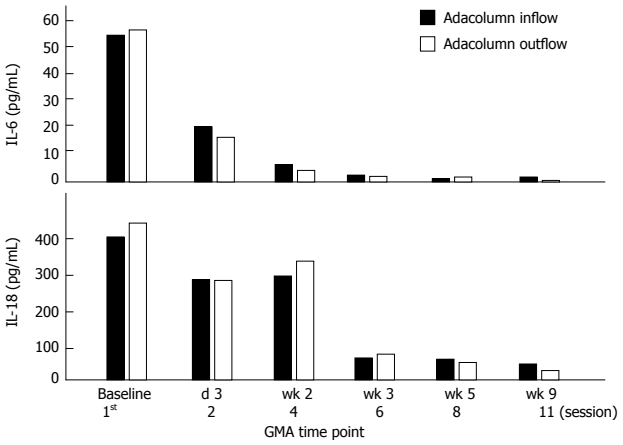

Figure 7 Similar to the data shown in Figure 6, here we see changes in blood levels of IL-6 and IL-18 were seen in one typical case during an 8 wk GMA course.

that adhere to the Adacolumn leucocytapheresis carriers, with additional contributions from activated Th2 and B lymphocytes (IL-10). Blood levels of IL-6 and IL-18 did not change significantly during the 60 min GMA procedure. The likely explanation could be inactivation within the column by a strong flux of proteases and active oxygen derivatives released by adherent leucocytes.

Blood levels of anti- and pro-inflammatory cytokines during active UC and remission

Figure 4 shows blood levels of IL-10 and IL-1ra in patients with UC during active disease (n = 31), when in remission (n = 12) and in age matched controls (n = 12). The results show wide variations in the blood levels of these two anti-inflammatory cytokines during active disease, but for both cytokines, the levels are very low during remission, similar to the levels in healthy controls. The 12 patients in remission were from the 31 patients with active disease who achieved remission following GMA (wk 12).

Blood levels of IL-6 and IL-18 are presented in Figure 5. The data for these two pro-inflammatory cytokines are mirror images of the data in Figure 4 for two anti-inflammatory cytokines. The results show wide variations in the blood levels of these two cytokines during active disease, but for both cytokines, the levels are very low during remission, similar to the levels in healthy controls.

Blood levels of anti- and pro-inflammatory cytokines during GMA course

Figure 6 shows the changes in blood levels of IL-10 and IL-1ra in one typical case during an 8 wk GMA course. Two prominent features can be seen: higher levels during active disease; in the column outflow and decline with the number of GMA sessions. This is a case who responded to GMA and achieved remission during this therapy.

Figure 7 shows IL-6 and IL-18 levels in one typical case during an 8 wk GMA course. Also for these two pro-inflammatory cytokines, the levels were high during active disease and fell rapidly (IL-6) during the course of GMA therapy. However, unlike IL-10 and IL-1ra, the levels of these two cytokines did not increase in the column outflow.

Changes in CAI associated with GMA

Patients received up to 11 GMA sessions to deplete the activated and excessive peripheral blood granulocytes and

monocytes/macrophages. There was a significant ($P < 0.05$) fall in CAI at wk 6 and after 11 sessions, 24 of the 31 patients were in clinical remission (CAI ⩽ 4). The mean CAI value at entry was 11.1, ranging 5-25. The corresponding values one week after the last treatment session were 2.4, ranging 0-15.

Safety of GMA

All patients completed their GMA therapy, compliance was excellent. GMA was safe, no severe side effects were seen during or after the GMA procedures. Transient flushing and mild headache were seen in a small number of patients, similar to the side effects reported in previous GMA studies[4,31,33].

DISCUSSION

Factors which initiate and perpetuate or exacerbate UC are yet to be characterized. The current view is that treatment strategies based on understanding of the factors that initiate or exacerbate UC (targeted therapy) should have greater efficacy margins and less treatment-related side effects[11,19,34,35]. However, UC is an inflammatory disorder reflecting unphysiological activities of pro-inflammatory cytokines and an over-exuberant intestinal inflammatory response[11,34,35]. Hence, it is assumed that cytokines can initiate and perpetuate inflammation and currently represent the best therapeutic targets. With this in mind, we studied their circulating levels during active disease and remission. IL-10 and IL-1ra were chosen as two typical anti-inflammatory cytokines while IL-6 and IL-18 were considered to represent two typical pro-inflammatory cytokines. The circulating levels of all 4 cytokines were high in most patients during active UC, but low during remission, similar to the levels in healthy controls. Further more, most non-responders to GMA had low blood levels of IL-1ra. This study did not measure mucosal tissue levels of these 4 cytokines which might be more appropriate to intestinal inflammation. Since monocytes/macrophages and granulocytes are major sources of both pro- and anti-inflammatory cytokines, this might suggest that these leucocytes contribute to the circulating levels of cytokines. Accordingly, we targeted these leucocytes using GMA with Adacolumn. The column carriers adsorb about 65% of granulocytes, 55% of monocytes and a small fraction of lymphocytes from the blood in the column (FcγR and complement receptors bearing leucocytes). The procedure is followed by a marked increase in peripheral blood lymphocyte counts, notably CD4+ T cells[5] and CD10 negative (immature) neutrophils[36].

The major cellular sources of IL-1ra are known to be monocytes/macrophages and polymorphonuclear granulocytes[37] while the major cellular sources of IL-10 are reported to be monocytes/macrophages, also Th2 cells and B lymphocytes[28]. Similarly, IL-6 is produced by neutrophils, monocytes/macrophages as well as endothelial cells[15] while IL-18 is produced by monocytes/macrophages, epithelial and Kupffer cells[23,24]. Each of these cytokines has a different profile of inflammatory or anti-inflammatory action. Both IL-1ra and IL-10 are reported to have strong anti-inflammatory actions[26,27,29,38-42]. Overproduction of the pro-inflammatory cytokine, IL-1β is thought to be involved in the perpetuation of inflammatory bowel disease, while IL-1ra, the naturally occurring antagonist of IL-1β is believed to counteract the actions of IL-1β; an imbalance of IL-1β and IL-1ra production is thought to be a major factor in the perpetuation of intestinal inflammation[27,38]. The production of IL-1ra is reported to be stimulated by several substances including adherent IgG, certain cytokines like IL-10[26,37,39,42,43]. IgGs adsorb to cellulose acetate carriers of Adacolumn (see below) and this may be one explanation for the elevation of IL-1ra during GMA. Similarly, IL-10 is reported to be a major Th2 cytokine that is known to inhibit the production of IFN-γ, IL-1β, IL-6, IL-8, IL-12 and TNF-α limiting the emergence of Th1 cytokine field[30,44]. In contrast, IL-6 is recently reported to have complex inflammatory actions. Thus it has a major role in leucocyte extravasation by activating endothelial cells and stimulating the production of chemokines including IL-8 and monocyte chemoattractant protein[15]. This indicates that circulating IL-6 can be a major pro-inflammatory factor. IL-18 has been recognized to be a potent inducer of IFN-γ production by T-cells[24,45]. Either independently or in synergy with IL-12, the effects of IL-18 via induction of IFN-γ can lead to a rapid activation of the monocyte/macrophage system with an upregulation of these cells' innate immune capabilities[46,47] that may lead to a Th1 type inflammatory response[23,24]. Hence high levels of circulating IL-18 should be considered pro-inflammatory.

One obvious question which has been drawing our attention in this study was why a consistent increase in IL-6 and IL-18 at the Adacolumn outflow could not be detected as was seen for IL-1ra and IL-10. It is not to say that they were not released from cells which adhere to the column carriers, rather to say that no increase was detected. However, it is logical to view the inside the column as an environment in which very high levels of active oxygen derivatives and proteases (released from adherent leucocytes) prevail. It is likely that the cytokines we have measured have different stability within the column environment and those which survive in appreciable amounts show an increase at the column outflow.

Patients with autoimmune diseases are known to have circulating immune complexes (ICs) in their plasma[49,50]. The Adacolumn adsorptive leucocytapheresis carriers are made of cellulose acetate and cellulose acetate is known to adsorb IgG and ICs from plasma[50]. Upon adsorption, the binding sites on IgG and ICs become available for the Fcγ receptors on neutrophils and monocytes/macrophages[50-53]. Further more, cellulose acetate with adsorbed IgG and ICs generates active complement fragments including C3a, C4a and C5a[5,50,53]. The opsonins, C3b, C3bi C4b, C4bi, C5b and others derived from active complement fragments also adsorb onto the carriers[5,50,53-55] and serve as binding sites for the leucocyte complement receptors, CR1, CR2, CR3 (Mac-1, CD11b/CD18) and CR4[54-57]. Leucocyte adsorption to the cellulose acetate carriers of Adacolumn is governed by the Fcγ receptors (FcγRs) and the complement receptors on the leucocytes.

The expression of these two sets of receptors is common on neutrophils and monocytes/macrophages. In contrast, the expression of complement receptors is not a common feature of lymphocytes except on small subsets of B, T and NK (natural killer) cells[55,58]. Similarly, FcγRs are not widely expressed on lymphocytes except on a small population of $CD19^+$B cells[58] and $CD56^+$NK cells[59]. These basic processes should explain why the carriers selectively adsorb granulocytes and monocytes/macrophages, but not lymphocytes.

In conclusion, elevated blood levels of IL-6 and IL-18 together with peripheral blood granulocytes and monocytes/macrophages which in patients with UC show activative behaviour and increased survival time can be pro-inflammatory and are not counteracted by anti-inflammatory cytokines during active UC. Depletion of these leucocytes by GMA was associated with remission of UC in most of the treated patients and a decline in circulating cytokines. These observations support the assumption that peripheral blood granulocytes and monocytes/macrophages influence the circulating levels of cytokines, hence UC disease and should be appropriate targets of the GMA therapy.

Abstract

AIM: To evaluate the clinical and biochemical profile of patients with non alcoholic fatty liver disease (NAFLD) and to assess their histological severity at presentation.

METHODS: Consecutive patients presenting to the liver clinic of All India Institute of Medical Sciences (AIIMS) with raised transaminases to at least 1.5 times upper limit of normal, and histologically confirmed non-alcoholic fatty liver disease were included. Patients who had significant alcohol intake or positive markers of other liver diseases or who were taking drugs known to produce fatty liver were excluded. The clinical, biochemical and histological profile of this group was studied.

RESULTS: Fifty-one patients with NAFLD formed the study population. Their median age and BMI were 34(17-58) years and 26.7(21.3-32.5) kg/m^2 respectively and 46 (90.1%) were males. The majority of the patients had mild inflammation, either grade 1 [32 (63%)] or grade 2 [16 (31%)] and only 3 (6%) patients had severe (grade 3) inflammation. Twenty-three (45%), 19 (37%), 8(16%) and 1(2%) patient had stage 0, 1, 2 and 3 fibrosis respectively on index biopsy and none had cirrhosis. On univariate analysis, triglyceride levels more than 150 mg % (OR = 7.1; 95% CI: 1.6-31.5, P = 0.002) and AST/ALT ratio > 1 (OR = 14.3; 95% CI: 1.4-678.5, P = 0.008) were associated with high grades of inflammation and none was associated with advanced fibrosis. On multivariate logistic regression analysis, hypertriglyceridemia >150 mg% was the only factor independently associated with presence of high grade of inflammation (OR = 1.6; 95% CI: 1.3-22.7, P = 0.02), while none was associated with advanced fibrosis. Triglyceride levels correlated positively with inflammatory grade (r = 0.412; P = 0.003).

CONCLUSION: NAFLD in North Indian patients is a disease of young over-weight males, most of whom are insulin resistant and they tend to have a mild histological disease at presentation.

INTRODUCTION

With the increasing awareness and early recognition of asymptomatic patients with raised transaminases and the ongoing epidemic of the metabolic syndrome, non alcoholic fatty liver disease (NAFLD) has become a common cause of referral to hepatology clinics[1]. NAFLD can be divided into 4 histological types (types 1 to 4)[2]. Studies from the west have demonstrated that NAFLD, especially NAFLD type 3 and 4 can progress over a variable period, in 25%-40% patients, to cirrhosis and can contribute to liver-related mortality[2,3]. Recently there have been reports linking the development of hepatocellular carcinoma to non alcoholic steatohepatitis (NASH)[4,5]. Studies from Europe and United States have demonstrated that up to 40% patients with NAFLD have advanced fibrosis and a proportion even have cirrhosis on the index biopsy[6,7].

The prevalence of fatty liver in the general population of India has been shown to be as high as 24%[8], which is similar to that reported from some of the western countries, where it parallels the prevalence of obesity[9,10]. Despite the high prevalence of NAFLD in India and rapidly rising incidence of type 2 diabetes mellitus in this country, data on hepatic morphology, to indicate the severity of NAFLD is limited[11-13]. The above-mentioned 3 studies reported demographic and biochemical profile of patients with NAFLD. Histological parameters were studied in only a small number of patients. By now it is clear that histological type 3 and 4 NAFLD are

associated with progressive liver disease and therefore needs therapeutic interventions. The present prospective study was designed to assess the magnitude of advanced liver damage and fibrosis among consecutive patients with biopsy proven NAFLD.

MATERIALS AND METHODS

Study design

It is a cross sectional study to evaluate the clinical, biochemical and histological profile of patients with NAFLD. The study was approved by the ethics committee of the All India Institute of Medical Sciences(AIIMS), New Delhi.

Patients

Inclusion criteria: Consecutive patients presenting to the liver clinic of AIIMS, with raised transaminases to at least 1.5 times upper limit of normal, and histologically confirmed NAFLD, were included.

Exclusion criteria: Patients in whom alcohol intake exceeded 20 grams per day (history of alcohol intake was taken separately from the patients and the closest relatives), patients with positive markers for other liver diseases (hepatitis viruses A through E, autoimmune, Wilson's disease, alpha 1 anti-trypsin deficiency, hemochromatosis) and patients who were on medications known to induce fatty liver such as methotrexate, estrogens, amiodarone and tamoxifen were excluded.

Methods

All patients were evaluated with a thorough history and examination especially to exclude intake of significant amounts of alcohol and to exclude intake of potentially hepatotoxic drugs. Anthropometric measurements were taken at the initial visit. These included the weight, height, waist and hip circumferences. Body mass index (BMI) and waist hip ratios were calculated as weight/height^2. After an overnight fast, 10 mL of blood was collected for a complete blood count and biochemical investigations including a liver function profile, lipid profile, fasting serum insulin and fasting blood glucose.

Hepatitis virus serologies included hepatitis B surface antigen (HBsAg), total antibodies to hepatitis B core antigen (total anti-HBc) and antibodies to hepatitis C virus (anti-HCV). Anti-HCV was done using a sensitive commercial ELISA (Xcyton, Bangalore, India)[12] and the remaining viral serologies were done using commercial ELISA kits (Organon Teknika, Boxtel, The Netherlands). Serum ferritin and 24-h urinary copper estimation were done using conventional biochemical techniques[13,14]. Alpha one anti-trypsin (α1AT) phenotyping was done using isoelectric focusing (PHAST system; Pharmacia Biotech, Uppsala, Sweden)[15]. The anti-nuclear antibodies (ANA), anti- smooth muscle antibodies (ASMA) and anti-liver kidney and microsomal antibodies (anti-LKM1) were carried out using the immunofluorescence technique. Hepatitis C virus RNA was detected using the polymerase chain reaction method as standardized at our laboratory[15] .

Liver biopsy was done after an informed consent in all patients suspected to have NAFLD, using an 18-gauge Menghini's aspiration needle. Each biopsy specimen, after being fixed in 10% formalin, had routine hematoxylin-eosin stains and special stains such as reticulin, Masson's trichrome, Perl's iron stain and Orcein stain for copper and periodic acid Schiff after digestion with diastase. Immunoperoxidase staining to detect HBsAg and hepatitis B core antigen (HBcAg) was carried out in all patients to exclude the presence of chronic viral hepatitis. The classification given by Brunt *et al* was used to grade and stage NASH[16].

An ultrasonography scan of the upper abdomen was done in all patients in order to examine presence of fatty liver and to exclude any obstructive biliary pathology or the presence of any hepatic space occupying lesion.

Fasting serum insulin values were used along with simultaneous fasting blood glucose measurements to calculate HOMA-IR (homeostasis model assessment) according to the formula given below.

HOMA-IR = (fasting serum insulin (μIU/mL)×fasting plasma glucose (mg%))/(22.5 ×18)

Value of HOMA-IR more than 1.64 implied the presence of abnormally high insulin resistance[17].

Definitions

Diabetes was regarded to be present if the fasting venous plasma glucose was more than 126 mg%[18] . Patients with BMI of more than 23 were seen to be overweight and those with a BMI of >25 were labeled as obese (Asian standards)[19]. Hypertriglyceridemia was defined as a fasting serum triglyceride level of more than 150 mg%. Patients who had at least three of the following five components: hyperglycemia (fasting blood sugar >110 mg% or known type 2 diabetes mellitus, central obesity (as defined by a higher waist-hip ratio), hypertension, hypertriglyceridemia (serum triglyceride > 150 mg%), and low HDL cholesterol levels (< 50 for women and < 40 for men), were labeled to have the metabolic syndrome. Since we did not have waist hip ratio in a large number of patients, we used obesity (BMI > 25 kg/m^2) as a surrogate for high waist hip ratio, as one of the component of the metabolic syndrome[1,20].

Statistical analysis

The results were expressed as median (range) for continuous variables and as frequencies (proportions) for categorical variables. Factors suspected to influence the severity of grade and stage were tested in a univariate and multivariate logistic regression analysis. For the univariate and multivariate analyses, the dependent variable was the presence of mild inflammation (grades 0, 1) or severe inflammation (grades 2, 3) for assessing the association with inflammatory grade and mild fibrosis (stages 0, 1) or severe fibrosis (stages 2, 3, 4) for assessing association with fibrosis stage. The independent variables were age>35, sex, BMI > 25 kg/m^2, AST/ALT ratio >1, cholesterol >200 mg%, triglycerides >150 mg%, HOMA-IR >1.64, presence or absence of hypertension and metabolic syndrome. Correlation between histological severity and the above mentioned independent variables was carried out using Spearman's correlation. For skewed data, non-parametric tests were used wherever necessary. All data were analyzed using the SAS 8.0 statistical package.

RESULTS

From January 1999 to June 2005, 51 patients with histologically proven NAFLD were registered at the liver clinic of

AIIMS. This number formed 2.6% of all liver clinic referrals during this time period.

The median age of this cohort of patients was 34 (17-58) years, the BMI was 26.7 (21.3-32.5) kg/m^2 and 46 (90.1%) were males. Median AST/ALT ratio was 0.63 (0.31-2.61). Table 1 gives the baseline demographic and biochemical profile of the patients.

Prevalence of features of metabolic syndrome

Table 2 depicts the prevalence of individual features of the metabolic syndrome in these patients. Eighty percent patients had high HOMA-IR, while 69.4%, 40.8%, 36.4%, 11.8% and 10% had obesity, hypertriglyceridemia, low HDL cholesterol, hypertension and diabetes respectively. All the investigations and clinical features required for diagnosing the metabolic syndrome were available in 43 patients. Of these, 9(20.9%) patients fulfilled the criteria for a diagnosis of metabolic syndrome (presence of 3 or more components of the metabolic syndrome).

Histological severity and factors associated with severe disease

Twenty-eight (55%) patients had NASH (type 3 or 4 NAFLD) whereas the rest had only fatty liver with or without spotty necrosis without evidence of either necrosis or fibrosis (type 1 or 2 NAFLD).

Inflammatory grade: The majority of the patients had mild inflammation, either grade 1 [32 (63%)] or grade 2 [16 (31%)]. Only 3(6%) patients had severe or grade 3 inflammation.

We evaluated factors which could have been associated with moderate to severe inflammation (grade 2 or 3) versus those with mild inflammation (grade 0 or 1). On univariate analysis, triglyceride levels more than 150 mg % (OR = 7.1; 95% CI: 1.6-31.5, $P = 0.002$) and AST/ALT ratio > 1 (OR = 14.3; 95% CI: 1.4-678.5, $P = 0.008$) were significantly associated with high grades of inflammation. Presence of metabolic syndrome was more common among patients who had severe inflammation although it did not reach the significant value (Table 3). On multivariate logistic regression analysis, hypertriglyceridemia more than 150 mg% was the only factor independently associated with presence of high grade of inflammation on index biopsy (OR = 1.6; 95% CI: 1.3-22.7, $P = 0.02$). There was also positive correlation between the triglyceride levels and inflammatory grade ($r = 0.412$; $P = 0.003$) (Figure 1)

Fibrosis stage: Most of the patients had either no or minimal fibrosis. Twenty-three (45%) and 19 (37%) patients had stage 0 and stage 1 fibrosis respectively on liver biopsy. Eight (16%) had stage 2 and 1 (2%) had stage 3 fibrosis. No patient had cirrhosis on index biopsy. On evaluation of factors, which could have been associated with severe fibrosis (stages 2, 3, 4 *versus* stages 0,1), metabolic syndrome (OR = 5.6; 95% CI: 0.7-36.5, $P = 0.04$) and AST/ALT ratio > 1 ($P = 0.09$) were more commonly present among patients with advanced fibrosis but failed to reach significance (Table 4).

shown to be responsible for one third of patients with asymptomatic transaminitis in India, little is known about the baseline clinical, biochemical and histological profile of these patients. The present study described the baseline profile in North Indian patients with biopsy proven NAFLD.

Our study demonstrated NAFLD to be a disease of younger age group with a mean age at presentation being 33.3 (8.01) years. More than 90% of the patients were males. This predilection for involvement of males has been seen not only in other studies from Northern India[13-15] , but also in the United States[21]. This is different from what used to be the classical phenotype of NASH patients, where it was described to be a disease of middle-aged females. The reason for this male preponderance has been described as a higher waist-hip ratio in men as compared to women, an indicator of central obesity and insulin resistance. Twenty-one percent of our patients with NAFLD were found to have the metabolic syndrome. The prevalence rate of metabolic syndrome in the general population of India has been reported to be approximately 8% in men older than 20 years[22], but no study has earlier reported the prevalence of the metabolic syndrome in patients with NAFLD from India.

The present study also highlights certain important differences between the phenotype of the cohort of NAFLD as seen in Northern India versus that which has been described classically from the west. This difference would not be surprising, considering the fact that the body fat distribution and risk of cardiovascular complications with similar amount of body fat differs between Asian Indians and their western counterparts. This has even prompted lowering of BMI and waist-hip ratio cut-offs for defining overweight and obesity among Asians[23,24]. Since obesity and fat distribution are integral parts of the insulin resistance syndrome and fatty liver forms part of the spectrum of abnormalities associated with this syndrome, the difference in the baseline profiles of NAFLD patients would be obvious.

The mean age of presentation of our patients, most of whom were detected during workup of asymptomatic transaminitis was about a decade younger than the western patients. The younger age of presentation may suggest increasing health awareness among our population with lower thresholds for health check-ups during which the asymptomatic transaminitis is picked up and investigated. It may also suggest the

epidemic proportion of the metabolic syndrome in India, wherein the population which is fast acquiring western lifestyle gets exposed to the detrimental effects of high calorie diet and physical inactivity at an earlier age. In fact, Indians have been shown to have higher body fat percentage and adverse pattern of body fat distribution including abdominal adiposity even when the BMI is within limits considered as normal for Caucasians[25]. Further, in the age group of 11-17 years, the prevalence of overweight and obesity is 11.63% and 2.38% in urban and 4.7% and 3.63% in rural Indian population respectively[26]. The mean BMI of our patients [26.5 (2.8) kg/m^2] was similar to cohorts described in other studies from North India[13,14], but significantly lower than what has been described in the Caucasian populations, where the mean BMI has always been reported to be above 30[2,3,8,26,27]. As described earlier, Indian patients despite having a lower BMI have similar body fat percentage as the Caucasians. This would mean higher visceral fat distribution, evidenced by higher waist hip ratios, despite lower BMIs. Unfortunately, waist hip ratios were not available in the present study for most of the patients. However, 80% of our patients had high HOMA-IR which is an index of insulin resistance and has been correlated earlier with visceral adiposity and higher waist hip ratios.

Most important finding in the present study was the presence of histologically mild disease in the cohort. Two thirds of the patients had minimal or mild inflammation (grade 0 or 1). Severe (grade 3) inflammation was present in only 3 patients. Hypertriglyceridemia was found to be significantly and independently associated with presence of severe inflammation.

It has already been demonstrated that insulin resistance leads to higher free fatty acid load to the liver, consequently higher triglyceride synthesis and increased secretion of triglyceride rich very low density lipoprotein (VLDL) from the liver[28,29]. In fact, circulating VLDL triglycerides have been correlated with liver fat density[30]. Higher triglyceride and fatty acid deposits may provide substrates for oxidative stress, which is a putative second hit in pathogenesis of progressive NAFLD[31]. High triglyceride levels have been shown to be independently associated with septal or advanced fibrosis by Ratziu *et al*. They also demonstrated that septal fibrosis had a significant positive correlation with liver necroinflammatory activity, thereby indirectly linking hypertriglyceridemia with necroinflammation[9]. In the present study however, we have demonstrated a direct correlation between hypertriglyceridemia and necroinflammatory activity in the liver.

Interestingly, none of our patients had cirrhosis on the index biopsy and only 2% had advanced (stage 3 or 4) fibrosis. Most (> 90%) had minimal or no fibrosis on presentation. Similar mild histology among NASH patients has been reported in other studies from India[13-15] as well as one study from Israel[32]. This is in contrast to the reported series from the west, where advanced fibrosis or cirrhosis has been demonstrated to be present in up to 50% of NAFLD cohorts[7-9,24]. One reason which can be cited for mild fibrosis in our patients is the younger age at presentation, because extent of fibrosis has been shown to increase with increasing age and increasing duration of disease[8,9]. Therefore it is possible that the cohort in the present study happened to have been detected at an early stage and with advancing age the disease might progress. This can only be confirmed later when follow up histology is available in these patients. Another factor which could be responsible for milder disease in these patients is the lower BMI. But this may not be true, because as has been discussed earlier, Asians with lower BMI may also be predisposed to similar risk of developing the metabolic syndrome as Caucasians with higher BMI. Further the effect of BMI or age was not seen on the degree of fibrosis in the univariate analysis. No other factor was found to be associated with severe fibrosis in the present study. The lack of association might be due to small number of patients in the group of severe fibrosis, as only a minority of patients had advanced fibrosis. Studies from the west, however have reported higher BMI, older age, type 2 diabetes mellitus, AST/ALT ratio > 1 and hypertriglyceridemia to be independent risk factors for presence of advanced fibrosis on index biopsy[8,9]. The milder histological disease in the present cohort may also represent a genetic predisposition in our patients, just like their genetic predisposition to develop metabolic syndrome. Whether these patients with mild fibrosis continue to have a mild disease or they progress to a stage of cirrhosis can only be answered once we have an adequate follow up on them.

To conclude, NAFLD in North Indian patients is a disease of young overweight males, most of whom are insulin resistant and they tend to have a mild histological disease at presentation.

Abstract

AIM: To assess the prevalence and clinical value of p-ANCA in a sample of Mexican ulcerative colitis (UC) patients.

METHODS: In a prospective, IRB-approved protocol, p-ANCA was determined in 80 patients with UC (mean age, 32 ± 12.9 years). The severity and extension of disease were determined by clinical methods, searching a statistical association with p-ANCA status.

RESULTS: p-ANCA were detected in 41 (51%) patients. Severity of disease was the only clinical variable statistically associated with their presence ($P < 0.0001$; OR = 9; CI 95% = 3.2-24.7).

CONCLUSION: The prevalence of p-ANCA was similar to that reported in other countries. Their presence was associated to UC severity, but offered no more information than the obtained by clinical methods.

INTRODUCTION

Anti-neutrophil cytoplasmic antibodies (ANCA) have been described in subjects with different types of vasculitis, and they are essential to establish the diagnosis of Wegener´s granulomatosis, microscopic polyangiitis, Churg-Strauss Syndrome and renal-limited vasculitis[1-4]. Perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA), a subset of ANCA, have been described in patients with inflammatory bowel disease, mainly ulcerative colitis (UC). However, their role in pathogenesis and diagnostic value are still controversial[5]. Previous reports have suggested that p-ANCA might be a sensitive and specific test to diagnose UC[6], to distinguish it from Crohn's disease and other colitides[7], and to provide a prognosis regarding response to medical treatment and risk of pouchitis following the pelvic pouch[8,9].

The prevalence of p-ANCA in patients with UC varied from 40% to 88%[10-13]. High titers have been reported by some authors in subjects with active disease, but its clinical value is controversial because others have not found any correlation between their levels and the activity or extension of disease[14-18].

The value of a diagnostic test, such as p-ANCA, should be evaluated by several practical factors like costs, availability, and usefulness for clinical decisions before accepting them as a standard diagnostic tool.

The aim of this study was to assess the prevalence and clinical usefulness of p-ANCA in a sample of Mexican patients with UC.

MATERIALS AND METHODS

A prospective study was performed at the Instituto Nacional de Ciencias Medicas y Nutricion Salvador Zubiran, which is a referral center for gastrointestinal diseases in Mexico City. The protocol was reviewed and approved by the Institutional Review Board. All patients invited to participate in the study signed an informed consent before inclusion. Eighty consecutive patients with diagnosis of UC were included. In all cases, the diagnosis of UC was based on clinical, endoscopic and histopathologic findings. The extension of disease was determined by total colonos-

copy, and categorized into pancolonic or left-sided colitis. The severity of disease was determined on clinical basis according to the Truelove and Witts criteria[19], and categorized into mild, moderate and severe. Clinical data, including severity and extension of disease were collected by an investigator who was blind to the results of p-ANCA.

p-ANCA determination

Detection of ANCA was done by Indirect Immunofluorescence (IFL), in accordance with the recommendation of the International Workshop[20]. Human neutrophils were prepared from peripheral blood of patients and normal healthy volunteers. The slides were fixed in 98% ethanol at 4℃ for five minutes and dried quickly in air. After using phosphate-buffered saline (PBS) in a dilution of 1:40, the elements where dissolved twofold until it reached 1:320. Following incubation for 1 h r at RT, the slides were washed three times with PBS and bound antibodies were incubated for 30 min and detected with FITC-conjugated rabbit anti-human IgG at RT. Subsequently, the slides were washed three times with PBS and covered with glycerin-phosphate-buffered saline. A titer of 1:20 or higher was considered positive.

The antigen-specific enzyme-linked immunosorbent assay (ELISA) method was used to test the sera for the presence of either mieloperoxidase (MPO) or anti-proteinase-3 antibodies. Human MPO or human proteinase-3 were diluted to 2 mg/L in carbonate buffer (pH 9.6) and 100 μL of each solution was placed in the wells of a 96-well microplate and left for 24 h at 4℃. After plate was washed with PBS three times, 100 μL of diluted sera (1:100 in PBS containing 0.1% tween 20 and 0.1% skim milk) was added to each well, and the plate incubated for 1 h at 37℃. After washing, the enzyme reaction was performed, and color development was measured with a microplate colorimeter. Optical density values > 2 SD more than the mean of the control subjects were considered positive.

Statistical analysis

The student t- -test was used for dimensional variables, and the association between categorical variables was studied by means of the χ^2 with Yates correction. The *P* values were 2-tailed and less than 0.05 was considered statistically significant.

RESULTS

Eighty patients with diagnosis of UC were included. There were 41 men and 39 women, with a mean age of 32 ± 12.9 years. The mean duration of disease was 7.2 ± 6.6 years. Pancolitis was present in 58% and left-sided colitis in 42%. Disease severity was categorized as severe in 20 (25%), moderate in 7 (10%), mild in 15 (18%), and there was no evidence of activity in the remaining 38 (47%) patients. Extraintestinal manifestations were present in 43%; and corresponded to arthritis (23%), primary sclerosing cholangitis (7.5%), erythema nodosum (5%), ankylosing spondylitis (2.5%), pyoderma gangrenosum (2.5%), anterior uveitis (2.5%), and aphthous ulcers (2.5%). Fourteen (25%) patients required surgical treatment due to failure of medical therapy.

Table 1 Clinical features in UC patients with positive and negative p-ANCA

Clinical feature	p-ANCA + *n* = 41	p-ANCA - *n* = 39	*P* value	OR	CI 95%
Pancolitis	22	24	0.62	0.72	(0.29-1.76)
Left-sided	19	15			
Colectomy	7	7	0.84	0.94	(0.29-2.98)
No colectomy	34	32			
EIMs present	14	17	0.52	0.67	(0.27-1.65)
EIMs absent	27	22			
Severe	31	10	< 0.0001	9	(3.2-24.7)
No Severe	10	29			

OR = odds ratio; CI 95% = Confidential interval 95%; *n* = Number of patients.

The p-ANCAs were detected by IFL in 41 (51%) and c-ANCA in 4 (5%) subjects. Titers ranged from 1:20 to 1:160. The antigenic specificity of p-ANCA tested by ELISA in 33 patients showed a positive reaction for myeloperoxidase in 29 and proteinase-3 in 4. Age, gender and age at diagnosis was similar between patients with or without p-ANCA .

A statistical association was observed between p-ANCA status and the severity of UC (*P* = < 0.0001; OR 9, CI 3.2-24.7). Twenty-two (48%) patients with pancolitis and 19 (56%) with left-sided colitis were positive for p-ANCA (*P* = 0.47; OR = 0.72; 95% CI: 0.27-1.94). Seven out of the 14 (50%) patients who underwent surgical treatment were positive as compared with 34 of 66 (52%) who were not operated upon [*P* = 0.91; OR = 0.94; 95% CI: 0.26-3.34].No association was found between the presence of extraintestinal manifestations and p-ANCA. See Table 1.

DISCUSSION

The determination of p-ANCA could give information in subjects with UC in three different clinical issues: (1) as a marker of genetic heterogeneity; (2) to assess inflammatory activity, and (3) for prognosis regarding response to medical treatment and postoperative outcome (pouchitis).

The prevalence of p-ANCA in our series was 51%, within the range published by other authors in different parts of the world[9-13]. It supports that not all patients with UC exhibit the same immunologic pattern, a fact against a pathogenic role of ANCA's in subjects with UC. On the other hand, the wide range of prevalence reported in the literature that goes from 40 to 88% could be rather explained by ethnic or genetic variations than by technical difficulties since both, IFL and ELISA, are simple, sensible, and reproducible assays, as observed in the present study[14,21].

Ethnic and genetic variability have been consistently reported in patients with IBD[22,23]. In a previous study, the authors found that Mexican patients with UC had an increased frequency of HLA-DR1 (DRB1*0102 and 0103) and HLA-DR2 (DRB1*15) when compared with healthy controls. HLA-DRB1*0103 and *0102 were associated

with more severe disease and necessity of surgical treatment[24]. Yang *et al* observed a linkage between p-ANCA positive UC patients and HLA-DR2[25]. The clinical usefulness of p-ANCA as a genetic marker was suggested many years ago by Shanahan who found a higher prevalence of p-ANCA in first-degree relatives of patients with UC[26]. This finding was confirmed by Lee[27] *et al*, in a different ethnic group. So, p-ANCA determination could be useful as a marker of genetic predisposition. However, today there is no information about predictive values of p-ANCA in this setting, and more research is necessary to answer this important question.

Several studies, although not all, have demonstrated a correlation between serum levels of p-ANCA and severity of UC[5,12,15,29-31]. In the present study, an association between the presence of p-ANCA and a subset of patients with severe UC was found but, as other studies, there was no correlation between levels of p-ANCA and the activity of disease evaluated by clinical and biochemical methods. From the point of view of the authors, a sophisticated laboratory exam such as the p-ANCA determination may not currently have a role in the evaluation of severity because it can be evaluated by simple and reproducible methods.

Fleshner *et al*, reported high pre-operative levels of p-ANCA in subjects who developed chronic pouchitis after the ileo-anal pouch[8]; however, it should be noted that some patients with acute and chronic pouchitis were p-ANCA negatives. The follow-up of patients in our series is still too short to analyze this aspect.

In conclusion, the prevalence of p-ANCA in this series was similar to that reported in other countries. Their presence was associated to severity of UC, but offered no more information than the obtained by clinical methods. Future research may clarify their role as a screening test for the first-degree relatives of UC patients, or for patients requiring an ileo-anal pouch.

Abstract

AIM: To investigate the influence of experimental obstructive jaundice and exogenous bombesin (BBS) and neurotensin (NT) administration on the expression of the tight junction (TJ)-protein claudin-4 in intestinal epithelium of rats.

METHODS: Forty male Wistar rats were randomly divided into five groups: I = controls, II = sham operated, III = bile duct ligation (BDL), IV = BDL+BBS (30 μg/kg per d), V = BDL+NT (300 μg/kg per d). At the end of the experiment on d 10, endotoxin was measured in portal and aortic blood. Tissue sections of the terminal ileum were examined histologically and immunohistochemically for evaluation of claudin-4 expression in intestinal epithelium.

RESULTS: Obstructive jaundice led to intestinal barrier failure demonstrated by significant portal and aortic endotoxemia. Claudin-4 expression was significantly increased in the upper third of the villi in jaundiced rats and an upregulation of its lateral distribution was noted. Administration of BBS or NT restored claudin-4 expression to the control state and significantly reduced portal and aortic endotoxemia.

CONCLUSION: Experimental obstructive jaundice increases claudin-4 expression in intestinal epithelium, which may be a key factor contributing to the disruption of the mucosal barrier. Gut regulatory peptides BBS and NT can prevent this alteration and reduce portal and systemic endotoxemia.

INTRODUCTION

Patients with obstructive jaundice, especially when exposed to the additional stress of an invasive diagnostic or therapeutic procedure, are prone to septic complications and renal dysfunction contributing to high morbidity and mortality rates[1]. Systemic endotoxemia appears to play a key role in the development of these complications[2]. Experimental and clinical studies have shown that obstructive jaundice increases intestinal permeability permitting the escape of endotoxin from the gut lumen[3,4]; however, little is known of the molecular events leading to intestinal permeability alterations.

Tight junctions (TJs) are located at the apical part of lateral membranes of polarized epithelial and endothelial cells forming a barrier that regulates the permeability of ions, macromolecules and cells through the paracellular pathway[5,6]. Up to now, three groups of macromolecules are considered as bona fide integral components of the tight junction: occludin, claudins and junctional adhesion molecule[6]. We have recently demonstrated using immunohistochemistry that intestinal mucosal barrier dysfunction in obstructive jaundice is associated with regional loss of occludin expression in the intestinal epithelium, observed mainly in the upper part of the villi[7]. Our findings were recently confirmed by other

investigators using immunoblotting[8].

Claudins comprise a multigene family consisting of 24 members believed to be major functional elements of TJ[9]. TJ strands are copolymers of heterogeneous claudin species and occludin, and heterogeneous claudin species constitute the backbone of TJ strands *in situ*[10]. The localization and contribution to barrier function of each member of the claudin family vary among tissues. Claudin-4 is highly expressed in rat intestine[11], with a preferential localization in the epithelium overlying the tips of intestinal villi and the follicle associated epithelium (FAE) of gut associated lymphoid tissue (GALT)[12]. We focused on this molecule because in obstructive jaundice loss of occludin expression was observed mainly at the upper part of the villi where claudin-4 is preferentially expressed.

Regulatory peptides bombesin (BBS) and neurotensin (NT), with a wide spectrum of biological actions on gastrointestinal tissues (influencing intestinal growth and adaptation, intestinal motility, blood flow, secretion, nutrient absorption and immune response), exert a protective role in preserving gut barrier integrity after various injurious insults[13-18]. Beyond their potent enterotrophic action we have shown that BBS and NT fully restored intestinal occludin expression in bile duct ligated rats, thus preventing endotoxin translocation. It suggests a role of these peptides as molecular modulators of TJs[7].

The present study was undertaken to investigate the effect of experimental obstructive jaundice on intestinal claudin-4 expression and examine the potential effect of BBS and NT on this parameter of intestinal mucosal barrier.

MATERIALS AND METHODS

Animals

Forty male albino Wistar rats, weighing 250-320 g, were used in the study. They were housed in stainless-steel cages, three rats per cage, under controlled temperature (23℃) and humidity conditions, with 12-h dark/light cycles, and maintained on standard laboratory diet with tap water *ad libitum* throughout the experiment, except for an overnight fast before surgery.

The experiments were carried out according to the guidelines set forth by the Ethics Committee of Patras University Hospital, Patras, Greece.

Experimental design

Animals were randomly divided into five groups: I (n = 8), controls; II (n = 8), sham operated; III (n = 8), bile duct ligation (BDL); IV (n = 8), BDL and BBS treatment and V (n = 8), BDL and NT administration. All surgical procedures were performed under strict sterile conditions, and light ether anesthesia. Rats from groups II, III, IV and V underwent laparotomy on d 0. *Via* a 1 cm upper midline incision, the gastroduodenal ligament was isolated and the common bile duct was mobilized. In groups III, IV and V, the common bile duct was further doubly ligated in its middle third with a 4-0 silk suture and was transected between the two ligatures. The abdominal incision was closed in two layers with chromic 4-0 cat gut and 4-0 silk.

For the 10 subsequent days, the animals of groups IV and V were treated daily with BBS (10 μg/kg, subcutaneously, three times a day) and NT (300 μg/kg, intraperitoneally, once a day) respectively, while the animals of groups I, II, and III were divided to receive daily either three subcutaneous or one intraperitoneal injection of 0.5 mL normal saline. All injections were given after topical application of an antiseptic solution of povidone iodine 10%. Previous studies have shown that the way of saline administration does not affect the results[7]. On the 10th d, all animals were operated (group I) or reoperated (groups II, III, IV and V). Samples were obtained according to the experimental protocol, after which the rats were sacrificed by exsanguination.

Peptides preparation

Bombesin: A stock solution of BBS (Sigma Chemical Co, St. Louis, Missouri, USA) was prepared by first dissolving the amount of peptide needed for the study in 1 mL sterile water containing 0.1% (w/v) bovine serum albumin and then diluted with normal saline containing 1% (w/v) bovine serum albumin, so that the amount of BBS needed for each injection to be contained in a volume of 0.1 mL. The solution was divided into equal aliquots of 0.1 mL which were stored in plastic tubes at -20℃. At the time of administration, in order to prolong absorption, each aliquot was mixed with 0.4 mL of a solution 8% (w/v) hydrolyzed gelatin (Sigma Chemical Co, St. Louis, Missouri, USA). A final volume of 0.5 mL, containing 10 μg BBS/kg body weight, was injected subcutaneously three times daily. Selection of dose and route of administration was based on previous reports[7].

Neurotensin: A stock solution of NT (Sigma Chemical Co, St. Louis, Missouri, USA) was prepared by first dissolving the amount of peptide needed for the study in 1 mL sterile water containing 0.1% (w/v) bovine serum albumin and then diluted with normal saline containing 0.1% (w/v) bovine serum albumin, so that the amount of BBS needed for each injection to be contained in a volume of 0.1 mL. The solution was divided into equal aliquots of 0.1 mL which were stored in glass vials at -20 ℃. At the time of administration, each aliquot was further diluted with 0.4 mL sterile saline to a final volume of 0.5 mL and was given intraperitoneally through a bolus injection containing 300 μg NT/kg body weight. Selection of dose and route of administration was based on previous reports[7].

Bilirubin and endotoxin measurements

For the determination of total bilirubin, 0.5 mL of blood was collected from all animals, by transecting the tip of their tail. Then a laparotomy was performed and in all groups, the portal vein and the abdominal aorta were punctured and samples of 1 and 2 mL of blood, respectively, were obtained for estimation of endotoxin. Bilirubin concentrations were assayed using a standard biochemical technique and expressed in mg/dl. Endotoxin concentration was determined by the quantitative chromogenic Limulus Amebocyte Lysate test (QCL-1000, BioWhittaker, Walkersville, USA) and expressed in EU/mL. Samples were processed according to the manufacturer's instructions. By this test it is possible to measure concentrations of endotoxin $\geqslant$ 0.01 EU/mL.

Immunohistochemistry for claudin-4

In tissue sections of the terminal ileum from all rats a standard immunohistochemical technique was applied to detect claudin-4. Deparaffinization, rehydration and microwave antigen retrieval were performed in Trilogy™ solution (Cell Marque, Hot Springs, AK). Then slides were incubated for 1 h at room temperature with a commercially available mouse monoclonal anti-claudin-4 antibody (1:40, ZYMED Laboratories, San Francisco, CA), followed by antigen-antibody detection using the DAKO ChemMate EnVision detection kit (DAKO A/S, Glostrup, Denmark). Colour was developed with diaminobenzidine (Sigma Fast DAB tablets, D-4293, St. Louis, Mo) and counterstained with Harris hematoxylin. All procedures took place at room temperature and between steps sections were washed in TBS. In negative control slides, the primary antibody was substituted by mouse serum. Twenty randomly selected adjacent perpendicularly sectioned villi from each case (n = 8 cases per group) were evaluated. The frequency of claudin-4 immunohistochemical expression in the upper third of the villi was recorded by dividing the number of claudin-4 positive enterocytes by the total number of enterocytes in the upper third of each villous.

Statistical analysis

The results are expressed as mean (SD). Comparisons among multiple groups were performed using the one-way ANOVA, followed by Dunnette's T3 post hoc test. Variance equality was tested by Levene statistical analysis. Differences were considered significant when $P < 0.05$.

RESULTS

Animal outcomes

All animals survived and were in good health throughout the experiment. Bile duct ligated rats were clinically jaundiced within three days. At reoperation on d 10 it was found that the ligation and division of the common bile duct in groups III, IV and V had been successful in all cases and resulted in dilatation of the common bile duct remnant proximal to the ligature without signs of bile leakage.

Bilirubin and endotoxin concentrations

Bile duct ligation led to significantly raised total bilirubin levels in groups III, IV and V compared with control and sham groups ($P < 0.001$). Figure 1 demonstrates endotoxin values, measured in blood collected from portal vein and aorta. Jaundiced animals (group III) presented significantly elevated endotoxin concentrations in portal and aortic blood compared with groups I and II ($P < 0.001$). When ligation of common bile duct was followed by either BBS or NT treatment, endotoxin values were significantly reduced both in portal vein ($P < 0.001$, respectively) and aorta ($P < 0.001$, respectively).

Evaluation of histology and claudin-4 immunostaining

Overall, the ileal architecture remained intact and epithelial continuity was retained, in all specimens studied, while no significant pathology was observed. Obvious alterations of claudin-4 immunohistochemical expression in the intestinal epithelium were observed among experimental groups. In control and sham operated rats claudin-4 was expressed in a few villous surface epithelial cells (Figure 2A), while occasionally unstained villi were observed. Claudin-4 was detected as membranous immunostaining, stronger on the basolateral sides than on the apical sides, with weak cytoplasmic staining (Figure 2A). In jaundiced rats, claudin-4 was expressed in most epithelial cells lining throughout the upper third of the villi, and this staining was observed in every villous (Figure 2B). Also the lateral expression of claudin-4 was upregulated in jaundiced rats (Figure 2D). In BBS or NT-treated rats claudin-4 expression was restored to the control state (Figure 2C). The frequency of claudin-4-positive cells in the upper third of the villi was significantly increased in jaundiced rats as compared with control and sham operated ($P < 0.001$), whereas it was reduced in rats administered BBS or NT ($P < 0.001$ as compared to BDL) (Figure 3).

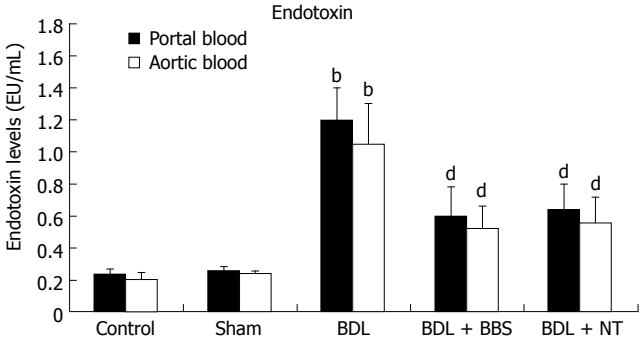

Figure 1 Portal and aortic endotoxin concentrations. Values are mean ± SD, $^{b}P < 0.001$ *vs* sham; $^{d}P < 0.001$ *vs* BDL. BDL, bile duct ligation; BBS, bombesin; NT, neurotensin.

DISCUSSION

Increased intestinal permeability has been postulated to be a key factor contributing to bacterial and endotoxin translocation and the pathogenesis of the so called "gut derived sepsis"[19]. In obstructive jaundice, increased intestinal permeability has been demonstrated not only in animal models but in patients as well and has been positively correlated with severity of biliary obstruction[3,4]. The present study, using an experimental model of biliary obstruction for 10 d in rats, demonstrated significant portal and aortic endotoxemia, a clinically important marker of ineffective intestinal barrier, accompanied by altered immunohistochemical expression of the TJ-protein claudin-4 in intestinal epithelium.

The molecular mechanisms responsible for permeability alterations in obstructive jaundice have not been adequately investigated until now. Previously we had shown for the first time that intestinal mucosal barrier dysfunction in obstructive jaundice is associated with regional loss of expression of the TJ-protein occludin in the intestinal epithelium, observed mainly at the upper part of the villi[7]. Our immunohistochemical observations were confirmed with immunoblotting method by other investi-

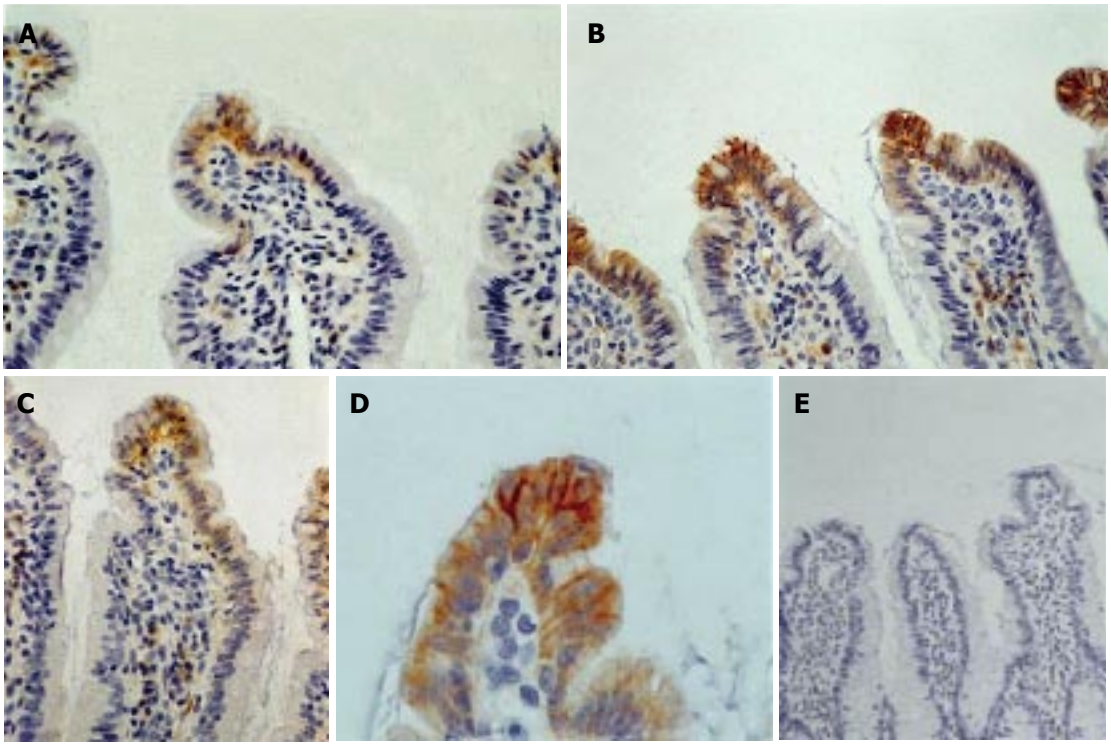

Figure 2 Immunohistochemical expression of claudin-4 in the mucosa of terminal ileum: In control and sham operated rats claudin-4 is expressed on the basolateral sides of a few villous surface epithelial cells (**A**: original magnification x 400). In obstructive jaundice, immunoreactivity for claudin-4 is stronger and this molecule is expressed by most epithelial cells lining throughout the upper third of the villi and not only in the tip (**B**: original magnification x 400). At higher magnification we can see the enhancement of the lateral distribution of claudin-4 in obstructive jaundice (**D**: original magnification x 1000). In bombesin or neurotensin-treated rats claudin-4 expression is restored to the control level (**C**: original magnification x400). Substituting anti-claudin-4 antibody by mouse serum no staining is observed (**E**: original magnification x 200).

gators, who additionally showed that obstructive jaundice led to decreased mucosal expression of the TJ-associated protein zonulin-1 as well[8]. The present study offered further insight into TJs alterations in the intestinal mucosa in obstructive jaundice, demonstrating upregulation of claudin-4 expression in the upper part of the villi.

The results obtained by the present study may initially seem paradoxical and a question raised is how increased expression of a TJ-protein may lead to increased permeability. Claudins are the only known variable elements in TJs and different expression, combination and mixing ratios of various members of the claudin family are essential in the regulation of barrier properties of TJs[20]. Overexpression of some claudins is often associated with the expected reduction of permeability, e.g. claudin-1 overexpression in Madin-Darby canine kidney (MDCK) cells increases transepithelial resistance[21]. On the other hand, increased blood-brain barrier permeability in inflammatory pain is associated with significant increase of claudin-3 and -5 expression, while occludin expression is decreased[22]. Regarding the functional role of claudin-4 in the intestinal epithelium, it may be associated with loosening of intercellular junctions and opening of the paracellular route, as indicated by findings of previous studies[12]. For instance, it has been shown that there is a close association between the locations of claudin-4 and TUNEL-positive apoptotic cells in intestinal villi and the FAE of GALT, suggesting that claudin-4 may be involved in the process of peeling off epithelial sheets of apoptotic enterocytes. In addition, claudin-4 is preferentially expressed at the apices of intestinal villi and the FAE, which represent important antigen-sampling sites. Given that both apoptosis and antigen capturing are associated with looseness of intercellular junctions, Tamagawa *et al* suggested that claudin-4 expression contributes to the formation of relatively loose intercellular junctions[12]. The present study provides support to the above proposal. Furthermore, taking into consideration our recent findings of decreased intestinal occludin expression in obstructive jaundice[7] and the results of the present study showing increased intestinal claudin-4 expression, one could hypothesize the existence of a novel "switch mechanism" by which claudin-4 may replace occludin and lead to increased permeability of tight junctions. The key role of claudin-4 and occludin in obstructive jaundice-associated intestinal permeability alterations is further evidenced by improvement of gut mucosal barrier

after restoration of their expression by regulatory peptides administration.

Which is the critical factor inducing these alterations in obstructive jaundice? The present study cannot answer this question due to the interplay of several factors in the intact organism. However, a recent *in vitro* study has shown that bile is crucial for maintenance of intestinal TJs integrity[8]. Beyond absence of intraluminal bile other factors such as systemic endotoxemia, cytokinemia and intestinal oxidative stress may contribute to intestinal barrier failure in obstructive jaundice[5,23-25]. Oxidative stress, attracting a growing research interest, has been recognized as an important modulator of TJs. It has been shown that oxidative stress increases epithelial permeability through modulation of the assembly, localization, expression and function of the molecular components of the TJ structural complex[24]. We have recently shown that experimental obstructive jaundice induces intestinal oxidative stress, demonstrated by increased lipid peroxidation, protein oxidation and oxidation of non-protein and protein thiols[25]. Therefore, oxidative stress may be implicated in altered occludin and claudin-4 expression in the intestinal mucosa of jaundiced rats.

The present study also showed that when jaundiced rats were treated with either BBS or NT, claudin-4 expression in the intestinal epithelium was restored to the control state and endotoxin levels in portal and aortic blood were significantly reduced. These regulatory peptides may have restored claudin-4 expression via a direct receptor-mediated mechanism. Animal studies provide evidence for the presence of BBS and NT receptors in intestinal epithelial cells[26,27]. Binding to peptides' specific G protein-coupled receptors activates multiple intracellular signals including protein phosphorylation pathways, accumulation of cyclic-adenosine monophosphate and mobilization of intracellular Ca^{++}[28], which may account for the maintenance of structurally and functionally effective TJs[6,20]. A potential molecular mechanism mediating the effect of BBS and NT on claudin-4 expression is activation of protein kinase C (PKC). PKC plays a central role in transducing neuropeptides' signals[28] and recent studies have shown that PKC activity is required for normal claudin assembly and the integrity of the intestinal epithelial barrier[29]. Also the antiapoptotic effect of BBS and NT on the intestinal epithelium of jaundiced rats[25] may be related to their modulating action on the expression of claudin-4, since there is evidence that intestinal apoptosis and claudin-4 expression may be interconnected[12]. Additionally, indirect mechanisms such as reduction of systemic endotoxemia, improvement of energy supply to enterocytes through splachnic vasodilatation[30,31] and reduction of intestinal oxidative stress[25] may contribute to the regulatory action of BBS and NT on the TJ structure and function.

In conclusion, our results show that enhanced claudin-4 expression in the upper part of the intestinal villi represents an important molecular mechanism for increased intestinal mucosal permeability in obstructive jaundice. Gut regulatory peptides BBS and NT, acting as molecular modulators of TJs, totally restored this alteration thus preventing endotoxin translocation from the gut lumen. These findings offer further insight into the pathophysiology of gut barrier failure in obstructive jaundice and suggest the potential therapeutic efficacy of regulatory peptides. However, further investigations to elucidate the details of the functional mechanisms and possible side effects of BBS and NT are needed before their clinical application.

Abstract

AIM: To investigate the probable role of soluble triggering receptor expressed on myeloid cells-1 (sTREM-1) in the pathogenesis of inflammatory bowel disease (IBD).

METHODS: Fifty-eight patients were enrolled; nineteen healthy volunteers served as controls; 8 patients were diagnosed with Crohn's disease, and 31 with ulcerative colitis. Clinical and endoscopic activity indexes of patients with Crohn's disease and ulcerative colitis respectively were estimated. Upon admission blood was sampled; sTREM-1 and TNFα were measured by an immunoassay and malondialdehyde (MDA) by the thiobarbiturate assay, after passage through an HPLC system.

RESULTS: Median ± SE of TNFα of controls, patients with Crohn's disease and patients with ulcerative colitis were 6.02 ± 3.94, 7.98 ± 5.08 (P = NS *vs* controls), and 8.45 ± 4.15 ng/L (P = 0.018 *vs* controls) respectively. Respective values of sTREM-1 were 53.31 ± 32.93, 735.10 ± 197.17 (P = 0.008 *vs* controls) and 435.82 ± 279.71 ng/L (P = 0.049 *vs* controls). sTREM-1 was positively correlated with Crohn's disease activity index and clinical and endoscopic activity indexes of ulcerative colitis (P = 0.002, 0.001 and 0.009, respectively). sTREM-1 of patients with ulcerative colitis was positively correlated with TNFα (P = 0.001).

CONCLUSION: sTREM-1 seems to behave as a novel mediator in IBD in correlation with the degree of the inflammatory reaction of the intestinal mucosa.

INTRODUCTION

Accumulated evidence over the last decade demonstrates that inflammatory bowel disease (IBD) is a heterogeneous group of diseases resulting from different pathogenetic mechanisms with a common symptomatic expression[1]. Dysfunction of the innate and adaptive immune systems associated with gut mucosa might involve impairment of mucosal barrier function and development of localized or systemic inflammatory and autoimmune processes[2,3]. Triggering receptor expressed on myeloid cells (TREM)-1 is a recently discovered receptor expressed on the surface of neutrophils and monocytes in the presence of microbial components. Engagement of TREM-1 has been reported to trigger the synthesis of proinflammatory cytokines, though its expression failed to elevate in several autoimmune diseases[4,5]. Expression of TREM-1 was not identified on cell membranes of macrophages of intestinal lamina propria; its absence was connected with prevention of excessive inflammatory reactions by bacterial flora, and thus, of any tissue damage of the intestine[6].

A soluble form of TREM-1, named sTREM-1, has been found; it is thought to be released from cell membranes as a result of the severity of inflammation. sTREM-1 was found elevated in samples of gastric juice of patients with peptic ulcer disease; its correlation with gastritis score leads to the assumption of a probable implication of sTREM-1 in the pathogenesis of gastritis[7]. Based on the latter findings in gastric diseases, the present study aimed to clarify the significance of sTREM-1, if any, in inflammatory bowel disease.

MATERIALS AND METHODS

Subjects

Fifty-eight patients were enrolled in the prospective

study from January 2001 to June 2001; nineteen healthy volunteers served as controls; eight patients were diagnosed with Crohn's disease; and 31 with ulcerative colitis. Exclusion criteria for the study were (1) gastric or colonic neoplasia, (2) liver cirrhosis, (3) any history of administration of monoclonal anti-TNFα antibodies (infliximab, adalimubab) or soluble TNFα receptors (etanercept), (4) concurrent existence of infectious or ischemic colitis and (5) patients with Crohn's disease type L4B2 and L4B3 classified according to Vienna classification system[8].

Crohn's disease was confirmed by findings on barium radiography, endoscopy, and histopathology, as described by others[9]. The activity of Crohn's disease among patients was defined according to Crohn's Disease Activity Index (CDAI). Patients with CDAI score ranging between 150 and 400 were thought to have mild activity of the disease and patients with CDAI score ranging between 400 and 600 were thought to have severe activity. Remission was considered when CDAI score was less than 150[10].

The diagnosis of ulcerative colitis relied on history, stool examination, the sigmoidoscopic or colonoscopic appearance and the histological assessment of rectal or colonic specimens. Activity of ulcerative colitis was defined by its clinical and endoscopic severity. According to its clinical severity patients were categorized as suffering from disease remission, or mild, moderate, and severe disease as described previously; the latter disease activity was graded between 0 and 3, respectively[11]. According to endoscopic findings a system scaling between 0 and 4 was applied. The latter system is as follows: 0: normal mucosa, 1: loss of vascular pattern, 2: granular mucosa, 3: friability on rubbing and 4: spontaneous bleeding or ulceration of the mucosa[12].

Patients with no clinical, laboratory, histological and endoscopic abnormalities who underwent colonoscopy served as controls. The study was conducted in accordance to the Helsinki Declaration. Upon admission, a total of 20 mL of blood were collected after puncture of one forearm vein. Ten mL was added into 40 mL of trypticase soy broth (Becton Dickinson) for quantitative blood culture. The other 10 mL of blood was collected in a sterile tube and centrifuged; the supernatant was kept at -70℃ until assayed. Serum was applied for the estimation of sTREM-1, TNFα and malondialdehyde (MDA).

Estimation of sTREM-1

Estimation of sTREM-1 was performed by a home-made enzyme immunoassay. Capture antibody of sTREM-1 (R&D Inc, Minneapolis, USA) was diluted to 4000 mg/L and distributed in a 96-well plate at a volume of 0.1 mL per well. Samples of serum were centrifuged at 12 000 g for 10 min and the supernatants were removed. After overnight incubation at 25℃, wells were thoroughly washed with a 0.5 g/L solution of Tween in PBS (Merck) (pH: 7.2-7.4). Then 0.1 mL of standard concentrations of sTREM-1 (15.1-4000 ng/L, R&D Inc) diluted with reagent diluent (10 g/L BSA in PBS, pH 7.2-7.4, 0.2 micron filtered) serving as a buffer or of serum was added in wells. After incubation for two hours, wells were washed thrice, and 0.1 mL of one 400 ng/mL dilution of sTREM-1 detection antibody (R&D Inc) was added per well. The plate was then incubated for two hours, and attached antibodies were signalled by streptavidin. Concentrations of sTREM-1 in each well were estimated by the optical density detected at 450 nm after addition of one 1:1 solution of H_2O_2: tetramethylbenzidine as a substrate (R&D Inc). sTREM-1 concentration was expressed in ng/L. All determinations were performed in duplicate; the inter-day variation of the assay was 5.23%.

Estimation of TNFα

Tumor necrosis factor alpha was measured in serum with an enzyme immunoassay (Amersham, London, UK). Lowest limit of detection was 0.5 ng/L. All measurements were performed in duplicate and cytokine concentrations were expressed as ng/L.

Estimation of malondialdehyde (MDA)

Lipid peroxidation was estimated by the concentration of MDA, as already described[13]. Briefly, a 0.1 mL aliquot of each sample was mixed to 0.9 mL of trichloroacetic acid 200 g/L (Merck) and centrifuged at 12 000 g, 4℃ for 10 min. The supernatant was removed and incubated with 2 mL of thiobarbituric acid 2 g/L (Merck) for 60 min at 90℃. After centrifugation, a volume of 10 μL of the supernatant was injected into a high-performance liquid chromatography system (HPLC, Agilent 1100 Series, Waldbronn, Germany) with the following characteristics of elution: Zorbax Eclipse XDB-C18 (4.6 mm × 150 mm, 5 μm) column below 37℃; mobile phase consisting of a 50 mmol/L K_3PO_4 (pH 6.8) buffer and methanol 990 g/L at a 60/40 ratio with a flow rate of 1 mL/min; fluorometric detection with signals of excitation at 515 nm and emission at 535 nm. The retention time of MDA was 3.5 min and it was estimated as μmol/L by a standard curve created with 1, 1, 3, 3-tetramethoxy-propane (Merck). All determinations were performed in duplicate.

Statistical analysis

Comparison between groups was made by Mann-Whitney U test. Correlations between concentrations of sTREM-1, TNFα and MDA and severity indexes were performed according to Spearman's rank of order. $P < 0.05$ was considered as significant.

RESULTS

Patients' clinical and demographic characteristics are shown in Table 1. Blood cultures obtained from patients of all study groups were sterile. Concentrations (Median ± SE) of sTREM-1 of controls, patients with Crohn's disease, and patients with ulcerative colitis were 53.31 ± 32.93, 735.10 ± 197.17 ($P = 0.008$ *vs* controls), and 435.82 ± 279.71 ($P = 0.049$ *vs* controls) ng/L, respectively (Table 1). Respective concentrations of TNFα were 6.02 ± 3.94, 7.98 ± 5.08 (P = NS *vs* controls), and 8.45 ± 4.15 ($P = 0.018$ *vs* controls) ng/L (Table 1). Respective concentrations of MDA were 0.93 ± 0.23, 1.46 ± 0.56, and 1.49 ± 0.61 ($P = 0.041$ *vs* controls) μmol/L (Table 1). The concentrations

of sTREM-1 were higher in patients with severe degree of Crohn's disease than in patients in remission of Crohn's disease ($P = 0.032$, Table 2).

Correlation between sTREM-1 and TNFα of patients with ulcerative colitis was significant ($P = 0.001$) (Figure 1). No correlation in patients with ulcerative colitis was found between sTREM-1 and MDA, and TNFα and MDA, consecutively; nor was correlation found in patients with Crohn's disease between sTREM-1 and TNFα, sTREM-1 and MDA and TNFα and MDA.

DISCUSSION

Triggering receptor expressed on myeloid cells (TREM-1) is a recently discovered receptor on cell membranes of neutrophils and monocytes involved in inflammatory processes and activated by microbial components. Engagement of TREM-1 has been reported to trigger the synthesis of proinflammatory cytokines[4]. sTREM-1 is the soluble counterpart of TREM-1 that is increased in gastric juice of patients with peptic ulcer disease[7]. Based on the latter involvement of sTREM-1 in diseases of the gastric mucose, it was hypothesized that sTREM-1 might be implicated in inflammation of intestinal mucosa. Our data revealed that sTREM-1 was increased in the sera of patients with ulcerative colitis and Crohn's disease (Tables 1 and 2). Various hypotheses could be made to explain the mechanism of increase of sTREM-1 based on the role of bacteria and fungi to trigger TREM-1[14]. It might be assumed that sTREM-1 was increased as a consequence of two probable conditions related with a microbial infection; (1) bacteremia as a result of bacterial translocation through the inflamed intestinal mucosa, and (2) infectious colitis. Both mechanisms are unfavorable for the following two reasons: (1) patients with infectious colitis were excluded from the study, and (2) quantitative blood cultures obtained from patients of all study groups were found sterile. Furthermore no differences were found for white blood cell and platelet counts between controls and patients with

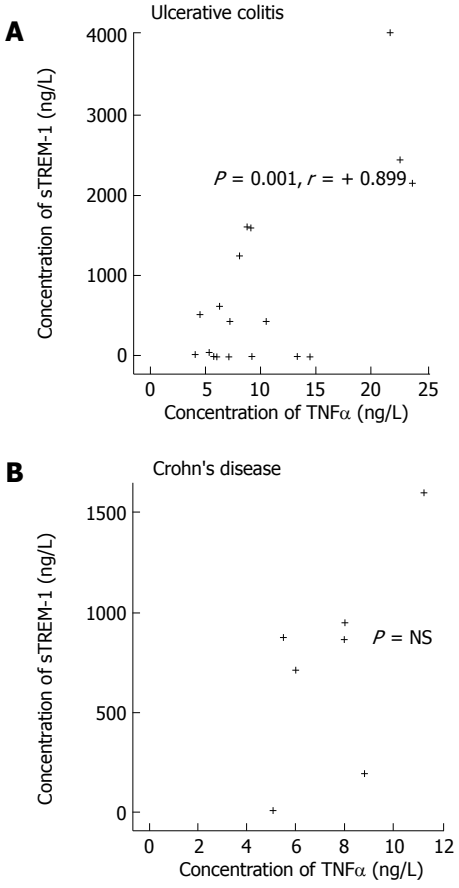

Figure 1 Correlations between sTREM-1, TNFα of IBD patients.

ulcerative colitis as well as between controls and patients with Crohn's disease (Table 2). So, it might be presumed that sTREM-1 increase was not a result of a microbial infection.

The similar kinetics of sTREM-1 and TNFα might indicate the implication of sTREM-1 in the pathogenetic mechanisms leading to IBD. Evolution of IBD seems to

result from the derangement of balance between pro-inflammatory cytokines and mediators with anti-inflammatory activity. The latter imbalance contributes to impairment of mucosal barrier function leading to colonic inflammation[15]. sTREM-1 was increased only in IBD of moderate and severe degree signifying the possibility that sTREM-1 might be an indicator of the severity of the colonic inflammation (Table 2) reflecting the degree of the inflammatory reaction taking place in the intestinal mucosa.

The significance of MDA increase in IBD has already been described by others[16,17]. MDA is a compound functioning as an indicator for the severity of oxidative stress. Oxidative stress seems to be involved in the pathogenesis of several inflammatory processes[16,17]. In the present study, MDA was not correlated with sTREM-1. The latter finding could be explained due to the fact that MDA is an indicator of lipid peroxidation that is not specific to IBD. The present data show for the first time, to our knowledge, that sTREM-1 levels correlate with clinical disease degree and TNFα levels in ulcerative colitis, raising the possibility that it is a mediator in this condition. Further research is mandatory to elucidate the role of sTREM-1 in the evolution from the initial immunologic events occurring in the inflamed intestinal mucosa to the development of inflammatory bowel disease.

Abstract

AIM: To study the prevalence and clinical effects of occult HBV infection in haemodialysis patients with chronic HCV.

METHODS: Fifty chronic hemodialysis patients with negative HbsAg, and positive anti-HCV were included in the study. These patients were divided into two groups: HCV-RNA positive and HCV-RNA negative, based on the results of HCV-RNA PCR. HBV-DNA was studied using the PCR method in both groups.

RESULTS: None of the 22 HCV-RNA positive patients and 28 HCV-RNA negative patients revealed HBV-DNA in serum by PCR method. The average age was 47.2 ± 17.0 in the HCV-RNA positive group and 39.6 ± 15.6 in the HCV-RNA negative group.

CONCLUSION: The prevalence of occult HBV infection is not high in haemodialysis patients with chronic HCV in our region. This result of our study has to be evaluated in consideration of the interaction between HBsAg positivity (8%-10%) and frequency of HBV mutants in our region.

INTRODUCTION

In most cases, occult HBV infection is defined with low existence of HBV infection in HbsAg deficiency. Serum HBV-DNA level in these patients is generally lower than 10^4 copies/mL. It is reported that there is a high prevalence of occult HBV infection in patients with chronic hepatitis C, HCC and haemodialysis patients, criptogenic liver disease, drug injection users and HIV patients, and in those undergoing frequent blood transfusion (those with hemophilia disease, etc.) and blood donors[1-8]. The existing data is limited on occult HBV among patients on long-term dialysis. It has been recently suggested that occult HBV infection might be associated with a lower response of hepatitis C virus (HCV) to standard interferon therapy in patients with normal renal function. The prevalence of occult HBV infection in renal dialysis patients ranges between 0% and 58% in published reports. The aim of this survey is to address epidemiological and clinical significance of occult HBV infection in patients receiving regular dialysis in Turkey.

MATERIALS AND METHODS

A total of 50 patients with chronic renal failure receiving haemodialysis have been chosen with negative HbsAg and positive anti-HCV for at least 6 months and accepted for this study from among the patients of dialysis unit, and from among patients who have applied to Internal Diseases, Faculty of Medicine, Dicle University. These patients were divided into two groups, HCV-RNA positive (22 patients) and HCV-RNA negative (28 patients). Average haemodialysis periods were 4.9 ± 2.3 years in the HCV-RNA positive group[1-9] and 4.6 ± 2.1 years in the HCV-RNA negative group[1-8]. There were 13 male and 9 female subjects in the HCV-RNA positive group, with an average age of 47.2 ± 17.0 years[18-24]. There were 17 male and 11 female subjects in the HCV-RNA negative group, with an average age of 39.6 ± 15.6 years[13-16]. Cirrhosis existence in patients was externalized both clinically and through laboratory tests.

Fifteen ml blood was taken from the patients, centrifuged at 2500 r/min for 5 min, and stored at -25 ℃ with separated serum samples. Hepatitis panel (HBsAg, anti-HBs, anti-HBc IgG) was studied by "Macro Enzyme Immune Assay (Macro EIA) " method in Elecsy 2010 (Roche) device and with similar brand kits; and anti-HCV was studied with the Cobas Core II Immunochemical system (Roche). The "Real-time PCR method" with Robo Gene

(Roboscreen, Leipzig, Germany) kits in ABI PRISM 5700 (Applied Biosystems) device HCV-RNA was used. HBV-DNAs of cases included in the study were quantitatively evaluated by PCR method. Techne Cylogene Thermal Cycler (Techne Cambridge Ltd) Duxford-Cambridge U.K. device was used for HBV-DNA PCR amplification. For PCR amplification, viral DNA was insulated from 100 μL serum in the incubation tampon containing 1 mg/mL Proteinase K at 37℃ through phenol-chloroform extraction and ethanol precipitation following a 3-h incubation.

RESULTS

Patients included in the study were divided into two groups, HCV-RNA positive and HCV-RNA negative. Demographic and clinical characteristics of these patients are shown in Table 1. Thirty (60%) of 50 patients were male, while 20 (40%) patients were female, with an age range of 13-84 years, and averaging 42.9 ± 16.5 years.

HCV-RNA PCR examination was positive in 22 (44%) patients, and negative in 28 (56%) patients. No HBV-DNA (0%) was detected through the high-sensitivity PCR study in both patient groups with positive and negative HCV-RNA. Accordingly, occult HBV infection was detected in none of the 50 patients in our study.

Results in anti-HCV positive and HCV-RNA positive group (22 patients) are as shown in Table 1. Considering both groups together, the results in 50 patients are as follows.

Serum ALT levels are above normal in 12 (24%) of the 50 patients, 8 showed persistent and meaningful ALT level in their six-month monitoring. HCV-RNA was positive in 7 of the 8 patients, and negative in 1 patient. With regard to the duration of haemodialysis, only 6 of the 50 patients were receiving haemodialysis for less than 3 years, 44 patients were receiving haemodialysis treatment for 3 years and over. The minimum haemodialysis duration was 1 year. Twelve (57.1%) out of a total of 21 patients in the two groups with insulated anti-HBs seropositivity received HBV vaccination in their history.

Table 1 Demographic and clinical characteristics of patients

	HCV-RNA Positive (*n* = 22)	HCV-RNA Negative (*n* = 28)	Total (*n* = 50)
Average age (yr) (age range)	47.2 ± 17 (18 - 24)	39.6 ± 15.6 (13-76)	42.9 ± 16.5 (13 - 84)
Sex Male	13 (59.1%)	17 (60.7%)	30 (60%)
Sex Female	9 (40.9%)	11 (39.3%)	20 (40%)
Average Haemodialysis period (yrs) (haemodialysis range)	4.9 ± 2.3 (1 - 9)	4.6 ± 2.1 (1-8)	4.8 ± 2.2 (1-9)
ALT (IU/mL)	52.9 ± 52.8 (4 - 186)	29.3 ± 20.9 (2-88)	39.7 ± 39.7 (2 - 186)
Insulated anti-HBs Seropositivity	7 (31.8)	14 (50%)	21 (42%)
Insulated anti-HBc IgG seropositivity	3 (13.6%)	1 (3.5%)	4 (8%)
Anti-HBs and anti-HBc IgG Seropositivity	10 (45.4%)	6 (21.4%)	16 (32%)
Anti-HBs and anti-HBc IgG Seronegativity	2 (9.1%)	7 (25%)	9 (18%)
HBV-DNA (PCR) Positivity	0 (0%)	0 (0%)	0 (0%)

DISCUSSION

In most cases, occult HBV infection is defined with low existence of HBV infection in HbsAg deficiency. Serum HBV-DNA level in these patients is generally lower than 10^4 copies/mL. It is reported that there is a high prevalence of occult HBV infection in patients with chronic hepatitis C, HCC and haemodialysis patients, in those with criptogenic liver disease, drug injection users and HIV patients, and in those who underwent frequent blood transfusion (those with hemophilia disease, etc) and blood donors[1-8].

As they are similar transmission models, HBV and HCV co-infection are prevalent clinical presentations. Anti-HBc prevalence reported in patients with chronic HCV infection is 50%-55%[1,2,9]. This ratio is a close value, 59% (13/22) in our study. Most studies show that HBV-DNA genome existence is 22%-87%[10,11] in patients with negative HBsAg and positive HCV-RNA. HBV-DNA is seen in 46% of anti-HBc positives, and in 20% of anti-HBc negatives[11]. In chronic HCV related liver diseases, frequency of detectable HBV-DNA is apparently higher than HCV non-related liver diseases[11]. However, variable prevalence of occult HBV infection is seen in the permanence of HBV-DNA PCR[12]. And this makes us think that HBV viremia shows fluctuations during occult HBV infection.

Clinical interaction of HCV and occult HBV infection is still controversial. Some studies report that cirrhosis is seen more frequently in those patients with HCV and occult HBV co-infection than in those with HCV infection alone[11]. However, there are also studies that are not in support of this[13]. Parallel to this, HCV and occult HBV co-infection had a lower incidence in non-cirrhotic hepatitis[14]. Occult HBV co-infection is related to higher ALT levels and histological activity. Despite this, other studies reveal that the incidence of liver related complication in these patients is at a level comparable to those with HCV infection alone[9-13]. Patients with active HBV and HCV co-infection tend not to respond to interferon treatment. Some studies show that such low interferon response exists in patients with HCV and occult HBV co-infection[14-16]. However, other studies reveal that occult HBV co-infection has no effect on the interferon response of HCV infection. Interferon treatment may accelerate HCV clearance in patients with HCV and occult HBV co-infection, but HBV-DNA remains at detectable level. HCV-RNA level is apparently higher in patients with occult HBV co-infection than patients with HCV infection alone. Despite all these, three recent studies show a lower prevalence of chronic HCV and occult HBV co-infection and that the effects of occult HBV infection on chronic HCV infection remained low in these patients[17-19]. While one of these studies report occult HBV co-infection prevalence at 6.7% in patients

with chronic HCV infection, no difference was found in the frequency of occult HBV infection between those with and without a marker for HBV infection in their history[18]. Another study found that occult HBV infection had no effect on the early phase response of chronic HCV infection combined treatment[17]. And the last study states that occult HBV infection has no significant effect on treatment response upon HCV viral titre, liver enzymes, histological parameters and HCV and interferon-α and ribavirin in patients with chronic hepatitis C[19].

In a study on chronic haemodialysis patients, serum in PCR and HBV-DNA in PBMC was studied in 67 patients. While serum HBsAg and HBV-DNA were found negative in all of these patients, HBV-DNA was positive in 5 patients (7.5%) in PBMC[6].

Another study focused on the disease etiology in 107 patients with negative HCC and cirrhosis HbsAg and 192 chronic hepatitis patients as control group with negative HbsAg. In the group with HCC, HCV was blamed as etiological factor in 73 (68%) patients, criptogenic liver disease in 29 (27%) patients and alcohol in 5 (5%) patients. HCV was blamed in 153 (80%) patients of the group with chronic hepatitis HCV, criptogenic liver disease was blamed in 32 (17%) patients and alcohol was blamed in 7 (4%) patients[2]. HBV-DNA PCR was checked in these patients, being positive in 68 (64%) patients with HCC, 63 (33%) patients with chronic hepatitis. In patients with HBV-DNA positive HCC, anti-HBc positivity was found higher than anti-HBc negativity percentage (64% and 56%, respectively). Frequency of occult HBV infection varies in patients with HCC. The prevalence of anti-HBc/Anti-HBs is 43% in such patients, and the HBV-DNA prevalence varies between 5%-80%[2-20].

Although there are strong evidences aimed at the relationship between occult HBV infection and HCC, the role and place of HBV is not clear in this series of incidents. Is it a silent bystander, a cofactor, or criminal alone? There are strong evidences about the etiological relationship between chronic HBV infection and HCC. It is unlikely that occult HBV infection is only a silent bystander in patients with HCC. The high prevalence of occult HBV infection in patients with HCC supports the role of occult HBV infection in the development of HCC compared with the results in patients with cirrhosis or chronic hepatitis. It is quite possible that occult HBV infection plays a role as cofactor in HCC development. Two viruses may mutually interact, causing more painful inflammation and quicker cirrhosis progress. Alternatively, direct oncogenic effect of two viruses may be additive or synergistic[2]. This has been an issue of interest in patients with occult HBV coinfection. Evidences relating to occult HBV infection in patients with HCC related to HCV are being gradually seen more frequently[1,2,4]. In a study made in Spain, in 109 anti-HCV negative and HBsAg negative patients with increased liver enzymes with unknown etiology, 19% HBV-DNA was detected in serum[21]. Again in another study, in 50 patients with criptogenic chronic hepatitis, there was detectable HBV-DNA in 15/50 (30%) patients. Of these 15 patients, 66% had increased liver enzymes and 53% suffered from painful fibrosis and cirrhosis. In their repeated liver biopsies during follow-up, in 2/11 (18.2%) patients, the disease progressed from chronic hepatitis to cirrhosis. Generally considering, clinical results of occult HBV infection after delayed HBsAg clearance vary. These results depend upon the underlying liver disease, duration of active HBV infection and degree of liver damage before HBsAg clearance[1,2].

An increased frequency of occult HBV infection was reported in immune-dominant patients[1]. Lymphoma, aplastic anemia or cythotoxic treatment for leukemia, allongenic or otolog bone marrow transplantation practice in patients with occult HBV infection chronic might cause reactivation of Hepatitis B or development of fulminant hepatic insufficiency[22,23]. However, chronic hepatitis B reactivation with induced treatment is less frequent and painful in those with occult HBV infection before the treatment than those with chronic hepatitis B with positive HBsAg before the treatment[1]. Viral infection progresses with the application of immune-suppressive agent, destruction starts with immune intermediary in hepatocytes infected with HBV after the regaining of immunity with the interruption of this agent.

In patients with fulminant hepatic insufficiency, the pathogenetic role of occult HBV infection has been very well defined. In these patients, positivity of serum HBV-DNA ranges between 0%-47%[24-26]. Recurrence of HBV infection following liver transplantation for fulminant hepatic insufficiency shows possible HBV replication in these patients[24,25]. However, the pathogenetic role of occult HBV infection in patients with fulminant hepatic insufficiency is doubtful and weak. A multi-centered study in the USA shows that occult HBV infection is not related with acute liver insufficiency[26].

Occult HBV infection was found in 81/180 patients (45%) in drug injection users in Baltimore[7]. In a study, 10% occult HBV infection was detected in patients with HIV[8]. In Japan, occult HBV infection was detected in 22 (51.2%) of 43 hemophilia patients[5]. It has been reported that in numerous studies covering wide populations conducted in many different countries, occult HBV infection incidence varied between 0%-15% in blood donors[3].

Most of the relevant authors are mostly unable to provide clear replies to the question what is the responsibility and effect of occult HBV infection in the pathogenesis of diseases where there is a high prevalence of occult HBV infection and where the pathogenetic role of apparent HBV infection is well known. And they are still suspicious on most things. Although there are questions in minds about the subject, pathogenetic role of occult HBV infection is accepted best in HCC.

It is reported that the prevalence of occult HBV infection is parallel with the prevalence of apparent HBV infection in that region[1,2]. For example, occult HBV infection prevalence varies between 7%-19% among blood donors in endemic regions where 70%-90% of the population are exposed to HBV[2]. In Western countries (e.g., there is pre-reported HBV exposure in 5% of the American population), frequency of occult HBV infection ranged between 0%-9%[2]. Prevalence of occult HBV infection can also be affected by incorrect negative and incorrect positive results based on the sensitivity and specificity of the HBV-DNA PCR method. Therefore, the

specificity of the methods has to be verified and cross-contamination has to be prevented. Moreover, in order to positively consider the result in HBV-DNA PCR method, one needs to show at least two different primers from different areas of the HBV genome clone. Most of the studies so far mentioned the sample collection method at very few occasions[1,2,4]. Cross contamination may occur particularly in retrospective studies where the blood samples used in the past are collected.

In a study made by Beşışık *et al*. in 33 patients with chronic hepatitis C and at the same time chronic haemodialysis with negative HBsAg and positive HCV-RNA, serum HBV-DNA PCR study yielded positive results in 12 (36.4%) patients. YMDD mutation was detected in 6 (50%) of these 12 patients[27]. According to this study, there is increased occult HBV infection incidence in patients with chronic hepatitis C treated with chronic haemodialysis and YMDD mutation is the responsible agent in an important part of them. In our study, according to the HCV-RNA condition of the 50 cases chronic haemodialysis with negative HbsAg and positive anti-HCV, the study group was divided into two groups, positive HCV-RNA (22 patients) and patients with negative HCV-RNA (28 patients). None (0%) of the patient groups revealed HBV-DNA in serum by PCR method despite the HCV-RNA positive group has been studied twice in different times. Contrary to the above-mentioned similar study, there is no increased incidence of occult HBV infection in patients with chronic haemodialysis with chronic hepatitis C in our region. In our study, 3 patients showed insulated anti-HBc IgG seropositivity and positive HCV-RNA (13.6%), and 1 patient showed negative HCV-RNA (3.5%). And the percentage of having at least one of the markers of past HBV infection was 89.9% (20 patients) in HCV-RNA positive group and 75% (21 patients) in HCV-RNA negative group. However, no increase was detected in occult HBV infection incidence in our sturdy.

The result of our study has to be evaluated in consideration of the interaction between the HBsAg positivity (8%-10%) for Diyarbakır region and the frequency of HBV mutants in this region. Besides, it has become necessary to review the sensitivity and specificities of still non-standardized HBV-DNA PCR methods and define a common method of diagnosis accordingly.

Abstract

AIM: To examine the relationship between cyclooxygenase-2 (COX-2) overexpression and p53 accumulation in gallbladder carcinoma and its precursor lesions.

METHODS: Sixty-eight gallbladder tissue samples comprising 14 cases of normal gallblader epithelium, 27 cases of dysplasia (11 low-grade dysplasia and 16 high-grade dysplasia) and 27 adenocarcinomas were evaluated by immunohistochemistry for COX-2 expression and p53 accumulation. The relationship among COX-2 expression, p53 accumulation and clinicopathological characteristics was analysed.

RESULTS: COX-2 was expressed in 14.3% of normal gallbladder epithelium, 70.3% of dysplastic epitehlium, and 59.2% of adenocarcinomas. When divided into low- and high-grade dysplasia, COX-2 was positive in 5 (45.4%) cases of low-grade and 14 (87.5%) of high-grade dysplasia (P = 0.019). Accumulation of p53 was detected in 5 (31.2%) cases of high-grade dysplasia and in 13 (48.1%) of carcinomas. No p53 accumulation was found in normal epithelium or low-grade dysplasia. COX-2 overexpression was observed in 17 of 18 (94.4%) cases with p53-accumulation in comparison with 20 (40.0%) out of 50 cases without p53 accumulation (P < 0.001).

CONCLUSION: The significant differences in COX-2 expression among normal epithelium, low-grade dysplasia and high-grade dysplasia suggest that overexpression of COX-2 enzyme is an early event in gallbladder carcinogenensis. Furthermore, since accumulation of p53 correlates with COX-2 expression, COX-2 overexpression observed in gallbladder high-grade dysplasia and carcinoma might be partly due to the dysfunction of p53.

INTRODUCTION

Gallbladder carcinoma is the fifth most common malignancy of the digestive tract. Recent molecular genetic studies have shown that selected proto-oncogenes and tumor-suppressor genes are involved in the development and progression of gallbladder carcinoma, and a different spectrum of molecular genetic changes appears to be responsible for each of the different preneoplastic conditions[1]. An association of gallbladder carcinoma with cholelithiasis or an anomalous arrangement of the pancreaticobiliary duct suggests that long-term inflammation may modulate tumorigenesis as well as the progression of this type of carcinoma[2,3]. Based on the histopathological examination of surgically resected gallbladder, an assumption has been made that epithelial changes found adjacent to invasive carcinomas in the gallbladder wall are premalignant and may progress to carcinoma. The rarity of most presumptive premalignant conditions has made it difficult to obtain better knowledge of the biological characteristics of precursor lesions of gallbladder carcinoma. At present, three major putative pathways of gallbladder carcinogenesis seem to be important: dysplasia, adenoma and anomalous pancreaticobiliary ductal junction. Roa[4] suggested that the period required to transform dysplasia into an advanced carcinoma is about 15 years. However, gallbladder carcinomas are usually diagnosed at an advanced stage, representing a challenge in the management because they respond poorly to therapy and are therefore associated

with a poor prognosis. A postoperative 5-year survival rate between 5% and 13% has recently been reported[5,6]. Since this type of cancer is so difficult to cure by surgery alone, new molecular targets are needed for its prevention and treatment.

Prostaglandins (PGs), a family of lipid-derived autocrine and paracrine mediators, can favor tumorigenesis by altering cell proliferation, differentiation and adhesion, such as by modulating vascular response and immune surveillance. PGs are derived from arachidonic acid. The key step in the conversion of free arachidonic acid to PG is catalysed by the cyclooxygenase enzyme (COX)[7]. Three isoforms of COX (COX-1, COX-2 and COX-3) have been identified. While COX-1 is constitutively expressed as a housekeeping gene in most cells, COX-2 is not detected in normal tissues, except in kidney, liver and pancreatic islands, although it is expressed as an early response to many stimuli, such as inflammatory cytokines, growth factors and oncogens[8]. There is only little information about the recently identified COX-3 isoform. PGs have been shown to mediate gallbladder inflammatory response, since non-steroidal anti-inflammatory drugs (NSAIDs) have been proved to decrease gallbladder inflammation[9]. Accumulating evidences suggest that increased PGs levels via overexpression of the inducible COX-2 isoform are important in the development of human cancer[10]. Though increased levels of PGs and COX-2 expression have frequently been found in malignant growths of the digestive tract (colon, stomach, oesophageal cancer) similar data about biliary tumors are rare[11,12].

Point mutations or deletions of the p53 gene are observed in approximately 50% of cancers. Wild-type p53 is a key molecule in the cellular DNA damage response, causing restriction of cell proliferation by inducing cell cycle arrest and apoptosis. The product of mutant p53 has often been found to be a stable protein with a long half-life, while wild-type p53 has a short half-life and is not generally accumulated to a sufficient high level to be detectable by standard immunohistochemistry. An increase in the p53 protein level can therefore be used as an indication of p53 mutation, although there are still some discrepancies[13]. Immunohistochemically, p53 accumulation was detected in 36%-67.8% of gallbladder carcinomas[14-15]. In gallbladder carcinogenesis, an accumulation of p53 protein was reported in association with premalignant transition to malignancy[16]. p53 and COX-2 are thus two important molecules intimately linked to tumorigenesis. COX-2 has been implicated in positive regulation of growth and tumorigenesis, while the tumor suppressor p53 is a negative regulator of these processes. However, there is evidence of COX-2 expression normally suppressed by wild-type p53, suggesting that loss of p53 function may influence COX-2 overexpression[17]. Conversely, COX-2 can in turn inhibit p53-dependent transcription[18].

The purpose of this study was to evaluate the relationship and potential role of COX-2 and p53 in gallbladder carcinogenesis. Immunohistochemically, we analysed the expression profile of COX-2 in gallbladder dysplasia and carcinoma and its correlation with p53 protein accumulation.

MATERIALS AND METHODS

Subjects

A retrospective analysis was performed on 68 gallbladder tissue specimens, including 14 normal epithelium, 11 low-grade dysplasia, 16 high-grade dysplasia and 27 adenocarcinomas, obtained from patients treated with cholecystectomy in the period from 1998 to 2000. No patient had a history of regular ingestion of selected drugs such as NSAIDs or COX-2 inhibitors. We studied 14 cases of normal gallbladder epithelium without dysplastic and/or carcinomatous epithelial changes and 11 with low-grade dysplasia from elective cholecystectomy because of gallstones. In addition, 16 samples of high-grade dysplasia and 27 adenocarcinoma samples were obtained from patients who underwent cholecystectomy due to gallbladder adenocarcinoma. Dysplasia was defined histologically by varying degrees of pseudostratification, nuclear atypias, loss of polarity, and mitotic figures. Depending on the severity of changes, dysplasia was divided into low- and high-grade types. Adenocarcinomas were graded according to the World Health Organisation classification of gallbladder tumors[19]. There were 8 well differentiated, 4 moderately differentiated and 15 poorly differentiated adenocarcinomas.

Methods

COX-2 and p53 expression were investigated by immunohistochemistry. Formalin-fixed, paraffin embedded specimens were sectioned in series at a thickness of 5 μm. After deparafinisation, the slides were immersed for 30 min in 0.3% hydrogen peroxide/methanol to deplete endogenous peroxidase. Antigen retrieval was achieved using the pressure-cooking method for 4 min in citrate buffer (pH = 6.0). For COX-2 expression, polyclonal anti-human COX-2 antibody (Cayman Chemical Company, Ann Arbor, MI, USA) was used in a dilution of 1:500. For p53 analysis, monoclonal mouse anti-human p53 antibody, DO-7 (DAKO, Glostrup, Denmark) diluted at 1:100 was used. After the application of primary antibodies, the specimens were treated with biotinylated secondary antibody for 30 min. Antigen visualisation was achieved by applying a standard streptavidin-biotin complex (ABC, DAKO, Denmark) for 30 min followed by diaminobenzidin chromogen (DAB, Sigma Chemical CO, Germany) in 0.1% H_2O_2 PBS solution. The specimens were counterstained with haematoxylin. The specificity of the applied antibodies was checked with positive or negative controls. Specimens treated without primary antibodies served as negative controls. For positive controls of p53, specimens of human colon carcinoma with known p53 immunoreactivity were processed in the same way as the gallbladder samples. Vascular endothelial cells and fibroblasts observed in all gallbladder specimens provided internal positive controls for COX-2 staining.

Immunostaining was independently evaluated by two investigators (AC and ML) and a consensus agreement was achieved. COX-2 expression was evaluated according to the percentage of positive cells and the intensity of staining. The percentage of positive cells was scored as 0

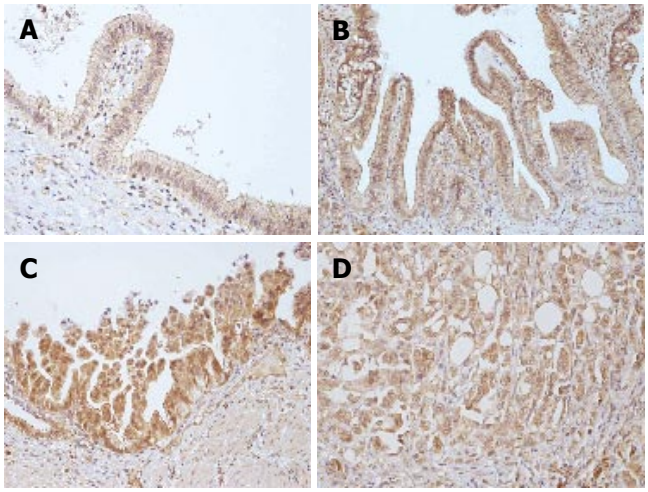

Figure 1 COX-2 expression. **A:** Normal gallbladder epithelium; **B:** Low-grade dysplasia; **C:** High-grade dysplasia; **D:** Gallbladder adenocarcinoma.

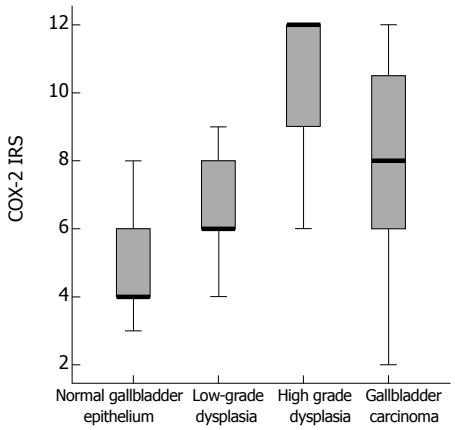

Figure 2 COX-2 – IRS index.

(0%), 1 (< 10%), 2 (10-50%), 3 (51%-80%) or 4 (> 80%). The staining intensity was scored as 0 (negative), 1 (weak), 2 (moderate) or 3 (strong). For immunoreactive score (IRS), the percentage of positive cells and the staining intensity were multiplied, resulting in a value between 0 and 12. To separate tumors with weak from those with strong COX-2 expression and to define a cut-off point that might be reproducible for future studies, we united samples with an IRS of 0-6 into one group with negative to weak COX-2 expression (the COX-2 negative group) and those with an IRS of 7-12 (the COX-2 positive group). The minimum requirement for positive IRS was therefore either moderate expression in > 80% of cells or strong expression in > 50% of cells. The expression of p53 was evaluated according to the percentage of positive cell nuclei. The reaction to p53 was considered positive when at least 20% of the nuclei in tumor cells were stained.

Statistical analysis

SPSS 11.0 for Windows (SPSS Inc., Chicago IL) was used. Chi-square tests were used to analyse the correlation between COX-2 overexpression and p53 accumulation and pathological features. The relationship between COX-2 and p53 expression was evaluated by the Mann-Whitney U-test. $P < 0.05$ was considered statistically significant.

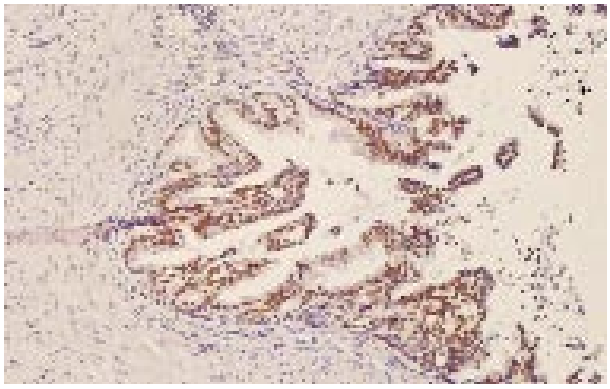

Figure 3 Accumulation of p53 in nuclei of high-grade gallbladder dysplasia.

RESULTS

Surgical specimens of the gallbladder were obtained from 68 patients who had undergone cholecystectomy for clinical chronic cholecystitis or cholelithiasis (n = 51) and primary gallbladder carcinoma (n = 27). There were 43 female and 25 male patients, the median age of patients was 59 years (range from 36 to 78 years). The expression of COX-2 and p53 was analysed by immnohistochemistry in 14 cases of normal gallbladder epithelium, 27 cases of dysplasia and 27 adenocarcinomas. The cytoplasm of gallbladder epithelial cells was stained for COX-2 to various degrees (Figure 1). Additionally, COX-2 immunoreactivity was observed in fibroblasts, endothelial cells, and smooth muscle cells in all specimens. Normal gallbladder epithelium was COX-2 positive (according to the cut-off criteria of the IRS index) in only 2 (14.3%) cases. Of 27 cases of dysplasia, 19 (70.3 %) were COX-2 positive. When we divided this group into low- and high-grade dysplasia, COX-2 was positive in 5 (45.4%) cases of low-grade dysplasia and 14 (87.5%) cases of high-grade dysplasia (P = 0.019). The differences between normal epithelium and low-grade dysplasia were not statistically significant (P = 0.085). COX-2 was positive in 16 (59.2%) of 27 carcinomas.

The greatest positivity for COX-2 was in poorly differentiated carcinomas (73.3%). The differences between high-grade dysplasia and carcinoma were not statistically significant (P = 0.113). COX-2-IRS values detected in normal gallbladder epithelium, dysplasia and carcinoma are shown in Figure 2.

p53 was negative in normal gallbladder epithelium and low-grade dysplasia,. Accumulation of p53 protein was identified in the nuclei of 5 (31.2%) cases of high-grade dysplasia (Figure 3) and 13 (48.1%) carcinomas. Accumulation of p53 protein was the highest (80%) in poorly differentiated gallbladder carcinoma. In the whole spectrum of 68 tissue samples, we found only one COX-2 negative case among 18 p53 positive cases. Of 50 p53 negative cases, 30 (60 %) cases were COX-2 negative ($P < 0.01$).

DISCUSSION

Our analysis of COX-2 and p53 expression in normal, dysplastic (premalignant) and malignant gallbladder epithelium is an attempt to reveal a possible relationship between the two molecules, as well as their role in

gallbladder carcinogenesis. The role of COX enzymes in the process of carcinogenesis has been dramatically emphasized by confirmation that NSAIDs decrease the number of colonic polyps in humans with adenomatous polyposis and lower the incidence of colorectal cancer[20]. Gallbladder cancer has several analogous characteristics with this type of neoplasia. It is preceeded by a lengthy precancerous process taking several years. This process is characterized by chronic inflammation, lithyasis, intestinal metaplasia, and dysplasia in the epithelium of the surrounding mucosa[4]. We observed overexpression of COX-2 in 14 (87.5%) of 16 gallbladder high-grade dysplastic tissues in comparison to 5 out of 11 (45.4%) low-grade dysplasia and 2 (14.3%) of 14 normal gallbladder epithelium. Some slight COX-2 immunoreactivity in normal gallbladder epithelium was not unexpected and could be explained by the well-established connection between COX-2 expression and inflammation[20]. In carcinomas, COX-2 overexpression was found in 16 (59.2%) of 27 gallbladder samples. Our results are consistent with studies by Asano *et al*[11] and Zhi *et al*[21], who found 67.3% and 71.9% gallbladder tumour samples with COX-2 overexpression, respectively. Recently, Tsuchida[3] reported that COX-2 inhibitor meloxicam suppresses carcinogenesis in the gallbladder in an animal model. Our observation that COX-2 overexpression was highest in high-grade dysplasia supports the hypothesis of the role of COX-2 in early carcinogenesis. Liang[22] first suggested that COX-2 expression might be involved in the early proliferative phase but not in the late metastatic phase of the evolution of colorectal cancer. Our study is in agreement with Luzar[23] , who distinguished three histological degrees of gallbladder epithelial changes according to the number of hTERT signals: a) normal and regenerative gallbladder mucosa, b) low-grade dysplasia and c) high-grade dysplasia and adenocarcinoma of the gallbladder. We found no statistical differences in our study in COX-2 expression between normal gallbladder epithelium and low-grade dysplasia ($P = 0.085$), probably due to COX-2 expressed in normal mucosa on account of inflammation. However, the differences were significant between low-grade and high-grade dysplasia. No direct data are yet available about the progression rate of high-grade dysplasia to invasive carcinoma of the gallbladder. For comparison, high-grade dysplasia in the stomach was detected to regress in only 5% of cases, persisted in 14%, and progressed in 81%-85%[24] .

In high-grade dysplasia, p53 protein accumulation was found in 5 (31.2%) cases. Low-grade dysplastic and normal epithelium was p53 negative. Thirteen (48.1%) of 27 carcinomas were p53 positive. The clone against which the p53 antibody was raised (DO-7) results from the recognition of wild type and mutated protein. However, p53 detection was not expected in normal cells. The appearance of a nuclear accumulation of p53 protein might arise from mutation of the protein itself, resulting in failure of its degradation pathway or a mutation of the human mouse double minute (hMDM)-ubiquitin pathway, resulting from the failure of degradation. Accumulation of the wild-type p53 protein owing to a failure of degradation might push the cell into cell cycle arrest and apoptosis. Such cells would occur rather sparsely in tumors because they could not proliferate as malignant clones. It therefore seems very likely that the accumulation of p53 in dysplastic and malignant gallbladder epithelium resulted from p53 mutation[25]. Our results are consistent with some previous reports about p53 gene mutations involved in the carcinogenesis of the gallbladder epithelium[26-27] that p53 overexpression appeard in only 84.6% of gallbladder carcinomas and in 18.7% of patients without carcinoma. Matsubara[28] detected p53 gene mutation in 38.5% of noncancerous biliary epithelial lesions and in 57.1% of adenocarcinomas.

Data about the inter-relationship between p53 and COX-2 are conflicting. Our results are consistent with studies of Shigemasa[29] and Erkinheimo[30]. In both their studies, performed on ovarian carcinoma, a significant positive correlation was found between COX-2 expression and p53 accumulation. The same correlation was accepted in a study of head and neck tumors[31], suggesting that restoration of wild-type p53 expression might interfere with tumour growth by inhibiting the COX-2 pathway. In endometrial carcinoma[32] and colon carcinoma[22], higher COX-2 expression was also associated with p53 accumulation. In contrast, Cho[33] observed no association between COX-2 overexpression and p53 accumulation in renal cell carcinoma. Subbaramaiah[34] demonstrated that wild-type p53 suppressed COX-2 expression by inhibiting its promotor activity. The level of COX-2 protein and mRNA was found markedly decreased in cells expressing wild-type, but not mutant p53[35]. A study of head and neck carcinoma cell lines[36] confirmed that wild-type p53 overexpression has some anti-tumor effects through the suppression of COX-2 gene activity. However, Swamy[18] reported that COX-2 at least in part contributes to the dysfunction of p53 and that celecoxib, a COX-2 selective inhibitor, protects p53 functional activity.

In conclusion, our study is the first to analyse the relationship of COX-2 expression and p53 accumulation in various histological stages of gallbladder epithelial abnormalities and gallbladder adenocarcinoma. Our results suggest that COX-2 might play an important role in gallbladder carcinogenesis. Overexpression of COX-2 appears to be an early event in gallbladder carcinogenesis, already occurring at the stage of preneoplastic epithelial changes (e.g. high-grade dysplasia) and may be, at least in part, related to p53 dysfunction.

Abstract

AIM: To determine the GI of some cereals and tubers produced in China in an effort to establish the database of glycemic index (GI) of Chinese food.

METHODS: Food containing 50 g carbohydrate was consumed by 8-12 healthy adults after they have been fasted for 10 h and blood glucose was monitored for 2 h. Glucose was used as reference food. GI of food was calculated according to a standard method.

RESULTS: GI of 9 types of sugar and 60 kinds of food were determined.

CONCLUSION: Food GI is mainly determined by nature of carbohydrate and procession. Most of cereals and tubers produced in China have similar GI with their counterparts produced in other countries.

INTRODUCTION

GI is a useful index initially coined by Jenkins[1] *et al* to describe the extent to which certain food can increase the blood glucose in human. It is an accurate determination of change of blood glucose after consumption, digestion and absorption of certain food. GIs of 60 kinds of food were determined and reported by Jenkins in 1981. Since then, GI of local foods have been reported by Miller and other scientists[2,3]. Up to date, GI of about 2000 foods have been determined and reported around the world.

The study of GI was limited to clinic research and dietary treatment of diabetes in the early stage of GI study. Since the late 1990s, more and more attention has been paid to the application of GI in body weight maintenance and chronic disease controlling and positive links have been established between diet GI and some pathological conditions such as obesity[4], heart disease[5], diabetes[6].

China is an Asian country with more than thirteen billion people of 56 nationalities and various eating habits and foods. With the rapid development of economy, lifestyle of Chinese people is changing also and a cluster of chronic diseases are emerging, some of which have become health threat of the people as seen in the western countries. Therefore, links between dietary habits and chronic diseases should be investigated and strategies should be developed for the prevention, as well as treatment of such diseases. It is urgent and necessary for us to determine the GI values of Chinese foods. The current study was designed to determine the GI of about 150 types of cereals and tubers by a standard method.

MATERIALS AND METHODS

Subjects

Healthy volunteers (aged 20-45 years, BMI in kg/m^2 range 18.5-25) from Beijing (north China), Chengdu (southwest China), Liaoyang (northeast China) and Yinchuan (northwest China) were involved in the study. All subjects were free from obesity, diabetes and other metabolic diseases and postmenopausal women were excluded. All subjects gave their written informed consent and ethical approval for the study was obtained from the Ethical Committee of Chinese Centers for Disease Control and Prevention.

Test foods: All the foods used in this study were purchased from local supermarket and raw foods were cooked by traditional method used in daily-life of

Chinese. The carbohydrate (CHO) content of the test food was calculated based on food composition data of China according to the following formula: weight of test food = 50/CHO proportion of test food. In cases when CHO content of test food was less than 10%, food weight used to determine its GI was reduced to 25 g. Each food was tested in 10-12 volunteers.

Methods

Oral glucose tolerance test (OGTT): About 10-12 volunteers received OGTT each time. After fasting for 10 h, volunteers were required to arrive at the laboratory at 8 o'clock in the morning. Venous blood samples were obtained before and 15, 30, 45, 60, 90, 120 min after consumption of 50 g glucose dissolved in 200 mL drinking water. Blood was collected into a syringe with sodium fluoride.

Test of glucose response of food: Volunteers with normal glucose tolerance were allowed to receive the glucose response test two days later. When volunteers fasted for 10 h arrived at the laboratory, venous blood samples were collected before and 15, 30, 45, 60, 90, 120 min after consumption of food containing 50 g carbohydrate. For each sample, blood glucose was determined. Each test was repeated and each group of volunteers received no more than tests of three foods. Between tests, at least two days was required for wash-out.

Determination of blood glucose: Calculation of GI: Glucose (GI = 100) was used as reference. The calculation was based on the method developed by Wolever[7]: GI = [(area under the 2-h blood glucose curve for food)/(area under the 2-h blood glucose curve for the same amount of glucose)]× 100

Statistical analysis

The values of GI were expressed as mean ± SD. Dixon test was used to evaluate differences between values of the same group. $P = 0.05$ was selected as level of significance.

RESULTS

Nine sugars were selected as test foods. When glucose was used as the reference (GI of glucose: 100), the GI rank of these sugars from high to low was maltose > white sugar > honey > sucrose > lactose > fructose (Table 1). The GI values of maltose of different source were not equal, which maybe was resulted from procession and the difference of purity.

GI of cereals

Cereals refer to a variety of foods rich in carbohydrate, including traditional starchy food such as steamed bread and noodle, and food processed by modern technology such as breakfast cereals and some instant foods. The significant difference of GI of different cereal foods suggested that food procession and food type were factors influencing the value of GI (Table 2).

GI of some tubers

Tubers also include various types of foods, of which potato, yam, taro and lotus are commonly eaten by Chinese people. Their GI values are shown in Table 3.

Table 1 Glycemic index of some sugars (mean ± SD)

Name	*n*	GI
Glucose	10	65.0 ± 6.3
Fructose	10	23.0 ± 4.6
Lactose	10	46.0 ± 3.2
Chocolate	10	49.0 ± 8.0
Maltose	10	105.0 ± 5.7
Maltose 2	10	75.0 ± 20.3
White sugar	10	83.8 ± 12.1
Honey	10	73.5 ± 13.3

DISCUSSION

Carbohydrate is a major source of energy of human being. Nutrition surveillance in China shows that carbohydrate intake is 360 g/d, which provides 60%-70% of total energy of a person. Cereals and food produced from cereals account for 90% of total dietary carbohydrate. It is obvious that cereals are critical for the health of Chinese.

Because people have realized that overtake of fat is associated with a cluster of chronic diseases, increasing the intake of carbohydrate has been the major concern of nutritionists in dietary recommendation. But controversies still remain as to how and what kind of carbohydrate should be increased in diet.

Food GI is a quantitative physiological parameter used to describe the relative glycemic effect of carbohydrate-containing food compared with reference food (glucose or white bread)[8]. After ingestion, all the digestible carbohydrates are conversed to monosaccharide and absorbed in the intestine, then blood glucose is increased and satiety is ensured. Insulin and other hormones secretion is induced by the increased blood glucose and blood glucose level is then reduced toward the basic level, thus homeostasis is maintained. Avoiding dramatic fluctuation of blood glucose is critical to both the healthy and the diabetic persons. A lower postprandial blood glucose peak and slower decreasing rate are seen after intake of low GI food compared with high GI food. It is evident that carbohydrate content of one food does not always reflect its availability. GI provides a new method for the nutritional evaluation of food.

Food is categorized into three groups according to their GI[8], food with GI < 55 is called low GI food, and high GI food means food with GI >75, food with GI ranging between 55-75 is called medium GI food. Consumption of low GI food will ensure a longer lasting satiety and keep more stable blood glucose, at the same time overtake can be avoided easily compared with consumption of high GI food. High GI food is not good for diabetes and people with impaired glucose tolerance.

GI is a concept comprehensively reflecting the digestibility and utility of food. Factors affecting the GI of food such as composition, content, and type of carbohydrate, physical character and procession are all taken into account in this concept[9,10]. Our results showed that different types of carbohydrate have different

Table 2 Glycemic index of cereal products (mean ± SD)

Food name	*n*	GI	Food name	*n*	GI
Cooked rice	12	83.2 ± 3.1	Steamed bread (refined)	9	88.1 ± 20.2
Brown rice (cooked)	10	87.0 ± 5.0	Wheat pancake	10	79.6 ± 11.5
Sticky rice (cooked)	10	87.0 ± 7.0	Wheat dough, deep-fried	8	74.9 ± 21.0
Sticky rice2 (cooked)	9	88.0 ± 5.6	Bread (refined wheat)	10	87.9 ± 10.2
Sticky rice (higher amylose)	10	50.0 ± 6.0	Bread (whole wheat)	10	69.0 ± 10.4
Rice porridge	10	69.4 ± 18.5	Bread (whole wheat with dried fruit)	10	47.0 ± 7.0
Sticky rice porridge	9	65.3 ± 20.6	Wheat Noodle(dried)	10	46.0 ± 5.8
Black rice porridge	9	42.3 ± 9.0	Wheat Noodle(fresh)	8	81.6 ± 19.1
Rice bran porridge	9	19.0 ± 3.0	Dumpling (shallot + meat)	10	28.0 ± 9.9
			Steamed stuffed bun (shallot + meat)	10	39.1 ± 13.0
Rice cake	8	82.0 ± 7.2	Biscuit (thin)	9	81.0 ± 7.5
Instant rice (in hot water 3 min)	10	46.0 ± 8.5	Biscuit	9	72.0 ± 15.5
Instant rice (cooked 6 min)	10	87.0 ± 5.5	Danone biscuit 1	9	47.1 ± 12.4
Corn powder porridge	10	68.0 ± 10.6	Danone biscuit 2	9	39.3 ± 11.8
Corn granule	10	51.8 ± 9.2	Cake crisp	10	59.0 ± 6.0
Corn flake	9	78.5 ± 12.2	Powder (buckwheat)	8	54.0 ± 3.0
Corn flake 2	9	74.0 ± 10.0	Noodle (buckwheat)	9	59.3 ± 3.0
Oatmeal (unpackaged)	9	55.0 ± 6.1	Bread (buckwheat)	8	66.7 ± 6.0
Oatmeal	8	83.0 ± 18.7	Instant noodle (buckwheat)	8	53.2 ± 5.0
Porridge (instant)	8	69.4 ± 7.2	Millet porridge	8	61.5 ± 9.0
Popcorn	6	55.0 ± 2.0	Powder (various cereals)	9	57.9 ± 3.5
Sweet corn (cooked)	10	55.0 ± 5.0	Whole wheat powder	10	42.0 ± 7.5
Oat biscuit	10	55.0 ± 2.5	Nutritional pancake	8	65.7 ± 5.3
Barley flake	7	69.0 ± 7.3	Biscuit	7	70.0 ± 8.3
Rice (S+R) porridge	9	65.5 ± 16.0	WoTao (Corn+wheat)	10	64.9 ± 16.5

influence on blood glucose. For example, rice rich in amylopectin has high absorption rate and consequently high blood glucose because digestive enzyme can easily reach the structure of starch chain. The opposite is true as to the amylose. Possible explanation for GI difference of different food is: first, food rich in dietary fiber, resistant starch or other indigestible carbohydrate has stronger resistance to digestive enzymes and its digestion and absorption in the intestine is slow and incomplete. Under this kind of conditions, low blood glucose is seen. Second, physical properties of food such as the size of granule and maturity are factors determining GI. Third, time and temperature in procession have significant effect on food GI as seen in the case of potato and vermicelli. It is also obvious that procession is a crucial factor in determining food GI as demonstrated by GI values of different corn, rice, potato and wheat products.

Table 3 Glycemic index of tubers (mean ± SD)

Food	*n*	GI
Potato (cooked)	10	66.4 ± 3.8
Potato (steam)	10	62.0 ± 5.7
Potato crisp (oil fry)	10	60.3 ± 7.0
Potato noodle (with meat)	9	16.7 ± 10.4
Cake (Cushawand potato)	8	108.0 ± 13.4
Yam (steam)	10	51.0 ± 12.0
Yam (cooked)	10	54.0 ± 5.5
Potato mashed	10	73.0 ± 9.2
Potato noodle	9	13.6 ± 2.1
Sweet potato (red, cooked)	8	76.7 ± 12.3
Taro (cooked)	7	47.7 ± 12.7
Pill potato+yam powder	9	34.5 ± 11.7
Lotus root powder	8	32.6 ± 17.0

In accordance with literatures, we found that GI of sucrose is not so high as and the GI of starch is not so low as predicted. The GI of sucrose is lower than expected because sucrose is disaccharide consisting of glucose and fructose which is absorbed and directly transferred to the liver where it is ultimately transformed into glucose and therefore has a lower GI (GI = 23). About half of all the sucrose we ingest is glucose, and fructose accounts for another half. Refined sugar is used in most of processed foods which has a GI of about 60, which is the mean of glucose GI and fructose GI. The GI of starchy foods depends on the rate at which the food can be absorbed and transferred into the blood, and the extent to which the food can raise the concentration of blood glucose. The GI of food with rapid digestibility is usually high. Compared with GI data of other countries, we found that GI of foods produced in China has similar GI to that of counterpart foods produced abroad with the exception of maltose, honey and white sugar. In the present study we found that maltose from different source shows different GI (105 *vs* 75); the GI of honey (67) and white sugar (83) are higher than that published by other authors (GI of honey and white sugar were 58 and 70, respectively). The explanation for this discrepancy is the difference of procession and origin of food. For example, maybe honey and white sugar were supplemented with glucose syrup.

Food of low GI often implies lower utilizable energy. In practice, control of quantity of total energy remains a primary concern in dietary prevention and treatment of obesitic diabetes. GI has been proved a useful and simple concept in food selection, diets arrangement and dietary regulation of blood glucose. GI is not only useful in the dietary treatment of diabetes, hypertension patients and obesity, but also can be applied to dietary

management of athletes, food procession and study of relationship between dietary intake and chronic disease[11]. Establishment of GI values of Chinese foods is the first step of GI study in China. More studies should be conducted in this field.

Abstract

AIM: To evaluate the efficacy of interruption of intrauterine infection of HBV with HBIG in pregnant women with positive HBeAg and HBsAg.

METHODS: A prospective randomized controlled trial was adopted. Sixty cases with positive HBeAg and HBsAg were coincident with the criteria of inclusion, and 8 cases were excluded. Fifty-two cases were analyzed (28 cases in trial group and 24 in control group). All cases in trial group received 200 IU HBIG intravenously every 4 wk for 3 times from the 28th wk. The cases of control group received placebo in the same way. All pregnant women were detected for HBeAg and HBV-DNA at the beginning of the trial and end of the trial (delivery). The cord blood of all newborns were collected for detecting HBeAg and HBV-DNA simultaneously.

RESULTS: For investigation of HBeAg of newborns in trial group, 6 of 28 cases of newborns had positive HBeAg, the HBeAg positive rate being 21.4%, the total rate of 95% CI being 8%-41%. In control group, 19 of 24 cases of newborns had positive HBeAg, HBeAg positive rate was 79.2%, the rate of 95%CI being 5%-93%. By statistical analysis, χ^2 = 17.26, P < 0.01, RR = 0.27, 95% CI (6.3 × 10^{-6}, 8.6 × 10^{-5}). For investigation of HBV-DNA of newborns in trial group, 7 of 28 cases of newborns had positive HBV-DNA, HBV-DNA positive rate being 25%, the total rate of 95% CI being 11%-45%. In control group, 20 of 24 cases of newborns had positive HBV-DNA, HBV-DNA positive rate was 83.3%, the total rate of 95% CI being 63%-95%. By statistical analysis, χ^2 = 17.62, P < 0.01, RR = 0.30, 95% CI (1.5 × 10^{-5}, 1.7 × 10^{-4}). The results indicated that there was significant difference in HBeAg positive rate and HBV-DNA positive rate of newborns between the two groups. In trial group, 7 of 28 newborns had HBV-DNA positive, but the HBV-DNA load of newborns was lower than that of their mothers. In control group, 20 of 24 newborns still had HBV-DNA positive, and the HBV-DNA load of newborns was close to those of their mothers. Statistical analysis indicated that there was no significant difference in HBV-DNA load between postnatal women without HBIG intervention and their filial generations (T = 81.5, P > 0.1).

CONCLUSION: It is effective and safe to prevent intrauterine infection of HBV with HBIG from the 28th wk in pregnant women with positive HBeAg and HBsAg. In clinical application, those pregnant women with negative HBeAg and positive HBV-DNA also need to be interrupted by HBIG.

INTRODUCTION

Hepatitis B virus(HBV) is highly endemic in China. It has been estimated that there are more than 1.2 million of chronic carriers of HBV nationwide. Most of them are infected by mother-infant transmission. Mother-infant infection of HBV can result in chronic HBV carrier state, chronic hepatitis, cirrhosis, hepatecellular carcinoma and the cycling of mother-infant transmission. So to prevent mother-infant transmission is a key strategy to control hepatitis B prevalence in our country. For a long time, it has been successful to vaccinate the infants of HBV positive mother with hepatitis B vaccine or both with hepatitis B immune globulin (HBIG) after birth. However, 10%-20% of the infants have no response to vaccination[1]. The main reason of failing to immunization is intrauterine

infection of HBV. Therefore, it will be meaningful to interrupt the intrauterine infection of HBV. In this study, we try to explore the effects of interruption of intrauterine infection of HBV with HBIG in pregnant women with positive HBeAg. It will be reported as follows.

MATERIALS AND METHODS

Design of clinical trial

A prospective randomized controlled trial was adopted. Trial group and control group were determined by randomized number table. The study (from January. 1997 to May, 2002) were undertaken by 4 sub-centres, including the First Affiliated Hospital, Xinjiang Medical University, Urumqi Military General Hospital; Maternal and Children' s hospital; Xinjiang Jian Gong Hospital. According to the estimation of sample number, 30 cases were included in each group. With regard to the missing of follow-up, we started the clinical trial based on 40 cases in each group.

Subjects

The criteria for inclusion and exclusion were determined before starting the trial. The criteria for inclusion: the pregnant women given pre-labor checkups at obstetric clinic of above hospitals, with positive HBeAg and better general condition, without threatened abortion or threatened premature labor, and hypertension, with normal liver function, and to deliver at the same hospital. The criteria for exclusion: to stop pregnancy for some reasons, to deliver at other hospitals and lose follow-up, and to be administered HBIG not according the regulation.

Sixty cases of pregnant women were coincident with the criteria for inclusion, but 8 cases were excluded, including , 3 cases who stopped pregnancy; 2 cases who transferred to other hospitals; 2 cases who lost to follow-up for unknown reasons and 1 case who used HBIG not according the regulation. So at last, 52 cases were analyzed, including 28 cases in trial group and 24 cases in control group. There was no significant difference about pregnant age, parity, fetal age, delivery mode and median of HBV-DNA (respectively 4.3×10^8 and 3.98×10^8 copy/mL) between those two groups. There was no history of fetal distress in all newborns of the two groups. Fifty-two pregnant women with positive HBeAg labored 52 newborns. No side effects were observed in trial group.

Methods of treatment

All cases in trial group received 200 IU HBIG intravenously every 4 wk for 3 times (28 wk, 32 wk, 36 wk). And side effects were observed. The cases of control group were followed up for checkups, without any treatment.

HBeAg and HBV-DNA test

All pregnant women were detected for HBeAg and HBV-DNA at the beginning of the trial and the labor day. The cord blood of all newborns were collected, separated for serum and stored at -20℃ for detecting HBeAg and HBV-DNA simultaneously. HBeAg was tested by ELISA (commercial kit from Huamei Biotechnology Company, No 20020605), HBV-DNA was tested by FQ-PCR (commercial kit from Da`an Biotechnology Company, No.s19990003). The procedures of detection were performed according to the instruction of the manufacturers.

Table 1 Comparision of cord blood: HBeAg and HBV-DNA positive rate

Groups	cases	HBeAg(+)		HBV- DNA(+)	
	n	*n*	%	*n*	%
Trial	28	6	21.4	7	25
Control	24	19	79.2	20	83.3

Table 2 HBV-DNA levels in 7 mother-infant pairs in trial group (gene copy/mL)

Pair No.	Pregnant women	Filial generation
1	1.16×10^8	1.88×10^5
2	4.45×10^8	2.84×10^4
3	2.74×10^8	1.83×10^5
4	4.78×10^7	3.56×10^5
5	1.53×10^8	2.66×10^5
6	3.94×10^8	2.92×10^4
7	2.28×10^8	1.68×10^5

Statistical analysis

Relative risk (RR) and 95% CI were calculated, χ^2 test was used to compare the difference of qualitative data, Wilcoxon matched rank test was used to compare the difference of HBV-DNA load.

RESULTS

In trial group, 6 of 28 cases of newborns had positive HBeAg (Table 1). HBeAg positive rate was 21.4%, the total rate of 95% CI being 8% and 41%. In control group, 19 of 24 cases of newborns with HBeAg positive (Table 1), HBeAg positive rate was 79.2%, the rate of 95%CI being 5% and 93%. By statistical analysis, $\chi^2 = 17.26$, $P < 0.01$, RR = 0.27, 95% CI: 6.3×10^{-6} and 8.6×10^{-5}. The results indicated that there was significant difference in HBeAg positive rate of newborns between the two groups. The risk of intrauterine transmission could be reduced by immunoprophylaxis with HBIG. In trial group, 7 of 28 cases of newborns had positive HBV-DNA (Table 1), HBV-DNA positive rate was 25%, the total rate of 95% CI being (11%, 45%), In control group, 20 of 24 cases of newborns had positive HBV-DNA, (Table 1), HBV-DNA positive rate was 83.3%, the total rate of 95% CI being 63% and 95%. By statistical analysis, $\chi^2 = 17.62$, $P < 0.01$, RR = 0.30, 95% CI 1.5×10^{-5} and 1.7×10^{-4}. It indicated that there was significant difference in HBV-DNA positive rate of newborns between the two groups. It was effective to decrease the HBV-DNA load of pregnant women with HBV-DNA positive by application of HBIG.

In 28 cases of postnatal women with HBIG intervention, 21 cases of newborns had negative HBV-DNA, 7 cases had HBV-DNA positive, but the HBV-DNA

load was lower than that of their mothers (Table 2). By Wilcoxon matched rank test (T = 28, $P = 0.02$), it indicated that the HBV-DNA levels of filial generation decreased after intervention with HBIG. In control group, only 4 of 24 cases with negative HBV-DNA, the others were still HBV-DNA positive, and the HBV-DNA load was close to those of their mothers. By Wilcoxcon matched rank test (T = 81.5, $P > 0.1$), it indicated that there was no significant difference in HBV-DNA load between postnatal women without HBIG intervention and their filial generations.

DISCUSSION

The prevention of HBV infection by vaccinating newborns has been previously demonstrated to be extremely efficacious. However, some newborns fail to respond to immunization[2]. Intrauterine infection is regarded as the main reason of failure. It has been reported that the rate of intrauterine infection is up to 10%-44%[3]. It shows that intrauterine infection plays an important role in mother-infant transmission of HBV. The intrauterine infection may occur as early as on the 19th wk of pregnancy, but the main time is possibly in the third-trimester of pregnancy[4]. Recently more and more researchers are trying to interrupt the intrauterine infection by intervention. HBIG is a common method to prevent HBV transmission from mother to baby[5,6].

The mechanism of intrauterine infection of HBV has been studied by some researchers[7,8], the findings proved that the main route of HBV transmission from mother to fetus is transplacental. HBIG is an antibody of IgG type. The nourish cells with Fc recepter in placenta can transmit the IgG antibody from mother to infant since the 20 wk during pregnancy. In one study[9], HBIG was injected frequently to pregnant women with positive HBeAg starting from the 20th wk during pregnancy, the positive rate of anti-HBs of newborns was up to 91.42% and no side effect and birth defect were observed in both mothers and newborns. The result showed that anti-HBs can get into the body of infants via placenta after using HBIG during pregnancy. That is to say the mechanism of preventing intrauterine infection of HBV by HBIG is production of fetal passive immunity[9].

This study is a randomized controlled trial to interrupt intrauterine transmission of HBV by HBIG in pregnant women with positive HBeAg. The results showed that it was effective to waken the effectiveness of mother-infant transmission of HBV after using HBIG frequently. In trial group, a few newborns were still HBeAg positive , but the HBV-DNA load had decreased obviously. It was likely the result of application of HBIG before labor. We presume that HBV-DNA load may decrease further if we keep on using HBIG and hepatitis B vaccine to those newborns with positive HBeAg. This deserves to study in the future. No side effect was found in both mothers and babies during the clinical trial.

Why were there still 7 cases of newborns with HBeAg positive in trial group, in our opinion., one of reasons was that cord serum used for HBeAg test was not better than vein serum, because cord serum is easy to be contaminated by the blood of mother with positive HBeAg. Another reason may be the high load of HBV-DNA in serum of these 7 mothers.

How to improve the effects of interruption of intrauterine transmission, other methods can be taken into consideration. Yue *et al*[10] used HBIG and together with hepatitis B vaccine to interrupt 30 pregnant women every 4 week from the 20th wk until delivery. The results showed that 29 newborn were HBsAg negative, 27 HBV-DNA negative and 10 were anti-HBs positive. In another chinical trial[11], 56 cases were given 200 IU HBIG intramuscularly every 4 wk from the 28th wk, while 43 cases received 100 mg lamivudine orally every day, 52 cases in the control group received no special treatment. The results demonstrated that the risk of HBV intrauterine infection effectively reduced in the 3rd trimester of HBsAg positive pregnant women, and there was no significant difference between HBIG and lamivudine groups. In present study, *Su et al*[12] has reported that 38 cases of pregnant women were given lamivudine before pregnancy, during pregnancy, until after labor. The result showed that none of 38 newborns was chronic carrier of HBsAg. In infant animals, lamivudine does not cause dysplasia however evidence of safety in human infants is limited. So some researchers prefer to use lamivudine from the 16th wk or 24th wk to those pregnant women with positive HBeAg for the safety of infants. We are waiting for the outcomes.

HBeAg is a marker which indicates active duplication of HBV, high concentration of HBV and strong possibility of infection. So we chose HBeAg positive pregnant women as subjects in this study. However it is unsuitable for clinical application to prevent from intrauterine transmission of HBV because the mutation of pre-C region of HBV can result in negative HBeAg , but they still had high load of HBV-DNA[13]. In clinical application, those pregnant women with negative HBeAg and positive HBV-DNA also need to be interrupted by HBIG. It has been reported that there is closed relationship between HBV-DNA load of serum of pregnant women and intrauterine infection[14,15]. Therefore it will be better to guide the application of prevention of mother-infant transmission of HBV by HBV-DNA load test quantitively.

It is clear that intrauterine infection is the main route of HBV transmission. According to present study, there is still a route of paternal-infants transmission of HBV[16]. Zhang *et al*[17]detected HBV markers of sperm of male patients with hepatitis B, HBV markers of peripheral blood of their partners and their newborns, the outcome was: HBV markers of mothers were negative, HBV markers of newborns were positive, situations were same as those of their fathers. It indicated that there was possibility of HBV transmission from farther to infant. Zhao *et al*[18] have detected HBV-DNA of sperma in male patients with hepatitis B, then a capture test of normal sperma was performed. The samples of infants from induced labor were tested for HBsAg and HBV-DNA, the result showed that HBV can cause vertical transmission via sperma. So in order to control intrauterine infection of HBV, we need to consider both mother and father. For noninfected pregnant women, while their partners are HBV carriers, application of pro-

phylaxis also should be considered in these fathers.

The limited number of HbsAG positive women and excluded cases may have produced a bias in our results warranting further study.

Abstract

AIM: To detect the biological characters of the SGC7901 gastric cancer cell-dendritic cell fusion vaccines.

METHODS: The suspending living SGC7901 gastric cancer cells and dendritic cells were induced to be fusioned by polyethylene glycol. Pure fusion cells were obtained by selective culture with the HAT/HT culture systems. The fusion cells were counted at different time points of culture and their growth curves were drawn to reflect their proliferative activities. The fusion cells were also cultured in culture medium to investigate whether they could grow into cell clones. MTT method was used to test the stimulating abilities of the fusion cells on T lymphocytes' proliferations. Moreover, the fusion cells were planted into nude mice to observe whether they could grow into new planted tumors in this kind of immunodeficiency animals.

RESULTS: The fusion cells had weaker proliferative activity and clone abilities than their parental cells. When they were cultured, the counts of cells did not increase remarkably, nor could they grow into cell clones in culture medium. The fusion cells could not grow into new planted tumors after planted into nude mice. The stimulating abilities of the fusion cells on T lymphocytes' proliferations were remarkably increased than their parental dendritic cells.

CONCLUSION: The SGC7901 gastric cancer cell-dendritic cell fusion vaccines have much weaker proliferative abilities than their parental cells, but they keep strong abilities to irritate the T lymphocytes and have no abilities to grow into new planted tumors in immunodeficiency animals. These are the biological basis for their anti-tumor biotherapies.

INTRODUCTION

With the development of modern immune research, biotherapy has brought new hopes for gastric cancer patients to conquer this kind of malignant tumors[1]. The anti-tumor vaccines based on dendritic cells (DC) play important roles in anti-tumor biotherapies[2]. Researchers obtain the cancer cells' antigens by various methods to irritate the dendritic cells, and increase the antigen presenting and immune stimulating abilities of dendritic cells[3,4]. Researchers usually destroy the cancer cells by frozen or ultrasound[5] methods. The components of the destroyed cancer cells were used as cancer antigens to irritate the dendritic cells. Many other researchers transmitted the cancer cell related mRNA into dendritic cells [6] or mix-cultured the cancer cells and dendritic cells[7]. They also attempted to improve the antigen presenting and immune stimulating abilities of dendritic cells by these methods. Although all these methods could partially enhance dendritic cells' capabilities and anti-tumor immune function of cancer patients, they still have some limitations. In recent years, methods to induce the dendritic cells and cancer cells to be fusioned together have been developed in order to investigate whether the fusion cells have stronger immune stimulating abilities than normal dendritic cells. Gastric cancer cells have no strong and specific tumor antigens, which makes it difficult for gastric cancer biotherapies. If gastric cancer cells and dendritic cells could be fusioned together, the cancer cell antigens might be presented more efficiently and more obvious anti-tumor effects might be achieved. In this research, the gastric cancer cells and dendritic cells were induced to be fusioned together by cell fusion technology. We detected the fusion cells' biological characters so to provide experimental data for gastric cancer biotherapies.

MATERIALS AND METHODS

Reagents

The reagents used included rhGM-CSF (Promega Co. Ltd, USA), rhIL-4 (R&D System Co. Ltd), TNF-a(R&D System Co. Ltd), Polyethylene glycol (Sigma, USA), Hypoxanthine (Sigma, USA), Aminopterin (Sigma, USA), Thymidine (Sigma, USA).

Preparation for suspending SGC7901 gastric cancer cells and dendritic cells

The frozen stored SGC7901 gastric cancer cells were cultured in the DMEM culture medium, and the suspending living cancer cells were prepared for the fusion process. The peripheral blood mononuclear cells were separated from venous blood of gastric cancer patients by use of lymphocytes separating solution. rhGM-CSF (100 ng/mL), rhIL-4 (50 ng/mL) and TNF-α(20 ng/mL) were added into the cultured peripheral blood mononuclear cells to induce them to transform into dendritic cells.

Preparation for SGC7901 gastric cancer cell-dendritic cell fusion vaccines

Suspending living SGC7901 gastric cancer cells and dendritic cells were mix-cultured with the ratio of 10:1. The two kinds of parental cells were induced to be fusioned by polyethylene glycol and selectively cultured by HAT/HT culture solutions. After the culture process, we obtained pure fusion cells as anti-tumor vaccines. Simultaneously, the suspending living SGC7901 gastric cancer cells and dendritic cells were mix-cultured with the same ratios, but were not induced to the fusion process. This group was designed as control group.

Growth curves of fusion cells

The obtained pure fusion cells (cell density 1.2×10^6/mL) were inoculated into the culture media on the culture slabs. During the culture process, we counted the cell numbers daily. After fourteen days, we drew the growth curves of cells. The SGC7901 cancer cells' and dendritic cells' growth curves were drawn at the same time respectively, and these curves were served as control.

Cloning abilities of fusion cells

The suspending living fusion cells (cell density 1×10^4/mL) were inoculated into the agar culture medium on twenty-four holes culture slabs. The cell numbers in each hole were 1000, 2000 and 10 000 respectively. After two weeks' cultivation, the cell clones which included more than 50 cells were counted under the microscopes. At the same time, the clone abilities of SGC7901 gastric cancer cells and dendritic cells were tested by the same methods.

Abilities of fusion cells to stimulate T lymphocyte proliferation

T lymphocytes were separated from peripheral blood of gastric cancer patients by using nylon hair. The cell densities of T lymphocytes, fusion cells and mix-cultured dendritic cells were adjusted to 5×10^6/mL. The fusion cells and mix-cultured dendritic cells were cultured on the culture slabs with 96 holes. T lymphocytes were added. The ratios of T lymphocytes to fusion cells and mix-cultured dendritic cells were 100:1, 50:1, 10:1 and 1:1 respectively. For each ratio, six holes were repeated in order to decrease the systemic errors. After sixty hours' cultivation, ^{3}H-TdR was added into each hole on the slabs (1Ci per hole). Twelve hours later, the CPM values were tested by Beckman liquid scintillation counting. The culture groups which included T lymphocytes only or DMEM culture medium were designed as control groups.

Abilities of fusion cells to grow into new planted tumors in nude mice

The suspending living pure fusion cells (cell density 1×10^9/mL, cell number 5×10^8) were planted subcutaneously into the back of the BALB/c nude mice. The injections were performed every three days for about two weeks. We observed whether the planted fusion cells could grow into new planted tumors in the nude mice, and the percentages of planted tumor cells growing into new planted tumors were tested. At the same time, the SGC7901 gastric cancer cells were planted into other groups of nude mice. These groups were designed as control groups.

Statistical analysis

Data were imported into Systat software (SPSS) for statistical computations and graphing. One-way analysis of variance (ANOVA), independent-samples T test and Chi-Square tests were used to evaluate the differences between groups. $P < 0.05$ was considered as significant.

RESULTS

Growth curves of fusion cells

We obtained the fusion cells after the selective culture process. The fusion cells' phenotypes and morphological characters were examined by flow cytometer and histological methods. The parental SGC7901 gastric cancer cells proliferated fast during their cultivation. After the subculture, the cancer cells stayed in proliferative delitescence for a short period, and then they entered into the logarithmic growth period with cell number increasing quickly. The cancer cells' proliferation slowed down and their number decreased gradually (Figure 1). Dendritic cells had much weaker proliferative abilities than SGC7901 cancer cells. During their cultivation, the cells' number did not increase remarkably. Like the parental dendritic cells, fusion cells also had weak proliferative abilities with a flat growth curve. This indicated that fusion cells' proliferative characters were much similar to parental dendritic cells (Figure 2).

Cloning abilities of fusion cells

Clone abilities effectively reflect the proliferation of single cells. If a kind of cell could grow into numerous cell clones in the agar culture medium, it indicates these cells have strong abilities to proliferate. In our study, we found that SGC7901 gastric cancer cells had strong proliferative abilities. They grew into numerous cell clones fast. Like the parental dendritic cells, fusion cells also had much weaker proliferations. During their cultivation, they could not

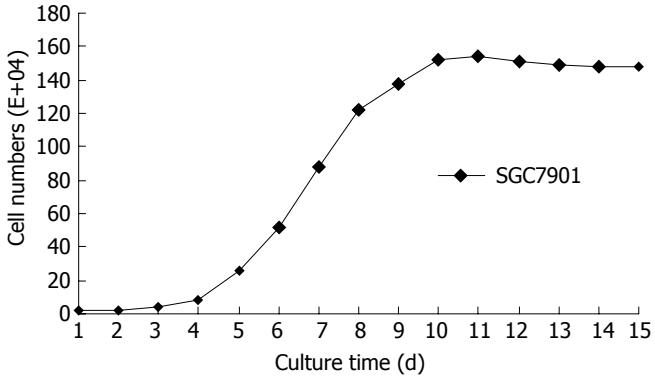

Figure 1 The growth curve of SGC7901 gastric cancer cells.

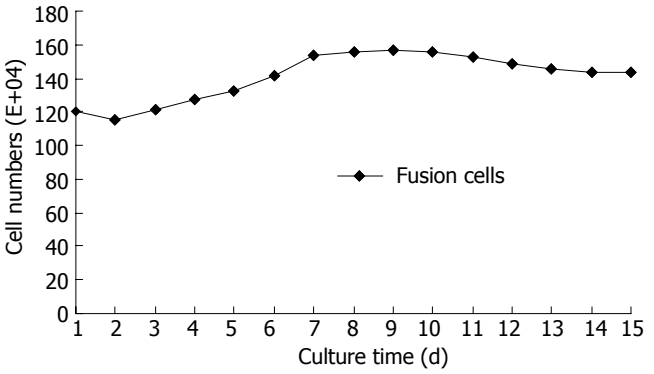

Figure 2 The growth curve of SGC7901-DC fusion cells.

grow into visible cell clones.

Abilities of fusion cells to irritate T lymphocytes' proliferation

The abilities of fusion cells to irritate T lymphocytes were much stronger than the mix-cultured DC group ($P < 0.01$) (Table 1).

Abilities of fusion cells to grow into new planted tumors in nude mice

After injected subcutaneously into the back of the BALB/c nude mice, the SGC7901 gastric cancer cells grew into new planted tumors quickly, whereas the fusion cells could not grow into new tumors in nude mice, even with a higher cell density and injection frequency, suggesting that fusion cells had no abilities to proliferate and grow into new planted tumors in immunodeficiency animals.

Table 1 Abilities of different cells to irritate T lymphocytes' proliferations (mean ± SD, CPM)

Groups	1:1	1:10	1:50	1:100
Fusion vaccine group	1 5083 ± 231[1]	9608 ± 83[2]	4214 ± 135[3]	3020 ± 28[4]
Mix-cultured DC group	5977 ± 272	3019 ± 38	2086 ± 58	1500 ± 41

[1]$P = 0.005$, [2]$P = 0.003$, [3]$P = 0.002$, [4]$P = 0.003$ *vs* Mix-cultured DC group.

DISCUSSION

Characters of fusion cells' growth curves, cloning abilities in vitro and their biological significance

Cell number and growth curves could directly reflect cell proliferative characters[8]. Clone ability is an important criterion to judge cells' growing capabilities[9]. The stronger the growth powers, the more cell clones could be formed. Cancer cells had strong abilities to proliferate. In our research we found that when the SGC7901 gastric cancer cells were subcultured, they quickly grew into the logarithmic proliferation period and the cell number increased remarkably[10]. After a short period the cell number was doubled. They grew into clearly cell clones only after seven days' cultivation. On the contrary, dendritic cells had much weaker proliferative abilities with a flat growth curve. There were no remarkable increases of the cell number during their cultivation, nor did cell clones formed. We found that fusion cells' growth characters were similar to their parental dendritic cells. They also had much weaker proliferative abilities and could not grow into cell clones during their cultivation. The cell number maintained a stable level and the growth curves were just a flat line. The SGC7901-DC fusion cells kept more biological characters of their parental dendritic cells. Different from their parental cancer cells, the fusion cells had no abilities to proliferate fast and grow into cell clones. These indicate that fusion cells were safe to be used as anti-tumor vaccines, which are biological basis for fusion cells research in cancer treatment.

Characters of fusion cells to irritate T lymphocyte's proliferation and their biological significance

After tumor antigens were presented by the dendritic cells, T lymphocytes were irritated and showed anti-tumor biological effects[11]. T lymphocytes *in vivo* can be divided into several sub-groups which have different phenotypes and biological effects. The most important sub-groups are CD4+ T lymphocytes (Th) and CD8+ T lymphocytes (Tc/CTL)[12]. The in-activated pre-Tc cells were irritated and became active Tc cells *in vivo* by the tumor antigens and CD4+ Th cells. These activated Tc cells exerted anti-tumor biological effects by the double signal approaches[13]. The cell number and activities of T lymphocytes directly affected anti-tumor immune responses of cancer patients[9]. Our purposes of modifying dendritic cells as anti-tumor vaccines were to increase their abilities of stimulating T lymphocytes' proliferation and their activities[14,,15]. Some researchers reported that when the tumor antigen related genes were transmitted into dendritic cells T lymphocytes *in vivo* could be strongly irritated to become CD4+ Th cells and CD8+ Th cells [16,17]. In our research, we found that the SGC7901-DC fusion cells could strongly irritate T lymphocytes' proliferation, while the mix-cultured dendritic cells could not. This indicated that fusion cells had much stronger abilities to activate anti-tumor immune responses. So, fusion cells are possible to be used as anti-tumor vaccines.

Abilities of fusion cells to grow into new planted tumors in immunodeficiency animals and their biological significance

New planted tumors in immunodeficiency animals are

perfect models for oncology researches[18]. We injected the SGC7901 cancer cells and SGC7901-DC fusion cells into different groups of nude mice and found that SGC7901 cancer cells could grow into new planted tumors quickly but the fusion cells could not, even when much higher cell densities and more injection frequencies were applied. This implied that SGC7901-DC fusion cells had no abilities to grow into new planted tumor in nude mice. This is the most important difference between the parental SGC7901 cells and the SGC7901-DC fusion cells. This character together with the growth curves and clone abilities indicated that fusion cells were safe when used as anti-tumor vaccines *in vivo* and *in vitro*.

The strong abilities of SGC7901-DC fusion cells to irritate T lymphocytes' proliferation and the characters that the fusion cells could not grow into new planted tumors *in vivo* are the precondition of anti-tumor biological therapy.

Abstract

Granular cell tumor (GCT) was described for the first time by Abrikosoff in 1926. It is a relatively rare neoplasm that may occur at many sites, but most commonly in the skin or soft tissues. The occurrence of GCT in the gastrointestinal tract is rare, accounting approximately for 8% of all tumors, among which the most common site is the esophagus, whereas gastric localization is very rare. Gastric GCTs can be solitary or, more frequently, associated with other gastrointestinal localization. Although GCTs are usually clinically and histologically benign, some malignant cases have been reported. Histologically, these tumors consist of polygonal and fusiform cells disposed in compact "nests" and immunohistochemical staining for S-100 protein supports the proposed derivation from Schwann cells. A correct preoperative diagnosis of this tumor can only be made in 50% of all patients and it is always based on endoscopic biopsy. Laparoscopic or conventional wedge resection represents the treatment of choice. In this study, the authors reported a case of a 49-year-old woman with a solitary granular cell tumor of the stomach with infiltrative pattern, successfully treated with surgical resection. A review of literature is also presented with emphasis on diagnostic criteria concerning the malignant form.

INTRODUCTION

Granular cell tumors (GCT) were described for the first time by Abrikosoff in 1926. They are uncommon, usually benign, soft tissue tumors rarely seen in clinical practice. They may occur at many sites, although it affects most frequently skin or subcutaneous tissues of the chest and upper extremities, tongue, breast and female genital region. The onset of this type of tumor in the gastrointestinal (GI) tract is rare. Approximately 8% of all GCTs occur in the digestive tract[1] and among these the most common site is the esophagus, followed by the large intestine[2]. Gastric localization is seldom seen. Yasuda et al[3], reported a case of gastric GCT in 1995 and underlined that this lesion was previously found in the stomach only in 24 patients. Since 1996, five more cases have been described[4-9].

In this study, we report a case of a woman with a solitary GCT of the stomach, incidentally found upon GI endoscopy, which had an infiltrative growth pattern and was successfully treated by surgical resection.

CASE REPORT

A 49-year-old woman was admitted to our Unit for further evaluation of a gastric mass which had been incidentally in an abdominal ultrasound examination for her nonspecific dyspeptic symptoms (Figure 1). She had no remarkable past medical history, and no significant alcohol consumption or history of smoking or drugs. Upon hospitalization, physical examination, biochemical data and tumor markers (CEA, CA-19-9) were all within normal limits. Upper gastrointestinal endoscopy was performed and revealed a hemispherical mass of about 3 cm in diameter, located on the lesser curvature of the gastric antrum and overlaid by normal mucosa. Search for *H pylori* by biopsy urease (Pantorc® *Hp* Test, Byk Gulden Italia S.p.A.) was negative. The esophagus, duodenum and the remaining parts of stomach were normal. Multiple deep (jumbo) biopsies from the gastric mass and from the surrounding gastric mucosa were performed. Histopathological examination of mass biopsies showed a pattern compatible with GCT, whereas other mucosal biopsies were normal. A subsequent CT scan of the abdomen showed a solid mass, with a slight contrast enhancement, of about 3 cm in diameter with well-defined margins located near the gastric angulus, arising from a layer of the gastric wall. Neither further invasion beyond the gastric wall, nor visible metastatic lesions in the liver or enlarged lymph nodes were observed. During laparotomy a tumor mass was found on the anterior wall of the lesser

Figure 1 Echo tomography of gastric region. A solid hypoechogenic mass with a diameter of 2.7 cm × 2.2 cm protruding from beyond the anterior wall of the stomach.

Figure 2 Macroscopic appearance of resected specimen: section of surgical specimen: a soft yellow mass of about 2 cm in diameter.

Some of the tumor cells are positive for Ki-67.

curvature of the stomach. There were no liver metastases or regional lymph node swelling. A wedge resection, with a gastric section performed at a distance of about 1.5 cm from the macroscopic margin of the tumor, was carried out, obtaining a total removal of the lesion.

In the resected specimen, the tumor measured 2 cm in diameter and appeared as a yellow mass (Figure 2). Microscopically, the tumor was located mainly in the muscle layer of the stomach. It formed solid nests of cells ranging from round to polygonal shape associated with few spindle cells. The nuclei were of different sizes with nucleoli at times evident and finely dispersed chromatin. The cytoplasm was abundant and finely granular. Mitotic activity was very low. The tumor focally infiltrated near muscular layer but did not affect mucosal surface (Figure 3A). Immunohistochemistry showed, S-100 protein present nearly in all cells within the tumor mass (Figure 3B), p53 in 40% of cells (Figure 3C) and Ki-67 in less than 9% of cells (Figure 3D). These histological findings met the criteria for a diagnosis of benign GCT[10].

The postoperative course was uneventful and the patient was discharged on postoperative fifth day. She remained asymptomatic and no recurrent disease was observed after a two year follow-up.

DISCUSSION

From an extensive review of literature about gastric GCT, no differences of tumor incidence was found as regard to gender, whereas fourth through sixth decades of life seem to be more affected. In term of ethnical issue of affected patients, the most reported cases were described in Japanese population. Moreover, in 50% of cases, gastric GCT proved to be associated with esophageal synchronous localization and was rarely associated with other benign or malignant gastric diseases. In only two reported patients,

Table 1 Characteristics of reported gastric granular cell tumors since 1998

Authors (yr)	Country	Age (yr)	Gender	Tumor size (cm)	Gastric site	Simultaneous occurrences of GCT	Simultaneous gastric lesions	Treatment

NR: non reported; GCT: granular cell tumor.

similarly to our case, gastric GCT did not show multiple localizations or was associated with other gastric lesions[3,11] (Table 1).

These gastric tumors are mostly confined macroscopically to submucosa. Their size may range from few millimeters to some centimeters, never surrounded by capsule. Histologically, gastric GCTs are composed by polygonal and fusiform cells arranged as compact "nests". Immunohistochemical staining for S-100 protein supports the proposed origin of the tumor from Schwann cells[12].

Although GCTs are usually benign clinically and histologically, some malignant cases have been reported. There are less than 30 reported cases of malignant GCTs in world literature[13] and the only documented case of a malignant GCT of the stomach was reported in 1996 by Matsumoto *et al*[9] (Table 1).

Features associated with malignancy include local recurrence, rapid growth to a size greater than 4 cm, cell necrosis, spindling of tumor cells, cytologic atypia and high mitotic activity, vescicular nuclei with large nucleoli, and a high nuclear-to-cytoplasm ratio[5,10]. It has also been reported that, on immunohistochemical staining, positivity rate of more than 50% for p53 and more than 10% for the Ki-67 index respectively, was significantly correlated with malignancy[7,10]. Extent of infiltration[5] or highly developed tumor microvessels[14] or focal pleomorphism[7] have never been considered as a criterion for diagnosis of malignancy. Altogether, these features are suggestive for malignant potential of the tumor. The tumor mass in our patient infiltrated only focally and marginally the muscular layer and did not display high expression of p53 and Ki-67. Furthermore, after the follow-up for two years, no evidence of recurrences was seen.

It is questionable whether these tumors always produce GI symptoms[15], even when they are of small size. It is quite likely that, if small, a change (pre-symptomatic) was found during upper GI endoscopy, X-ray or ultrasound examination performed for nonspecific dyspepsia. When large, gastric GCTs may instead present as gastric outlet obstruction[11], or massive upper GI hemorrhage[16].

A correct preoperative diagnosis of this tumor can be made by endoscopic biopsy. It is generally accepted that the best way to obtain an appropriate sampling of such tumors beneath the mucosa is either by boring or by performing a jumbo biopsy. A definitive diagnosis can only be established by endoscopic biopsy in 50% of the patients[17]. Endoscopic ultrasonography has recently been used more frequently for determining the depth of tumor invasion in the gastrointestinal wall, and may also be useful to evaluate GI tract submucosal tumors[2]. Endoscopic excision of GCT should be strongly considered[3]. If the tumor is attached to muscularis propria, an injection of saline can be useful to increase the distance, so that endoscopic removal can be performed more safely[3]. Therefore, since the gastric GCT is without capsule and focal areas of infiltration of the gastric wall can be present, laparoscopic or conventional wedge resection, including at least one centimeter of normal tissue, is the best therapeutic option. Laparoscopic approach could be difficult due to tumor localization beneath the posterior wall or lesser curvature, or mass size (very large or very small). Almost all gastric GCTs, observed from 1990 to date, were treated with conventional surgical approach.

Abstract

A 67-year-old man, who had undergone surgery to resect multiple gastric cancers 4 years ago, visited our hospital for surveillance colonoscopy. Colonoscopy revealed a discolored, 7-mm in diameter, flat-elevated lesion with central depression in the transverse colon near the splenic flexure. Although the findings of endoscopy and barium enema were suggestive of submucosal invasion, the patient chose to undergo endoscopic mucosal resection. Pathological examination of the resected specimen revealed signet-ring cell carcinoma and a positive surgical margin. A second operation was performed, and no residual tumor or metastasis to lymph nodes was found in the resected specimens. Primary colorectal cancers composed of signet-ring cell carcinoma detected and treated at an early stage are extremely rare. We present a case and review the literature.

http://www.wjgnet.com/1007-9327/12/3446.asp

INTRODUCTION

Signet-ring cell carcinoma is uncommon in the colon and rectum, with a reported incidence ranging from 0.1% to 0.9%[1,2]. In general, signet-ring cell carcinoma shows the characteristic appearance of "linitis plastica" and behaves more aggressively than carcinoma of other histological types[1,2]. As symptoms usually appeared late, signet-ring cell carcinomas are commonly detected at advanced stages. Therefore, cases detected and treated at early stage are rare. In this case report, we present our experience with a signet-ring cell carcinoma in the transverse colon detected at early stage and review the literature.

CASE REPORT

A 67-year-old man visited our hospital 4 years ago with a history of 4 synchronous primary cancers of the stomach. He underwent total gastrectomy, and the surgical specimen contained 2 early cancers which invaded the mucosa and submucosa, and 2 advanced cancers which penetrated serosa without invasion of adjacent structures. No components of signet-ring cell carcinoma were found on histology. He had a brother and a sister, and the family history included that his father had died of a gastric cancer at the age of 68, and his sister had an advanced sigmoid colon cancer and a uterine cancer at the age of 62 and 65, respectively. The patient's past history included an operation for synchronous gastric cancers, however there was no history of inflammatory bowel disease. He also had a focal cancer in an adenoma with moderate atypia, which had been completely resected endoscopically one year before. Therefore, he underwent surveillance colonoscopy at our department of endoscopy. Findings on laboratory tests were unremarkable. Total colonoscopy, with a magnifying colonoscope (CF-200Z, Olympus Optical Co., Japan) was easily introduced into the cecum without complications. Colonoscopy revealed a discolored flat-elevated lesion with central depression, 7 mm in diameter, in the transverse colon near the splenic flexure (Figure 1A). The tumor bled easily from the depressed area without contact from the endoscope and had convergent mucosal folds suggesting submucosal cancer involvement. After spraying of 0.2% indigo-carmine dye, the depression was seen more clearly (Figure 1B). After chromoendoscopy with 0.2% indigo-carmine dye and 0.05% crystal violet staining, we attempted to observe the surface structure of this

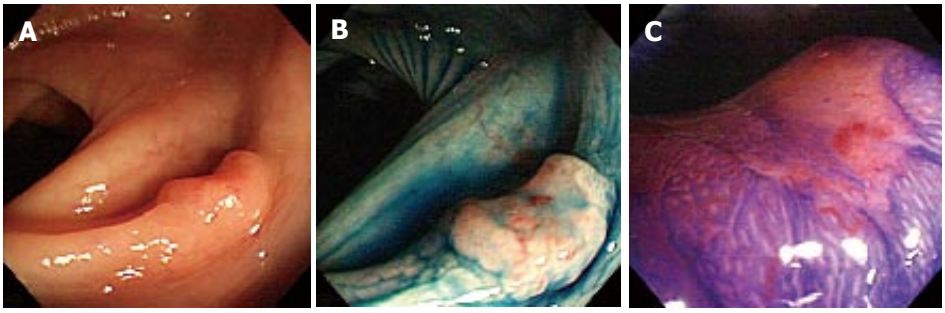

Figure 1 A: Colonoscopy revealed a discolored, flat-elevated lesion with central depression, 7 mm in diameter, in the transverse colon near the splenic flexure; **B:** Chromoendoscopy with 0.2% indigo-carmine dye showed the depressed area more clearly; **C:** Magnifying colonoscopy after 0.05% crystal violet staining was attempted but failed to detect the pit pattern for depth estimation, as the depressed area was covered by dense mucus, which could not be removed by repeated water washing.

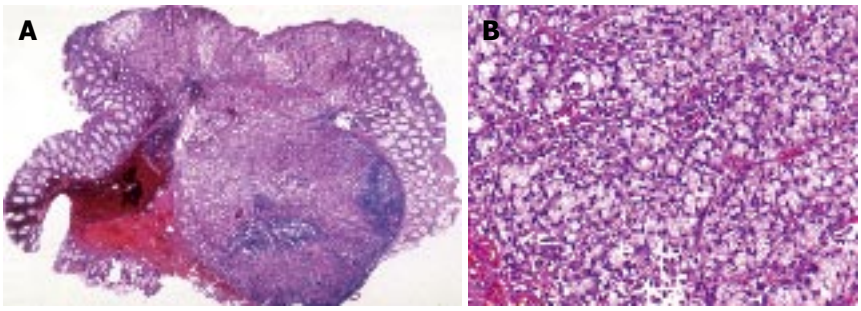

Figure 2 A, B: Histologically, the resected specimen showed a signet-ring cell carcinoma that had deeply invaded into the submucosal layer, and the vertical cut end of the resected tumor was positive for carcinoma cells.

lesion, the so-called "pit patterns", at a higher magnification to estimate the depth of invasion[3,4]. However, the pit patterns could not be detected, as dense mucus coated the surface and could not be removed by repeated washing (Figure 1C)[5]. The findings of barium enema and conventional colonoscopy suggested submucosal cancer invasion, and thus, surgical resection, including node dissection, was recommended for curative treatment. However, the patient refused surgical resection but consented to endoscopic mucosal resection (EMR). The lesion was successfully removed en bloc with EMR without complications. The resected specimen was 7 mm in diameter. The resected specimen was fixed with 20% formalin, and then the mucus on the surface was removed for better staining and observation. The fixed lesion was stained with 0.05% crystal violet and observed stereomicroscopically under water immersion. Stereomicroscopy revealed a type V (non structural) pit pattern in the depressed area. These findings suggested that this lesion had deeply invaded the submucosal layer[3,6]. Histologically, the tumor was composed of signet-ring cell carcinoma, without accompanying adenoma or other types of cancer cells, that had infiltrated deeply into the submucosal layer with invasion of lymphatic vessels (Figure 2A-B). Immunostaining was used to examine the expression of MLH1 and MSH2 of the resected specimen; the tumor was positive for MSH2 but negative for MLH1. A cut end of the resected specimen was positive for carcinoma cells. Systemic diagnostic imaging including abdominal computed tomography showed no evidence of distant metastasis or ascites. Thereafter, the patient consented to undergo an additional laparotomy. The resected specimen revealed no residual carcinoma at the EMR site and showed no metastasis to lymph nodes. The postoperative course was uneventful, and the patient is still alive and in apparent good health 5 years after the operation.

DISCUSSION

More than 96% of signet-ring cell carcinomas arise in the stomach, and the rest occurred in other organs, including the colon, rectum, gallbladder, pancreas, urinary bladder, and breast[7]. The case described here was believed to be a primary lesion of the transverse colon because a thorough workup did not reveal any other sites of involvement. Although the patient's history included surgical resection of an advanced gastric carcinoma, a secondary carcinomatous deposit should also be excluded. Metastasis from gastric carcinoma is probably the most common secondary carcinoma in the colon and rectum[8]. It may present itself as single or multiple strictures mimicking primary colorectal carcinoma or inflammatory bowel diseases[8,9]. Furthermore, multiple flat and depressed lesions or polyps have also been reported as rare presentations of colonic metastasis from gastric signet-ring cell carcinoma[10-13]. Our case presented a solitary depressed lesion without metastasis or lymphatic, hematogenous or peritoneal involvement, and the patient is still alive 5 years after surgery; therefore, on the basis of these findings, this case could be judged as a primary lesion. Crystal violet staining is commonly used to evaluate pit patterns, especially for lesions in which there is the suspicion of submucosal invasive carcinoma. Unfortunately, the pit patterns could not be detected in this case, as dense mucus coated the surface and failed to be removed by repeated washing endoscopically. This might reveal that signet-ring cell carcinoma produces abundant mucus.

Primary signet-ring cell carcinoma of the colon and rectum, as first described by Laufman and Saphir in 1951, is rare[14]. The reported incidence is about 1%[1,2]. The histological appearance of the tumor is characterized by cells with abundant intracytoplasmic mucin and peripherally placed nuclei. Signet-ring cell carcinomas of the colon and

rectum are usually diagnosed at an advanced stage, because symptoms usually develop late. Thereafter, cancers limited to the mucosal and submucosal layers are rarely detected; to the best of our knowledge, only 26 cases, including ours, have been reported[15-20]. The clinicopathological details of the reported cases are summarized in Table 1. The patients included 21 males and 5 females with a mean age of 57.1 years (range of 6-79 years). The mean size of the tumors was 16.0 mm (range, 2 to 45 mm). Macroscopically, 16 (61.5%) cases were flat or depressed. The smallest tumor was a tiny, discolored, flat lesion 2 mm in diameter. Despite the small size, it surprisingly metastasized to lymph nodes[18]. Tsujinaka et al have described the first case of early signet-ring cell carcinoma of the colon without an adenomatous component. It was a depressed lesion that was believed to have arisen via a de novo pathway[15]. This tumor only showed signet-ring cancer cells without accompanying adenoma or other types of cancer cells. It is unknown whether signet-ring cell carcinoma usually arises from a pre-existing adenomatous polyp or as a so-called de novo carcinoma[21]. However, according to the reviewed articles, there are 3 reported cases with an adenomatous component; therefore, an adenoma-signet-ring cell carcinoma sequence also exists[16,17].

The sites of reported cases are mostly in the right-sided colon (50%, 13 cases), but 7 are in the left-sided colon and 6 are in the rectum (Table 1). In our case, the transverse colon was the most commonly involved site. Eight of the reported cases also had multiple synchronous colorectal cancers. The right-sided predilection, histological characteristics, and the tendency to multiplicity are now well documented in hereditary non-polyposis colorectal cancer. However, in the present case, the family history and past history did not fulfill the diagnostic criteria[22,23]. Considering the clinicopathological characteristics of this case, immunostaining was used to examine expression of MLH1 and MSH2 of the resected specimen; the tumor was positive for MSH2 but negative for MLH1. Signet-ring cell carcinomas have been analyzed for microsatellite instability, which is present in approximately 30% of tumors[24]. Furthermore, although not available in our case, mutations of K-ras and p53 gene have been reported in signet-ring cell carcinomas of the colon and rectum; however, the frequency of K-ras gene mutation in signet-ring cell carcinomas is significantly lower than that of well and moderately differentiated carcinomas[24]. These results suggest that the genetic background of signet-ring cell carcinomas might differ from that of well or moderately differentiated carcinomas of the colon and rectum. DNA-replication errors are suggested to be at least partly involved in the carcinogenesis of signet ring cell colorectal carcinoma[24]. Although, our patient did not have inflammatory bowel disease, an association of inflammatory bowel disease and signet-ring cell carcinoma of up to 14% has been reported[25]. Psathakis et al. reported two (14.3%) of 14 patients with signet-ring cell carcinoma, who had a long history of ulcerative colitis[26]. Anthony et al. reported two cases of Crohn's disease that developed signet-ring cell carcinoma[27].

In conclusion, we have reported a rare case of primary signet-ring cell carcinoma of the colon detected and treated at early stage, and reviewed the literature.

Table 1 Clinicopathological details in patients with primary early colorectal signet ring cell carcinomas

Mean age (range) (yr)	57.1 (6-79)
Sex (male/female)	21/5
Mean size (range) (mm)	16.0 (2-45)

Abstract

We report a case of postoperative refractory bile leakage managed successfully by intrahepatic biliary ablation with ethanol. A 75-year-old man diagnosed with hepatocellular carcinoma underwent extended posterior segmentectomy including the caudate lobe and a part of the anterior segment. The hepatic tumor attached to the anterior branch of the bile duct was detached carefully and resected. Fluid drained from the liver surface postoperatively contained high concentrations of total bilirubin, at a constant volume of 150 mL per day. On d 32 after surgery, a fistulogram of the drainage tube demonstrated an enhancement of the anterior bile duct. Endoscopic retrograde cholangiography demonstrated complete obstruction of the proximal anterior bile duct and no enhancement of the peripheral anterior bile duct. On d 46 after surgery, a retrograde transhepatic biliary drainage (RTBD) tube was inserted into the anterior bile duct under open surgery. However, a contrast study of RTBD taken 7 mo post-surgery revealed that the fistula remained patent despite prolonged conservative management, so we decided to perform ethanol ablation of the isolated bile duct. Four mL pure ethanol was injected into the isolated anterior bile duct for ten minutes, the procedure being repeated five times a week. Following 23 attempts, the volume of bile juice reached less than 10 mL per day. The RTBD was clamped and removed two days later. After RTBD removal, the patient had no complaints or symptoms. Follow-up magnetic resonance imaging demonstrated atrophy of the ethanol-injected anterior segment without liver abscess formation.

INTRODUCTION

Bile leakage is one of the major postoperative complications that may occur after hepatectomy. The reported incidence of postoperative bile leakage ranged from 4.8% to 7.6%[1-3]. Biliary complications including bile leakage after hepatic surgery are a major cause of morbidity and extended hospital stays. Lo *et al*[4] reported a high mortality rate in patients who required reoperation for biliary complication after liver resection. Biliary drainage is usually important and necessary for the treatment of bile leakage, but sometimes fails to improve bile leakage despite prolonged conservative drainage[5].

We report a case of postoperative refractory biliary leakage managed successfully by intrahepatic biliary ablation with ethanol.

CASE REPORT

A 75-year-old man was referred to our hospital with a diagnosis of hepatic tumor. Abdominal computed tomography confirmed a 63 mm × 59 mm hepatic mass locating mainly in segment I with invasion into segment VI, VII, VIII, and V. This tumor obstructed the posterior branch of the bile duct, and oppressed the anterior branch of the bile duct, middle hepatic vein and infra vena cava (Figure 1A, B). Abdominal angiography revealed a hypervascular tumor in the right lobe at the early enhanced phase (Figure 1C). Serum alpha-fetoprotein (AFP) and protein induced by vitamin K absence or antagonist-II (PIVKA-II) was 227 ng/mL (normal, < 20) and 62 mAU/mL (normal, < 40), respectively. He had no additional underlying liver disease. We diagnosed him as hepatocellular carcinoma and decided upon surgery for radical treatment. An extended posterior segmentectomy including the caudate lobe and a part of the anterior segment was performed. Consistent

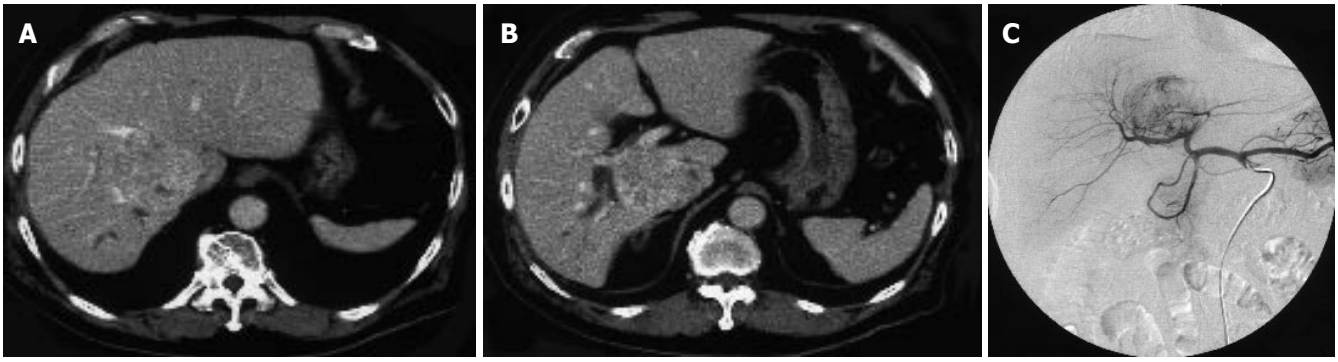

Figure 1 **A**, **B**: Abdominal computed tomography confirmed a 63 mm × 59 mm hepatic mass locating mainly in segment I with invasion into segment VI, VII, VIII, and V. This tumor obstructed the posterior branch of the bile duct, and oppressed the anterior branch of the bile duct; **C**: Angiography revealed a hypervascular tumor in the right lobe at the early enhanced phase.

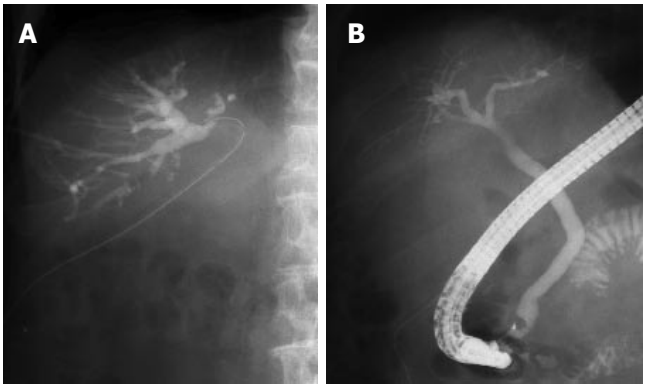

Figure 2 **A**: A fistulogram from the drainage tube demonstrated a connection between the anterior bile duct and fistula; **B**: Endoscopic retrograde cholangiography showed obstruction of the anterior bile duct, and no connection between the common bile duct and the anterior bile duct.

with the findings of the preoperative computed tomography, the tumor was attached to the anterior branch of the bile duct, middle hepatic vein, and inferior vena cava, and was detached carefully from them and resected. During surgery, no particular problems were seen, including bile leakage. Postoperatively, the fluid from a drain locating in the resected liver surface contained total bilirubin (61.2 mg/dL), the volume of which was constant at 150 mL per day without decrease. This was thought to be caused by bile leakage. On d 32 after surgery, a fistulogram obtained from the drainage tube demonstrated a conduit between the anterior bile duct and fistula (Figure 2A). Endoscopic retrograde cholangiography performed on d 39 after surgery demonstrated obstruction of the anterior bile duct (Figure 2B). Taken in sum, these examinations suggested a hole in the distal part of the anterior bile duct with its proximal obstruction. We tried to insert a biliary drainage tube into the anterior branch by percutaneous and endoscopic procedures to decrease the intraductal pressure and close the fistula, but failed. On d 46 after first surgery, a retrograde transhepatic biliary drainage (RTBD) tube was inserted into the anterior bile duct under open surgery. We waited to close the fistula in the outpatient follow-up, however a contrast study of the RTBD taken 7 mo post-surgery showed that the fistula remained patent. Because external biliary drainage continued despite prolonged conservative management, we decided to perform ethanol ablation of the isolated bile duct.

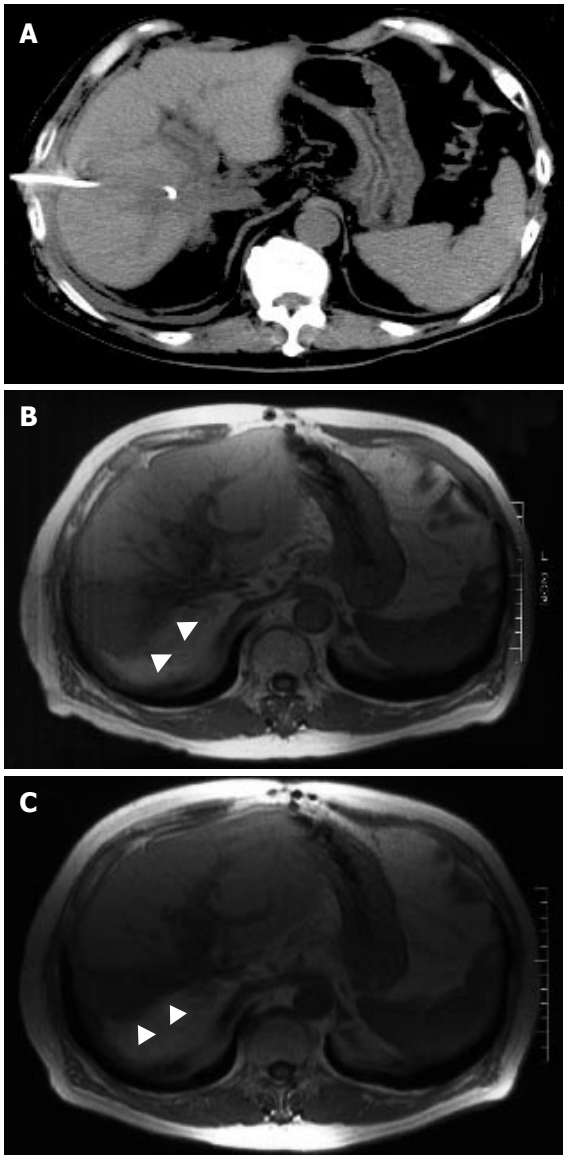

Figure 3 Follow-up computed tomography taken before ethanol injection (**A**), magnetic resonance imaging 3 mo (**B**) and 15 mo (**C**) after injection. Arrows indicate the atrophy of the ethanol-injected anterior segment.

A 5 Fr balloon occlusion catheter was placed in the

anterior bile duct through an RTBD tube. After the balloon was inflated to prevent leakage of the injected ethanol from the bile duct to the fistula, 4.0 mL pure ethanol was injected for ten minutes. Ethanol injection over 4.0 mL caused upper abdominal discomfort, so we decided that 4.0 mL was the appropriate volume. The ethanol injection was repeated five times a week. The volume of bile drainage was diminished to less than 100 mL after five injections, and the injections were continued thereafter. On the 23rd attempt, the volume of bile juice dropped to below 10 mL per day, and then the RTBD was clamped and removed two days later. Total bilirubin concentration of the drainage was also decreased from 61.2 mg/dL pre-injection to 6.9 mg/dL on the 11th attempt, and to 3.9 mg/dL on the 20th attempt. After RTBD removal, the patient had no complaints or symptoms. Compared with computed tomography taken before ethanol injection (Figure 3A), magnetic resonance imaging demonstrated atrophy of the ethanol-injected anterior segment without liver abscess formation (Figure 3B-C).

DISCUSSION

This report indicates that ethanol ablation may be effective in unfortunate cases of refractory biliary leakage after hepatectomy. However, this method can be performed in only biliary fistula without communication with the bile duct of the other remaining liver, because ethanol affects the remaining bile duct and causes irreversible damage. From this point of view, the reported case is thought to be one particularly suitable for ethanol biliary ablation.

Ethanol has been generally used as an injected agent percutaneously or angiographically for the treatment of various tumors because of its highly destructive properties, which lead to cell death by causing cell membrane lysis and protein denaturation[6]. Percutaneous transhepatic ethanol injection to the biliary tract has been reported. Controversy has surrounded chemical ablation of the gallbladder as an alternative to cholecystectomy for over a decade[7-11]. Recently, selective intrahepatic biliary ethanol injection as an alternative to preoperative portal vein embolization[12] or postoperative bile leakage[13] has been introduced. Kyokane *et al* reported that selective intrahepatic biliary ethanol injection destroyed the biliary epithelium, permeated parenchyma, induced hepatocyte denegeration, and resulted in compensatory hypertrophy of the non-injective hepatic lobe in an animal study. Compared with portal embolization, biliary ethanol injection was reported not to cause such severe side effects. In biliary ethanol injection, the hepatocyte denegeration with preservation of hepatic blood supply may prevent clinical liver necrosis or abscess[12]. Li *et al*[14] also demonstrated that biliary injection using phenol plus cyanoacrylate could achieve the effect of chemical hepatectomy.

Although this patient complained of abdominal pain during excessive ethanol ablation, this symptom was promptly relieved when the injection was stopped and the ethanol was removed from the bile duct via an RTBD tube. We were able to find the optimal injected ethanol dose through the patient's complaint and fistulography, after which the patient did not complain of abdominal pain. In this method, the decision on the optimal injected dose may be important to prevent side effects[15].

Unfortunately, biliary leakage is sometimes encountered, and it can be complicated when it does occur[3,5,16]. Ethanol ablation of the bile duct provides a management option in cases in which conservative treatment has failed and a surgical approach is relatively difficult.

Abstract

Anorectal melanoma is a very rare tumor with poor prognosis. Rectal bleeding is the most frequent symptom and surgical treatment ranges from local excision to radical abdominoperineal resection. We report a case of a 75-years-old male patient who presented with a history of recurrent rectal bleeding, and whose histopathological diagnosis was melanoma. Macroscopically, we found two distinct tumors in anorectal region, 0.5 cm and 1.5 cm from dentate line. The first one was pedunculated, on a thin stalk, measuring 1 cm in greatest diameter, and the second one was sessile and nodular measuring up to 2.8 cm in largest diameter. Microscopic examination and immunohistochemical analysis of both tumors confirmed the diagnosis of melanoma. This case represents multiple synchronous primary melanoma of the anorectal region, with a possibility that one of the lesions is primary melanoma and the second one is a satellite lesion.

Balicevic D, Tomic K, Bekavac-Beslin M, Kovacevic I, Mijic A, Belicza M, Kruslin B. Synchronous anorectal melanoma. *World J Gastroenterol* 2006; 12(21): 3453-3455

http://www.wjgnet.com/1007-9327/12/3453.asp

INTRODUCTION

Anorectal melanoma is a rare condition accounting for 0.2%-3% of all melanoma cases, and 0.1%-4.6% of all malignant tumors of the rectum and anus[1,2,3]. Melanoma is defined as "rectal" when it occurs in the rectum above the anorectal junction[4], while anal canal is below anorectal line. Rectal bleeding was the most common reported symptom, and sometimes the importance of the bleeding is underestimated as it was assumed to be a sign of hemorrhoid disease causing a delay in making the correct diagnosis and starting treatment[4,5]. Surgical treatment of this tumor ranges from the radical abdominoperineal resection with bilateral inguinal lymphadenectomy, to the conservative local excision alone[4]. Long-term survival is very low; approximately 6.7% to 12% of patients were reported to be free of disease five years after their operations[6,7]. Most recent studies did not find correlation between tumor necrosis and blood vessel invasion and survival rate, while correlation of survival and tumor thickness is controversial. In the most studies, tumors evaluated by flow cytometry that showed aneuploidy correlated with poorer prognosis. S-phase fraction higher than 15% also correlated with a worse prognosis[4,5].

CASE REPORT

A 75-year-old male patient presented with a history of recurrent rectal bleeding which had become more frequent and severe during the previous year. Colonoscopy revealed only one polipoid and fragile mass in the rectum, and punch biopsy showed pigmented melanoma. Computed tomography (CT) scan and ultrasound did not find enlargement of regional lymph nodes.

Pathologic examination of the received specimen revealed two distinct tumorous masses; the first one that was pedunculated, on a thin stalk, 0.5 cm above dentate line, measuring 1 cm in greatest diameter. The second one was sessile and nodular, 1.5 cm above dentate line, measuring up to 2.8 cm. Both tumors were bluish brown on cut sections (Figure 1A).

After surgery, all specimens were formalin fixed, paraffin embedded, cut at 5 μm and routinely stained with hematoxylin and eosin. Deparaffinisation and immunohistochemical staining was performed following Microwave Streptavidin ImmunoPeroxidase (MSIP) protocol on DAKO TechMate™ Horizon automated immunostainer. We used primary antibodies to HMB-45 and S-100 (purchased from DAKO, Copenhagen, Denmark). Microscopically, both tumors were composed of atypical spindle cells with prominent nucleoli and highly pigmented. First tumor, the smaller one, was covered with squamous epithelium, partially ulcerated, infiltrating mucosa and submucosa but without extension to the

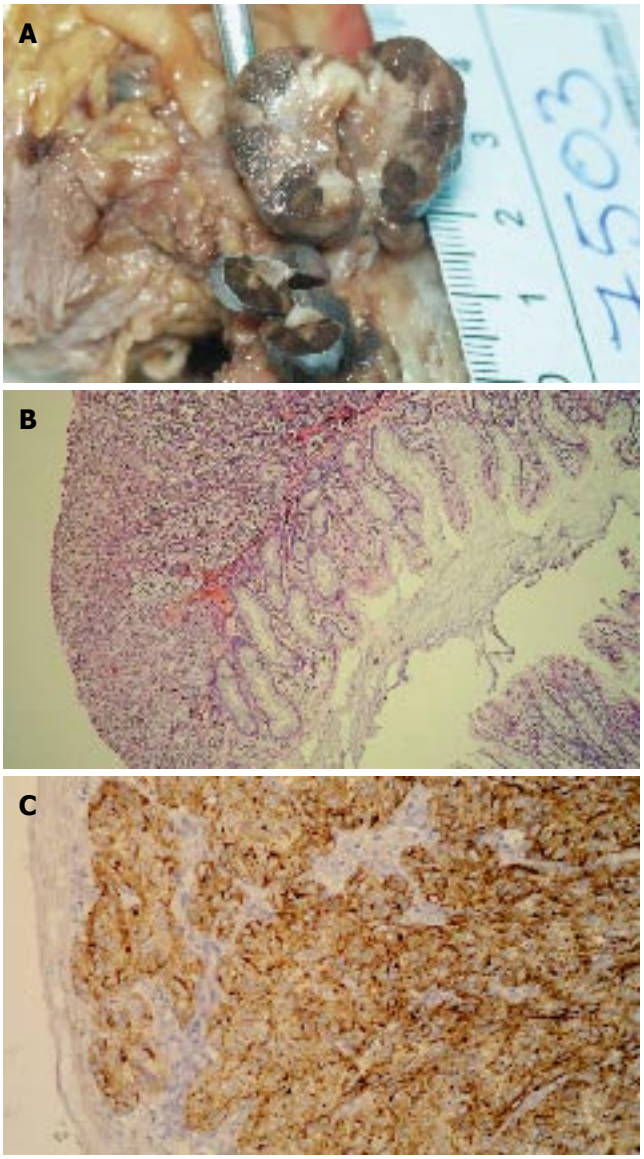

Figure 1 **A**: Macroscopical appearance of anorectal region with two melanomas; **B**: Photomicrograph of rectal melanoma covered with columnar epithelium (HE, original magnification x 100); **C**: Photomicrograph of anal melanoma covered with squamous epithelium showing strongly positive immunostaining for HMB-45 (original magnification x 200).

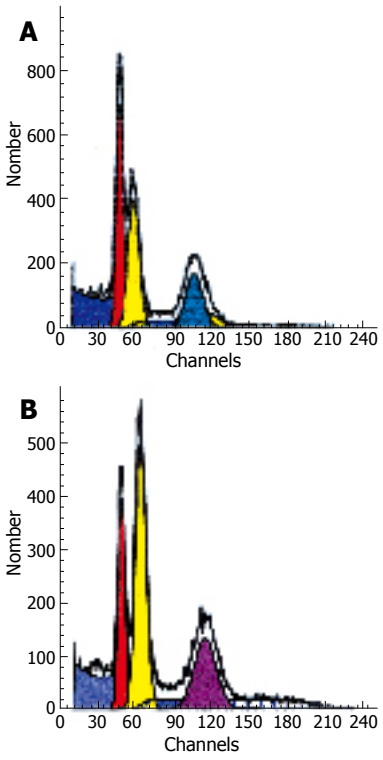

Figure 2 DNA histograms. **A**: Smaller tumor with two aneuploid peaks: left peak-hypodiploid population with DNA index of 1.22; right peak-hyperdiploid population with DNA index of 2.22. Middle peak-the diploid population of non tumoral cells; **B**: Larger tumor with two aneuploid peaks: left peak-hypodiploid population with DNA index of 1.32; right peak-hyperdiploid population with DNA index of 2.33. Middle peak-the diploid population of non tumoral cells.

muscle layer. Mitotic rate was 10/10 HPF. The larger tumor was covered with partially ulcerated columnar epithelial cells, without muscle layer infiltration (Figure 1B). Mitotic rate was 13/10 HPF. Tumor thickness, measured by computer program, was 5.75 mm for the smaller tumor, and 9.11 mm for the larger one. Both tumors showed immunohistochemically positive reaction for HMB-45 and S-100 (Figure 1C).

Paraffin embedded specimens were processed for the flow cytometry. Cellular DNA content and proliferative activity were analyzed on a FACSCalibur flow cytometer (Becton Dickinson, San Jose, CA) using excitation wavelength at *A*488 nm and 15-mW argon ion laser. DNA histograms were generated on at least 20 000 nuclear events with a Mod-FitLT V2.0 (Verity Software House Inc.,Topshame, ME and Becton Dickinson).

DNA flow cytometry analysis showed two aneuploid peaks (hypodiploid and hyperdiploid populations) in both tumors, but with different DNA indexes and S-phase fractions (Figure 2A, 2B). S-phase fraction for the polipoid tumor, covered with squamous epithelium was 11.84%, and for the nodular one, covered with columnar epithelium was 26.82%.

DISCUSSION

Anorectal melanoma is a very rare neoplasm, and in the reviewed literature we did not find any similar case of anorectal melanoma, either with satellite lesion or with multiple melanomas in anorectal region. We found only one reported case of metachronous melanoma in the upper digestive system, involving esophagus and stomach[8]. The case presented in this paper is specific by reporting two, synchronous melanomas, of which one of the tumors was found in anal canal, and it was partially covered by ulcerated squamous epithelium, while the other one was in rectum, covered with partially ulcerated columnar epithelium. Between described tumors there was an area of normal rectal mucosa without tumor involvement. For almost 30 years patient had recurrent bleeding because of hemorrhoid disease, which probably caused delay in making a correct diagnosis. Although some authors did not find difference in overall survival between patients treated with local excision and those with abdominoperineal resection[2,9], the study from the Memorial Sloan Kettering Cancer Center by *Brady et al.* suggested abdominoperineal resection as a better approach for patients without advanced disease, because patients treated with abdominoperineal resection were more commonly associated with better long-term survival than those treated with other procedures[4,6]. After physical, CT scan and ultrasound examination which did

not find any signs of metastatic disease, patient was treated by radical abdominoperineal resection.

The most important doubt in this case is the nature of both lesions. Are they both primary anorectal melanoma or is one of the two tumor primary, and which one, and the second one is probably a satellite lesion?

In skin melanomas, satellite lesions are defined as tumor nests or nodules within 2 cm of the primary tumor, while in-transit metastasis involves skin or subcutaneous tissue more than 2 cm from the primary tumor, but not beyond the regional lymph nodes. The significance of their presence is seen in survival studies, where lymph node metastasis is one of the most important predictor factors of survival in melanoma patients, and presence and number of involved lymph nodes is more important than actual gross dimension of the involved lymph node. In new melanoma staging system, patients with in-transit metastases or satellite lesions without lymph node disease have a similar prognosis to those with positive lymph node metastases. In the revised staging system, these patients are now upstaged as having N2c disease compared with the 1997 staging system in which these patients were considered as having T4 disease[10].

In this case, it is likely that one of the lesions is primary tumor and the second one is the satellite lesion. Concerning colonoscopy, which was performed few months before surgery, and which found only one polipoid tumor, it is possible that the smaller tumor is primary, and the second one is a satellite lesion. Hypothesis that one of the tumors is a satellite lesion is also supported with histological findings, because both tumors are composed of the same histological type. However, the surface of both tumors is ulcerated, making it very difficult to establish connection of the tumor cells with the surface, and concerning different S-fases on DNA flow cytometry there is still a possibility that this is the case of a multiple synchronous primary melanoma in anal canal and rectum.

Importance of distinguishing exact nature of the found lesions, if we could apply the same rules as for staging cutaneous melanoma, is better staging and predicting prognosis.

This case represents the multiple synchronous primary melanoma of the anorectal region, with a possibility that one of the lesions is primary melanoma and the second one is a satellite lession.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

http: //www.wjgnet.com
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included.

Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Patent (list all authors)

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

COPY EDITOR FOR THIS ISSUE: Yogesh K Chawla and Atif Iqbal, MD

World Journal of Gastroenterology (*World J Gastroenterol , WJG*), a leading international journal in gastroenterology and hepatology, has an established reputation for publishing first class research on esophageal cancer, gastric cancer, liver cancer, viral hepatitis, colorectal cancer, and *Helicobacter pylori* infection, providing a forum for both clinicians and scientists, and has been indexed and abstracted in *Index Medicus*, MEDLINE, PubMed, Chemical Abstracts, EMBASE, Abstracts Journals, Nature Clinical Practice Gastroenterology and Hepatology, CAB Abstracts and Global Health. *WJG* is a weekly journal published by The *WJG* Press. The publication date is on 7th, 14th, 21st, and 28th every month. The *WJG* is supported by The National Natural Science Foundation of China, No. 30224801 and No.30424812, which was founded with a name of *China National Journal of New Gastroenterology* on October 1,1995, and renamed as *WJG* on January 25, 1998.

Abstract

Patients who are chronically infected with the hepatitis C virus often develop chronic liver disease and assessment of the severity of liver injury is required prior to considering viral eradication therapy. This article examines the various assessment methods currently available from gold standard liver biopsy to serological markers and imaging. Ultrasound is one of the most widely used imaging modalities in clinical practice and is already a first-line diagnostic tool for liver disease. Microbubble ultrasound contrast agents allow higher resolution images to be obtained and functional assessments of microvascular change to be carried out. The role of these agents in quantifying the state of hepatic injury is discussed as a viable method of determining the stage and grade of liver disease in patients with hepatitis C. Although currently confined to specialist centres, the availability of microbubble contrast-enhanced ultrasound will inevitably increase in the clinical setting.

INTRODUCTION

It is estimated that 170 to 200 million people (around 3% of the global population) are chronically infected with the hepatitis C virus (HCV), while around 4 million people are newly infected each year[1]. There is a great degree of variation in prevalence, ranging from less than 1% in the United Kingdom to more than 20% in Egypt. In the developed world, the relatively low prevalence is mostly the result of intravenous drug abuse, while a World Health Organisation (WHO) anti-schistosomal vaccination programme in Egypt in the 1970s and other vaccination programmes in Mongolia and Bolivia have led to much higher rates in those countries[2]. Between 55% and 85% of those infected go on to develop chronic liver disease and even then, many remain asymptomatic, while the rest suffer primarily from chronic fatigue[3]. Around 20% of patients with fibrosis develop cirrhosis and 5% of these are susceptible to developing hepatocellular cancer each year (Figure 1)[4]. A number of factors have been linked to the progression of chronic hepatitis, with some being implicated not only in advancing the progression, but also worsening the overall prognosis[5]. These factors include age at infection greater than 55 years, male sex, excessive alcohol consumption, a long history of cigarette smoking and the presence of hepatic steatosis, obesity and diabetes mellitus (the metabolic syndrome)[5].

ASSESSING CHRONIC HEPATITIS C-RELATED LIVER DISEASE

An assessment of the severity of hepatic involvement is obviously required prior to considering antiviral treatment regimens with interferon and ribavirin in patients with hepatitis C. In addition, owing to the variable disease progression, the potentially life-threatening complications of end-stage liver disease and the development of hepatocellular carcinoma, it is also imperative to monitor hepatitis C-infected patients with established cirrhosis.

LIVER BIOPSY

For many years, the gold standard for assessing chronic

Table 1 Commonly available serological markers for assessing liver injury[8]

Group	Marker/panel	Comments
1	Prothrombin index	Highest diagnostic accuracy (cirrhosis) 86%
1	PGAA	Diagnostic accuracy 80%
1	AST/ALT ratio	Increase strongly correlated with decrease in hepatic function AST/ALT > 1 can diagnose cirrhosis with sensitivity of 77.8% and specificity 96.9%, but misclassified 7% as having cirrhosis and failed to diagnose 11%
1	FibroTest	Sensitivity 75%, specificity 85%
1	APRI	Predicts fibrosis in 51% patients Predicts cirrhosis in 81% patients
2	Hyaluronic acid (HA)	Only group 2 marker to show encouraging results, with a positive predictive value similar to Child-Pugh

hepatitis has been histological examination of liver biopsy material. However, this invasive procedure is not without risks with a small, but defined mortality rate and it has a significant error rate, sampling less than $1/50\,000^{th}$ of the liver volume even in cases of diffuse disease[6-8]. As a result of the problems associated with biopsy, there has been a steady drive in recent times to find an effective non-invasive method of evaluating liver injury, which has led to major developments in both serological markers of disease and imaging.

SEROLOGICAL MARKERS

An ideal serological marker for assessing liver injury should be liver-specific, easy to use and allow measurement of the stage of disease using the degree of fibrosis, the activity of matrix deposition and the activity of matrix removal[8]. These can be broadly classified into two groups. The first (Group 1 in Table 1) are those which are indirect markers of fibrosis, reflecting alterations in hepatic function, and include PGAA {prothrombin index, gamma glutamyl transpeptidase (γGT), apolipoprotein A_1 and α_2-macroglobulin}[8], AST/ALT (aspartate aminotransferase and alanine aminotransferase)[9], FibroTest (α_2-macroglobulin, α_2-globulin, γ-globulin, apolipoprotein A_1, γGT and total bilirubin)[10] and APRI (AST to platelet ratio index)[11]. The second (Group 2 in Table 1) are those which are direct markers of fibrosis, reflecting extracellular matrix metabolism (Group 2 in Table 1)[8]. The current issue is that many of these proposed panels have not been widely validated around the world and often remain championed largely by the research groups that initially proposed them. Currently, none fulfils all the criteria for an ideal serological marker and none has yet achieved the levels of sensitivity and specificity seen with liver biopsy.

IMAGING

Of all the proposed non-invasive alternatives to liver biopsy, imaging has shown some promise. Using routine grey-scale ultrasound, computed tomography (CT) or magnetic resonance imaging (MRI), it has been shown that a small right hepatic lobe, with relatively enlarged left and caudate lobes, are reliable markers of cirrhosis, having a sensitivity of 84%, specificity of 100% and diagnostic accuracy of 94%. These figures are well beyond any achieved by the many serological markers[8].

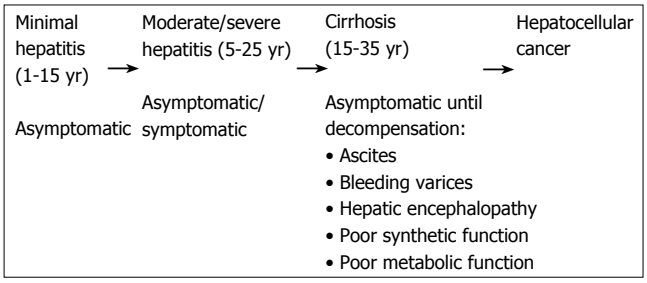

Figure 1 Time scale for progression of hepatitis C-related liver disease[3,4].

ULTRASOUND IMAGING OF THE LIVER

Ultrasound is one of the most widely used imaging modalities in clinical practice. The major attraction is that it is already the first line of imaging in the diagnosis of liver disease and is of particular interest, as it has been shown to be complementary in patients with equivocal biopsy results or where biopsy is contraindicated, but cirrhosis is suspected[8]. It is also used to screen patients with chronic hepatitis for hepatocellular cancer, enabling detection and characterisation of tumors[12]. In patients with cirrhosis, it is possible to demonstrate nodularity of the liver surface and parenchyma and sometimes atrophy of the right lobe[13], but for the most part, standard grey-scale imaging does not render much information on the extent of fibrosis in pre-cirrhotic disease. The most accurate diagnoses which can be made on grey-scale imaging are those of hepatic steatosis, demonstrated by parenchymal hyperechogenicity (Figure 2), and the presence of a nodular surface in cirrhosis (Figure 3). The need to discriminate pre-cirrhotic liver disease non-invasively has driven the development of additional ultrasound techniques, including elastography and a group of microbubble ultrasound contrast agents, in order to achieve better resolution images and allow a degree of hepatic functional assessment.

Transient elastography

Transient elastography has recently been used to characterize the stiffness of liver tissue *in vivo*, which has been correlated with the histological grade of fibrosis in hepatitis C[14]. A probe vibrating at a predetermined amplitude and frequency is placed against skin overlying the liver. The resultant shear wave is propagated through tissue at a velocity dependent on its stiffness. The velocity can be measured by one-dimensional ultrasound along the axis of the transmitted wave. Although correlation is good overall, there is significant overlap of stiffness as measured by elastography between the different stages of fibrosis. Elastography has been used in conjunction with the serological markers, FibroTest (Table 1 for details) and the aspartate aminotransferase (AST) to platelet ratio (APRI) to evaluate

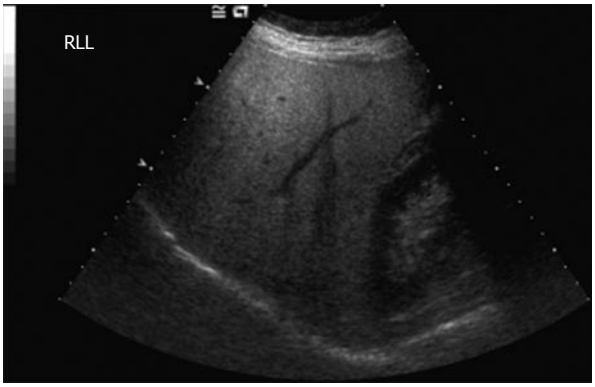

Figure 2 Ultrasound image of hepatic steatosis, showing increased echotexture of the liver parenchyma in comparison to the right kidney.

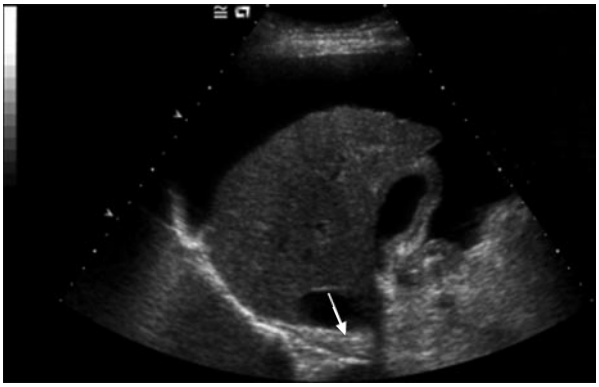

Figure 3 Ultrasound image of a typical cirrhotic liver with a shrunken right lobe, a nodular surface (white arrow), surrounding ascites and a heterogeneous echotexture.

liver fibrosis. There was correlation with histology, but significant overlap of elastography values between stages of fibrosis[15,16]. Further larger scale studies are required using this methodology.

Ultrasound contrast imaging using microbubbles

In the late 1960s, a group of echocardiographers discovered, quite by accident, that the microscopic bubbles of air which enter the circulation during intravenous injections produce strong echoes, where normally none is seen[17,18]. This discovery led to the development of the first type of microbubble contrast agents for ultrasound, which became available in the mid-1990s. Microbubbles are tiny, gas-filled bubbles with a shell (made from denatured albumin, phospholipids, surfactant or cyanoacrylate) which measure less than 10 μm in diameter and are small enough to pass through the cardiopulmonary circulation and also cross capillary beds[19].

In simple terms, microbubbles are echo-enhancers, which enhance both grey-scale and Doppler ultrasound signals by up to 25 dB, giving an increase of more than 300 folds[20]. The first microbubble agent to be licensed for use in the United Kingdom was Levovist® in 1997. Although it exhibited a degree of liver specificity, it had a short half-life and the bubbles were mostly destroyed by liver, meaning that only one pass through the liver was possible. The introduction of SonoVue®, a third-generation microbubble agent, in 2001 allowed real-time contrast-enhanced imaging and multiple passes through the liver.

Safety of microbubbles

As with all pharmaceutical agents, microbubble agents have to pass rigorous safety tests in order for them to be licensed. Extensive trials have established an excellent overall safety record with few significant adverse effects[20]. However, there are some concerns that disruption of their outer shells produces local bioeffects such as sonoporation (subcellular membrane damage) and cell lysis at diagnostic frequencies and that these effects are enhanced by perfluorocarbon gases. Despite this, no effects of these processes have been observed in humans[20]. Concern about administering volumes of gas into the blood stream has been shown not to be an issue as the amount given is under 200 μL, too small to exhibit an effect[21]. Overall, it has been shown that the safety of microbubbles compares favourably to that of conventional radiographic contrast agents and those used in contrast-enhanced MRI[21].

Applications of microbubbles to the assessment of liver disease

Microbubbles have a multitude of clinical uses, but are best known for imaging the vasculature, contrast-enhanced echocardiography, imaging the liver and functional studies. In these functional studies, following an intravenous bolus injection, their passage can be tracked through a tissue or organ and used to generate "transit time" curves in much the same way as those in nuclear medicine, CT and MRI are produced[20].

One of the major applications of transit times is in the assessment of liver disease and the non-invasive diagnosis of cirrhosis[21]. Severe liver disease leads to characteristic haemodynamic changes affecting hepatic blood flow. The development of a hyperdynamic circulation (increased cardiac output, reduced systemic vascular resistance, altered circulating vasoactive factors-glucagons and prostaglandins), pulmonary arteriovenous shunts, venous collaterals (due to increased portal pressure), intrahepatic shunts (between hepatic artery, portal vein and hepatic veins), and arterialisation of the liver capillary beds, results in the early arrival of a bolus of microbubbles injected peripherally (Figure 4). The hepatic vein transit time (HVTT) is the difference between the hepatic artery and the hepatic vein arrival times.

Many of the published studies[22-24] assessing HVTT in patients with chronic liver disease have employed measurements using the spectral Doppler technique, where the arrival time is calculated as a rise in Doppler intensity 10% above baseline. This requires specialized software to evaluate the HVTT, but is relatively straight-forward, as shown in Figure 5. The figure demonstrates a normal hepatic vein transit time (43 s) in a patient without significant liver disease (upper graph, Figure 5) and a comparative early HVTT in a patient with cirrhosis (14 s) (lower graph, Figure 5). There is a much shorter HVTT in the patient with cirrhosis. It is important to note that 20 s of baseline is collected before the injection of the microbubble contrast agent. The continuous horizontal line denotes a Doppler intensity 10% above baseline and hence the HVTT is taken

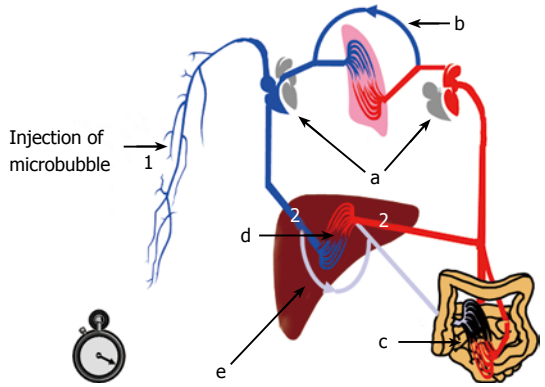

Figure 4 Characteristic haemodynamic changes seen in severe chronic liver disease which lead to the early arrival of microbubbles in the liver. Time is measured from injection (1) to arrival in the liver (2).

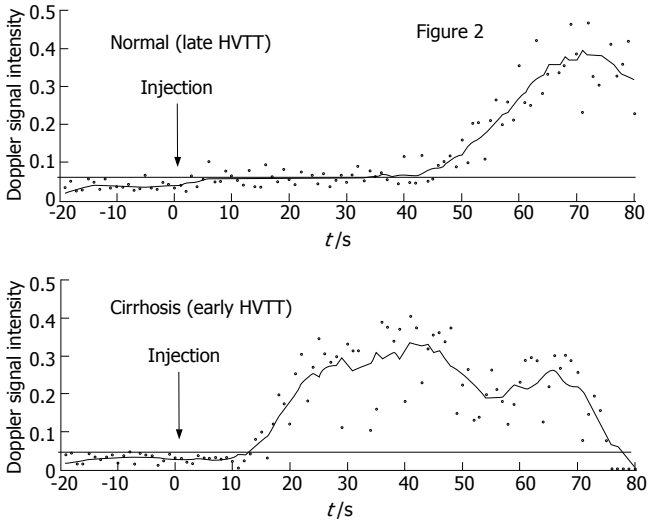

Figure 5 Hepatic vascular transit times (HVTT) following a bolus injection of a microbubble contrast agent, measured in a volunteer without significant liver disease (upper graph) and a patient with cirrhosis (lower graph). There is a much shorter HVTT in the patient with cirrhosis. Adapted from Lim *et al*[23].

as the intersection of this line with that of the Doppler intensity trace (Figure 5).

The development of newer more stable microbubbles, such as SonoVue® (Bracco, Milan, Italy) and improvement in ultrasound capabilities have allowed 'real-time' evaluation of the transit times which can be readily visualized arriving in the hepatic arteries and veins (Figures 5 and 6) without the need for 'off-line' processing.

A typical, simplified transit time assessment would now involve the injection of a bolus of the microbubble agent into an antecubital fossa vein and measurement of the time taken for the contrast agent to be seen in the liver. The first flash of microbubbles seen in the hepatic arteries is recorded as the hepatic artery arrival time. A continuous stream of microbubbles in the hepatic vein is recorded as the hepatic vein arrival time. The hepatic vascular transit time (HVTT) is thus the difference between the hepatic artery and the hepatic vein arrival times.

It has been shown that these transit times can be linked to progression in the Child-Pugh score, becoming shorter as the liver disease worsens[22]. Pre-cirrhotic disease due to hepatitis C can now be classified into mild ($\geqslant$ 28 s) or moderate to severe ($\geqslant$ 22 s, $<$ 28 s) according to transit times[20]. A recent study has shown that a transit time of $\geqslant$ 21 s is 100% sensitive and 96% specific for cirrhosis, making it a viable alternative when liver biopsy is contraindicated. It is also perhaps a method of monitoring disease progression in response to treatment[23]. Figure 6 is adapted from a recent study by Lim *et al*[23] which shows a progressive shortening of the HVTT with increasing severity of liver disease in a cohort of patients with HCV-related liver disease. There is clear separation between the groups (categorisation of patients was carried out according to the Ishak histological scoring system[25]). Importantly, there is a clear separation, not only between the patients with moderate hepatitis from those with cirrhosis, but also in the pre-cirrhotic groups, where there is good separation of patients with mild hepatitis from those with moderate hepatitis[23]. This may be clinically relevant and demonstrates for the first time the possibility that ultrasound techniques can actually monitor the severity of pre-cirrhotic disease non-invasively.

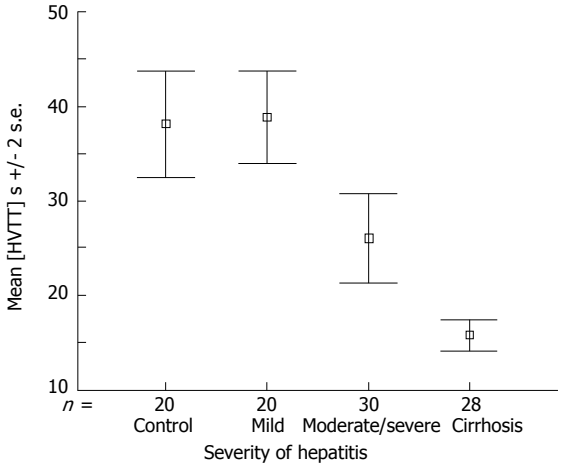

Figure 6 Graph showing hepatic vascular transit times (HVTT) in patients with mild hepatitis, moderate to severe hepatitis and established cirrhosis. There is progressive shortening of the HVTT with increasing severity of liver disease. Adapted from Lim *et al*[23].

Newer microbubble contrast agents

Levovist is at present the most commonly used microbubble agent, but there are several newer agents, such as SonoVue® (Bracco, Milan, Italy) or Definity® (Bristol-Myers-Squibb, New York, USA), which have different chemical properties to Levovist®, but also provide enhanced Doppler intensity when they arrive in the hepatic veins. It remains to be shown whether the HVTT for these agents are similar and whether they can be used interchangeably. A benefit of using these newer agents is that their arrival within a hepatic vein can be observed in 'real-time', using low acoustic power two-dimensional harmonic scanning modes. The main benefit of using these modes is that it would not require computer-aided post-processing of the data to calculate the HVTT, thus making it accessible to any department with a modern ultrasound machine.

CONCLUSION

There are clearly a number of very different methods currently available for the monitoring of hepatitis C-related liver disease. Although liver biopsy remains the gold standard, it is a highly invasive procedure that is not without risk and is open to sampling error, particularly in disease where there is patchy involvement. There is a continual drive towards minimally or non-invasive testing, and therefore, alternatives to liver biopsy are being actively sought.

The use of serological markers remains somewhat confused, with prothrombin index having the highest diagnostic accuracy, despite many other panels being suggested. Further research by independent teams is required to understand exactly what role these markers can perform.

Developments in imaging technology in the past decade have yielded sensitivities and specificities similar to that of liver biopsy for the first time. Ultrasound continues to be the primary imaging modality of choice when investigating liver disease. Although currently limited to a few specialist centers, microbubble contrast agents will inevitably become much more widely used. Hepatic vein transit time measurement using an ultrasound microbubble agent is a simple, non-invasive test which can be used to stage and grade pre-cirrhotic liver disease with clear separation between mild hepatitis and cirrhosis, and statistically significant differences between these two groups and moderate to severe hepatitis. The response to treatment using hepatic vein transit times needs to be assessed in future longitudinal studies, but the methodology is potentially translatable as an efficient, quick and discriminative test for the assessment of disease severity in hepatitis C to any ultrasound department anywhere in the world.

Abstract

Cytosolic Ca^{2+} is an important second messenger in virtually every type of cell. Moreover, Ca^{2+} generally regulates multiple activities within individual cells. This article reviews the cellular machinery that is responsible for Ca^{2+} signaling in cholangiocytes. In addition, two Ca^{2+}-mediated events in cholangiocytes are discussed: bicarbonate secretion and apoptosis. Finally, emerging evidence is reviewed that Ca^{2+} signaling is involved in the pathogenesis of diseases affecting the biliary tree and that Ca^{2+} signaling pathways can be manipulated to therapeutic advantage in the treatment of cholestatic disorders.

INTRODUCTION

Cytosolic Ca^{2+} is an important second messenger in virtually every type of cell. Ca^{2+} regulates a wide range of cell functions, including contraction, gene transcription, cell growth, differentiation, apoptosis, membrane fusion, ion channel activation, and secretion[1]. Moreover, Ca^{2+} generally regulates multiple activities within individual cells. Temporal Ca^{2+} signaling patterns, such as Ca^{2+} oscillations, and spatial signaling patterns, such as Ca^{2+} gradients and waves, permit Ca^{2+} to exhibit this differential regulation of cell function. Therefore, the manner in which cells organize their Ca^{2+} signals is critical for the types of signals they can produce, and thus is critical for the ways in which Ca^{2+} can regulate cell function. There are certain common mechanisms for generating Ca^{2+} signals among cell types, but each cell type has distinct features of signaling machinery as well. Here we will review the machinery that is responsible for Ca^{2+} signaling in cholangiocytes. We also will discuss in detail two Ca^{2+}-mediated events in cholangiocytes, bicarbonate secretion and apoptosis. Finally, we will review emerging evidence that Ca^{2+} signaling plays an important role in the pathogenesis of diseases affecting the biliary tree and in the treatment of cholestatic disorders.

Ca^{2+} SIGNALING MACHINERY IN CHOLANGIOCYTES

Cytosolic Ca^{2+} signals originate from two general sources, release from intracellular Ca^{2+} stores and influx across the plasma membrane. The initial component of Ca^{2+} signals in cholangiocytes and other epithelia is due entirely to Ca^{2+} release from intracellular stores, since this component is unchanged in Ca^{2+}-free medium[2,3]. In contrast, the role of extracellular Ca^{2+} is to maintain cytosolic signals over longer time intervals and to replenish intracellular stores. This review will therefore focus on intracellular Ca^{2+} release mechanisms. There are two intracellular Ca^{2+} release channels that are principally responsible for Ca^{2+} release in nearly every cell type, the ryanodine receptor (RyR) and the inositol 1,4,5-trisphosphate (InsP3) receptor (InsP3R)[1]. The RyR is most heavily expressed in excitable cells such as myocytes and to a lesser extent in neurons. The RyR also is expressed in some nonexcitable cells, including certain polarized epithelia, such as pancreatic acinar cells[4]. The RyR is localized to sarcoplasmic or endoplasmic reticulum (ER), where most intracellular Ca^{2+} is stored. Activation of the receptor allows Ca^{2+} to be released from the ER into the cytosol. The RyR can be activated in several different ways, including through direct coupling with certain plasma membrane Ca^{2+} channels, *via* stimulation with the second messenger cyclic ADP-ribose, or by stimulation with Ca^{2+} itself (Ca^{2+}-induced Ca^{2+} release). Many epithelia, including cholangiocytes[5] as well as hepatocytes[6], do not express the RyR.

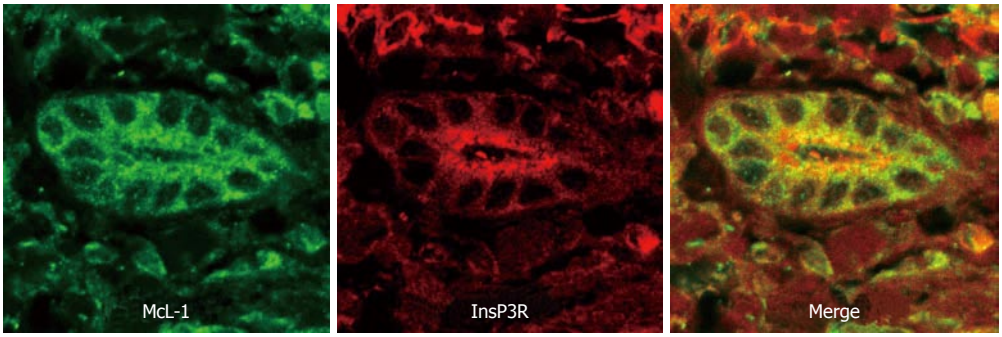

Figure 1 Distribution of the InsP3 receptor and Mcl-1 in human bile ducts. This confocal immunofluorescence image was obtained from a paraffin-embedded biopsy specimen from a normal liver. The specimen was double-labeled with antibodies against Mcl-1 (green) and the type III InsP3R (red). Note that the Mcl-1 is distributed diffusely throughout the cytosol, while the InsP3R is most concentrated in the apical region.

The InsP3R is expressed in virtually every cell type, is the predominant Ca^{2+} release channel in epithelia, and is the only intracellular Ca^{2+} release channel in cholangiocytes[5]. Like the RyR, the InsP3R is expressed in the ER. The endogenous ligand for the InsP3R is InsP3, which is formed from phospholipase C (PLC)-induced hydrolysis of phosphatidyl inositol bisphosphate (PIP2)[7]. This biochemical pathway can be activated by stimulation of either G protein-coupled receptors or receptor tyrosine kinases[1]. Therefore, stimulation of cholangiocytes with certain hormones or growth factors results in InsP3-mediated increases in cytosolic Ca^{2+}. Hormone-induced Ca^{2+} signaling is mediated entirely by InsP3 in cholangiocytes, since Ca^{2+} signaling is blocked by microinjection of the InsP3R inhibitor heparin[2]. There are three InsP3R isoforms, each of which has distinct biophysical properties[8,9]. These properties result in different effects on Ca^{2+} signaling. For example, in DT40 cells engineered to express only a single InsP3R isoform, activation of the type Ⅰ InsP3R results in transient Ca^{2+} oscillations, while the type Ⅱ InsP3R induces sustained oscillations, and the type Ⅲ isoform results in a single, transient increase in Ca^{2+}[10]. Similarly, in CHO cells in which expression of each one of the three isoforms has been silenced, ATP-induced Ca^{2+} signals are preferentially converted from oscillations to either sustained or transient increases in Ca^{2+}[11]. Many cell types express multiple InsP3R isoforms, and some cells[12,13], including cholangiocytes[5], express all three isoforms. Even among cell types that express all three isoforms, there is considerable variability in terms of how much of each isoform is expressed, and in terms of the subcellular region in which each isoform is expressed. In cholangiocytes, the type Ⅲ InsP3R accounts for about 80% of InsP3Rs, while the types Ⅰ and Ⅱ isoforms each account for about 10%. Moreover, the type Ⅲ InsP3R is most concentrated in the apical region (Figure 1), while the other two isoforms are not distributed in a polarized fashion[5]. Hormone-induced Ca^{2+} signals in cholangiocytes begin as apical-to-basal Ca^{2+} waves[5], similar to what is observed in other polarized epithelia[6,14]. In cholangiocytes, this polarized Ca^{2+} signaling pattern is likely due to the apical concentration of the type Ⅲ InsP3R, although it is not clear if this is because the receptor has properties that permit it to trigger Ca^{2+} waves[8], or simply because of the increased InsP3R concentration in the apical region[15]. Ca^{2+} signals also can spread among neighboring cholangiocytes. This effect is mediated by gap junctions in most epithelia[16], including cholangiocytes[17]. The predominant gap junction protein in cholangiocytes is connexin 43, although connexin 32 is expressed in these cells to a lesser extent[17]. Permeability of cholangiocyte gap junctions is decreased by protein kinases A and C[17], which provides additional ways in which Ca^{2+} signals can be modulated in intact bile ducts.

INTERCELLULAR MESSENGERS THAT ACT THROUGH Ca^{2+}

Several intercellular messengers have been identified that increase cytosolic Ca^{2+} in cholangiocytes. Each messenger molecule interacts with specific G protein-coupled receptors that increase Ca^{2+} *via* activation of PLC and formation of InsP3. Acetylcholine (ACh) increases Ca^{2+} by stimulation of M3 muscarinic receptors, which have been identified on cholangiocytes by RT-PCR, immunoblot, and immunochemistry[18]. These receptors are expressed on the basolateral membrane[2]. ACh-induced increases in Ca^{2+} can have both indirect and direct effects on downstream signaling pathways. ACh-induced increases in Ca^{2+} activate calcineurin, which potentiates increases in cAMP that are induced by secretin[18]. Stimulation of cholangiocytes with ACh can result in a sustained, transient, or oscillatory increase in cytosolic Ca^{2+}[2]. The likelihood that a particular pattern of Ca^{2+} signal will be elicited is not dose-dependent, though. ATP also increases Ca^{2+} in cholangiocytes[2]. Like ACh, ATP can induce a sustained, transient, or oscillatory increase in cytosolic Ca^{2+}. Unlike ACh, lower concentrations of ATP predominantly induce Ca^{2+} oscillations, while higher concentrations induce single (either sustained or transient) increases in Ca^{2+}[2]. RT-PCR evidence suggests that cholangiocytes express P2Y1, P2Y2, P2Y4, P2Y6, and P2X4 nucleotide receptors[19]. Pharmacologic evidence using microperfused bile duct segments isolated form rat liver suggests that each of the four P2Y subtypes are expressed on the apical membrane of cholangiocytes. P2Y receptors also are expressed on the basolateral membrane, but the actions of ATP in that region are attenuated by ecto-nucleotidases expressed at that membrane[19] or by nearby portal fibroblasts[20]. Pharmacological studies suggest that there is little or no functional expression of P2X receptors in cholangiocytes[19]. These findings suggest that the principal route for signaling to cholangocytes through ATP is *via* bile. ATP may be released from cholangiocytes to signal in an autocrine or paracrine fashion[21], and this pathway is important for cell volume regulation[22]. ATP also can be secreted into bile from hepatocytes[21,23], which provides a pathway through which hepatocytes can signal

to cholangiocytes[24]. The manner in which this signaling pathway is regulated has not been established, but certain bile acids appear to activate this pathway in order to stimulate ductular bicarbonate secretion[23].

Cholangiocytes also express receptors for a number of neuropeptides that act through Ca^{2+} signaling. Cholangiocytes express both the serotonin 1a and 1b receptor on their basolateral membrane[25]. Stimulation of this receptor inhibits the bile duct proliferation that occurs following bile duct ligation. This is likely mediated through Ca^{2+} signaling, since receptor stimulation is associated with an increase in InsP3 and the effects on cholangiocyte proliferation are blocked by chelation of cytosolic Ca^{2+}[25]. Work in cholangiocyte cell lines has shown that these cells also express CCK-B gastrin receptors. As with serotonin receptors, stimulation of gastrin receptors inhibits cholangiocyte growth. The effect of gastrin also is blocked by chelation of cytosolic Ca^{2+}[26]. Cholangiocytes express alpha-1 adrenergic receptors, primarily on their basolateral membrane. The alpha-1 adrenergic agonist phenylephrine increases secretin-stimulated ductal secretion, as measured in both intact rat liver and isolated rat bile duct units. Phenylephrine also potentiates the effects of secretin on cAMP production, and directly increases cytosolic Ca^{2+} and InsP3 in cholangiocytes[27]. Pharmacologic evidence suggests that cholangiocytes express D2 but not D1 or D3 dopamine receptors. Stimulation of these receptors inhibits rather than stimulates secretin-induced ductular secretion and cAMP production. This is thought to be because D2 receptor stimulation co-activates PKC-gamma, whereas gastrin receptor stimulation co-activates PKC-alpha[28]. Thus, although several types of receptors link to Ca^{2+} signaling in cholangiocytes, they can have distinct downstream actions because of differential effects on Ca^{2+} signaling patterns as well as because of differential activation of related signaling pathways.

REGULATION OF SECRETION *VIA* Ca^{2+}

Cholangiocytes comprise less than 5% of normal liver, but play an important role in the process of bile secretion[29,30]. Cholangiocytes can be stimulated to increase bile flow by up to 50%[31], although cholangiocytes typically affect the pH rather than the volume of bile[32]. Two parallel signaling pathways exist to regulate ductular bicarbonate secretion, which are mediated by either cAMP or Ca^{2+}. Evidence in isolated cholangiocytes and bile duct units suggests that cAMP stimulates chloride secretion *via* the cystic fibrosis transmembrane conductance regulator (CFTR), and that bicarbonate secretion then occurs *via* an associated chloride-bicarbonate exchanger. Some evidence in isolated cell systems suggests that Ca^{2+} analogously stimulates chloride secretion *via* a Ca^{2+}-activated chloride channel, and that bicarbonate secretion then occurs *via* an associated chloride-bicarbonate exchanger[33]. Alternative evidence instead suggests that Ca^{2+} stimulates ductular secretion by calcineurin-mediated potentiation of the cAMP pathway[18]. The mechanism of ductular secretion has also been investigated in the intact liver, by bivascular perfusion of the isolated liver *via* both the hepatic artery and the portal vein[32]. This bivascular perfusion model is necessary to use because the blood supply of cholangiocytes is derived *via* the hepatic artery in normal liver. Thus, for example, the effects of secretin on ductular secretion can be readily detected when this hormone is infused *via* the hepatic artery, but are difficult to detect when infused *via* the portal vein[32]. These studies show that ductular bicarbonate secretion induced by the Ca^{2+} agonist ACh depends upon both chloride channels and chloride-bicarbonate exchange. This observation supports the idea that Ca^{2+}-mediated bicarbonate secretion results from serial activation of chloride channels, and then chloride-bicarbonate exchange. However, bivascular perfusion studies show that cAMP-mediated bicarbonate secretion depends upon chloride channels but not chloride-bicarbonate exchange[32]. This observation supports the idea that ductular bicarbonate secretion induced by cAMP may occur directly *via* CFTR, similar to what has been described in intestine[34,35].

REGULATION OF APOPTOSIS *VIA* Ca^{2+}

Apoptosis in all cell types is regulated in part through Ca^{2+} signaling pathways, and there are special considerations in cholangiocytes. Apoptotic pathways are modulated through mitochondrial permeabilization, which in turn is regulated through Ca^{2+} signaling. The interrelationship between mitochondria and Ca^{2+} signaling results from the close proximity between mitochondria and InsP3Rs[36]. As a result of this physical association, mitochondria are subjected to more intense increases in Ca^{2+} than typically occur in cytosol[36]. Excessive increases in mitochondrial Ca^{2+} result in increases in mitochondrial permeability that are associated with leakage of cytochrome c into the cytosol, which leads to apoptosis[37]. Cytochrome c released from mitochondria binds directly to nearby InsP3Rs, which potentiates release of Ca^{2+} from the receptor[38]. This leads to a positive feedback loop that further increases mitochondrial permeability and promotes apoptosis[38]. On the other hand, the anti-apoptotic Bcl-2 family members Bcl-xL and Bcl-2 inhibit apoptosis by inhibiting InsP3-mediated Ca^{2+} release. Bcl-xL decreases expression of InsP3R, which reduces InsP3-mediated Ca^{2+} release in order to protect against apoptosis[39]. Bcl-2 itself increases leakage of Ca^{2+} from the ER, which also has the net effect of decreasing Ca^{2+} signals in both the cytosol and mitochondria[40]. Mcl-1 is the principal Bcl-2 family member in cholangiocytes[41] (Figure 1). Like other Bcl-2 family members, it appears to inhibit apoptosis through effects on Ca^{2+} signaling. Unlike Bcl-xL or Bcl-2, however, Mcl-1 does not affect either InsP3R expression or ER Ca^{2+} stores[42]. Instead, Mcl-1 inhibits Ca^{2+} signaling directly within mitochondria[42].

All three isoforms of the InsP3R can induce apoptosis[11]. However, each isoform has a different propensity to induce apoptosis[11]. Recent evidence suggests that this may be due in part to their differential distribution relative to mitochondria. Specifically, in cells that co-express each InsP3R isoform, the type Ⅲ $InsP_3R$ is most effective in transmitting Ca^{2+} signals to mitochondira as well as in inducing apoptosis[11]. Furthermore, the type Ⅲ isoform co-localizes most strongly with mitochondria at the light level[11]. Thus, the type Ⅲ InsP3R has a particular propensity to form signaling microdomains with mitochondria. The

type Ⅲ $InsP_3R$ is most concentrated in the apical region of cholangiocytes[5], as described above, but little is known about the factors that regulate this subcellular targeting. It also remains unknown whether apical, type Ⅲ InsP3Rs associate with mitochondria in cholangiocytes, or whether such an association is needed to mediate apoptosis in bile ducts.

Ca^{2+} SIGNALING IN HEALTH AND DISEASE

Ca^{2+} signaling is universal among cells, so one might expect altered Ca^{2+} signaling to play an important role in pathogenesis of disease. In fact, the spectrum of human diseases that had been found to result from alterations in Ca^{2+} signaling has been remarkably limited. These have included a mutation in the RyR, which results in malignant hyperthermia[43]; mutations of the Ca^{2+}-ATPase pump, which are associated with deafness[44]; and an animal model of loss of the types Ⅱ and Ⅲ InsP3Rs, which together results in pancreatic insufficiency and failure to thrive[45]. However, it now appears that loss of InsP3Rs is a common event in human cholestatic disorders. Specifically, expression of the type Ⅲ InsP3R is decreased in the cholangiocytes of patients with primary biliary cirrhosis, sclerosing cholangitis, biliary atresia, and ductular obstruction[46]. This loss of InsP3R expression also occurs in animal models of cholestasis, where it is associated with impaired Ca^{2+} signaling, as well as impaired Ca^{2+}-induced secretion in cholangiocytes[46]. However, cAMP-mediated secretion is maintained in cholangiocytes despite the loss of InsP3Rs. Interestingly, the loss of InsP3Rs that is seen in patients with cholangiopathies is not seen in patients with hepatitis C viral infections, even though such infections are associated with inflammation in the region of the portal triad[46]. This suggests that loss of InsP3Rs from cholangiocytes is not merely a nonspecific effect of local inflammation. Together, these findings suggest that Ca^{2+} signaling pathways are necessary for ductular secretion as it occurs *in vivo*, and that loss of InsP3Rs results in cholestasis, although direct support for this hypothesis is lacking.

Just as impaired Ca^{2+} signaling in cholangiocytes is associated with the development of cholestasis, stimulation of Ca^{2+} signals may be beneficial for the treatment of cholestasis. Ursodeoxycholic acid (UDCA) and its taurine conjugate (TUDCA) are of therapeutic benefit in a range of cholestatic disorders[47]. Recent evidence suggests that these but not other bile acids selectively induce hepatocytes to secrete ATP into bile[23]. In addition, luminal perfusion of isolated intrahepatic bile duct segments with ATP increases Ca^{2+} in cholangiocytes and stimulates ductular bicarbonate secretion, while perfusion with TUDCA does not[23]. These findings suggest that UDCA and TUDCA may promote ductular secretion through a paracrine signaling pathway whereby hepatocytes release ATP to activate apical purinergic receptors on cholangiocytes, which link to Ca^{2+}-mediated secretion of chloride and bicarbonate into bile. Further work is needed to understand how these bile acids induce hepatocytes to secrete ATP, and to demonstrate that this action is in part responsible for their therapeutic effects.

CONCLUSION

Ca^{2+} signaling is a ubiquitous mechanism for regulation of cell function. A range of neuroendocrine and paracrine messenger molecules exert their effects on cholangiocytes through Ca^{2+} signaling. It is already established that these effects include regulation of bicarbonate secretion and regulation of apoptosis. By extension from what has been shown in other cell types, it is likely that Ca^{2+} signaling also regulates other aspects of ductular secretion, including fluid secretion and vesicular targeting and exocytosis, as well as other aspects of cell proliferation, including gene transcription and progression through the cell cycle. Future areas of investigation are likely to more fully identify the range of actions of Ca^{2+} in cholangiocytes. Such information may in turn reveal specific ways in which impaired Ca^{2+} signaling leads to cholangiopathies and related disease states, which then may lead to targeted therapies that are based on correcting such impairments.

Abstract

Cholangiocytes, the epithelial cells lining the biliary ducts, are the target cells in several liver diseases. Cholangiopathies and cholangiocarcinoma generate interest in many scientists since the genesis. The developing mechanisms, and the therapeutic tools of these diseases are still undefined. Several studies demonstrate that many hormones, neuropeptides and neurotransmitters regulate malignant and non-malignant cholangiocyte pathophysiology in the course of chronic biliary diseases. The aim of this review is to present the findings of several studies published in the recent years that contributed to clarifying the role of nervous and neuroendocrine regulation of the pathophysiologic events associated with cholestasis and cholangiocarcinoma development. This manuscript is organized into two parts. The first part offers an overview of the innervation of the liver and the origin of neuroendocrine hormones, neurotransmitters and neuropeptides affecting cholangiocyte function and metabolism. The first section also reviews the effects played by several neuroendocrine hormones and nervous system on cholangiocyte growth, survival and functional activity in the course of cholestasis. In the second section, we summarize the results of some studies describing the role of nervous system and neuroendocrine hormones in the regulation of malignant cholangiocyte growth.

INTRODUCTION

Cholangiocytes are the epithelial cells that line the intrahepatic biliary tree. Their physiologic role is to modify the bile of canalicular origin, through a wide array of absorbtive and secretive processes[1,2]. Indeed, although in normal conditions they represent approximately the 4%-5% of the liver mass, they contribute for at least the 10%-30% of the bile flow[1].

Cholangiocytes are the target of chronic diseases, termed cholangiopathies[3,4], that are commonly characterized by dysregulation of the balance between cell growth and survival. In the course of such diseases there is impaired proliferative response to duct injury and increased cell death by apoptosis, that leads to vanishing of bile ducts[3] and functional liver failure at the end stage. Cholangiopathies thus represent a daily challenge for the clinicians, since definitive medical treatments are not available yet. As a consequence, 20% of liver transplants among adults and 50% of those among pediatric patients are due to these disorders[5].

The malignant transformation of cholangiocytes gives origin to cholangiocarcinoma[6]. Cholangiocarcinoma is often diagnosed at late stages; its surgical resection has given very limited success, as response of this neoplasm to conventional chemotherapy[6] is minimal. These features make cholangiocarcinoma a malignancy characterized by a very poor prognosis. In addition, the incidence and prevalence of cholangiocarcinoma are increasing worldwide[7].

Many of the problems that arise in the management

of cholangiopathies and of cholangiocarcinoma can at least in part be ascribed to the poor knowledge about their pathophysiology. Very little is in fact known on which factors are able to affect cholangiocyte biology, with particular regard to those endogenous molecules or systems that affect either cholangiocyte proliferation, survival or functional activity[4].

Bile acids are endogenous factors that have been historically investigated more in this regard, and their properties in modulating cholangiocyte biology and cholangiocarcinoma development are now unanimously accepted[8-13]. More recently, several studies demonstrated that many hormones, neuropeptides and neurotransmitters are able to affect malignant and non malignant cholangiocyte biology as well. This data showed that the biliary epithelium is similar to the gastric or intestinal epithelia, for which the key role played by nerves and neuroendocrine hormones has been known for years[14]. Moreover, it has been shown that in the course of chronic cholestasis, cholangiocytes acquire a neuroendocrine phenotype, that is not proper for these cells in normal conditions[15]. Immunohistochemical studies have also reported that many biliary tract carcinomas (up to the 70% of the cases) show a neuroendocrine differentiation[16,17].

The purpose of this review is therefore to summarize the evidences from the several studies published in the recent years that contributed to clarify the role of nervous and neuroendocrine regulation of the pathophysiologic events associated with cholestasis and cholangiocarcinoma development. In particular, we will focus on how these factors affect cholangiocyte cell biology. We suggest those who might be interested to learn the effects of nerves and neuroendocrine hormones on other liver cell type biology to other reviews recently published on this subject[18-20].

ORIGIN OF NEUROENDOCRINE HORMONES, NEUROTRANSMITTERS AND NEUROPEPTIDES AFFECTING CHOLANGIOCYTES

Neuroendocrine hormones are secreted by neuroendocrine cells, that are diffusely present in the whole gastrointestinal tract, in particular the stomach, small bowel[21], as well as pancreas[22]. If these cells are considered the main source of the neuroendocrine hormones, in this review some studies suggest that cholangiocytes them-selves can synthesize some of these peptides in the course of cholestasis.

The liver is innervated by both sympathetic and parasympathetic nerves, whose fibers are located around the hepatic artery, portal vein, intrahepatic and extrahepatic bile ducts[23,24]. Sympathetic nerves originate from the celiac ganglion, whereas the parasympathetic from the vagus nerve[23,24]. Besides catecholamines and acetylcholine, autonomic fibers that innervate the liver can also release other neurotransmitters, like neuropeptide Y (NPY)[25,26], calcitonin gene related peptide (CGRP), somatostatin, vasoactive intestinal polypeptide (VIP), enkephalin and bombesin[27-30]. Nerve terminations mostly follow the vascular structures of the portal tract, and have been identified around bile ducts and vessels. Many of the above mentioned neurotransmitters have been shown to modulate intrahepatic hemodynamics[31-33].

Table 1 Neuroendocrine hormones affecting cholangiocyte biology

Hormone	Receptor	Effect on cholangiocyte biology	Reference
Secretin	SR	Stimulates HCO_3^- secretion through the increase of cAMP/PKA and opening of CFTR	1, 34-43
Somatostatin	$SSTR_2$	Counteracts the effect of secretin; stimulates bile absorption	44, 45
Insulin	IR	Counteracts the effect of secretin	46
ET-1	ET_A-ET_B	Counteracts the effect of secretin; reduces the SR expression	47
VIP	unspecified	Increases HCO_3^- and water secretion	48, 49
Bombesin	unspecified	Increases HCO_3^- and water secretion	50
Gastrin	CCK-B/ gastrin	Counteracts the effect of secretin; reduces cell proliferation	40, 51
Estrogens	ERα-ERβ	Stimulate cell proliferation	52-55
Serotonin	$5HT_{1A}$-$5HT_{1B}$	Synthesized and secreted by cholangiocytes in the course of cholestasis. Counteracts the effect of secretin and reduces cell growth	58
GH/IGF-1	GH-R-IGF-1R	Stimulate cell proliferation	59

NERVOUS AND NEUROENDOCRINE REGULATION OF THE PATHOPHYSIOLOGY OF CHOLESTASIS

Regulation of cholangiocyte growth, survival and functional activity by neuroendocrine hormones (Table 1)

The close link between cholangiocytes and neuroendocrine hormones has its basis on the early studies that showed the hormone secretin as the most potent regulator of cholangiocyte functional activity[34,35]. In 1988, Alpini *et al* demonstrated that in a rat model of cholestasis (induced by bile duct ligation, BDL) the infusion of secretin was associated with a marked increase of the bile flow and bicarbonate biliary excretion[35]. After that "landmark" manuscript, a large series of investigations later defined the intracellular mechanisms by which secretin induces such a potent functional stimulus. It is now known that secretin stimulates ductal secretion[1,34-36] by selective interaction with secretin receptors, expressed only by cholangiocytes in rat liver[37]. The interaction of secretin with its own receptors[37] leads to an increase in intracellular cAMP levels[1,36,38-40], activation of PKA[41], opening of CFTR Cl^- channels[42] with activation of the Cl^-/HCO_3^- exchanger[1,36,41,43], which leads to secretion of bicarbonate into bile[35].

Other neuroendocrine hormones were then discovered to affect cholangiocyte choleretic activity. One of the first molecules studied was somatostatin. It was demonstrated that cholangiocytes express the $SSTR_2$ receptor; the interaction of somatostatin with this receptor markedly diminished the effect of secretin on the biliary excretion

of water and bicarbonate by cholangiocytes in cholestatic conditions[44]. Such an effect of somatostatin was due to the fact that the activation of the $SSTR_2$ receptor prevented the increase of the adenylyl-cyclase elicited by secretin[44]. In later studies conduced in IBDUs isolated from wild type and $SSTR_2$-knock out mice, it was also found that somatostatin not only reduces cholangiocyte choleresis, but it also stimulates ductal bile absorption[45].

Cholangiocytes also express at the apical pole the receptor for insulin[46]. Upon its activation, a marked reduction of the secretin-induced choleresis was observed, both if the hormone was administered *in vivo* to BDL rats and if microinjected into the lumen of IBDUs isolated from animals with cholestasis. It was observed that the activation of the insulin receptor determined a cascade of intracellular events that resulted in the inhibition of secretin-stimulated cAMP and PKA activity. Such a chain of events seemed to have its core event in the enhancement of the intracellular Ca^{2+} levels and the consequent activation of the Ca^{2+}-dependent PKCα[46]. An effect similar to the one of insulin has been described for endothelin-1 (ET-1), which interacts with the specific receptors expressed in the biliary epithelium (ET_A and ET_B) and blunts the secretin-induced choleresis of the BDL rat and reduces the expression of the secretin receptor on cholangiocytes[47].

In contrast to somatostatin and insulin, vasoactive intestinal polypeptide (VIP) and bombesin have been found to be able to enhance cholangiocyte choleresis. Both the hormones induced a potent fluid and bicarbonate excretion in IBDUs, but not in hepatocytes, isolated from normal and cholestatic rats. Interestingly, neither VIP nor bombesin had any significant effect on modulating intracellular cAMP levels[48-50]. Detailed pH studies indicated that the underlying intracellular mechanism, at least for bombesin, is its ability to stimulate the activity of Cl^-/HCO_3^- exchange in association with a counterbalancing secondary activation of electrogenic Na^+/HCO_3^- symport[50].

In more recent studies, increasing evidence regarding the ability of neuroendocrine hormones to affect cholangiocyte growth, and functional activity, hvee been reported.

If the infusion of gastrin to BDL rats is associated with the reduction of the choleretic response to secretin by cholangiocytes[40], its chronic administration through an intraperitoneal minipump resulted not only in reduced functional activity, but also in a marked decrease of the bile duct mass[51]. Cholangiocytes indeed express the CCK-B/gastrin receptors[51], which, upon activation, elicit the intracellular Ca^{2+} release, the increase of IP_3 levels, and the membrane translocation (e.g. activation) of the Ca^{2+}-dependent PKCα[51]. In turn, the gastrin-activated PKCα, as above mentioned, is able to interfere with the secretin signaling and modulate the adenyl-cyclase activity, thus reducing the intracellular cAMP levels and PKA activity. These observations, demonstrated that bile acids also activate this intracellular pathway to modulate cholangiocyte growth[8], contribute to elucidate which intracellular signalings sustain the proliferative response of cholangiocytes to cholestasis and by which mechanisms it is possible to modulate them. Moreover, since cAMP/PKA resulted the key molecules implicated in cholangiocyte proliferation, this helped to explain the association between increase of duct mass and enhanced biliary choleresis[8,35].

A major contribution to this field of research has been given by the studies that clarified the effects of estrogens on the biliary epithelium. Both the estrogen receptor (ER) α and β were observed in cholangiocytes[52], their expression being up-regulated after BDL[53]. When cholangiocytes were stimulated *in vitro* with 17-β-estradiol, their proliferation was markedly increased, as a consequence of the ER-dependent activation of Src/Shc/ERK1/2 intracellular pathway[54]. To demonstrate the physiological and pathophysiological relevance of estrogens on cholangiocyte proliferative response to cholestasis, when BDL male rats were treated *in vivo* with antiestrogens like tamoxifen or Ici 182 780[52] or when BDL female rats were subjected to ovariectomy[53], the growth of the biliary tree was blunted and the biliary epithelium underwent programmed cell death by apoptosis[52,53]. This evidence suggested that estrogens are required for a separative response of the biliary tree to injury. These studies produced in the last few years by Alvaro represent a significant change in the knowledge of the role played by the neuroendocrine system on the biliary cell biology. Indeed, primary biliary cirrhosis (PBC), the most common from of cholangiopathies[4], is much more frequent in women than in men, and has its clinical outcome typically after menopause, when the endogenous estrogen levels suddenly drop[55]. Therefore, these observations by Alvaro seem to provide the biological confirmation of the role of estrogens in the progression of PBC, a role that was, earlier, only hypothesized on the basis of epidemiological data. To further support this concept, Alvaro also demonstrated that the ER expression in cholangiocytes is markedly reduced in late stages of PBC[55]. Altogether, Alvaro's studies made clear that gaining knowledge on the role of neuroendocrine hormones on cholangiocyte biology might also be an effective strategy to further understand the pathophysiology of the cholangiopathies and thus eventually to design novel therapeutic strategies.

The neuroendocrine hormone serotonin has been hypothesized to be involved in the genesis of certain clinical features of PBC, like fatigue and pruritus[56,57]. Interestingly, it has been recently shown that cholangiocytes express the serotonin 1A and 1B receptors[58]. When they are activated by selective agonists, the proliferation of BDL cholangiocytes are dramatically reduced, both *in vivo* and *in vitro*[58], in association with the loss of the response to secretin of the markers of cholangiocyte functional activity[58], like the bile flow, the bicarbonate excretion and the intracellular cAMP levels[34]. Such an effect seems more to be mediated by the cross-talk between the Ca^{2+} and the cAMP/PKA signalings. If the serotonin 1A and 1B receptors are activated, there is an increase of Ca^{2+}, IP_3 and PKCα levels, with the consequent reduction of the intracellular cAMP levels and PKA activity. Most interestingly, it was observed that hyperplastic cholangiocytes isolated from BDL rats are able to synthesize and secrete serotonin.[58] If, *in vitro* or *in vivo*, cholangiocyte-secreted serotonin is neutralized,

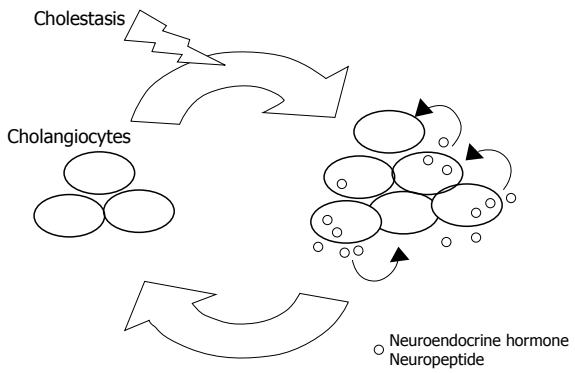

Figure 1 Proposed working model for the existence of an autocrine/paracrine loop of neuroendocrine hormones and neuropeptides that regulate the proliferative response of cholangiocytes to cholestasis. A chronic cholestatic condition induces cholangiocyte proliferation and their transdifferentiation in neuroendocrine-like cell. This allows the biliary epithelium to start to synthesize and secrete a number of peptides that aim to counterbalance the effects of cholestasis itself on cell growth, as a sort of negative feed-back.

Table 2 Neurotransmitters/neurotrophins affecting cholangiocyte biology

Peptide	Receptor	Effect on cholangiocyte biology	Reference
Acetylcholine	M3	Potentiates the effect of secretin. Required for cholangiocyte response to BDL: sustains cholangiocyte proliferation and prevents apoptosis	43, 60, 61, 64, 65
Epinephrine/ Norephinephrine	α_1	Potentiates the effect of secretin	67
Epinephrine/ Norephinephrine	β_1-β_2	Required for cholangiocyte response to BDL: sustains cholangiocyte proliferation and prevents apoptosis	70
Dopamine	D2	Inhibits secretin-induced ductal secretion	73
NGF	TrkA	Secreted by hyperplastic, cholestatic cholangiocytes; sustains the rpoliferative response to BDL	74

cholangiocyte proliferation in response to cholestasis further increases[58]. This study, therefore, proposes an additional novel working model (as shown in Figure 1): in the course of cholestasis, cholangiocytes acquire a neuroendocrine phenotype that allow them to synthesize some neuroendocrine hormones, like serotonin. Once secreted, these hormones aim to counterbalance the excessive proliferative response of the biliary epithelium. It is thus possible to postulate the existence of an autocrine/paracrine loop of peptides and neuroendocrine hormones that modulate with a negative (or an eventually positive) feed-back the response of cholangiocytes to liver injury[58]. The investigation of the presence of other peptides and hormones that are likely to participate with serotonin in this autocrine/paracrine loop might thus be needed to understand certain still obscure clinical aspects of cholangiopathies.

Recent evidence demonstrated that a "stimulatory" autocrine/paracrine loop should also exist. It has been found that cholangiocytes are the target of the growth hormone (GH)-insulin like growth factor (IGF)-1 axis[59]: GH induces IGF-1 expression and release in isolated cholangiocytes, with the consequent stimulation of cell growth by IGF-1[59].

Regulation of cholangiocyte growth, survival and functional activity by neurotransmitters (Table 2)

A number of studies showed that cholinergic nerves regulate bile secretion[60,61]. In bile-fistula dogs with interrupted enterohepatic circulation, distal stimulation of the vagus nerve increases bile bicarbonate secretion, whereas vagotomy decreases basal bile flow and bicarbonate output[60,61].

In early studies[62] it seemed that cholangiocytes might express both the M1 and the M3 acetylcholine (ACh) receptor subtypes and that the cholinergic agonist, carbachol, stimulates bile flow of the isolated perfused rat liver. These observations were not confirmed by successive investigations. In 1996, Nathanson *et al* demonstrated that, in accordance with the concept that cholangiocytes, but not hepatocytes, express ACh receptors, ACh did not affect the functions of hepatocytes, but elicited Ca^{2+} increase and oscillation in IBDUs, due to both an influx of extracellular Ca^{2+} and the mobilization of thapsigargin-sensitive Ca^{2+} stores[63]. A year later, Alvaro *et al* showed that cholangiocytes express, at the basolateral domain, M3 (but not M1 and M2) Ach receptors.[43] In that study it was shown that ACh has no effect on the basal activity of the Cl^-/HCO_3^- exchanger, but it significantly potentiates the stimulatory effect of secretin on this anion exchanger[43]. Presumably, the significance of ACh-regulation of bicarbonate secretion by bile ducts is to be researched in the need of bicarbonate-enriched secretion in the small intestine during the digestive phase, when, indeed, the parasympathetic system activity is high. By selectively interacting with M3 receptor subtypes, ACh induces a Ca^{2+}-calcineurin mediated potentiation of the secretin-induced adenylyl cyclase activity, which leads to activation of the Cl^-/HCO_3^- exchanger with bicarbonate secretion into bile[43]. Furthermore, recent studies have shown that ACh sustains cholangiocyte proliferation, since interruption of the cholinergic innervation by vagotomy induces a marked decrease in total bile duct mass caused by both impaired cholangiocyte proliferative capacity and intracellular cAMP levels, and enhanced cell death by apoptosis[64,65]. These studies also show that maintenance of intracellular cAMP levels (by chronic administration of forskolin) prevents the effects of vagotomy on cholangiocyte apoptosis, proliferation and secretion[65].

There is growing information regarding the role of adrenergic and dopaminergic innervation in the regulation of cholangiocyte proliferation and secretion. An intact sympathetic innervation is required for hepatocyte and cholangiocyte proliferation following partial hepatectomy[66]. Recent studies demonstrated that: (1) cholangiocytes from BDL rats express alpha-1, alpha-2, beta-1 and beta-2 adrenergic receptors; and (2) alpha-1 (but not beta-1) adrenergic receptor agonists increase secretin-stimulated ductal secretion[67]. Similar to what is shown in the gut, adrenergic innervation may play a role in counterbalancing the stimulatory effects of cholinergic

nerves[65] on ductal bile secretion in chronic cholestatic liver diseases.

In support of the concept that adrenergic innervation plays an important role in the regulation of cholangiocyte functions, administration of a single intraportal injection of 6-hydroxidopamine, which induces degeneration of dopaminergic terminal fibers[68,69], blunts the cholangiocyte functional and proliferative response to cholestasis and induces cell death by apoptosis[70]. Chronic administration of clenbuterol (a beta-2 adrenergic agonist)[71] and dobutamine (a beta-1 adrenergic agonist)[72] prevents the decrease in cAMP levels and secretion induced by 6-OHDA, maintains cholangiocyte proliferation and decreases cholangiocyte apoptosis due to 6-OHDA[70]. Furthermore, it has been shown that cholangiocytes express the D2 (but not the D1 and D3) dopaminergic receptors and that the D2 dopaminergic agonist, quinelorane inhibits secretin-induced ductal secretion in BDL rats through activation of the Ca^{2+}-dependent PKC gamma (but not PKC alpha, beta I and II) and inhibition of secretin-stimulated cAMP levels and PKA activity[73].

The relationship between the biliary epithelium and nerves appears to be more than what was thought at the beginning. Cholangiocytes express the receptor for neurotrophin Nerve Growth Factor (NGF), the activation of which strongly promotes biliary cell growth[74]. Moreover, it has been found that cholangiocytes themselves can produce and secrete NGF and that when this neurotrophin is immunoneutralized the growth of the biliary tree in the BDL rat is strongly diminished[74].

Altogether, these data suggest that the autonomic innervation plays a substantial role in the regulation of cholangiocyte biology, thus enlightening the need of studying whether the liver denervation after transplantation might affect the functions of the grafted biliary tree. Of major interest would also be to investigate whether other endogenous factors, instead of nerves, can support cholangiocyte functions in the denervated organ. In this view, some evidence suggest that bile acids could be important. It has been found that administration of taurocholic[64] or ursodeoxycholic acid[75] counteracts the loss of bile ducts induced by cholinergic denervation in the BDL rat. Similarly, taurocholic acid administration also prevents the loss of bile ducts induced by adrenergic denervation[76].

NERVOUS AND NEUROENDOCRINE REGULATION OF BILIARY CARCINOGENESIS

Cholangiocarcinoma, the primary cancer that originates from the epithelial cells lining the bile ducts, is a devastating malignancy characterized by poor prognosis and high mortality[6,77]. The only curative treatment, even if only possible at an early stage of this neoplasm, is surgical. However, patients often present this tumor at an advanced stage, when a curative surgery is unlikely. In fact, at the time of diagnosis, more than two-thirds of patients affected by biliary tract cancer present as an unresectable disease[78] and patients with an operable tumor have a high rate of recurrence. Overall survival rate, including resected patients is quite poor, with less than 5% of patients surviving 5 years, a rate which has remained unchanged over the past 30 years[77]. Chemotherapy and radiation therapy have been used in an attempt to control this disease and improve survival and quality of life of patients with unresectable, recurrent and metastatic cholangiocarcinoma, but these therapies have not shown to be effective in prolonging long-term survival. For these reasons there is a compelling need to discover novel molecules and agents to target the cholangiocarcinoma cells and to regulate their destructive growth[79]. There is growing information regarding the role of nerves and neuropeptides as modulators of cholangiocyte function and metabolism[14]. Moreover, several reports suggest that nervous stimuli are involved in the regulation of growth of biliary malignancies[16,17,80].

Table 3 Neuroendocrine hormones affecting cholangiocarcinoma cell biology

Hormone	Receptor	Effect on cholangiocarcinoma cell biology	Reference
Estrogens	ER	Stimulated SK-ChA-1 human cholangiocarcinoma cell growth	81
		Tamoxifen induced dose-dependent growth inhibition of OZ and SK-ChA-1 human cells *in vitro*; reduced growth of a SK-ChA-1 tumor cell xenografts implanted in athymic nude mice	81
		Tamoxifen stimulated SK-ChA-1 human cholangiocarcinoma apoptotic cell death	82
		Tamoxifen induced human cholangiocarcinoma cell apoptosis *in vitro* and inhibited tumor xenograft growth after pretreatment with IFN-gamma	83, 84
Gastrin	CCK-B /gastrin	Inhibited Mz-ChA-1, HuH-28, and TFK-1 human cell lines proliferation and induced Mz-ChA-1 cell apoptosis	90
CCK	CCK	Reduced the growth of SLU-132 human tumor xenografts implanted in nude mice; stimulated the release of carcinoembryonic antigen (CEA) by SLU-132 cells	93

Regulation of malignant cholangiocyte growth by neuroendocrine hormones (Table 3,Table 4)

The involvement of neuroendocrine system in regulating cholangiocarcinoma cell proliferation has been suggested by several studies. Tamoxifen, an estrogen antagonist, cause a dose-dependent decrease of proliferation of two human cholangiocarcinoma cell lines *in vitro*[81]. On the other hand, 17-β estradiol stimulate human cholangiocarcinoma cell growth *in vitro*[81]. In addition, tamoxifen induced a growth reduction of a cholangiocarcinoma tumor implanted in athymic nude mice[81]. Tamoxifen exerts its inhibitory effect in human cholangiocarcinoma cells by stimulating apoptotic cell death and this is likely mediated through the Fas/APO-1 (CD95) signaling pathway via a calmodulin-dependent mechanism[82].

A further study showed that tamoxifen exposure to human cholangiocarcinoma after pre-treatment with

IFN-gamma allows for induction of apoptosis *in vitro* and significant inhibition of tumor growth[83]. Thus, the combination of IFN-gamma and estrogen antagonists, including tamoxifen, could be useful to have a sustained and valid inhibitory effect on cholangiocarcinoma cell growth[83,84].

Gastrointestinal polypeptide hormones regulate the growth of various normal gastrointestinal tissues as well as certain visceral cancers. Gastrin, which belongs to the superfamily of cholecystokinin receptors (CCK-A, CCK-B/gastrin receptors), is a trophic factor within the normal gastrointestinal tract and is also a mitogen for a number of gastrointestinal and non-gastrointestinal tumors such as gastric, colonic and pancreatic[85-88]. In contrast, CCK-B/gastrin receptor signaling in the human pancreatic cell lines MiaPaca-2 and Panc-1 leads to inhibition of cell growth[89]. It has been shown that malignant cholangiocytes express gastrin receptors[90] and that gastrin, interacting with CCK-B/gastrin receptors, inhibited the proliferation of Mz-ChA-1, HuH-28 and TFK-1 cholangiocarcinoma cell lines, also inducing apoptosis in Mz-ChA-1 cells by activation of the Ca^{2+}-dependent PKC-α signaling[90]. The blockage of CCK-B receptors did not totally reverse the inhibitory effect of gastrin on Mz-ChA-1 cell growth. This finding could be explained by the fact the gastrin may exert its effect not only through CCK-B/gastrin receptors, but also through other receptor types, as suggested by studies in other carcinomas cell lines (*e.g.* colonic cancer cells)[91]. This partial inhibitory effect by CCK-B/gastrin receptor inhibitors might also be due to altered processing of the CCK/B receptor by malignant transformed cells, as previously described[92]. A previous study by Hudd *et al* showed that human cholangiocarcinoma cells expressed CCK receptors and chronic treatment with CCK octapeptide reduced the growth of human cholangiocarcinoma tumors implanted in nude mice[93].

Somatostatin receptors (SS), most commonly the SS receptor type 2 (SSTR2), have been described in several neuroendocrine and epithelial malignancies[94], such as in malignant cholangiocytes[95,96]. Studies demonstrated that somatostatin and its analogues inhibit *in vitro* cholangiocarcinoma cell proliferation. Indeed, chronic administration of lanreotide, a long-acting SS analogue, reduces the growth of human cholangiocarcinoma cells when implanted in athymic mice[95,96] and the inhibitory effect of somatostatin in cholangiocarcinoma cell growth was accompanied by no changes in cellular cyclic adenosine monophosphate (cAMP) or calcium intracellular levels. Furthermore, Zhao *et al* showed that octreotide inhibits cholangiocarcinoma cells growth through G0/G1 cell cycle arrest rather than through the process of apoptosis. These effects were partially mediated by enhancing the expression of $p27^{kip1}$, and by decreasing the amounts of cyclin E-CDK2 complex[95]. Taken together, these findings suggested possible use of SS analogues in the diagnosis or therapy of cholangiocarcinoma. However, a subsequent phase II study showed absence of therapeutic efficacy of the somatostatin analogue lanreotide in the treatment of advanced primary hepatic cholangiocellular cancer and gallbladder adenocarcinoma, despite *in vivo* somatostatin-receptor expression[97].

Table 4 Neuroendocrine hormones affecting cholangiocarcinoma cell biology

Hormone	Receptor	Effect on cholangiocarcinoma cell biology	Reference
Somatostatin, analogues (octreotide, lanreotide)	$SSTR_2$	Inhibited human cholangiocarcinoma cell proliferation *in vitro* and reduced human cholangiocarcinoma cell growth implanted in athymic mice	96
		Inhibited RBE, NEC, QBC939, and SSP-25 cell proliferation *in vitro* through cell cycle arrest and QBC939 xenografts growth	95
GABA	$GABA_{A,-B,-C}$	Inhibited human Mz-ChA-1, HuH-28 and TFK-1 cell proliferation *in vitro*; reduced malignant cholangiocyte migration. Reduced Mz-ChA-1 xenograft tumor growth implanted in athymic mice	98
NPY	NPY-Y5	Inhibited Mz-ChA-1 cell proliferation *in vitro*	99

Liver represents the most important site of GABA synthesis and metabolism outside the central nervous system. Recently, our group demonstrated that cholangiocarcinoma cells express $GABA_{A,-B,-C}$ recep-tors and respond to GABA stimulation with growth inhibition. GABA inhibitory effect on malignant cholangiocyte proliferation was evident *in vitro* and also *in vivo*, by reducing the growth of cholangiocarcinoma tumors injected subcutaneously in nude mice. Moreover, GABA has been shown to be able to inhibit malignant cholangiocyte migration, a peculiar characteristic of the cholangiocarcinoma cells[98].

Another neurotransmitter available in the liver parenchyma and biliary tract is the neuropeptide Y (NPY)[99]. Recent preliminary data from our group showed that NPY inhibits cholangiocarcinoma growth by interaction with a G-protein coupled receptor by Ca^{2+} dependent modulation of Src/ERK1/2 phosphorylation[99].

Regulation of malignant cholangiocyte growth by neurotransmitters (Table 5)

Autonomic nervous system regulates the growth of several tumors[100-102]. For example, alpha-blockers, terazosin and doxazosin, suppress prostate growth by inducing apoptosis among the epithelial cells in the benign and malignant prostate[103]. Also, phenylephrine reduced $HepG_2$ cell growth through $alpha_{1B}$-adrenergic receptors activation[104]. Moreover, activation of a β-2 adrenergic receptor/Gsα fusion protein leads to the inhibition of cAMP-sensitive S49 lymphoma and carcinoma carB cells proliferation *in vitro*[105].

A specific role of sympathetic nervous system in the regulation of cholangiocarcinoma growth has been described by Kanno *et al*, that showed that cholangiocarcinoma cell lines Mz-ChA-1 and TFK-1 express the α_{2A}-, α_{2B}-, α_{2C}- adrenergic receptor subtypes[80]. Furthermore, stimulation of malignant cholangiocytes by UK14, 304, an α_2-adrenoreceptor agonist, causes up-regulation of cAMP, which inhibits EGF-induced MAPK activity through

Table 5 Neurotransmitters/neurotrophins affecting cholangiocarcinoma cell biology

Peptide	Receptor	Effect on cholangiocarcinoma cell biology	Reference
Epinephrine/ Norephinephrine	α_2	UK 14,304 inhibited human Mz-ChA-1 and TFK-1 cell proliferation *in vitro*	[80]
Acetylcholine	M1	Carbachol produced an increase of IP3 and Ca^{2+} intracellular levels in Mz-ChA-1 cells	[62]

an acute increase of Raf-1 and sustained activation of B-Raf[80], thus reducing tumor cell proliferation. Since inhibition of cholangiocarcinoma cell growth through activation of α_2-adrenergic receptor occurred downstream to Ras, this study suggested that adrenergic stimulation or other stimulants of cAMP may overcome the Ras mutations present in malignant cholangiocytes and offer a new therapeutic approach in patients with cholangiocarcinoma[80].

Other studies showed that Mz-ChA-1 cells express muscarinic acetylcholine (ACh) receptors[62]. In support of the hypothesis that such receptors modulate cholangiocarcinoma cell growth, stimulation of malignant biliary cells with carbachol, a muscarinic acetylcholine receptor agonist, triggers IP_3 formation and a subsequent increase of intracellular Ca^{2+} levels[62]. Even if several studies show IP_3 and Ca^{2+} levels play an important role in the inhibition of cholangiocarcinoma cell growth after stimulation with several molecules[13,90,98]. the specific action of parasympathetic nervous system in modulating cholangiocarcinoma cell growth is still unknown.

However, recent data showed that muscarinic receptors are directly activated by other molecules. In fact, recent studies showed that bile acids, interacting with M3 Ach receptors, transactivate EGFR and stimulate colon cancer cell proliferation by inducing p90RSK phosphorylation via a calcium-, MEK- and MAPK-dependent pathways[106].

Recent findings suggest that cholangiocarcinoma and other liver tumors could arise from activated hepatic progenitor cells[107-109]. Several evidences indicate that hepatic progenitor cell activation in diseased liver is regulated by neural and neuroendocrine factors such as vagal innervation[110,111], suggesting an important involvement of autonomic nervous system in developing biliary carcinogenesis.

SUMMARY AND FUTURE PERSPECTIVES

The amount of evidences indicating the substantial role of neuroendeocrine hormones, neuropeptides and neurotransmitters in modulating malignant and non malignant cholangiocyte biology is rapidly increasing. There is still much to understand on how actually these peptides create a network that affects the response of biliary cells to liver injury. On the other hand the other frontier is no doubt represented by the identification of the most proper way of modulating such a network of peptides. Will we be able to interfere with it in order to divert or relent the progression of cholangiopathies and cholangiocarcinoma?

Abstract

It is remarkable that microarray technologies have nearly reached a pinnacle. Establishment of further analysis and management of enormous data derived from microarray technology is currently the highest priority. The heterogeneous functions of cholangiocytes regulate the pathophysiology of the biliary epithelium in relation to secretory, proliferative and apoptotic activities. Distinct expression profiles of two murine cholangiocyte lines, termed small and large have been revealed by microarray analysis. The features of the two cholangiocyte cell lines, categorized partly according to gene ontology, indicate the specific physiological role of each cell line. The large cholangiocytes are characterized as "transport" and "immune/ inflammatory responses". In contrast, small cholangiocytes are associated with properties of limited physiological functional ability and proliferating/migrating potential with specific molecules like Eph receptors, comparable to mesenchymal cells. 'Omic study will be of great help in understanding the heterogeneity of cholangiocytes.

INTRODUCTION

Several research avenues have established novel scientific theories. We initially examined phenotypic manifestations of various forms of induction, analogy and abduction. Subsequent preliminary studies resulted in a firm-working hypothesis. We then tested this hypothesis in order to establish our theoretical groundwork. However, recent advances in the field of bioinformatics have become routine, especially in regards to the initial speculative step in designing a rational approach. Since the initial DNA microarray analysis experiment[1], microarray has developed rapidly and is now well established, with manufacturers meeting market demand[2]. The number of scientific papers with "microarray" as a key word steadily increased on PubMed from 2001 to 2004, reaching a total of 8603 papers. Moreover, an enormous quantity of raw data potentially contained in "microarray" papers is anticipated in the near future, and the estimate is based on the number of the genes analyzed in each paper (e.g. 30 000-40 000 genes expressed in mammalian cells). Therefore, it is essential for future advances to reliably preserve a database containing all the raw data. The establishment of data analysis system as well as data mining and data sharing, is anticipated to be the highest priority in this field. We will focus on such issues pertaining to general microarray experiments as well as the methods and the results of microarray analyses designed to characterize cholangiocytes in this chapter.

MICROARRAY ANALYSIS

We will simply give an overview of the current status, analytic method and data-sharing aspects of microarray analysis, partly in accordance with the description of Knudsen[3]. One of the currently popular microarray systems is the Affymetrix DNA Chip®, which employs *in situ* oligonucleotide synthetic technology as well as mass-production compatible to that of silicon chips. Several microarrays and expression analysis services are commercially available from several companies including Amersham, Clontech (TAKARA), Invitrogen and so on. As in other experiments, the quantity of RNA samples should be standardized, otherwise correction steps will be necessary for the evaluation of the results by

"scaling" generally employing internal controls. Moreover, verification of the linearity of spot intensity-sample quantity curves for all applied spots is also necessary in microarray experiments. The companies supplying ready-made products have overcome these problems and established quality control, making their products popular with researchers applying commercial products to limited numbers of samples. Although array technologies at the bench have nearly reached a zenith during the past several years, there are some in silico systems under development. The parametric *t*-test and non-parametric Wilcoxon's rank-sum/ Mann-Whitney tests are the most popular methods applicable to test the significance of differences between pairs of samples. The normality of each spot intensity for the samples becomes an issue if the *t*-test or ANOVA is used with a routine microarray having thousands of spots. The most conservative statistical method, Bonferroni's correction, which defines the level of significance more strictly according to the number of tested items, might be applicable even to microarray experiments[4]. Even if we employ other less conservative approaches[5], we may need to verify the differential expressions of the specific molecules by other methods in some cases. Several software programs are available, including some that are free like Cluster (http://rana.lbl.gov/EisenSoftware.htm)[6], for analysis of microarray data. Cluster analysis categorizes each gene into distinct clusters according to Euclidian distance based on the variation among the samples at multiple time-points or under the different conditions. Each gene in a cluster shows a similar expression pattern under different conditions, which may indicate a common transcription pathway, RNA degradation process, and/ or similarities of gene function in a cluster. In other words, microarray technology holds promise for elucidating the complex regulatory mechanisms of RNA transcription as well as unknown gene functions. Every gene is currently being systematically defined, allowing organization according to gene ontology (http://www.geneontology.org/). The gene ontology project was originally designed to create a thesaurus-like hierarchy of gene properties, based on molecular function, biological processes and cellular components, in order to integrate databases in a unified way. The combination of raw microarray data and this unified classification will greatly facilitate developing the speculative groundwork for our experiments. This approach differs from the usual methodology based on molecular properties including domain structure, 3D structure, evolution or expression patterns. Therefore, raw microarray data can be a source of new hypotheses, regardless of the original aim of the experiment. This may make it difficult to share raw microarray data. The unified approach, termed MIAME (http://www.mged.org/Workgroups/MIAME/miame.html), for submission of microarray data is described in the guidelines of each paper contributing data to be shared and for peer review. The statement that "MIAME is neither a dogma, nor a legal document-it assumes a cooperative data provider and a fair reviewer" suggests potential difficulty in data sharing, probably stemming from the complexities of ownership and intellectual property rights to data. Microarray data is clearly precious, even in the current era of non-sharing, and should be carefully stored by each lab, organization or government. Such data should be viewed as common property, with potential future benefits to mankind.

FEATURES OF CHOLANGIOCYTES

Bile flows from canalicular spaces, encircled by hepatocytes, through the canals of Hering, interlobular bile ducts (branches of which are 20-100 μm in diameter and lined by cuboidal epithelium), and septal bile ducts (which are more than 100 μm in diameter and lined by a simple tall columnar epithelium) to hilar intrahepatic bile ducts[7]. The cholangiocytes that line the interlobular and bolder bile ducts[7] also contribute to bile secretion[8,9]. The mechanism underlying this phenomenon, described elsewhere in detail, is explained briefly by out-intraluminal vectorial passive transport of water caused by the osmotic gradient which is formed by active transport of several substrates driven by cholangiocytes[10,11]. This physiological function, conserved even in cultured cell lines, characterizes the specialized cholangiocytes. Isolated rat cholangiocytes are classified as large or small, depending on their size. Large cholangiocytes, regarded as representative functional biliary epithelial cells *in vivo*, respond to secretin with increased choleresis[12]. In contrast, little is known about the properties of small cholangiocytes. Cholangiocytes are sometimes altered in a disease-specific manner. For example, primary biliary cirrhosis (PBC), a potentially fatal cholestatic disorder due to ductopenia, is a representative disease characterized by specific destruction of interlobular bile ducts. CD8+ cytotoxic T cells are suspected to play a major role in this type of destruction. Tetramer technology reveals the existence of an E2 subunit of the pyruvate dehydrogenase complex (PDC-E2)$_{159\text{-}167}$-specific to autoreactive cytotoxic T cells in PBC[13]. Hypothetically, there are several specific properties (e.g. adhesion molecules, MHC antigens[14], specific autoantigens, variations in apoptosis and so on) of cholangiocytes lining interlobular bile ducts, which make them vulnerable to attack by cytotoxic lymphocytes. A novel disease etiology was proposed by Gershwin *et al*[15], who demonstrated that IgA class anti-mitochondrial antibodies, transported via transcytosis from the basolateral to the apical surface co-localize with PDC-E2 in cholangiocytes. Moreover, molecules that bind PDC-E2 monoclonal antibody are expressed on the apical membranes of PBC cholangiocytes[15]. These observations indicate the cytotoxicity associated with functional impairment of cholangiocytes to be caused by interaction with IgA-PDC-E2. In this regard, the mechanism of transcytosis may specifically dictate the underlying disease process. Such a hypothesis could be explained by cholangiocyte heterogeneity based on the recognition that large and small cholangiocytes are derived from bile ducts of corresponding diameters[16]. The susceptibility of bile ducts to pathological conditions (e.g. chronic ductopenic rejection[17], GVHD[18], ischemic cholangitis[19], PBC or ductopenia resulting from other pathologies) is due not only to the specific destruction of cholangiocytes, but also to the difficulty in regeneration of the bile ducts i.e. with normal structures, in contrast to the

Table 1 Differences in cDNA expression between small and large cholangiocyte lines

The entire dataset obtained from the Atlas Glass Array mouse (Clontech, Takara Bio Inc., Shiga, Japan) was analyzed by ArrayGauge software (Fuji Photo Film Co., Ltd., Tokyo). [1]gene ontology, [2,3]spot intensities of all samples from small or large cholangiocytes.

rapid regeneration of hepatocytes in cases with acute liver injury. The proliferation of cholangiocytes that potentiate the regeneration of bile ducts occurs in a characteristic manner, *i.e.* secretin, somatostatin or bile duct ligation results in proliferation of large cholangiocytes[20], whereas chemical injury of bile ducts with CCl_4 increases the numbers of small cholangiocytes[21,22]. Therefore, to clarify the mechanisms sustaining cholangiocyte growth it is essential to understand the regulation of bile duct regeneration. We identified an Eph receptor, a membrane bound-type tyrosine kinase, as one of the key molecules for reorganization/proliferation of cholangiocytes, and a subtype of this family, which is expressed mainly in small cholangiocytes[23]. Thus, the heterogeneous expression profile of cholangiocytes is expected to facilitate further study of these cells.

ANALYSIS OF HETEROGENEOUS CHOLANGIOCYTES

For the evaluation of genes that are expressed by small and large cholangiocytes see Table1. Several liver diseases, including non-alcoholic fatty liver disease[24], liver cirrhosis[25], hepatocellular carcinoma[26,27] and cholangiocellular carcinoma[28] have been studied extensively using microarray techniques. Some studies have examined whole liver samples, consisting of various cell types, probably for the purpose of disease classification. Sample size is critical for the detection of subtle changes in the expression of meaningful genes[29], a possible problem in assessing rare diseases. Another problem in the study of biliary diseases like PBC by microarray is that cholangiocytes account for only 3% of the cell population even in the normal liver[30]. Over 75% of the cell population is regarded as necessary to test the significance of differences in expression levels[2]. Therefore, for the purpose of analyzing chlangiocytes, isolation[31] or microdissection[32] is necessary prior to analysis. Our study goals were to characterize the physiological role of biliary epithelia in the mouse and to analyze cholangiocyte heterogeneity. Due to the complexities of the isolation steps, maintaining quality control or reproducibility was possible when obtaining a large sample of RNA from freshly isolated cholangiocytes. Moreover, given the necessity of conducting further functional assays, we immortalized and subcloned the isolated Balb-c mouse cholangiocytes by introducing the SV40 large T antigen[33]. The established large and small cholangiocyte cell lines were evaluated by their morphologies and responsiveness to secretin. We revealed 230 genes (4.74%) showing different expression patterns in the two cells lines, among 4800 genes tested by combining two types of ready-made microarrays[34]. Our large cholangiocyte line was characterized by gene ontology, transport and immune/inflammatory responses, which were apparent, even without the statistical tests presented in the table. The term

"transport" includes movement of anions, water and bile acids, and thus represents the physiological functions of bile ducts. These observations indicate a special feature of large cholangiocytes which presumably play a role in local immune reactions. In contrast, our small cholangiocytes are categorized into a subgroup characterized by rapid cell cycle turnover as well as poor physiological functional ability. In addition to these fundamental properties, our small cholangiocytes are characterized by abundant expressions of actin and vimentin and poor expression of E-cadherin. Together with rich spindle-type cell processes, small cholangiocytes have a feature in common with mesenchymal cells probably originating from epithelial-mesenchymal transition[35]. This remains a controversial issue. Another important feature of cholangiocyte is its capability of the responsiveness to hormones and neuropeptides. Specifically, estrogen receptor[36] and receptor for IGF-1(insulin like growth factor 1)[37], NGF(nerve growth factor)[38] and acetylcholine (M3)[39] have been shown to play a major role in modulating cholangiocyte proliferation. Estrogen receptor expresses at a minimal level in both types of cell lines. In contrast, IGF receptor was preferentially expressed in large cholangiocyte line in our microarray study. The expression of estrogen receptor inducible under pathological conditions like bile duct injury[40] may explain the discrepancy between the experiments results. Predominant expression of IGF receptor in large cholangiocytes may be a marker of differentiated biliary epithelial cells as well as a proliferating effector of maturated cholangiocytes.

CONCLUDING REMARKS

Microarray is a powerful tool for elucidating functional cholangiocyte heterogeneity. Although the evaluation of some crucial biological regulatory processes like protein modification requires methodologies other than microarray, the potential of microarray technology is anticipated to grow with the development of data-analysis theory for the comprehension of complex networks.

Abstract

Vanishing bile duct syndromes (VBDS) are characterized by progressive loss of small intrahepatic ducts caused by a variety of different diseases leading to chronic cholestasis, cirrhosis, and premature death from liver failure. The majority of adult patients with VBDS suffer from primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). Ursodeoxycholic acid (UDCA), a hydrophilic dihydroxy bile acid, is the only drug currently approved for the treatment of patients with PBC, and anticholestatic effects have been reported for several other cholestatic syndromes. Several potential mechanisms of action of UDCA have been proposed including stimulation of hepatobiliary secretion, inhibition of apoptosis and protection of cholangiocytes against toxic effects of hydrophobic bile acids.

INTRODUCTION

Cholestasis is defined as an impairment of bile flow and failure to adequately secrete cholephilic compounds into bile often associated with clinical manifestations such as jaundice and pruritus and biochemical alterations such as an elevation in serum alkaline phosphatase and γ-glutamyl transpeptidase. The liver damage observed in chronic cholestasis has long been attributed to accumulation and retention of potentially toxic bile acids within hepatocytes. Chronic cholestasis is the main feature of vanishing bile duct syndromes (VBDS) characterized by progressive loss of small intrahepatic ducts caused by a variety of different diseases. In children, biliary atresia and Alagille syndrome are rare ductopenic diseases classified as VBDS. The majority of adult patients with VBDS suffer from primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). Other diseases associated with ductopenia include autoimmune cholangitis, chronic hepatic allograft rejection, graft-versus-host disease (GVHD), chronic cholestatic sarcoidosis and ischemic (vascular) cholangiopathies. Among the various causes of VBDS, drugs have an increasing importance. Drug reactions are related especially to antibiotics, phenothiazine derivates and carbamazepine. It is increasingly clear that immunopathogenetic mechanisms involving innate and adaptive immune responses contribute to ductopenia in most of these diseases. Prognosis varies from hepatic failure and death or liver transplantation to resolution of cholestasis and normal liver function.

Ursodeoxycholic acid (UDCA) is a hydrophilic dihydroxy bile acid (chemical structure: 3α, 7β-dihydroxy-5β-cholanoic acid) which was first identified in the bile of the Chinese black bear[1]. UDCA is a physiologic bile acid also present in man albeit in a low concentration of about 3% of the bile acid pool, where it is formed by 7β-epimerization of the primary bile acid chenodeoxycholic acid in the gut by intestinal bacteria[2,3]. It has been used for centuries in traditional Chinese medicine for the treatment of liver diseases. Reports from Japan and Europe first revealed that UDCA was able to dissolve gallstones[4-6]. In 1985, Leuschner and coworkers observed improved serum liver tests in patients with chronic active hepatitis treated with UDCA for gallstone dissolution[7], and similar observations were made previously in Japan. Since then, various trials have shown the beneficial effect of UDCA for different cholestatic syndromes.

PHARMACOKINETICS AND METABOLISM OF UDCA

After oral administration, UDCA is absorbed by passive nonionic diffusion mainly in the small intestine (-80%)

and less in the colon (-20%) following solubilization in mixed micelles of endogenous bile acids in the proximal jejunum[2,8]. Its absorption rate is enhanced when it is given with a meal and may be decreased in patients with cholestasis and decreased biliary secretion of endogenous bile acids[9]. After intestinal absorption, UDCA is taken up from the portal blood by the hepatocytes at their sinusoidal domain *via* specific bile acid transporters namely, NTCP and OATP, conjugated mainly with glycine and to a lesser extent with taurine and is subsequently transported across the canalicular domain into the bile ducts *via* another bile acid carrier molecule, designated BSEP[2,10]. UDCA conjugates reach the small intestine and are reabsorbed mainly from the distal ileum *via* an active Na^+-dependent transport mechanism undergoing an effective enterohepatic circulation. Non-absorbed UDCA and UDCA conjugates pass into the colon and, after bacterial deamidation of conjugates, are mostly converted to lithocholic acid by intestinal bacteria and eliminated *via* the feces[2]. Only minute amounts of the insoluble lithocholic acid are reabsorbed *via* the colonic mucosa, sulphated in the liver, secreted into bile and excreted in the feces. Under continuous oral treatment at pharmacological doses (13-15 mg/kg per day) UDCA becomes the predominant bile acid in the liver and the systemic circulation, comprising 40% to 60% of total bile acid[2,8].

MECHANISMS OF ACTION OF URSODEOXYCHOLIC ACID

The mechanisms underlying the beneficial effects of UDCA in cholestasis are being increasingly unraveled[11-14]. Initial research interest was focused on changes in bile acid pool composition, hepatocyte membrane protective effects, immunomodulatory effects, and bicarbonate-rich hypercholeresis induced by UDCA. Over the past decade, it has, however, become evident that UDCA is a potent intracellular signaling agent that induces stimulation of impaired hepatocellular secretion, anti-apoptotic effects and may mediate cholangiocyte protection. Depending on the pathophysiology and the stage of the underlying liver disease, the predominant mechanisms of action of UDCA may vary.

Stimulation of hepatobiliary secretion

Cholestatic liver diseases are characterized by an impairment of hepatobiliary secretion. As a consequence, bile acids and other potentially toxic cholephiles accumulate in the hepatocyte and may lead to liver cell injury, apoptosis and necrosis. UDCA stimulates biliary secretion of bile acids and other organic compounds (e.g. bilirubin glucuronides, glutathione conjugates, bromosulfophthalein) in various experimental models such as the isolated hepatocytes, isolated perfused rat liver and bile fistula rat model and counteracts cholestasis induced by hydrophobic bile acids in rat liver[15-22]. In line with these observations, biliary secretion of bile acids and phospholipids is stimulated and elevated serum levels of the hydrophobic bile acid, chenodeoxycholic acid, and of bilirubin are decreased in patients with PBC and PSC during UDCA treatment[23-28]. Thus, the beneficial effects of UDCA in cholestatic liver disease may be partly due to the enhanced elimination of toxic compounds from the hepatocytes. The secretory capacity of the hepatocytes is determined by the number and activity of transporter proteins in the canalicular membrane. UDCA stimulates the expression of transporter proteins for biliary secretion in the liver and the targeting and insertion of transporter molecules into the canalicular membrane at a transcriptional and posttranscriptional level[15,29-31]. As such, UDCA stimulates the overall gene expression of both canalicular (Mrp2, Bsep) and alternative basolateral carriers (Mrp3, Mrp4) in mouse liver, which facilitates alternative efflux of bile salts and other organic anions into the systemic circulation[32,33]. UDCA also stimulates murine renal (Mrp2, Mrp4) and intestinal (Mrp2, Mrp3) efflux transport proteins, resulting in an increased overall elimination capacity for potentially toxic biliary compounds[32]. In addition to these transcriptional effects, UDCA also stimulates vesicular exocytosis and insertion of transporter proteins into the canalicular membrane by modulating complex intracellular signalling cascades including calcium, protein kinase C and different mitogen-activated protein kinases[15,31,34-36]. Moreover, UDCA may also directly activate canalicular transporters through modification of their phosphorylation status[37]. While effects of UDCA on mRNA and protein levels of transporters may be important for long-term regulation, the effects on the insertion into the canalicular membrane and the activity of transporters may determine short-term regulation of secretion. In conclusion, UDCA modulates hepatobiliary secretion by transcriptional and posttranscriptional mechanisms in experimental models *in vivo* and *in vitro*. Thus, upregulation of synthesis, apical targeting and insertion, and activation of key canalicular transporters may represent key mechanisms to explain the anticholestatic action of UDCA in patients with cholestatic liver disease.

Inhibition of apoptosis

Apoptosis, or programmed cell death, is an important mechanism of cell death in cholestatic liver diseases[14,38,39]. For example, apoptotic features causing bile duct loss have been observed more frequently in liver tissue from patients with PBC than in normal controls[40]. Toxic bile acids can induce apoptosis in hepatocytes at concentrations comparable to those found in chronic cholestasis and the mechanisms of bile acid-induced apoptosis have increasingly been understood (reviewed by Higuchi *et al*[41]). Endogenous hydrophobic bile acids such as glycochenodeoxycholic acid (GCDCA) or glycodeoxycholic acid (GDCA) induce apoptosis by ligand-independent activation of the Fas death-receptor, followed by activation of caspase 8 and Bid, a pro-apoptotic member of the Bcl-2 protein family, which chaperones another pro-apototic Bcl-2 molecule, Bax, to the mitochondrial membrane inducing mitochondrial membrane permeability transition (MMPT). MMPT causes a sudden increase in permeability of the inner mitochondrial membrane to ions followed by

mitochondrial swelling and release of cytochrome c from the intermembrane space to the cytosol. In the cytosol, cytochrome c interacts with the apoptotic protease-activating factor 1 (APAF-1), which leads to activation of caspase 9 and subsequently causes apoptotic cell death[40,42].

A number of studies showed that UDCA can block apoptosis *in vitro* as well as *in vivo* in the rat and in human hepatocytes by interrupting classic pathways of apoptosis[43-45]. Antiapoptotic effects of UDCA were associated with a reduction of the MMPT and mitochondrial cytochrome c release[14,45]. UDCA protects rat hepatocytes against bile acid-induced apoptosis by preventing bile acid-induced, c-Jun N-terminal kinase-dependent Fas trafficking to the plasma membrane[46]. Apoptosis can not only be inhibited by blocking pro-apoptotic pathways, but also by activation of intracellular survival signals. Indeed, UDCA was shown to induce a survival signal in hepatocytes *via* activation of the epidermal growth factor receptor (EGFR) and mitogen-activated protein kinase (MAPK) that may contribute to the antiapoptotic effect[47]. Thus, UDCA appears to be a bile acid that partially activates pro-apoptotic signals, but also simultaneously a strong MAPK-dependent survival signal, which makes UDCA an overall non-toxic bile acid. Although intriguing, the impact of antiapoptotic mechanisms for the beneficial effects of UDCA in cholestatic liver disease remains unclear at present.

Protection of cholangiocytes against toxic effects of hydrophobic bile acids

Hydrophobic bile acids damage cell membranes of hepatocytes and cholangiocytes and exert extracellular cytotoxicity at millimolar concentrations present in bile[48-50]. Indeed, levels of hydrophobic bile acids are about 1000-fold higher in bile than in serum even under physiological conditions. The proposed mechanisms of bile acid-induced cell damage extend from simply binding to plasma membranes to the induction of apoptosis or even necrosis. UDCA has been shown to counteract hydrophobic bile acid-induced membrane disruption *in vitro* presumably by alteration of the structure and composition of simple and mixed micelles rather than by direct membrane interactions[50,51]. UDCA treatment at therapeutic doses of 13-15 mg/kg per day renders the bile acid composition of bile less hydrophobic leading to a relative enrichment of UDCA to about 40%-50% of total biliary bile acids[8]. To achieve this effect in isolated cells or whole organ a high (millimolar) concentration of UDCA is required. Thus, the membrane protective effects of UDCA play a role mainly at the bile duct level, since high concentrations of bile acids are only present within the biliary tree[52]. UDCA decreases the degree of cholangiocellular injury, portal inflammation and ductular proliferation in the Mdr2-knockout mouse, an animal model of cholestasis which shares morphological features with PSC resulting from the toxic effect of bile acids on the biliary epithelium in the absence of protective mixed micelle formation with phospholipids[53,54]. In line with these observations, the (peri-) portal inflammatory reaction is less severe in patients with PBC and PSC under UDCA treatment as compared to those treated with placebo[27,28,55,56]. The effects of UDCA conjugates on cholangiocytes are apparently mediated by Ca^{2+}- and protein kinase Cα-dependent mechanisms which have been implicated in stimulation of biliary secretion in cholestatic hepatocytes as outlined above. Although the protection against the consequences of bile duct destruction is likely to be one mechanism of action of UDCA, the underlying pathophysiologic events leading to the ongoing bile duct destruction are probably not influenced by UDCA.

UDCA IN VANISHING BILE DUCT SYNDROMES

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease characterized by chronic inflammation and destruction of intrahepatic bile ductules, which leads to progressive ductopenia. ultimately resulting in fibrosis and biliary cirrhosis. The prevalence differs considerably in different geographic areas, ranging from 40 to 400 per million. It primarily affects women, with a female to male ratio as high as 10 to 1[57,58]. Current theories on the pathogenesis of PBC favor the hypothesis that the disease develops as a result of an inappropriate immune response following stimulation by an environmental or infectious agent. The pathogenetic mechanism is believed to be caused by a defect in immunologic tolerance, resulting in the activation and expansion of self-antigen specific T and B lymphocyte clones and the production of circulating autoantibodies in addition to a myriad of cytokines and other inflammatory mediators. The serologic hallmark of PBC is the presence of autoantibodies to mitochondria, especially to the E2 component of the pyruvate dehydrogenase complex (PDC)[59]. 50% to 60% of patients are asymptomatic at diagnosis, and the disease is initially detected on the basis of screening liver-biochemistry profiles. Fatigue and pruritus are the most common presenting symptoms[60], occurring in up to 78% and 70% of patients, respectively. Jaundice develops usually later, often associated with progression of the disease[61]. Eventually, complications of cirrhosis and portal hypertension, such as ascites, variceal bleeding, and hepatic encephalopathy, develop.

UDCA is now the mainstay of therapy for PBC. In 1987 Poupon and co-workers reported benefit from UDCA treatment[62]. Since then, several randomized double-blind placebo-controlled studies have shown that UDCA improves biochemical parameters including serum bilirubin levels which are used as a prognostic marker for PBC[25,27,55,63-66]. Indeed, it has been shown that the mean survival in patients with serum bilirubin levels above 34 μmol/L is 4 years; in those with values of more than 103 μmol/L only 2.1 years[67]. This prognostic value of serum bilirubin is similar in UDCA-treated patients as in non-treated patients. The benefit from UDCA therapy on liver fibrosis progression in PBC has been shown by Corpechot *et al*[68] using Markov modeling: A fivefold decrease in progression rate from early-stage disease toward extensive fibrosis or cirrhosis was found in UDCA-treated

patients compared with placebo-treated patients. At 4 years, the probability of UDCA-treated patients to remain in early stage disease was 76% (95% confidence interval: 58%-88%), as compared with 29% (15%-52%) in placebo-treated patients. These findings are consistent with recent data showing that a 2-year treatment with UDCA reduces periportal necroinflammatory lesions, improves ductular proliferation, and delays the progression of histologic stage when given at the earlier stages (stages I-II) of the disease[69]. When started later in the disease course, UDCA can still ameliorate inflammation and ductular proliferation but is not capable of reversing fibrosis.

What is still more debatable is the effect of UDCA treatment on long-term survival. A combined analysis of three larger randomized trials, in which patients with primary biliary cirrhosis were randomly assigned to receive UDCA (n = 273) or placebo (n = 275) suggested that survival free of liver transplantation was significantly improved in patients who received UDCA treatment for 4 years[70]. This benefit was seen in patients with moderate to severe disease but not in those with mild disease (serum bilirubin concentration < 23.9 μmol/L or histologic stage I or II) probably because progression to end-stage disease did not occur in the short time interval of the study in patients with mild disease[70]. Lindor *et al* showed that survival of patients treated up to 6 years with UDCA was increased as compared with a placebo group or the predicted survival from the Mayo model[71]. In a large cohort of UDCA-treated PBC patients (225 patients) followed for up to 10 years survival free of liver transplantation was significantly higher than survival predicted by the Mayo model and 10-year survival among UDCA-treated patients is slightly lower than that of an age- and sex-matched population, the difference being mainly explained by mortality among cirrhotic patients[72]. However, the efficacy of UDCA in PBC has also been questioned. The extended follow-up of another clinical trial[73], as well as a randomized controlled trial with the longest follow-up[55], did not show a favorable effect of UDCA on the incidence of death or liver transplantation. In addition, a systematic review and meta-analysis of 11 randomized controlled trials, including 1272 patients, and six reports of the switch-over phases did not find a beneficial effect of UDCA on the incidence of liver-related death, liver transplantation, or the development of complications of liver disease[74]. Similarly, another meta-analysis of 16 randomized clinical trials evaluating UDCA against placebo (n = 15) or no intervention (n = 1) in 1422 patients did not detect a significant effect of UDCA on mortality[75]. However, these meta-analyses included trials of different length of follow-up, mostly only up to 24 mo, which were performed with various doses of UDCA, in part less than 13-15 mg/kg per day, a dose currently regarded as optimal for PBC. Thus, these meta-analyses have to be interpreted with caution, because survival analyses in a disease with a very long natural history over decades are ideally based on longer follow-up periods. In a further analysis including five studies with a follow-up of at least 4 years, a 32% reduction in the risk of death or need of liver transplantation was reported in patients treated with UDCA[76]. Nonetheless, to clarify the true efficacy of UDCA in the long-term treatment of PBC, additional data are needed. At present, the general recommendation is to treat PBC patients with UDCA at a dose of 13-15 mg/kg per day. Treatment should be started as early as possible, since patients with mild or moderate disease are likely to have a greater benefit from therapy than those with advanced disease.

Primary sclerosing cholangitis (PSC)

Primary sclerosing cholangitis (PSC) is a rare chronic cholestatic disease of the intra- and extrahepatic bile ducts that is generally progressive and leads to end-stage liver disease with a median survival from diagnosis to death or liver transplantation, currently estimated at 12 years[77-80]. PSC is characterized by diffuse inflammation, concentric obliterative fibrosis and progressive stricturing and dilatation of the biliary tree. The etiology and pathogenesis is unknown, but as in PBC, immune dysregulation plays an important role in the development of the disease. In Western populations, the estimated prevalence of PSC is 8.5 cases per 100 000 persons[81] and 70%-80% of PSC patients have or will develop inflammatory bowel disease. Of importance, patients with PSC have an increased risk of developing cholangiocarcinoma with an estimated yearly incidence of 1.5% after diagnosis of PSC[82-85] and patients with both PSC and ulcerative colitis may be at higher risk for developing colorectal aneuploidy, dysplasia, or cancer than UC patients without PSC[86,87]. Based on the beneficial effect of UDCA in patients with PBC, UDCA was evaluated in a number of small trials for patients with PSC in the early 1990s[28,88,89]. Although small, these studies observed significant biochemical and histologic improvements for patients receiving UDCA. Similar to the treatment of PBC, no major side effects were reported. In contrast to these promising results, the first large randomized placebo-controlled study including 105 patients with PSC could not find a clinical benefit of UDCA treatment with respect to time to treatment failure or histologic findings in a dose of 13-15 mg/kg per day during a mean follow-up period of 2.2 years[26]. A meta-analysis of six randomized clinical trials showed no difference between UDCA and placebo in the effects of incidence on death, treatment failure (including liver transplantation, varices, ascites, and encephalopathy), liver histological deterioration or liver cholangiographic deterioration[90]. However, most trials were small with an average sample size of 37 patients and the follow-up period might have been too short to show a clinical benefit, since PSC has usually a long natural history of over a decade. A large percentage of the patients had advanced disease and as in PBC, these patients might respond less to medical treatment than patients in earlier stages of disease. Finally, UDCA therapy alone will not suffice to treat the bile duct strictures typical for PSC, but may need additional mechanical intervention. Indeed, major bile duct strictures develop during UDCA treatment[91]. Based on these observation, UDCA treatment was combined with endoscopic dilatation of bile duct strictures in an 8-year prospective study. The survival of patients receiving this combination therapy was significantly better than the calculated survival without treatment[92]. As biliary enrichment of UDCA is expected to be lower in cholestasis and because of discouraging results with standard doses of UDCA (13 -15

mg/kg per day), use of high doses of UDCA in PSC has a rationale and has been evaluated by three groups[93-95]. The first study compared high-dose UDCA (20 mg/kg per day) (n = 13) to placebo (n = 13) for 2 years in 26 patients with PSC and demonstrated a significant improvement in serum levels of AP and γ-GT (no effect on bilirubin and albumin levels), and a significant reduction in progression of cholangiographic features and liver fibrosis as assessed by disease staging without significant side effects. UDCA did not improve symptoms[94]. Harnois *et al*[93] reported similar results in a 1-year open-label study of 30 PSC patients treated with UDCA at a dose of 25-30 mg/kg per day. Changes in the Mayo risk score at 1 year of treatment and projected survival at 4 year were compared with that observed in patients randomized to placebo or UDCA at a dose of 13-15 mg/kg per day in a previous study. A significant improvement in serum alkaline phosphatase activity, AST, albumin and total bilirubin occurred at 1 year of therapy with high-dose UDCA. The expected survival at 4 years was significantly improved for patients in the high-UDCA group when compared with a historical placebo control, but not between the dose of 13-15 mg/kg per day and placebo. As in the first study, high-dose UDCA was well tolerated. Finally, in the biggest placebo-controlled prospective study in PSC ever performed, a total of 219 patients were randomized to 17 to 23 mg/kg per day of UDCA (n = 110) or placebo (n = 109) for 5 years[95]. No statistically significant benefit from 20 mg/kg UDCA on survival without liver transplantation or prevention in cholangiocarcinoma in PSC was shown in this study. However, there was a tendency to improved survival in the UDCA-treated patients and the study was underpowered to show a possible positive effect.

UDCA has also been shown to have colon cancer chemopreventive effects in preclinical studies[96,97]. In addition, two clinical studies suggested that UDCA also decreases the risk for developing colorectal neoplasia in UC patients with PSC[98,99]. In a cross-sectional study by Tung *et al* involving 59 patients with ulcerative colitis and primary sclerosing cholangitis who were undergoing colonoscopic surveillance for colonic dysplasia, UDCA use was strongly associated with decreased prevalence of colonic dysplasia (odds ratio, 0.18, 95% confidence interval, 0.05 to 0.61; P = 0.005)[98]. In a blinded, prospective study by Pardi *et al*[99], 52 patients with ulcerative colitis and PSC were randomized to receive UDCA or placebo and were followed-up for a total of 355 person-years. Those originally assigned to receive UDCA had a relative risk of 0.26 for the development of dysplasia or cancer (95% confidence interval, 0.06-0.92; P = 0.034) suggesting a significant chemoprotective effect for UDCA in these patients.

In conclusion, UDCA therapy (13-20 mg/kg per day) of PSC is warranted and should be initiated as soon as possible and be continued life-long. In addition, major strictures should be dilated regularly in centers with experienced endoscopists. In patients with PSC and ulcerative colitis, who carry a considerable lifetime risk for colorectal neoplasia, UDCA may act as a chemopreventive drug. Due to the unresolved issues of optimal dosing and the true long-term benefit of UDCA in PSC, patients should be included in trials if possible.

Intrahepatic cholestasis of pregnancy

Intrahepatic cholestasis of pregnancy (ICP) is the most common pregnancy-related liver disorder characterized by pruritus associated with a mild or moderate increase in serum aminotransferases and serum bile acids starting in the second or third trimester of pregnancy and disappearing after delivery. ICP is associated with increased risk of intrauterine fetal death and premature delivery[100,101]. There is increasing evidence that genetically determined dysfunction in the canalicular ABC transporters bile salt export pump and multidrug resistance protein 3 might be risk factors for ICP development[102]. In small controlled trials and several observational trials, UDCA improved maternal pruritus and serum liver chemistries such as serum bilirubin and transaminases, and diminished the number of premature deliveries. The medication seems to be well tolerated by pregnant women and no adverse effects in mothers or newborns have been detected[103-105]. A recent prospective, randomized trial (n = 84) comparing cholestyramine (8 g daily) and UDCA (8-10 mg/kg daily) for the treatment of ICP further supported these findings. Pruritus was more effectively reduced by UDCA than cholestyramine. Newborns were delivered significantly closer to term by patients treated with UDCA, than those treated with cholestyramine. Serum alanine and aspartate aminotransferase activities were markedly reduced by 78.5% and 73.8%, respectively, after ursodeoxycholic acid, but by only 21.4%, each, after cholestyramine therapy. Ursodeoxycholic acid, but not cholestyramine was free of adverse effects[106]. In ICP, the relief of cholestasis by UDCA has been suggested to be due to stimulation of vesicular exocytosis resulting in mobilization of an increased number of transport proteins to the canalicular membrane and, thereby, stimulation of transport systems involved in the biliary secretion of steroid mono- and disulfates. In conclusion, data that are available support the use of UDCA as first-line therapy for ICP in the third trimester.

Hepatic complications of allogeneic bone marrow transplantation

Hepatic graft-versus-host disease (GVHD) is a frequent complication after bone-marrow transplantation usually associated with a cholestatic picture characterized by elevated serum alkaline phosphatase and hyperbilirubinemia attributed to damage of the small bile ducts. UDCA has been reported to be effective in the treatment of manifest GVHD[107,108]. In an open-label study 12 patients with refractory chronic GVHD of the liver after allogeneic bone marrow transplantation were given UDCA (10 to 15 mg/kg per day) for 6 wk. Serum tests of cholestatic liver injury showed improvement compared with baseline. After discontinuation of UDCA therapy, 11 patients were followed for 6 additional weeks. All showed significant worsening in liver function test results. Symptom scores were unchanged throughout the study. No adverse effects were observed[107]. In addition, the efficacy of UDCA has also been reported as a prophylaxis for veno-occlusive disease (VOD) of the liver after

allogeneic bone marrow transplantation. In a randomized, double-blind, placebo-controlled study including 67 consecutive patients undergoing transplantation with allogeneic bone marrow with a preoperative regimen of busulfan plus cyclophosphamide were randomly assigned to receive UDCA 300 mg twice daily or placebo. The incidence of VOD was 40% in placebo recipients and 15% in the UDCA-treated recipients ($P = 0.03$)[109]. Thus, further studies are certainly needed, but UDCA may be considered for prophylaxis of VOD and treatment of GVHD of the liver.

Cystic fibrosis

Cystic fibrosis (CF) is an autosomal recessive disorder caused by mutations in the CFTR (cystic fibrosis transmembrane conductance regulator) gene resulting in the secretion of viscous bile. This may lead to the formation of bile duct plugs within small bile ducts, biliary obstruction and ultimately result in (focal to multilobular) biliary cirrhosis. Hepatobiliary complications increase with patient age and up to 7% of children and young adults with CF may present with liver cirrhosis[110]. Early uncontrolled studies showed that UDCA significantly improved laboratory tests and nutritional status of patients with CF[111-113]. A small randomized, placebo-controlled study showed clinical, biochemical and nutritional improvement in CF patients treated with UDCA (15 mg/kg per day) for one year[114]. Improvement of liver histology of CF patients treated with UDCA (10-15 mg/kg per day) for 2 years has been reported as well[115]. A higher dose of 20 mg/kg per day may be more efficious than lower doses (5-15 mg/kg per day)[111,116]. Thus, UDCA may be considered as potentially effective in CF patients. However, whether UDCA affects the natural history of liver disease in CF-particularly amelioration of the complications of portal hypertension, need for liver transplantation, or a measurable survival is unknown and further well-designed, adequately powered, randomized controlled trials should address these issues. Stimulation of biliary secretion may be the major mechanism for the therapeutic effect. Interestingly, it has been hypothesized that the therapeutic effect of UDCA is mediated in part by stimulation of ATP release into bile and subsequent ATP-induced bicarbonate secretion by bile-duct epithelia *via* calcium-dependent chloride channels distinct from the CFTR[117].

Abstract

Primary canalicular bile undergoes a process of fluidization and alkalinization along the biliary tract that is influenced by several factors including hormones, innervation/neuropeptides, and biliary constituents. The excretion of bicarbonate at both the canaliculi and the bile ducts is an important contributor to the generation of the so-called bile-salt independent flow. Bicarbonate is secreted from hepatocytes and cholangiocytes through parallel mechanisms which involve chloride efflux through activation of Cl^- channels, and further bicarbonate secretion *via* AE2/SLC4A2-mediated Cl^-/HCO_3^- exchange. Glucagon and secretin are two relevant hormones which seem to act very similarly in their target cells (hepatocytes for the former and cholangiocytes for the latter). These hormones interact with their specific G protein-coupled receptors, causing increases in intracellular levels of cAMP and activation of cAMP-dependent Cl^- and HCO_3^- secretory mechanisms. Both hepatocytes and cholangiocytes appear to have cAMP-responsive intracellular vesicles in which AE2/SLC4A2 colocalizes with cell specific Cl^- channels (CFTR in cholangiocytes and not yet determined in hepatocytes) and aquaporins (AQP8 in hepatocytes and AQP1 in cholangiocytes). cAMP-induced coordinated trafficking of these vesicles to either canalicular or cholangiocyte lumenal membranes and further exocytosis results in increased osmotic forces and passive movement of water with net bicarbonate-rich hydrocholeresis.

INTRODUCTION

Hepatocytes and cholangiocytes are the epithelial cells in the liver, and they both participate in the production of bile. The hepatocytes, the major liver cell population (65%), generate the primary bile at their canaliculi[1]. As an important complement, the epithelial cells lining intrahepatic bile ducts or cholangiocytes (5% of the liver cell population) exert a series of reabsorptive and secretory processes which dilute and alkalinize the bile flow during its passage along the biliary tract[2-6]. Modifications of ductal bile appear to be tightly regulated by the action of nerves, biliary constituents, and some peptide hormones like secretin. Accordingly, it is possible to distinguish between three different bile flow fractions: (1) the canalicular bile salt-dependent flow (30% to 60% of spontaneous basal bile flow) that is driven by concentrative secretion of bile acids by the hepatocytes followed by a facilitated efflux of water[7,8]; (2) the canalicular bile salt-independent flow (another 30% to 60% of spontaneous basal bile flow)[1,8-10], which is also created by hepatocytes but through active secretion of both inorganic and organic compounds (mainly bicarbonate[11,12] and glutathione[13], respectively); and (3) the ductal bile flow, that is the bile salt-independent flow fraction modified and contributed by cholangiocytes, mainly through production of a bicarbonate-rich fluid in response to secretin[2,14-17] and other regulatory factors[2,5,6,17,18].

In the last decade, the use of molecular- and cell-biology tools and the availability of suitable experimental models have greatly facilitated our knowledge on the processes involved in bile generation and modification. This review summarizes some of the experimental models employed in biliary studies, and focuses on the biliary excretion of bicarbonate, the chief factor responsible for ductal bile alkalinization and fluidization, and the role and interactions of regulatory factors.

STUDY MODELS

Biliary studies started over one hundred years ago. In 1902 Bayliss and Starling discovered the hormone secretin as an agent with stimulatory effects on pancreatic secretion and bile flow[19]. About 25 years later secretin was reported as a cholagogue, i.e. an agent capable of stimulating the flow of bile into the duodenum[20], as well as a choleretic agent that could stimulate the production of bile in the liver[21]. In spite of this, although the role of hepatocytes for bile generation was widely recognized quite early, the contribution of cholangiocytes to the production of bile with an adequate composition was accepted more recently. Knowledge of the cholangiocyte contribution was facilitated by the availability of experimental models and the development of both *in vivo* and *in vitro* sophisticated procedures.

In vivo models

The initial experimental studies on the bile flow and bile composition were carried out by using *in vivo* models of conscious or anesthetized mammals with biliary fistulas. In the case of total biliary fistulas, there was a major concern because of the interruption of the enterohepatic circulation and the subsequent depletion of the bile acid pool. However, this can be overcome by continuous intravenous or intraduodenal administration of exogenous bile acids at controlled rates. On the other hand, partial biliary fistula allows controlled interruption of the enterohepatic circulation, and a portion of bile collected can be returned to the stomach or duodenum, thereby replenishing the pool of natural bile acids[10]. Fistula animals have also been useful to estimate canalicular bile flow by measuring the biliary clearance of selected inert solutes (mainly erythritol and mannitol). This procedure assumes that these solutes are sufficiently permeable to enter the canalicular bile by passive processes while being unable to cross the ductal epithelium[22,23]. It appears that this might be the case in some animal species but not in all[24]. Moreover, bile duct cannulation allows direct interventions in the biliary tract through retrograde intrabiliary injection[25-28]; this procedure has been employed to obtain animal models of hepatitis[29] and toxic-induced biliary disease[30], as well as for experimental gene therapy[31,32]. Retrograde intrabiliary injection has also been employed to assess the effects of toxic substances or inhibitors on the bicarbonate-rich choleresis upon stimulation. For instance, ursodeoxycholate-induced bicarbonate-rich choleresis has been shown to be sensitive to intrabiliary phenol[33]. More recently, secretion of bicarbonate in secretin-stimulated rats has been found to be sensitive to intrabiliary administration of particular ion-transport blockers[17].

In humans, *in vivo* assessment of biliary bicarbonate secretion has employed cumbersome maneuvers like nasobiliary drains in hepatic bile ducts[34]. In a context of surgical interventions, invasive procedures similar to those employed in animals (for instance T-tube insertion into the common bile duct[35,36] or percutaneous transhepatic cholangio-drainage[37]) were also used. Recently, non-invasive assessment of biliary bicarbonate secretion was developed by using positron emission tomography (PET)[38]. This imaging technique allows evaluation of baseline and stimulated organ functions after intravenous injection of short half-live positron emitting isotopes[39,40]. Thus, 2-3 min after bicarbonate labeled with carbon-11 (half live of 20.4 min) was given to healthy volunteers, label uptake was observed in the abdominal region corresponding to the liver parenchyma and hepatic hilum. Interestingly, administration of secretin increased bicarbonate uptake in the parenchymal region, this being followed by accumulation of the label in the perihilar area[38]. Currently, the availability of micro-PET systems may also facilitate non-invasive *in vivo* studies of biliary bicarbonate secretion in small laboratory animals.

Animal models of bile ductal cell hyperplasia have also been developed, mainly in rodents, to study the pathophysiology of bile ducts[41-43]. These models are closely associated with increased secretin-stimulated ductal secretion. The increased responsiveness seems to occur regardless of the procedure employed to obtain the hyperplasia of cholangiocytes: partial hepatectomy[44], chronic feeding of bile acids[45] or α-naphthylisothiocyanate (ANIT)[46], chronic administration of phenobarbital plus CCl_4 to rats[47] or just CCl_4 in mice[48], or bile-duct ligation (BDL)[41,49]. In contrast, a decreased secretin-stimulated ductal secretion can be observed in BDL rats with ductopenia following interruption of the cholinergic innervation by total vagotomy[50], or selective damage of large (but not small) cholangiocytes by acute feeding with CCl_4[51,52].

The development of genetically modified murine models has contributed to ascertain the role of selective genes, like those for the cystic fibrosis transmembrane conductance regulator *Cftr*[53,54] and the P-glycoprotein PGY3/MDR2-3/ABCB4 *Mdr2*/*Abcb4*[55], among others. In *Cftr*$^{-/-}$ mice, for instance, induction of colitis has been shown to result in increased bile duct injury[53]. In *Mdr2*/*Abcb4*$^{-/-}$ mice, a multistep process of bile-duct damage leading to sclerosing cholangitis has been described[55]. Spontaneous mutant animals can also serve as useful *in vivo* models. The PCK rat, a model of the autosomal recessive polycystic kidney and hepatic disease (PKHD), has been used for studies on possible trigger factors of biliary cystogenesis. This mutant was spontaneously developed in the rat strain Crj:CD/Sprague-Dawley because of a germ line mutation of the *Pkhd1* gene[56,57]. The TR$^-$ rat model is widely used for studying canalicular secretion of organic anions. This mutant lacks the functional canalicular isoform of the conjugate export pump MRP2/ABCC2 because of one-nucleotide deletion in the *Mrp2*/*Abcc2* gene[58].

In vitro models

Isolated perfused liver preparations are useful experimental models to evaluate the liver effects of single factors in a manner independent of systemic or humoral effects[59]. There are two modalities of these preparations, as the liver can be isolated and perfused *in situ* or *ex situ*, i.e. attached to or removed from the animal body. Livers can be isolated from many animal species (rat[1,59], hamster[60], guinea pig[61], cat[62], rabbit[63], dog[64], sheep[65], calf[66], pig[67], and

monkey[68]), the isolated perfused rat liver (IPRL) being the model most widely used[69]. All these models allow repeated collection of both the perfusate and the bile, and permit easy exposure of the liver to different concentrations of test substances. Test substances may be given intravascularly through just the portal vein[1,59-61,70], which provides flow to essentially all hepatocytes[71], or through both the portal vein and the hepatic artery (i.e. isolated bivascularly perfused liver)[72,73]. The latter bivascularly perfused model is particularly adequate to investigate ductal physiology because the predominant blood supply to the bile ducts is *via* the hepatic artery[74,75]. For studies on ductal secretion, test substances and drugs may also be administered intrabiliary (as retrograde intrabiliary injection[76]). Altogether, these *in vitro* preparations of isolated perfused liver had provided very valuable data on liver physiology and pathophysiology, the regulation of bile secretion included. However, extrapolation of that data to the *in vivo* situation should be cautious, as *in vivo* effects of local factors may be tightly influenced by systemic players such as humoral factors and innervation.

Membrane vesicle preparations derived from rat liver have been useful to distinguish transport across the cell membrane from intracellular events. They may be selectively enriched in basolateral or apical plasma membrane, or in intracellular membranes[77]. The first identification of liver anion exchange activity was carried out in canalicular plasma membrane vesicles[78].

While isolated couplets of hepatocytes was particularly useful as primary secretory units to study canalicular secretion[79], the development in the last decade of the model of isolated bile duct units (IBDU), mainly from rat[16,80,81], but also from mouse[82] is making a great contribution to better study the regulation of ductal bile secretion[83]. Both models permit micropuncture for electrophysiological studies as well as video microscopic optical planimetry to determine bile secretion[16,81,84]. Isolated cholangiocytes[85-89] are also widely employed for transport studies. The preparation of different size subpopulations of cholangiocytes and IBDU isolated from specific portions of the rat intrahepatic biliary tree has made it possible to define the functional heterogeneity of cells lining specific sized intrahepatic ducts[2,90]. Furthermore, knockout and mutant animal models are being used to isolate cholangiocytes and bile duct units to carry out different *in vitro* studies[91-93]. Moreover, studies have been performed in isolated cholangiocytes from patients with cytic fibrosis (i.e. patients with mutations in the *CFTR* gene)[94,95]. Finally, a major advance is coming from the development of polarized primary cultures of intrahepatic cholangiocytes from both rat[96,97] and humans[98-101].

As the excretion of bicarbonate to bile involves a change in intracellular pH (pH_i) and a counterbalance through ion transporters in the responsible epithelial cells, several procedures and maneuvers have been developed to study pH_i regulation. The main strategy is based on the pH_i recovery towards its initial values after loading cells with acid or alkali. This type of experiment requires techniques for rapid and efficient monitoring of the pH_i. Although the most direct and accurate method seems to be the insertion of double-barreled microelectrodes sensitive to $[H^+]_i$ into the cell, this has important limitations; tested cells should have large dimensions and a special ability to manipulate the electrodes. Thus a valuable alternative is microfluorimetry, a procedure based on the sensitivity of intracellular fluorescent dyes to pH_i. The indicator most widely employed is the membrane-permeable compound 2', 7'-bis-(2-carboxyethyl)-5(6)-carboxyfluorescein-acetoxymethylester (BCECF-AM)[102-104]. Uncharged BCECF-AM rapidly enters the cell, where it is enzymatically cleaved into its charged, membrane impermeant, fluorescent form BCECF. When bound to H^+ ions, BCECF exhibits a shift in its emission fluorescence spectrum, and the ratio between the pH-sensitive emission at 495 nm wavelength, and the pH-insensitive (background) emission at the isosbestic point (440 nm) can be estimated. Once proper adjustments are set up (correcting for cellular autofluorescence, minimizing dye leakage, bleaching, or compartmentation, and preventing photodynamic damage to the cells), this methodology allows for continuous measurements of pH_i, with a very rapid response time. The technique can be applied to studies with a fluorimeter, flow cytometer, inverted epifluorescent microscope connected to a photon-counting photometer and a TV camera attachment plus a digital image-processing software[105]. An example of successful use of this methodology is the measurement of the Na^+-independent Cl^-/HCO_3^- anion exchange (AE) activity in both cell clusters and single cells. After inducing intracellular alkalinization by administration and further withdrawal of the cell-permeant weak acid propionate in Krebs-Ringer bicarbonate buffer (KRB), it is possible to estimate the anion exchange activity as the rate of spontaneous recovery of pH_i[106]. Rates of pH_i recovery can be measured as $\delta pH_i/\delta t$ from the tangent to the experimental plot; transmembrane acid fluxes (or equivalent transmembrane base fluxes, i.e. J_{OH}) are usually calculated as $\beta_{tot} \times \delta pH_i/\delta t$, β_{tot} being the total intracellular buffering power in the presence of CO_2/HCO_3^-, estimated as described[107,108].

The collection of additional important methodologies which enabe a continuous progress in bile secretion pathophysiology is still large. Thus, microcomputed tomography[109], scanning and transmission electron microscopy[89,110], immunoelectron microscopy[111], and dual labeled immunogold[112,113] are only a few among those techniques deserving a brief mention. Moreover, concerning molecular biological tools, the techniques of gene silencing through RNA-interference show great potential for clarifying the function of selective genes in bile duct cells. Currently, RNA-interference may be achieved with small interfering RNAs (siRNA) and through microRNAs (miRNA) and short/small hairpin RNA (shRNA)[114]. siRNAs had been used in normal rat IBDU to examine the role of fibrocystin in ciliary morphology and biliary cystogenesis[57] and that of aquaporin-1 (AQP1) in the transport of water by biliary epithelia[115]. Also siRNA experiments had been carried out in cholangiocarcinoma cells to identify factors involved, for example, in the growth of these cells[116] or their resistance to tumor necrosis factor-related apoptosis-inducing ligand (TRAIL)[117]. Usual transfection protocols are not very efficient to internalize the siRNAs in cultured

cholangiocytes. Viral vectors that incorporate shRNA expression cassettes have thus been developed. Recently, a recombinant adenovirus with this design has been constructed and employed to efficiently infect normal rat cholangiocytes in culture and test the function of AE2/SLC4A2 anion exchanger in these cells[17].

MECHANISMS INVOLVED

Bile formation is regarded as an osmotic water flow in response to active solute transport. Bile salts are secreted in the canaliculi through a specific export pump referred to as BSEP/SPGP/ABCB11 (from bile salt export pump, sister of P-glycoprotein, and ATP-binding cassette, subfamily B, member 11, respectively)[118-120], allowing for the generation of the bile salt-dependent flow fraction. Remaining bile-salt independent flow fractions can be driven by supplementary solutes secreted at both the canaliculi (the so-called canalicular bile salt-independent flow), and the bile ducts (named as ductal bile salt-independent flow)[1,2,10,14,121]. Estimates for the magnitude of each bile flow fraction in humans are shown in Table 1.

Table 1 Estimated bile flow rates in humans[10]

Bile flow fraction	Flow rate
Canalicular bile acid-dependent flow	0.15-0.16 mL/min
Canalicular bile acid-independent flow	0.16-0.17 mL/min
Ductal secretion of bile flow	0.11 mL/min
Daily total bile flow	620 mL/d

Table 2 Estimations of canalicular bile-salt independent flow in different species

Species	Flow rate[122] (μL/min/kg)	Percentage of the canalicular bile flow
Humans	2	30%[128,129]
Monkey	7	
Dog	5	20%[9]
Rat	70	> 60%[1,131,132]
Rabbit	60	> 50%[133]

Canalicular bile-salt independent flow

In addition to bile acid secretion, the canalicular membranes of hepatocytes show active secretion of other organic and inorganic compounds, mainly glutathione[13] and bicarbonate[11,12,122], respectively. Glutathione can be secreted *via* the organic anion transporter MRP2/ABCC2[123], while the efflux of bicarbonate occurs through a DIDS-sensitive Na^+-independent Cl^-/HCO_3^- exchange in association with other ion transport systems (Figure 1)[78,124-127]. Both glutathione and bicarbonate seem to have an equivalent major input in canalicular bile flow generation, each driving up to 50% of the bile salt-independent fraction[11]. For this to be accomplished, resultant osmotic forces need to be associated with aquaporin-mediated transcellular movement of water molecules from plasma to the bile canaliculi[128]. In any event, the relative contribution of the canalicular bile salt-independent fraction to the whole canalicular bile flow may vary substantially between animal species (Table 2).

Canalicular bicarbonate excretion has been reported to be regulated by glucagon[134,135], a hormonal oligopeptide secreted by the pancreatic α-cells. This hormone is encoded by the gene *GCG*, which belongs to the same multigene family as secretin (*SCT*), vasoactive intestinal peptide (*VIP*), and gastric inhibitory peptide (*GIP*) genes, among others. Following its synthesis in the pancreas, glucagon may reach the liver and stimulate the hepatocytes *via* its interaction with the glucagon receptor (Figure 2). Interestingly, this receptor and the receptors for secretin, VIP, GIP and other small peptidic hormones, are included in a superfamily of receptors characterized by a 7-transmembrane domain structure and by their coupling to adenylate cyclase (ADCY) *via* GTP-binding proteins (G proteins). Glucagon-glucagon receptor interaction in hepatocytes leads to increased intracellular levels of cAMP, PKA activation, stimulation of canalicular Cl^-/HCO_3^- exchange activity[126,134,135], and enhanced AQP8-mediated water permeability at the canalicular membrane[128,136-138]. Current data strongly suggests that these choleretic effects of glucagon are microtubular-dependent and involve mobilization of intracellular vesicles[126,128,136,139,140]. These effects of glucagon in hepatocytes resemble those of secretin in cholangiocytes (Figure 2). After their interaction with their specific G-protein-coupled receptors, both hormones appear to use a similar cAMP-dependent PKA pathway to co-redistribute cell-type specific intracellular vesicles with flux proteins towards the apical plasma membrane of the target cell. But some of the flux proteins involved in bile formation may differ between hepatocytes and cholangiocytes. While AQP8 is the involved water chanel in hepatocytes[128,136,137,140], it changes to AQP1 in cholangiocytes[112,141,142]. Moreover, there are data suggesting that in hepatic cells in baseline situation, the water channel AQP8, the glutathione carrier MRP2/ABCC2 and the chloride bicarbonate exchanger AE2/SLC4A2[138,140] are present in pericanalicular vesicles that might migrate to the canalicular membrane upon glucagon stimulation[128]. These data, together with previous findings on AE2/SLC4A2 expression at the canaliculi and the pericanalicular area[143,144], point towards the canalicular bicarbonate excretion occurring *via* an AE2/SLC4A2-mediated Cl^-/HCO_3^- exchange[127]. Although a number of observations suggest that this excretion of bicarbonate in exchange for chloride functions in connection with an apical chloride channel that maintains favorable Cl^- gradients[78,124,127], the specific chloride channel(s) involved need yet to be identified (see Figures 1 and 2). While in cholangiocytes AE2/SLC4A2 colocalizes with CFTR[112], this particular cAMP-responsive Cl^- channel is not expressed in hepatocytes. Therefore, it might be expected that a Cl^- channel other than CFTR[145-148] be physically and/or functionally associated with AE2/SLC4A2 in hepatocytes. Moreover, previous findings have established an important link between bicarbonate excretion to bile and changes in pH_i. Canalicular Cl^-/HCO_3^- exchange is a major hepatic acid loading mechanism; at resting pH_i and in the absence of any stimulation it shows low activity, but it is rapidly activated by intracellular alkalosis, whereas cAMP stimulation leads to intracellular acidification

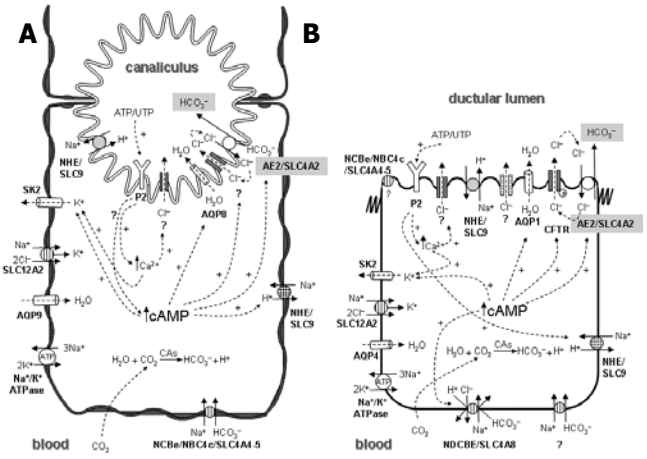

Figure 1 The major ion carriers implicated in pH_i regulation and secretion of bicarbonate to bile from liver cells. **A:** Hepatocytes; **B:** Cholangiocytes.

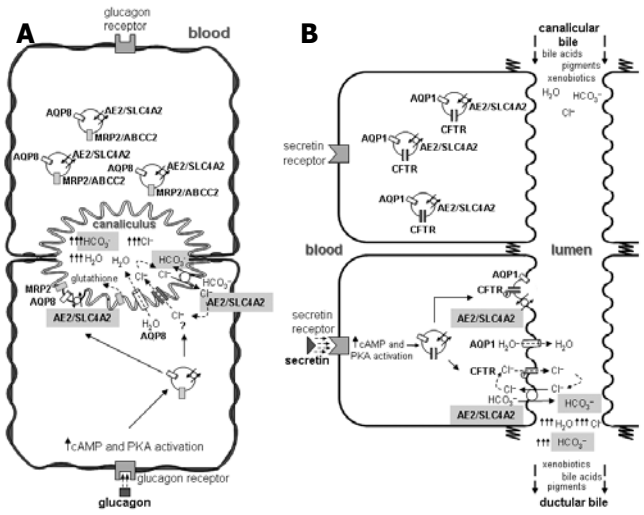

Figure 2 Hormonal stimulation of bicarbonate excretion from hepatocytes and cholangiocytes. **A:** In hepatocytes, glucagon may induce an exocytic trafficking of vesicles with the anion exchanger AE2/SLC4A2 and the water channel AQP8, which can results in canalicular bicarbonate-rich hydrocholeresis. MRP2/ABCC2, while being a carrier for organic anions like glutathione rather than an inorganic ion transporter, is hereby depicted because of its possible colocalization with the other two flux proteins; **B:** In cholangiocytes, secretin induces trafficking of vesicles with the chloride channel CFTR, the anion exchanger AE2/SLC4A2, and the water channel AQP1, and further exocytosis to the lumenal membrane of these cells, which results in ductal bicarbonate-rich hydrocholeresis.

which requires appropriate counterbalance[124,127]. Figure 1 summarizes several carriers putatively involved in these events in hepatocytes (as well as in cholangiocytes), including acid/base transporters and related proteins. A brief recall on bicarbonate loaders -and therefore acid extruders- highlights the role of electrogenic Na^+-HCO_3^- cotransporters (NBCe)[149-151] and the carbonic anhydrase/CA-CO_2 pathway[152,153]. Intracellular load of bicarbonate may increase upon hydration of intracellular CO_2 by carbonic anhydrase(s)[154] and subsequent H^+ efflux *via* Na^+/H^+ exchange (NHE) (Figure 1). The involved exchanger is mainly the basolateral NHE1/SLC9A1[155-157], but NHE4/SLC9A4[158] and the canalicular NHE3/SLC9A3[159] may also participate. The other relevant way of loading bicarbonate into hepatocytes, i.e. through electrogenic Na^+-HCO_3^- cotransport, functions upon membrane depolarization following intracellular acidification[160]. The specific proteins mediating this cotransport in hepatocytes remain to be defined. The only two members of the SLC4 family of bicarbonate transporters[161] known to be electrogenic are NBCe1/SLC4A4 and NBCe2/NBC4/SLC4A5[162]. NBCe1/SLC4A4 is widely expressed in most tissues, but its expression is negligible in the liver[163,164], while mRNA expression for NBCe2/NCB4/SLC4A5 is high in this tissue[165]. Of the known human NBCe2/NCB4/SLC4A5 variants, only the rat NBC4c ortholog can be detected in the rat liver by RT-PCR[164]. Moreover, NBC4c immunoreactivity had been observed at the basolateral membrane of rat hepatocytes[164]. Altogether these findings suggest that the basolateral NBC4c variant might be a relevant bicarbonate loader that enables hepatocytes for canalicular secretion of bicarbonate through the apical AE2/SLC4A2 anion exchanger.

Ductal bile

As previously mentioned, primary canalicular bile undergoes a process of fluidization and alkalinization along the biliary tract that is influenced by several factors including hormones (mainly secretin in most species[2,14-17]), innervation/neuropeptides[2,50,166,167], and biliary constituents[2,5,6,17,18]. This process results in net ductal secretion of a bicarbonate-rich watery fluid. The magnitude of the ductal contribution varies between species, representing 30% of basal bile flow in humans and 10% in rats[6]. Cholangiocytes are provided with specific transport systems that participate in bile modifications[2,168]. They are able to take up bile salts *via* an apical Na^+-dependent transporter (SLC10A2, formerly ASBT/ISBT and occasionaly ABAT)[45,169-172] and release them through a basolateral truncated isoform of the same carrier[173]. Indeed, transcellular transport through these carriers is specially important under cholestatic situations. In any case under normal conditions, biliary transport of bicarbonate appears as a relevant function of the bile duct epithelium. It is accomplished by specific acid/base carriers and related transporters that enable cholangiocytes to regulate their pH_i[105,174] (Figure 1).

Cholangiocyte acid extruders

The vectorial transport of HCO_3^- from cholangiocytes to duct lumen starts with the accumulation of HCO_3^- in the cells *via* mechanisms which vary between animal species. In rat cholangiocytes, for instance, HCO_3^- loading is mediated by transport systems similar to those in hepatocytes, i.e. by electrogenic Na^+-HCO_3^- cotransport activity[168,174-176] and the carbonic anhydrase/CA-CO_2 pathway coupled to subsequent carrier-mediated H^+ extrusion[153,154]. Carbonic anhydrases (CAs) catalyze the hydratation of carbon dioxide, $CO_2 + H_2O \Leftrightarrow HCO_3^- + H^+$ (reviewed in ref. 153). Thus far, several CA isoenzymes have been identified which differ in organ distribution, subcellular location, and function (cf. Table I in ref. 153). Compared with other secretory organs, the mammalian liver contains relatively low levels of total CA activity. Thus, the cytoplasmic CA-II (CA2)

is mainly expressed in bile duct cells (but it may also be found in hepatocytes), and appears to be involved in the production of HCO_3^- for its further secretion to bile[153,177]. Also, the biliary epithelial cells express the membrane associated CA-IV and CA-IX, which on the basis of their location might be involved in acidification and concentration of the bile, even though the exact mechanisms have not been described[153].

Among electrogenic Na^+-HCO_3^- cotransporters[161,162] only the NBC4c variant of NBCe2/NBC4/SLC4A5 was found to be expressed in the rat liver, being immunolocalized to both hepatocytes and cholangiocytes[164]. Interestingly, NBC4c immunoreactivity was basolateral in hepatocytes but apical in cholangiocytes, suggesting a potential role for this cotransporter in the luminal fluid secretion and/or absorption[164]. In humans cholangiocytes, however, Na^+-HCO_3^- cotransport is not active in the physiological range of pH_i, being active only at very low pH_i, and bicarbonate influx occurs mainly through electroneutral Na^+-dependent Cl^-/HCO_3^- anion exchange[176,178]. Thus far, NDCBE/SLC4A8 is the only Na^+-dependent Cl^-/HCO_3^- exchanger cloned in humans[179]. Although Northern blot analysis could not detect its messenger RNA in the whole liver[179], this cannot rule out that NDCBE/SLC4A8 be expressed in cholangiocytes (which account for just 5% of the liver cell population).

In both rat and human cholangiocytes, H^+ extrusion takes place essentially through NHE activity (Figure 1) -while in pig cholangiocytes H^+ extrusion is mediated by a cAMP-activated H^+-ATPase[180]. Thus far, several members of the NHE/SLC9 family have been described in rat cholangiocytes. They include NHE1/SLC9A1, restricted to the basolateral membrane and highly sensitive to amiloride, and the amiloride-insensitive isoform NHE2/SLC9A2, which is likely to be active on the side facing the lumen[106]. Moreover, NHE3/SLC9A3 has been immunolocalized to the apical membrane of rat cholangiocytes, where it may play an important role in fluid absorption from the bile duct lumen[159]. Also NHE4/SLC9A4 -an isoform seemingly activated by hypertonicity and with K^+/H^+ exchange activity[181], was identified in whole liver extracts by Western blot[158]. Some findings in the stomach of *Nhe4/Slc9a4*$^{-/-}$ mice had led to speculations on a possible functional coupling of NHE4/SLC9A4 with the AE2/SLC4A2 anion exchanger in parietal cells[182]. In any case, the specific cellular expression and function of this NHE isoform in the liver remains to be determined.

Cholangiocytes acid loaders

As previously reported in hepatocytes, the main acid loader mechanism in bile duct cells is the apical Na^+-independent Cl^-/HCO_3^- exchange[17,106,174,176]. Such an AE activity might secrete HCO_3^- into the lumen which is exchanged for Cl^- influx. This exchange is electroneutral, being facilitated by the outside to inside transmembrane gradient of Cl^- at relatively high intracellular concentration of HCO_3^-, specially upon secretin stimulation[16,81,106,175,183] (Figure 2). Actually, several bicarbonate transporters have been described as exerting Na^+-independent Cl^-/HCO_3^- exchange activity. This is the case for the SLC4 anion exchangers (AE1/SLC4A1, AE2/SLC4A2 and AE3/SLC4A3)[161,184] as well as several members of the SLC26 gene family of multifunctional anion exchangers (DRA/CLD/SLC26A3, PDS/DFNB4/SLC26A4, and SLC26A6[185] and more controversially SL26A7[186,187]). But none of these carriers except AE2/SLC4A2 had been described to occur in the liver. Moreover, AE2/SLC4A2 was localized not only to the canaliculi but also to the lumenal membrane of bile duct cells[143]. Recent experiments of RNA intereference with recombinant adenovirus expressing shRNA have shown that AE2/SL4A2 is indeed the main effector of both basal and stimulated Na^+-independent Cl^-/HCO_3^- exchange in rat cholangiocytes[17].

Other ion-loaders/extruders

Besides acid/base transporters cholangiocytes possess other ion carriers like those for Cl^-, Na^+, and K^+, which greatly contribute to pH_i regulation and bicarbonate secretion (Figure 1). Thus, the cAMP-responsive Cl^- channel CFTR had been localized at the apical side, where it plays a role in biliary excretion of HCO_3^-[188,189]. Although HCO_3^- permeability through activated CFTR has been shown in several cell systems[190-194], its main contribution to biliary bicarbonate secretion appears to occur through a coordinated action with AE2/SL4A2[17,175,195]. In addition to CFTR, cholangiocytes possess a dense population of Ca^{2+}-activated Cl^- channels. These channels are responsive to interaction of the purinergic-2 (P2) receptors with nucleotides (mainly ATP or UTP)[196-199], and they appear to be related to the Ca^{2+}-calmodulin-dependent protein kinase II[188,200,201]. Resultant Ca^{2+}-stimulated Cl^- efflux might be up to 2-fold greater than that mediated by cAMP[202]. Additional high conductance anion channels which are insensitive to both Ca^{2+} and cAMP were identified in rat bile duct cells[203], but their specific role remains to be defined. The efflux of Cl^- from cholangiocytes to the ductular lumen is counterbalanced not only *via* apical Cl^-/HCO_3^- exchange but also through other Cl^- uptake systems, mainly the basolateral Na^+-K^+-$2Cl^-$ cotransporter NKCC1/SLC12A2[196,204]. In addition to maintain high intracellular Cl^- concentration facilitating apical Cl^- excretion, this forskolin-stimulable cotransporter has been reported to participate in cell volume homeostasis[205] and cell proliferation[204,206,207]. Because the NKCC1/SLC12A2-mediated influx of Cl^- occurs together with the entry of Na^+ and K^+, cholangiocytes possess other systems that sustain the gradients of these cations and the membrane potential difference. Thus a basolateral sodium pump (the Na^+/K^+-ATPase)[208,209], extrudes Na^+ and uptakes K^+ with a 3:2 stoichiometry[210]. Accumulation of K^+ within cholangiocytes is prevented by its exit through K^+ channels. Intracellular cAMP and/or Ca^{2+} concentration may activate basolateral K^+ conductance that hyperpolarizes the cell[211]. The small conductance K^+ channel SK2/KCNN2 has been identified in rat and human hepatocytes[212] and in rat and human biliary epithelia[202,212], the activity of which is stimulated by small increases in intracellular Ca^{2+} in an apamin-sensitive manner[213]. Although SK2/KCNN2 immunoreactivity has been localized in cholangiocytes at both apical and basolateral membranes, functional studies in polarized preparations have demonstrated a significantly greater basolateral Ca^{2+}-stimulated K^+ conductance[202].

Because the nonselective K^+ channel blocker Ba^{2+} is able to cause a greater degree of inhibition than apamin[202], apamin-insensitive channels not yet identified may also be involved in the conductance of K^+.

In a context of cAMP- and/or Ca^{2+}-stimulated Cl^- channels, cell hyperpolarization due to K^+ conductance facilitates the transcellular Cl^- movement into the lumen. Recycling of K^+ can be held up through the basolateral Na^+-K^+-$2Cl^-$ cotransport and the Na^+/K^+-ATPase. All these ionic fluxes across cholangiocyte membranes may ultimately lead to biliary excretion of bicarbonate *via* its exchange with lumenal chloride, which is facilitated by the outside to inside transmembrane gradient of chloride at relatively high intracellular concentration of bicarbonate[16,81,106,175,183]. The apical fluxes of anions result in increased osmotic forces in the bile duct lumen which in the presence of aquaporins contribute to the generation of ductal bile flow. This view has been strongly supported by the finding that AE2/SLC4A2 and CFTR both colocalize with AQP1 in cholangiocyte intracellular vesicles which co-redistribute to the apical cholangiocyte membrane upon both cAMP and secretin stimulations[112].

Water transporters or aquaporins

Aquaporins are water channels that mediate a bidirectional passive movement of water molecules across epithelial cells in response to osmotic gradients established by ions and solutes. Thus far, rodent cholangiocytes have been described to possess two types of aquaporins. Thus, in addition to the AQP1 locating in the intracellular vesicles which may traffic to the apical membrane upon agonist stimulation[112], there occurs another water channel at the basolateral membrane of cholangiocytes named AQP4, which is not sensitive to secretin[214,215] (Figures 1 and 2). However, there can be differences between species. For instance, immunohistochemical analysis in liver pig has shown the presence of AQP1 and AQP9 in cholangiocytes, while AQP3, AQP4, AQP7, and AQP8 were absent in these cells[216].

REGULATORY FACTORS

The bile duct epithelium is constantly regulated by the action of multiples factors that contribute to the formation of bile flow with an adequate final composition. Among these factors secretin is a relevant hormone peptide which may induce bicarbonate-rich hydrocholeresis in many animal species. Thus, secretin regulation of ductal bile flow and the concurrence of other factors are briefly summarized as follows:

Relevance of secretin stimulation

In 1902, Bayliss and Starling[19] described an active agent originating from the intestinal mucosa, which they referred to as secretin because of its capacity to stimulate pancreatic secretion in the dog. They also used the word "hormone" to designate this sort of compound that can be produced in an organ and carried through the circulation to exert its effect on another organ. Some years passed before the choleretic effect of secretin in the liver was reported in several animal species and humans[217-219]. Secretin was found to stimulate bile flow together with a decrease in the concentration of bile salts[217-219]. In the late 1960s the role of bile ducts in secretin-induced hydrocholeresis was postulated because of the observation that this secretin effect was associated with reciprocal changes in the biliary concentration of bicarbonate and chloride anions[35].

Meanwhile secretin was purified from most species, first in 1962 from pig[220,221] and then from humans, dog, goat, guinea pig, rabbit, rat, mouse and chicken. Secretin has only 27 amino acids, which allowed for its chemical synthesis as early as 1968[222]. There is close homology between mammalian secretins, but also between the regulatory peptides (more than 10) currently grouped in the secretin/glucagon/ VIP superfamily.

Secretin is produced in many organs but mainly in the mucosa of upper small intestine (duodenum and jejunum)[223,224]. Its release to blood occurs mainly in the postprandial period, being stimulated by gastric acid delivered into duodenal lumen[225], as well as by pancreatic and intestinal secretions[226,227]. Secretin release appears to be mediated by a luminal secretin-releasing peptide contained in these gastrointestinal juices[228-230]. In addition to its mentioned bilary and pancreatic effects, secretin may function as feedback inhibitor of gastrin (GAST) release and gastric acid secretion[231], and may also regulate gastric motility[232]. The physiological activities of secretin are subjected to hormone-hormone and neuro-hormonal interactions. Inhibition of gastric acid secretion by secretin is thus mediated by somatostatin (SST) and prostagladins[233,234], and secretin inhibition of gastric motility involves a vagal afferent pathway[235,236].

Secretin exerts its physiological actions *via* interaction with the N-terminal extracellular tail of its specific glycoprotein receptor SCTR[237-239]. Like the glucagon receptor and other members of the same receptor super-family, SCTR is coupled to adenylate cyclase/ADCY through an oligomeric GTP-binding protein. In the liver SCTR is exclusively expressed at the basolateral membrane of cholangiocytes[240,241]. As previously noted, the action of secretin in cholangiocytes runs parallel with the choleretic effect of glucagon in hepatocytes (Figure 2). Thus, both glucagon and secretin may stimulate the bile salt-independent bile flow, but each at a different level, i.e. canalicular for the former and ductular for the latter(cf. ref. 242).

Secretin-SCTR interaction in cholangiocytes results in increased intracellular levels of cAMP[15,16,243]. Further PKA activation[175,183] can induce microtubule-dependent co-redistribution of the intracellular vesicles with AE2-CFTR-AQP1 flux carriers to the apical membrane[112]. Additionally, the CFTR is phosphorylated and activated[244], thus resulting in Cl^- efflux to the ductular lumen. In consequence, Cl^- secreted by CFTR can be exchanged with HCO_3^- through AE2/SLC4A2. This mechanistic model has been consistently confirmed *in vitro* using rat IBDU[16,175] and cholangiocytes[174]. For *in vivo* studies, most experiments with rats have used some of the aforementioned models with bile duct proliferation[41,43,46,112,245,246], since normal rats appear to respond very poorly to secretin (likewise rabbit, but in contrast with guinea pig among rodent species)[15,41,46,47,247]. Indeed the expression of

SCTR is increased in BDL rat cholangiocytes[245,246] but the receptor is also expressed in normal rat cholangiocytes[240]. In the model of IPRL[248], intra-arterial secretin increased biliary concentration of bicarbonate, but had no effect on the net bile flow. Because the effect of secretin was blocked only by the CFTR inhibitor NPPB and not by the anion exchanger inhibitor DIDS (both administered intra-arterially), it was proposed that Cl^-/HCO_3^- exchange would have no role in the ductal secretion of bicarbonate in the normal rat[248]. However, recent experiments indicate that secretin does increase bile flow and biliary Cl^- and HCO_3^- excretions in the normal rat, but when they maintain the bile acid pool *via* continuous infusion with taurocholate[17]. Moreover, these effects of secretin were distinctively blocked by the inhibitors given by intrabiliary retrograde injection. While secretin effects were all blocked by intrabiliary NPPB, DIDS only inhibited secretin-induced increases in bile flow and bicarbonate excretion but not the increased chloride excretion[17]. These findings provide evidence for the role of biliary Cl^-/HCO_3^- exchange in secretin-induced bicarbonate-rich choleresis in the normal rat model.

The role of the bile acid pool

In line with former findings in earlier experiments with dogs[14,249], the aforementioned observation that secretin also has effects on the normal rat when infused continuously with taurocholate[17] confirms the notion that bile acids are relevant for secretin actions. In a previous study in normal rats secretin and taurocholate were tested and no secretin effects were observed[41]. But in that study, taurocholate infusion was interrupted before secretin administration[41]. It is already known that bile acids can enter into cholangiocytes through the carrier ASBT[45,169-172] and exert their effects on these cells (reviewed in refs. 2 and 250). For instance, it has been recently reported, activation of CFTR by ASBT-mediated bile salt absorption, which is seemingly independent from cAMP or cGMP signaling[251].

The bile salt-dependent canalicular flow is related to the osmotic activity of bile acids, but some bile acids such as ursodeoxycholic acid (UDCA), 23-nor-UDCA, and 23-nor-chenodeoxycholate[252-254], have a higher choleretic effect than can be accounted for by their secretion into bile (the so-called hypercholeretic effect). This hypercholeretic effect is associated with a marked stimulation of bicarbonate secretion into bile. A classic hypothesis referred to as "cholehepatic shunt pathway"[253] claimed that the hypercholeretic effect may involve intraductal protonation of unconjugated bile salts which results in the formation of bicarbonate anions derived from hydrated CO_2 (i.e. H_2CO_3 or H^+ plus HCO_3^-). Passive diffussion of uncharged bile acids through cholangiocytes to the periductular vessels and further uptake in hepatocytes could be followed by their canalicular resecretion as unconjugated bile salts (reviewed in ref. 250). After the identification of apical and basolateral bile acid carriers in cholangiocytes (ASBT and tASBT, respectively[45,169-173]), the cholehepatic shunt hypothesis has received a boost, being updated for the conjugated bile salts[250]. ASBT activity acutely increases upon secretin stimulation[172], which may accentuate the cholehepatic bile acid shunting in the postprandial period.

Neurovegetative liver innervation

The liver is directly regulated by the neurovegetative innervation. Indeed, the release of the neurotransmitter acetylcholine from the intrahepatic parasympatic terminals induces, *via* selectively interaction with M_3 Ach receptors on cholangiocytes, an increase in both secretin-stimulated cholangiocyte cAMP synthesis and Cl^-/HCO_3^- exchanger activity by Ca^{2+}-calcineurin-mediated PKC-independent modulation of adenylate cyclase/ADCY[255,256]. In fact, infusion of acetylcholine in the IPRL model was found to potentiate the effect of secretin on biliary HCO_3^- excretion[248]. Furthermore, interruption of parasympatic innervation in BDL rats by vagotomy has been reported to inhibit secretin-stimulated ductal secretion, as well as to decrease cholangiocyte intracellular cAMP levels[50].

The intrahepatic biliary epithelium also receives dopaminergic innervation[257,258], but in contrast to the cholinergic system, the dopaminergic system inhibits secretin-induced choleresis. Although both systems exert their functions through increased intracellular ions (1, 4, 5) P_3 and Ca^{2+}, the cholinergic system acts *via* calmodulin and calcineurin but without recruitment of PKC[256], whereas the D_2 dopaminergic system inhibits secretin-stimulated ductal secretion through increased expression and activation of PKC-γ[259].

Moreover, cholangiocyte secretion can also be regulated by the action of the adrenergic system[260,261]. The α_2-adrenergic receptor agonist UK-14304 has been reported to inhibit cholangiocarcinoma growth through time course-dependent modulation of Raf-1 and B-Raf activities[260], and the α_1-adrenergic agonist phenylephrine can potentiate secretin-stimulated ductal secretion through the amplification of the ADCY system *via* a Ca^{2+}- and PKC-dependent mechanism[261].

Hormones

In addition to secretin, there are gastrointestinal hormones and neuropeptides such as bombesin/gastrin releasing peptide (BN/GRP), VIP, endothelin-1 (ET1/EDN1), somatostatin/SST, and gastrin/GAST, which may also modulate the ductular bile salt-independent flow (reviewed in ref. 2). Some of these factors operate through a secretin-independent mechanism, while others influence the release of secretin or interact with the secretin signaling in cholangiocytes, depending very much on the animal species. For instance, the neuropeptide bombesin/BN/GRP can act either by increasing the secretin release in dogs[262,263], or inducing ductal secretion with activated Cl^-/HCO_3^- exchange *via* secretin-independent mechanisms in isolated rat cholangiocytes[2,264-266]. The effect of VIP on cholangiocytes depends also on the animal species[2,267-271]. While VIP appears to increase secretin-stimulated bile flow and bicarbonate excretion in humans[267,268], studies in rat IBDU show that VIP can stimulate basal fluid and bicarbonate secretion through a cAMP-independent pathway[2,269].

The cyclic tetradecapeptide somatostatin/SST is able to inhibit basal and secretin-stimulated bicarbonate-rich choleresis *via* its interaction with the SSTR2 receptor

subtype[2,272]. In rat, inhibition of secretin-stimulated ductal secretion by SST is associated with decreased expression of the secretin receptor SCTR in cholangiocytes and reduced secretin-stimulated cAMP levels[49,272]. In mice SST has also been shown to stimulate ductal fluid absorption, a process involving intracellular cGMP synthesis and inhibition of secretin-stimulated cAMP synthesis[273]. Moreover, in dogs, SST has been shown to diminish the acid-induced release of secretin from the duodenal mucosa[262]. Similarly SST, the gastrointestinal hormone gastrin/GAST may also modulate cholangiocyte secretion[2]. In BDL rats, GAST has been reported to inhibit secretin-stimulated ductal secretion by reducing both SCTR expression and secretin-induced cAMP levels[274].

Other peptide hormones like insulin and insulin-like growth factor 1 (IGF1) can also modulate the biliary epithelium. Insulin was reported to inhibit secretin-induced secretion in BDL rats through activation of PKC and inhibition of secretin-stimulated cAMP and PKA activity[275]. On the other hand, studies using a liver cell line (though from hepatoma rather than cholangiocytic type), showed that insulin may stimulate membrane turnover with increased exocytosis/endocytosis of vesicles containing ion channels[276]. In rats IGF1 was found to stimulate choleresis[277] as well as cholangiocyte proliferation[278]. IGF1 can be synthesized and released from cholangiocytes under the control of the growth hormone (GH)[278]. Biliary IGF1 may in turn interact with its receptor (IGF-R) located at the apical pole of cholangiocytes[278]. Expression of both IGF1-R and IGF1 is markedly enhanced in cholangiocytes following bile duct ligation[278].

Also steroidal hormones like corticosteroids and estrogens have effects on the biliary epithelium. Corticosteroids are choleretic and increase biliary bicarbonate excretion[277,279]. However, estrogen-induced cholestasis results in diminished biliary bicarbonate excretion[280]. Reduced bicarbonate excretion might be caused by a reflux of biliary bicarbonate *via* leaky tight junctions as it is not associated with impaired activity of the Cl^-/HCO_3^- exchanger[280].

Purinergic stimulation

Both hepatocytes and cholangiocytes are able to release ATP and UTP, which leads to increased biliary concentration of nucleotides and nucleosides (the latter being a result of nucleotide dephosphorylation by membrane-associated nucleotidases)[281-283]. Stimulation of the different subtypes of purinergic receptors (PR) at the lumenal membrane of cholangiocytes by either extracellular nucleosides (P1 family receptors) or extracellular nucleotides (P2 family receptors) may control cholangiocyte secretion and ion channel activities[281,283-286]. Most subtypes of purinergic receptors are G protein-coupled receptors except the P2X subtypes which are ligand-gated channels[281,283]. P2 activation stimulates cholangiocyte biliary efflux of K^+, HCO_3^-, and Cl^-, and reabsorption of Na^+[281,283,286]. Whereas Cl^- efflux seems to be mediated by a calcium-stimulated Cl^- channel[284], HCO_3^- is secreted from cholangiocytes *via* an AE2/SLC4A2 mediated Cl^-/HCO_3^- exchange[17,105,174,284,287]. Of notice, the $P2Y_{11}$ subtype receptor has been reported to mediate secretion *via* cAMP in pancreatic duct epithelial cells[288], which suggests that a similar mechanism may also occur in cholangiocytes (as well as in hepatocytes). Finally, P2 receptors may stimulate the basolateral NHE1/SLC9A1 activity in cholangiocytes[287].

Cytokines and related factors

Some cytokines such as IL5 and the combination of the proinflammatory cytokines IL6, IFN-γ, IL1, and TNF-α can inhibit secretin-induced choleresis[289,290]. Moreover, proinflammatory cytokines can impair the barrier function of biliary epithelia[290], and stimulate the biliary epithelium to generate NO, *via* induction of inducible nitric oxide synthase 2A (NOS2A/INOS). Resultant reactive nitrogen oxide species (RNOS) may cause ductular cholestasis through inhibition of both the soluble adenylate cyclase (SAC) and the cAMP-dependent HCO_3^- and Cl^- secretory mechanisms[195]. Such a pathogenetic sequence may contribute to ductal cholestasis in inflammatory cholangiopathies[195].

In conclussion, biliary secretion of bicarbonate is an important contributor to the generation of the bile-salt independent flow. Bicarbonate is secreted from both hepatocytes and cholangiocytes through parallel mechanisms which involve chloride efflux through activation of Cl^- channels, and further bicarbonate excretion *via* AE2/SLC4A2-mediated Cl^-/HCO_3^- exchange. Glucagon and secretin are two relevant hormones which act very similarly in hepatocytes and cholangiocytes, respectively. These hormones interact with their specific receptor, resulting in increased intracellular cAMP levels and activation of cAMP-dependent Cl^- and HCO_3^- secretory mechanisms. Both hepatocytes and cholangiocytes seem to have cAMP-responsive intracellular vesicles in which AE2/SLC4A2 may colocalize with cell specific Cl^- channels (CFTR in cholangiocytes and thus far undetermined in hepatocytes) and aquaporins (AQP1 in cholangiocytes and AQP8 in hepatocytes). cAMP-induced coordinated trafficking of these vecicles to either canalicular or cholangiocyte lumenal membranes and further exocytosis results in increased osmotic forces and passive movement of water with net bicarbonate-rich hydrocholeresis.

Abstract

Basic and translational wound healing research in the biliary tree lag significantly behind similar studies on the skin and gastrointestinal tract. This is at least partly attributable to lack of easy access to the biliary tract for study. But clinical relevance, more interest in biliary epithelial cell (BEC) pathophysiology, and widespread availability of BEC cultures are factors reversing this trend. In the extra-hepatic biliary tree, ineffectual wound healing, scarring and stricture development are pressing issues. In the smallest intra-hepatic bile ducts either impaired BEC proliferation or an exuberant response can contribute to liver disease. Chronic inflammation and persistent wound healing reactions in large and small bile ducts often lead to liver cancer. General concepts of wound healing as they apply to the biliary tract, importance of cellular processes dependent on IL-6/gp130/STAT3 signaling pathways, unanswered questions, and future directions are discussed.

INTRODUCTION

Wound healing in the biliary tract significantly contributes to the development of liver disease. For example, ineffectual wound healing, mural scarring, and stricture development in the large extra-hepatic bile ducts are responsible for diseases such as extra-hepatic biliary atresia and primary sclerosing cholangitis. These are leading indications for liver transplantation (http://www.optn.org). A similar problem occurs in 10%-15% of all liver allografts-the biliary sludge syndrome. Conversely, an exuberant wound healing response, or ductular reaction, contributes to the development of cirrhosis from a variety of causes[1-3].

BEC lining the extra-hepatic and large intra-hepatic bile ducts have a different embryologic origin and are distinct phenotypically from BEC lining small intrahepatic bile ducts. But considerations with respect to wound healing are similar to each other and to wound healing at other sites. Unique aspects of the biliary tract that have the potential to impact significantly on wound healing include: (1) anatomy and physiology; (2) exposure to high concentration of bile; and (3) triggering of reactions in the smallest intra-hepatic bile ducts by insults other than, or in addition to, direct injury and ulceration. In addition, chronic inflammation and persistent wound healing reactions in either the large or small bile ducts often precede the development of cancers.

In the skin and intestines, mechanisms of wound repair depend on the depth of injury. Superficial wounds or simple erosions are healed primarily by a two-step process: restitution and regeneration. Restitution begins immediately after creating a superficial wound in barrier epithelia. Cells near the edge of the defect lose close contacts with neighboring cells, undergo shape changes, spread, migrate, and then contract to close the hole. However, restitution is necessarily limited because remaining cells can cover only so much of the denuded surface area. In large wounds, regeneration or proliferation of the remaining epithelial cells is also needed. Eventually the epithelium is restored to a nearly original state[4,5], although surviving cells may carry a legacy of DNA damage and senescence-related changes[6]. Deeper wounds involve the epithelia and underlying stroma. Processes such as angiogenesis; activation, migration, and proliferation

of (myo-) fibroblasts and endothelial cells; formation of granulation tissue; and wound contraction are needed to close these larger/deeper defects. These more extensive wounds are also frequently inflamed and, in general, stromal involvement and inflammation greatly increase the risk of subsequent scarring[7-10].

Epithelial aspects of wound repair are often studied, *in vitro*, by producing linear "wound" tracks in confluent epithelial monolayers. The restitution phase is isolated by treating the cultures with chemical mito-inhibitors to prevent cell proliferation from contributing to wound closure. Distances migrated by the epithelial cells from the edge of the wound at predetermined time points measure the effectiveness of restitution. We developed a BEC model using a collagen-matrix substrate to prevent premature BEC senescence, which occurs routinely when BEC are plated on plastic or collagen-coated plates, from interfering with the assay[11].

"Front row cells", or those epithelial cells nearest the defect, experience dissolution of epithelial cell-cell contacts and changes in cell shape[5,12]. They can also acquire some mesenchymal characteristics and, under some circumstances, can undergo complete epithelial-mesenchymal transition (EMT)[13,14]. Changes in front row cells and EMT function to disaggregate epithelial units and reshape the epithelia for movement. Epithelia in transition lose polarity, adherens junctions, tight and gap junctions, desmosomes, and down-regulate cytokeratin intermediate filaments in order to rearrange their F-actin stress fibers and express filopodia and lamellopodia[5,12-14]. When wound closure is complete and proliferation has replenished the lost cells, re-establishment of inter-epithelial junctions restores the barrier. Coordinating these processes is critically important for barrier adaptation and wound healing[13,14].

POTENTIAL INFLUENCES OF BILIARY TREE PHYSIOLOGY AND ANATOMY ON WOUND HEALING

The biliary tree can be thought of as a delicate, relatively complex, self-contained organ that communicates with, and is enveloped by, the liver (Figure 1). It monitors, alters the composition of, and triages bile into the intestine. The tenuous only arterial blood supply can be damaged easily by diseases and by surgical procedures. A close relationship and cross-talk between BEC and periductal (myo-)fibroblasts exists throughout the entire biliary tree: damage to one population usually results in reactive changes in the other. For example, periductal (myo-) fibroblasts often undergo activation and proliferation in response to significant BEC growth, injury, and bile leakage from the small[15-21] or large bile ducts [22-24]. In extra-hepatic and large intra-hepatic bile ducts, this results in mural stricturing and luminal narrowing. In smaller intra-hepatic bile ducts, liver fibrosis and/or obliteration of the bile duct lumen can occur. A rich lymphatic network envelopes bile ducts that drains into regional hilar lymph nodes[25,26]. Numerous intramural peribiliary glands in the extra-hepatic bile ducts can become walled off after trauma and produce mucoceles. All of these potential

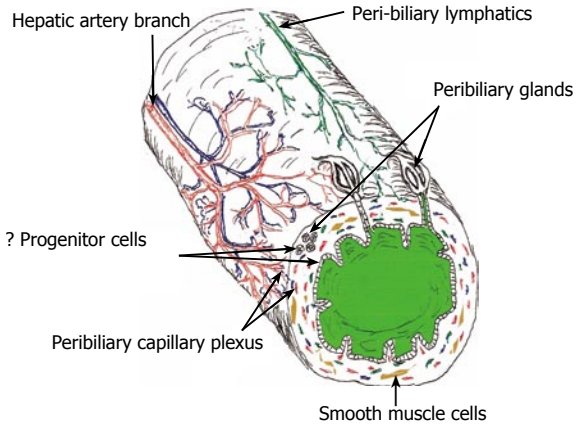

Figure 1 Diagram of the extra-hepatic and large intra-hepatic bile ducts highlighting some important anatomic and physiologic considerations that can potentially impact wound healing. Except for the peribiliary glands and some features of the BEC, small intra-hepatic bile ducts have a similar anatomy. All of the bile ducts, including the small intra-hepatic bile ducts are supplied only by the hepatic artery and the peribiliary vascular plexus, shown in red. All bile ducts also contain either smooth muscle cells and/or facultative myofibroblasts in their wall. Deep wounds to the biliary tree result in activation and/or transformation of myofibroblasts that greatly increase the risk of wound contraction, fibrosis, and stricture formation.

sources of problems contribute to the well-deserved moniker of the biliary tree as the "Achilles heel" of liver transplantation.

Bile contains bile salts that can induce[27-30] or protect BEC from apoptosis[31], cross-activate EGFR *via* TGFα ligand binding[32], induce COX-2 expression[33], or trigger BEC IL-6 and other cytokine production[34]. Bile also normally contains several growth factors (e.g. HGF), cytokines (IL-6), and other molecules[35]. Understanding the effect of various bile constituents on wound healing (esp. restitution) is critical because bile composition can be altered therapeutically (e.g. treating patients with ursodeoxycholic acid) [36,37].

BEC lining the smallest intra-hepatic bile ducts are derived from hepatoblasts and are thought to contain a population of liver stem cells that can differentiate into either hepatocytes or BEC[38-41]. Changes in the intra-hepatic environment other than, or in addition to, direct injury and ulceration can trigger wound repair reactions in these smallest ducts. These "ductular reactions" are recognized as BEC and surrounding myofibroblasts at the interface zone of diseased livers[3,42,43]. Ductular reactions can be provoked by: (1) local BEC injury and inflammation[44,45]; (2) increased intra-biliary tract pressure, and (3) the combination of: (a) a strong liver regenerative stimulus, such as partial hepatectomy or chronic necro-inflammatory liver disease and (b) hepatocyte mito-inhibition because of carcinogen exposure or chronic oxidative stress[1-3]. Insufficient BEC regeneration in the smallest ducts leads to liver diseases such as chronic "ductopenic" rejection and drug-induced ductopenia[44].

WOUND HEALING IN THE EXTRA-HEPATIC BILIARY TREE

Importance of arterial blood flow and wound depth

Study of the biliary sludge syndrome in liver allografts

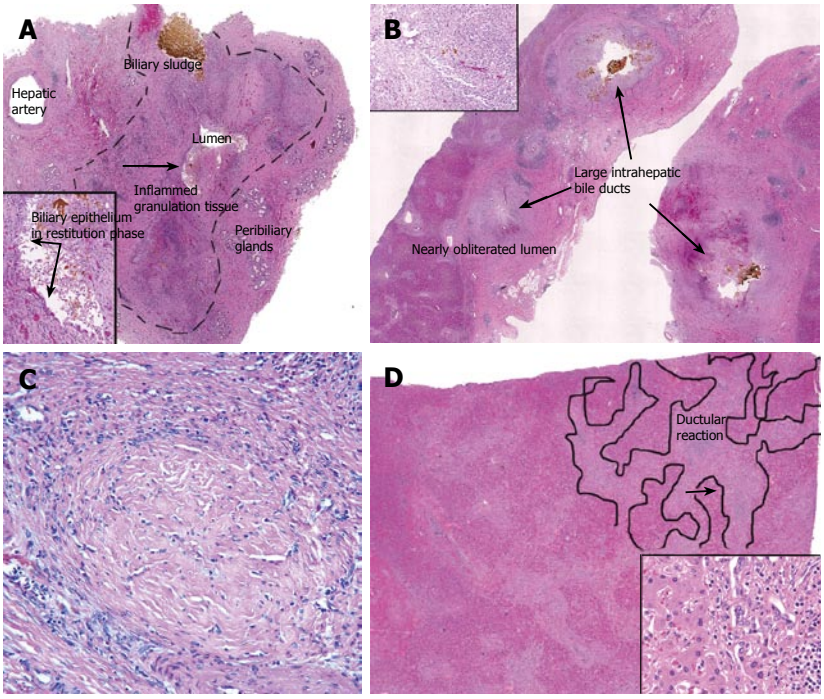

Figure 2 A: Cross-section of an extra-hepatic bile duct (outlined by dashed lines) from a liver allograft that failed because of the biliary sludge syndrome. Note the hepatic artery branch traveling along the outer wall, the peribiliary glands, mucosal ulceration, and that the lumen is nearly obliterated. Ulceration exposes the underlying stroma to bile, which results in inflammation, granulation tissue, and myofibroblast activation and proliferation in the underlying stroma. The inset shows at higher magnification the area near the arrow; note the bile sludge, BEC in restitution phase, and stromal inflammation and granulation tissue (arrows); **B**: Cross-section of several large intra-hepatic bile ducts from the same liver. Note that the same processes are occurring in these ducts. The duct lumen in the lower left is nearly obliterated by inflamed granulation tissue and myofibroblasts (inset); **C**: The final stages of "pathologic wound healing" in the intra-hepatic ducts can result in complete fibrous obliteration of the bile duct lumen by concentric rings of fibrous tissue, as shown here; **D**: Sections from the periphery of the same liver show a prominent ductular reaction consisting of BEC and periductal myofibroblasts (inset). This occurs because of increased pressure in the biliary tree distal to the site of luminal obliteration. Notice that the cholangioles and myofibroblasts form a wedge of tissue that arises from the portal tract and distorts the liver architecture (outlined on the right side of image).

has been particularly illustrative of pathophysiologic mechanisms involved in biliary wound healing. This relatively common and particularly frustrating complication affects about 10% of all liver allografts. There are many potential causes of ineffectual biliary wound healing including abnormal anatomy created by the operation; suboptimal arterial blood flow because of technical problems, anastomotic narrowing, thrombosis, or antibody mediated rejection; recurrent ascending cholangitis; recurrent primary sclerosing cholangitis; and ischemic-preservation injury[46]. Regardless of the cause, impediments to bile drainage results in progressive intrahepatic fibrosis, which in turn, increases morbidity and decreases organ half-life.

The extra-hepatic biliary tree is sustained only by the hepatic artery, which drains into three terminal classical capillary microvascular networks that supply: (1) the bile ducts (peribiliary plexus), (2) the connective tissue of the portal tracts, and (3) the hilar and perihilar structures[47]. The allograft biliary tree is especially vulnerable to arterial ischemia for the first several months after the operation. Preservation injury damages the microvasculature of the peribiliary plexus. The transplant operation can injure the arterial blood supply and it can also disrupt the normal collateral circulation typical of the arterial cascade arrangement supplying all gastrointestinal organs, including the liver[46]. Interference with arterial flow at any level can result in "ischemic cholangitis" - a succinct phrase used to describe the common association between poor arterial flow and biliary ischemia that manifests as persistent ulcers, inflammation, sludge, and strictures[48,49].

Cold ischemic-preservation injury depletes energy stores in microvascular endothelial cells and BEC. This results in activation of metalloproteinases, detachment of endothelium and BEC from the underlying matrix, and in the microvasculature, predisposition to thrombosis after reperfusion[50,51]. Reperfusion with blood after transplantation also delivers leukocytes that become activated by tissue damage. Activated leukocytes release effector molecules, which in turn, cause more tissue damage and further promote thrombogenesis[50,51]. Hydrophobic bile salts remaining in the biliary tree also further damage marginally viable BECs[50,52] already weakened by preservation injury. Damaged BEC are sloughed into the bile[53]. Although patient and allograft survival during the first several weeks after transplantation are dependent primarily on parenchymal function, long term allograft viability is determined primarily by biliary wound healing and adequate bile drainage[54,55]. Allografts that eventually fail show biliary sludge, mucosal ulcers, and inflamed granulation tissue and myofibroblast activation/proliferation in the wall of extra-hepatic and large intra-hepatic bile ducts[55] (Figure 2). Exposure of the underlying stroma to bile appears to serve as a nidus for crystallization of biliary sludge and a stimulus for inflammation and activation of myofibroblasts. This leads to wound contraction and fibrosis, and eventually, to strictures in large caliber ducts and to luminal obliteration of smaller caliber ducts (Figure 2C).

Two observations illustrate the critical and primary importance to wound healing of an adequate arterial blood supply. First, any insult that directly interferes with the arterial flow is usually associated with large bile duct ulcers and strictures. Second, perfusion of the hepatic artery and peribiliary plexus with low viscosity preservation solutions before transplantation dramatically decreases the incidence of biliary complications after transplantation in otherwise susceptible extended criteria donor livers with long cold ischemic times[56]. This maneuver is thought to flush thrombogenic material from the peribiliary plexus and facilitate reperfusion and oxygenation after transplantation. As with many clinical observations, confirmation of this mechanism is lacking. But it is reasonable to conclude that without sufficient arterial flow biliary wound healing is

unlikely to proceed normally. Once adequate arterial flow is ascertained, other factors that also significantly contribute to BEC wound repair can then be studied in greater detail.

Deep wounds of extra-hepatic bile ducts precipitate stromal involvement in wound healing. Granulation tissue and inflammation, local production of interferon-γ[57] and transforming growth factor beta (TGF-β)[58] at this site are of importance in wound contraction and scarring. Our laboratory has focused primarily on BEC aspects of wound repair with an emphasis on interleukin-6/gp130 signaling-dependent cellular processes. This signaling pathway is also critically important for wound healing in the gastrointestinal tract[59] and skin[60,61].

Cellular and molecular mechanisms of BEC repair involving IL-6/gp130 signaling

IL-6/gp130 is pleiotropic cytokine signaling system that has diverse effects in many different organ systems and cell types(reviewed in[62,63]). gp130 is one of the most promiscuous cytokine receptors[62], binding to many different ligands including, interleukin (IL)-6, IL-11, leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), and cardiotrophin-like cytokine (CLC)[62,63]. Ligand binding to gp130 generates two major signaling pathways: (1) Jak/STAT3 and (2) SHP2/ERK/MAPK and there is reciprocal negative feedback regulation between them[63,64]. Non-canonical STAT3 signaling pathways also exist, but are not well delineated[65].

In normal livers, IL-6 is produced at low levels by the BEC, perhaps stimulated by the bile salts[34], and secreted into the bile[66]. Active IL-6/gp130/STAT3 signaling can be detected in normal IL-$6^{+/+}$ but not in normal IL-$6^{-/-}$ mice livers, as evidenced by the detection of phospho-STAT3 by Western blotting and immunohistochemistry. Biliary tree pSTAT3 in normal liver localizes to occasional BEC lining large bile ducts, but more prevalent expression is seen in BEC lining the peribiliary glands[11].

Virtually any bile duct insult, such as obstruction[67-69], infection[69,70], or immunologic damage[66,71,72] triggers sharp increases in IL-6 mRNA and protein production by BEC and peribiliary hematolymphoid cells[3]. This, in essence, alerts BEC to environmental stimuli and leads to subsequent autocrine, paracrine, and juxtacrine gp130/STAT3 signaling in BEC at the sites of injury[11,67,68,73]. As in the gastrointestinal tract[59] and skin[60,61], an absence of IL-6 in IL-6-deficient (IL-$6^{-/-}$) mice leads to impaired wound healing[11] and biliary tree integrity[11,73,74]. For the last several years our laboratory has focused on cellular and molecular mechanisms that might contribute to impaired BEC wound healing and biliary barrier defects in the IL-$6^{-/-}$ mice and how the findings might apply to humans. Using a combination of knowledge gained from the gastrointestinal tract and skin, mRNA microarray expression analyses, and pathophysiologic studies, we first searched for genes that were: (1) expressed in BECs, (2) regulated by IL-6/gp130/STAT3 signaling, and (3) possibly involved in barrier function and/or repair. Two of the most interesting candidates, studied in greater detail, included intestinal trefoil family factors (TFF)[59,75-78] and small protein rich proteins (SPRR)[11,73]. The reader is referred to recent reviews of IL-6/gp130/ SHP2/ERK/MAPK signaling and other growth factors and cytokines involved in the regenerative phase of BEC wound healing[3,67,68,79-81].

Trefoil family factor (TFF) proteins are comprised of one or more trefoil motifs, which consist of 6 cysteine residues. TFF proteins increase mucous viscosity and thereby contribute to optimal protection of the intestinal mucosa from injury[77,82-84]. By enhancing intestinal epithelial spreading and migration, TFF proteins also stimulate the restitution phase of wound healing[76,85]. Each of the three known TFF proteins is differentially regulated in the gastrointestinal tract[59,75]: TFF1 and TFF2 are expressed primarily in the stomach[86,87]. TFF3 predominates in the small and large intestines[78] and in the biliary tree[11] of mouse and human livers[88-91]. IL-6/gp130/STAT3 signaling is crucial for BEC TFF3 expression. In normal liver, pSTAT3 and TFF3 mRNA and protein expression are significantly higher in IL-$6^{+/+}$ than in IL-$6^{-/-}$ mice livers. Constitutive expression of TFF3 and pSTAT3 localizes to mucin secreting BEC lining large intrahepatic and extrahepatic bile ducts and peribiliary glands[11]. Medium and small-sized intra-hepatic bile ducts are generally negative for mucin secreting BEC, pSTAT3, and TFF3 expression[11,91,92].

IL-$6^{+/+}$ BEC consistently show higher levels of TFF3 mRNA and protein expression and significantly better migration and wound healing than IL-$6^{-/-}$ BEC[11], *in vitro*. Defective migration in the IL-$6^{-/-}$ BEC can be partially, but significantly, reversed by treatment with recombinant TFF peptides[11]. *In vivo*, biliary TFF3 is dynamically regulated by various factors after bile duct ligation. Included are the reciprocal negative regulation known to exist between the STAT3 and MAPK signaling pathways[59], and other cytokines and growth factors, such as HGF and TGF-β, which can down-regulated BEC TFF3 expression[11]. However, a chronic deficiency of pSTAT3 signaling during bile duct injury, as seen in IL-$6^{-/-}$ mice after bile duct ligation, leads to a chronic deficiency of biliary TFF3 expression and impaired biliary barrier function[11]. In humans, p-STAT3 and TFF3 are newly co-expressed in BEC involved in florid duct lesions in primary biliary cirrhosis and at other sites of BEC injury, but not in similarly-sized normal bile ducts from the same livers[11,89,92]. This likely constitutes a primitive or innate mucosal defense system that guards against injury and stimulates repair.

Our BEC TFF3 studies are consistent with studies focused on the colon and carried out in mice harboring mutations that selectively block all gp130-mediated STAT activity ($gp130^{\Delta STAT}$), but preserve gp130-mediated MAPK signaling. These mice show decreased colonic TFF3 expression, increased sensitivity to sodium dextran sulfate-induced colitis, and impaired mucosal wound healing[59,75]. Thus, it is reasonable to conclude that IL-6/gp130/STAT3 signaling contributes significantly to normal BEC cytoprotective mechanisms and to migration during wound healing, at least in part, by stimulating BEC TFF3 expression[11].

Small proline-rich proteins (SPRR) are encoded by a tandemly arranged four-member gene family

contained within a 170-kilobase region of the epidermal differentiation complex (EDC). The EDC is a cluster of more than 50 genes located on chromosome 1q21[93-95] whose products are involved in terminal differentiation of the human epidermis. Included are formation of the cornified envelope that is an effective barrier against the external environment [93,96]. The four SPRR gene families, SPRR1-4, are distinguished on the basis of the number of amino acids in the repeats of the protein's central domain and the consensus of that sequence[95]. There are two Sprr1 genes and one copy each of Sprr3 and Sprr4 genes[95]. SPRR2 genes are the most diversified family: there are seven in humans and eleven in mice[95]. In the skin and other squamous epithelia, SPRR genes are usually regulated coordinately as part of the EDC (i.e. high expression of most EDC genes, as in papillomas, or very low expression of most genes, as in newborn skin). SPRR genes encode for a series of highly homologous proteins that function primarily as critical cross-linkers. They form bridges among other EDC proteins, intermediate filaments, and cornified envelope constituents[94,95,97], such as desmoplakin, loricrin, and tricohyalin, through the catalytic action of transglutaminases[98] .

The diverse SPRR2 genes are also non-coordinately expressed, or expressed preferentially, without similar upregulation of other EDC family members[73,97]. This occurs most commonly in non-keratinizing epithelia in curious situations that cannot be explained by squamous differentiation or formation of a cornified envelope. Examples include greater than 100-fold increases of SPRR2A in the intestine after small bowel resection[99] or after introduction of commensal bacteria into germ-free mice[100,101] or after intentional infection with intestinal parasites[102]. In uterine epithelium SPRR2A mRNA and protein expression is, at least in part, regulated by estrogen[103]. Therefore, it is highly and non-coordinately upregulated during certain stages of the oestrous cycle[104,105] and is especially high at the blastocyst implantation site[103]. SPRR2A mRNA and protein are also expressed in bronchial and intestinal epithelium during allergic reactions[106]. Barrier remodeling, as a response to stress[94,105], inflammation, and/or growth, is a common condition of these diverse circumstances. Potential molecular and cellular processes affected by non-coordinate SPRR2A expression are currently under investigation in our laboratory.

In the liver, we have shown that SPRR2A mRNA and protein are not expressed in normal mouse liver, but are non-coordinately upregulated only in BEC after the stress of bile duct ligation[73]. Expression after bile duct ligation is not related to squamous metaplasia and shows strong dependence on IL-6/gp130/STAT3 signaling. In BEC lining the large bile ducts, SPRR2 protein localizes subjacent to the apical plasma membrane. SPRR2 expression is more diffusely distributed throughout the cytoplasm of cholangioles participating in ductular reactions and in large duct BEC engaged in the restitution phase of mucosal wound healing. Deficient BEC *SPRR2A* expression in IL-$6^{-/-}$ mice after bile duct ligation is associated with impaired barrier function[73]. IL-6 replacement therapy restores *SPRR2A* expression to levels seen in wild type controls and reverses the barrier defect in IL-$6^{-/-}$ mice. In a series of ongoing investigations, preliminary data suggest that BEC SPRR2A expression is associated with BEC restitution.

WOUND HEALING IN SMALL INTRA-HEPATIC BILE DUCTULES-DUCTULAR REACTIONS

Wound healing responses can be triggered in BEC lining the smallest intrahepatic bile ducts by environmental changes other than, or in addition to, direct injury and ulceration. This often occurs in chronic necro-inflammatory liver disease regardless of the underlying cause. For several years we were puzzled by the observation that ductular reactions represent a survival advantage for BEC and myofibroblasts over hepatocytes, yet hepatocytes and BEC share the same responses to many cytokines and growth factors that are upregulated in chronic liver disease (e.g. HGF, EGF, IL-6, TGFβ, *etc*.[81,107]). Why then do BEC and myofibroblasts survive preferentially under these circumstances? To answer this question it is helpful to view chronic necro-inflammatory liver disease as a "Darwinian" selection pressure applied to the liver. A survival advantage for BEC can occur because of a relative increase in the rate of proliferation, a relative decrease in the rate of death, transformation of hepatocytes into BEC, or various combinations of the above. Regardless of the mechanism, the end result is a relative decrease in volume percentage of hepatocytes and a relative increase in biliary epithelial cells and myofibroblasts-a pattern typical of evolving cirrhosis[1,74]. When combined with sufficient time[1,2], even a small deficit of hepatocyte survival is enough to evoke a ductular reaction that distorts the hepatic architecture.

Using an established mouse model of decompensated biliary cirrhosis[74] and p21-deficient mice, we tested the hypothesis that hepatocyte mito-inhibition combined with the regenerative stimulus of bile duct ligation would accentuate the ductular reaction and accelerate architectural distortion. Results showed that after long-term (12-wk) ligation mice prone to decompensation show significantly more oxidative stress and hepatocyte nuclear p21 expression, a cyclin dependent kinase inhibitor and important mediator of hepatocyte mito-inhibition[1]. As expected, mice prone to decompensation also showed less hepatocyte proliferation, an exaggerated ductular reaction, and accelerated architectural distortion compared with compensation-prone controls[1]. We next subjected p21 deficient mice to bile duct ligation for 12 wk with the expectation that p21 deficient mice would be better able than wild-type controls to compensate for long-term BDL because of significantly greater hepatocyte proliferation. Indeed, results of these experiments showed that p21-deficient mice showed a larger liver mass because of more hepatocyte proliferation, a less florid ductular reaction, and less architectural distortion than wild type controls[1].

We next wanted to determine whether this concept was applicable to other, non-cholestatic or non-biliary, liver diseases. To accomplish this task, we first showed that hepatocyte nuclear p21 expression in humans awaiting liver replacement directly correlated with pathological disease stage and model of end-stage liver disease scoring[1]. We

also engaged in a collaborative study with Clouston *et al* who had previously shown that HCV-related liver disease progresses more rapidly when there is co-existent hepatic steatosis[108]. Liver biopsies from 115 patients with HCV scored for steatosis, inflammation, and fibrosis showed a strong correlation between (a) a ductular reaction and portal fibrosis and (b) steatosis and impaired hepatocyte replication[2]. Steatosis correlated with the ductular reaction and greater hepatic progenitor cell proliferation, but was not an obligate feature. The highly significant correlation between the ductular reaction area and fibrosis stage remained even after multivariate analysis[2]. Impaired hepatocyte replication, as determined by p21 expression, was independently associated with hepatic progenitor cell expansion, increased body mass index, and lobular inflammation.

The observation that ductular reactions often appear when hepatocyte mito-inhibition is combined with a liver regenerative stimulus is not new. It was made originally years ago while treating experimental animals with genotoxic carcinogens and then subjecting them to partial hepatectomy (reviewed in[3,109,110]). These maneuvers stimulate oval cell, or liver epithelial progenitor cell[111], expansion/proliferation at the interface zone-a ductular reaction. However, in carcinogenesis experiments, the ductular reaction eventually resolves without fibrosis.

Our studies show that this concept is applicable to ductular reactions associated with chronic necro-inflammatory liver diseases and the development of fibrosis/cirrhosis[1] (Figure 3). Hepatocytes are more susceptible to injury and mito-inhibition during chronic necro-inflammatory liver disease because they: (1) produce and secrete bile and are the major site of bile stasis; (2) are more complex metabolically and able preferentially to store lipids and metals, such as iron and copper, which are generators and/or catalysts for free oxygen radical formation; and, (3) support HBV and HCV replication, and (4) maybe most importantly, contain many more mitochondria than BEC and mitochondria are the major site of superoxide production[112]. Diverse disorders such as cholestasis[1], HCV replication[113,114], steatosis[2,115], copper deposition[116], and alcohol[117] preferentially stress or injure hepatocytes and this causes nuclear expression of the cyclin-dependent kinase inhibitor, p21[1,2], which in turn, inhibits hepatocyte proliferation.

When small intrahepatic bile ductules are destroyed (ductopenia), due to drugs or chronic allograft rejection, classical cirrhosis usually does not develop[45,109,118,119]. Despite ongoing immunologic liver injury and fibrosis, regenerative nodularity and the associated complications of portal hypertension rarely occur. BEC survival and proliferation in response to injury in these small ductules is related to a combination of immunologic injury, environmental influences, and importantly, arterial blood flow[120], as in the large bile ducts. Perhaps the arterial disease also inhibits regenerative nodule formation (Figure 4).

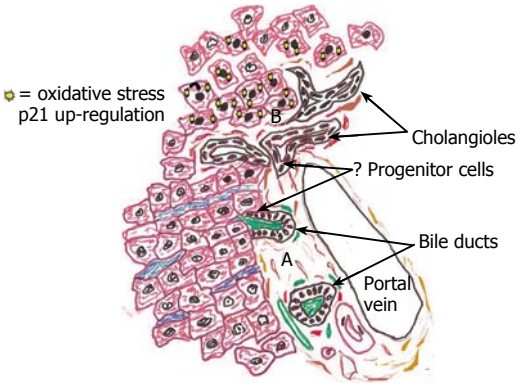

Figure 3 This diagram illustrates the peripheral aspects of the biliary tree, including the portal tract and periportal hepatic parenchyma in normal (A: bottom of figure) and in diseased livers (B: top of figure). A: Rare liver progenitor, or stem cells, are thought to reside within the Canals of Herring, or the portion of the bile ductules that connects BECs to hepatocytes. The same close relationship between BEC, the arterial supply, and periductal myofibroblasts seen in the large ducts continues to the biliary tree periphery, as shown here. B: During chronic necro-inflammatory liver diseases a variety of insults, such as cholestasis[1], HCV replication[114,115], steatosis[2,116] copper deposition[117], and alcohol[118] can cause oxidative stress, preferentially in hepatocytes. The stress upregulates hepatocyte nuclear p21 expression (illustrated by solid nuclei at top of diagram), which in turn, inhibits hepatocytes proliferation and accentuates ductular reactions[1,2]. A close relationship between BEC and periductal myofibroblasts in the smallest bile ductules usually results in co-activation of these populations recognized as ductular reactions, which often precede the development of cirrhosis.

PROGENITOR CELL ACTIVATION, PERSISTENT WOUND REPAIR AND CANCER

Persistent ductular reactions in human chronic necro-inflammatory diseases can activate progenitor cell populations, as in the experimental animal carcinogenesis models, discussed above (Reviewed in refs 38, 39, 41). Several groups, including ours, have shown that oval cell expansion in mice is dependent significantly on IL-6/gp130/STAT3 signaling[121,122]. This raises the possibility that ductular reactions accelerate the development of cirrhosis and potentially increase the risk of hepatocellular carcinoma. Since oval cells eventually differentiate into hepatocytes[111], exposure to carcinogens or genotoxic damage from oxidative stress imprint genetic mutations in putative liver stem cells. These cells then divide, differentiate, and spread initiated cells more widely throughout the entire hepatocyte population. Liver cancers occur when initiated hepatocytes are subjected to tumor promoters that generally cause hepatocyte proliferation. Chronic liver disease is an excellent cancer-promoting environment.

In the skin, STAT3 signaling enables epidermal stem cells to the escape apoptosis induced by exposure to cutaneous carcinogens[123]. Initiated stem cells survive, divide, differentiate, and subsequently give rise to skin cancers in a promoting environment[123]. Similar processes might occur in hepatocellular and cholangiocarcinomas. Interleukin-6/gp130/STAT3 signaling might provide important survival signals for initiated liver epithelial progenitor cells that later give rise to liver cancers in the context of chronic necro-inflammatory disease. In evolutionary biology[124] this process is referred as "antagonistic pleiotropy" - a short term survival benefit at the expense of long-term increased risk of cancer.

IL-6/gp130/STAT3 signaling is indeed increased in a very wide variety of neoplasms, including hepatocellular carcinomas, melanomas, leukemias and myelomas, and

lung, breast cancer, kidney, prostate, pancreatic, colon, gastric, cervical, ovarian, and head and neck cancers[125,126]. This signaling pathway participates and/or regulates many pathways important in oncogenesis including cell-cycle progression, apoptosis, tumor angiogenesis, tumor-cell invasion and metastasis, and tumor-cell evasion of the immune system (reviewed in[125,126]).

Whether this concept is applicable to cancers arising in extrahepatic and large intrahepatic bile ducts is uncertain because the mechanisms of BEC renewal at these sites have not been studied in any great detail. In the larger bile ducts there are two potential sources of new BEC: (1) proliferation of mature BEC; and (2) proliferation and/or maturation of progenitor cell populations. These potential sources are not mutually exclusive and only one study in the literature even indirectly addresses this topic. Koike *et al*[127] used pulse and continuous DNA labeling studies to show, in rats, that a proliferative zone, consistent with a BEC progenitor cell population, localized to peribiliary glands (called "crypts" in their study). Long-term follow-up of the animals showed that labeled BEC migrated gradually to the surface and were shed into the lumen with a transit time of about 30-40 d[127]. They concluded the arrangement and pattern of BEC renewal in the extra-hepatic bile ducts was similar to the intestine and colon, but kinetics of BEC turnover was slower[127]. More definitive work is needed in this area.

UNANSWERED QUESTIONS AND FUTURE DIRECTIONS

The following are a few examples of the many unanswered questions in the study of biliary wound healing that have stimulated research in our laboratory. For example, are there progenitor cell populations within the peribiliary glands or crypts of extra-hepatic and large intra-hepatic bile ducts? If progenitor cells exist in the extra-hepatic biliary tree, where exactly do they reside, and how are they recognized? Are they activated during wound repair, and do they contribute to the development of bile duct cancers?

EMT contributes significantly to wound healing and to kidney fibrogenesis. Is EMT an important process in BEC wound healing and hepatic fibrogenesis? Can, and do, BEC transform into myo-(fibroblasts)? BEC appear to migrate and can acquire mesenchymal characteristics during the ductular reaction and hepatic fibrogenesis. They transform from polarized cuboidal epithelial cells into a spindle or dendritic-shaped vimentin-positive cells after bile duct ligation and in PBC[128,129]. In embryonic liver, ductal plate BEC "invade" or migrate into the portal tract connective tissue to form mature intrahepatic bile ducts. During migration BEC express vimentin[130] and down-regulate membranous E-cadherin[131] expression. Once mature bile ducts are formed BEC revert totally to an epithelial phenotype. Preliminary studies from our laboratory suggest that IL-6/gp130/STAT3 signaling triggers BEC changes under some circumstances that can induce BEC EMT. The extent to which EMT contributes to BEC wound healing, however, requires further study.

Several studies show that IL-6 pre-treatment can prevent liver parenchymal ischemic-preservation injury[132-136]. We have shown similar results in intestinal allografts: IL-6 pretreatment limits epithelial damage and promotes repair[137]. Would pretreatment of donor livers with IL-6, particularly in the aortic flush, have beneficial effects on preservation injury of the peribiliary plexus and promote wound healing in the biliary tree? We would expect IL-6/gp130 signaling to help lessen the incidence of biliary strictures because it upregulates anti-apoptotic molecules in the microvascular endothelium[133,136], preserves epithelial integrity[11,137], and stimulates BEC restitution[11,73] and regeneration[79] after injury.

Several other strategies might be used to prevent biliary strictures[138,139], such as reducing eosinophil and mast cell accumulation with Tranilast[140,141] and Captopril[142-144], reducing activation and transformation of myofibroblasts with anti-oxidants such as alpha tocopherol (vitamin E) and peroxisome proliferator-activated receptors-γ (PPAR-γ) ligands, such as the thiazolidinedione family of drugs[145-147].

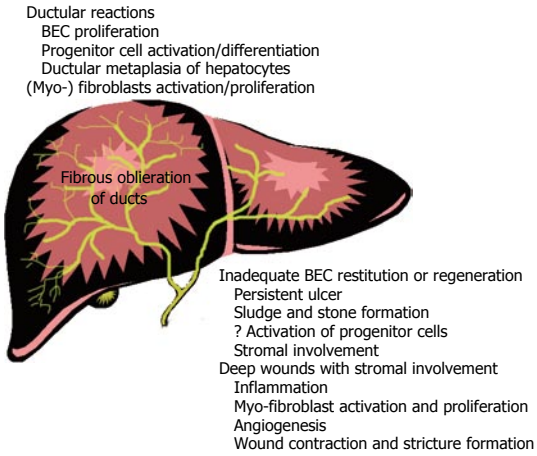

Figure 4 Summary of the most common "wound repair" reactions that contribute to the development of chronic liver disease and liver cancers. Although all of the processes described in the text can occur at any site in the biliary tree, certain types of responses are more common at certain sites. For example, in the extra-hepatic and large intra-hepatic bile ducts (lower right), inadequate or ineffectual epithelial restitution or proliferation results in persistent ulcers and stone and sludge formation. This, in turn, leads to possible activation of progenitor cells and stromal involvement, which can also be triggered by "deep wounding" of the large ducts. Stromal involvement is usually accompanied by inflammation, angiogenesis, and activation and proliferation of myofibroblasts. All of these processes contribute to wound contraction and stricture formation, which is one of the most common and clinically significant problems in the large ducts.

In the small bile ducts, ductular reactions are the most commonly encountered "wound healing" response. Ductular reactions can occur because of BEC proliferation, progenitor cell activation and differentiation, and ductular metaplasia of hepatocytes. They also usually trigger myofibroblast activation and proliferation and together these cell populations form a tissue wedge at the interface zone that progressively distorts the liver architecture.

In medium-sized bile ducts, fibrous obliteration is probably the most common serious wound healing response. This occurs because the response to injury of the periductal myofibroblasts overwhelms the BEC response and the duct lumen is obliterated.

Abstract

The objectives of this review are to outline the recent findings related to the morphological heterogeneity of the biliary epithelium and the heterogeneous pathophysiological responses of different sized bile ducts to liver gastrointestinal hormones and peptides and liver injury/toxins with changes in apoptotic, proliferative and secretory activities. The knowledge of biliary function is rapidly increasing because of the recognition that biliary epithelial cells (cholangiocytes) are the targets of human cholangiopathies, which are characterized by proliferation/damage of bile ducts within a small range of sizes. The unique anatomy, morphology, innervation and vascularization of the biliary epithelium are consistent with function of cholangiocytes within different regions of the biliary tree. The *in vivo* models [e.g., bile duct ligation (BDL), partial hepatectomy, feeding of bile acids, carbon tetrachloride (CCl_4) or α-naphthylisothiocyanate (ANIT)] and the *in vivo* experimental tools [e.g., freshly isolated small and large cholangiocytes or intrahepatic bile duct units (IBDU) and primary cultures of small and large murine cholangiocytes] have allowed us to demonstrate the morphological and functional heterogeneity of the intrahepatic biliary epithelium. These models demonstrated the differential secretory activities and the heterogeneous apoptotic and proliferative responses of different sized ducts. Similar to animal models of cholangiocyte proliferation/injury restricted to specific sized ducts, in human liver diseases bile duct damage predominates specific sized bile ducts. Future studies related to the functional heterogeneity of the intrahepatic biliary epithelium may disclose new pathophysiological treatments for patients with cholangiopathies.

ANATOMICAL AND MORPHOLOGICAL CHARACTERISTICS OF THE BILIARY EPITHELIUM

Two kinds of epithelial cells, hepatocytes and cholangiocytes, are present in the liver[1-3]. While hepatocytes initially secrete bile into the bile canaliculus[4], cholangiocytes modify bile of canalicular origin by a series of coordinated spontaneous and hormone/peptide regulated secretion/reabsorption of water and electrolytes before it reaches the small intestine[3,5-7]. For more information on the mechanisms of bile formation we refer to recent reviews[4,5]. The human biliary system is divided into extrahepatic bile ducts and intrahepatic bile

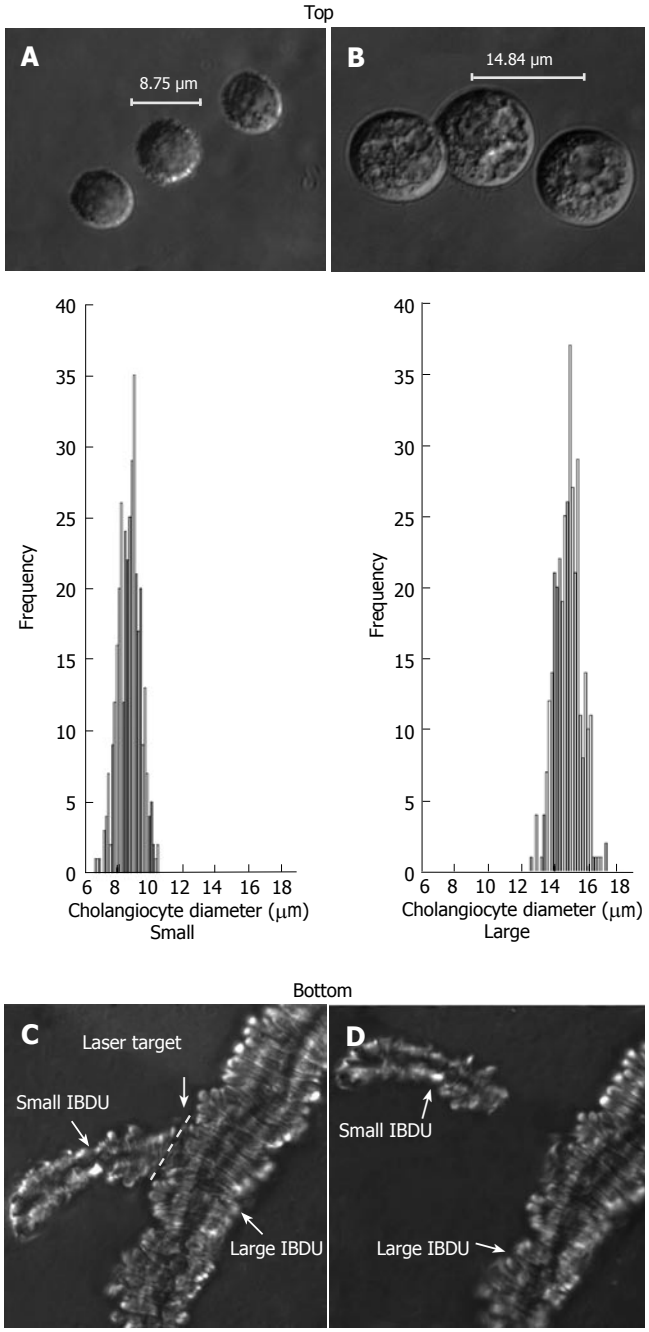

Figure 1 [**Top**] Isolation of small (**A**), approximately 8 μm diameter] and large (**B**), approximately 14 μm diameter] cholangiocytes from small and large ducts, respectively, from normal rats. Small and large cholangiocytes were purified by counterflow elutriation followed by immunoaffinity purification. Original magn., × 625. Reproduced with permission from Ref[12]. [**Bottom**] Isolation of small (**C**) and large (**D**) IBDU from normal rat liver. Small (< 15 μm in diameter) and large (> 15 μm in diameter) IBDU were pruned off from large ducts by a nitrogen pulsed dye laser and subsequently separated (**D**) by picking up IBDU with a micromanipulator micropipet. Original magnification × 2000. Reproduced with permission from Ref 13.

ducts, the latter further sub-divided into large and small bile ducts[2,3,8]. The intrahepatic bile ducts represent that part of the biliary tree proximal to the confluence of the hepatic ducts[9] extending from the canals of Hering to the large extrahepatic ducts[2,3,8]. In human liver, a study by Ludwig classified the intrahepatic bile duct system upon duct diameter[8], small bile ductules (< 15 μm), interlobular ducts (15-100 μm), septal ducts (100-300 μm), area ducts

Table 1 Terminology and relationship between human and rat intrahepatic bile ducts

Terminology for human bile ducts (diameter in μm)	Terminology for rat bile ducts (diameter in μm)
(Large bile ducts)	
Hepatic ducts (> 800)	
Segmental ducts (400-800)	
Area ducts (300-400)	
(Small bile ducts)	
Septal bile ducts (100-300)	
Interlobular bile ducts (15-100)	Large bile ducts (> 15)
Bile ductules (cholangioles) (< 15)	Small bile ducts (< 15)

These data have been obtained from studies[8,12,13] aimed to define the morphological characteristics of the biliary epithelium of rats, and humans. Reproduced with permission from Ref 2.

(300-400 μm), segmental ducts (400-800 μm) and hepatic ducts (> 800 μm)[8] (Table 1). Small ductules are lined by 4-5 cholangiocytes, have a basement membrane, tight junctions between cells and microvilli projecting into the bile duct lumen[10,11]. Cholangiocytes are progressively larger and more columnar in shape in larger bile ducts (lined by 10-12 cholangiocytes)[10,11].

In rats, morphological studies in liver sections and small and large intrahepatic bile duct units (IBDU) have shown[2,12-14] that the intrahepatic biliary tree is divided into: (1) small ducts (< 15 μm in external diameter) lined by small cholangiocytes (approximately 8 μm in diameter)[12,13]; and (2) and large ducts (> 15 μm in diameter) lined by large cholangiocytes (approximately 15 μm in diameter)[12,13] (Figure 1, Table 1). Specifically, we have shown[12] that the rat intrahepatic biliary epithelium is formed by ducts of different sizes (5 to 200 μm in external diameter) and cholangiocytes of different cell areas (3 to 80 μm^2). Furthermore, a direct relationship exists between cholangiocyte area and external duct diameter, a finding that demonstrates that small ducts are lined by small cholangiocytes, whereas larger ducts are lined by larger cholangiocytes[12-14]. The fact that small and large ducts are lined by small and large cholangiocytes, respectively, is important since it allows for the assignment of the secretory, apoptotic and proliferative functions (achieved in isolated small and large cholangiocytes) within the different portions of the intrahepatic biliary epithelium. Recently, Masyuk *et al*[15] have reconstructed the intrahepatic biliary epithelium that resembles a tree, with the common and hepatic ducts corresponding to the trunk, the intrahepatic bile ducts corresponding to the large branches and the small ducts corresponding to the smallest tree limbs of a tree.

Studies by Phillips *et al*[16] have shown that no major ultrastructural differences exist among cholangiocytes lining small and large bile ducts. However, in support of the concept that the intrahepatic biliary epithelium is morphologically heterogeneous, electron microscopic studies by Benedetti *et al*[14] in rat liver sections and IBDU have demonstrated that large bile ducts are lined by 8-15 cholangiocytes and small ducts by 4-5 cholangiocytes. The studies also showed that small and large cholangiocytes

have a multilobulated nucleus, numerous vesicles at the subapical region, tight junctions, high density of microvilli and lysosomes and a few mitochondria[14]. Other studies have shown the presence of microvilli and cilia in the apical plasma membrane of cholangiocytes[17,18], cilia that play an important role in the regulation of cholangiocyte functions[19,20]. While large cholangiocytes are columnar in shape, small cholangiocytes have a cuboidal shape[14]. Abundant Golgi apparatus was observed between the apical pole and the nucleus[14]. Rough endoplasmic reticulum was inconspicuous in the smallest ducts and increased only slightly in the largest[14]. While large cholangiocytes display a small nucleus and conspicuous cytoplasm, small cholangiocytes possess a high nucleus/cytoplasm ratio[14]. Cholangiocytes have distinct apical and basolateral membranes[14,17,18].Coated pits have also been observed on the apical and basolateral membranes of cholangiocytes, a finding suggesting receptor-mediated endocytosis at both domains of cholangiocytes[21]. Functional tight junctions are located between adjacent cholangiocytes in proximity to the apical domain[17].

INNERVATION

There is growing information regarding the role of the nervous system in the regulation of the pathophysiology of the biliary epithelium[3,22-27]. In the liver, adrenergic and cholinergic nerves are located around the hepatic artery, portal vein, and the biliary epithelium[28,29]. The intrahepatic arteries, veins, bile ducts and hepatocytes are also innervated[28,29]. In the autonomic nervous system, there are a number of regulatory peptides including neuropeptide tyrosine (NPY)[30,31], calcitonin gene related peptide (CGRP), somatostatin, vasoactive intestinal polypeptide (VIP) (mostly associated with parasympathetic fibers), enkephalin and bombesin[31-35]. NPY-positive nerves are present in extrahepatic bile ducts[36] and have been suggested to regulate bile flow by autocrine/paracrine mechanisms[37]. We have shown that NPY inhibits cholangiocarcinoma growth by interaction with a G-protein coupled receptor by Ca^{2+}-dependent modulation of Src/ERK1/2 phosphorylation[38]. Nerve fibers containing CGRP and substance P are present around blood vessels and bile duct radicles within portal tracts[39,40]. VIP-positive nerve fibers are located in the walls of hepatic arteries, portal veins and bile ducts[41].

VASCULARIZATION

The intrahepatic and extrahepatic bile ducts are nourished by a complex network of minute vessels [*i.e.*, peribiliary vascular plexus (PBP)], which originate from branches of the hepatic artery and flow principally into the hepatic sinusoids, either directly (lobular branch) or by portal vein branches (prelobular branches)[42,43]. Since the blood flows in the opposite direction (from the large towards the small ducts) to bile flow, the PBP presents a countercurrent stream of biliary reabsorbed substances to hepatocytes[44,45]. We have previously shown that the function of the intrahepatic biliary tree is linked to its vascular supply sustained by the PBP[44]. Changes in intrahepatic bile duct mass are associated with changes of the PBP architecture[44]. Following BDL, the PBP undergoes hyperplasia, thus supporting the increased nutritional and functional demands from the proliferating bile ducts[44]. In support of this concept, studies[46] have shown that following chronic feeding of ANIT (which induces increases in both cholangiocyte proliferation/apoptosis)[47], the hepatic artery and portal vein undergo marked proliferation, presumably to support the increased nutritional and functional demands of the proliferated bile ducts[44,46]. However, the proliferation of the PBP occurs only after the hyperplasia of bile ducts[44]. Recent studies have shown that small and large rat bile ducts have a different vascular supply[44]. The PBP is primarily present around large bile ducts and less visible around small bile ducts[44], a finding that may partly explain why large but not small cholangiocytes proliferate following BDL in rats[48] and why small and large ducts differentially proliferate or are damaged in other experimental models of cholangiocyte proliferation/loss including chronic feeding of certain bile acids (e.g., taurocholate and taurolithocholate)[49], ANIT[47] or acute gavage administration of CCl_4[50,51] (Figure 2) or partial hepatectomy[52].

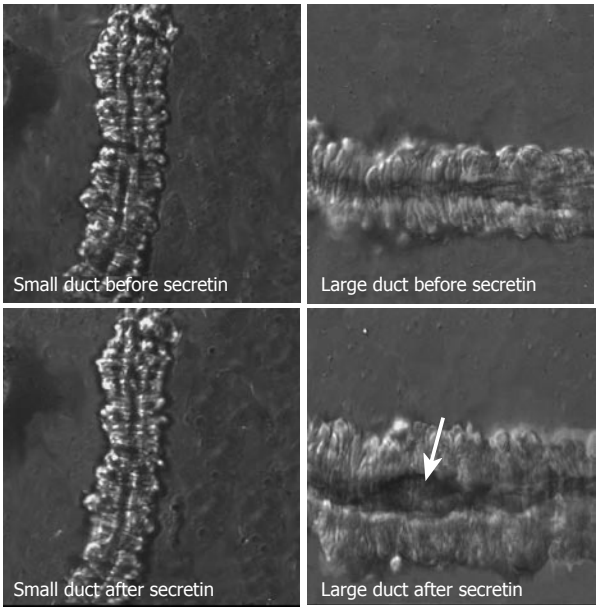

Figure 2 Measurement of H_3 histone gene expression in small and large cholangiocytes from 1-wk BDL rats and 1-wk BDL rats treated with CCl_4 or mineral oil. H_3 histone gene expression in large cholangiocytes decreased on d 2 before returning to control values on d 7 after CCl_4 treatment. H_3 histone gene expression (which was absent in small cholangiocytes from BDL rats) was expressed by small cholangiocytes on d 1 and 2 before returning to control undetectable values on d 7 after CCl_4 treatment. Administration of mineral oil to 1-wk BDL rats did not alter H_3 histone gene expression in large cholangiocytes. The message for H_3 histone gene was absent in small cholangiocytes from oil-treated rats. Comparability of RNA used was assessed by hybridization for GAPDH (housekeeping gene). Autoradiograms were quantified by densitometry. Densitometric values are means of 2 experiments. Reproduced with permission from Ref 50.

GENERAL BACKGROUND ON CHOLANGIOCYTE FUNCTIONS

The major function of cholangiocytes is to modify bile of canalicular origin[4] (by basal and hormone/peptide regulated secretion and reabsorption of

water and electrolytes) before reaching the small intestine[3,5,6]. Ductal secretion is coordinately modulated by gastrointestinal hormones (e.g., secretin, gastrin, insulin, somatostatin, bombesin and VIP)[3,5-7,12,53-58], gastrointestinal peptides (i.e., endothelin-1, ET-1)[59], enzymes (e.g., alkaline phosphatase)[60], bile acids (e.g., taurocholate, taurolithocholate, taurohyodeoxycholate, tauroursodeoxycholate, ursodeoxycholate and taurourso deoxycholate)[49,61-64] and cholinergic[23,26], adrenergic[65,66], serotoninergic[67] and dopaminergic[25] receptor agonists. Cholangiocytes, which have a low DNA turnover under normal physiological conditions[48,52,68], proliferate or are damaged in response to liver injury/toxins[2,3,6,26,47,48,50,52,68-72]. In rat liver, secretin is of particular importance since secretin receptors are only expressed by cholangiocytes[53], and its expression is upregulated under pathological conditions associated with enhanced cholangiocyte growth (e.g., after BDL)[48,71,72] and downregulated with cholangiocyte damage/loss (e.g., following acute CCl_4 administration)[50,51]. Thus, the secretin receptor is an important pathophysiological tool that allows us to evaluate the secretory, proliferative and apoptotic heterogeneity of the intrahepatic biliary epithelium in response to agonists and liver toxins/injury[2,3,12,13,47-51,54,61,71,73]. Interaction of secretin with its receptor is associated with increased intracellular cAMP levels[12,13,25,26,48,50-52,54,59,72]. Enhanced cAMP levels leads to phosphorylation of PKA[74], which induces opening of the cystic fibrosis transmembrane regulator (CFTR) channel[54] leading to the activation of the Cl^-/HCO_3^- exchanger[12,23,52] resulting in biliary bicarbonate secretion[6,52].

EXPERIMENTAL MODELS

A number of *in vivo* models (e.g., BDL, acute administration of CCl_4, partial hepatectomy, chronic feeding of ANIT or bile salts)[47-52] demonstrated that the intrahepatic biliary epithelium is functionally heterogeneous, with specific sized bile ducts (i.e., small and large) differentially responding to liver injury/toxins with changes in proliferative, apoptotic and secretory activities[2,3,12,47-52,54,62,71-73]. A number of *in vitro* experimental models (i.e., small and large cholangiocytes and IBDU and small and large immortalized normal murine cholangiocytes) (Figure 1)[12,13,47,48,50,51,75] have allowed us to suggest that the intrahepatic biliary epithelium is morphologically and functionally heterogeneous[2, 3,12,47-52,54,62,71-73]. The very first approach that was employed and that significantly contributed to lay down the basis of this field of research was the purification of small and large cholangiocytes from rat liver by counterflow elutriation[12,54,76]. Coupling such a technique to immunoaffinity separation[12,18,54], it was possible to isolate two distinct subpopulations of small (approximately 8 μm in diameter, obtained at the centripetal flow rate of 25 ml/min) and large (approximately 14 μm in diameter, collected at the flow rate of 55 mL/min) cholangiocytes (Figure 1)[12,54]. The two subpopulations of small and large cholangiocytes are further purified by immunoaffinity separation[18] using an antibody against an unidentified antigen (expressed by all intrahepatic cholangiocytes)[18] and characterized morphologically (by computerized image analysis) (Figure 1)[12,54], phenotypically (expression of γ-glutamyltransferase and cytokeratin-19 genes)[12,54] and functionally (by measurement of gene expression of secretin receptor, CFTR and Cl^-/HCO_3^- exchanger and basal and secretin-stimulated cAMP levels, Cl^- efflux and Cl^-/HCO_3^- exchanger activity)[12,54].

In addition, we have developed a technique for isolating small (diameter smaller than 15 μm) and large (diameter greater than 15 μm) IBDU from small and large bile ducts, respectively (Figure 1)[13]. This important tool allowed us to directly evaluate the differential secretory responses of different portions of the biliary epithelium to selected gastrointestinal hormones/peptides[13,25,65,77]. As shown in Figure 1, the small duct was pruned off from the large duct by a brief exposure of a laser focused on the junction between large and small ducts (arrow) leading to separation of small from large ducts[13]. Small and large IBDU were characterized by morphometric analysis, gene expression for secretin receptor, CFTR and Cl^-/HCO_3^- exchanger, secretin-induced cAMP levels, and secretion by change in luminal size in response to agonists including secretin, insulin, the α1-adrenergic receptor agonist, the α2-adrenergic receptor agonist, UK14,304 and the D2 dopaminergic receptor agonist, quinelorane[13,25,65,66,77].

Most recently. we have immortalized, from normal mice (BALB/c), small and large cholangiocytes by the introduction of the SV40 large T antigen gene, that allowed, after cloning, to establish small and large cholangiocyte cell lines[75]. The characteristics of the two subpopulations were evaluated by electron microscopy (EM) and measurement of trans-epithelial electrical resistance (TER), and secretin-stimulated cAMP levels[75]. EM, TER and differential cAMP response to secretin are consistent with the concept that small and large immortalized cholangiocytes originate from small and large ducts, respectively[75]. Microarray successfully displayed characteristic differential cDNA expression between small and large cholangiocytes[75]. Using the above described methods individually or in tandem, has allowed us to clearly demonstrate heterogeneity of the intrahepatic biliary epithelium and to dissect the differential physiological responses of these distinct subpopulations of cholangiocytes to endogenous stimuli.

HETEROGENEOUS EXPRESSION OF PROTEINS

The heterogeneous expression of some enzymes/proteins and membrane transporters/receptors in small and large ducts from mice, rats and humans is summarized in Table 2. In human liver, large septal bile ducts mainly express the sialylated $Lewis^a$ blood group antigen[78]. In normal and diseased human livers, hepatic, segmental, area, and septal bile ducts, and peribiliary glands express pancreatic enzymes such as pancreatic lipase, pancreatic α-amylase, and trypsin[79,80]. By microarray of RNA from small and large immortalized murine cholangiocytes, we have demonstrated the heterogeneous expression of approximately 80 proteins between small and large cholangiocytes[75]. The pathophysiological relevance of the

Table 2 Expression and function of proteins and surface transporters in small and large ducts from rats and human

Markers	Small ducts	Large ducts	Function	References
γ-glutamyl transpeptidase	Not expressed	Interlobular large rat bile ducts	Glutathione metabolism	[81]
Alkaline phosphatase	Not expressed	Interlobular large rat bile ducts	Inhibition of secretin choleresis	[81]
Leucine amino peptidase	Not expressed	Interlobular large rat bile ducts	Undefined	[81]
Cytochrome P4502E1	Not expressed	Expressed by large rat and human ducts	Dehalogenation of CCl_4	[50,81,104,105]
Lipase, α-amylase and trypsin	Human septal ducts	Large human ducts, and peribiliary glands	Biliary tree development	[79,80]
Bcl-2	Human small ductules	Not expressed	Anti-apoptotic protein	[109,143]
Secretin receptor	Not expressed	Expressed by large rat ducts	Stimulation of bicarbonate secretion	[12,13,48,54]
CFTR	Human but not rodent small ducts	Expressed by large rat ducts	Regulation of Cl^--secretion	[54]
Cl^-/HCO_3^- exchanger	Not expressed	Expressed by large rat and human ducts	Regulation of ductal bicarbonate secretion	[12,13,82]
Somatostatin receptor	Not expressed	Expressed by large rat ducts	Inhibition of secretin choleresis	[48]
D2 dopamine receptors	Unknown	Expressed by large rat ducts	Inhibition of secretin choleresis	[25]
α-1 adrenergic receptors	Expressed by small rat ducts	Expressed by large rat ducts	Stimulation of secretin choleresis	[65]
Endothelin receptors	Expressed by small rat ducts	Expressed by large rat ducts	Inhibition of secretin choleresis	[59]
Na^+-dependent ABAT	Not expressed	Expressed by large rat ducts	Regulation of ductal secretion	[88]

Heterogeneous expression of proteins and membrane transporters that may play a role in the modulation of the heterogeneous properties of the intrahepatic biliary tree of rats and human. Modified with permission from Ref 73.

differential expression of these messages remains to be addressed.

Secretory activity

Recent studies have demonstrated that large bile ducts are the major anatomical sites of cAMP-dependent ductal secretion by activation of cAMP/PKA/CFTR/Cl^-/HCO_3^- exchanger (Figure 3)[3,12,13,48,54]. Specifically, studies in isolated small and large cholangiocytes and IBDU from normal and BDL rats have shown that large (but not small) cholangiocytes express the messages for secretin receptor, CFTR and Cl^-/HCO_3^- exchanger and respond to secretin with increases in cAMP levels, Cl^- efflux and Cl^-/HCO_3^- exchanger activity and IBDU lumen expansion (Figure 3)[12,13,48,54]. In rat liver, large ducts express alkaline phosphatase and γ-glutamyltranspeptidase[81]. The expression of alkaline phosphatase in large ducts is consistent with our previous studies[81] showing that alkaline phosphatase inhibits secretin-stimulated choleresis by blockage of CFTR activity, which is expressed only in large ducts (Figure 3)[54]. Furthermore, large cholangiocytes (which is the only cholangiocyte subpopulation expressing the somatostatin receptor, $SSTR_2$)[48] are the major anatomical sites of somatostatin inhibition of secretin-stimulated ductal secretion (Figure 3)[48,55]. The inhibitory effects of somatostatin on secretin-stimulated secretion in large cholangiocytes are associated with reduced cAMP levels, Cl^- efflux and Cl^-/HCO_3^- exchanger activity[48,55,54]. The counter-regulatory effect of somatostatin on the choleretic effect of secretin is important in modulating ductal secretion in pathological conditions associated with cholangiocyte proliferation/loss[3]. Parallel with the findings observed in rat bile ducts[3,12,13,48, 4], in human liver secretin-stimulated duct secretory activity is heterogeneous, since only large bile interlobular ducts express the Cl^-/HCO_3^- exchanger[82].

We have demonstrated the presence of insulin and CCK-B/gastrin receptors in large cholangiocytes from normal and BDL rats and have shown that these two hormones inhibit secretin-stimulated ductal secretion of BDL rats by IP_3/Ca^{2+}/PKCα-dependent decrease of cAMP levels[7,72,77]. Similarly, we found that ET_A and ET_B receptors are expressed by large cholangiocytes and that ET-1 inhibits secretin-stimulated cAMP levels and ductal bile secretion of BDL rats by interaction with ET_A but not ET_B receptors[59]. Furthermore, recent data have shown that: (1) the D2 dopaminergic receptors are expressed by large BDL cholangiocytes; and (2) the D2 dopaminergic receptor agonist, quinelorane, inhibits secretin-stimulated ductal secretion by activation of the Ca^{2+}-dependent PKCγ[25]. The α2-adrenergic receptor agonist, UK14, 304, inhibits secretin-stimulated cAMP-dependent Cl^- efflux and Cl^-/HCO_3^- in large cholangiocytes and secretin-stimulated lumen expansion in large IBDU of BDL rats[66]. The α1-adrenergic receptor agonist, phenylephrine, stimulates cAMP levels and secretin-stimulated secretion of large BDL cholangiocytes by IP_3/Ca^{2+}-dependent activation of PKCα and PKCβ II[65]. We have recently demonstrated[26] that acetylcholine, by interacting with M3 receptor subtypes, potentiates secretin-stimulated cAMP levels and Cl^-/HCO_3^- exchanger activity in IBDU and purified cholangiocytes by a Ca^{2+}-calcineurin mediated but PKC independent modulation of adenylyl cyclase.

Following hepatocyte secretion[83], bile acids are reabsorbed by the biliary epithelium[84], then they return via the PBP to the hepatocytes for secretion into bile (cholehepatic shunting)[85]. As a mechanism for bile acids entry into cholangiocytes, the apical Na^+-dependent bile transporter, ASBT (structurally identical to the ileal bile acid transporter) is expressed on the apical membranes of large cholangiocytes[86]. Consistent with functional activity for ASBT in cholangiocytes, studies have shown Na^+-dependent and saturable uptake of taurocholate in normal

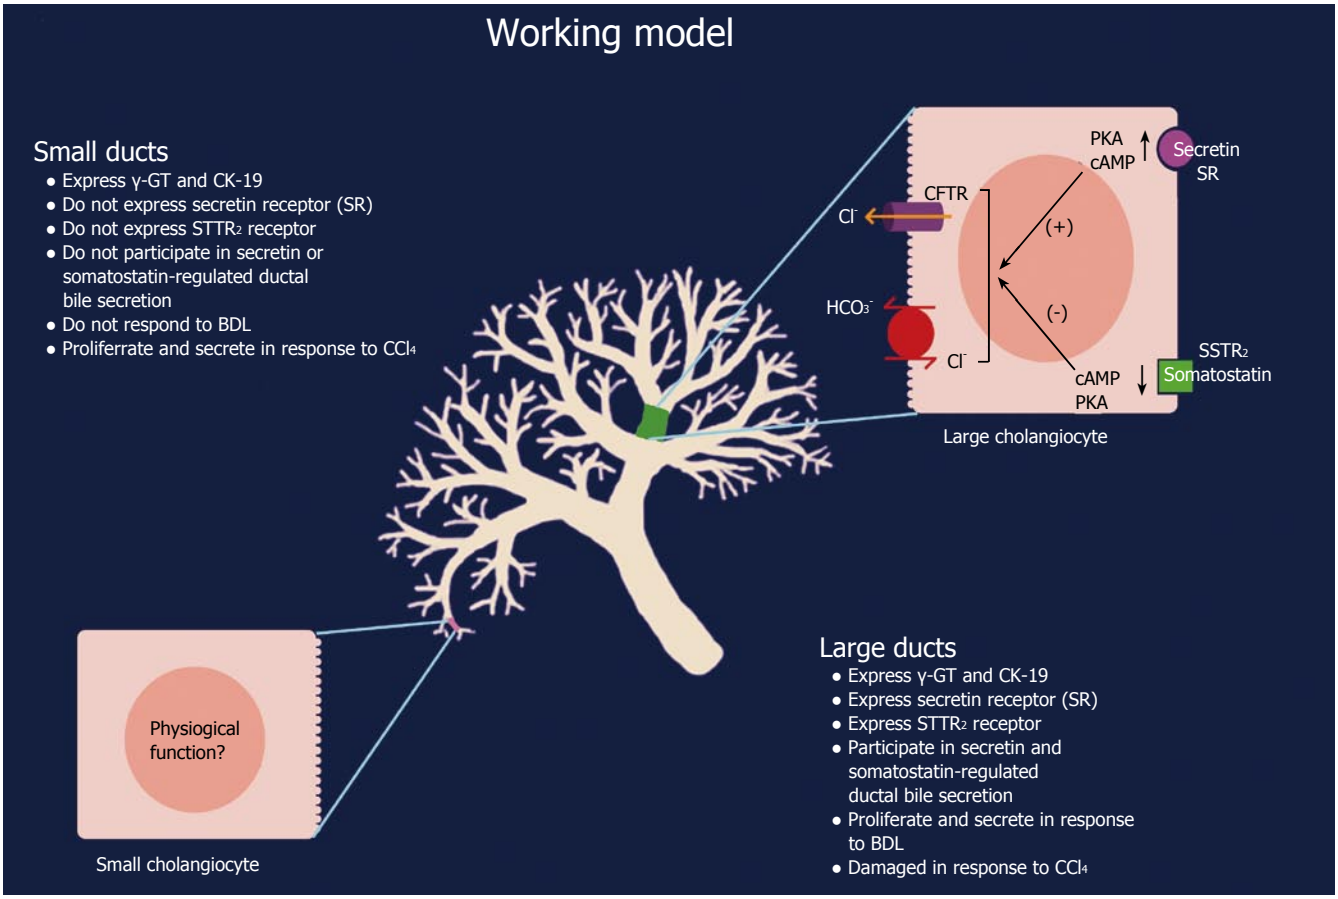

Figure 3 Working model for the heterogeneity of the intrahepatic biliary epithelium. The model proposes that: (1) bile ducts are morphologically heterogeneous with small ducts lined by small cholangiocytes and large ducts lined by large cholangiocytes; (2) small and large ducts similarly express both γ-GT and cytokeratin-19; and (3) large (but not small) ducts express the secretin and somatostatin receptor, CFTR and Cl^-/HCO_3^- and respond physiologically to these two hormones. The model also shows that following BDL, only large cholangiocytes proliferate and that a single dose of CCl_4 induces damage and loss of large duct function, whereas small cholangiocytes (resistant to CCl_4) *de novo* proliferate and secrete to compensate for the loss of large duct function. Reproduced with permission from Ref. 73.

cholangiocyte cultures[87] and large cholangiocytes[88]. These data suggests that after taurocholate and taurolithocholate enter into large cholangiocytes by ABAT, they stimulate secretin-stimulated ductal bile flow in these cholangiocyte subpopulations[88,89]. Other studies have shown that both taurocholate and taurolithocholate increase secretin-stimulated cAMP levels in large but not small cholangiocytes[89]. Chronic feeding of ursodeoxycholate and tauroursodeoxycholate to BDL rats inhibits secretin-stimulated ductal secretion in large cholangiocytes[62].

As evidence against the notion that small cholangiocytes may be primitive, undifferentiated cells that do not display secretory activity, recent studies have shown that in pathological conditions associated with damage of large cAMP-responsive ducts (e.g., after acute CCl_4 administration) (Figure 3)[50,51], small cholangiocytes transiently compensate for large cholangiocyte damage by *de novo* activation of secretory (including expression of secretin receptor and secretin-stimulated cAMP response)[50,51] and proliferative[50,51] (see below) activities. Following ANIT feeding and partial hepatectomy, small cholangiocytes proliferate and secrete by the *de novo* expression of secretin receptor and activation of cAMP response[47,52]. Since preliminary data and unpublished observations (Alpini, 2005) show that small rat and mouse cholangiocytes express receptors (ET_A, CCK-B/gastrin, α1-adrenergic, D2 dopaminergic, insulin, H1 histamine) signaling by activation of IP_3/Ca^{2+}/PKC[59,90], we propose that there is a secretory gradient in the intrahepatic biliary tree with small cholangiocytes secreting water and electrolytes by activation of the IP_3/Ca^{2+}/PKC pathway, whereas large cholangiocytes secrete bile by activation of the cAMP/PKA/CFTR/Cl^-/HCO_3^- exchanger[2,5,2,13,48,54].

PROLIFERATION AND APOPTOSIS

Cholangiocyte proliferation is coordinately regulated by a number of factors including gastrointestinal hormones/peptides, growth factors, cAMP and IP_3/Ca^{2+}/PKC pathways, nerves and bile acids[2,3,24,49,61,62,68,70-72,91-93]. Recent studies have shown that different sized cholangiocytes differentially proliferate or are damaged by apoptosis in response to injury, toxins, nerve resection and selected diets[2,26,48-52]. Following BDL, large but not small cholangiocytes proliferate with increases in basal and secretin-stimulated choleresis (Figure 3)[2,3,48]. We propose that large cholangiocytes selectively proliferate in response to BDL due to: (1) the predominant expression of VEGF in large compared to small cholangiocytes (Alpini *et al*, 2005, unpublished observation); and (2) the presence of the PBP mainly around large bile ducts, and less discernable around small bile ducts[44]. In support of this

concept, in rats with BDL proliferation of the peribiliary plexus occurs only around large ducts[44]. Furthermore, we have recently demonstrated[93] that neutralization of VEGF levels of large cholangiocytes (by administration of a neutralizing anti-VEGF antibodies) reduces cholangiocyte growth typical of BDL rats[6]. In support of the concept that PBP and VEGF play a role in the regulation of large cholangiocyte function, hepatic artery ligation in BDL rats is associated with: (1) the disappearance of the PBP; (2) increased apoptosis and impaired proliferation of large cholangiocytes; and (3) decreased cholangiocyte VEGF secretion[92]. The effects of hepatic artery ligation on PBP and large cholangiocyte function were prevented by chronic administration of r-VEGF-A that, by maintaining the integrity of the PBP and large cholangiocyte proliferation, prevents bile duct damage following ischemic injury[92].

A number of gastrointestinal hormones/peptides have been shown to regulate the differential proliferative response of small and large cholangiocytes. We have shown that cholangiocytes express α1, α2, β1 and β2 thyroid hormone receptors and that the chronic administration of the thyroid hormone agonist, 3, 3′, 5 L-tri-iodothyronine to BDL rats reduces *in vivo* the proliferation of large cholangiocytes[94], the only cholangiocyte subpopulation proliferating in this model[48]. In addition, in BDL rats we have shown that somatostatin inhibits the growth of large cholangiocytes by a decrease in cAMP levels[48]. Furthermore, gastrin inhibits large cholangiocyte proliferation in BDL rats by Ca^{2+}/PKC-dependent inhibition of cAMP levels[72].

We have demonstrated that ovariectomy in BDL female rats reduces the proliferation of large cholangiocytes and induces a decrease in the expression of α and β estrogen receptors[69]. We propose that estrogens play a role in the management of chronic cholestatic liver diseases.

Recent studies have shown that nerves regulate the differential proliferative response of intrahepatic ducts. We have shown that the activation of serotonin 1 A and 1 B receptors in cholangiocytes leads to the inhibition of large cholangiocyte proliferation in BDL rats[67]. Serotonin inhibition of large cholangiocyte proliferation was associated with activation of the IP_3/Ca^{2+}/PKC signaling pathway and the consequent inhibition of the cAMP/PKA/Src/ERK 1/2 pathway[67]. Since cholangiocytes secrete serotonin, we propose that serotonin limits the growth of intrahepatic bile ducts in the course of chronic cholestasis by an autocrine mechanism. Similarly, we have shown that cholangiocytes secrete NGF and that NGF secretion increases in proliferating BDL cholangiocytes compared to normal cholangiocytes[24]. *In vivo*, immunoneutralization of NGF (with an anti-NGF antibody) decreased large cholangiocyte proliferation[24]. The data suggest that NGF regulates cholangiocyte proliferation by an autocrine mechanism.

We have demonstrated that sensory innervation via α-calcitonin gene related peptide (α-CGRP) plays a role in adaptive proliferative responses of large cholangiocytes during cholestasis following BDL[95]. Specifically, we have shown that small and large murine cholangiocytes express the CGRP receptor components (calcitonin like receptor or CLR, receptor component protein or RCP and receptor activity modifying protein or RAMP1)[95]. Large, but not small, cholangiocytes proliferate in response to α-CGRP, proliferation that was blocked by CGRP[8-37], α-CGRP receptor antagonist[96]. α-CGRP stimulation of large cholangiocyte proliferation was associated with increased cAMP levels and phosphorylation of PKA and p38[96]. We observed a decrease in the number of proliferating large cholangiocytes in BDL knock-out mice (lacking α-CGRP) compared to BDL wild-type mice[95].

The role of the second messenger, cAMP, in the regulation of hepatic cell proliferation has been demonstrated in a number of animal models that stimulate hepatocyte and cholangiocyte proliferation via cAMP dependent mechanisms[26,50-52,54,97,98]. Following partial hepatectomy, there is an increase in intracellular cAMP levels in regenerating hepatocytes[99] and cholangiocytes[52]. Activation of $G\alpha_s$ coupled receptors leads to activation of adenylyl cyclase and increased cAMP levels, whereas activation of $G\alpha_i$ coupled receptors results in inhibition of AC activity and lowered intracellular cAMP levels[100]. cAMP response elements mediating transcriptional activation in response to increased intracellular cAMP levels have been identified[101]. In support of these findings, we have shown that chronic administration of forskolin to normal rats increased cAMP levels and the proliferation of large but not small cholangiocytes compared to rats receiving saline[70]. In purified cholangiocytes, forskolin increased large (but not small) cholangiocyte proliferation[70], which was blocked by Rp-cAMPs (a PKA inhibitor)[74], PP2 (a Src inhibitor)[102] and PD98059 (a MEK inhibitor)[103]. The effects of forskolin on large cholangiocyte proliferation were associated with increased phosphorylation of PKA, Src Tyr 139 and ERK1/2[70]. Maintenance of cAMP levels by forskolin administration prevents the effects of vagotomy on large cholangiocyte apoptosis (activation) and proliferation (inhibition)[26].

The acute administration of CCl_4 to normal and BDL rats induces decreased cAMP levels and loss of function of large cholangiocytes at d 2 and transient elevation of cAMP levels in small cholangiocytes[50,51]. In these models, small cholangiocytes *de novo* express secretin receptors, a key component of the biliary proliferative and secretory mechanisms, suggesting that intracellular cAMP plays a key role in the: (1) *de novo* expression of large cholangiocyte phenotypes by small cholangiocytes (to compensate for loss of large cholangiocyte function); and (2) perhaps the differentiation of small cholangiocytes towards a cholangiocyte subpopulation that has the capacity to secrete and proliferate by cAMP-dependent pathway[50,51].

Following partial hepatectomy, both small and large cholangiocytes proliferate and participate in the regeneration of the intrahepatic biliary epithelium[52]. A single gavage dose of CCl_4 to normal and BDL rats induces damage of large, cAMP-responsive cholangiocytes, whereas small cholangiocytes (resistant to CCl_4) *de novo* proliferate and secrete (by the activation of the secretin receptor and secretin-stimulated cAMP levels) to compensate for the damage and loss of functional activity of large cholangiocytes[50,51]. The differential resistance of small and large cholangiocytes to CCl_4 is presumably due to the presence

of cytochrome P4502E1 (the enzyme that converts CCl_4 to its radicals)[104] in large but not small cholangiocytes[50,51]. Chronic administration of the toxin, ANIT, induces proliferation of both small and large cholangiocytes, proliferation that (in contrast to other models including BDL)[26] was associated with enhanced apoptosis[47]. We propose that following ANIT or CCl_4 feeding, the proliferation of small cholangiocytes may be due to the presence of cholangiocyte apoptosis in these models[47,50,51]. We also propose that the lack of small cholangiocyte proliferation in BDL rats may be due to the absence of cholangiocyte apoptosis in this model[26]. Similar to what is observed following acute CCl_4 administration[50], the differential responses of small and large cholangiocytes to liver injury/toxins may be due to differential expression of other enzymes/proteins in small and large cholangiocytes. In support of this concept, phase I or mixed-function oxygenase enzymes (e.g., microsomal cytochrome P-450, aminopyrine-N-demethylases, G-6-PO_4, and NADPH cytochrome C reductase) and phase II or glutathione redox cycle enzymes (e.g., GSH-peroxidase, UDP-glucuronosyltransferase, and glutathione-S-transferase) drug-metabolizing enzymes are heterogeneously expressed by cholangiocytes[50,81,105]. Similarly, since small murine cholangiocytes express annexin-V[106] (that regulates cell apoptosis)[107], this finding may explain partly why small ducts are more resistant than large ducts to some hepatic injury/toxins[50, 51]. In support of this concept, recent studies have shown that bcl-2 (an anti-apoptotic protein)[108] is expressed by small bile ducts in normal human liver and human liver with cirrhosis and focal nodular hyperplasia[109], a finding that may also explain partly the greater resistance of small cholangiocytes to damage[3,50,51].

In vitro treatment of normal cholangiocytes with taurocholate and taurolithocholate increases the proliferation of large but not small cholangiocytes[89]. Chronic feeding of taurocholate and taurolithocholate to normal rats induces the *de novo* expression of ASBT and activation of proliferation of small cholangiocytes, which do not constitutively express ASBT and are mitotically quiescent, and increases the proliferation of large cholangiocytes[49]. Prolonged feeding of ursodeoxycholate and tauroursodeoxycholate to BDL rats reduces the growth of large cholangiocytes[62] that selectively proliferate in this hyperplastic model[48]. Furthermore, depletion of endogenous bile acids reduced large cholangiocyte proliferation compared with BDL rats[91]. Re-infusion of taurocholate to bile acid-depleted rats prevented the decrease in cholangiocyte proliferation that was maintained at levels similar to those of BDL rats[91].

Histamine, an aminergic neurotransmitter, regulates many pathophysiological functions. Four G-protein coupled histamine receptors (H_1, H_2, H_3 and H_4) exist[110]. While H_1 histamine receptors act via $G\alpha_q$ mobilizing $[Ca^{2+}]_i$[111], activation of H_2 histamine receptors is modulated by $G\alpha_s$ proteins, coupled to adenylyl cyclase[112]. H_3 and H_4 histamine receptors couple to $G\alpha_{i/o}$ proteins that inhibit adenylyl cyclase[113]. Based upon our preliminary data, we propose a model in which the overall outcome of histamine on cholangiocyte growth is represented by a balance between its stimulatory (by activation of H1 and H2 histamine receptors)[90,114] and its inhibitory (by activation of H3 and H4 histamine receptors)[115, 116] actions on small and large cholangiocyte proliferation. Specifically, we have shown that small but not large mouse cholangiocytes: (1) express the H_1 histamine receptors and the calcium-dependent CaMK I (but not II or IV) protein kinase; and (2) proliferate in response to H_1 histamine receptor agonists, proliferation that was blocked by BAPTA/AM, Gö6976 and W-7, a CAMK inhibitor[117]. IP_3 (but not cAMP) levels were increased in small cholangiocytes treated with HTMT dimaleate. Chronic administration of the specific H3/H4R agonist (RAMH) to BDL rats decreased large cholangiocyte proliferation and cAMP levels compared to BDL rats treated with NaCl[115,116]. This inhibition is mediated through negative regulation of the cAMP-dependent PKA/ERK1/2 pathway[115,116].

The mechanisms by which different sized ducts proliferate or are damaged in response to various liver injury/toxins (e.g., BDL, partial hepatectomy, vagotomy, feeding of ANIT, bile acids or CCl_4)[3,26,47-52] are unclear. Furthermore, the pathophysiology of small cholangiocytes is undefined in these models. Based upon preliminary data and unpublished observations from our laboratory, we propose that neural/hormonal-dependent (cholinergic and adrenergic) activation of the Ca^{2+}-dependent NFAT (Nuclear Factor of Activated T-lymphocytes) stimulates the proliferative response of small cholangiocytes, whereas neural/hormonal-dependent activation of the cAMP-dependent CREB stimulates the proliferation of large cholangiocytes. NFAT is a ubiquitous transcription factor that was initially described in T-lymphocytes. Five isoforms of NFAT have been identified. Four of these isoforms (NFATc1 to c4) are regulated by Ca^{2+} signaling[118]. Preliminary data shows that Ca^{2+}-dependent activation of NFATc1/c4 stimulates the proliferation of small cholangiocytes after CCl_4-induced damage of cAMP-responsive large bile ducts[119]. Specifically, we have shown that small but not large normal rat cholangiocytes express the NFAT isoforms, NFAT c1 and c4[119]. CCl_4 both *in vivo* and *in vitro* increased small cholangiocyte proliferation that was blocked by BAPTA/AM and 11R-VIVIT (NFAT inhibitor peptide)[120]. Furthermore, unpublished data from our laboratory show that the *de novo* growth of small cholangiocytes is regulated via adrenergic stimulation of Ca^{2+}-dependent activation of NFATc1/c4 (Ca^{2+}/calcineurin) and Sp1 (Ca^{2+}/PKC). NFAT and Sp1 cooperatively interact to regulate proliferative phenotypes in other cell types[121].

Recent studies have shown that bile acids have cytoprotective effects against apoptosis in large cholangiocytes. Feeding of taurocholate to BDL rats (treated with a single dose of CCl_4) prevents CCl_4-induced damage of large cholangiocytes, whereas small cholangiocytes (which are *de novo* activated following CCl_4-induced damage of large ducts)[50,51] remained mitotically dormant and unresponsive to secretin (Figure 3)[122]. *In vitro*, taurocholate prevented the inhibitory effects of CCl_4 on apoptotic, proliferative and secretory capacity of large BDL cholangiocytes[122]. The protective effects of taurocholate against CCl_4-induced damage of large BDL cholangiocytes are due to the

activation of PI3-K and AKT expression[122]. Furthermore, feeding of taurocholate to BDL + vagotomy rats prevented vagotomy activation of large cholangiocyte apoptosis and inhibition of large cholangiocyte growth[123], effects that were abolished by wortmannin, a PI3-K inhibitor[124]. Functional ASBT expression as well as phosphorylation of Akt were reduced by vagotomy but restored by taurocholate feeding[123]. Chronic feeding of taurocholate prevented the increase in cholangiocyte apoptosis and the damage of large cholangiocyte proliferation induced by adrenergic denervation by 6-OHDA administration[125]. Taurocholate effects are mediated by the PI3K pathway, since the simultaneous administration of wortmannin reverses such effects[125]. In addition, the feeding of ursodeoxycholate and tauroursodeoxycholate to BDL + vagotomy rats prevented the activation of apoptosis and the loss of proliferation of large cholangiocytes observed in this model[126]. In this study[126], the protective effects of these two bile acids were neutralized by the simultaneous administration of BAPTA/AM (an intracellular Ca^{2+} chelator)[72] or Gö6976 (a PKC inhibitor)[65]. Both ursodeoxycholate and tauroursodeoxycholate increased IP_3 and Ca^{2+} levels, together with enhanced phosphorylation of PKC-α[126]. The data suggests that bile acids are important in modulating large cholangiocyte proliferation in denervated livers.

HETEROGENEITY IN CHOLANGIOPATHIES

Chronic cholestatic liver diseases (cholangiopathies), which target intrahepatic and extrahepatic bile ducts, are characterized by the coexistence of cholangiocyte growth/apoptosis, inflammation and fibrosis[3,127]. Cholangiopathies differentially target the biliary epithelium with heterogeneous proliferative and apoptotic responses of different sized ducts[3,47,50,128-130]. Primary biliary cirrhosis is characterized by the selective proliferation/loss of small interlobular bile ducts[3,131]. Some studies demonstrated that damage of interlobular bile ducts is immune mediated[3,132]. The origin of primary sclerosing cholangitis (PSC), which is associated with inflammation and fibrosis of bile ducts, originates from multiple factors including autoimmune, bacterial, congenital, drug, or viral agents[3,73]. PSC affects mainly extrahepatic and interlobular or septal bile ducts although smaller bile ducts can be affected[3,73]. Patients with small duct PSC seem to have a good prognosis in terms of survival and development of cholangiocarcinoma[133]. Cholangiocarcinoma occurs frequently in patients with PSC and targets mainly the major bile duct bifurcation[3,134]. Peripheral cholangiocarcinoma occur within the liver rather than within large bile ducts may arise from small bile ducts[3,134]. Mutations in the CFTR gene are responsible for causing the human biliary disease, cystic fibrosis, due to defective transport of water and chloride presumably by large cholangiocytes expressing CFTR[135]. Our previous studies in rodent liver has shown that CFTR is expressed principally in large cholangiocytes and in bile ducts greater than 15 μM diameter[12,13] but in studies of human liver of cystic fibrosis patients, CFTR was expressed in both large and small ducts[136].

Defective chloride transport and chloridemediated bile secretion by large cholangiocytes may be responsible for the reduced fluidity and alkalinity of bile, leading to bile duct damage. Ca^{2+}-dependent Cl^- channels[137,138] (presumably expressed by both small and large cholangiocytes) may be able to secrete bile, thus compensating for loss of CFTR functional activity of CFTR in large cholangiocytes[54]. In polycystic kidney liver disease (PKLD), the genetic defect results in the growth of multiple epithelial cysts within the renal, liver parenchyma and intrahepatic bile ducts[139]. The disease targets presumably large bile ducts since the cystic ductal cells also secrete Cl^- and HCO_3^- (as normal large cholangiocytes)[2,3,54,71,73] but the secretion is diminished, likely due to reduced Cl^-/HCO_3^- exchanger activity in cystic ductal cells as compared with normal cholangiocytes[139]. Biliary atresia, which is the most common reason of cholestasis in infants and children, is a destructive, inflammatory process of the extrahepatic bile ducts but as the disease progresses smaller intrahepatic bile ducts are also involved[140]. The pathogenesis of biliary atresia is unknown but infections or toxic agents combined with genetic/immunologic susceptibility have been proposed[3, 141, 142].

SUMMARY

In this review, we have summarized the findings demonstrating that the intrahepatic biliary epithelium is heterogeneous regarding: (1) morphological characteristics, vascularization and innervation; (2) secretory activity in response to gastrointestinal hormones/peptides, nerve receptor agonists and bile salts; and (3) apoptotic and proliferative responses to liver injury/toxins and gastrointestinal hormones/peptides. Specifically, the intrahepatic biliary epithelium is formed by bile ducts of different sizes with small ducts lined by small cholangiocytes, whereas larger ducts are lined by larger cholangiocytes[12-14]. Following a general background on cholangiocyte functions, we discussed the *in vivo* and *in vitro* experimental models that allowed us to demonstrate that the biliary epithelium is morphologically and functionally heterogeneous. Following a brief review on the heterogeneous distribution of non-transport related proteins, we discussed the secretory functions of small and large cholangiocytes. While large cholangiocytes secrete water and electrolytes[12,13,48] by changes in cAMP/PKA/CFTR/Cl^-/HCO_3^-, small cholangiocytes may secrete bile by a transduction pathway (different from that observed in large cholangiocytes)[12,13,48] involving activation of IP_3/Ca^{2+}/PKC. We have presented data demonstrating that small and large cholangiocytes differentially proliferate or are damaged in response to liver injury/toxins. Small and large ducts also differ regarding the proliferative and apoptotic responses to liver injury/toxins[2,71,73]. We propose that activation of the Ca^{2+}-dependent NFAT stimulates the proliferation of small cholangiocytes, whereas neural/hormonal-dependent activation of the cAMP-dependent CREB stimulates the proliferation of large cholangiocytes. In the last part of the review, we have briefly outlined the heterogeneity of the biliary epithelium in relationship to chronic cholestatic liver diseases targeting different sized ducts.

FUTURE PERSPECTIVES

The concept that the biliary epithelium is functionally heterogeneous is clinically relevant since in chronic cholestatic liver diseases cholangiocyte proliferation/damage is an event restricted to a specific duct size. Further studies are needed for understanding the pathophysiology of small cholangiocytes in the overall contribution of the functions of the biliary epithelium. However, some preliminary studies from our laboratory suggest that small cholangiocytes secrete bile (by a IP_3/Ca^{2+}/PKC-dependent mechanism) and proliferate by activation of the Ca^{2+}-dependent transcription factor, NFAT. Further studies are necessary to evaluate the role of the nervous system in the regulation of the heterogeneous secretory, apoptotic and proliferative responses of different sized bile ducts to gastrointestinal hormones, injury/toxins and viruses. Since PBP proliferation is observed only in large proliferating cholangiocytes from BDL rats, we propose that blood supply and circulating factors (e.g., vascular endothelial growth factor and placental growth factor) may be important in the regulation of the heterogeneous response of cholangiocytes to liver injury/toxins.

Abstract

The scientific framework concerning estrogen effects on different tissues has expanded enormously during the last decades, when estrogen receptor (ER) subtypes were identified. Estrogens are not only essential for the female reproductive system, but they also control fundamental functions in other tissues including the cardiovascular system, bone, brain and liver. Recently, estrogens have been shown to target the biliary tree, where they modulate the proliferative and secretory activities of cholangiocytes, the epithelial cells lining bile ducts. By acting on both estrogen receptors (ER-α) and (ER-β) subtypes, and by activating either genomic or non-genomic pathways, estrogens play a key role in the complex loop of growth factors and cytokines, which modulates the proliferative response of cholangiocytes to damage. Specifically, estrogens activate intracellular signalling cascades [ERK1/2 (extracellular regulated kinases 1/2, PI3- kinase/AKT (phosphatidylinositol-3' kinase/AKT)] typical of growth factors such as insulin like growth factor (IGF1), nerve growth factor (NGF) and vascular endothelial growth factor (VEGF), thus potentiating their action. In addition, estrogens stimulate the secretion of different growth factors in proliferating cholangiocytes. This review specifically deals with the recent advances related to the role and mechanisms by which estrogens modulate cholangiocyte functions in normal and pathological conditions.

INTRODUCTION

The intrahepatic biliary tree is a complex three-dimensional network of interconnected ducts, which starts at the level of canals of Hering, continues into intrahepatic ducts of increasing diameter, and ends at the level of main extrahepatic bile ducts[1-3]. Recent studies demonstrated that the intrahepatic biliary tree plays a critical role in many liver functions including bile formation, regeneration, injury repair, fibrosis, angiogenesis and regulation of blood flow[4,5]. Most of these events are regulated by a complex network of neuropeptides, hormones, cytokines and growth factors, which target cholangiocytes[6,7], the epithelial cells lining the biliary tree. Cholangiocytes are the primary target of damage in a group of chronic cholestatic liver diseases, named cholangiopathies, with high social and economic impact due to their high prevalence and morbidity[8]. Altogether these pathologies represent a main indication for liver transplantation and, in fact, in 2003, 10% of OLT in the USA had as an indication PBC (primary biliary cirrhosis) and PSC (primary sclerosing cholangitis).

Although very heterogeneous in the etiology and pathogenesis (autoimmune, infectious, vascular, drug-

induced and cryptogenic)[8], the cholangiopathies share common pathological features such as the injury of intrahepatic bile ducts, the proliferation of residual ducts and the intralobular cholestasis[9]. In addition, most of these pathologies evolve towards ductopenia that represents the terminal stage of the disease[9]. For this reason, cholangiopathies have been also classified as vanishing bile duct syndromes[8,9]. In the early stage of the diseases, the disappearance of intrahepatic ducts is balanced by the proliferation of the residual bile ducts[10], which tends to compensate for the anatomical and functional loss of damaged ducts. In fact, proliferating bile ducts display enhanced secretory activities aimed to compensate for the impaired secretion of injured ducts[11]. Thus, the course of these diseases is characterized by a balance between damage (loss) of bile ducts and compensatory proliferation of the residual ducts[10]. In the terminal decompensated stages, the inefficacy of proliferation to balance for the loss of intrahepatic bile ducts leads to ductopenia, and thus to the clinical manifestations of overt cholestasis[12]. Therefore, the design of a therapeutic strategy aimed at supporting an efficacious cholangiocyte proliferation could delay the progression toward ductopenia and this represents a challenge for the future. For these reasons, during the last few years, mechanisms and agents involved in the modulation of cholangiocyte proliferation have been extensively evaluated, especially at the experimental level[5-7]. To this latter regard, the experimental model of the common bile duct ligated (BDL) rat was very helpful since the typical and selective cholangiocyte proliferation that follows BDL induces a tremendous expansion of cholangiocyte mass (30% of parenchymal hepatic cells with respect to 2% in normal) thus facilitating the study of cholangiocyte pathophysiology. Thanks to recent studies, we now know that cholangiocyte proliferation is regulated by several growth factors, hormones, neuropeptides and bile salts[5-7]. One of the objectives of these studies was related to estrogens[13-16] since, for many years, we have become aware that the clinical appearance and progression of different cholangiopathies are influenced by gender and changes of estrogen status in the body[17]. Nevertheless, only in the last few years we have learned that estrogens and their receptors influence the pathophysiology of cholangiocytes and that this mainly occurs during experimental and human conditions characterized by cholangiocyte injury and proliferation[13-16]. Estrogens have been considered for many years to play a role in the development and progression of pathologies involving the biliary tree[17,18]. This hypothesis was based on a number of clinical observations including: (1) PBC, the most prevalent acquired cholangiopathy, specifically affects females[17,19] with a clinical presentation typically occurring during the peri- and post-menopausal period[19-23]; (2) endocrine dysfunctions are frequent in PBC[17,19,21] including an increased incidence of menstrual disturbance and hysterectomy[19,21] and, the high incidence of post-menopausal osteoporosis that is a sign of estrogenic deficiency[24] and that is corrected by estrogen replacement therapy[25]; (3) chronic hepatic rejection leading to ductopenia more frequently from male donor into female recipient[26]; (4) in Turner syndrome, in which liver morphology resembles that of a newborn liver, bile duct pathology is frequent and is improved by estrogen replacement treatment[27]; (4) the progression of polycystic liver disease is significantly influenced by female sex, pregnancies and estrogen replacement treatment. In addition, marked alterations of estrogen hepatic metabolism occur in cholestasis[28], which is one of the hallmarks of cholangiopathies, leading to enhanced estradiol serum levels[28], which could influence disease progression. In spite of all these clinical considerations, the role and mechanism by which estrogens modulate cholangiocyte functions have been explored only in the last few years at both experimental and clinical levels[13-16].

EXPERIMENTAL STUDIES

In 1896, the British physician George Beatson, firstly showed that oophorectomy induces the regression of mammary tumors in a subset of premenopausal patients. Since then, a variety of clinical and epidemiological observations have further substantiated the involvement of estrogens as inducers of growth and differentiation of target cells expressing estrogen receptors (ERs)[29]. Estrogens exert their "trophic" action on many different target organs, among which is the liver[30], where they modulate growth and repair, contributing to neonatal liver growth and regeneration after injury in adults[29]. In injured liver, ERs expression increases with respect to normal liver where ERs are expressed at a very low level[30]. Furthermore, chronic administration of estrogens for pharmacological purposes, induces an enlargement of liver mass[31,32] and, after partial hepatectomy, ERs expression in hepatocytes increases and localizes predominantly into the nucleus with subsequent transcription of genes involved in proliferation, thus favoring the restoration of a normal liver mass[32]. Recent findings indicate that estrogens also target the biliary tree playing an important role in modulating cholangiocyte proliferation[13]. Even if ER-α and β subtypes are also expressed by normal rat cholangiocytes[14], their expression (especially ER-β) markedly increases in proliferating cholangiocytes of BDL rats, whereas hepatocytes, which do not proliferate after BDL, display a ten-fold decrease of ERs protein expression[13]. During cholestasis (after BDL) estrogen serum levels are increased[20, 28] and this could play a role in sustaining cholangiocyte proliferation by a complex loop of agent among which estrogens may act either directly or potentiating the effects of different growth factors. In addition ER antagonists (tamoxifen, Ici 182,780) block the BDL-induced increase in intrahepatic bile duct mass by impairing cholangiocyte proliferation and enhancing apoptosis[13-16]. Similarly, in hepatocellular carcinoma[33] and breast cancer cells, tamoxifen counteracts estrogen mitogenic effect either by antagonizing estrogens or by inducing apoptosis-related genes[33]. In cholangiocarcinoma cell lines[33-35], tamoxifen induces apoptosis mainly by the activation of Fas receptor/Fas ligand pathway. Interestingly, the involvement of Fas antigen has been also demonstrated in PBC and PSC[36,37], where the imbalance between proliferation and apoptosis could play an important role in disease pathogenesis and progression. All these findings suggest that, in BDL rats, estrogen antagonists could block cholangiocyte proliferation and activate apoptosis by a Fas dependent mechanism, even if other

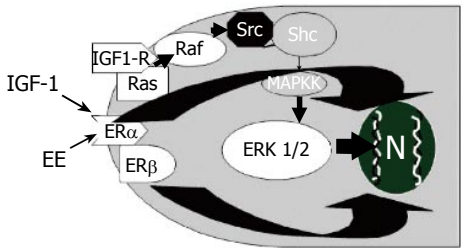

Figure 1 Additive effect of estrogens (EE) and insulin like growth factor-1 (IGF1) in the modulation of cholangiocyte proliferation. EE and IGF1 play additive effects on cholangiocyte proliferation by acting at both receptor and post-receptor levels IGF1 and EE induce, in cholangiocytes, additive increase of phosphorylated ERK1/2.

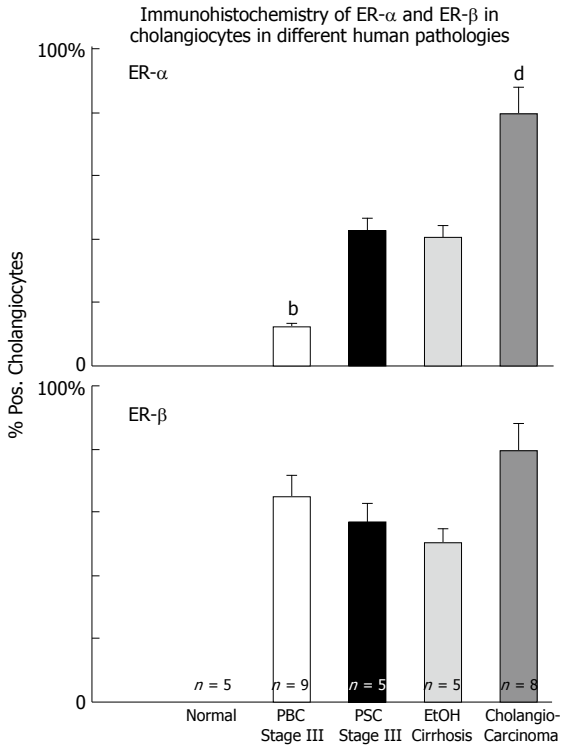

Figure 2 Immunohistochemistry of ER-α and ER-β in cholangiocytes in different human pathologies, $^{b}P < 0.01$, $^{d}P < 0.01$ *vs* other columns.

mechanisms of activation, especially for tamoxifen, cannot be excluded[32,33]. The concept that estrogens are positive modulators of cholangiocyte proliferation is further supported by the fact that, *in vitro*[13] 17β-estradiol significantly increases both proliferating cell nuclear antigen (PCNA) protein expression and 3H-thymidine incorporation into DNA and that two distinct ER antagonists (tamoxifen, Ici 182,780) block 17β-estradiol effects[13]. In addition, ovariectomy prevents cholangiocyte proliferation in BDL rats[15] and causes a 3-fold decrease of bile duct mass with respect to controls, in association with a 2.5-fold lower expression of Er-α and a 35-fold lower expression of ER-β[15]. When 17β-estradiol was administered in BDL + ovariectomy rats, bile duct proliferation was restored and ER expression in cholangiocytes returned similar to controls[15]. The proliferative effects of estrogens in target cells expressing ER can involve both a direct genomic pathway and an indirect nongenomic pathway where extracellular-regulated kinases (ERK1/2 = p42/p44 MAP kinases) are involved[38]. This has been also demonstrated in cholangiocyte proliferation occurring after BDL where estrogen administration increases the expression of phosphorylated ERK1/2[39]. In contrast, tamoxifen decreases phosphorylated ERK1/2 in association with impaired cholangiocyte proliferation[39]. The Src/Shc/ERK1/2 cascade is typically activated by several growth factors[40], thus suggesting that estrogens could potentiate the effects of growth factors by sharing similar intracellular signaling pathways. Consistently, in cholangiocytes, estrogens exert additive effect with NGF and IGF1[41,42] on modulating proliferation. As far as IGF1 is concerned, the cooperation with estrogens (Figure 1) occurs at both receptor and post-receptor level, since estrogens and IGF-1 increase phosphorylation of IGF1-R, ERK and AKT, whereas the interplay between NGF and estrogens occurs mainly at the level of PI3-kinase[42]. Another growth factor able to sustain cholangiocyte proliferation is VEGF. Very recently, we showed that estrogens induce VEGF synthesis and release in isolated cholangiocytes and this was markedly amplified in proliferating cholangiocytes[43]. This finding is very attractive since under estrogen stimulation, proliferating cholangiocytes can modulate, *via* VEGF release, their vascular supply whose adaptive response is critical for sustaining the enhanced functional and nutritional demands of the proliferating biliary tree[43]. Moreover, VEGF released in the peribiliary plexus by proliferating cholangiocytes following cholestasis could also favour the survival and repair of hepatocytes[43].

HUMAN STUDIES

Cholangiocytes of normal liver do not express ERs at the immunohistochemical analysis[16] but they stain positive for ER-α and -β in several pathological conditions including PBC[16], polycystic liver disease[44] and cholangiocarcinoma[45] (Figure 2). All these conditions are characterized by reactive or neoplastic cholangiocyte proliferation, suggesting that estrogens and their receptors may play a role in modulating the proliferative activities of cholangiocytes and therefore the course of these diseases.

ESTROGENS AND PBC

PBC is a chronic cholestatic liver disease, which represents the most frequent acquired cholangiopathy[46]. Actually, PBC is considered an autoimmune disease with a sexual dimorphism[46]. The disease, in fact, predominantly affects females (10:1 female/male ratio) with a typical clinical presentation occurring during the peri- and post-menopausal period[19,20,46]. The thought that estrogens can influence the clinical course of PBC, as for most autoimmune disorders, came from several studies showing that estrogens are able to modulate the humoral and cellular immune response[47] through the inhibition of Th1 pro-inflammatory cytokines (IL-12, TNF-alpha and IFN-gamma)[48]. By switching the immunological response toward the Th2 profile, estrogens stimulate the production of Th2 anti-inflammatory cytokines (such as IL-10, IL-4 and TGF-beta) thus potentiating the anti-inflammatory response[48]. In addition, estrogens can prevent oxidative stress in hepatocytes[49,50], which

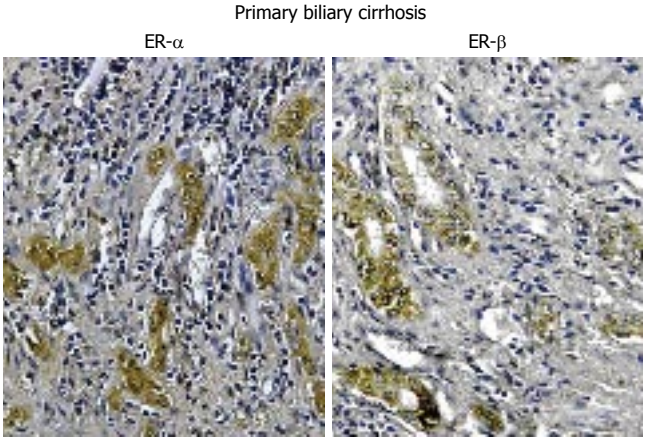

Figure 3 Immunohistochemistry for ER-α and ER-β. Biopsies of human primary biliary cirrhosis showing an intense positivity for both ER-α and ER-β in the proliferating bile ducts. Orig. magn., x 20.

are injured by cholestasis[12]. In spite of all these considerations, recent findings suggest that estrogens may influence the course of PBC by directly modulating the pathophysiology of cholangiocytes[13-16], which are the primary target of damage in this disease.

In PBC, such as in other chronic cholestatic conditions, estrogen serum levels are increased as a consequence of impaired hepatic metabolism and biliary excretion of estrogens and their metabolites[28]. Until recently, the high serum concentration of estrogens occurring in PBC patients was considered to have a negative effect on disease progression. For a long time, in fact, estrogens have been used in rodents as an experimental model of intrahepatic cholestasis[28]. Therefore, estrogen administration has been avoided in PBC patients. Recently, however, estrogen replacement therapy, as osteoporosis treatment, has been shown to be safe in PBC patients[51]. Thereafter, other studies[25] with the same end-points (i.e. osteoporosis treatment) indicate an improvement of liver serum enzymes (including cholestasis enzymes) during estrogen administration in PBC patients. These clinical studies allowed us to rule out the concept that administration of estrogens in PBC patients exerts deleterious effects on the liver but, on the contrary, suggest that they can improve liver function other than ameliorating bone mineral density.

Another old concept is the existence of a condition of estrogenic dysfunction in PBC[19-21]. This concept was based on the high frequency of menstrual abnormalities and hysterectomy[21], on the increased risk of breast cancer[22,23] and other malignancies[20], attributed to the increased estrogen serum levels, and increased prevalence of post-menopausal osteoporosis[24] which is corrected by estrogen replacement. However, these observations are still the object of controversies[21-23,52,53]. The incidence of extrahepatic malignancies[54], for example, in a cohort of Italian PBC patients, was shown to be lower with respect to the general population and to what was shown for American and Northern European PBC patients. In the same study, the incidence of breast cancer in PBC was comparable to that expected in the general population[54]. Also for metabolic bone disease associated with the progression of PBC, definitive data are still lacking. Recent studies[55,56] indicate that PBC is a risk condition *per se* for post-menopausal bone disease (osteoporosis and osteopenia), which occurs with the same incidence compared to other chronic liver diseases. Therefore, advanced liver disease, rather that PBC *per se*, represents a condition favouring the development of osteoporosis[55,56].

Nevertheless, recent studies indicate that estrogens play a role in the pathophysiology of PBC since both experimental and clinical studies indicate that they modulate cholangiocyte survival and death[13-16]. Cholangiocytes lining interlobular bile ducts of PBC patients, but not normal subjects, express both Er-α and -β subtypes, at the immunohistochemical analysis[16] (Figure 3). The ER expression varies according to different stages of disease and correlates with markers of proliferation (PCNA) and death (Tunel)[16]. ER-α expression increases from 1% of cholangiocytes in PBC stage I to 12 % in stage III while, ER-β is stably high (50%-65%) in all histological stages of PBC[16]. Interestingly, in stages I-III of PBC, ER-α expression correlates with and co-localizes with PCNA indicating that the expression of this receptor subtype is a typical feature of proliferating cholangiocytes[16]. Furthermore, in stage IV of PBC, when the maximal degree of ductopenia is reached, cholangiocytes are negative for ER-α and express the lowest PCNA/TUNEL ratio[16]. This raises the speculation of a relative proliferative deficiency of cholangiocytes in the terminal ductopenic stages of PBC, which is associated with the disappearance of ER-α. In addition, ER-α expression in cholangiocytes of PBC patients was markedly lower when compared with primary sclerosing cholangitis and alcoholic cirrhosis[16] (Figure 2), whose prevalence is higher in male sex[9], suggesting that the female predominance of PBC and the typical post-menopausal presentation could be related to a defect in proliferative response of cholangiocytes to estrogens. These findings could have important therapeutic implication, since the modulation of ERs could delay the progression of PBC toward ductopenia. During the last decade, estrogens have been involved in the pathogenesis of different diseases including atherosclerosis, Alzheimer disease, multiple sclerosis, Parkinson disease and obesity[57-61]. Estrogens, in fact, play biological activities in several organs[62] including the cardiovascular system, nervous system, digestive system (colon, liver) and "male" organs such as prostate. In target tissues, estrogens may exert opposite actions and heterogeneous effects, promoting the resistance to apoptotic damage, modulating reparative processes and controlling inflammation[63-65]. The expression pattern of ER subtypes is fundamental to evocate the different effects of estrogens[66]. ER-α, for example, is critical in estrogen induced protection against brain injury during stroke[66]. On the contrary, overexpression of ER-α has been linked with cancer development and progression in different organs[67]. The functions of ER-β are less known although recent findings suggest a protective effect against uncontrolled or neoplastic cell proliferation[68]. In our setting, the modulation of cholangiocyte proliferation exerted by estrogens and their receptors could open new therapeutic scenario suggesting appropriate trials aimed to evaluate the effects of ER selective modulators (SERMs) on PBC clinical expression. To this latter regard, preliminary clinical observations by us and

others[69,70] indicate that tamoxifen (mixed agonist/antagonist for ER-α and only antagonist for ER-β) improves biochemical parameters of cholestasis in PBC patients. We described three cases of PBC[69] that underwent tamoxifen treatment for breast cancer. In two patients, tamoxifen administration for approximately 18 mo, caused a marked decrease of alkaline phosphatase (70%-85%) and gamma-GT (60%-75%) serum levels and, in the third case, where tamoxifen was combined with UDCA, a strong reduction of liver enzymes was observed[69]. Moreover, during the observational period, none of these three patients developed complications of liver cirrhosis[69]. The positive effects of tamoxifen on the serum levels of cholestasis enzymes in PBC have been also described by Bassendine *et al* in two PBC patients who developed breast cancer and received tamoxifen, after surgical treatment[70]. However, other than acting as ER modulator in cholangiocytes, tamoxifen could improve cholestasis in PBC by additional mechanisms. Recently, in fact, tamoxifen has been shown to activate the human pregnane X receptor (PXR), a nuclear receptor linked with cytochrome p 450 function and considered to be relevant in the UDCA mechanism of action[71]. Therefore, tamoxifen could theoretically activate these promiscuous nuclear receptors thus improving UDCA effects[71]. Nevertheless, tamoxifen could have important side effects such as the increased risk of endometrial cancer when advised for disease lasting decades like PBC[72]. Second and third generation SERMs do not have these side effects and thus considered safer[73]. Our preliminary data (unpublished observations) indicates that raloxifene (a second generation SERM avoids the proliferative effects on reproductive tissues and which do not form adducts with DNA) causes biochemical improvement of cholestasis enzymes in PBC patients as shown for tamoxifen. Furthermore, it improves bone mineral density in PBC[74]. Thus a therapeutic strategy aimed to positively modulate estrogen proliferation during the early stages of PBC represents a challenge for the future, since cholangiocyte proliferation acts as a repair and compensatory mechanism and its stimulation is always associated with enhanced secretory activities[11]. Moreover, very recent studies elucidated that ER-α mediates many other "beneficial" effects of estrogen including immunoprotection in autoimmune disease[75]. ER-α activation, in fact, inhibits inflammatory gene expression by preventing NF-kappa B nuclear translocation[76]. Interestingly, through the ER-α, estrogens can positively modulate the GH/IGF-1 axis. This further supports a possible therapeutic role of ER-α positive modulators in cholangiopathies since we demonstrated that IGF- 1 and estrogens play additive effect on cholangiocyte proliferation (Figure 1)[42] and that the GH/IGF-1 axis plays a pivotal role in liver injury repair (unpublished observations). Consistently, IGF-1 replacement therapy shows clinical benefit in PBC and alcoholic cirrhotic patients[77].

ESTROGENS AND ADPKD

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most prevalent human genetic diseases with an incidence of 1:800 individuals[78]. Hepatic cysts are the most common extra-renal clinical manifestation of ADPKD and a significant source of morbidity[79]. That estrogens may have a role in the development and progression of hepatic cysts in ADPKD patients is suggested by a number of different clinical observations[82]. In ADPKD patients, the probability of developing hepatic cysts is higher in women with respect to men and among patients submitted to liver transplant for polycystic disease, more than 92% are women[80]. Furthermore, the number and size of hepatic cysts increase during post-menopausal hormonal replacement therapy[81] and nulliparae display less probability to develop hepatic cysts than pluriparae[82], where number and size of hepatic cysts correlate with the number of pregnancies[82]. As recently showed by us[44], interestingly, hepatic cysts are lined by cholangiocytes[83], that are different from normal biliary cells since they lack of both microvilli and primary cilia[84]. It is currently hypothesized that the lack of primary cilia, genetically determined, generates a cell phenotype characterized by hyperproliferating and hypersecretory properties. By acting on this cell phenotype, estrogens could sustain the enhanced proliferative and secretory activities, as experimentally shown in BDL rats[15], by acting either directly or potentiating the effects of growth factors. Recently, in fact, a number of different cytokines and growth factors (i.e. IL-8, IL6 and VEGF), markedly enriched in serum or hepatic cystic fluid, have been shown to promote the growth of hepatic cyst epithelium[85]. Immunohistochemical studies performed by our group (Alvaro, 2006, unpublished observations) showed that the epithelial surface of hepatic cysts of ADPKD patients display a marked and diffuse staining for ERs (mainly-β), IGF1 and IGF1-R. In addition, we demonstrated that[44] immortalized cell line (LCDE), derived from hepatic cyst epithelium of patients with ADPKD, also express ER-α and ER-β subtypes as well as IGF1 and IGF-R and that estrogens and IGF1 markedly stimulate the proliferation of this cell line by acting on their specific receptors[44]. Specific antagonists of ER (Ici 182,780) and an IGF1-R blocking antibody (α-IR3), in fact, inhibit the proliferating effect exerted by estrogens and IGF1 respectively[44] These recent findings may explain why estrogens induce the formation and worsen the progression of hepatic cysts in ADPKD patients. On the basis of our findings, the hepatic cyst epithelium of ADPKD patients could be considered a sort of estrogen responsive tissue, where the interaction between female sex hormones and growth factors, like IGF1 and VEGF, play a key role in modulating the pathophysiology. This could open new perspectives in pharmacological treatment of polycystic liver disease based on estrogen antagonism or on the use of selective SERMs.

ESTROGENS AND CHOLANGIOCARCINOMA

Cholangiocarcinoma is a tumor with increasing incidence and prevalence, that still represents a diagnostic and therapeutic challenge. It is one of the cancers with the worst prognosis, with a median 5-years survival rate of 7%-8% from the diagnosis and a median survival time of only seven months. The diagnosis is generally established late and

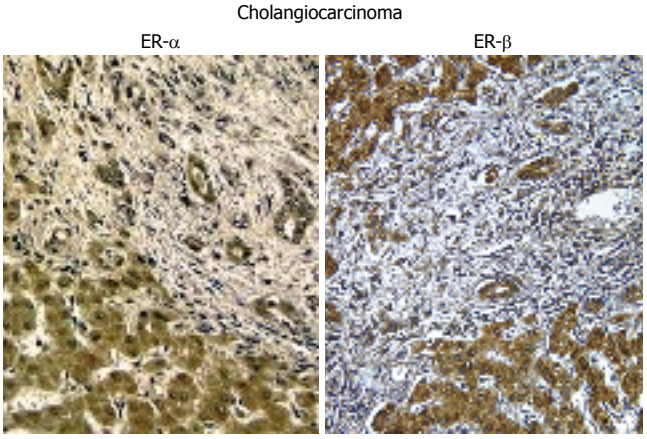

Figure 4 Immunohistochemistry for ER-α and ER-β. Biopsies of human cholangiocarcinoma showing an intense positivity for both ER-α and ER-β. Orig. magn., x 20.

surgery, when feasible, is the only effective treatment[86] Cholangiocarcinoma, in fact, shows a strong resistance to common chemotherapies and a treatment that slows the progression of the disease doesn't exist[86]. As for other cancers, an imbalance between proliferation and apoptosis leads to uncontrolled cell growth and expansion[37] We have recently shown, in human tissues and human cell lines, that estrogens play a key role in development and progression of cholangiocarcinoma[45]. Liver samples obtained from patients with intrahepatic cholangiocarcinoma were intensely positive for ER-α and ER-β subtypes (> 80% cholangiocarcinoma cells positive), while cholangiocytes of the normal liver were negative[45] (Figure 4). Interestingly, ER display both a cytoplasmic and nuclear staining, the latter being indicative of activated receptors[45]. When compared to benign cholangiocyte proliferation associated with non-neoplastic biliary disease (i.e. PBC, PSC), cholangiocarcinoma cells showed a higher expression of ER-α and increased ER-α/ER-β ratio[54] (Figure 2). This observation is in keeping with many different reports showing an increased ER-α/ER-β ratio in cancerous versus normal tissues, including ovary, prostate, colon and breast cancers[68]. In these tissues, primary events in neoplastic transformation and progression have been correlated with up-regulation ER-α and down-regulation of ER-β thus associating the function of ER-α subtype with a positive modulation of cell proliferation[68]. The opposite was suggested for ER-β[68]. Human intrahepatic cholangiocarcinoma also overexpress IGF1 and IGF1-R[45], another growth factor whose main source is liver and which is functionally linked with estrogens and their receptors[87,88]. IGF1 has been recently implicated in cancer development and progression since its serum concentrations correlate with an increased risk of breast, prostate, colorectal, pancreas and lung cancer[89-91] and, its receptor (IGF1R) is overexpressed in many tumor cell lines and in some human tumors. By studying a human intrahepatic cholangiocarcinoma cell line (HuH-28), similar to intrahepatic cholangiocarcinoma that over expresses ER-α, IGF1 and IGF1-R, we showed that IGF-1 and estrogens exert an additive proliferative effect[45] blocked by both ER antagonists (Ici 182,780) and IGF1-R blocking antibodies (α-IR3)[45]. Interestingly, IGF1-R seems to play a primary role also in the estrogen stimulation of neoplastic cell growth[45] since IGF1-R blocking antibody (α-IR3) partially inhibited the effects of 17β-estradiol and transfection of HuH-28 cell with IGF1-R antisense oligonucleotides caused a marked impairment of HuH-28 cells proliferation (90% decrease of PCNA expression)[45]. In estrogen sensitive tissues, a cross-talk between IGF1 and estrogen play a major role in the modulation of cell proliferation, where estrogens act at several points of the IGF signal transduction pathway[87]. Estrogens not only may regulate the expression of IGF1-R and IGF1-binding proteins but also that of crucial downstream proteins including IRS1, and the IGF1-R tyrosine kinase main substrate[88]. Finally, the signaling activated by estrogens and IGF-1 (Figure 1) may converge at different common transduction pathways, including ERK and phosphatidylinositol-3 kinase/Akt pathway[92,93], and this was observed in proliferating HuH-28 cells too. In addition, ER-α and IGF1-R, once activated coprecipitate and, their activation is potentiated by their coupling[45]. Nevertheless, estrogens can modulate other important mechanisms involved in cholangiocarcinoma growth such as COX-2[94]. These new evidences highlight the role of estrogens and IGF1 in regulating the growth of human cholangiocarcinoma and suggests that a therapeutic strategy based on the modulation of ERs and/or IGF1 system could be helpful for the management of this cancer.

CONCLUSIONS AND FUTURE PERSPECTIVES

In conclusion, recent studies support a relevant role of estrogens as modulators of benign (reactive) and neoplastic cholangiocyte proliferation[16,45,69,70]. In our hypothesis, estrogens act in concert with growth factors in sustaining the cholangiocyte proliferative machinery and in depressing apoptosis[41-43]. This may have a number of clinical implications for diseases involving the biliary epithelium, where cholangiocyte proliferation is a typical hallmark influencing disease progression[10]. As far as PBC is concerned, we believe that an impaired cholangiocyte response to estrogens characterizes the terminal ductopenic stages of the disease, where cholangiocyte proliferation is unable to balance for the enhanced apoptosis. On this basis, a SERM able to selectively stimulate the ER-α and conpemporarily depress the ER-β should be tested in controlled clinical trials. Furthermore, it is of interest that new generation SERMs, such as Idoxifene, play positive effects in controlling both the oxidative stress and fibrosis, which are foundamental processes in the progression of chronic cholestatic liver diseases[95-97]. As far as cholangiocarcinoma and ADPKD are concerned, pharmacological strategies aimed to inhibit estrogens binding to their receptors, to decrease their synthesis (by using aromatase inhibitors) and, finally, to down-regulate ERs protein levels (by using pure anti-estrogens such fulvestant), should be considered. Very recently an ER-X putative membrane associated estrogen receptor has been described in the brain and in the uterus[98]. Thus, further studies aimed to check the presence of this receptor subtype in cholangiocytes and to evaluate its role in the pathophysiology of the biliary tree are needed.

Abstract

The microvascular supply of the biliary tree, the peribiliary plexus (PBP), stems from the hepatic artery branches and flows into the hepatic sinusoids. A detailed three-dimensional study of the PBP has been performed by using the Scanning Electron Microscopy vascular corrosion casts (SEMvcc) technique. Considering that the PBP plays a fundamental role in supporting the secretory and absorptive functions of the biliary epithelium, their organization in either normalcy and pathology is explored. The normal liver shows the PBP arranged around extra- and intrahepatic biliary tree. In the small portal tract PBP was characterized by a single layer of capillaries which progressively continued with the extrahepatic PBP where it showed a more complex vascular network. After common duct ligation (BDL), progressive modifications of bile duct and PBP proliferation are observed. The PBP presents a three-dimensional network arranged around many bile ducts and appears as bundles of vessels, composed by capillaries of homogeneous diameter with a typical round mesh structure. The PBP network is easily distinguishable from the sinusoidal network which appears normal. Considering the enormous extension of the PBP during BDL, the possible role played by the Vascular Endothelial Growth Factor (VEGF) is evaluated. VEGF-A, VEGF-C and their related receptors appeared highly immunopositive in proliferating cholangiocytes of BDL rats. The administration of anti-VEGF-A or anti-VEGF-C antibodies to BDL rats as well as hepatic artery ligation induced a reduced bile duct mass. The administration of rVEGF-A to BDL hepatic artery ligated rats prevented the decrease of cholangiocyte proliferation and VEGF-A expression as compared to BDL control rats. These data suggest the role of arterial blood supply of the biliary tree in conditions of cholangiocyte proliferation, such as it occurs during chronic cholestasis. On the other hand, the role played by VEGF as a tool of cross-talk between cholangiocytes and PBP endothelial cells suggests that manipulation of VEGF release and function could represent a therapeutic strategy for human pathological conditions characterized by damage of hepatic artery or the biliary tree.

INTRODUCTION

Cholangiocytes are currently the object of extensive investigation since recent evidence demonstrates their involvement in different processes (secretion, absorption, proliferation, neoangiogenesis), which are fundamental for

the liver pathophysiology[1-4]. The metabolic and functional demands of cholangiocytes are sustained by the hepatic artery which forms a complex network of vessels, the peribiliary plexus, around the biliary tree[5-9].

The central role of liver vascularization in hepatic functions and the importance of microcirculation for liver zonal organization were developed in the 17th century by Marcello Malpighi[10] who first described the "acinus", a hexagonal structure of the liver parenchyma that was comparable with a glandular unit of the liver. This description correlates with the current concept of a liver morpho-functional unit, also termed "acinus", described by Rappaport in 1952[11]. A number of studies on liver vascularization clarified the typical microvascular architecture that supplies the biliary tree. This typical microvascular network runs along the intra- and extrahepatic biliary tree and, as previously mentioned, has been termed peribiliary plexus (PBP)[12,13]. The structural study of either the intrahepatic and extrahepatic PBP in the liver under normal conditions has been the subject of a number of studies using both two-dimensional and three-dimensional approaches[5,12,14,15].

Although it is well known that the liver has a dual blood supply from the hepatic artery (HA) and the portal vein (PV), controversies still remain concerning the distribution of hepatic arterial blood flow. It is generally accepted that terminal branching of the HA opens into sinusoids, as demonstrated by injection of dyes and vascular casting [5,16-24]. The question that remains is if the HA provides arterial blood directly to sinusoids[16,20-22,23,25] or rather runs in the portal tract stroma, thus feeding the PBP and the periportal plexus (PPP) to finally arrive at the sinusoids[26-30]. The presence of a double feeding to the sinusoids from the PV, at a pressure of 6-7 cm H_2O, and from the HA, at a pressure of 12-25 cm H_2O, has generated many studies in order to explain the prevalence of flow from the PV[31]. Arterio-portal anastomoses are mainly observed in terminal portal tracts[23] but other studies deny the presence of real arterio-portal venous anastomoses[16,27,32,33].

A number of reports indicate that structural changes of the biliary tree, associated with experimental models of liver damage or human pathologies, are followed by substantial adaptive modifications of the PBP. At the experimental level, the bile duct-ligated (BDL) rat has been widely used as a model of typical and selective cholangiocyte proliferation[9,34,35]. This model is characterized by a dramatic increase of cholangiocyte number which reaches 30% of the total parenchymal hepatic cells compared with 2% in the normal liver [36]. In order to investigate the adaptive changes of hepatic microvascular organization associated with an increased mass of the biliary tree following BDL, our group has used the method of vascular corrosion casts observed with Scanning Electron Microscopy (SEM). This technique provides the ability to follow the tiniest vessels in three dimensions and to distinguish arterial, capillary and venous vessels by surface characteristics[7,13,15,26,37]. As detailed above, this technique demonstrates how the evolution of PBP expansion follows the proliferation of biliary tree suggesting a role of proliferating cholangiocytes in sustaining, through the secretion of angiogenic factors, and the adaptive proliferation of their vascular supply. To this regard, recent reports demonstrate that cholangiocytes are an important source of vascular endothelial growth factor (VEGF) in the damaged liver and that VEGF secreted by cholangiocytes may play role in driving the adaptive changes of the PBP, which accompany the proliferation of the biliary tree. Therefore, cross talk between cholangiocytes and endothelial cells could be fundamental in determining the response of the liver to cholestatic damage[38].

In this manuscript, we review recent studies related to the physiopathology of hepatic microvasculature in experimental models of liver damage and discuss the biological and clinical implications.

BLOOD SUPPLY

The microvasculature organization was investigated in normal or BDL rats by means of the Scanning Electron Microscopy Vascular Corrosion Casts (SEMvcc) technique[9,15,35]. The casts of normal livers showed an even distribution of sinusoids closely surrounding portal spaces. In larger portal spaces the hepatic artery (HA) branches were always evidently smaller than the portal ones. In smaller portal spaces the HA was often difficult to visualize[12,13,39,40]. The terminal branches of the HA are always represented by either the extra- and intrahepatic Peribiliary Plexus (PBP) or the periportal plexus (PPP). In very small portal spaces a small capillary, representing the terminal branch of a HA, can continue the course of the arteriole and eventually run into the sinusoids. It must be pointed out that it has all the characteristics of a capillary as far as diameter and endothelial imprints are concerned. This typical microvascular organization around the extrahepatic and intrahepatic biliary tree takes origin from the HA[15]. Hepatic artery branches paralleled the divisions of the portal vein up to the interlobular vessels and always showed regular profile and spindle shaped endothelial nuclear imprints. The PBP and the PPP took their origin from both the HA and from short collateral vessels of larger arteries[13,39,42].

In larger portal spaces, the PBP is an anastomotic network between short collateral arterioles from arising from the same arterial branch. The network presents two layers only next to the hilum, being generally mono-layered. In smaller portal spaces the PBP is progressively reduced up to one single capillary[13,39].Capillaries are recognized by the poorly defined endothelial imprints and the irregular profile of the cast[37,43]. Sometimes, capillaries both from the PBP, the PPP as well as single capillaries, were more dilated than normal but always exhibited a smaller diameter than adjacent sinusoids[13,39]. The PPP can be recognized as a true net only in very large portal spaces. However, in other regions the PPP is represented by interstitial, isolated capillaries. In smaller spaces it is not possible to discern periportal from peribiliary capillaries[13,39].

The extrahepatic biliary tree shows a dense vascular network arranged around the circumference of the common bile duct[15]. Arterial and venous trunks are very easily distinguished by observing their different endothelial imprints on the cast surface. Two main layers

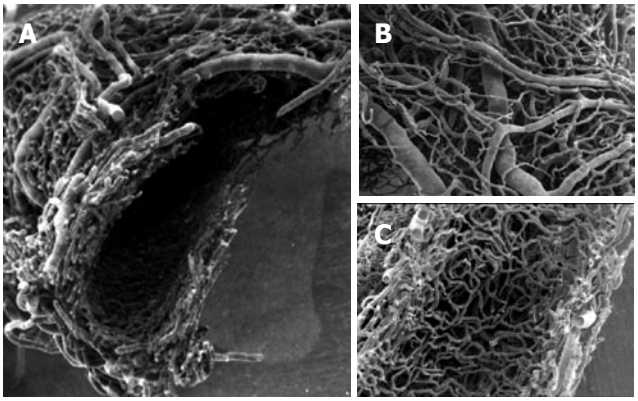

Figure 1 SEMvcc of normal rat liver (orig. magn., 20×). A dense vascular network is arranged around the circumference of the common bile duct. **A**: transverse section of Extrahepatic peribiliary plexus. Observe the arterial and venous vessels on the outer layer (**B**) and a dense capillary network in the inner layer of the plexus (**C**).

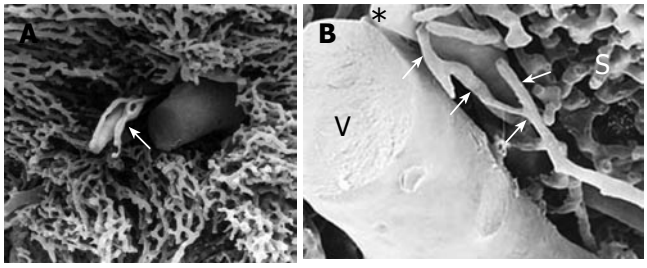

Figure 2 SEMvcc of normal rat liver (orig. magn., **A**: 40×; **B**: 110×). (**A**) small portal tract: PBP is characterized by a single layer of capillaries. (**B**) * = terminal hepatic artery, V = vena porta, arrows = peribiliary plexus, S = sinusoids.

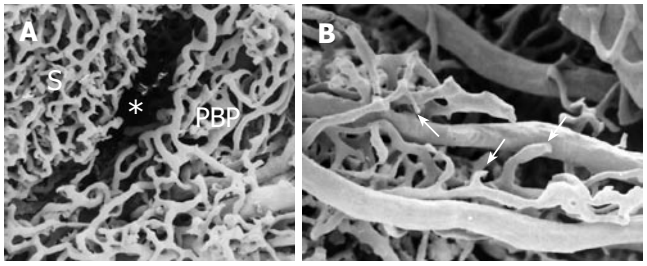

Figure 3 SEMvcc of BDL rat liver (orig. magn., **A**: 40×; **B**: 60×). (**A**) proliferated PBP run at the periphery of the lobule separated from the sinusoidal network (S) by an empty space (*) which corresponds to proliferating connective tissue. (**B**) not completely developed PBP with typical neovascular organization with dead end vessels (arrows).

were recognized in the cast. Closely meshed arterial and venous vessels formed the outer layer of the plexus and a dense capillary network in the inner layer (Figure 1). The arterial network (30-40 μm) ramifies into precapillaries. At the origin of some of precapillary vessels, an indentation produced by perivascular cells or the rearrangement of smooth muscle fibers can be observed[40,44]. The capillaries that originate from precapillary arterioles form a network plane organized in the same plane of the arterial and venous networks and in a deeper, denser and stratified capillary network. This capillary plane, if observed in its internal surface, exhibited well-delineated pits where the capillaries are arranged around a vascular space that, at LM observation, correspond to small acinar glands surrounded by thin capillaries. Large venous vessels can be observed at the same plane of the arterioles; these drained blood arising from both the superficial and inner capillary networks[15].

The extrahepatic PBP progressively continued with the intrahepatic PBP. It was composed of afferent arterial vessels and capillaries and was observed more easily in large portal tracts. In small portal tracts, the PBP was characterized by a single layer of capillaries that typically defined the periphery of the hepatic lobule (Figure 2).

PBP supports the bile epithelial function: the extension of the extrahepatic peribiliary tree underlies the ability of the bile duct to absorb water and electrolytes during the passage of bile through this collecting system[45]. Furthermore, the absence of the gallbladder in the rat emphasizes the role of EPBP in water reabsorption during the interdigestive phase[15]. Finally, the connection between the inner capillary venular plexus, portal venules and sinusoids, permits the transport of substances directly to the liver parenchyma where they can exert their actions. The reduction of complexity of the PBP inside the liver is strictly correlated with the progressive decrease of the diameter of the small bile duct, hence in the smaller portal tract the PBP can be reduced to only few capillaries[15].

Cholangiocyte proliferation started after BDL at the edge of the portal tract. During the first week from BDL the hepatic microcirculation did not show any alterations with respect to the normal liver. But after two weeks from BDL SEMvcc showed extention of the PBP from the portal tract. The proliferated PBP presented a three-dimensional net that did not arrange around a single lumen but delimited different troughs with a diameter of 20-30 μm. An empty space separated proliferated PBP and portal tract vessels from sinusoids. The sinusoids showed a normal organization with the typical structure of a classic lobule, in which sinusoids run evidently towards the central vein[9,13,15,24-26].

Three to four weeks after common BDL, a typical well-developed peribiliary microvascular plexus, originating from arterioles derived from hepatic arterial branches, is observed. The plexus runs at the periphery of the lobule and appears hypertrophic, but otherwise normal in its arrangement. The plexus is composed of many layers and shows an intimate meshed network, characterized by round loops, resembling the organization of the inner vascular layer of the extrahepatic peribiliary plexus (Figure 3A). Between the PBP and the sinusoidal network there is an empty space, which corresponds to proliferating connective tissue, digested during the casting procedure (Figure 3A). Infrequent vascular communications between the PBP and sinusoids are also visible. The efferent vessels that arise from the confluence of the capillaries form a small vein that tends to drain into the interlobular vein. In some areas of the liver the PBP does not seem to develop completely. In these areas there is a typical neoangiogenetic organization with interrupted vascular loops and dead-end vessels (Figure 3B). These structures may represent an attempt to increase metabolic exchange within the ductular lumen and PBP[45,46]. In contrast to the profound

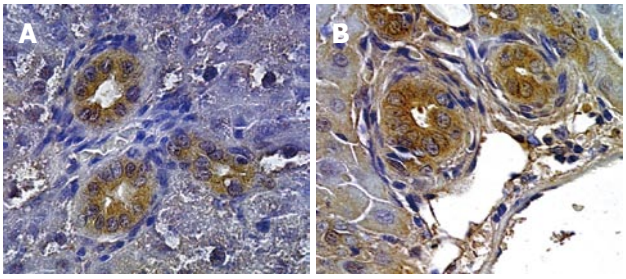

Figure 4 Immunohistochemistry for VEGF-A (**A**) and VEGF-C (**B**). Proliferating bile ducts in BDL rat show an intense positivity for both VEGF-A and VEGF-C (Orig. magn., 20×).

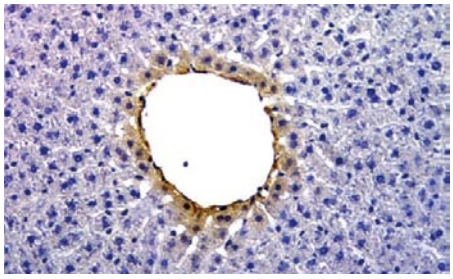

Figure 5 Immunohistochemistry for VEGF-A. Normal rat liver. The hepatocyte of pericentral zone shows positivity for VEGF-A (Orig. magn., 20×).

modification of the PBP, the sinusoidal organization remains quite normal even in BDL rats.

After BDL, the intrahepatic biliary epithelium undergoes cholangiocyte proliferation[48,50], which leads to bile duct mass expansion, followed by an adaptive proliferation of the PBP[9]. Proliferating bile ducts are characterized by enhanced cholangiocyte secretory and proliferative activities[47]. Cholangiocyte proliferation is modulated by a complex system of growth factors, neuropeptides and hormones[51-54]. Most of this information has been achieved in the BDL-rat model, which is characterized by cholangiocyte proliferation[55-57] followed by an adaptive proliferation of the PBP[9] that occurs after that of the intrahepatic biliary epithelium. Therefore, the adaptive proliferation of the PBP (and its circulating factors including VEGF) seems to be adequate for the increased mass of the bile ductal system.

VEGF REGULATION

Considering the enormous extension of the PBP during BDL, it is interesting to evaluate the possible role played by one of the most potent and well known angiogenic factors, the VEGF. VEGF is a member of a family of related growth factors that includes VEGF-A, -B, -C, -D, and -E, and placenta growth factor[58-61]. VEGF's role in vascular proliferation associated with tumour growth or wound healing has been widely documented in different organs[62]. The expression of VEGF and its receptors is not restricted to vascular endothelial cells, since their expression has been detected in vascular smooth muscle cells, osteoblasts, regenerating myotubes and hematopoietic stem cells[59-61,63]. Moreover, VEGF has also been secreted in a large number of normal epithelial cells, such as keratinocytes, goblet cells in nasal polyps, pulmonary cells, prostate cells, ductal cells derived from normal pancreas and also in normal hepatocytes[66-68]. Because cholangiocyte proliferation, as described above, is regulated by growth hormones, we investigated the expression of VEGF and its receptors in normal and proliferating biliary epithelia.

After immunohistochemistry of liver sections from normal and BDL rats, we found that intrahepatic cholangiocytes from both normal and BDL rats express VEGFR-2 and VEGFR-3 but not VEGFR-1[38]. This data was confirmed by immunoblot analysis in a purified cholangiocyte cell culture. Moreover, we found that intrahepatic cholangiocytes from normal and BDL rats express the protein for VEGF-A and VEGF-C[38]. Immunohistochemistry shows that the expression of VEGF-A and VEGF-C was higher in bile ducts from BDL rats (Figure 4) compared to bile ducts from normal rats[38]. In addition, we found VEGF in the supernatant of primary cultures of normal cholangiocytes, indicating that the intrahepatic cholangiocytes secrete VEGF. Following BDL, the amount of VEGF secreted by cholangiocytes into the supernatant significantly increased compared to the amount of VEGF secreted by normal cholangiocytes. In normal rat liver, pericentral hepatocytes show positivity for VEGF-A (Figure 5).

In order to confirm that VEGF plays an important role in the regulation of cholangiocyte proliferation, we also tested the effect of the administration of an anti-VEGF-A or an anti-VEGFC antibody to BDL rats. The administration of anti-VEGF to BDL rats induced an increased number of apoptotic cholangiocytes compared with BDL and a decrease in the number of PCNA and CK-19 positive cholangiocytes. In order to demonstrate that the proliferation of the PBP following BDL only occurs after cholangiocyte proliferation, we measured the number of PCNA-positive vascular endothelial cells and cholangiocytes in liver sections from rats with BDL for 1 or 2 wk. After BDL for 1 wk, PCNA was expressed only by proliferating cholangiocytes (and in rare hepatocytes), whereas endothelial cells were negative. In contrast, after BDL for 2 wk, both cholangiocytes and endothelial cells became positive for PCNA. This was confirmed by the immunohistochemical expression of Factor VIII-related antigen (a marker of endothelial cells)[69] in liver sections from normal, 1- and 2-wk BDL rats. The number of Factor VIII- related antigen positive cells increase, in comparison with normal rats, only after 2-wk BDL but it was unchanged after 1-wk BDL, thus confirming that the proliferation of PBP occurs after that of the biliary epithelium.

In addition, to better define the role of VEGF-A in the regulation of cholangiocyte and PBP proliferation during BDL we performed in: (1) normal rats and normal rats + hepatic artery ligation (HAL); (2) 1 wk BDL[4,5] rats; and (3) rats that (immediately after BDL or BDI + HAL) were treated by IP implanted with BSA or r-VEGF-A for 1 wk[70-73]. With the aim of evaluating PBP organization and the cholangiocyte VEGF protein expression, SEMvcc were performed. The peribiliary plexus, observed in BDL rats[9], was not demonstrated in BDL + HAL rats by the

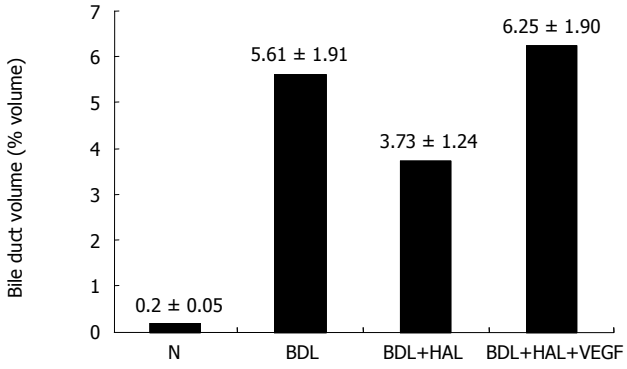

Figure 6 Effect of hepatic artery ligation and chronic administration of VEGF on bile duct volume.Bile Duct volume is measured as a volume fraction of the entire liver tissue specimen. HAL induced in BDL rats a disappearance of PBP and an impaired cholangiocyte proliferation. The effects of HAL on PBP and cholangiocyte functions were prevented by r-VEGF by maintaining the integrity of the peribiliary plexus and cholangiocyte proliferation.

SEMvcc technique. We did not observe PBP in BDL + HAL rats because the PBP is nourished by the HA. In normal rats, PBP was observed more easily in large portal tracts[9]. In small portal tracts, the PBP was characterized by single layer of capillaries or even by a single capillary; in BDL + HAL we do not observed PBP. Administration of r-VEGF-A to BDL + HAL rats prevented the HAL-induced microvascular modification (absence of PBP). The microvascular pattern observed after administration of r-VEGF-A to BDL + HAL rats demonstrated the presence of a PBP with similar characteristics previously described in BDL rats[9,70].

Immunohistochemistry in BDL liver sections shows that bile ducts express VEGF-A, VEGFR-2 and VEGFR-3. HAL induced a decrease in the number of cholangiocytes positive for VEGF-A and VEGFR-2 and VEGFR-3 receptors compared to liver sections from 1 wk BDL rats. Following the administration of r-VEGF-A to BDL + HAL rats, the expression of VEGF-A and VEGFR-2 and VEGFR-3 was similar or higher than that of BDL rats. VEGFR-1 was not expressed by cholangiocytes. These indicate that VEGF, predominantly by an autocrine mechanism, plays an important role in modulating cholangiocyte proliferation[70]. Furthermore, if we drastically reduced the HA blood flow in BDL rats by the HAL, we induced the absence of PBP, reduction of both VEGF and VEGF receptors at the cholangiocyte level and a reduction of bile duct mass with no induced effect in the liver of normal rats (Figure 6). Evidently, when the intrahepatic bile duct mass is expanded, as occurs after BDL[47], blood supply through the hepatic artery becomes fundamental in sustaining the enhanced nutritional and functional demands of proliferating intrahepatic biliary epithelium[9]. VEGF has been demonstrated to participate in a complex that sustains cholangiocyte proliferation after BDL[50]; therefore, concerning the effect of HAL on bile duct mass, the fall of synthesis and release of VEGF by cholangiocytes after HAL certainly has a role in compromising cell proliferation.

In conclusion, recent data highlights the role of arterial blood supply of biliary tree in conditions of cholangiocyte proliferation, such occurs during chronic cholestasis. On the other hand, the role played by VEGF as a tool of cross-talk between cholangiocytes and PBP endothelial cells suggests that manipulation of VEGF release and function could represent a therapeutic strategy for human pathological conditions characterized by damage of hepatic artery or the biliary tree.

Abstract

Cholangiocytes are exposed to high concentrations of bile acids at their apical membrane. A selective transporter for bile acids, the Apical Sodium Bile Acid Cotransporter (ASBT) (also referred to as Ibat; gene name Slc10a2) is localized on the cholangiocyte apical membrane. On the basolateral membrane, four transport systems have been identified (*t*-ASBT, multidrug resistance (MDR)3, an unidentified anion exchanger system and organic solute transporter (Ost) heteromeric transporter, Ostα-Ostβ. Together, these transporters unidirectionally move bile acids from ductal bile to the circulation. Bile acids absorbed by cholangiocytes recycle via the peribiliary plexus back to hepatocytes for re-secretion into bile. This recycling of bile acids between hepatocytes and cholangiocytes is referred to as the cholehepatic shunt pathway. Recent studies suggest that the cholehepatic shunt pathway may contribute in overall hepatobiliary transport of bile acids and to the adaptation to chronic cholestasis due to extrahepatic obstruction. ASBT is acutely regulated by an adenosine 3', 5'-monophosphate (cAMP)-dependent translocation to the apical membrane and by phosphorylation-dependent ubiquitination and proteasome degradation. ASBT is chronically regulated by changes in gene expression in response to biliary bile acid concentration and inflammatory cytokines. Another potential function of cholangiocyte ASBT is to allow cholangiocytes to sample biliary bile acids in order to activate intracellular signaling pathways. Bile acids trigger changes in intracellular calcium, protein kinase C (PKC), phosphoinositide 3-kinase (PI3K), mitogen-activated protein (MAP) kinase and extracellular signal-regulated protein kinase (ERK) intracellular signals. Bile acids significantly alter cholangiocyte secretion, proliferation and survival. Different bile acids have differential effects on cholangiocyte intracellular signals, and in some instances trigger opposing effects on cholangiocyte secretion, proliferation and survival. Based upon these concepts and observations, the cholangiocyte has been proposed to be the principle target cell for bile acids in the liver.

INTRODUCTION

In earlier studies of hepatobiliary physiology, it was generally concluded that biliary components do not appreciably interact with bile ducts and after canalicular secretion, bile acids and lipids pass through the biliary system as if bile ducts were inactive conduits[1]. Twenty-five years ago, the cholehepatic shunt pathway was proposed to explain the hypercholeretic nature of certain bile acids[2,3]. This hypothesis suggested that bile acids, in a protonated, uncharged form, undergo passive biliary absorption, followed by transfer of bile acids back to hepatocytes for re-secretion into bile (Figure 1)[2]. Later, other studies suggested that in the presence of complete bile duct obstruction, canalicular secretion of bile acids persists and bile acids may pass back through cholangiocytes to the circulation instead of the entering the intestine[4]. Subsequent to the discovery of the expression of a bile acid transporter on the apical membrane of cholangiocytes (apical sodium-dependent bile acid transporter or ASBT)[5-8], there has been renewed interest in the potential of cholehepatic shunting of bile acids. Cholangiocyte ASBT adapts to chronic cholestasis induced by bile duct obstruction by upregulation of cholangiocyte

transport capacity potentially leading to augmentation of cholehepatic shunting of bile acids and protection from cholestatic liver injury due to hepatocellular retention of bile acids[9].

Bile acids also interact with cholangiocytes leading to alteration of cholangiocyte secretion, proliferation, apoptosis and differentiation[7,8,10-12]. In both hepatocytes and stellate cells, bile acids when present intracellularly in low concentrations (e.g. less than 10 μmol/L) function as intracellular signals triggering wide variety of protein kinases, changes in intracellular Ca^{2+} and phosphorylation of proteins. Since bile acids do not appreciably enter cells in the absence of a membrane transporter, the expression of bile acid transporter is required for bile acid signaling, and the degree of bile acid transporter expression may determine the sensitivity of cells to bile acid signaling. Thus the bile acid transporter functions in some respects like a membrane receptor, determining both selective and sensitivity of the cell reactions to bile acid agonists. Bile acids, alter Ca^{2+}, cAMP, PKC and PI3K intercellular signaling systems in cholangiocytes. ASBT function was shown to be required for signaling and the level of ASBT expression correlated with cholangiocyte sensitivity to bile acids[7,8,10,13,14]. As a manifestation of the signaling properties of bile acids in cholangiocytes, studies show that bile acids may directly stimulate cholangiocyte proliferation and secretion[11,12] and thus accumulating bile acids due to chronic cholestasis may promote the ductal hyperplasia that occurs in chronic cholestatic liver disease. Changes in biliary bile acid composition or concentration may also modulate cholangiocyte survival[15,16]. Increasing biliary bile acid concentration, by bile acid feeding, reduces cholangiocyte apoptosis induced by CCl_4 or vagotomy in rats[15,16]. As another potential signaling function, bile acids may alter cholangiocyte differentiation, since small bile ducts following chronic exposure to bile acids begin expressing proteins and functions normally only present in large intrahepatic bile ducts[7]. Therapeutic bile acids (ursodeoxycholate), perhaps surprisingly, have opposing effects on cholangiocyte function compared to endogenous bile acids. Ursodeoxycholate appears to reduce cholangiocyte proliferation and reduce bile mass in animal models of bile duct hyperplasia[8]. The implications of these findings are discussed later.

The purpose of this review is familiarizing the reader in the role of bile acids in cholangiocyte biology and pathophysiology. Recent studies unexpectedly show that cholangiocytes transport bile acids and adapt to changes in biliary bile acids. Considering that one of the fundamental events in cholestasis is the retention in the liver of components that are normally secreted in bile, alternative pathways for elimination of biliary components would be an important adaptation of the liver to cholestasis. The review will outline mechanisms for bile acid transport in cholangiocytes, the role of bile acid regulation of cholangiocyte proliferation, secretion and apoptosis in animal models and human diseases. First the mechanisms for bile acid uptake at the cholangiocyte apical membrane will be reviewed. Second, basolateral bile acid efflux mechanisms are outlined. Third, the current evidence for cholehepatic shunting of bile acids is summarized.

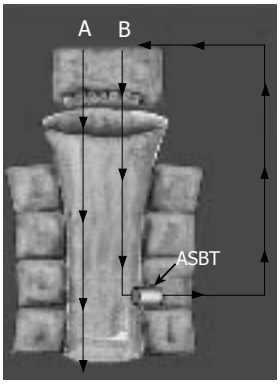

Figure 1 Classic cholehepatic shunt pathway (B) compared to direct biliary bile acid secretion (A). Bile acids that are poor substrates for coenzyme A (CoA) synthetase and inefficiently conjugated by hepatocytes are passively absorbed by biliary epithelium. After canalicular secretion, the unconjugated bile acid is absorbed by cholangiocytes because of the high lipophilicity of the protonated acid. The absorbed bile acid is returned to the hepatocyte mass *via* the periductular plexus. The osmotic effect of multiple passages of the unconjugated bile acid anions into canalicular bile results in hypercholeresis. The presence of ASBT on the apical membrane of cholangiocytes provides a potential mechanism for absorption of conjugated bile acids that then follows the same shunt pathway as described above.

Next the mechanisms responsible for acute and chronic regulation of ASBT activity in cholangiocytes are reviewed. Finally, the concept of intracellular bile acid acting as signaling molecules in cholangiocytes will be developed and the evidence for bile acid regulation of cholangiocyte secretion, proliferation and survival will be summarized.

CHOLANGIOCYTE BILE ACID UPTAKE

Although earlier studies have suggested bile acid uptake mechanisms were present in cholangiocytes, the identification of ASBT by Lazaridis *et al*[17] and Alpini *et al*[5] brought to the forefront the interest in bile acid transport in the biliary system. ASBT had previously been identified in ileum and kidney tubules[18] and ASBT has been proposed as the major transporter involved in the reclamation of bile acids in the intestine and in the nephron, respectively[18]. Studies by Alpini *et al*[5] showed the presence of gene expression for both the ASBT and ileal bile acid binding protein (IBABP) in cholangiocytes. Immunofluorescence studies showed that ABAT protein is expressed on the apical membrane of isolated cholangiocytes and isolated bile duct units (IBDU)[5]. Our studies showed the majority of [^{3}H]-taurocholate uptake is Na^+-dependent with a K_m of 43 μmol/L and a V_{max} of 190 pmol/min[5]. These values were lower compared to measurements by Lazaridis *et al*[17], however studies by Alpini *et al*[5] were performed in freshly isolated cholangiocytes (which may be a more physiological model) whereas those by Lazaridis were done in a rat cholangiocyte cell line. In addition, the kinetics for taurocholate uptake in freshly isolated cholangiocytes has a similar K_m and V_{max} as reported by other investigators for ASBT-mediated uptake in the ileum[19,20]. The K_m for a transporter is generally similar to the physiologic concentration of the transported substrate. The markedly lower K_m for ASBT in cholangiocytes compared to biliary bile acid concentration may be due to the effect of unstirred layer adjacent bile duct lumen membrane that would reduce the effective bile acid concentration immediately adjacent to the cholangiocyte apical membrane[21]. Lazaridis *et al*[17] demonstrated vectorial transport of bile acids from apical to basolateral direction and an absence of transport in the basolateral to apical direction in a normal rat cholangiocyte

cell line in a polarized culture system. No additional bile acid uptake proteins have as of yet been identified in the cholangiocyte apical membrane.

The natural substrate specificity of ASBT is narrow and restricted to unconjugated bile acids as well as their glycine- and taurine-conjugates[22]. ASBT appears to play a major role in the enterohepatic circulation of bile acids since dysfunctional mutations in the mouse or human ASBT genes cause profound bile acid malabsorption in humans[23]. In the renal tubule ASBT acts as a salvage mechanism to prevent urinary excretion of bile acids that undergo glomerular filtration. The role of ASBT in bile ducts is not as obvious as in the intestine and kidney. We have proposed that ASBT functions in a cholehepatic shunt where bile acids are absorbed in the biliary tract, secreted into the periductular capillary plexus, and carried directly back to the hepatocyte for secretion, thereby promoting bile flow. Alternatively, ASBT may function to sense bile acid concentration in bile, a mechanism that is dependent on bile acid uptake by ASBT and bile acid-dependent activation of intracellular signaling systems in cholangiocytes. The principles of cholehepatic shunting and bile acid signaling are discussed in a later section.

Intracellular bile acid movement in cholangiocytes

In hepatocytes, cytosolic binding proteins have been shown to sequester bile acids in a bound state that may prevent the cytotoxicity of free intracellular bile acids[24,25]. The presence of high affinity binding sites would significantly reduce the rate of transcellular transport of bile acids. Indeed, previous studies have shown that the transcellular transport comprises the greatest proportion of time in the overall transcellular transport of conjugated bile acids in hepatocytes[26].

The ileal bile acid binding protein (IBABP) is expressed in cholangiocytes[5]. Very little is known as to whether it functions to prevent intracellular toxicity, modulates transcellular transport or it changes in expression in response to increased bile acid flux in cholangiocytes or in the presence of cholestasis. Recent studies show expression of IBABP in the ileum is regulated by bile acid concentrations through the effects of farnesoid X receptor[27].

Bile acid efflux in cholangiocytes

Since Lazaridis *et al*[17] studies have shown that bile acid transport in cholangiocytes is vectorial (e.g. apical-to-basolateral), mechanisms are likely present in the basolateral membrane that facilitates the efflux of bile acids into peribiliary plexus circulation. Four mechanisms have been identified in previous studies that together account for bile acid efflux in cholangiocytes. The first mechanism was identified employing bile duct fragments. The studies showed that fluorescent bile acid analogs can be taken up across the cholangiocyte basolateral membrane[28]. The uptake process involved an anion exchanger mechanism that was identified by inhibition of bile acid uptake in the absence of Cl^- or HCO_3^- or the presence of 4, 4'-diisothiocyanostilbene-2, 2'-disulfonic acid[28]. Although the authors studied uptake across the basolateral membrane in their model, they proposed that their studies reflected physiologically an anion exchanger that effluxes bile acids out of cholangiocytes subsequent to apical uptake. The protein responsible for this anion exchanger was not identified.

The second mechanism for bile acid efflux was identified by Lazaridis *et al*[6]as an exon-2 skipped, alternatively spliced form of ASBT, designated *t*-ASBT. Alternative splicing causes a frameshift that produces a 154-aa protein. *T*-ASBT is expressed in rat cholangiocytes, ileum, and kidney and is localized to the basolateral domain of cholangiocytes[6]. Transport studies in *Xenopus* oocytes revealed that *t*-ASBT functions as a bile acid efflux protein. Compared to ASBT, alternative splicing changes the cellular targeting of ASBT provides a mechanism for rat cholangiocytes to efflux bile acids at the basolateral membrane[6]. The regulation of *t*-ASBT expression in response to biliary or circulatory bile acid concentrations or in the presence of cholestasis has not been determined. The regional distribution of *t*-ASBT in large and small ducts is not known. The third mechanism for bile acid efflux in cholangiocytes is MDR3. Previous studies have shown that MDR3 is expressed on the basolateral membrane of cholangiocytes and MDR3 is upregulated in chronic cholestasis associated with type 3 progressive familial intrahepatic cholestasis[29]. It has been proposed that up-regulation of MDR3 may promote cholehepatic shunting in chronic cholestasis, thus preventing the toxic effects of accumulating bile acids in cholangiocytes[29]. Similar upregulation of MDR3 in hepatocyte basolateral membranes has been proposed to pump bile acids out of hepatocytes with canalicular cholestasis[30] and MDR3 is upregulated in patients with Dubin-Johnson syndrome[31]. There is no direct evidence that shows MDR3 effluxes bile acids in cholangiocytes or provides a mechanism for prevention of accumulation of bile acids in cholangiocytes during cholestasis.

Recently the Ostα-Ostβ heteromeric transporter was initially identified in the liver, ileum, and kidney[32]. In contrast to all other organic anion transporters identified to date, transport activity requires the coexpression of both Ostα and Ostβ proteins. Substrates for this transporter include the bile acid taurocholate, other steroids (estrone 3-sulfate and digoxin), and prostaglandin E2[33]. Ostα and Ostβ mRNA expression along the mouse gastrointestinal tract mirrors that of ASBT, and both Ostα and Ostβ proteins are localized to the basolateral surface of ileal, renal and bile duct cells[32]. Studies of bile acid transport in Ostα and Ostβ expressing *Xenopus laevis* oocytes showed bile acid efflux and trans-stimulation, indicating that transport occurs by facilitated diffusion. The selective localization of Ostα and Ostβ to the basolateral plasma membrane of epithelial cells responsible for bile acid and sterol reabsorption, the substrate selectivity of the transporter, suggest that heteromeric Ostα and Ostβ is an important basolateral bile acid transporter in biliary, ileal and renal epithelial cells.

Cholehepatic shunting of bile acids

Hoffman proposed bile acids may cycle between cho-

langiocytes and hepatocytes through a cholehepatic shunt pathway[3]. Unconjugated bile acids[34] or non-charged bile acids (norursodeoxycholate)[34] were observed to induce a greater degree of bile flow per bile acid molecule excreted in bile. To account for this hypercholeretic effect, it was proposed that unconjugated bile acids may be passively absorbed by bile ducts; enter the peribiliary plexus adjacent to intrahepatic bile ducts, then forwarded to the hepatic sinusoids to be returned to cholangiocytes by hepatocyte secretion[3]. Typically, cholehepatic shunting initiated by passive absorption of non-ionized bile salt results in the generation of bicarbonate molecules in bile, which then increases biliary bicarbonate excretion. Other criteria for cholehepatic shunting besides hypercholeresis and alkalinization of bile have been identified. With the hypercholeresis, the biliary transit time for the unconjugated or non charged bile acids was greater than expected which would be predicted by longer retention time in the liver due to more than one passage through the hepatobiliary axis[34]. Back perfusion of the isolated perfused liver (infusion into the hepatic vein), a route where the blood from the peribiliary plexus does not appreciably enter the hepatic sinusoids, reduced the hypercholeretic effect of ursodeoxycholic acid[35]. Increased number of bile ducts in animal models of cirrhosis was associated with increased hypercholeresis due to ursodeoxycholic acid infusion, an observation that was attributed to increased cholehepatic shunting due to increase bile duct mass[36]. Similarly, bile duct proliferation in Mdr2(-/-) mice is associated with a disproportionably high bile flow in response to tauroursocholate acid infusion, a finding that was interpreted as due to enhanced cholehepatic shunting of bile salts due to increased number of bile ducts. The magnitude of absorption of bile acids under physiologic or pathophysiologic conditions in man is not known.

Identification of apical and basolateral bile acid transport proteins in cholangiocytes, points to the possibility that the cholehepatic shunt pathway functions in bile secretion and may adapt in response to cholestasis. From a functional point of view, the pathway provides a mechanism to enhance bile acid-dependent bile flow and biliary lipid excretion. With multiple passages of bile acids through the canalicular membrane (as a result of recycling through cholangiocytes), the cholehepatic shunt pathway has the potential to increase the efficiency of bile acid-induced biliary lipid excretion and bile acid-dependent bile flow[3]. From the pathophysiologic point of view, the pathway provides an alternative route for continuation of hepato-cholangiocyte flux of bile acids despite the presence of complete bile duct obstruction[37]. The latter may well be an important pathophysiologic response of the liver to bile duct obstruction.

In support of ASBT initiating cholehepatic shunting, our studies[38] have shown that following the administration of secretin to bile duct ligated rats, there is acute upregulation of ASBT in cholangiocytes (as described in the next section). With secretin stimulation of ASBT activity in cholangiocytes, there is a marked increase in taurocholate-induced choleresis (12 ± 2 μL per μmol bile acid excreted with basal cholangiocyte ASBT activity compared to 38 ± 6 μL per μmol bile acid excreted during high cholangiocyte ASBT activity). Similarly, with experimental augmentation of cholangiocyte ASBT activity, taurocholate induces a much greater increase in biliary phospholipid (1.5-fold increase in μmol phospholipid per μmol bile acid excreted compared to basal) and cholesterol secretion (2-fold increase in μmol cholesterol per μmol bile acid excreted compared to basal). Finally, following the administration of secretion, the taurocholate transit time is increased by 7 min. The taurocholate-induced hypercholeresis, increased biliary lipid excretion and increased taurocholate transit time are consistent with enhanced taurocholate cholehepatic shunting due to up regulation of ASBT by secretin. Additional studies will be needed to establish the degree of cholehepatic shunting of conjugated bile acids in normal rats.

OVERVIEW OF THE REGULATION OF ASBT EXPRESSION IN CHOLANGIOCYTES

Alteration of bile acid transporter activity may occur physiologically in response to local bile acid concentrations to fine tune bile acid transport capacity. For instance, ASBT has been shown by some studies to be upregulated in the ileum with increased intestinal bile concentration[39], so as to provide increased intestinal bile acid transport activity in response to increased intestinal bile acid load. Alternatively, bile acid transporter expression may be chronically modified in pathologic conditions to prevent intracellular accumulation of toxic bile acids due to altered bile acid metabolism or retention[40]. For instance, in chronic cholestasis due to bile duct obstruction, there is downregulation of hepatocyte sinusoid transporters and upregulation of hepatocyte canalicular transporters that provides the combined effect to reduce hepatocyte intracellular retention of bile acids that occurs with cholestasis[41]. Regulation of bile acid transporters may also occur regionally within anatomical confines of an organ. For instance, ASBT expression is present exclusively in the distal ileum (and not proximal small bowel)[42], restricted to the mature enterocytes lining the villus, with little or no detectable expression in the small intestinal crypt. Sinusoidal transporters are present to a greater degree in the periportal region compared to the pericentral region of the hepatic lobule[41]. Temporally, regulation of bile acid transporters has been shown to occur gradually through changes in gene expression[39,40,43,44], or acutely by changes in cell membrane transporter content by transporter translocation[45,46] or by changes in the rate of protein degradation.

Acute regulation of ASBT in cholangiocytes

Previous studies have shown that ASBT transport activity acutely increases in cholangiocytes and ileal epithelial cells by a cAMP-dependent mechanism[38,47]. In cholangiocytes, increased cAMP induced by secretin doubles Na^+-dependent bile acid uptake in isolated cholangiocytes[38] and in perfused bile duct fragments[48]. This effect is likely due to protein translocation, since pretreatment of cholangiocytes with the microtubule inhibitor colchicine prevents the cAMP-induced increase of Na^+-dependent

bile acid transport[38]. The effects of secretin on protein translocation of ASBT to the apical membrane of cholangiocytes were studied employing isolated apical membranes from cholangiocytes[38]. These studies showed that cAMP increases apical membrane ASBT only in the absence of colchicine. A model for cAMP-dependent recycling of ASBT in the cholangiocyte apical membrane is shown in Figure 2. The model shows that cAMP increases apical ASBT membrane content, but also suggests that ASBT recycles back to latent intracellular stores once the secretin/cAMP stimulus has abated. This mechanism for acute induction of ABAT activity in cholangiocytes has been proposed to provide an accentuation of cholehepatic bile acid shunting in the postprandial period, thus accentuating bile flow and biliary lipid secretion (see cholehepatic shunting section above)[38].

Chronic regulation of ASBT expression in cholangiocytes

ASBT expression in cholangiocytes changes chronically in response to biliary bile acid concentrations, the presence of cholestasis[7-9,15] or inflammation. With increase in biliary bile acid concentration, due to feeding taurocholate to rats, there is an increase in total liver ASBT[7]. In this model, the increased ASBT is due to both increased number of cholangiocytes in the liver and the maintenance of ASBT expression per cell. In bile duct ligated rats depleted of biliary bile acids for 12 h by external biliary drainage, there is a marked decrease in cholangiocyte ASBT gene and protein expression and transport activity[49]. ASBT gene and protein expression and transport activity can be restored in bile-depleted rats by infusion of taurocholate to maintain biliary bile acid concentration[49]. These studies employing bile acid feeding and bile acid depletion show that ASBT expression in cholangiocytes is chronically regulated in a direct proportion to biliary bile acid concentration. In contrast to taurocholate feeding which increases cholangiocyte ASBT expression, feeding ursodeoxycholic acid to bile duct ligated rats markedly reduces cholangiocyte ASBT gene and protein expression and taurocholate transport activity[8]. Although the mechanism for differential effects of different bile acids on ABAT expression in cholangiocytes has not been defined; they are consistent with our studies showing differential effects of different bile acids on cholangiocyte secretion and proliferation (see below).

With chronic cholestasis due to bile duct ligation, intrahepatic bile ducts markedly increase in number (approximately 10 fold increase after 1 wk). In this model, ASBT expression per cholangiocyte is maintained[9], so that overall there is an effective increase in biliary bile acid absorptive capacity in BDL rats. We propose that the increased ASBT in BDL rats provides an alternative excretory pathway in the presence of biliary obstruction so as to prevent the bile acid stasis in the liver and the subsequent accumulation of toxic bile acids in hepatocytes[9].

Recently it was demonstrated that bile acids modulate ASBT expression through activation of the peroxisome proliferator-activated receptor alpha (PPARalpha)[18] and activator protein 1 (AP-1) element regulates the transcription of the rat ASBT gene[44].

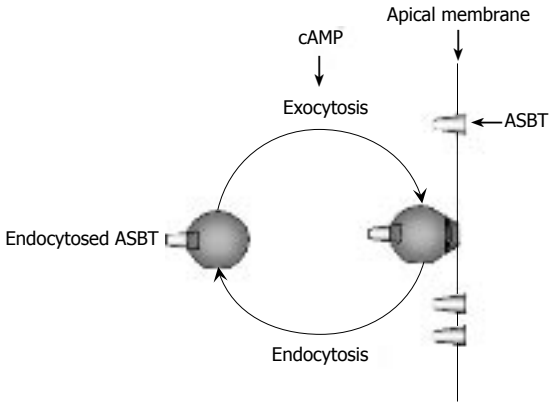

Figure 2 Membrane recycling of ASBT. Increased cAMP enhances bile acid uptake in cholangiocytes. Under basal conditions, intracellular ASBT resides in an inactive position within the cytoplasm of cholangiocytes as well as on the apical membrane. Increased cAMP results in translocation of ASBT to the apical membrane where it inserts by exocytosis. Once on the apical membrane, ASBT becomes active and mediates absorption of bile acids from bile. Membrane recycling of ASBT is completed by removal of ASBT from the apical membrane by endocytosis.

Previous studies have shown that the stress induced alteration of ASBT genetic expression due to inflammation and bile acids is a consequence of trans-activation of the ASBT promoter by c-Jun/c-Fos and liver receptor homologue-1, respectively[10,47] and that hepatocyte nuclear factor-1α is critical for basal expression of ASBT.

Recently, the inflammatory cytokine IL-1β has been shown to rapidly down-regulate ASBT in the terminal ileum[50]. Dysregulation of the ASBT adaptation to cholestasis (due to increased expression of IL-1β) could blunt the compensatory up-regulation of ASBT in response to cholestasis and promote bile acid-induced liver damage. Recent data demonstrates that the ubiquitin-proteasome degradation system affects the activity of some membrane transporters[51,52]. The system is responsible for the disposal of many of the short-lived proteins in eukaryotic cells. The ubiquitin-proteasome pathway targets proteins for degradation *via* covalent tagging of the substrate protein with a polyubiquitin chain[53]. This degradation pathway is implicated in the regulation of many short-lived proteins involved in essential cellular functions, including cell cycle control, transcription regulation, signal transduction, and protein translocation. We speculated that the initial ASBT down-regulation due to ileal inflammation or due to IL-1β *in vitro* is caused by enhanced ASBT disposal by the ubiquitin-proteasome pathway. Our studies showed that ASBT is an unstable protein that is rapidly degraded with a half-life of approximately 6 h. We showed that the rapid IL-1β -dependent reduction of ASBT in cholangiocytes is due to increased ASBT disposal *via* the ubiquitin-proteasome pathway. IL-1β mediated down-regulation of ASBT expression requires phosphorylation of ASBT since mutation of two ASBT phosphorylation sites reduces the rate of ASBT disposal under basal conditions and markedly reduces IL-1β -dependent ubiquitination and disposal of ASBT. These results indicate that the proteasome plays an important role in the regulation of ASBT protein level in cholangiocytes.

Regional ASBT expression in the biliary tree

Regionalization of bile duct function occurs in rat liver[5]. Large (greater than 20 μm diameter bile ducts) that are lined by large cholangiocytes contribute to hormone-induced ductal secretion whereas small (smaller than 20 μm diameter bile ducts) do not contribute to hormone-induced ductal secretion[54,55]. Studies by Alpini *et al*[5] showed that ASBT is expressed in large cholangiocytes but not small cholangiocytes. The absence of ABST expression in small intrahepatic bile ducts may lead to more efficient hepatobiliary excretion of bile acids, since bile acid uptake in small ducts, closely adjacent to the canalicular bile acid secretion process, may hinder the post canalicular assembly of polymolecular bile acid-lipid micelles and vesicles. Recently, experimental models have been developed where ASBT gene, and protein expression and transport activity have been shown to extend into small bile ducts[7]. In taurocholate fed rats, a model where biliary bile acid concentrate increases approximately two fold, Alpini *et al*[7] found *de novo* ASBT expression in small ducts. The authors suggested that with expansion of the bile acid pool and increased biliary bile acid concentration, the extension of ASBT expression into small ducts leads to enhanced cholehepatic shunting of bile acids. Whether ASBT expression in small ducts alters bile acid-lipid micelles or vesicle formation has not been determined.

BILE ACID SIGNALING IN CHOLANGIOCYTES

Overview

In a variety of cells, bile acids have been shown to function as intracellular signals and to profoundly alter cellular functions such as proliferation, differentiation, secretion, and apoptosis[56-61]. These studies have shown that cellular uptake is required for bile acids to signal cellular processes. In cells not expressing a bile acid transporter, (which normally do not respond to the presence of bile acids in the media) experimental expression of a bile acid transporter activates *de novo* bile acid signaling[62]. Once intracellular, bile acids at concentrations of less that 1 μmol/L, have been shown to alter intracellular Ca^{2+}, PKC, MEK, ERK and PI3K pathways in hepatocytes or cholangiocytes[16,59,61,63-66]. Through these downstream signals, bile acids have been shown to alter cell proliferation, secretion, apoptosis and gene expression[8,16,61,63-67]. In addition, bile acids have been shown to induce activation (by phosphorylation) of the EGF receptor in hepatocytes[64] and cholangiocytes[68]. The signaling effects of bile acids should be distinguished from the toxic effects of bile acids, where bile acid in high concentration, through changes in membrane lipids induces, in a nonspecific manner, cellular damage[69].

Bile acid signaling of cholangiocyte secretion

It had previously been observed that ursodeoxycholic acid increases biliary bicarbonate excretion into bile. Shimokura *et al*[66] found that ursodeoxycholic acid directly increases cholangiocyte secretion. They demonstrated ursodeoxycholic acid increases intracellular Ca^{2+} and increases chloride channel activity in a malignant cholangiocyte cell line[66]. The ursodeoxycholate effect on chloride channel activity was dependent on the increase in intracellular Ca^{2+}. Our studies have shown that in freshly isolated cholangiocytes, taurocholic acid or taurolithocholic acid (1-20 μmol/L) increases secretin-stimulated cAMP levels and secretin-stimulated Cl^-/HCO_3 exchanger activity[12]. These effects were dependent on taurocholate uptake by ASBT, since the stimulatory effect of taurocholate was not present in the absence of Na^+[12]. Dependence of bile acid effects on cholangiocyte secretion and ASBT transport activity, we found the K_m for ASBT in cholangiocytes to be close to the concentration where in bile acids exert their maximum response in cholangiocytes[12]. Similar to their effect *in vitro*, taurocholate or taurolithocholate feeding to normal rats for 7 d increased secretin-stimulated cAMP and Cl^-/HCO_3^- exchanger activity in cholangiocytes and resulted in an increase of secretin-stimulated ductal bile flow *in vitro*[7]. The studies show that both *in vitro* and *in vivo*, bile acids can augment secretin-stimulated ductal bile flow but the intracellular signals responsible for this effect have not been completely elucidated. Recently, cAMPindependent, bile activation of CFTR was shown to be present in ileal cells[70]. Like cholangiocytes, ASBT-dependent bile acid uptake was required for CFTR activation but the molecular mechanism for CFTR activation was not disclosed in this study.

In contrast to the stimulatory effects of taurocholate and taurolithocholate, ursodeoxycholate inhibits secretin-stimulated cAMP synthesis and Cl^-/HCO_3^- exchanger activity in isolated cholangiocytes and secretin-stimulated ductal bile flow *in vivo*[8]. Inhibition of cholangiocyte secretion by ursodeoxycholic acid was found to be dependent on the ability of ursodeoxycholic acid to increase intracellular calcium and activate PKCalpha in cholangiocytes[8]. We have proposed that the stimulatory and inhibitory effects of taurocholate and ursodeoxycholate, respectively on cholangiocyte secretion is due to their differing ability to activate intracellular Ca^{2+} and to activate different PKC isoforms[8].

Bile acid signaling of cholangiocyte proliferation

In vitro, taurocholate and taurolithocholate in 1-20 μmol/L concentrations increase H_3-histone expression (a maker of cholangiocyte proliferation)[12]. Feeding taurocholate or taurolithocholate to rats increases ^{3}H-thymindine uptake in cholangiocytes, increases bile duct mass 2 to 3 fold[11] and consistent with a ductal hyperplasia there is accentuation of secretin-stimulated cAMP synthesis and ductal bile flow. The effects of taurocholate and taurolithocholate on bile duct proliferation in the bile acid feeding models occur in the absence hepatic inflammation[11]. Recent studies[68] show that taurocholate can induce phosphorylation of EGF receptor in cholangiocytes, similar to that reported in hepatocytes[64] and the transactivation of the EGF receptor requires transforming growth factor alpha and matrix metalloproteinase[71].

In contrast to taurocholate and taurolithocholate, ursodeoxycholate inhibits cholangiocyte proliferation both *in vitro* in isolated cholangiocytes and *in vivo* in bile duct

ligated rats[8]. The inhibition of cholangiocyte proliferation was found to be dependent on activation of PKCalpha and calcium-dependent pathways[8]. The inhibitory effect of ursodeoxycholate on cholangiocyte proliferation may be one mechanism for the histological and biochemical improvement of diseases targeting the biliary tree (e.g. primary biliary cirrhosis) with ursodeoxycholate treatment. Inhibition of cholangiocyte proliferation may reduce the number of proliferating cholangiocytes that release proinflammatory cytokines[72] or profibrotic signaling molecules such as platelet-derived growth factor[73]. The lack of therapeutic effect for ursodeoxycholic acid in the late stage primary biliary cirrhosis may be at least partially related to lack of proliferating ducts (e.g. ductopenia) as the disease progresses[74]. In a cholangiocarcinoma cell line, we demonstrated that ursodeoxycholic acid inhibits growth by inhibition of Raf through PKC-dependent mechanism[13]. This study supports the need for clinical trials examining the effect of ursodeoxycholic acid in the promotion and progression of cholangiocarcinoma in patients with primary sclerosing cholangitis.

Bile acid signaling of cholangiocyte death and survival pathways

Previous studies in hepatocytes have shown bile acids may be either cytotoxic[75-78] or cytoprotective[79]. Bile acid cytotoxicity may be induced by abrupt permeability of the inner mitochondrial membrane to ions leading to mitochondrial membrane permeability transition (MMPT), depolarization of the mitochondrial membrane potential and uncoupling of oxidative phosphorylation[80]. The uncoupling of oxidative phosphorylation, if extensive, results in ATP depletion and cellular death by necrosis[80]. Furthermore, the associated mitochondrial swelling has also been linked to redistribution of cytochrome c from the intermembrane space to the cytosol. In the cytosol, cytochrome c interacts with apoptotic protease-activating factor 1 to activate caspase 9 and subsequently to cause apoptosis[81]. Bile salt-induced hepatocyte apoptosis also entails activation of the Fas death-receptor and subsequent activation of caspase 8 followed by activation of Bid which leads to mitochondrial dysfunction[75].

Alternatively, bile acids may provide cytoprotective effects. Heuman *et al*[82] proposed that the protective effect of ursodeoxycholic acid in opposing the hepatotoxicity of bile acids was due to its direct interaction with plasma membranes of hepatocytes. Ursodeoxycholic acid may provide membrane stability *via* a physicochemical effect by reducing the toxic bile salt disruption of cholesterol-rich model membranes[82]. More recent studies, revealed that ursodeoxycholic acid does not directly stabilize membranes but rather prevents hydrophobic bile acid-induced membrane disruption by alteration of the structure and composition of mixed micelles[83].

In cholangiocytes, Benedetti *et al*[78] showed that *in vitro*, unconjugated but not conjugated bile acids induce ultrastructural evidence of cytotoxicity. These findings were not observed *in vivo*. Even taurine depleted livers did not show evidence of cytotoxicity despite having high concentration of unconjugated bile acids in bile[78]. The authors concluded that bile acid toxicity, although potentially present in biliary epithelium, is prevented in the intact liver by the presence of active bile acid transport in cholangiocytes.

Our studies have shown that taurocholate feeding is protective against cholangiocyte apoptosis induced by either CCl_4[16] or vagotomy[15]. In CCl_4 treated animals, cholangiocyte apoptosis, demonstrated by the presence of nuclear fragmentation, positive annexin staining and loss of cholangiocyte function (secretin-stimulated cAMP synthesis), was not observed in CCl_4-treated rats that were fed taurocholate[16]. Similarly, CCl_4-induced apoptosis *in vitro* was ablated by pretreating cholangiocytes with 20 μmol/L taurocholate. The taurocholate inhibition of CCl_4-induced apoptosis required activation of PKCalpha[16]. Taurocholate feeding also prevents vagotomy induced cholangiocyte apoptosis[15]. In the vagotomy-induced model, apoptosis is associated with loss of PI3K activity and activation of caspase activities[15]. Taurocholate feeding prevented cholangiocyte apoptosis, loss of PI3K activity and activation of caspase activity. Thus, taurocholate is protective against CCl_4- and vagotomy-induced cholangiocyte apoptosis by activation of the PKC and PI3K-dependent pathways, respectively.

Feeding ursodeoxycholate inhibits the ductal hyperplasia in BDL rats, however these studies showed that the effect of ursodeoxycholate was on inhibition of proliferation without increasing cholangiocyte apoptosis[8]. In contrast, Que *et al*[84] showed that ursodeoxycholate inhibits beauvericin-induced apoptosis in a cholangiocarcinoma cell line and that the inhibition was dependent on preventing cytochrome C release from mitochondria and subsequent activation of caspases.

BILE ACID SYNTHESIS AND CONJUGATION IN CHOLANGIOCYTES

Bile acids, phospholipids and cholesterol are synthesized in a cholangiocarcinoma cell line[85]. Cholangiocytes have also been shown to conjugate bile acids[85]. The contribution of cholangiocyte bile acid synthesis and conjugation to the over all bile acid pool seems minimal since less than 3 percent of the total liver mass is composed of cholangiocytes[86].

Our preliminary data suggests that bile acid synthesis through the alternative (mitochondrial) pathway by cholesterol 27-hydroxylase (Cyp27) maybe important in the regulation of cholesterol transport and prevent cholesterol toxicity due to oxysterols in cholangiocytes[87]. Oxysterols (which increase with a higher cell cholesterol pool) are cytotoxic to smooth muscle and endothelial cells and are potentially carcinogenic.

Oxysterols are present in bile, have been shown to induce cholangiocyte apoptosis and may be carcinogenic in biliary epithelium by increasing expression of COX-2[88]. The mechanisms for preventing oxysterol lipotoxicity in cholangiocytes are unknown. Our preliminary studies show normal rat cholangiocytes express the cholesterol transporters ATP binding cassette subclass A (ABCA1) on the basolateral membrane and Niemann-Pick C1 Like

1 (NPC1L1) on the apical membrane[87,89]. The nuclear receptors involved in sensing lipids liver X receptor β (LXRβ) and peroxisome proliferator-activated receptor δ (PPARδ) and Cyp27 are abundantly expressed in cholangiocytes[87]. Activation of LXRβ, PPARδ, or both in cholangiocytes induces ABCA1 gene and protein expression and increases basolateral excretion of cholesterol. Added oxysterols activate LXR expression and increase basolateral membrane cholesterol efflux. Elevated bile acid levels decrease CYP27 expression. Cholangiocytes absorption of cholesterol at the apical membrane is dependent on the expression of NPC1L1, a cholesterol transporter recently shown to be required for cholesterol absorption in the intestine. Like ABCA1, NPC1L1 is upregulated by PPARδ ligands. We propose that upregulation of CYP27 leads to production of oxysterols, which then activate LXR and cholesterol efflux in cholangiocytes. These studies identify a potential reverse cholesterol transport pathway in cholangiocytes regulated by the cholangiocyte cholesterol and bile acids pools. We propose, like the reverse cholesterol transport involving macrophages, cholesterol or oxysterols taken up from bile by cholangiocytes is released into the circulation return to hepatocytes for elimination. The cholangiocyte reverse cholesterol transport pathway may function to prevent biliary damage due to oxysterols.

GALLBLADDER EPITHELIAL CELLS

Gallbladder epithelial cells and cholangiocytes share a number of functions, however their primary role in the liver and their reaction to disease are quite different. Similar to cholangiocytes, gallbladder epithelial cells express ASBT, and taurocholate have been shown to increase intracellular calcium, activate chloride channels and stimulate mucin secretion[90]. In contrast, ursodeoxycholate, through a PKCalpha-dependent pathway inhibits gallbladder mucin production[90]. The authors proposed that ursodeoxycholate inhibition of gallbladder mucin could provide benefit to biliary disorders such as cystic fibrosis.

BILE ACID EFFECTS ON CHOLANGIOCYTE FUNCTION OR DYSFUNCTION IN HUMANS

Compared to the understanding of the effects of bile acids on rodent cholangiocytes, very little is known regarding bile acid signaling of cholangiocyte function in health and disease in humans. Previous studies of biliary bicarbonate secretion in humans, by employing PET scanning, show that biliary bicarbonate secretion is reduced in primary biliary cirrhosis, the prototypic disease of bile duct damage in humans[91]. After treatment with ursodeoxycholate, biliary bicarbonate secretion in primary biliary cirrhosis patients is increased compared to the pretreatment values[91]. It is not clear why ursodeoxycholic acid inhibits cholangiocyte secretion in bile duct ligated rats but increases cholangiocyte secretion in primary biliary cirrhosis in humans. It is likely that the pathophysiology of these two forms of biliary injury is different.

Cystic fibrosis also targets biliary epithelium in the liver[92]. Clinical studies have shown that ursodeoxycholate may improve liver tests in cystic fibrosis patients[93]. It has been proposed that the mechanism for action of ursodeoxycholate in cystic fibrosis is increased ductal bile flow [as demonstrated by the opening of chloride channels by Shimokura *et al*[66]] that reduces the bile plugs and obstruction due to thick biliary secretions[94]. Ursodeoxycholate has been found to have measurable clinical effects in other diseases that target biliary epithelium (graft versus host disease involving the liver, liver allograft rejection and bile-duct paucity syndromes)[95]. Finally, ursodeoxycholate has been used in other chronic cholestatic liver disorders where biliary epithelium is not the primary target (intrahepatic cholestasis of pregnancy, progressive familial intrahepatic cholestasis, non alcoholic steatohepatitis, alcoholic liver disease, autoimmune hepatitis)[95]. The potential therapeutic effect of ursodeoxycholate in human liver diseases is reviewed elsewhere[95].

In summary, bile acids interact with cholangiocytes in numerous ways. A specific bile acid transporter (ASBT) is localized on the apical membrane, posed to absorb biliary bile acids[5,17]. On the basolateral membrane, four transport systems have been identified (*t*-ASBT, MDR3, an anion exchanger system and the Ostα-Ostβ heteromeric transporter)[6,28,29]. Studies in cultured cholangiocytes show that cholangiocytes transport bile acids from the apical to the basolateral membrane[17]. Indirect evidence for a cholehepatic shunt pathway initiated by bile acid absorption from bile by ASBT that leads to bile acids return *via* the peribiliary plexus to hepatocytes for secretion into bile[7,34,36-38,41]. The contribution of the cholehepatic shunt pathway in overall hepatobiliary transport of bile acids and the role of the cholehepatic shunt pathway in the adaptation to chronic cholestasis due to extrahepatic obstruction remains to be determined. ASBT is both acutely regulated by a cAMP-dependent translocation to the apical membrane[38] and chronically regulated by changes in gene expression in response to biliary bile acid concentration and ubiquitination-dependent proteasome disposal[9]. Biliary bile acid concentration and composition may regulate cholangiocyte functions. After uptake by ASBT, bile acids signal calcium, PKC, PI3K, MEK and ERK intracellular signals in cholangiocytes with resultant changes in cholangiocyte secretion, proliferation and survival[11,12,59,61,66,96]. Different bile acids have differential effects on cholangiocyte intracellular signals, resulting in opposite effects on cholangiocyte secretion, proliferation and survival[12,96,97].

In future studies, the mechanisms explaining how bile acids with different structures can differentially regulate different intracellular signals will be determined. To address the question of how chronic cholestatic liver disease may adapt by changes in cholehepatic shunting, new experimental paradigms to directly quantify bile acid absorption in bile ducts in experimental animals will be developed. Since multiple transporters with varying substrate specificity are present in the sinusoidal and canalicular membrane of hepatocytes, additional bile acid transporters may be found in cholangiocytes. When the mechanisms for bile acid cytoprotective effects in cholangiocytes are defined, a new therapeutic window

in human biliary disorders may open that operates through modulation of biliary bile acid concentration and composition. Finally, the role of cholangiocyte bile acid transport in the promotion or adaptation to human liver disease needs to be determined.

Abstract

The occurrence of both primary gastric lymphoma and gastric adenocarcinoma in the same patient is a rare entity. The possible causative factors of synchronous or metachronous occurrence of both malignancies and varieties in the treatment modalities are reviewed according to published cases in English language medical literature.

INTRODUCTION

Secondary malignancies associated with Hodgkin's or non-Hodgkin's lymphoma are commonly detected in relation with the improvement in overall survival rate of these patients. The most common type of secondary malignancy seen with lymphoma is acute myelogenous leukemia, however, epithelial malignancies are also reported[1-3]. Intensive radiotherapy and chemotherapy administered to these patients have raised questions about the long-term effects of these therapeutic modalities on the development of secondary malignancies. Primary gastric lymphoma is a relatively uncommon malignancy, occurring in only 1%-7% of all malignant neoplasms of the stomach[4]. The occurrence of both primary gastric lymphoma and gastric adenocarcinoma in the same patient is a rare entity. We review the possible causative factors of synchronous or metachronous occurrence of both malignancies and varieties in the treatment modalities according to published cases in English language medical literature.

INCIDENCE

Since the first description of multiple gastric cancers by *Barth* in 1855[5], case reports of benign and malignant multiple primary tumors have been appearing with an increasing frequency. The incidence of multiple simultaneous gastric cancers is high, ranging from 3.4% to 67.4%[6]. In the first published case series in Germany, authors did not mention the incidence of simultaneous occurrence of malignant lymphoma and adenocarcinoma in the stomach[7]. Thereafter, case series from Japan appeared in the literature. Kasahara *et al*[8] reviewed data of 35 Japanese patients without giving incidence rate for synchronous occurrence. Noda *et al*[9] found an association of both tumors in 2 of 2438 (0.08%) gastric carcinoma cases. The incidence of simultaneous occurrence was 3.7% (9/247) in primary gastric lymphomas and 0.098% (9/9150) in gastric carcinomas in series by Nakamura *et al*[10]. Despite definite expression of incidence rate for synchronous cases, the incidence of metachronous occurrence of both tumors has not been mentioned in the literature.

SYNCHRONOUS CASES

Since the first case reported by Rabinovitch *et al*[11], 56 cases of synchronous occurrence of gastric adenocarcinoma and lymphoma have been published in English language medical literature[7-31]. Majority of these reports included detailed analysis of histopathologic features of tumors instead of clinical follow-up of patients. Basic characteristics of the patients are summarized on Table 1. Twenty-three cases were from the Eastern and 33 cases were from the Western countries. The overall median age was 66 (range 27-85) years. The median age for the Eastern population was 67 and for the Western population was 72 years. Male predominance was observed in both the Western (1.75:1) and the Eastern (3:1) populations. Overall, 62.5% of patients had early gastric carcinoma (EGC) and 30.4% of pa-

m: male, f: female, NM: not mentioned, EGC: early gastric carcinoma, AGC: advanced gastric carcinoma, GC: gastric carcinoma, I: intestinal type, D: diffuse type, W: well differentiated, P: poor differentiated, M: moderately differentiated, MALT: mucosa-associated lymphoid tissue, HG: high grade, LG: low grade, S. gastrectomy: subtotal gastrectomy, T. gastrectomy: total gastrectomy.

tients had advanced gastric carcinoma (AGC), the type of gastric carcinoma was undefined in the rest of the patients. EGC constituted a majority of the Eastern cases (82%), whereas 48% of cases were from the Western countries. Before the report by Kelly *et al*[18] in 1994, the presence of *H pylori* was not mentioned by the authors. Since then, reported *H pylori* infection rate reached 79%. The infection rate in the East (86%) was higher than that in the West (72%). The prevalence of *H pylori* was higher in EGC (86%) than that in AGC (64%). There was no significant correlation between the prevalence of *H pylori* and the differentiation of adenocarcinoma. The declared results of adenocarcinoma histopathology were not uniform in relation to the variations in the classification systems used by the authors. However, differentiation of the tumor was clearly revealed by all authors. Poor and well differentiated adenocarcinomas showed an equal distribution in the Eastern (43.5% and 52%, respectively) and the Western cases (42% and 42%, respectively).

Majority of the lymphomas were MALT (mucosa-associated lymphoid tissue) type lymphoma (69.6%) and low grade one (87.2%). The association of *H pylori* with MALToma was 86% in the Eastern cases and 72% in the Western cases. Six of 7 (86%) patients with other types of gastric lymphoma associated with gastric adenocarcinoma were *H pylori*-positive. There was no data about the size of the tumor found in 32% of the cases. The size of the lymphoma was larger than carcinoma in 57% of cases. Overall, lymph node metastasis was found in 41% of the cases. In patients with early carcinoma and positive lymph node metastasis, the origin of metastatic lymph node was usually lymphoma (89%). In the presence of advanced carcinoma, metastases originated from the adenocarcinoma, either alone or in combination with the lymphoma. The topographic interrelation of both tumors was also revealed in the reports (n = 53/56). Majority of the cases (n = 29, 54.7%) had independent tumors. There was no significant difference between the Eastern and the Western cases in this respect. Collision of both tumors was reported in 14 (26.4%) cases. There were 4 cases with contiguous and 5 cases with intermingling tumors.

METACHRONOUS CASES

In contrast to synchronous occurrence of gastric adenocarcinoma and lymphoma, majority of cases (90%, 27/30) with metachronous occurrence of both tumors were reported from the Western countries[10,32-47]. In 1950, McNeer *et al*[32] published the first case in the literature. The features of the 30 patients are summarized in Table 2. The median age was 50 (8-82) years. Of these patients, 18 were male and 12 were female. Previously detected malignancy in 28 patients was lymphoma. Only 2 cases reported by Nakamura *et al*[10] were diagnosed as lymphoma after the treatment of gastric adenocarcinoma. One of these tumors developed in the remnant stomach in the 7th year after subtotal gastrectomy and the other developed in the 13th month after endoscopic mucosal resection. Rest of the patients suffered from various types of lymphoma previously. Leading type of lymphoma was MALT lymphoma (30%), followed by large cell lymphoma (20%). The existence of *H pylori* was not mentioned in the reports published before 1997. Thereafter, 9 of 10 reported cases were found infected with *H pylori*. Median interval between the treatment of lymphoma and the diagnosis of gastric adenocarcinoma was 90 (6-408) mo. The reported interval after the treatment of MALToma (median 27, range 6-108 mo) was shorter than the other types of lymphoma (median 120, range 42-408 mo). Adequate description of histopathology of adenocarcinoma was determined in 26 of 30 cases. After the latent period, majority of cases suffered from advanced gastric adenocarcinomas (65%) and 9 patients had EGC.

PATHOLOGIC ASPECTS OF SYNCHRONOUS OCCURRENCE

The relation of both tumors in the stomach was classified in four categories: (1) separate tumors; (2) collision tumor; (3) contagious tumor, without any intermingling between malignant components; and (4) intermingling (admixture) of both tumors. Histological classification of gastric lymphomas is based on systems originally designed for nodal lymphomas as Musshoff modification of the Ann Arbor staging system, Working formulation or Kiel classification. However, these are not optimal for the documentation of specific relevant features of primary extranodal lymphoma in the gastrointestinal tract. Several modifications on TNM staging system and alternatives have been proposed[48,49]. Recently, the European Gastro-Intestinal Lymphoma Study Group (EGILS) proposed a new modification of TNM staging system for the gastric lymphomas[50]. In 1983, the histologic relationship of extranodal B-cell lymphomas and MALToma was recognized by Isaacson and Wright, and classification as a separate entity of MALT-NHL was proposed - the MALT lymphoma concept[51,52]. However, the first report of synchronous occurrence of MALToma with gastric adenocarcinoma appeared in the literature in 1990. Metachronous occurrence of MALToma was reported at the end of 1990's. Therefore, it is easily speculated that authors are affected by the classification systems for nodal lymphomas before 1990.

Histopathological disorders of gastric mucosa are not specific for any neoplasm, but intestinal-type adenocarcinomas frequently showed atrophy, intestinal metaplasia, and not uncommonly, dysplasia of the surrounding non-neoplastic gastric mucosa. Diffuse-type adenocarcinomas did not frequently show such lesions. Primary lymphomas displayed expansive lymphoid follicles and also a high percentage of atrophy and intestinal metaplasia of the surrounding gastric mucosa[53]. In addition to the similar histopathological findings in the surrounding gastric mucosa of intestinal-type adenocarcinoma and primary gastric lymphoma, lymphocytic gastritis was found more frequently in patients with gastric carcinoma and primary gastric lymphoma than in unselected patients undergoing endoscopy[54]. This finding suggests that these two disparate gastric tumors may share an immunological dysfunction or a common pathogenesis. Zamboni *et al*[55] pointed out that foveolar lymphoepithelial lesions or signet-ring cells were found in 37% of MALT lymphomas. Like in MALT

Table 2 Metachronous cases reported in the literature

Reference	Age/sex	Lymphoma type	Lymphoma therapy	Interval	Adenocarcinoma therapy

Raderer[47]	67/f	MALT	Antibiotic therapy for *H pylori* (for 9 mo)	9 mo	S. gastrectomy
	61/f	MALT	Antibiotic therapy for *H pylori* (for 14 mo); 2CdA chemotherapy (4 courses)	27 mo	S. gastrectomy

m: male, f: female, NM: not mentioned, MALT: mucosa-associated lymphoid tissue, HG: high grade, LG: low grade, S. gastrectomy: subtotal gastrectomy, T. gastrectomy: total gastrectomy, [1]Only 2 cases reported by Nakamura *et al* were diagnosed as lymphoma after the treatment of gastric adenocarcinoma.

lymphomas, gastric carcinomas are invariably accompanied by lymphoid proliferations ranging from reactive lymphoid follicles to MALT lymphomas[56]. These observations also supplied the theory of common pathogenesis of MALT-type lymphoma and gastric carcinoma.

The incidence of early gastric carcinoma in synchronous tumors was remarkably high. Especially in the Eastern countries, routine screening for gastric carcinoma is practiced, and up to about 50% of gastric carcinoma diagnosed in the early stage[57]. This observation, together

with the finding that most lymphomas were larger than adenocarcinomas, suggested that lymphomas might develop before adenocarcinomas or that the presence of MALT lymphoma might increase the risk of developing gastric carcinoma.

ETIOLOGIC FACTORS OF SYNCHRONOUS OCCURRENCE

H pylori

It is tempting to hypothesize that *H pylori* is a common etiological agent for synchronous occurrence of gastric adenocarcinoma and primary gastric lymphoma. Since 1994, the existence of *H pylori* has been investigated in almost every report. In the present analysis, in areas with high prevalence (Eastern) and low prevalence (Western) of *H pylori*, synchronous tumors are associated with *H pylori* infection rates of 86% and 72%, respectively, and are similar to or higher than the reported infection rates of isolated gastric adenocarcinoma and isolated MALT lymphoma or other primary gastric non-hodgkin lymphoma[20,58-60]. Therefore, *H pylori* may have an important etiological role for synchronous tumors in both high and low prevalence areas.

H pylori plays a key role in the natural history of gastric MALT lymphoma, representing an example of antigen-mediated tissue stimulation and lymphoproliferation, with possible subsequent lymphomagenesis[58,61]. Antigenic mimicry between *H pylori* and the host mucosa was held responsible for inducing autoimmune responses which lead to development of the disease[62,63]. Kawahara *et al*[64] found that the increase of antibody titers to HCG-27 cells in *H pylori*-positive patients with MALT lymphoma compared to titers in patients with other gastroduodenal diseases and in healthy subjects. Lymphoid follicles which are not present in the normal stomach show development in the setting of chronic gastritis. Genta *et al*[65] have observed a strong correlation between follicular gastritis and *H pylori* infection. Wotherspoo*n et al*[58] suggested that *H pylori* might trigger the acquisition of MALT in the gastric mucosa, and this lymphoid tissue is thought to harbor the precursor cells in MALT-NHL. These precursor cells change gradually into malignant lymphoma cells with autonomous and uncontrolled growth by accumulation of genetic alterations such as mutations, deletions, and amplifications. *In vitro* experiments have demonstrated that in the earlier phases of development, the growth of genetically altered lymphoid cell is not yet fully autonomous, and proliferation partly depends on *H pylori*-related proteins and T cells[66-69]. On the other hand, *H pylori* infection has been linked to the intestinal-type gastric adenocarcinoma through a chain of events that starts as acute gastritis and progresses to chronic gastritis, atrophic gastritis, intestinal metaplasia, dysplasia, and eventually, adenocarcinoma formation[70,71]. A recent meta-analysis has revealed that *H pylori* infection is associated with a 2-fold increase in developing gastric adenocarcinoma[72]. These epidemiologic and pathologic data about the relation of *H pylori* infection with gastric adenocarcinoma and primary gastric lymphoma are supported by a recent genetic study[73]. *H pylori* genotyping on archived gastric tissue revealed that *H pylori* strains with certain combinations of virulence subtypes are associated with gastric carcinoma or MALT lymphoma. Thus, the virulence subtype composition vacA s1a and iceA1 occurs mainly in gastric carcinoma, whereas the vacA s1t/m2 iceA1 combination is found in MALT lymphoma[73]. Therefore, in the future studies, the composition of virulence subtypes might be taken into account during the evaluation of possible sequelae of gastric mucosal damage caused by *H pylori* infection.

Epstein-Barr virus

Studies of Epstein-Barr virus (EBV) suggest that an aberrant antibody response to infection may occur years before the appearance of a tumor[74]. The frequency of EBV detection has been reported to be 6%-18% in gastric lymphomas[75-77] and 7%-16% in ordinary gastric adenocarcinomas without lymphoid stroma[78-80]. Whether EBV plays a pathogenic role in either of these tumors is still unclear[81]. Although any mechanism related to EBV in tumorigenesis of gastric malignancies remains highly speculative, it has been demonstrated that there is a delay in apoptosis in EBV-positive gastric carcinomas (associated with up-regulation of BCL-2 and p53) and a decrease in cellular differentiation (associated with decreased E-cadherin expression)[82]. Nakamura *et al*[10] found no specific association between EBV infection and these double malignancies.

Exposure to atomic blast

It is controversial whether the incidence of gastric carcinoma is higher in persons exposed to an atomic blast in comparison to non-exposed subjects[83-85], but Suehiro *et al*[83] suggested that the incidence is the highest in persons exposed within a 2.0-Km radius ground zero. The relation of primary gastric lymphoma and atomic bomb exposure is under debate. Recently, t (11; 18) (q21; q21) and t (1;14) (p22; q32) translocations have been reported to be associated with MALT-type lymphoma. The former translocation results in the formation of fusion protein API2-MALT1, and the latter in the fusion protein pf BCL10 and IgH. These fusion transcripts are thought to be molecular markers for MALT-type lymphoma not responding to *H pylori* eradication and highly correlated with aberrant nuclear BCL10 expression, which may serve as a screening tool for fusion[86-88]. These investigations support the etiologic role of atomic bomb blast on the formation of MALT-type lymphoma.

ETIOLOGIC FACTORS OF METACHRONOUS OCCURRENCE

Epithelial malignancies, the common cancers of adulthood, are detected rarely in the post-treatment course of Hodgkin's disease and other lymphomas[2,3,26]. However, Greene and Wilson[88,89] observed a significant increase in the incidence of gastric carcinoma in the period following the treatment of non-Hodgkin lymphomas.

Previous gastric surgery

Previous gastric surgery is a well known precancerous con-

dition[90,91]. Gastroesophageal reflux and gastritis, formation of nitrosamines due to gastric pH decrease and untreated *H pylori* infection may play a role in carcinogenesis of the gastric remnant[92]. So-called "stump carcinoma" develops between 13-27 years after resection in patients treated with gastrectomy for benign conditions[91].

Radiotherapy and chemotherapy

Though the stomach is considered relatively radio-resistant compared to other parts of the gastrointestinal tract, side effects and complications progressively increased when the total dosage delivered was above 4500 cGy[93,94]. The effects of radiotherapy on the risk of carcinogenesis are well known[95]. Hirose *et al*[96] demonstrated that localized radiation induced gastric adenocarcinoma development in an experimental model. Brown *et al*[97] reported a slight increase in the incidence of gastric adenocarcinoma in patients with ankylosing spondylitis under radiation therapy. In contrast, when the relatively low dose (less than 3400 cGy) radiotherapy was used to decrease acid production in 2049 peptic ulcer patients, only two cases of leiomyosarcoma were reported. The elapsed time between radiotherapy and the diagnosis of these cases were reported as 14 and 26 years[98].

Both series reported by Stanford and Milan concluded that combined administration of chemotherapy and radiotherapy increases the occurrence rate of secondary malignancies[1,2]. In these series, the most common secondary malignancy was especially acute myelogenous leukemia. Its occurrence was associated with the administration of alkylating agents (nitrogen mustard, vincristine, prednisone, and procarbazine in Milan series)[2]. Solid tumors were commonly associated with radiation therapy[1,2]. Brumback *et al*[40] concluded that secondary gastric adenocarcinoma occurred in one of these cases probably due to oral administration of procarbazine for Hodgkin's disease. In addition to these factors, *H pylori* infection was also held accountable for metachronous occurrence of both tumors, as discussed above.

DIFFICULTIES IN DIAGNOSIS

It may be difficult to diagnose the two different tumors in the stomach before surgery. Because most of the patients with gastric adenocarcinoma and coexisting primary gastric lymphoma are associated with *H pylori* infection, the presence of MALT-type or other types of primary gastric lymphoma should be taken into consideration when gastric adenocarcinoma with gastritis is detected on endoscopy. In surgical specimens, not only the lesions of adenocarcinoma but also the background mucosa of cancerous lesions must be examined with regard to infiltration of lymphocytes, and the presence of gastritis, as well as the presence of *H pylori*. Signet-ring cells around MALT lymphomas or lymphoid proliferations around gastric adenocarcinomas should be kept in mind against over-diagnosis during the histopathological examination. Considering the metachronous occurrence of gastric adenocarcinoma and gastric lymphoma, proper endoscopic follow-up should be performed in the remnant stomach, especially when *H pylori* infection is present.

TREATMENT

Treatment modalities for synchronous cases

Treatment of synchronous cases is generally applied according to the presence of adenocarcinoma. Distal or total gastrectomy is performed depending on the tumor localization. Preoperative chemotherapy was preferred only in two cases. Cammarota *et al*[27] decided to administer etoposide, epirubicin, cisplatin chemotherapy according to the presence of locally advanced tumor stage (T3 N1) in laparoscopic exploration. Older patients in the series by Ishihama *et al*[23] were exposed to 10 courses of vincristine, endoxan, predonisdone, adriamicin chemotherapy and endoscopic resection of the tumor. Postoperative chemotherapy was administered only to 6 (10.7%) patients.

Treatment modalities for metachronous cases

Eight of thirty patients underwent subtotal gastrectomy and radiotherapy against lymphoma. Chemotherapy was administered in different combinations with other treatment modalities in 7 patients. Two patients were treated by only chemotherapy. Radiotherapy was performed solely in 2 patients. Overall, 10 cases with lymphoma were treated without surgical treatment. All patients with MALToma were treated with antibiotic regimen against *H pylori*, except cases reported by Nakamura *et al*[10] *and* Montalban *et al*[26], the authors of both did not mention anything about the treatment of *H pylori* infection in their reports. Every patient with *H pylori* infection was eradicated and no one was re-infected or re-colonized during the follow-up period. Except cases with widespread metastasis, total gastrectomy or palliative resections were performed in patients with AGC. Patients with EGC were exposed to more conservative surgery, such as endoscopic mucosal resection[10,45].

Surgery

Clear guidelines for management have not been designed for synchronous adenocarcinoma and primary gastric lymphoma. Traditionally, aggressive surgical resection has been the mainstay of gastric lymphoma treatment because by this treatment modality it would be possible to collect definitive tissues for pathologic examination, allow exploration of the abdomen, reduce the tumor burden and obviate the concern that gastric hemorrhage or perforation would complicate medical treatment of lymphomas. Recently, radical gastrectomy is disputed and considered unnecessary for gastric lymphomas. Lesser procedures are now accepted where resection of the gross disease and involved lymph nodes will provide adequate results[99-102]. Some authors advocate wide resection and extensive lymph node dissection alone for adequate treatment of stage 1E or pure MALT lymphomas with a survival rate of > 95%[103,104]. In a retrospective study from Italy patients in different stages of gastric lymphoma who underwent surgical resection when feasible, the ten-year actuarial survival rates were markedly higher (100% and 80%, respectively) for stage IE and IIE as compared with stage IIIE and IVE (21% and 0%, respectively)[105]. Surgical resection with clear margins for lymphoma is advised in order to maximize the chance of cure[100,106]. However, others have found no difference in survival, whether the margin of resection was

clear or not, as long as post-operative chemotherapy was given[107]. Operative mortality rates for gastric lymphoma reached 25% in cases with advanced tumor stage[108]. Therefore, aggressive surgery for gastric lymphoma is not indicated due to increased morbidity which outweighs the benefit gained in terms of survival[107]. Surgery for gastric lymphoma is now often reserved for patients with localized disease, residual disease after non-surgical therapy or for rare patients with complications[109]. If the coexisting adenocarcinoma is diagnosed correctly, surgical treatment, a first-line therapy, is preferred according to adenocarcinoma treatment principles. Total or subtotal gastrectomy with D1 or D2 dissection must be performed.

In metachronous cases, generally, the occurrence of primary gastric lymphoma precedes gastric adenocarcinoma, resection of the remnant stomach must be done with or without a combination of other treatment modalities. However, a close follow-up of the patients undergoing gastric lymphoma treatment allows early detection of carcinogenesis. Limited endoscopic resections might be an alternative treatment for these cases. Similar to gastric lymphoma as a previous malignancy, patients in whom limited resection is performed for gastric adenocarcinoma should undergo a close endoscopic follow-up. The *H pylori* status with histopathologic alterations in the resected stomach and in the remnant stomach must be detected and followed up for early detection of metachronous occurrence of gastric lymphoma.

Chemotherapy

The effect of chemotherapy as a sole treatment for gastric lymphomas is still under debate. The needs behind trying chemotherapy were the considerable morbidity and mortality associated with resection[108]. Some authors reported better survival rates in patients with primary gastric lymphoma treated by chemotherapy alone or combination with radiotherapy when compared to surgical treatment alone[110,111]. Other reports showed no apparent difference in survival between patients treated by chemotherapy or surgery and chemotherapy with survival rates of 67% and 60%, respectively. The fear of chemotherapy-related complications, for instance, bleeding and perforation, has been disputed, and less significant compared with surgical resection[111,112]. Therefore, chemotherapy has been suggested and adopted as a primary mode of treatment for primary gastric lymphomas. Whereas cyclophoshamide, vincristine and prednisolone were adopted for low grade lymphomas, high grade tumors were treated with doxurubicin, teniposide, cyclophosphamide and prednisolone. The combination of both regimens with surgical resection has increased the survival rates up to 80% and 100%, respectively[113]. In contrast to primary gastric lymphomas, chemotherapy regimens have not been used as a sole therapy in the treatment of gastric adenocarcinoma, except in cases with metastatic disease. Systemic chemotherapy for metastatic disease has a marginal survival benefit when compared with best supportive care, while no standard worldwide regimen has been established yet. In Japan, especially the number of patients treated with endoscopic mucosal resection for early gastric adenocarcinoma is increasing year by year. Chemotherapy may be a more important part of treatment protocols in these patients in near future, because of the increasing survival rates. Cisplatin, 5-fluorouracil and mitomycin C were commonly used in various combinations for patients with gastric adenocarcinoma[114].

Radiotherapy

In most instances, radiotherapy is used as an adjuvant to surgery, chemotherapy or both for primary gastric lymphoma. It has rarely been tried as a single mode of therapy[115,116]. However, limited trials have suggested that radiotherapy can be utilized as a primary mode of treatment with a reasonable outcome[116,117]. Radiotherapy has been studied in comparison with other treatment modalities for stage IE and IIE of primary gastric lymphomas with a comparable outcome of 80%-89% survival[115,118,119]. Radiation was used post-operatively in high- and low-grade lymphomas, for residual tumors in stages I and II to improve the disease-free survival[120]. Combination of radiotherapy with chemotherapy might improve the chance of stomach conservation of these patients which may approach 100%[121]. Contradictory studies have found combined radiotherapy with either resection or chemotherapy no significant difference in both modalities, with a survival rate of 82%-88%[116,119]. Radiation therapy has a limited but well established role in the care of those afflicted with gastric adenocarcinoma. Radiation therapy can provide considerable relief of local gastric cancer symptoms. Approximately 50% to 75% of patients have had symptomatic improvement of problems, such as obstruction, bleeding and pain in a variety of trials[122,123].

Antibiotic therapy

Because gastric MALT lymphomas have a high association with *H pylori* infection, eradication of *H pylori* with antibiotics is very important[58,60,124,125]. Isaacson *et al*[125] suggested that antibiotic eradication of *H pylori* removes the growth stimulus from gastric MALT lymphoma without necessarily eradicating the neoplastic B-cell clone. This clone may re-expand, but in the absence of concomitant re-infection with *H pylori*, this is likely to be a self-limiting event. Short and long-term follow-up results of medical eradication of *H pylori* in patients with gastric MALT lymphoma have been published in the literature[124,125]. However, patients still require periodic surveillance endoscopies and may require more traditional treatment of their lymphoma. Antibiotic therapy may fail to cure gastric lymphomas when there is a bulky tumor with a high-grade component or when the gastric lymphoma is associated with carcinoma[126]. A combination of partial gastrectomy and antibiotic therapy might be an alternative treatment for primary gastric lymphomas. However, periodic surveillance endoscopies are required after partial gastrectomy and antibiotic therapy. There has been no defined role of antibiotic therapy against *H pylori* in the treatment of gastric adenocarcinoma. Eradication of *H pylori* infection can be placed in preventive measures of gastric adenocarcinoma. If *H pylori* infection is detected in the partially resected

stomach secondary to adenocarcinoma, the postoperative antibiotic treatment against *H pylori* may be administered for hindering metachronous occurrence of primary gastric lymphoma.

PROGNOSIS

Reported period of follow-up for synchronous cases ranged from 1 to 132 mo. Overall, data about surveillance of patients were insufficient to perform analysis. Some authors did not mention follow-up data whereas others did not report treatment modalities. However, shorter postoperative survey was observed in cases with AGC (up to 23 mo) when compared to cases with EGC. The follow-up study conducted by Nakamura *et al*[10] revealed that the survival rate of patients with synchronous occurrence of gastric lymphoma and adenocarcinoma appeared to be similar to that for previously reported patients with gastric adenocarcinoma without lymphoma, and was significantly worse than patients with primary gastric lymphoma without adenocarcinoma. As discussed above, majority of metachronous cases suffered from advanced gastric adenocarcinomas after the latent period. Eleven of 17 patients with AGC died within 18 mo. Despite incomplete survival data of cases with EGC, Zauber *et al*[42] reported 96 mo disease-free survival after total gastrectomy. Nakamura *et al*[10] did not reveal any survival data regarding primary gastric lymphoma occurring after treatment of gastric adenocarcinoma.

In summary, with the help of case reports or series, the synchronous or metachronous occurrence of primary gastric lymphoma and gastric adenocarcinoma have evolved in various aspects. Clinicians should be alert for the possible synchronous or metachronous occurrence of both tumors during diagnosis or follow-up of each other. Authors suggest the application of principles for gastric adenocarcinoma treatment to cases with synchronous occurrence. The biologic behavior of the latest diagnosed tumor determines the accurate management of metachronous occurrence of primary gastric lymphoma and gastric adenocarcinoma.

Abstract

AIM: To study the epidemiology of HCC in Lebanon and prognostic factors predictive of early mortality.

METHODS: An observational follow-up cohort study of HCC cases diagnosed over a five-year period was carried out. Multivariate analysis was conducted to identify prognostic factors in comparison to Cancer of the Liver Italian Program (CLIP) score. Multiple variables including the etiology of underlying liver disease, the demographic characteristics of patients, and the severity of liver disease evaluated by the Child-Pugh score were studied. Tumor parameters included the time of diagnosis of HCC, alpha-fetoprotein level, number and size of nodules, presence of portal vein thrombosis, and treatment modalities. Death or loss of follow-up was considered as an end-point event.

RESULTS: Ninety-two patients (mean 60.5 ± 22.3 years) were included. Etiology of underlying disease was hepatitis B, C, and alcohol in 67%, 20%, and 23.5% respectively. Child-Pugh class at diagnosis was A, B, and C in 34.8%, 39.3% and 25.8% respectively. Overall survival was 44.8%, 32.8% and 17.6% at 1, 2 and 3 years respectively (mean F/U 40.2 ± 23.5 mo). Multivariate analysis identified three predictors of early mortality (< 6 mo): bilirubin > 3.2 mg/dL (P < 0.01), HCC as first presentation of liver disease (P = 0.035), and creatinine > 1 mg/dL (P = 0.017). A score based on these variables outperformed the CLIP score by Cox proportional hazard. ROC curve showed both models to be equivalent and moderately accurate.

CONCLUSION: HBV is the leading cause of HCC in Lebanon. Independent predictors of early mortality are elevated bilirubin, creatinine and HCC as first manifestation of disease. Prospective validation of a score based on these clinical parameters in predicting short-term survival is needed.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a malignancy occurring most often in the setting of liver cirrhosis. The causes of the underlying liver disease differ according to the geographical distribution. Common risk factors for HCC include infection with hepatitis B virus (HBV), hepatitis C virus (HCV), cirrhosis of any cause, alcoholic liver disease, and inherited metabolic diseases such as hemochromatosis and α1-antitrypsin deficiency. HCC occurs most commonly in sub-Saharan Africa and parts of the Far East such as China, Taiwan, Korea, Japan, and Vietnam. HCV infection with advanced fibrosis or cirrhosis is the main cause of HCC in Japan, South Africa, Egypt, the United States and Southern Europe[1-4]. In Northern and Central European countries, ethanol is still the leading cause of cirrhosis and is responsible for the majority of HCC cases[5]. There has been no report on the epidemiology of HCC in Lebanon. Epidemiologic data from neighboring countries differ widely with the primary risk factor for HCC attributable to HBV in Turkey[6], HBV/HDV in Jordan[7], and HCV in Saudi Arabia[8,9].

The expected survival of patients with HCC is an important parameter in predicting mortality on a liver transplantation waiting list. The prognostic factors for survival in patients with HCC have been identified in previous studies and sub-classified into 3 groups: (1)

demographic characteristics including age and gender; (2) factors related to HCC such as tumor size, the number of nodules, vascular invasion, the presence of a tumor capsule or metastasis; and (3) factors related to underlying liver disease severity, including ascites, encephalopathy, or serum bilirubin. The Child-Pugh classification, used in patients with cirrhosis, only considers liver disease and not tumor characteristics. Orthotopic liver transplantation (OLT) is an excellent treatment for early hepatocellular carcinoma. There is, however, a paucity of data on survival according to intention-to-treat analysis and on the rate of dropout from the waiting list for OLT among patients with HCC due to shortage of grafts. This is compounded by the fact that up to 30% of eligible patients develop contraindications to the procedure while waiting for a donor. All of the above result in less than optimal prediction of early mortality in HCC patients, particularly in populations who present with advanced disease and where therapeutic options may be limited. The aim of the present study was to describe the epidemiology of HCC in Lebanon, and to identify factors predictive of early mortality in our patients who could seldom benefit from liver transplantation.

MATERIALS AND METHODS

Patients

The study is a multicenter follow-up cohort study consisting of 92 patients diagnosed with HCC between 1998 and 2003. The study involved three university hospitals in Beirut: Hotel-Dieu de France (Université Saint Joseph), American University of Beirut Medical Center, and Saint-Georges Hospital (Balamand University Medical School). Patients were identified from the medical records and from specialty liver clinics. Information regarding deceased patients was obtained from medical records and prospective follow-up was continued for new and existing patients. Multiple variables including the etiology of underlying liver disease, the demographic characteristics of patients including age and gender, and the severity of liver disease evaluated by the Child-Pugh score were studied. Tumor parameters included the time of diagnosis of HCC, alpha-fetoprotein level, number and size of nodules, presence of portal vein thrombosis, and treatment modalities. Death or loss of follow-up was considered as an end-point event.

HCC was diagnosed according to any one of the following criteria: (1) an abnormal liver morphology with a tumor nodule that is enhanced during the arterial phase following intravenous contrast injection on CT-scan or MRI. (2) an elevated alpha fetoprotein level > 400 ng/mL in the presence of a liver nodule, and (3) biopsy-proven HCC[10]. Patients who did not meet one or more of these diagnostic criteria were not included in the study. Cirrhosis was confirmed according to histology and/or by clinical and biochemical signs of hepatic insufficiency, ascites, esophageal varices, and ultrasonographic signs of portal hypertension. Tumor eligibility-for-treatment criteria included: a single nodule of less than 5 cm without evidence of vascular invasion, or less than 3 nodules of < 3 cm each with the absence of portal vein thrombosis.

Table 1 Characteristics of the 92 patients with hepatocellular carcinoma *n* (%)

Age(yr)	At diagnosis of cirrhosis before development of HCC	56.0 ± 26.3
	At HCC diagnosis	60.5 ± 22.3
Gender	Male	78 (84.8)
Etiology	HBV	62 (67.4)
	HCV	18 (19.6)
	HBV + HCV	77 (83.7)
	Alcohol abuse	22 (23.9)
Liver disease severity at time of diagnosis	Child-Pugh A	32 (34.8)
	Platelet count < 75 000	16 (17.4)
	Bilirubin > 3.2 mg/dL	25 (27.2)
	Albumin < 30 g/L	46 (50)
	Mean MELD score	9.43 ± 7.58
Tumor characteristics	Single nodule	41 (44.6)
	2-3 nodules	19 (20.7)
	Diffuse	33 (35.9)
	Portal vein obstruction[1]	31 (34.8)
Follow-up and survival	HCC as first presentation of liver disease	53 (57.6)
	Mean F/U prior to HCC in those with known liver disease	40.2 mo
	Mean follow-up after HCC diagnosis	16.4 mo
	Mean survival	14.9 mo

[1]Three patients had multiple nodules without details regarding vascular invasion or size of the nodules.

Tumors more than 5 cm in diameter were considered eligible for surgical resection when there was no evidence of vascular invasion and when surgical resection was technically possible. These patients were not considered eligible for any other curative treatment namely liver transplantation, percutaneous ethanol ablation, or radio frequency ablation. Patients who had tumors eligible for a curative treatment were further selected according to transplantation indication with an upper age limit of 65 years.

Statistical analysis

Biochemical data were collected at the time of diagnosis of hepatocellular carcinoma. Quantitative data were expressed as mean ± standard deviation and range. Group comparisons used the two-sample *t*-test or the Mann-Whitney test for quantitative variables and the two-tailed Fischer's exact test was used for qualitative variables. Comparison of survival used the Kaplan-Meier model, the log-rank test and receiver operating characteristic (ROC) curve.

RESULTS

Etiology

Characteristics of the 92 HCC patients are shown in Table 1. The mean age was 60.5 ± 22.3 years and the sex ratio was 5.6:1 (M/F, 78/14). In 77 patients (83.7%), the etiology of the underlying liver disease was viral. HBV infection was found in 62 patients (67.4%) compared to 18 patients (19.6%) with HCV infection. Alcohol abuse was found in 22 patients (23.9%) but was the only cause of

liver disease in only 8.2% of our patients. Miscellaneous causes included autoimmune hepatitis, primary biliary cirrhosis, hemochromatosis, and tyrosinemia and accounted for 5.9% of cases.

Liver disease severity

HCC occurred in the setting of cirrhosis in all but one patient. The Child-Pugh class at time of diagnosis of HCC was A, B, and C in 32 (34.8%), 35 (39.3%), and 23 (25.8%) cases respectively. Model of end stage liver disease (MELD) score was calculated in 79 patients, and the mean was 9.4 ± 7.6. MELD score was < 12, 12-16, 16-24, and >24 in 68.4%, 12.7%, 12.7%, and 6.3% of patients respectively.

Tumor characteristics

The diagnosis of HCC was established during follow-up of liver cirrhosis in 36 patients (42.4%) with a mean follow-up period of 40 mo (median = 24 mo). In 13 patients (36.1%), HCC was diagnosed during the first two years following the diagnosis of cirrhosis, and in 26 patients (72.4%), within 5 years. The size of tumor nodules ranged from 1 cm to 20 cm with a mean of 5.6 cm. The number of nodules was 1, 2, and 3 in 41 (46.1%), 14 (15.7%), and 5 (5.6%) patients respectively; 29 patients (32.6%) had diffuse HCC. Portal vein thrombosis was present in 29 patients (38.2%). Forty patients (43.5%) had a single tumor of less than 5 cm or less than 3 nodules < 3 cm of diameter; ten of those patients had evidence of vascular invasion. The number of patients having a tumor considered eligible for a curative treatment was 32 (34.8%) versus 60 (65.2%) that were ineligible for curative resection on account of diffuse disease or tumor-associated with portal vein thrombosis.

Eligibility for curative treatment

Thirty-two patients had tumors considered eligible for curative treatment, but only 15 (46.9%) patients could benefit from such therapy. This was primarily due to the inability to perform a curative treatment at first intent because of age, tumor location for surgical resection, the lack of regular organ allocation program, or general contraindications other than hepatic disease severity quantified by the Child-Pugh score. When patients older than 70 or 65 were excluded, eligibility for a curative treatment decreased to 25.8% or 20.2% respectively. Other causes of failure to treat were the surveillance of small nodules of 1-2 cm of diameter, or patients awaiting OLT with no other therapeutic possibilities. Fifty-nine patients (64.1%) did not benefit from any treatment because of either decompensated liver disease or advanced tumor cases; in the remaining cases, treatment consisted of percutaneous ethanol injection (7 patients), chemoembolization (17 patients), OLT (8 patients) and surgical resection (7 patients). Eight patients had more than one treatment modality. There was a trend towards a difference in eligibility for treatment between patients presenting with HCC as first manifestation of liver disease (21% eligible for a curative treatment), compared to those discovered on routine screening for HCC (41% eligible for a curative treatment), although this difference did not reach statistical significance ($P = 0.13$).

Table 2 Univariate analysis of overall survival in HCC patients

	Criteria	Median survival (mo)	Mean survival (mo)	Log rank P
Age at diagnosis of HCC (yr)	< 55	18	40	0.008
	> 55	8	14	
Child-Pugh score	A	25	31.44	0.103
	B	10	18.14	
	C	4	24.5	
Bilirubin	< 3.2 mg/dL	15	23	0.015
	> 3.2 mg/dL	3	14	
HCC diagnosis	Known liver disease	25	33	0.003
	As first manifestation of liver disease	6	12	
Eligibility for treatment	No	15	6	0.005
	Yes	27	33	
INR	< 2	12	23	0.029
	> 2	2	9	
Portal vein thrombosis	Absent	14	23	0.021
	Present	3	12	

Survival and follow-up

Overall survival was 44.8%, 32.8%, and 17.6% at 1, 2, and 3 years respectively. Individual prognostic factors were studied using the Log rank method. Survival was studied with respect to multiple parameters including prothrombin time, platelet count, bilirubin value, albumin, creatinine, alpha-fetoprotein, the diameter of the largest nodule, the presence of portal vein thrombosis, eligibility for curative treatment, Child-Pugh score, MELD score, the presence of ascites, the etiology of liver disease, and the grading of esophageal varices. Prognostic factors identified in univariate analysis included age > 55, bilirubin < 3.2 mg/dL, HCC as the first manifestation of liver disease, eligibility for a curative treatment, International Normalized Ratio (INR) < 2, MELD score > 18, and the presence of portal vein thrombosis. Univariate analysis of overall survival (Table 2) failed to demonstrate a significant difference in survival with respect to Child-Pugh score in HCC patients. The mean survival was 31.4, 18.1, and 24.4 months respectively in Child-Pugh class A, B, and C patients ($P = 0.10$). In multivariate analysis using Cox regression model; survival in HCC patients was related to age < 55 at diagnosis of HCC ($P = 0.004$), bilirubin value < 3.2 mg/dL ($P = 0.014$), and HCC developing in the setting of known liver disease ($P = 0.016$).

Factors associated with six month survival are shown in Table 3. Death occurred within six months in 31 patients (38.3%). Survival beyond six months was associated with INR < 2, bilirubin < 3.2 mg/dL, tumor less than 5 cm of diameter or three nodules of less than 3 cm of diameter without portal vein thrombosis, MELD score < 16, lower Child-Pugh class, and the absence of portal vein thrombosis. Mean creatinine level, INR, and MELD score were lower in patients with > 6 mo survival. In multivariate analysis using Cox regression model, bilirubin

Table 3 Factors associated with six months survival *n* (%)

	Survival[1]		
	< 6 mo	> 6 mo	*P*
Child-Pugh score A	4 (14.3)	14 (35.9)	0.032[2]
INR < 2	22 (70.9)	43 (93.5)	0.012[2]
Bilirubin < 3.2 mg/dL	17 (58.6)	35 (83.3)	0.033[2]
MELD score < 16	37 (90.2)	18 (62.1)	0.006[2]
Portal vein thrombosis	17 (54.8)	13 (30.9)	0.035[2]
Tumor < 5 cm or 3 nodules < 3 cm without portal vein thrombosis	3 (10.3)	11 (31.4)	0.042[2]
Mean creatinine (mg/dL)	1.57 ± 0.89	1.19 ± 0.49	0.021[3]
Mean INR	1.68 ± 0.47	1.47 ± 0.42	0.041[3]
Mean MELD score	13.26 ± 8.12	8.12 ± 6.54	0.005[3]

[1]Patients treated curatively by OLT or surgical resection were excluded from this analysis. [2]Fischer exact test. [3]Mean comparisons by independent sample *t*-test.

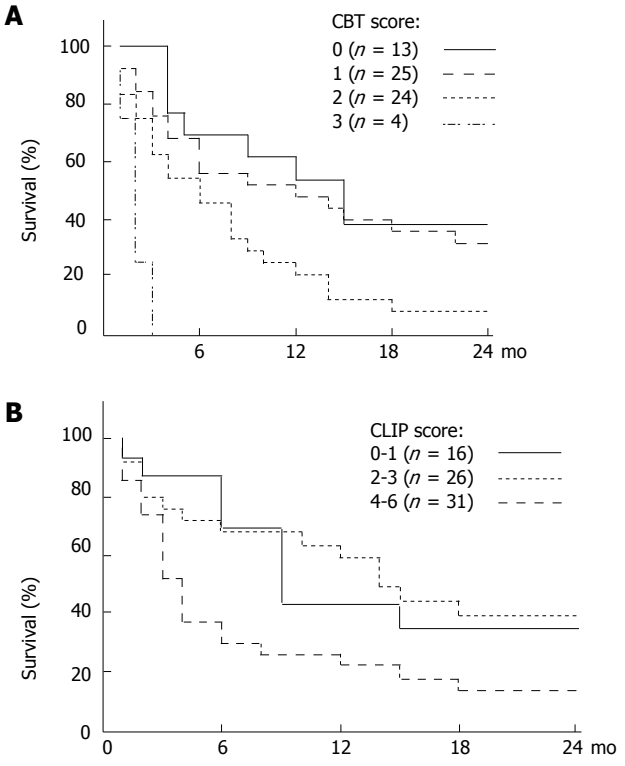

Figure 1 **A**: Kaplan-Meier survival curves for 68 patients with hepatocellular carcinoma based on 3 clinical criteria CBT (Creatinine, Bilirubin, and Tumor as primary manifestation); **B**: Kaplan-Meier estimated survival curves according to the Cancer of the Liver Italian Programme (CLIP) classification.

> 3.2 mg/dL ($P = 0.001$), creatinine > 1 mg/dL ($P = 0.017$), and HCC as the first manifestation of liver disease ($P = 0.035$) were independent predictors of survival less than six months ($P = 0.006$). Short-term survival (> 6 mo) was 69.2%, 56%, 45.8%, and 0% when none, one, two, or all of these 3 independent factors were present ($P = 0.0002$) (Figure 1). In comparison, the CLIP score predicted short-term survival in our patient population was 69.3%, 68%, and 29.6% when the score was respectively 0-1, 2-3, or 4-6 (Log rank $P = 0.047$) (Figure 1). A score based on the 3 clinical variables identified above (CBT score for creatinine, bilirubin, and tumor) outperformed the CLIP score by Cox proportional hazard. ROC curve showed

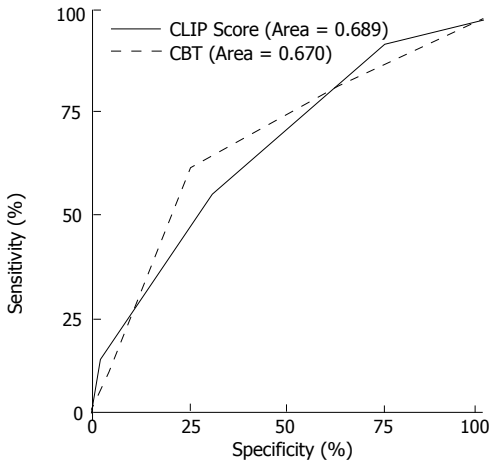

Figure 2 Receiver Operating Characteristic (ROC) curve for early mortality using the CBT (Creatinine, Bilirubin, and Tumor as primary manifestation) and CLIP scores.

both prognostic models to be equivalent and of moderate accuracy (Figure 2).

DISCUSSION

HCC is a relatively rare cancer in Lebanon, ranking 14th among both males and females, with an age standardized rate of 3.5 and 2.2 per 100 000 respectively[11]. Understanding the risk factors for HCC and predictors of poor survival are important in prevention and treatment. The results of our study show that most HCC patients in Lebanon have HBV-related liver cirrhosis, accounting for nearly two thirds of our patients. This is concordant with previous findings regarding the etiology of liver cirrhosis in Lebanon where HBV was the most important cause accounting for more than 50% of cirrhosis, followed by HCV, and alcohol abuse[12]. Of note, the HBV and HCV carrier state in Lebanese blood donors is 1%-2% and 0.1%-0.6% respectively[13-15]. Interestingly, there were no cases of non-alcoholic steatohepatitis- or cryptogenic cirrhosis-related HCC in this study population. Studies from neighboring Middle Eastern countries showed wide variation in the etiology of HCC. In Saudi Arabia, HCV plays a major role in the epidemiology of HCC where 39.5% of patients were anti-HCV antibody positive[8]. This is in contrast to an overall HCV seroprevalence of 1.1%-2.9% among Saudi- blood donors[9] versus 0.6% among Lebanese-blood donors[13]. In Jordan, an association between HDV-positive status and HBs-antigen positive primary HCC was found. The prevalence of hepatitis D viral infection in Jordan was 23% in patients with chronic liver disease and in 67% of patients with HCC[7]. In contrast, none of our HCC patients was seropositive for HDV. Lastly, HBV infection was found to be the leading cause of HCC in Turkey, followed by HCV infection, and alcoholic liver disease[6]. Hepatitis B, hepatitis C, excessive alcohol intake were detected in 56%, 23.2%, and 15.9% of Turkish HCC patients respectively.

Previous studies have identified multiple prognostic factors in HCC[16-19]. Gender differences were studied showing significantly longer median survival in females (14 mo) than in male patients (4 mo)[20]. This does not

seem to be the case in our patients. Previous multivariate analysis demonstrated that high serum alpha-fetoprotein levels, venous invasion, extrahepatic metastasis, and lack of therapy were independent factors related to unfavorable prognosis[17]. In another study, only type of estrogen receptors and bilirubin showed independent predictive value for mortality[21]. In Child B and C cirrhosis patients, factors predictive of prolonged survival were albumin level (≥ 30 g/L), absence of esophageal varices, tumor size (≤ 3.0cm), tumor number (solitary), and alpha-fetoprotein (AFP) level (< 400 ng/mL)[18]. In our study, factors predictive of prolonged survival were bilirubin (< 3.2 mg/dL) at diagnosis, age (less than 55), and HCC developing in the setting of known liver disease. Serum creatinine and INR values were not independent factors associated with long-term survival, nor was the etiology of the underlying liver disease. This explains somehow that the MELD score was associated with the outcome in univariate analysis, whereas this score has limited value for HCC since prognosis is not only related to liver failure, but also to tumor evolution which is not taken into account in this score. Furthermore, the etiology of underlying liver disease does not seem to play a role in prognosis either in univariate or multivariate analysis. The finding that HCC developing in the setting of known liver disease is an independent predictor of outcome further supports the role of routine screening for HCC in cirrhosis since some of those patients may be amenable to curative treatment.

Data on short-term survival, particularly from the Middle East, is scarce in the literature. Such data is important for the evaluation of early mortality on liver transplantation waiting lists. In a study from Kuwait involving 145 HCC cases, the CLIP score was found to be superior to the Okuda stage as a prognostic indicator[22]. However, the results from a study by Siddique et al seem to reflect the natural history of the disease (91% did not receive any specific therapy for HCC)[22]. In our study, factors predictive of six month survival were bilirubin, creatinine, and HCC developing in the setting of known liver disease. Even for short-term survival, MELD score does not seem to be fit for the evaluation of early mortality in HCC patients. MELD score did, however, show a significant difference in Kaplan-Meier survival analysis when the chosen cut-off was 16, but no difference in survival was found when the cut-off was 24. Again, the etiology of liver disease does not seem to play a role in the early mortality of HCC neither in univariate nor in multivariate analysis.

Our study is limited by the fact that the number of patients was relatively small which restricts the number of variables that can be examined with confidence by multivariate analysis. HCC is however, an uncommon cancer in Lebanon, ranking 14th among both males and females, with an age standardized rate of 3.5 and 2.2 per 100 000 respectively[11]. With a population of just over 3 million, the number of HCC in the whole of Lebanon over a one-year period is estimated at less than 90 cases. It is estimated that a third to half of these cases are referred to the three major university hospitals involved in this study for evaluation and management. We believe, therefore, that our study cohort is relatively large for Lebanon and is likely to be well representative of the population at large particularly as it relates to etiology and outcome.

In conclusion, our study shows that HCC in Lebanon is primarily related to HBV cirrhosis with HCV and alcohol abuse ranking as distant second and third risk factors. The probability for a curative treatment is still low in Lebanon because of advanced tumor stage at presentation and the lack of a regular liver donation program. Thus determination of independent prognostic factors for early mortality is necessary, which include bilirubin (> 3.2 mg/dL), creatinine (> 1 mg/dL), and HCC as first presentation of liver disease. Further studies are needed to validate the above identified prognostic factors and to evaluate drop-out and mortality on the waiting list taking into account these factors.

ACKNOWLEDGMENTS

The authors thank the Lebanese National Research Council for partial funding of this project, the staff and patients of the three university hospitals for their excellent co-operation.

Abstract

AIM: To investigate the effect of exogenous ceramide-induced apoptosis on human colon carcinoma HT-29 cells.

METHODS: Light microscope, transmission electron microscope and fluorescence microscope were used to observe the morphology change of apoptosis in HT-29 cells. Agarose gel electrophoresis was performed to detect the DNA fragment. Mitochondrial function was detected by MTT assay. mRNA expression of Bcl-2 family gene members was determined by reverse transcription polymerase chain reaction (RT-PCR) assay.

RESULTS: After C_2-ceramide treatment, typical characteristics of apoptosis, such as nuclear chromatin breakage, apoptotic body and DNA ladder, could be observed. After exposure to 50 μmol/L C_2-ceramide for 12 and 24 h, cell apoptosis was 64.1% and 81.3% respectively, which had a time-and dose-effect relationship. Mitochondrial function started to decrease from 6 h after exposure to ceramide. Meanwhile, ceramide up-regulated or down-regulated the mRNA expression of Bcl-2 family gene members.

CONCLUSION: Ceramide induces apoptosis of human colon carcinoma HT-29 cells by affecting the expression of Bcl-2 family gene members and impacting the mitochondrial function.

INTRODUCTION

Ceramide (N-acetyl-sphingosine) is a fundamental unit of sphingomyelin which is a moiety of cytoplasmic membrane. Ceramide, also an important bioactive compound *in vivo*, can conduct specific signal transduction from cell surface receptor and environmental stress to nuclei, and then provoke multiple cytobiologic effects[1]. Meanwhile, ceramide is a common second messenger molecule participating in sphingomyelin cycle, apoptosis and differentiation of many cell types[2,3]. Apoptosis can be induced by surrounding stimulating factors, such as tumor necrosis factor α (TNF-α), endotoxin, FAS ligand, radiation, chemotherapeutics and heat shock, and is associated with ceramide. Recent studies indicate that ceramide has a close relationship with genesis and progression of digestive tract tumor. But little information about Bcl-2 family gene member and mitochondrial function is available concerning the effect of ceramide-induced apoptosis in colon carcinoma which is one of the most aggressive forms of cancer. Even ceramide could induce apoptosis of HT-29 cells. This study was to determine how ceramide induces apoptosis of human colon carcinoma cells and to discuss its mechanism.

MATERIALS AND METHODS

Materials

C_2-ceramide (N-acetyl-D-sphingosine) was purchased from Sigma, dissolved to 5 mmol/L in DMSO as a stock solution. Hoechest 33 258 and MTT were purchased from Sigma, dissolved in PBS solution. The two solutions were preserved at 4℃ from light. Apoptosis DNA extract kit was from Shanghai Huashun Biotechnology Company. RPMI-1640 media, DMSO and fetal bovine serum (FBS) were bought from GIBCO. Trypsin and EDTA were obtained from Amresco.

Cell culture

HT-29 cells were provided by the Institute of Tumor Prevention and Cure in Beijing, China. Cells were cultured in RPMI-1640 media supplemented with 10%

Table 1 Primer sequences of Bcl-2 family gene members

Gene	Primer sequence	Size (bp)	Temperature (℃)
Bax	Sense: 5′-CCAGCTGCCTTGGACTGT-3′ Antisense: 5′-ACCCCCTCAAGACCACTCTT-3′	135	61
Bcl-xl	Sense: 5′-GTAAACTGGGGTCGCATTGT-3′ Antisense: 5′-TGGATCCAAGGCTCTAGGTG-3′	146	60
Bcl-2	Sense: 5′-GGCAATGTGACTTTTTCCAA-3′ Antisense: 5′-GGCTGATATTCTGCAACACTG-3′	137	55
Bad	Sense: 5′-AGGGCTGACCCAGATTCC-3′ Antisense: 5′-GTGACGCAACGGTTAAACCT-3′	178	60
Bid	Sense: 5′-GCTTCCAGTGTAGACGGAGC-3′ Antisense: 5′-GTGCAGATTCATGTGTGGATG-3′	116	60
β-actin	Sense: 5′-GTGGACATCCGCAAAGAC-3′ Antisense: 5′-TCAACGCAATGTGGGAAG-3′	303	58

FBS and 2 mmol/L glutamine. Antibiotics added to the media were 100 U/mL penicillin and 100 U/mL streptomycin. Cells maintained in a humidified atmosphere of 95 mL/L air and 50 mL/L CO_2 at 37℃ were then passed at pre-confluent densities in a solution containing 0.25% trypsin and 0.02% EDTA. Exponentially growing cells were used throughout all experiments.

Light microscopy

HT-29 cells were treated with C_2-ceramide at final concentrations of 12.5, 25 and 50 μmol/L for 24 and 48 h respectively. DMSO served as negative control. During the procedure, cell morphology was observed under light microscope for different time.

Transmission electron microscopy

Cells were collected and fixed with 4% glutaraldehyde in phosphate buffer overnight at 4℃. After post-fixation with 1% OsO_4 in cacodylate buffer for 1h at 4℃, the pellet was dehydrated in graded ethanol solutions and embedded in Epon. Ultrathin sections of pellet were counterstained with uranyl acetate and lead citrate and observed under transmission electron microscope.

Fluorescence microscopy

Cells (4×10^4) were treated as above, suspended with FBS and incubated with Hoechest 33 258 for 30 min at 37℃ from light. Then the cells were observed under fluorescence microscope. Three hundred cells were counted and apoptotic cell rate was calculated.

Detection of DNA fragmentation

Cells (2×10^6) were treated as above and collected. Fragmented DNA was extracted according to the manufacturer's instructions of apoptosis DNA extract kit and underwent electrophoresis on 2 g/L agarose gel containing 0.5 g/L of ethidium bromide and visulized by UV transillumination.

Detection of mitochondrial function (MTT assay)

Cells (1.5×10^4) were cultured in 96-well plates and treated with C_2-ceramide for 1, 3, 6, 9, 12 and 24 h as above. Then MTT and DMSO were added by turns. Absorbance was determined with a multi-well plate reader at wavelength 570 nm.

Table 2 Apoptosis rate of HT-29 cells induced by C_2-ceramide (mean ± SD, %)

C_2-ceramide	Cell count (*n*)	12 h	24 h
0 μmol/L	300	5.33 ± 1.53	8.67 ± 2.52
12.5 μmol/L	300	14.7 ± 2.52[a]	28.0 ± 9.85[a]
25 μmol/L	300	33.3 ± 8.37[a]	43.3 ± 12.3[a]
50 μmol/L	300	64.7 ± 7.51[a]	81.3 ± 9.07[a]

[a]$P < 0.05$ *vs* control.

RT-PCR

Cells (1×10^6) were treated for 24 h as above. Total RNA was isolated from the treated cells with Trizol and reversely transcribed into cDNA with human specific primers for Bax, Bad, Bid, Bcl-2, Bcl-xl and β-actin. Sequences of primers are shown in Table 1. Briefly, 35 cycles of PCR amplification were performed at 94℃ for 30 s, annealing at 60℃ for 30 s and extension at 72℃ for 30 s in a 25 μL reaction system. PCR products were confirmed by 1.5 g/L agarose gel electrophoresis and visualized by UV transillumination. mRNA expression of genes was assessed by correcting housekeeping gene β-actin, which served as an internal control.

Statistical analysis

All statistical analyses were performed with SPSS 10.0 statistical package for Microsoft Windows. Data were expressed as mean ± SD for all measurements. $P < 0.05$ was considered statistically significant.

RESULTS

C_2-ceramide induced morphology changes of apoptosis in HT-29 cells

With increasing concentration of C_2-ceramide and exposure time, HT-29 cells became round, atrophic and poorly adherent and floating cells increased under light microscope. Cells from control showed normal distribution and morphology in all cellular organelles except for a few necrotic cells under transmission electron microscope. The main ultra-microstructural changes seen in all treated groups were chromatin aggregation, mitochondrial denaturation and apoptotic body, as well as cytoplasmic compartments, swelling and disappearance of mitochondrial cristae, *etc* (Figure 1). The necrotic changes were more pronounced in cells treated with 50 μmol/L C_2-ceramide.

Apoptotic cells determined by Hoechest 33 258 assay increased in a time- and dose-dependent manner after treatment with C_2-ceramide (Table 2). Normal cellular chromatin did not change and uniformly spread over the whole nuclei displaying diffusion uniformity fluorescence. However, apoptotic chromatin was identifiable by its scattered drop-like structure locating on the area of the original nuclei which displayed high brightness lump or punctiform fluorescence. The total size of apoptotic nuclei

appeared smaller and more shrunken than the intact cells (Figure 2).

C_2-ceramide induced DNA fragmentation of HT-29 cells

DNA ladder was seen through DNA agarose gel electrophoresis, especially pronounced in the cells treated with 50 and 25 μmol/L C_2-ceramide for 12 and 24 h. Cells treated with 12.5 μmol/L C_2-ceramide and DMSO kept their integrity, having no ladder appearance (Figure 3).

C_2-ceramide damaged mitochondrial function of HT-29 cells

The absorbance value increased gradually with increased concentration of C_2-ceramide and prolongation of exposure time. But the absorbance value after treatment with 50 and 25 μmol/L C_2-ceramide was obviously lower than that in the control, showing statistical significance from 6 to 24 h, indicating that C_2-ceramide could decrease mitochondrial function (Table 3).

C_2-ceramide affected mRNA expression of apoptosis-related genes

After cells were treated with C_2-ceramide for 24 h, the mRNA expressions of Bax, Bad and Bid genes were up-regulated. However, the expressions of Bcl-2 and Bcl-xl were down-regulated (Figure 4). Moreover, the ratio of Bcl-2 to Bax in 50 μmol/L C_2-ceramid group was less than 1.

DISCUSSION

Recently, the importance of ceramide in cell metabolism has been broadly investigated. The biological effect of ceramide on different cell lines is different. The role of ceramide-induced apoptosis has been confirmed[4]. Recent studies indicate that ceramide is a common second

messenger molecule of apoptosis. Apoptosis induced by stimulating factors is mediated by ceramide from sphingomyelin circulation way[5,6]. The effect of ceramide on apoptosis has been studied extensively in neoplastic cells but rarely in solid tumor cells. Ceramide is closely related with genesis and progression of digestive tract tumor. Decreased ceramide content increases the risk of developing digestive tract tumor since ceramide content in human colon carcinoma cells is lower than that in normal colon mucosa cells[7].

To some extent, tumor chemotherapy is to induce apoptosis. In this experiment, human colon cancer cells were exposed to exogenous C_2-ceramide. Results indicated that C_2-ceramide could induce typical characteristics of apoptosis, such as nuclear chromatin break and apoptotic body as well as DNA ladder in a time-and dose-dependent manner. Succinate dehydrogenase (SDH) in the mitochondria is an index of cellular respiration and energy, which reflects mitochondrial function. MTT assay suggested that C_2-ceramide could decrease mitochondrial function. By studying Bcl-2 family gene members, we also found that C_2-ceramide could up-regulate or down-regulate the mRNA expression of these genes, suggesting that exogenous C_2-ceramide induces apoptosis of human colon carcinoma cells *in vitro* by affecting the expression of Bcl-2 family gene members and damaging the mitochondrial functions.

C_2-, C_6 and C_8-ceramides could induce apoptosis of cell lines, but dihydroxy-ceramide lacking C_4-C_5 trans-double bond located in basal framework of sphingolipid could not induce apoptosis[8].

Studies also indicate that ceramide has many target sites inducing apoptosis, such as ceramide-activated protein kinase (CAPK)[9], ceramide-activated protein phosphatase (CAPP)[10], protein kinase C (PKC) family[11], stress-activated protein kinase/c-JUN N-terminal kinase (SAPK/JNK)[12] and caspase cascade reaction[13]. There is a body of evidence that mitochondria are involved in apoptosis, for example, release of cytochrome C from mitochondria triggers apoptosis[14-16].

In conclusion, mitochondria is the target of ceramide. The importance and mechanism of mitochondria in ceramide-induced apoptosis need to be further studied.

Abstract

AIM: To investigate the mechanism of fibroblast cell proliferation stimulated by the *Opisthorchis viverrini* excretory/secretory (ES) product.

METHODS: NIH-3T3, mouse fibroblast cells were treated with *O. viverrini* ES product by non-contact co-cultured with the adult parasites. Total RNA from NIH-3T3 treated and untreated with *O. viverrini* was extracted, reverse transcribed and hybridized with the mouse 15K complementary DNA (cDNA) array. The result was analyzed by ArrayVision version 5 and GeneSpring version 5 softwares. After normalization, the ratios of gene expression of parasite treated to untreated NIH-3T3 cells of 2-and more-fold upregulated was defined as the differentially expressed genes. The expression levels of the signal transduction genes were validated by semi-quantitative SYBR-based real-time RT-PCR.

RESULTS: Among a total of 15 000 genes/ESTs, 239 genes with established cell proliferation-related function were 2 fold-and more-up-regulated by *O. viverrini* ES product compared to those in cells without exposure to the parasitic product. These genes were classified into groups including energy and metabolism, signal transduction, protein synthesis and translation, matrix and structural protein, transcription control, cell cycle and DNA replication. Moreover, the expressions of serine-threonine kinase receptor, receptor tyrosine kinase and collagen production-related genes were up-regulated by *O. viverrini* ES product. The expression level of signal transduction genes; *pk*C, *pdgfrα, jak* 1*, eps* 8*, tgfβ* 1*i*4, *strap* and *h ras* measured by real-time RT-PCR confirmed their expression levels to those obtained from cDNA array. However, only the up-regulated expression of *pkC, eps* 8 *and tgfβ* 1*i*4 which are the downstream signaling molecules of either epidermal growth factor (EGF) or transforming growth factor-β (TGF-β) showed statistical significance ($P < 0.05$).

CONCLUSION: *O. viverrini* ES product stimulates the significant changes of gene expression in several functional categories and these mainly include transcripts related to cell proliferation. The TGF-β and EGF signal transduction pathways are indicated as the possible pathways of *O. viverrini*-driven cell proliferation.

INTRODUCTION

An *Opisthorchis viverrini* infection or opisthorchiasis is the most important health problem in Southern Asia, including Northeastern Thailand, Loas, Vietnam and southern China[1]. It is a definite cause of bile duct cancer or cholangiocarcinoma (CC) in humans and has been classified as a carcinogen. Parkin *et al*[2] performed

a case-control study of patients and estimated that two-thirds of CC cases in Thailand were caused by *O. viverrini* infestation. Nowadays, CC remains a major public health problem in many parts of Southeast Asia. The incidence rate of CC around the world is different with increasing tendency[3,4]. The highest incidence is in the Northeastern part of Thailand with the rate of 188 per 100 000[5]. The pathogenesis of *O. viverrini*-associated CC may be a complex process, involving several mechanisms. The effect of parasites on the bile duct epithelium is classified, as both mechanical and chemical irritations. The mechanical irritation is the direct contact of parasites to the bile duct epithelium; the chemical irritation is believed to be caused by the excretory/secretory (ES) product released from the flukes. These chronic irritations caused by the parasite later result in the proliferation of bile duct epithelium and leads to epithelial hyperplasia[6]. This is an important step in the genesis of cancer because hyperplastic cells are vulnerable to a carcinogen and can easily turn to adenomatous and finally cancerous cells[7]. Moreover, the alterations of immune response and the stromal cells which are mainly composed of fibroblasts were observed in opisthorchiasis and CC in both animal models and human. The fibrosis and mononuclear cell infiltration with lymphocyte aggregation and, additionally, ductal dilatation were observed in the gall bladders and extrahepatic bile ducts of the hamsters infected with *O. viverrini*[8]. In addition, the chronic inflammation and fibrosis of the bile ducts may contribute to the strikingly enhanced susceptibility to CC among people with heavy liver fluke infection[9]. The malignant transformation of bile duct epithelium *via* dysplasia was detected in the abnormal intrahepatic biliary tree of the patients with congenital hepatic fibrosis[10]. There is the important relationship between the gradual decreases of inflammation with a concomitant increase in fibrosis after *O. viverrini* re-infection in the experiment hamsters[11]. All of these data provide evidence of the importance of fibrosis in the formation of cholangiocarcinoma.

Fibrosis is the excessive accumulation of extracellular matrix proteins produced from the active and accumulated fibroblasts. It occurs in most types of chronic diseases including chronic liver disease. Liver fibrosis is considered a model of the wound-healing response of the liver to repeated injury[12]. Activated hepatic stellate cells, portal fibroblasts, and myofibroblasts have been identified as the major collagen-producing cells in the repeatedly injured liver[13]. In the fibrogenesis, the increased numbers and then the accumulation of fibrogenic cells including the fibroblasts and myofibroblasts are the main observations. As aforementioned, there is the correlation of fibrosis with the development of CC. The interaction of *O. viverrini* and the host immune cells has been proven to be the main causative issue for chronic inflammation in opisthorchiasis. The cytokines released from the immune cells will lead to the formation of fibrosis later. Moreover, direct contact of *O. viverrini* which have been strongly proven to induce bile duct epithelium erosion and cell proliferation replacement that occurs later on, may indirectly induce the surrounding fibroblasts around the affected area to proliferate[14]. The importance of hyperproliferative fibroblasts regarding the induction of epithelial cancer has been increasingly reported[15,16]. Though this phenomenon has not been investigated in CC, the direct effect of *O. viverrini* ES product to induce fibroblast cell proliferation has recently been reported *in vitro*[14,17]. So far, there are no data for the explanation of the fibroblast cell proliferation induced by the *O. viverrini* ES product.

From all the evidence described above, it would appear to be of great interest to study the mechanism of how *O. viverrini* ES product induces fibroblast cell proliferation. In order to know the response of cell to *O. viverrini* ES product, the gene expression analysis of fibroblast cell non-contact co-cultured with adult *O. viverrini* was performed. The expression level of genes was compared to those without *O. viverrini* ES product treatment. The cell proliferation-associated gene expression was discussed in relation to their roles in *O. viverrini* ES product-induced fibroblast cell proliferation. The expression levels of some signal transduction genes were also analyzed and validated by real-time RT-PCR to indicate the possible signal transduction pathway(s) utilized by *O. viverrini* in the induction of fibroblast cell proliferation.

MATERIALS AND METHODS

Parasite preparation

Opisthorchis metacercariae were obtained from naturally infected cyprinoid fish captured from fresh-water reservoirs in the endemic area of Khon Kaen province, Thailand. Pepsin-HCl was used to digest the flesh to obtain metacercariae, which were then introduced to the 6-8-wk-old hamsters *ad libitum*. After 1 mo, the adult *O. viverrini* were collected from the bile ducts of the hamsters and were washed several times with PBS containing 100 mg/L penicillin and 100 kU/L streptomycin. To prevent microbial contamination, the adult *O. viverrini* were then incubated for 30 min in PBS containing antibiotics before being used in the non-contact co-culture technique. The animal holding protocol was approved by the Animal Ethics Committee of Khon Kaen University (AEKKU011/04), based on the Ethics of Animal Experimentation of National Research Council of Thailand.

Cell culture and non-contact co-culture

To prepare the fibroblasts stimulated with *O. viverrini* ES product, the non-contact co-culture between the fibroblasts and the adult parasites was performed. The mouse fibroblast cell line, NIH-3T3, was bought from the American Type Culture Collection (ATCC; Manassas, VA, USA). It was maintained in DMEM (Gibco, Gaithersburg, MD, USA) containing 100 mL/L calf serum (CS) (Gibco, Gaithersburg, MD, USA), designated as the complete medium, followed by incubation in a 50 mL/L CO_2 incubator at 37℃ and passaging twice a week. Trypan blue staining was used to measure the viability of cells. The cells with more than 95% viability were collected for performing non-contact co-culture.

The NIH-3T3 cells and the intact viable *O. viverrini* were non-contact co-cultured in a 24-well transwell (Costar, Corning Incorporated, Cambridge, NY, USA). The

parasites were incubated in the upper chamber containing the 8-μm porous plate, which allowed the ES product to diffuse to the lower chamber where the NIH-3T3 cells adhered. The cell proliferation induction of ES product to the NIH-3T3 cells was confirmed by the viable cell count using trypan blue staining. Briefly, 10 000 NIH-3T3 cells were plated onto the lower chamber of a 24-well double-chamber culture plate for 2 d with complete medium to let most of cells adhere to the well. Then the media were changed to DMEM without CS, serum-free medium. Five viable adult *O. viverrini* were added to the upper chamber of each well. The NIH-3T3 cells cultured in complete medium and serum-free medium were used as positive and negative controls, respectively. The cell numbers obtained from the *O. viverrini* treatment cultured for 2 d was compared to those of the negative and positive controls with the same culturing time.

Hybridization and array data analysis

The in-house prepared mouse cDNA array was prepared by Dr. Kazuhiko Uchida, Department of Biochemistry and Molecular Oncology, Comprehensive Human Science, Graduate School, University of Tsukuba, Japan. It consists of 15 K of either mouse or human genes/ESTs. Firstly, the total RNA extraction from NIH-3T3 cells treated and untreated with adult *O. viverrini* ES product was performed. Briefly, total of 2-5 × 10^6 cells were collected in RNAlater solution (Ambion®, Hilden, Germany) and processed for total RNA with a commercial kit (ISOGEN; Nippon Gene, Tokyo, Japan) according to the manufacturer's protocol. The RNA quality was confirmed by subjecting the samples to electrophoresis on formaldehyde-agarose gel and staining the 18S and 28S RNA bands for visualization. Then, a 2-μg portion of the intact total RNA was dissolved in 8 μL of RNase-free water, and 2 μL of oligo (dT) primer (1 g/L; Invitrogen, Carlsbad, CA, USA) was then added. The sample was heated for 10 min at 70℃ and immediately chilled on ice. The following reagents were then added to the sample: 5 μL of first-strand cDNA synthesis buffer, 1 μL of DTT (0.1 mol/L final concentration), 1.5 μL of deoxynucleotide triphosphates (20 mmol/L dATP, dGTP, and dTTP), 1.5 μL of SuperScript (200 MU/L; Invitrogen), and [α-^{33}P]dCTP (111 PBq/mol; Amersham). The reaction was incubated at 37℃ for 90 min. Labeled cDNA was then denatured for 3 min at 95℃. The array was prehybridized at 42℃ for 2 h in MicroHyb solution (Invitrogen, Carlsbad, CA, USA) with 0.5 mg/L poly(dA) and 1 mg/L *COT1* DNA (Invitrogen, Carlsbad, CA, USA). The probes were hybridized at 42℃ overnight in the same solution. The membrane array was washed twice at 50℃ with 2 × SSC-10 g/L SDS for 20 min and at room temperature with 0.5 × SSC-10 g/L SDS for 15 min. The membrane array was exposed to an imaging plate which was scanned with a BAS 5000 Imaging Analyzer (Fuji Film, Tokyo, Japan). Spot intensity was quantified with ArrayVision version 5.0 software (Imaging Research, Ontario, Canada). GeneSpring version 5.0 software (Silicon Genetics, Redwood, CA) was used to normalize values for each gene for data analysis.

Real-time RT-PCR

The mRNA was isolated using a Total RNA Extraction Miniprep System (Viogene, Fegersheim, France) according to the manufacturer's instructions. The DNA contaminated in the extracted RNA was destroyed by DNaseI (Promega Corporation, Madison, WI, USA) at 37℃ for 30 min. The DNaseI inactivation reaction was performed at 75℃ for 10 min. The first-strand cDNA was synthesized from 1 μg of mRNA using the Reverse Transcription System (Promega Corporation, Madison, WI, USA). Semi-quantitative PCR was performed with the SYBR-based method in 12.5 μL reaction in Rotor Gene RG-3000 (Corbett Research). After the denaturing of cDNA at 95℃ for 10 min, the reaction profile was subjected to 50 amplification cycles, each cycle consisted of denaturation at 95℃ for 30 s, annealing at different temperatures for each gene (52, 55, 58, 58, 54, 52, 52, 52, 65, and 60℃ for *abl* 1, *pk*C, *pdgfrα*, *jak* 1, *eps* 8, *tgfβ* 1*i*4, *strap*, *csnk* 1α1, *h ras, and* β_2*m*, respectively) for 30 s, and extension at 72℃ for 45 s. After the PCR, a melting curve was constructed by increasing the temperature from 50 to 99℃. β_2-microglobulin (β_2m), whose expression was found to be directly proportional to the amount of mRNA that presented in the sample stimulated by any growth factors[18], was used as the internal control. The standard curve between the CT of each gene expression and the amount of the starting total RNA was performed. The CT of the samples was then compared to the corresponding standard curve and quantitated the amount of the starting mRNA in that sample. The RT-PCR was performed three times for each gene.

Table 1 shows the PCR primers designed by the Gene Fisher Program according to the mRNA sequences of each gene in the GenBank database. The primer sequences can then be categorized into groups of growth factors they belong to, in this case, the signal transduction molecules. The result was analyzed for the statistical significance by STATA version 8 (StataCorp LP, Texas, USA).

RESULTS

Gene responding to O. viverrini ES product

Using a mouse cDNA array, we examined the gene expression profile of cell proliferation stimulated by *O. viverrini* ES product. A total of 15 000 genes and ESTs were tested. *O. viverrini* caused widespread alteration in gene expression. The ratios of gene expression between treated and untreated with the parasite ES product equal and greater than 2 were focused on because of their striking changes. Among all genes/ESTs in 15K cDNA array, 885 genes fitted to this criterion. Among these genes, only 536 genes had a variety of molecular functions and only 239 genes within these 536 genes had cell proliferation-related functions. These 239 genes were categorized in groups as proteins playing roles in energy and metabolism, signal transduction, protein synthesis and translation, matrix and structural protein, transcription control, cell cycle and DNA replication. The percentage distribution of genes in each group is 25.2, 21, 18.9, 17,

Table 1 List of signal transduction genes[1] validated the expression by real-time RT-PCR, their corresponding PCR primers[2], annealing temperature and product sizes

Group of stimulating growth factor	Gene	Primer sequence	Annealing temperature (℃)/ product size (bp)
PDGF /EGF	*abl* 1	Forward: 5′-TGAAGTTGGTGGGCTGCA-3′ Reverse: 5′-TTTTCACTGGGCCCGCA-3′	52/148
	pkC	Forward: 5′-GGCATGCCTTGTCCTGGAGA-3′ Reverse: 5′-TGTAGCCCTGCCTCGAGAGA-3′	55/149
	jak 1	Forward: 5′-CAGCCTCGCTCGTCCTT-3′ Reverse: 5′-CCAAGCCCTTCAGAGCT-3′	58/147

[1]They are classified based on their functions as the downstream signaling molecules of the specific growth factor. [2]Primers for the internal control (β_2m) are: 5′-CATGGCTCGCTCGGTGA-3′ (forward) and 5′-AATGTGAGGCGGGTGGAA-3′ (reverse). The annealing temperature and the product size of RT-PCR for β_2m are 60℃ and 148 bp, respectively. PDGF: platelet-derived growth factor; EGF: epidermal growth factor; TGF-β: transforming growth factor-β.

12.6, 3.3, and 2, respectively. The examples of genes in each group are summarized in Table 2.

Response of signal transduction-related genes to O. viverrini ES product

A total of 59 genes/ESTs categorized by their molecular function as the signal transduction genes showed 2-fold and more up-regulation after *O. viverrini* ES product stimulation. They are the downstream signal transduction molecules for a variety of growth factors. The signal transduction genes that corresponded to the stimulation of either PDGF or EGF, PDGF, EGF and TGF-β were categorized and summarized in Table 3. The most up-regulated expressions were *tgfβ* 1*i*4 and *abl* 1 which are the representatives of TGF-β- and either PDGF- or EGF-stimulated signal transduction pathways, respectively.

In addition to the different signal transduction molecules responded to different growth factors, the receptors for PDGF/EGF and TFF-β are classified in different types as tyrosine kinase and serine-threonine kinase receptors, respectively. The cDNA array data represented the different up-regulated expression levels between these 2 types of receptors (Table 4).

Nine signal transduction genes, which responded to the specific growth factor as mentioned in Table 3, were selected and tested for their expression levels by semi-quantitative RT-PCR. The single peak of the melting curve for each gene confirmed the appropriate PCR condition (data not shown). The result indicated similar responses in both cDNA array and RT-PCR analyses of *pk*C, *jak* 1, *h ras*, *pdgfrα*, *eps* 8, *tgfβ* 1*i*4, and *strap*. However, the significant ($P < 0.05$) up-regulation was only found for those of *pk*C, *eps* 8, and *tgfβ* 1*i*4. The opposite result of mRNA expression level was detected in *abl* 1 and *raf* 1 (Figure 1).

DISCUSSION

Cell proliferation is regulated by the intricacy of cell growth regulators, signaling cascades, and mediators of cell cycle progression including cyclins, cyclin-dependent kinases (CDKs). Anti-proliferative genes coding for the apoptotic protein, cyclin/CDK inhibitors are important in controlling cell proliferation. Addition of growth factors induces cell proliferation including the fibroblasts[19]. The changes in gene expression that accompany this proliferative response have been the subject of many studies, and the responses of dozens of genes have been characterized[19]. A recent study indicated the effect of *O. viverrini* ES product in induction of fibroblast cell proliferation *in vitro*[17]. We have examined the effect of this parasitic product in the gene expression profile using a cDNA array. The NIH-3T3 cells were used because it not only had the marked response to *O. viverrini* ES product[17], but also being classified as the mesenchymal cells as the real target of *O. viverrini* ES product; the stellate cells and myofibroblasts. Among all genes/ESTs in 15K cDNA array, 885 genes showed 2-fold and more up-regulation after stimulation by *O. viverrini* ES product. Among these genes, only 536 genes had a variety of established molecular functions. Moreover, 239 of these 536 genes had cell proliferation-related functions and were primarily focused into groups based on their specific functions because of their striking increased changes (≥ 2-fold).

Most of the genes which increased their expression by *O. viverrini* ES product stimulation were the proteins controlling the enzymatic metabolism and biosynthesis. The expressions of glyceraldehyde-3-phosphate dehydrogenase, alpha-enolase and aldehyde dehydrogenase involve the glycolysis pathway. Cytochrome C oxidase and ATP synthase involve energy production from the electron transport chain. These phenomena could be easily understood because high levels of energy production and synthesis of biological macromolecules are required for the stimulation of quiescent fibroblasts by *O. viverrini* ES product into the cell cycle progression. These data suggest the possibility that ES product acts like a growth factor to stimulate cell proliferation basically by the stimulation of energy production-related gene expression[20].

In cell proliferation, the DNA replication is needed. Many proteins, including RPII215 polymerase and topoisomerase II, required for chromosome segregation at mitosis; and DNA primase, required for DNA replication, all increased their expressions in *O. viverrini* ES product-treated cells. These increased expressions will help cells undergo into cell cycle and consequently cell division. Ribonucleotide reductase is associated with the anabolic pathway of deoxynucleotide. The increased expression of this enzyme causes an increase in the deoxynucleotide triphosphate (dNTP) pool in the nucleus, which facilitates DNA synthesis and repair[21]. In addition, when cells are activated by the growth factors and then commit to enter

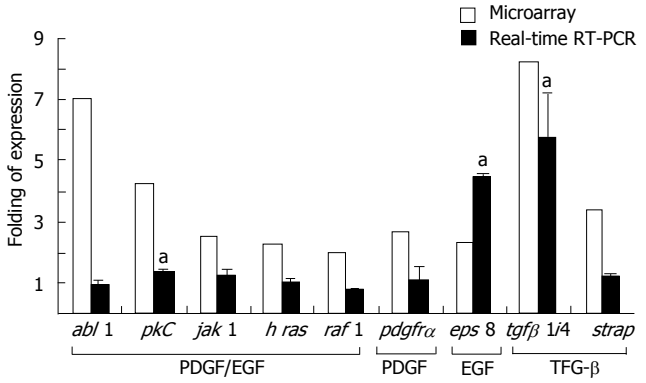

Figure 1 RT-PCR analysis of signal transduction genes up-regulation by *O. viverrini* ES product. The results of DNA array and RT-PCR are shown in comparison for each gene (mean ± SD, $^{a}P < 0.05$).

Table 2 Proliferation-related genes with 2-fold and more[1] up-regulation in fibroblast cell proliferation activated by *O. viverrini* ES product compared to the negative control (not exhaustive)

A Energy and metabolism	Glyceraldehyde-3-phosphate dehydrogenase (*gapd*), cytochrome C oxidase, alpha-enolase, ATP synthase beta subunit[2], thioredoxin, aldehyde dehydrogenase
B Signal transduction	Transforming growth factor beta-1-induced transcript 4 (*tgfβ* 1*i*4), tyrosine kinase (*abl* 1), interleukin 1 receptor-associated kinase, MAP kinase phosphatase (*mkp* 6), colony stimulating factor 3 receptor, protein kinase C, Janus kinase 2 (*Jak* 2), casein kinase I alpha (*csnk* 1*a*1), *c-myc*
C Protein synthesis and translation	Polyubiquitin C (*Ubc*) gene, ribosomal protein S27a[2], ribosomal protein L27, elongation factor Tu, RNA polymerase 1-2, translation initiation factor 4 gamma[2]
D Matrix and structural protein	Lysophospholipase 1 (*lypla* 1)
E Transcription control	Transformation/transcription domain-associated protein (*trrap*)[2], telomeric repeat binding factor 1 (*terf* 1), transcription factor EB (tcfeb), DEAD-box RNA helicase (*ddx* 21)[2]
F Cell cycle	Kinesin family member 3a (*kif* 3*a*), mitotic kinesin-linked protein 1[2], cyclin-dependent kinase 4 (*cdk* 4), *cdk* 5, cyclin B1
G DNA replication	RPII215 polymerase II large subunit, topoisomerase II alpha, DNA primase p58 subunit (*prim* 2), ribonucleotide reductase

[1]Sequence in each group is ordered from high to low expression increases; [2]represents human gene.

Table 3 Up-regulation of signal transduction-related genes in NIH-3T3 treated with *O. viverrini*, categorized in groups according to the response to the specific growth factor

Related growth factor (Accession number)	Gene name/production	Folding

	Protein tyrosine kinase 9 (AW544421)	1.83
	Downstream of tyrosine kinase 1 (AW557123)	1.59

the cell cycle, the cascade of gene expression within the cells is needed. This means it is important that the initial gene expressed to be protein for the expression of the later ones. This is the action of protein classified as the transcription factor. In cells treated with *O. viverrini* ES products, a variety of transcription factors are activated.

Cyclins and CDKs are the important proteins in cell cycle progression[22]. The response of cell to *O. viverrini* ES product indicated the increased expression of many CDKs and cyclins. CDK4 and 5 are important at the G1 phase, whereas cyclin B1 is crucial in G2 phase. The increased expression of phosphorylated cyclin D1 was reported in fibroblast proliferation induced by *O. viverrini* ES product[17], thereby supporting the increased expression of

CDK4 in this study. This result supports the importance of cyclin D1-CDK4 expression in the re-entry of the serum-stimulated fibroblasts into the cell-division cycle[23]. Moreover, *O. viverrini* ES product induced the expression of kinesins which are a family of microtubles and are involved in many crucial cellular processes including cell division[24]. The kinesin family member 3a (*kif 3a*) and mitotic kinesin-like protein are crucial for spindle assembly and function, chromosome segregation, mitotic checkpoint control, and cytokinesis in higher eukaryotes[25]. Cells cannot divide without the appropriate functions of these genes.

Rapid and efficient production of macromolecule in protein synthesis and degradation of superfluous proteins play important role in cell cycle progression[26]. The increased RNA polymerase which determines the efficiency of mRNA production supports the capability of other genes to increase their expressions. The ribosomal proteins as the component of ribosomes, translation initiation factors and elongation factors increased their expressions which normally occur to promote proteins synthesized for cell division. In addition, the expression of polyubiquitin C (*ubc*) increased to get rid of the superfluous proteins already synthesized and that have reached their expired period. The increased expression of these genes is crucial for the turnover of the appropriate proteins for the right stimuli at the right time.

Matrix and structural proteins are important in supporting cell proliferation[27]. In this study, some matrix and structural proteins increased their expression level by *O. viverrini* ES product stimulation. Lysophospholipase D (lysoPLD) catalyses the production of lysophosphatidic acid (LPA) from the lysophosphatidylcholine (LPC). LPA has been demonstrated to be a potent inducer of cell proliferation of multiple cell lineages[28]. Taken together, all the data presented in this study confirm that *O. viverrini* ES product can activate cell proliferation resulting in the response of gene expression profile like a serum or growth factor[29].

Array analysis is not only crucial in understanding the effect of the ES product on cells but also to predict what should be the growth factor available in *O. viverrini* ES product. In this work, we took the advantage of this technology to decipher the possible genome expression circuit induced by *O. viverrini* ES product. The comparison of *O. viverrini* ES product-induced gene expression profile with that of established growth factor profiles may be useful to know the cell signaling pathway utilized by *O. viverrini* ES product in induction of cell proliferation. The *O. viverrini* ES product stimulated cell proliferation like the response of cells to the calf serum[19]. There are many types of growth factors contained in the calf serum including platelet-derived growth factor (PDGF), epidermal growth factor (EGF), transforming growth factor-β, and insulin-liked growth factor (IGF). Each of them stimulates a different signal transduction profile which is the most important feature used to distinguish the types of growth factor-stimulated cell responses[30,31]. In this study, the signal transduction genes selected from the array data can be categorized based on their functions as the downstream signal transduction molecules of both PDGF and EGF (PDGF/EGF), only PDGF, only EGF, and only TGF-β, according to the previous reports[30,31]. Though PDGF and EGF are different growth factors using different cell surface receptors, they used, in part, the same signal transduction pathway[32] including *abl* 1, *pk*C, *csnk* 1*a*1, *ras* and *jak* 1. The results of this study showed that *O. viverrini* ES product stimulated the expression of these genes. It may be possible that *O. viverrini* ES product activated cell proliferation *via* PDGF/EGF-driven signaling pathway. Moreover, *pdgfrα*, *eps* 8, and *tgfβ* 1*i*4, the specific genes for PDGF, EGF, and TGF-β, respectively, were found to be up-regulated as well. Based on the increased expression, *tgfβ* 1*i*4 was ranked in the uppermost expression level. It is supposed that *O. viverrini* ES product stimulated cell proliferation *via* TGF-β signaling pathway as well.

The difference between signal transduction pathways activated by TGF-β and PDGF/EGF is mainly focused on their different types of receptors. The receptors of TGF-β are membrane-bound receptors exhibiting intrinsic serine-threonine kinase activities, whereas the tyrosine kinase receptor is activated by EGF or PDGF[30,31]. From cDNA array data, the activation of serine-threonine kinase and tyrosine kinase receptors encoded gene expression showed the involvement of both types of receptors in the stimulation by *O. viverrini* ES product. This evidence still supports the possibility that TGF-β and EGF/PDGF can be the candidate signal transduction pathway induced by *O. viverrini* ES product.

Since the uncertain mRNA expression level was detected by cDNA array analysis, RT-PCR was used to measure the exact expression. From the list of up-regulated signal transduction-related genes, we selected 9 genes for additional analysis to validate the array expression data. The result showed marked increase of *tgfβ* 1*i*4 expression. It has been proven that *tgfβ* 1*i*4 is a direct target of TGF-β[33,34] and also is the transcriptional modulator stimulated by TGF-β. The *tgfβ* 1*i*4 gene expression was transcriptionally activated by TGF-β, phorbol 12-myristate 13-acetate, and serum but not appreciably by EGF[34]. The up-regulation of *tgfβ 1i4* expression induced by *O. viverrini* ES products may indicate the stimulation of the TGF-β-activated signal transduction pathway. The normal expression of *strap*, the inhibitor of the TGF-β signal transduction cascade[35], supports this conclusion.

For the EGF and PDGF-stimulated signal transduction pathways, the expressions of the common genes, including *abl* 1, *jak* 1, *h ras* and *raf* 1, were not significantly increased. Moreover, the specific gene related to PDGF-stimulated signal transduction, *pdgfrα*, was expressed at the same level as in cells without *O. viverrini* ES product treatment. This result excludes the potential of *O. viverrini* ES product in stimulating cell proliferation through the PDGF-mediated signal transduction pathway. For the EGF-stimulated signal transduction pathway, *eps* 8 is the transcription factor required in the EGF-stimulated cell proliferation and is confirmed to be the gene product that represents a novel substrate for tyrosine kinase receptors[36]. Adoptive expression of *eps* 8 cDNA in fibroblastic or hematopoietic target cells expressing the EGFR resulted in an increased mitogenic response to EGF, implicating the *eps* 8 product

in control of mitogenic signals activated by EGF[36]. That the *O. viverrini* ES product markedly stimulated the expression of this gene represents the possibility that this parasitic product stimulates cell proliferation *via* EGF-mediated signal transduction cascade. There are 4 main pathways induced by EGF, including the activations of Ras/Raf/ERK, phosphatidylinositol 3-kinase (PI3K), phospholipase C-γ (PLC-γ)/protein kinase C (PKC) and c *jun*-N-terminal kinase (JNK). These pathways lead to different cellular actions[37]. Only the Ras/Raf/ERK and JNK-transduced signal transduction pathways involve cell proliferation. In this study, the expression of *h ras* and *raf* 1 was slightly up-regulated by *O. viverrini* ES product, indicating *O. viverr*ini ES product stimulates cell proliferation *via* other pathways rather than the common pathway of Ras/Raf/ERK. The up-regulated expression of *pk*C represents the possibility of cell proliferation activated by *O. viverrini* ES product *via* the EGF-stimulated PKC signal transduction pathway. This is opposed to the data that *pk*C-mediated signal transduction pathway stimulated by EGF does not involve in control of cell proliferation[37]. Moreover, the array data showed the increased expression of JNK (2.78-fold, data not shown) represents the possibility that EGF-associated JNK pathway may be the pathway activated by *O. viverrini* ES product.

Taken all together, *O. viverrini* ES product activates cell proliferation *via* either TGF-β- or EGF-mediated signal transduction pathways. These two signal pathways have been proved to be strongly correlated with cancer development[37,38]. TGF-β also mediates tumor-promoting effects, through differential effects either on tumor or stromal cells[38]. Its signaling pathway is being evaluated as a prognostic or predictive marker for cancer patients. Over-expression of EGF has been found in many cancer types[37]. The roles of TGF-β and EGF in cholangiocarcinogenesis need further investigations. Regardless of the exact signal transduction pathway stimulated by *O. viverrini* ES product, the induction of fibroblast cell proliferation and the accumulation of extracellular matrix (i.e. collagen) have been proven to be associated with the fibrogenetic process[13]. The increased expression of collagen type I, III, and IV (between 2-3-fold increase) was observed in cDNA array analysis (data not shown). This supports the hypothesis that *O. viverrini* ES product can stimulate cell proliferation and collagen production leading to the fibrosis formation. Since the fibrosis has been detected in cholangiocarcinoma in both animal models and human[9-11], it is possible that *O. viverrini* ES product-induced fibrosis may be one component in cholangiocarcinogenesis. Moreover, it may be proposed that the ES product-induced fibrosis may act synergistically with the immunological response against the parasites to promote CC.

In summary, this study demonstrates the gene expression profile obtained from cDNA array analysis to determine the possibility of *O. viverrini* ES product as the growth factor in induction of fibroblast cell proliferation. Signal transduction-related genes may have a significant expression increment in cells exposed to this parasitic product. Among this set of genes, *tgfβ* 1*i*4 and *eps* 8 were found to have the strongest expression levels with corroboration data obtained by both cDNA array and RT-PCR. These two genes are the specific signal transduction molecules for TGF-β- and EGF-stimulated pathways. It may therefore be proposed that *O. viverrini* ES product activated cellular proliferation *via* the pathways of these growth factors. The issues of whether one type of growth factor is capable to cross-stimulate the two pathways or two types of growth factors are available in the *O. viverrini* ES product, needs future experiments to be clearly elucidated. This report is an important resource to indicate the mechanism of *O. viverrini* ES product-stimulated fibroblast cell proliferation *via* TGF-β- or EGF-stimulated signal transduction pathways. Since the activated fibroblast has been shown to initiate non-tumorigenic epithelium to carcinoma[16], *O. viverrini* ES product-stimulated fibroblast may play a part to change bile duct epithelium into CC. The ongoing research in understanding the signaling pathways stimulated by *O. viverrini* ES product and roles of fibroblasts in the development of CC will provide a novel target for chemoprevention and treatment of fibrosis in this cancer which may delay the formation of CC.

Abstract

AIM: To evaluate the effects of abdominal trauma on hemorrhagic shock-induced acute lung injury in rats.

METHODS: Five groups were allocated (n = 8) in the study. Group I was taken as the control group, group II as the hemorrhagic shock group, group III as hemorrhagic shock + laparotomy, group IV as hemorrhagic shock + splenectomy and group V as splenectomy + omentectomy + hemorrhagic shock group. Hemorrhagic shock was induced by drawing blood and reducing mean arterial pressure (MAP) to 40 mmHg within 10 min. After a hypotensive period of 1 h, animals were resuscitated. Bronchoalveolar lavage (BAL) was performed to recover cells from the alveolar space with 40 mL of BAL fluid after resuscitation malondialdehyde (MDA) and L-γ-glutamyl-L-cysteinyl-glycine (GSH) levels were measured in serum, erythrocytes and lung tissue.

RESULTS: Serum, erythrocyte, lung tissue MDA and GSH levels were significantly increased in hemorrhagic shock groups II-V (P < 0.05). Lymphocyte, neutrophil and alveolar macrophage counts in BAL fluid indicated a significant difference between control and shock groups (P < 0.05).

CONCLUSION: The degree of trauma increases hemorrhagic shock-induced acute lung injury.

INTRODUCTION

Acute respiratory distress syndrome (ARDS) and acute lung injury (ALI) frequently occur after major trauma with a high mortality[1,2]. Clinically, acute lung injury is characterized by altered gas exchange, dyspnea, decreased static compliance, and nonhydrostatic pulmonary edema[3]. Firmly implicated mediators are endotoxin, cytokines, and products of arachidonic acid metabolism, leukocyte-derived proteolytic enzymes, and toxic oxygen species. The basic mechanisms of lung injury are focused on oxidant-mediated damage[4]. Recent evidence supports that leukocyte activation and the subsequent release of large quantities of highly reactive oxygen radicals and hydrogen peroxide are partially responsible for diffuse microvascular and tissue injury in patients with hemorrhagic shock. It has been shown that neutrophils in trauma patients release greater amounts of superoxide anion, proteases, and proinflamatory cytokine[5]. In addition to neutrophils, alveolar macrophages and circulating macrophages as well as endothelial cells aggravate lung injury and alveolar neutrophil sequestration[6]. In response to various inflammatory stimuli, lung endothelial cells, alveolar cells, airway epithelial cells, and alveolar macrophages, produce both nitric oxide and superoxide[7].

To address these issues we designed a trauma model of controlled hemorrhagic shock. Free oxygen radical metabolism of serum, erythrocyte, lung tissue and cellular change in alveolar epithelium was investigated in this model, but the main objective was to understand the role of abdominal injury in hemorrhagic shock.

MATERIALS AND METHODS

Animals

Adult male Wistar Albino rats weighing 243-325 g were used in experiments. Animals were housed and kept at 25℃ in a 12 h light/dark cycle and used in studies after an acclimatization period of 7 d. Rats were allowed to have

Table 1 Serum, erythrocyte, tissue MDA and GSH levels, and lymphocyte, neutrophil, alveolar macrophage counts in BAL fluid of different groups (mean ± SD)

	Group I	Group II	Group III	Group IV	Group V
Serum MDA (μmol/L)	1.374 ± 0.24[a]	2.095 ± 0.246	2.54 ± 0.18	3.04 ± 0.12	3.57 ± 0.23[c]

[a]$P < 0.05$ *vs* hemorrhagic shock groups; [c]$P < 0.05$ *vs* other groups.

free access to rodent chow and water before experiment. All animals were maintained in accordance with the recommendations of the Guide for the Care and Use of Laboratory Animals. The Süleyman Demirel University Medical School Animal Use and Care Committee approved all experiments. In the experiments, forty rats were used and allocated into five groups ($n = 8$). Group I was taken as the control group, group II as the hemorrhagic shock group, group III as hemorrhagic shock + laparotomy group, group IV as splenectomy + hemorrhagic group, and group V as splenectomy + omentectomy + hemorrhagic shock group.

Methods

Animals were intraperitoneally anesthetized with 80 mg/kg ketamine and 8 mg/kg xylazine. The right carotid artery was cannulated with a 24-gauge angiocathether for monitoring the mean arterial pressure (MAP), blood sampling, and resuscitation. Hemorrhagic shock was induced by drawing blood and reducing MAP to 40 mmHg for 10 min. Blood was collected into 0.1 mL citrate to prevent clotting. After a hypotensive period of 1 h, animals were resuscitated by transfusion of blood and Ringer lactate in a volume equal to that of blood. After a period of two hours blood samples were taken *via* carotid artery, and the catheter was removed with the artery ligated. The cervical incision was extended towards midline to isolate trachea. Trachea was catheterized with a feeding tube (No: 8) and stabilized with 4/0 silk suture to perform bronchoalveolar lavage (BAL). BAL was performed to recover cells from the alveolar space with 40 mL of BAL fluid. Lung tissue was resected to measure tissue malondialdehyde (MDA) and L-γ-glutamyl-L-cysteinyl-glycine (GSH) levels after bronchoalveolar lavage. Control animals underwent the same procedures, but hemorrhage was not induced.

In groups III-V, additional surgical procedures were added. In group III (hemorrhagic shock + laparotomy) after hemorrhagic shock was maintained, a midline incision in 2 cm length was performed on the abdominal wall. The incision was sutured with 4/0 silk suture. In group IV (hemorrhagic shock + laparotomy + splenectomy) after laparotomy splenectomy was performed with its vessels ligated, laparotomy incision was sutured as in group III. In group V (hemorrhagic shock + laparotomy + splenectomy + omentectomy) omentectomy was added. All vessel boundaries were ligated when the omentum was removed.

BAL fluid and its analysis

The lungs were lavaged using the feeding tube with BAL fluid containing cold phosphate buffered saline (PBS), 8 mmol/L sodium phosphate, 2 mmol/L potassium phosphate, 0.14 mol/L sodium chloride, and 0.01 mol/L potassium chloride (pH7.4) and 0.1 mmol/L ethylenedia minetetraacetic acid (EDTA). Forty mL of BAL solution was used for lavage in each animal, and about 90% was re-collected. The fluid was centrifuged at 700 r/min for 15 min. Supernatant was collected and re-suspended in 1 mL of the same solution. Two slides were prepared from each sample, and stained with Wright-Giemsa stain. A total number of 100 cells were counted in each slide with immersion objective (100 ×) and the number of neutrophils, lymphocytes and alveolar macrophages was counted respectively.

MDA and GSH levels in serum, erythrocyte and lung tissue

Hemolysate and serum of the blood specimens were prepared and stored at -70℃ until assay. The lung specimens were homogenized with a mechanic homogenizator (Ultra-Turrax T25) and sonicated (Bandelin D.12207) in phosphate buffered saline (pH7.4). The homogenate was centrifuged at 10000 r/min for 15 min at 4℃ and supernatant was used for determination of the MDA and GSH concentrations. MDA, an end product of lipid peroxidation, was assayed by the method of Drapper and Hadley[8]. GSH levels were determinated by the method of Beutler *et al*[9].

Statistical analysis

All data were analyzed by one-way ANOVA with *post hoc* test Bonferroni. Data were expressed as mean ± SD. $P \leqslant 0.05$ was considered statistically significant.

RESULTS

There was no difference in MAP values before and after hemorrhagic shock between the groups ($P > 0.05$). Serum, erythrocyte and lung tissue MDA levels were significantly higher in hemorrhagic shock groups (groups II-V) than in control group ($P < 0.05$, Table 1). MDA levels were also significantly different in groups II-V. Serum MDA

levels had a trend to increase with hemorrhagic shock and additional surgical injury ($P < 0.05$). The same trend could be seen in erythrocyte and lung tissue MDA levels ($P < 0.05$, Table 1).

Serum, erythrocyte and lung tissue GSH values were significantly lower in groups II-V than in control group ($P < 0.05$, Table 1). All GSH levels were decreased especially in group V ($P < 0.05$), but the difference in groups II-IV was not significant ($P > 0.05$). The decreased serum GSH levels were parallel to the severity of trauma, but the difference in groups II-V was not statistically significant ($P > 0.05$, Table 1). Similar GSH levels in lung tissue were obtained. Tissue GSH level in group V was significantly lower than that in other groups ($P < 0.05$).

Lymphocyte, neutrophil and alveolar macrophage counts in BAL fluid indicated a significant difference between groups ($P < 0.05$, Table 1). The highest lymphocyte and neutrophil counts were found in group V. Although there was no significant difference in group II-V, lymphocyte, neutrophil and alveolar macrophage counts were significantly higher in groups II-V than in control group.

DISCUSSION

Many mediators of acute lung injury in animal models and ARDS in human beings have been implicated as causative factors. Selection of agents that can abrogate these mediators is based on the efficacy of these agents in whole animal models, and their relative potency and potential toxicity. Through examination of metabolic processes, GSH has been shown to be important in host defenses against oxidative stress[3]. Another important agent showing oxidative stress is MDA, a marker of free radical activity[3]. After ischemia-reperfusion, lipid peroxides induce a substantial drop in intracellular GSH levels[10,11]. In this study, hemorrhagic shock and resuscitation significantly elevated serum, erythrocyte and lung tissue MDA levels ($P < 0.05$). GSH levels were significantly lower in hemorrhagic shock groups than in control group ($P < 0.05$). It was reported that oxidative stress significantly elevated MDA levels and reduced GSH levels[12,13]. These significant alterations were also seen in our study. MDA levels were significantly higher in group V (laparotomy + splenectomy + omentectomy) than in other groups ($P < 0.05$). Serum GSH levels of erythrocyte and lung tissue were also altered in hemorrhagic shock groups ($P < 0.05$). All these findings support the hypothesis that ischemia-reperfusion affects free oxygen radical metabolism and additional surgical trauma increases this effect. Lipid peroxidation seems the main mechanism of free radical toxicity and results in alterations of structural integrity and function of cellular membranes[14]. Intracellular overproduction is not the only mechanism of free radical-induced lung injury[15]. Hypoxia can damage alveolar macrophages, which may release chemotactic and activating factors for polymorphonuclear neutrophils[16]. The release of toxic oxygen may result in endothelial injury, which is an early event in the course of oxygen-induced lung damage.

Neutrophils sequestered in the lung play a central role in the pathogenesis of ARDS. Lung polymorphonuclear neutrophile accumulation in ARDS occurs as a result of a cascade of cellular events initiated by either infectious or noninfectious inflammatory stimuli[17]. Neutrophil and lymphocyte counts were significantly increased in BAL fluid of hemorrhagic shock groups in this study ($P < 0.05$). There was also a significant difference between these groups. The count of these cells increased significantly with the degree of surgical trauma ($P < 0.05$). Alveolar macrophage count was similarly increased in BAL fluid in shock groups ($P < 0.05$), the difference between these groups was not significant. There was no relation between the degree of trauma and alveolar macrophage count increase ($P > 0.05$). These observations can be explained with the findings in the studies of Jorens *et al*[18] and Bernard *et al*[19]. Acute lung injury in ARDS is largely due to activated neutrophils, which not only aggravate oxidative stress in the lungs but also release mediators, including cytokines and lipids.

In conclusion, oxidative stress and surgery increase free oxygen radicals in serum, erythrocytes and lung tissue and lead to epithelial injury in the lungs. The observed injury seems related with the degree of trauma.

Abstract

AIM: To analyze the importance in predicting patients risk of mortality due to upper gastrointestinal (UGI) bleeding under today's therapeutic regimen.

METHODS: From 1998 to 2001, 121 patients with the diagnosis of UGI bleeding were treated in our hospital. Based on the patients' data, a retrospective multivariate data analysis with initially more than 270 single factors was performed. Subsequently, the following potential risk factors underwent a logistic regression analysis: age, gender, initial hemoglobin, coumarines, liver cirrhosis, prothrombin time (PT), gastric ulcer (small curvature), duodenal ulcer (bulbus back wall), Forrest classification, vascular stump, variceal bleeding, Mallory-Weiss syndrome, RBC substitution, recurrent bleeding, conservative and surgical therapy.

RESULTS: Seventy male (58%) and 51 female (42%) patients with a median age of 70 (range: 21-96) years were treated. Their in-hospital mortality was 14%. While 12% (11/91) of the patients died after conservative therapy, 20% (6/30) died after undergoing surgical therapy. UGI bleeding occurred due to duodenal ulcer (n = 36; 30%), gastric ulcer (n = 35; 29%), esophageal varicosis (n = 12; 10%), Mallory-Weiss syndrome (n = 8; 7%), erosive lesions of the mucosa (n = 20; 17%), cancer (n = 5; 4%), coagulopathy (n = 4; 3%), lymphoma (n = 2; 2%), benign tumor (n = 2; 2%) and unknown reason (n = 1; 1%). A logistic regression analysis of all aforementioned factors revealed that liver cirrhosis and duodenal ulcer (bulbus back wall) were associated risk factors for a fatal course after UGI bleeding. Prior to endoscopy, only liver cirrhosis was an assessable risk factor. Thereafter, liver cirrhosis, the location of a bleeding ulcer (bulbus back wall) and patients' gender (male) were of prognostic importance for the clinical outcome (mortality) of patients with a bleeding ulcer.

CONCLUSION: Most prognostic parameters used in clinical routine today are not reliable enough in predicting a patient's vital threat posed by an UGI bleeding. Liver cirrhosis, on the other hand, is significantly more frequently associated with an increased risk to die after bleeding of an ulcer located at the posterior duodenal wall.

INTRODUCTION

Acute bleeding from the upper gastrointestinal (UGI) tract remains a major cause of morbidity and mortality. Over the last decades, mortality after UGI bleeding has been reported to range between 8% and 14% of cases[1-8]. Selected groups, i.e. patients who underwent surgical therapy for UGI bleeding, die at a risk of about 21%[9].

Despite improved diagnostic measures, emergency endoscopy[10], improved conservative and surgical treatment[5,11], mortality after UGI bleeding remains high[1]. An increase in the number of high-risk patients with reduced ability to compensate for the consequences of bleeding may be one of the reasons for this phenomenon[11,12]. Further, UGI bleeding is the most common emergency in gastroenterology, with an incidence of about 50 to 150 bleeding episodes per 100 000 inhabitants per year[4,11,13,14].

Numerous prognostic factors have been described in literature to be associated with a lethal outcome; however, to date, it remains unclear whether a single or a combination of these parameters is valid in predicting the vital threat of a patient with an UGI bleeding[1,13,15,16]. Some

factors were assessed for decision making on early surgical therapy in patients with bleeding ulcers[5,17]. However, they have not become clinical routine due to their poor reliability.

There are very few studies which report on risk factors for an increased threat after UGI bleeding based on multivariate analysis[1]. Thus, our retrospective study was designed to evaluate published risk factors for their value in predicting the threat to patients with UGI bleeding.

MATERIALS AND METHODS

Patients

A database was established retrospectively using information on consecutive admitted patients, with evidence of UGI bleeding treated in the Department of General Surgery, Ruprecht-Karls-University, Heidelberg, Germany during 4 consecutive years from January 1st, 1998 to December 31st, 2001.

The patients were identified with endoscopy, patients' admission (electronic patients chart SARA-Med), and an operation protocol database. Within the evaluated 4 years, a total of 264 patients with the suspicion of UGI bleeding were found (Figure 1). Thirty-six of these were treated temporarily in the outpatient clinic. In these cases no hospitalization was necessary. Further 38 patients were excluded from analysis since their charts could not show enough evidence of an UGI bleeding. Forty-two patients' charts were not available for analysis. Thus, these patients were excluded from further analysis. Twenty-six cases have not been documented in the way needed for an appropriate analysis. Since a gap-free documentation is needed for statistics, a total of 65 patients were excluded from this study. Moreover, patients were excluded from this study if UGI bleeding was due to previous surgery or endoscopic intervention (n = 1).

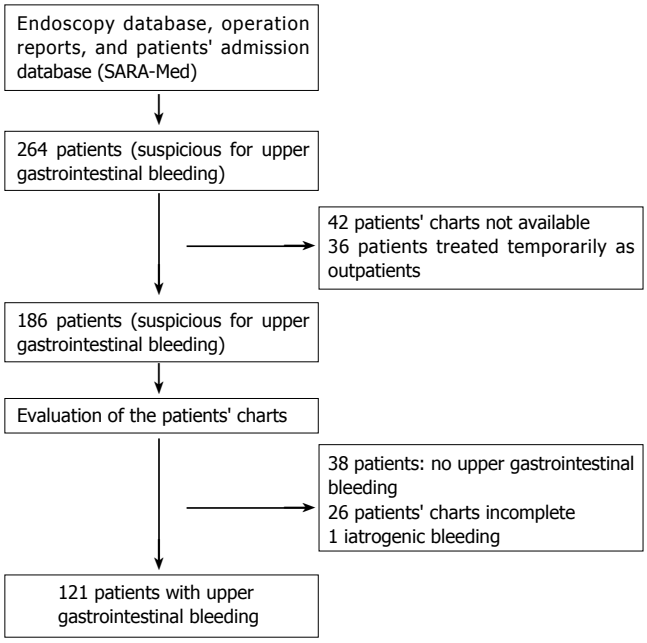

Figure 1 Identification of patients with an UGI bleeding qualifying for statistical analysis (Identification of all patients with an UGI bleeding who received clinical treatment within a period of 4 years from January 1st, 1998 to December 31st, 2001).

Literature research

MedLine was searched for gastrointestinal hemorrhage, gastrointestinal bleeding, bleeding peptic ulcer, peptic ulcer hemorrhage, bleeding from the upper gastrointestinal tract, stigmata of hemorrhage, prediction of mortality, emergency endoscopy, predictive factors, and further hemorrhage. Fifty-five publications on prognostic factors and risk factors of UGI bleeding were found, including papers mentioned in their references. Subsequently, factors (i.e., renal failure, heart failure, diabetes mellitus and others; n = 79) were classified according to the frequency of their appearance. Factors which fulfill at least one of the following conditions have been included: Factors which have been mentioned at least twice in the context of risks and prognosis for mortality, recurrence of bleeding, failed endoscopic therapy or necessity of surgery and a significant correlation between the parameter and mortality after univariate or multivariate analysis.

Analysis at different time points of therapy

During various stages of therapy, different information was available. Thus, analysis was performed at the time of admission, right after endoscopy and after completed therapy. The following information on the patients were given and analyzed:

At admission: Age, gender, medication [i.e. coumarines, acetyl salicylic acid (ASS), non-steroidal antirheumatics (NSA)], liver disease, laboratory findings (i.e. hemoglobin, PT) were recorded.

At endoscopy: In addition to information obtained at admission, the localization, the Forrest classification and the presence of a vascular stump were elucidated.

At the end of therapy: In addition to the aforementioned information, the number of blood units transfused, frequency of re-bleeding and the number of operations were recorded.

Statistical analysis

The in-hospital survival was chosen as the endpoint. It was analyzed as to how the probability of survival depends on covariates by means of stepwise logistic regression[18] where the significance level for entry of a covariate was chosen as 0.2 and the significance level for staying was chosen as 0.15.

Only parameters which were documented for all of our 121 patients with a special focus on clinical relevant parameters published before were analyzed. The possible covariates which were considered are: gender, age (dichotomised at 70 years), medication (ASS, NSA, and coumarines), liver cirrhosis, gastric ulcer (small curvature), duodenal ulcer (bulbus back wall), varices, Forrest classification, vascular stump, prothrombin time (dichotomised at 50%), hemoglobin concentration (dichotomised at 60 g/L), transfused blood units (dichotomised at 6 units), recurrence of bleeding and operations.

Three models were applied. The first considered the knowledge of covariates before the first gastroduodenoscopy. The second model takes only the patients with

Table 1 Reason for the occurrence of upper gastrointestinal (UGI) bleeding

Reason for bleeding	Duodenal ulcer	Gastric ulcer	Erosive mucosal lesion	Esophageal varicosis	Mallory-Weiss-syndrome	Cancer	Coagulopathy	Lymphoma	Benign tumor	Unknown reason
%	29.8	28.9	16.5	9.9	6.6	4.1	3.3	1.7	1.7	0.8
Number (n = 125)[1]	36	35	20	12	8	5	4	2	2	1

[1]Four patients presented with both duodenal and gastric ulcers with each showing an endoscopic evidence of bleeding and thus each ulcer was counted as a whole.

Table 2 Logistic regressions analysis of covariables recorded at admission of 121 patients considering their ability in predicting the patients' lethality

Covariable	*P*	Statistical inclusion in model	Odds ratio	95% confidence interval
Cirrhotic liver disease	0.005	Yes	4.5	1.4-13.8
Hb	0.256	No		
Medication	0.419	No		
PT	0.672	No		
Age	0.822	No		
Gender	0.879	No		

bleeding in the ulcers where the Forrest classification is valid into account, whereas the third model considers the covariates which are known after the termination of bleeding[18].

RESULTS

Patients

The total of 121 patients with UGI bleeding included in our analysis comprised of 70 males (58%) and 51 females (42%), making a gender distribution of 1.4:1. The median age distribution of the patients was 70 years, the youngest being 21 and the oldest 96 years. The most frequent cause for UGI bleeding was duodenal ulcer (n = 36; 30%) of which n = 13 were located at the bulbus back wall. Other reasons for UGI bleeding in descending order of occurrence were gastric ulcer (n = 35; 29%) of which n = 12 were located at the lesser curvature, erosive lesions of the mucosa (n = 20; 17%), esophageal varicosis (n = 12; 10%), Mallory-Weiss syndrome (n = 8; 7%), cancer (n = 5; 4%), coagulopathy (n = 4; 3%), lymphoma (n = 2; 2%), benign tumor (n = 2; 2%) and an unknown reason (n = 1; 1%). Four patients had both duodenal and gastric ulcers with each ulcer showing endoscopic evidence of bleeding, and hence each ulcer was counted as one (Table 1).

Total lethality

Out of the 121 patients analyzed, 17 died, resulting in a total mortality of 14%.

Logistic regression analyzed at different time points of therapy

At admission: Of all the prognostic parameters which were considered for logistic regression, only the prognostic parameter of cirrhotic liver disease could improve the predictability of dying as a result of an UGI bleeding. Liver cirrhosis at admission increased the risk of mortality due to UGI bleeding by 4.5 fold (P = 0.005, 95%-confidence interval: 1.4-13.8). The other prognostic parameters recorded at admission (Hb, PT, age, gender and medication) did not have a predictive value (Table 2).

At endoscopy: Sixty-seven patients with duodenal or gastric ulcers were analyzed; fourteen prognostic parameters which were recorded during endosopic examination were tested on how far they prove to be a threat to the patients' survival. Three of the tested parameters were taken up into the model, as their existence could help in predicting the faith of an ulcer patient. Cirrhotic liver disease (P = 0.029; 95%-confidence interval: 1.1-34.4) increased the mortality risk 5.9-fold as a result of UGI bleeding. Furthermore, male patients had a 4.8-fold higher risk of not surviving an UGI bleeding (P = 0.065; 95%-confidence interval: 1.0-34.8). An ulcer located at the bulbus back wall increased a patient's lethality 3.5-fold (P = 0.135; 95%-confidence interval: 0.6-20.7). Other parameters, such as the Forrest classification, played no substantial role in improving the predictive strength of the statistic model (Table 3).

At the end of therapy: Only 2 of the 12 different prognostic parameters tested at the end of therapy were of significance; a patient with cirrhotic liver disease had a 5.7-fold higher risk of dying of an UGI bleeding (P = 0.005; 95% confidence interval: 1.7-19.3) as compared with a patient with healthy liver. An ulcer located at the bulbus back wall increased the lethality 3.4-fold (P = 0.092; 95%-confidence interval: 0.7-14.7). All remaining parameters did not improve the predictability and were not taken up in model (Table 4).

Subgroup analysis of liver disease patients

The logistic regression analysis at the 3 different time points showed that the covariable cirrhotic liver disease significantly increased the predictive value at all time points. In 21 of our evaluated patients liver disease occurred, analysis of the correlation between these patients and 9 covariables showed following findings: an initial Hb < 6 mg/dL increased the risk of dying of an UGI bleeding 9.75-folds (P = 0.077; 95%-confidence interval: 0.8-121.8). When these patients experienced recurrence bleeding during their hospital stay, the risk was increased 4.5-folds (P = 0.135, 95% confidence interval: 0.6-32.3). Moreover, additional surgical treatment resulted in a 4.5-fold risk increase (P = 0.164; 95% confidence interval: 0.5-37.4). On the contrary, the necessity to transfuse more that 6 units red blood cells (RBCs) as well as the location of a gastric ulcer at the small curvature did not increase the risk factor (Table 5).

Table 3 A logistic regression analysis evaluating 14 prognostic parameters in their ability to increase the predictability of lethality of 67 patients with UGI bleeding resulting from duodenal or gastric ulcer

Covariable	*P*	Statistical inclusion in model	Odds ratio	95% confidence interval
Cirrhotic liver disease	0.029	Yes	5.9	1.1-34.4

DISCUSSION

The lethality of our evaluated patient group of 14% confirms with records of selected patient groups in other surgical departments[9]. These findings compared to the standards of today's medicine where a lethality of more than 10% is classified as high, depict that the lethality of UGI bleeding patients has been underestimated tremendously. Although many risk factors are listed in literature and many scores[5,17] as well as indices[13,16] have been suggested, there is still ongoing uncertainty as to which parameters are threatening or which patient group is to be classified as high-risk group. The many univariate analysed records found in today's literature do not fully make up for the multi-factorial situation of an UGI bleeding, which requires multivariate analysis. The disadvantages of prospective study designs, when it comes to long-term studies, made us choose the limited but short-termed retrospective study design.

The results of our multivariate analysis which showed that of all the possible risk factors considered at admission of a patient with UGI bleeding, only the covariable liver cirrhosis proved to be a strong enough prognostic factor in predicting the lethality of such patients. The only multivariate study, which also evaluated patients at admission[19], reported further risk factors such as age above 75 years, diagnosed carcinoma, evidence of blood in gastric aspirate and a systolic blood pressure below 90 mmHg. These findings could not be confirmed in our study. The covariable blood in gastric aspirate was considered by us as a diagnostic criterion and hence not taken into consideration.

The analysis of data gained after endoscopy showed in our study that only the evidence of cirrhotic liver disease as covariable could significantly increase the ability to predict the lethality of a patient being treated because of UGI bleeding. Other variables, such as male gender and an ulcer located at the bulbus back wall, were found to be of weaker predictable strength. On the other hand, other studies reported an evidence of disease[20,21], recurrent bleeding[2,21,22], transfusion of more than 5 units of RBCs[20,22] and an ulcer size of more than 1 cm[20,22] as significant prognostic parameters. However, the parameters including patients age above 60 years[2,22], evidence of gastric bleeding[2], an initial Hb below 100 g/L and complications[21] as prognostic parameters applicable for a patient with ulcer bleeding could not be confirmed in our multivariate analysis.

Other multivariate analyses of prognostic parameters for patients after UGI bleeding therapy found in literature confirm our result that the covariable cirrhotic liver disease is significant in predicting the lethality of patients[13,23]. Other reports which noted factors such as elevated serum transaminases[19,23], high albumin levels[23] and existence of life-threatening disease[24] tend to confirm our findings as well, as these listed factors could be interpreted as descriptive of liver disease.

The existing correlation between liver disease and the covariables; Hb, the number of operations and recurrent

bleedings during treatment of UGI bleeding suggests their probable influence on the lethality of this patient group. The relationship could be due to the fact that these parameters tend to outline the risk profile of liver disease patients. A study which reports that the lethality of patients with liver disease correlates with the number of bleeding occurrences and the extent of renal failure[25], confirms our results.

In summary, most prognostic parameters used in clinical routine today are not reliable enough in predicting the patient's vital threat due to UGI bleeding. Liver cirrhosis is the only risk factor which shows a significantly more frequent association with a fatal course after UGI bleeding in our patients.

Abstract

AIM: To evaluate roles of syndecan-1, bcl6 and p53 in diagnosis and prognostication of immunoproliferative small intestinal disease (IPSID) and to study profiles of kappa (κ) and lambda (λ) light chains and IgA heavy chain.

METHODS: The study consisted of 11 cases of IPSID and similar number of controls which included 11 of normal intestinal mucosa and 11 of high grade B cell lymphoma of ileum. The parameters analyzed included clinical profiles, biochemical and other laboratory investigations, radiologic and histological findings including immunohistochemistry.

RESULTS: All IPSID cases had demonstrable serum IgA heavy chain and heavy mucosal plasma cell infiltration. According to Galian's histological staging, there were 4 patients with stage A and 7 with stage B. κ and λ light chains were over-expressed in 7 patients; 1 stage A patient had *H pylori*-positive active gastritis and eradication of *H pylori* led to disease remission. Stage A biopsies had higher expression for syndecan-1, while stage B had higher expression for bcl6 and p53. Syndecan-1, κ and λ light chains and IgA heavy chain showed inverse relationship with bcl6 and p53. All patients were treated with doxycycline. CHOP regime was added in 5 patients who developed frank lymphoma. Three died of the disease due to extensive organ infiltration.

CONCLUSION: Certain immunomarkers like syndecan-1, κ and λ light chains and IgA heavy chain could be of much help in identifying early stage IPSID. Stage B IPSID showed higher expression for bcl6 and p53 than stage A IPSID. bcl6 and p53 expressions correlated with a more advanced disease stage and aggressive tumour behavior.

INTRODUCTION

Immunoproliferative small intestinal disease (IPSID) or alpha heavy chain disease is quite frequently seen in Mediterranean countries[1-7] compared to rest of the world[8-12]. It usually affects young individual of low socio-economic status. Reduction in incidence has been observed with improvement of living conditions[13-15]. Plasma cells of IPSID secrete bio-chemically abnormal IgA heavy chain in all body fluids[16-18]. Monoclonality in plasma cell of early stage IPSID has been demonstrated by immunohistochemistry and polymerase chain reaction[19-23]. IPSID is known to have an indolent course. Complete remission could be obtained with long-term antibiotic therapy in stage A IPSID, though the ultimate outcome of the disease is unpredictable[22,23]. Syndecan-1 is a member of cell surface trans-membrane heparan sulphate proteoglycans[24] and is expressed by pre-B, mature plasma cell and myeloma cell line[25-27]. In *in vitro* studies, syndecan-1 has inhibitory effect on growth of myeloma cell line and B cell lymphoma[27,28]. Reduction in syndecan-1 expression has been observed with dedifferentiation of non-plasma cell malignant tumors[29] and down-regulation of p53 and Ki67 expression[30]. *bcl6* gene product, a nuclear phospho-protein, is expressed independently of *bcl6* gene rearrangement[31]. bcl6 expression is restricted to germinal center B cell and certain percentage of intra-follicular T cell[32]. It is over-expressed in high grade B-cell lymphoma, marginal zone B cell lymphoma and in some cases of follicular lymphoma and nodular lymphocytic predominance Hodgkin's lymphoma[31-35]. In good number of gastric MALTomas and intestinal diffuse

large B-cell lymphoma, expression patterns of bcl6 have been evaluated[36]. *p53* gene plays an important role in cell cycle by checking and controlling apoptotic pathways and abnormal cell proliferation. In absence of a functional *p53* gene, apoptotic pathway does not become activated and cell cycle progresses without the repair of the defective DNA. Hence, it is known as "gate-keeper gene"[37]. Mutation in *p53* gene results in proliferation of abnormal cell by blocking the apoptotic pathways and is seen in various pre-malignant and malignant conditions[37-39]. *H pylori*-associated early stage MALToma are known to regress following eradication of *H pylori*. This observation suggests evolvement of MALToma from benign antigen-driven B cell[40-42]. IPSID, like in *H pylori*-associated MALTomas, likely represents follicle center and/or marginal zone B-cell response to chronic infection by bacteria or parasites and eventually acquiring uncontrolled proliferation and probably monoclonality. Early staged IPSID usually responds to antibiotic therapy alone[43,44].

Histologically, Galian *et al*[23] has classified IPSID into 3 stages. Stage A is characterized by mucosal infiltrate by mature plasma cell and lymphocytes. In stage B, mucosa shows presence of atypical or immature plasma cells and lymphocytes, which could extend to deeper portion of the intestinal wall. Stage C is the frank lymphomatous stage with involvement of draining lymph nodes. Stage A is treated by antibiotics alone and stage B requires additional cytotoxic drugs[45,46]. Differentiating between stage A and B is of therapeutic and prognostic importance. With the advancement in imaging techniques, clinical staging is based on observations made on CT and MRI, without subjecting the patient to laparatomy[7]. The protocol was hence planned to study (1) histological profiles of IPSID in endoscopic biopsies, (2) to evaluate roles of syndecan-1, bcl6 and p53 in diagnosis and prognostication of IPSID, and (3) expressions of kappa (κ) and lambda (λ) light chains, and IgA heavy chain.

MATERIALS AND METHODS

Materials

The study included 11 cases of IPSID who presented with features of malabsorption. All had demonstrable serum alpha heavy chain by immuno-electrophoresis. Endoscopic biopsies of 11 patients showed heavy mucosal infiltration predominantly by plasma cell with lymphocyte. According to Galian's *et al*[23], histological grading was done as follows: stage A identified by heavy lamina propria infiltration by mature plasma cell and lymphocyte; stage B by lamina propria infiltration with extension into sub-mucosa and/or with few scatter immature plasma cell; and stage C by infiltrating immature plasma cell with variable degree of intestinal wall infiltration and regional lymph node involvement. In all patients studied, 3 to 5 mucosal biopsy fragments were available from involved segments of the intestine. Additional two tissue fragments from pyloric antrum, one each from anterior and posterior wall, were taken only when there was abnormality i.e. either involvement by the ongoing disease or if there was changes of gastritis.

Methods

Baseline assessment of all the biopsies was done on H&E-stained sections for all the eleven patients. Peroxidase anti-peroxidase technique was used for immunohistochemistry. Primary antibodies used were: (1) Syndecan-1 (dilution 1: 50, Dako), (2) bcl6 (pre-diluted, Neomarker), (3) p53 (pre-diluted, DO7, Dako), (4) κ and λ light chains (dilution 1:100, Dako), and (5) IgA specific for heavy chain (dilution 1:800, Dako). Antigen binding epitope site exposure was done by heating in a microwave oven placing the slides in a Coplin jar containing citrate buffer (pH 6) for 12 min in three divided cycles. Detection system used was Envision (Dako). Di-aminobenzedine (DAB) was used for labeling and samples were counterstained lightly with haematoxylene.

The controls included positive control and normal control: (1) CD20-positive non-maltomatous high grade diffuse lymphoma of jejunum served as positive control; and (2) normal intestinal mucosa from margin of surgically resected small intestine served as normal control.

Immunostainings were interpreted with respect to positively stained plasma cells and lymphocytes in percentages of the total cells counted. Mean values were calculated. Light chain over-expression was documented when more than 75% of plasma cells and lymphocytes showed positivity for one of the light chains.

Informed consent was obtained from all patients before subjecting them to endoscopic procedure. Ethic Committee of the Institute approved the protocol.

Statistical analysis

Chi-square test and paired Student's *t* test were used for comparison. *P* value less than 0.05 was considered statistically significant.

RESULTS

The case collection ranged over thirteen years period. The clinical details are depicted in Table 1. Besides anemia, 1 patient had low platelet count (37 000 /mL). Urinary D-xylose excretion test (within 5 h after 5 g of oral D-xylose administration) was abnormal in 10 patients (normal > 1 g). Nine had increased fecal fat (7.67-30 g in 24 h, normal < 6 g/24 h). Abnormal D-xylose excretion test was recorded in 3 stage A and 7 stage B IPSID patients. Fecal fat level was increased in 3 and 4 patients with stage A and stage B IPSID, respectively. Stool examination for ova, cyst and parasite were negative in all patients. All cases had increased level for serum IgA. Pattern of intestinal involvement in radiology and endoscopy are shown in Table 1. Diagnosis of IPSID was based on demonstration of alpha heavy chain in serum and increased IgA levels (range, -340 to 660 mg%). Histology of all the 11 cases showed heavy plasma cell infiltration of the lamina propria admixed with variable amount of lymphocytes and scattered eosinophils. As a result of heavy mucosal cellular infiltration, increased mucosal thickness and wide spacing of the glands were observed (Figure 1). The mucosal infiltrating cell showed extension to sub-mucosa in 7 patients, and scattered

immature plasma cells were also observed in 5 cases. One patient had histological evidence of active gastritis with *H pylori* in the gastric antral biopsy. In remaining cases, antral biopsies showed mild chronic inflammation of superficial mucosa and were negative for *H pylori*. Histologically (Galian's staging), stage A was found in 4 cases (1 case with *H pylori* infection) and stage B in 7 cases. Bone marrow was examined in 7 patients of stage B, but no atypical cells were detected in any biopsies.

Immunohistochemistry

Total number of positively stained cells was expressed in percentages and a total of 1000 cells were counted for each biopsy (Table 2).

Syndecan-1 expression: As shown in Figure 2, plasma cells had strong cytoplasmic positivity. Epithelial, endothelial and stromal cells showed faint cytoplasmic positivity. Only the plasma cells were counted and expressed in percentages. The mean values were significantly higher in IPSID patients compared to normal and lymphoma controls ($P < 0.05$). Stage A cases though had higher expression of syndecan-1 compared to stage B IPSID, the difference did not reach statistical significance.

bcl6 expression: As shown in Figure 3, bcl6 expression

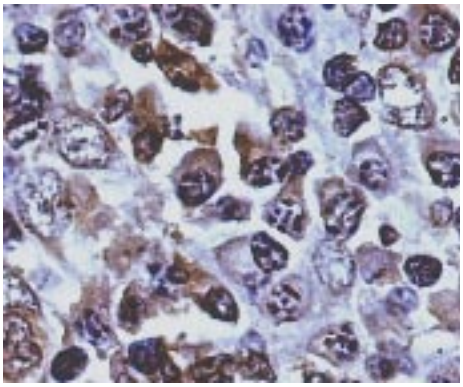

Figure 2 Photomicrograph showing strong syndecan-1-positive cells (PAP, × 440).

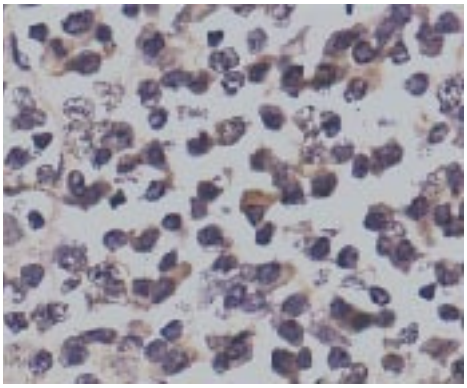

Figure 3 Photomicrograph showing bcl6-positive cells (PAP, × 440).

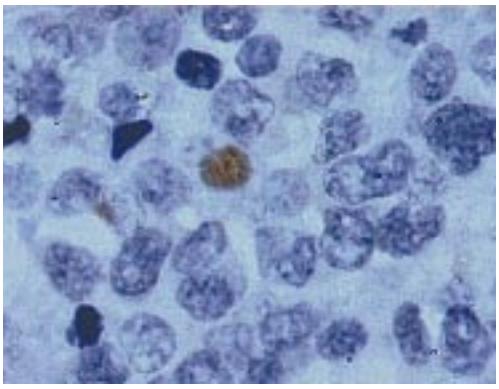

Figure 4 Photomicrograph showing p53 positivity in nuclei (PAP, × 1000).

was low on the whole; higher number of positively stained cells were seen in stage B IPSID and lymphoma control than stage A IPSID and normal control. Four of normal controls failed to stain. The differences between the mean values were not significant.

p53 expression: As shown in Figure 4, p53 expression was low and comparable amongst the different groups. Lymphoma had maximum number of positive cells, while lowest or negligible positive cells were observed in normal control. Stage A IPSID and normal control showed significantly lower mean values compared to lymphoma control ($P < 0.05$). However, no significant difference was observed between stage A, stage B and normal control.

Light chains

κ light chain: The expression of κ light chain was seen both in plasma cell and lymphocyte. Highest value was detected in stage A patients ranging from 12% to 80%; two patients had 78% and 80%, respectively, one patient had 12%, and the 4th patient had 58%. Stage B patients had the values ranging from 46% to 87%, and 4 patients showed more than 75%. Lymphoma had a range of 18% to 82% and 5 had more than 75%. Normal control had a range of 39% to 53%. Stage A and B IPSID patients had significantly higher values compared to normal and lymphoma controls ($P < 0.05$). κ light chain over-expression (> 75%) was seen in 2 of stage A and 4 of stage B patients. Few lymphocytes and plasma cells failed to stain.

λ light chain: The expression of λ light chain was found to be inversely correlated with κ light chain expression. There was a wide range for λ light chain expression. One stage A patient with λ light chain over-expression had a value of 78%. Those patients with κ light chain over-expression had values less than 25%. Two of stage A patients with κ light chain over-expression had 9% and 15% for λ light chain. The 4th stage A patient had 38%. Stage B patients had values ranging from 9% to 40%. The four patients with κ light chain over-expression had 9%, 15%, 20% and 18% of λ light chain, respectively. In the rest 3 patients, no over-expression of any of the two light chains had 30%, 36% to 40% for λ light chain. Lymphoma control had a range of 12% to 29% and one had 69%. Normal control had a range of 26% to 37%. Seven IPSID patients (3 stage A and 4 stage B patients) showed light chain over-expression (i.e. κ light chain in 6 and λ light chain in 1).

Heavy chain

IgA heavy chain expression was higher in IPSID patients compared to other groups. Stage A patients had values ranging from 58% to 81% and stage B had 40% to 91%. No significant differences were observed between stage A and B IPSID patients. Similarly, no significant differences were found between the patients of stage A and B with light chain over-expression and without light chain over-expression. Lymphoma control had values ranging from 13% to 30% and 5 of the control cases failed to express heavy chain. Normal control had values ranging from 32% to 45%. Stage A and B patients had significantly higher values than the two controls ($P < 0.05$).

Treatment and outcome

All cases were treated either with doxycycline (100 mg BD for 4 wk, followed by 100 mg OD for the next 6 to 12 mo) or tetracycline (500 mg TDS for 6 to 12 mo). Three patients initially received anti-tubercular drugs for a month with no clinical response. Subsequently, all three were diagnosed as IPSID (1 stage A and 2 stage B) based on demonstration of serum alpha heavy chain and heavy plasma cell infiltration in the endoscopic biopsies.

Stage A IPSID: The patient with λ light chain over-expression received 8 mo of doxycycline and remained disease-free at 120 mo of follow-up. Two patients with κ light chain over-expression responded initially to 9

mo of doxycycline and developed sub-acute intestinal obstruction at 18 and 11 mo of follow-up. Laparotomy revealed patches of proximal jejunal loops thickening. Resected intestinal segments showed trans-mural plasma cell infiltration mixed with lymphocyte and scattered immature plasma cell. Both patients received CHOP regime for six cycles and remained disease-free at 36 and 29 mo of follow-up, respectively. One patient with duodenal and proximal jejunal involvement had associated *H pylori*-positive active gastritis. Following treatment for *H pylori* (Omeprazole 20 mg BD, amoxycilin 500 mg BD and clarithromycin 250 mg TDS for 2 wk), he showed marked clinical improvement. Two weeks latter, repeat radiology and endoscopy showed no residual disease and no evidence of gastritis on repeat follow-up biopsy. He remained disease-free at 40 mo of follow-up. This particular patient did not have positivity for bcl6. The other 2 stage A patients failed show positive staining for bcl6. The 2 patients who developed frank lymphoma on follow-up had higher p53 and low syndecan-1 expression.

Stage B IPSID: Three patients received doxycycline for 9, 9 and 12 mo, respectively; all remained disease-free at 165, 93 and 46 mo of follow-up, respectively. One patient with κ light chain over-expression with hepatosplenomegaly and involvement of splenic flexure and stomach responded to 6 courses of CHOP and remained in remission for 6 mo. She went into relapsed with no response to treatment. At autopsy, terminal part of small intestine and proximal half of colon showed diffuse thickening with mucosal nodularity. Histology showed features of immunoblastic lymphoma with hepatic and splenic infiltration. One case with κ light chain over-expression was disease-free at 57 mo of follow-up. Three patients with κ light chain over-expression responded to doxycycline therapy and remained in remission at 35, 42, and 57 mo of follow-up. The first two patients had recurrence of the symptoms after 35 and 42 mo and biopsies from proximal jejunum revealed high-grade lymphoma. Subsequently, both were put on CHOP regime but failed to respond and died of the disease. Syndecan-1 expression was higher in four patients (57%, 61%, 65%, and 69%) and all remained disease-free at follow-up compared to the patients who had disease recurrence or died of the disease (36%, 40%, and 42%) ($P < 0.05$). Those 3 patients with unfavorable prognosis also had higher values for bcl6 but the differences were not significant ($P > 0.05$) (8%, 7%, and 5%) than those in remission (0.5%, 2%, 3%, and 3%). Expression of p53 was also obviously higher in those who succumbed to their illness (i.e. 11.5%, 9%, and 7%) than the ones who were in remission (1%, 4%, 5%, and 6%) ($P < 0.05$).

DISCUSSION

Syndecan-1 expression was found to be higher in all cases of IPSID compared to other groups. This would be in relation to number of plasma cell present. Higher mean values observed in stage A than stage B would suggest a phenotypic alteration of the cells i.e. benign to malignant clone. Syndecan-1-positive cell was significantly lower in lymphoma control cases ($P < 0.01$). Patients of stage A and B IPSID with unfavorable disease outcome also had low syndecan-1 expression compared to the ones with favorable outcome ($P > 0.05$). A higher syndecan-1 expression (> 50% positive) would infer a better prognosis. Similarly, such distinctive difference in the number of positive cell has been recorded in certain other types of tumors[26-30]. bcl6 expression was weak and low. Stage B IPSID patients and control lymphoma had comparatively higher values than stage A IPSID patients and other groups ($P > 0.05$). These three stage B cases subsequently developed high grade tumor had higher bcl6 expression. In our study, bcl6 appears to be a poor prognostic indicator. Similar observations have been made in diffuse large and marginal zone B-cell lymphomas and nodular variant of Hodgkin's lymphoma[31,34-36]. Besides, bcl6 expression would infer IPSID cells originating from germinal center B cell. Ariatti *et al*[33] made such suggestion with respect to bcl6-positive lymphoma. Mutant form of p53 is over-expressed by many malignant tumors including lymphomas. Similar to bcl6 expression, higher p53 values were recorded in those cases with poor outcome, whereas lower value was seen in those cases who were in remission at follow-up ($P < 0.05$). Minimum value was expressed by normal control followed by stage A and B IPSID and highest by lymphoma control.

Over-expression of one type of light chain was exhibited by our cases, as had been observed in few other studies[19-21,23]. Number of cases with κ light chain over-expression was more than that of λ light chain. Over-expression of λ light chain had also been reported in one case by Isaacson *et al*[19,20]. Monoclonality, exhibited by our patients, further strengthens the view expressed in previous studies, as an inherent character of IPSID as in lymphoma. However, monoclonality appeared not to influence the ultimate outcome of disease process. But study in more number of cases would be required before drawing such conclusion. IgA heavy chain over-expression was diffuse and uniformly strong in IPSID cases. This character of IPSID could be interpreted with important clinical implication. And this would help to identify and differentiate patients of IPSID, especially stage A, from other similar clinical conditions and investigative findings including histology.

Similar to our cases of *H pylori*-positive stage A IPSID, Fishbach *et al*[44] reported one patient in whom the underlying disease was controlled following eradication of *H pylori*. As stage A IPSID could be successfully treated with antibiotics, this effect of anti-*H pylori* could be more generalized rather than specifically related to *H pylori* eradication. Exposure to a long-standing cause and effect relationship between *H pylori* infection and IPSID localizing to foregut requires critical analysis and documentation in more number of cases. Gastric biopsy in the rest of cases did not show evidence of *H pylori* infection, though 1 case had evidence of infiltration by underlying disease process.

Colonic and hepatosplenic involvement in IPSID is usually seen only with overt lymphomatous conversion or in recurrent disease[47-50]. Three of our patients had gastric and colonic involvement at presentation with no overt lymphomatous conversion. But within one-year period, all the three cases developed overt lymphoma and two of the

cases succumbed to their illness in spite of the treatment

In conclusion, over-expression of syndecan-1, IgA and light chain would help in differentiating stage A IPSID from normal and stage B IPSID. Expression of bcl6 and p53 would indicate an aggressive behavior and a more advanced disease stage. bcl6 and p53 exhibited an inverse relationship with syndecan-1 expression. Gastric *H pylori* infection, though was seen only in one case with the active gastritis, would be advisable to look for in all cases of IPSID by carrying out gastric or pyloric antral biopsies.

ACKNOWLEDGMENTS

We would like to thank Ms Anu Khuller and Monica Ahuja for carrying out the immunostainings, Ms Surekha Sharma for typographical help and Ms Tranum Kaur (Research Scholar) for statistical calculation.

Abstract

AIM: To study the expression levels of E- selectin, integrin β1 and immunoglobulin supperfamily member-intercellular adhesion molecule-1 (ICAM-1) in human gastric carcinoma cells, and to explore the relationship between these three kinds of cell adhesion molecules and gastric carcinoma.

METHODS: The serum contents of E-selectin, integrin β1 and ICAM-1 were detected by enzyme-linked immunosorbent assay (ELISA), in 47 healthy individuals (control group) and in 57 patients with gastric carcinoma (gastric carcinoma group) respectively prior to operation and 7 d after operation.

RESULTS: The serum E-selectin, ECAM-1 and integrin β1 were found to be expressed in both control and gastric carcinoma groups. However, they were highly expressed in patients with gastric carcinoma patients before operation or with unresectable tumours. The expression levels of ICAM-1 and integrin β1 were significantly higher in gastric carcinoma patients than in controls ($P < 0.01$). A comparison of the E-selectin levels between the two groups showed statistically insignificant difference ($P = 0.64$). In addition, the expression levels were all decreased substantially in the postoperative patients subjected to radical resection of the tumours, indicating that the high level expressions of these compounds might be the important factor for predicting the prognosis of these patients.

CONCLUSION: Serum E-selectin, ICAM-1 and integrin β1 expression levels are probably related to the metastasis and relapse of gastric cancer.

INTRODUCTION

The adhesion between endothelial cells and cancer cells is the essential intermediate link for tumor metastasis mediated by specific cellular surface receptors including selectin, integrin and cell adhesion molecule family[1]. Many investigations indicate that adhesion family members are involved in the progression of cancer[2]. The binding of cancer cells to endothelial cells mediated by the E- selectin is reportedly related to their metastatic potentials[3]. The intercellular adhesion molecule-1 (ICAM-1) a member of the immunoglobulin superfamily, its ligand is the adhesion molecule (LFA-1) of the immunoglobulin superfamily. Integrin-β1 is a member of the adhesion superfamily, which not only mediates the adhesion between cells and extracellular matrix, but also mediates the adhesion between leucocytes and blood vessel endothelial cells. The expression of E-selectin, ICAM-1 and integrin β1 on small blood vessels in tumour-infiltrating area at a high level is capable of suggesting the interaction between endothelial cells[4]. In the present study, we detected the serum E- selectin, ICAM-1 and integrin β1 contents in patients with gastric carcinoma in order to evaluate their clinicopathologic significance.

MATERIALS AND METHODS

Patients and healthy individuals

A total of 57 patients with gastric carcinoma, including 31 males and 26 females, at the age of 34-77 years , with a median age of 55 years, in Zhejiang Provincial People's Hospital and First People's Hospital of Taizhou were diagnosed as gastric carcinoma by pathological examination from January 2000 to December 2003. According to the WHO staging standard, 13 patients were classified into stage I, 5 patients stage II, 31 patients stage III, and 8 patients stage IV. These patients could also be

classified into intestine type and diffuse type based on Lauren's histological typing principle, and classified into well-, moderately- and poorly- differentiated types based on the predominant differentiation mode, respectively. All patients did not receive radiotherapy, chemotherapy, blood transfusion, steroid and opium drugs prior to operation. All the patients were followed up for 9 mo (1-48 mo) and their dates and causes of death were recorded.

Forty-seven healthy individuals, consisting of 31 males and 16 females, (at the age of 32-68 years, with a medium age of 51), were recruited as the control group. They were selected as blood donors and did not have any disease.

Assay procedure

The healthy individuals and patients were all fasted overnight. Blood samples were collected from their peripheral veins at 8-9 h AM next day, and then the blood samples were stored at -80℃ after the sera were separated by centrifugation. The blood samples from the patients with gastric carcinoma were collected both before and 7 d after operation respectively.

Assays for serum E-selectin, ICAM-1 and integrin β_1 were carried out using the solid phase ELISA test kit provided by the Parameter R &D Systems (USA), following the manufacturer's instructions. The test sensitivities were estimated to be 1 ng/mL, 2 ng/mL and 0.3 ng/mL for E-selectin, integrin β_1 and ICAM-1, respectively. Any resulting values for the patients which were 95% higher than those for the control were defined as the elevated contents of serum adhesion molecules. The cut-off values of E-selectin, ICAM-1 and integrin β_1 were 50.4 ng/mL, 337 ng/mL and 5.2 μg/mL, respectively. Therefore, if the cut-off values were higher than the above values, the high level expression should be considered as positive.

Statistical anaiysis

All data were analyzed by the SPSS 10.0 statistical software package, and their abnormal distributions were distinguished from the normal ones. At the same time, the variability of the medium values and the distributive ranges for the experimental data were evaluated using the unvariate analysis. The non-matched and matched data were evaluated using the variate Kruskal-Wallis analysis (analysis of variance, ANOVA), Mann-Whitney *U* test and Wilcoxon grade-related test. The multivariate analysis was conducted using Cox Proportional Hazards Regression Mode after the predicted variability was determined using the single factor analysis.

RESULTS

Contents of E-selectin, integrin β_1 and ICAM-1 and their comparison

The E-selectin, integrin β_1 and ICAM-1 were detected in all serum samples. The content of serum integrin β_1 in the preoperative gastric carcinoma group and control group was 4.8 μg/mL and 2.1 μg/mL, respectively (P = 0.00002). The content of ICAM-1 in the preoperative gastric carcinoma group and control group were estimated to be 271 ng/mL and 193 ng/mL, respectively. (P = 0.0004). The content of E-selectin in the preoperative gastric carcinoma group and control group was 42.1 ng/mL and 39.6 ng/mL, respectively (P = 0.64).

Table 1 Diagnostic value of elevated E- selectin, ICAM-1 and integrin β_1 levels in prediction of gastric carcinoma

Diagnostic value	E- selectin (> 50.4 ng/mL)	ICAM-1 (> 337 ng/mL)	Integrin β_1 (> 5.2 μg/mL)
Sensitivity (%)	24.6	33.3	28.1
Specificity (%)	95.7	95.7	95.7
Positive prediction value (%)	87.5	90.5	88.9
Negative prediction value (%)	51.3	54.2	52.3
Predominance ratio	7.32	11.25	8.78
95% confidence region	1.57-34.15	2.46-51.42	1.9-40.73

Expression levels of E-selectin, ICAM-1 and integrin β_1 in gastric carcinoma patients

The positive rates of E-selectin, ICAM-1 and integrin β_1 expression in gastric carcinoma group were 25.0%, 32.7% and 28.8%, respectively. The accuracy for diagnosing gastric carcinoma based on the expressions of these 3 adhesion molecules is shown in Table 1.

In gastric cacinoma group, 38 patients died in the progressive stage of gastric carcinoma, and tumours relapsed in 3 of the 19 remaining survivors. The serum E-selectin, ICAM-1 and integrin β_1 levels were higher in the progressive stage of tumour, and the elevated levels were significantly correlated with the tumour staging (P < 0.05).

No correlations were found between tumour T staging and serum E-selectin (P = 0.053) and ICAM-1 (P = 0.1)level. The serum E-selectin level [47.5 (36.8-58.3) ng/mL] in the patients with T4 tumour, was significantly higher than that [33.8 (28.4-41) ng/mL] of the patients with T_{1-3} tumour (P = 0.006) . Furthermore, the serum ICAM-1 level [292 (201-437) ng/mL] in the patients with T_3 and T_4 tumour-infiltrating serous membrane layer was significantly higher than that [231 (154-266) ng/mL] of the patients with T_1 and T_2 tumours in mucous membrane, submucous layer and proper muscular layer (P = 0.023).

The serum expression levels of E- selectin, ICAM-1 and integrin in patients with lymph node metastasis were higher than those in patients with no lymph node metastasis (the former *vs* the latter: P = 0.04, 0.004, and 0.0018, respectively). As compared with the non-remote metastatic group, the remote metastatic group had higher serum E-selectin, ICAM-1 and integrin β_1 levels (P < 0.05). The serum E-seletin, ICAM-1 and integrin β_1 levels were not correlated with the tumour location (gastric antrum, gastric body or gastric cardia), tumour typing and differentiation degree (Table 2).

Effect of surgery on expression of E-selectin, ICAM-1 and integrin β_1

Among the 57 patients with gastric carcinoma, 41 were subjected to radical gastric resection and regiongal lymph node cleaning, 16 had unresectable tumours. All the patients had no postoperative complications. The postoperative serum E-selectin, ICAM-1 and integrin

Table 2 Variability analysis of the prognoses and predictive factors in patients with gastric carcinoma

Variables	Risk ratio	95% confidence region	*P*
Age	0.97	0.94-1.01	0.2
Sex	0.77	0.39-1.54	0.47
Tumor location (gastric antrum, gastric body or gastric cardia)	0.95	0.62-1.45	0.81
Tumour histology (intestine type and diffusion type)	1.32	0.70-2.52	0.38
Tymour differentiaton degree (high,moderate, low)	1.19	0.71-1.96	0.49
Tumour staging (stages I-IV)	2.65	1.71-4.11	0.000
T (T_1-4)	2.75	1.75-4.34	0.000
N (No, N_1)	4.33	1.65-11.36	0.003
M (Mo, M_1)	7.36	2.98-18.2	0.000
E-selectin (elevated, normal)	2.81	1.40-5.63	0.003
ICAM-1 (elevated, normal)	2.71	1.37-5.36	0.004
Integrin β_1 (elevated, normal)	2.1	1.05-4.18	0.035

β_1 contents decreased significantly (P = 0.04, 0.01, and 0.001, respectively). Conversely, the postoperative serum E-selectin, ICAM-1 and integrin β_1 levels in the16 patients with nonresectable tumours were similar to those before operation (P = 0.08, 0.09, and 0.2, respectively).

Variability analysis of prognosis and predictive factors in patients with gastric carcinoma

The monovariate analysis revealed that the TNM staging, tumour-infiltrating deepth in gastroparietes (T status), lymph node metastasis, remote metastasis, as well as the preoperative serum E-selectin, ICAM-1 and integrin β_1 levels were the important factors affecting the total survival rate of the patients (Table 2). The multiple statistical analysis of all the factors was carried out, the results indicated that tumour staging was the only independent factor for predicting the survival of the patients.

DISCUSSION

The present study demonstrated that the preoperative high levels of ICAM-1, integrin β_1 and E-selectin in patients with gastric carcinoma had higher specificity and lower sensitivity for the diagnosis of gastric carcinoma. The serum contents of the three kinds of adhesion molecules significantly correlated with tumour staging, gastropariete infiltrating, lymph node metastasis and remote metastasis. Although the relationship between serum ICAM-1 and metastasis in the present study further proved the previous observations, the correlation between the serum E-selectin and integrin β_1 contents and remote metastasis is reportedly contradictory sometimes[5-8].

Previous investigations showed that certain kinds of cytokines are able to induce the expression of E-selectin, ICAM-1 and integrin β_1[9,10]. Monocytes are the only origin of sICAM-1. Large amounts of sICAM-1 in serum could be found in the culture of certain tumour cell strains' indicating that tumour cells may also be the origin of sICAM-1 which may explain the decreased serum sICAM-1 in patients with gastric carcinoma after resecting of their tumours. Moreover, sICAM-1 could not be produced through different forms of mRNA splicing[8,10].

In the present study, all the preoperative serum E-selectin, ICAM-1 and integrin β_1 levels in the patients with gastric carcinoma were found to be an important factor affecting the prognosis of the patients, suggesting that the levels of E-selectin, ICA-1 and integrin β_1 can be used as supplementary markers to determine the disease condition, stage and prognosis, as well as the therapeutical efficacy in the patients. However, multiple statistical analyses of all the factors have revealed that tumor staging could be used to predict the survival of cancer patients as an independent factor. The discrepancy between effects of the adhesion molecule levels in peripheral circulation on the prognosis of patients with gastric carcinoma in different reports is possibly attributed to the different number of patients used and the different progression stage of the disease[9-11].

Abstract

Peliosis hepatis is a rare condition characterized by dilatation of hepatic sinusoids and blood-filled spaces in the liver mainly observed in subjects exposed to toxic substances or estrogens, which is frequently asymptomatic. Non-cirrhotic idiopathic portal hypertension (NCIPH) is also a vascular disease of the liver rarely observed in European countries, which is usually diagnosed only when the hemorrhagic complications of portal hypertension occur. We report a case of NCIPH in a young Caucasian male who was diagnosed with liver peliosis, showing ultrasonographic and endoscopic signs of portal hypertension four years after. A second biopsy was diagnostic for NCIPH. Even if the pathogenesis remains obscure, peliosis hepatis can be considered as an early sign of vascular disease of the liver, which may progress to more definite conditions.

INTRODUCTION

Portal hypertension in Europe is mainly due to intra-hepatic causes, almost exclusively by liver cirrhosis, which leads to an increase in sinusoidal pressure. While the identification of pre-hepatic causes such as extra-hepatic portal vein thrombosis is now feasible by non invasive means such as eco-color-Doppler and CT-scan, rarer forms of intra-hepatic pre-sinusoidal portal hypertension such as non cirrhotic idiopathic portal hypertension (NCIPH) are difficult, and rely on invasive techniques such as hepatic vein catheterisation and hepatic biopsy. We describe a case of NCIPH developed in a young Italian man who was first diagnosed as peliosis hepatis carrier. Hepatic vein catheterisation confirmed the clinical suspicion, and the diagnosis was finally ascertained by histology. This is the first reported case in which NCIPH follows a peliosis hepatis. This may represent an early histological finding in case of vascular diseases of the liver.

CASE REPORT

A 36-year-old Italian man was referred to our unit for a sonographic evaluation of chronic liver disease. He was in very good clinical condition, did not drink alcohol, and was neither exposed to toxic substances nor to any drugs. The patient also denied any exposure to anabolic steroids. Family history indicated a grandmother died of digestive bleeding in the setting of end-stage primary biliary cirrhosis (PBC). Relevant findings in patient's history were a persistent slight elevation of gamma-glutamyl-transferases and aminotransferases associated with leuco- and thrombocytopenia noticed for the first time at the age of 26 years. At the age of 28 years, the patient suffered from spontaneous bilateral sublaxation of the shoulder, for which he underwent surgical repair. A muscle biopsy taken during the intervention was normal. Due to the persistence of abnormal laboratory findings mentioned above, at 32 year-old he was examined in another hospital and screened for chronic liver disease. Laboratory tests excluded viral, metabolic and autoimmune causes of liver disease. Abdominal ultrasound scan showed only a slight enlargement of the spleen (longitudinal diameter 130 mm), while liver and portal system were normal, no sign of portal hypertension was evident. A liver biopsy was performed, showing the typical aspects of microscopic peliosis. The patient also underwent a bone marrow

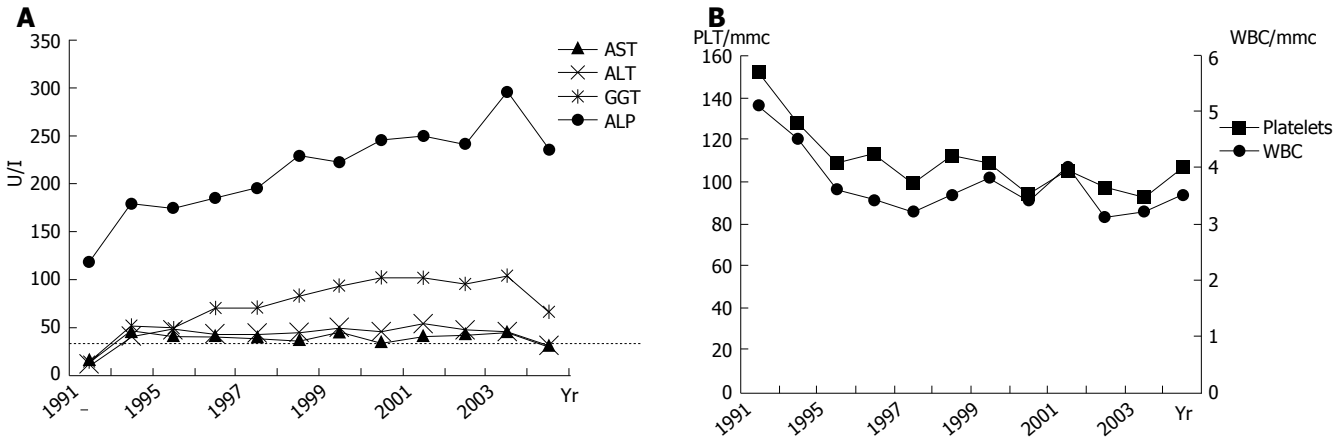

Figure 1 Aminotransferases and cholestasis enzymes (**A**) and white blood cells (WBC) and platelets (**B**) during follow-up.

Table 1 Laboratory findings on admission and after ursodeoxycholic acid (UDCA)

	On admission	During UDCA treatment (one year)
Haemoglobin (g/L)	146	148
White cells (× 10^3/mL)	3.12	3.5
Neutrophils (%)	59.2	60.3
Platelets (× 10^3/mL)	93	107
Creatinine (mg/dL)	1.08	0.9
Na^+(mEq/L)	143	140
K^+ (mEq/L)	3.9	4.1
AST (IU/L)	44	31
ALT (IU/L)	47	31
ALP (IU/L)	241	235
GGT (IU/L)	95	67
CPK (IU/L)	182	160
LDH (IU/L)	284	225
INR	1.03	1.11
Albumin (g/L)	4.3	4.1
Bilirubin (mg/dL)	1.04	0.6
Cholesterol (mg/dL)	212	228
Triglycerides (mg/dL)	81	89

biopsy in the same year, due to persistent leuco- and thrombocytopenia, which revealed a normal pattern.

The Echo-color-Doppler performed at our unit demonstrated a coarse liver echo-texture, splenomegaly (longitudinal diameter 155 mm), patency of portal vein and intrahepatic branches, with normal portal blood flow velocity (15 cm/s, normal value > 14), patency of splenic vein and superior mesenteric vein, and US signs of portal hypertension, namely ectasia of left gastric vein with hepatofugal flow and a small spontaneous spleno-renal shunt. Intraparenchymal branches of hepatic and splenic artery showed high resistance and pulsatility indices. Hepatic veins were patent and showed a normal triphasic flow.

Since portal hypertension had not been detected before, the patient was hospitalized to perform a diagnostic procedure.

Physical examination demonstrated that the patient's stature was 1.65 m, his weight 70 Kg, arterial blood pressure was 115/70 mmHg, and heart rate was 48 bpm. He showed hypertrophy of proximal muscles of upper and lower limbs (the patient made no significant physical activity), multiple small telangiectasias on the trunk and lower limbs, splenomegaly, and white striae on the flanks.

Figure 1 shows laboratory findings in patient's history, and Table 1 lists those at the moment of first visit at our unit. Alanine aminotransferasis (ALT) and gamma-glutamyl transferases (GGT) were persistently elevated during the last 10 years, but no sign of liver failure was present. Autoantibodies for PBC, primary sclerosing cholangitis, connective tissue diseases and autoimmune thyroiditis tested were negative. Inherited thrombogenic disorders and hematologic diseases were also excluded. An electrocardiogram showed sinus bradycardia (48 bpm) but no other pathological aspects. An upper digestive tract endoscopy confirmed portal hypertension showing small esophageal varices. The patient also underwent an invasive hepatic hemodynamic study. By accessing *via* right brachial vein under fluoroscopic control, a 5F balloon-catheter was advanced in the main hepatic vein and hepatic venous pressure gradient (HVPG) was obtained by the difference between wedged (by inflating the balloon) and free pressures. Figure 2 shows tracing of hepatic vein pressures. Free pressure was normal, wedge pressure and HVPG were only slightly elevated (HVPG 7 mmHg, normal value 1-5 mmHg), suggesting idiopathic portal hypertension. A needle liver biopsy was then obtained. Liver tissue samples were examined by the same experienced pathologist (F.C.) who studied the first ones. Histology showed periportal fibrosis, obliteration of small portal veins and some areas of nodular regenerative hyperplasia (NRH), which were consistent with the diagnosis of NCIPH. No alteration of bile ducts was noted nor cholestasis. Peliosis hepatis was no more observable.

Due to the slightly cholestatic feature of liver disease, we empirically treated the patient with a high dosage (15 mg/Kg of body weight) of ursodeoxycholic acid (UDCA). After one year of treatment GGT decreased to near-normal levels and aminotransferases became normal (Table 1 and Figure 1A).

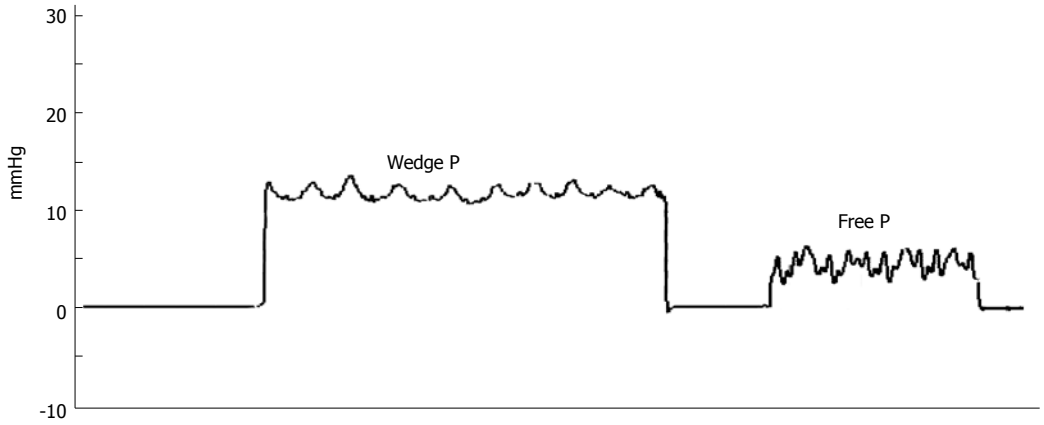

Figure 2 Hepatic hemodynamic findings consistent with the diagnosis (wedge pressure 12 mmHg, free pressure 5 mmHg, hepatic venous pressure gradient 7 mmHg).

DISCUSSION

Peliosis hepatis is a rare disorder characterized by the presence of cystic, blood-filled spaces of variable size in the liver[1]. Endothelial cells cover the internal surface of these cavities, and adjacent hepatocytes can be normal or show atrophic or degenerative changes[2]. A microscopic form and a macroscopic form have been described. In the microscopic form ultrasound and CT do not show any macroscopic change in the liver. It has been reported mainly in adult patients in association with chronic diseases (AIDS, malnutrition, tuberculosis, lepropsy, vasculitis, haematological neoplasias, hepatocellular adenoma and hepatocarcinoma), various pharmacological agents (androgenic anabolic steroids and estrogens, immunosuppressive drugs, tamoxifene), toxic substances (arsenic, vinyl chloride), infections (Bartonella henselae)[3], and in renal transplant recipients receiving immunosuppressive treatment[4,5]. The morphogenesis of peliosis is controversial. It has been attributed to an increased sinusoidal pressure because of difficulties in blood outflow from the liver, the disappearance of normal parenchyma by necrosis of liver cells, and sinusoid wall weakness. Since the disease is very rare, data about its natural history are scarce and clinical spectrum varies from asymptomatic cases to severe complications, such as hemoperitoneum[3].

Idiopathic non-cirrhotic intrahepatic portal hypertension (NCIPH) was first identified by Banti in 1898[6]. An increased portal pressure with patent portal and hepatic veins characterizes it, in the absence of cirrhosis[7]. The anatomic basis for these alterations is an increased fibrous component in portal vessel wall and periportal and perisinusoidal space, inducing a pre- and perisinusoidal resistance to flow of portal venous blood. Therefore wedge hepatic venous pressure does not reflect the increased pre-sinusoidal portal pressure and HVPG is usually normal or near-normal[8].

NCIPH is clinically characterized by the signs of portal hypertension (varices and portosystemic collateral vessels), overt splenomegaly with pancytopenia, and relatively mild abnormalities in liver function tests[9]. Bilirubin is reported to be normal in NCIPH series, but literature does not mention GGT levels. To our knowledge this is the first reported case in which GGT is elevated at presentation.

While NCIPH is quite common in India and Japan, it is rarely observed in developed countries[10,11]. The clinical course of the disease is usually silent until gastrointestinal bleeding secondary to variceal rupture develops. If variceal bleeding can be controlled, 5-year survival rate is about 95%[9].

The recognized causes are varied. Schistosomiasis[12] and toxic substances (arsenic, vitamin A) are the most frequent ones, interestingly the latter ones are the same agents recognized as causes of peliosis hepatis. In many cases the etiology remains unknown, and the disease is defined "idiopathic". In these cases immunological disturbance (autoimmune diseases such as scleroderma, mixed connective tissue disease, autoimmune thyroiditis), thrombophilic status, latent myeloproliferative disorders, infections and/or increased fibrogenesis in the portal tract are suspected as being candidates for the primary agents[13]. Hillaire and colleagues[14] have recently analysed a series of patients with NCIPH identifying a thrombophilic status (overt or latent) in the majority, but this could be excluded in the case we report.

As for biopsy features, many pathological entities such as idiopathic portal hypertension, benign intrahepatic portal hypertension, hepatoportal sclerosis, nodular regenerative hyperplasia, and incomplete septal cirrhosis can be grouped under the term idiopathic NCIPH, as they frequently show a number of overlapping features[14,15]. The finding of peliosis hepatis in the first biopsy of our patient suggests that this entity may represent a praecox presentation of the vascular changes, which occur in NCIPH. Our observation is supported by the paper of Cavalcanti and colleagues[4], who performed serial liver biopsies in a group of kidney-transplanted patients with peliosis hepatis, showing that the disease can evolve, leading to regenerative nodular hyperplasia, perisinusoidal fibrosis and cirrhosis in some cases.

Another interesting finding in our patient is a second grade relative affected by primary biliary cirrhosis (PBC). Among autoimmune diseases, PBC has been shown to have a strong heritability[16], and some familial cases describing the involvement of second-degree relatives have been reported[17,18]. PBC is a cause of non-cirrhotic portal hypertension in the first stage of the disease, and some cases of PBC resembling NCIPH have been previously reported[19]. Even if bile ducts were found to be normal in

our patient's biopsy and no clear evidence of an overlap could be proved, interestingly an empiric treatment with UDCA induced a normalization of aminotransferases and a reduction of GGT (Table 1).

When all the known causes of NCIPH are excluded the finding of previous bilateral glenohumeral instability, white striae at flanks, hypertrophy of proximal muscles of upper and lower limbs and peliosis hepatis in the same individual make conceivable to hypothesize that some unrecognized disturbances of connective tissue can be linked to all these conditions, eventually leading to NCIPH.

Abstract

Noni juice (*Morinda citrifolia*) has been approved for use as a safe food within the European Union, following a review of safety. Since approval, three cases of acute hepatitis in Austrian noni juice consumers have been published, where a causal link is suggested between the liver dysfunction and ingestion of anthraquinones from the plant. Measurements of liver function in a human clinical safety study of TAHITIAN NONI® Juice, as well as subacute and subchronic animal toxicity tests revealed no evidence of adverse liver effects at doses many times higher than those reported in the case studies. Additionally, *M. citrifolia* anthraquinones occur in the fruit in quantities too small to be of any toxicological significance. Further, these do not have chemical structures capable of being reduced to reactive anthrone radicals, which were implicated in previous cases of herbal hepototoxicity. The available data reveals no evidence of liver toxicity.

TO THE EDITOR

Morinda citrifolia (noni) fruit juice was approved as a novel food ingredient in pasteurized fruit drinks by the European Commission Decision of 05-06-2003. This approval was based on the opinion of the EU Scientific Committee on Food (SCF) of Tahitian Noni® Juice, following a safety review of this product[1].

During 2004, an Austrian case report was published in which it is suggested that noni fruit juice may be responsible for acute hepatitis[2]. A second report was published in the August 2005 issue of this journal in which noni juice was again suggested to be the cause of two other cases of acute hepatitis in Austria[3]. In both publications, the authors suggest the presence of anthraquinones in the juice may be responsible for the liver dysfunction observed in their patients. However, experimental data fails to reveal any direct liver toxicity from noni juice.

TAHITIAN NONI® Juice, the brand associated with the latest case reports, was investigated in a human clinical study (unpublished data. Mugglestone C *et al*. A single centre, double-blind, three dose level, parallel group, placebo controlled safety study with TAHITIAN NONI® Juice in healthy subjects, BIBRA International Ltd. UK, 2003). Ninety-six subjects were randomly assigned to four groups. These groups included a placebo group and three test groups, receiving up to a dose of 750 mL TAHITIAN NONI Juice per day. For 28 d, subjects drank 750 mL of either the placebo or juice containing one of three doses of TAHITIAN NONI Juice.

Several parameters were investigated with measurements being made at study screening, d 0 (baseline), wk 2, wk 4, and wk 6. The measurements most applicable to the evaluation of liver function and hepatocellular disease were alkaline phosphatase (ALP), alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (BIL), gamma-glutamyl transferase (GGT), total protein, and prothrombin time (which is useful for determining the extent of hepatocellular disease).

Other study measurements included hemoglobin, hematocrit, mean cell volume, red cell count, activated partial thrombin time, total and differential white cell count, platelet count, lipids (LDL, HDL, cholesterol, triglycerides), creatine kinase, creatinine, gamma-glutamyl transferase, glucose, total protein, and uric acid. Additionally, urinalysis involved semi-quantitative ("dipstick") analysis for leucocytes, nitrite, urobilinogen, protein, pH, blood, specific gravity, ketones, bilirubin and glucose. Where necessary, a urine cyto-bacteriological examination was performed to characterize or count crystals, casts, epithelial cells, white blood cells, red blood cells and bacteria. Vital signs were measured, including systolic and diastolic blood pressure and heart rate. ECG measurements (12 lead) were also made for each subject. All adverse events were recorded. Selected mean laboratory values for the various groups are presented in Table 1.

Differences between mean values were clinically insignificant and well within the range of normal values. Furthermore, there was no evidence of any dose-related adverse events. The study results indicate that TAHITIAN

NONI® Juice is safe to consume, in quantities up to 750 mL/d, confirming the EU SCF opinion that high consumption quantities are appropriate.

The aqueous extract of *M. citrifolia* fruit was evaluated in a repeat dose oral toxicity assay in rats[4]. For 28 d, Sprague Dawley rats received 1000 mg/kg body weight. Animals were observed for clinical symptoms, body weight was recorded, and hematology and serum chemistry parameters were measured.

Among the serum chemistry measurements were AST, ALT, and GGT. There were no significant differences between the males and females of the test and control groups, with the exception of a lower AST value observed in the females of the treatment group, and an exceptionally low ALT value for the males of the control group that resulted in a statistical difference for treated males. In either instance, however, the values observed in the treatment groups were within the normal range for these animals and did not correspond to a dose-response relationship. These results did not reveal any adverse liver effects.

Two 13-wk oral toxicity studies of TAHITIAN NONI® Juice in rats were performed (unpublished data, Glerup P. TAHITIAN NONI® Juice-A 13-wk oral (gavage) toxicity study in rats. Scantox Biologisk Laboratorium, Lille Skensved, Denmark, Lab no. 35 207, March 2000; and Glerup P. TAHITIAN NONI® Juice-A 13-wk oral (gavage) toxicity study in rats. Scantox Biologisk Laboratorium, Lille Skensved, Denmark, Lab no. 39 978, May 2001). In each study, 80 Sprague Dawley rats (40 males and 40 females) were included. Six consecutively higher doses were examined in each study, with a high dose equivalent to 80 mL TAHITIAN NONI® Juice/kg per day (20 mL/kg of 4-fold concentrated juice).

Study measurements indicative of liver effects were ALT, AST, ALP, GGT, total bilirubin, total protein, protein by electrophoresis, globulins, albumin/globulin ratio, and prothrombin time. Additionally, clinical observations included liver weights, and macroscopic and microscopic (histological) examination of the livers. Laboratory data for liver function for each dose group in each study are mentioned in Tables 2, 3, 4, and 5.

No treatment-related changes were observed in any of the dose groups for any of these measurements, including histological examinations, demonstrating a lack of toxicity to the liver. Consequently, the No Observable Adverse Effect Level (NOAEL) was determined to be greater than 80 mL TAHITIAN NONI Juice/kg per day.

The NOAEL is much higher than the amounts ingested

by the patients described in the case studies. In the most recent publication, the first patient consumed a daily dose of 71.4 mL (1.5 L consumed over 3 wk). The second case reported in this publication describes a daily consumption rate of 23.8 mL (2 L consumed over 3 mo). The weight of each patient is not given, but assuming an average weight of 70 kg, the doses consumed would be 1.02 mL/kg per day and 0.34 mL/kg per day. The NOAEL of the animal studies is almost 80 times greater than these two doses. The high dose in the clinical study was approximately 10 times higher.

The first published case report claims that the patient drank a glass of noni juice every day for a few weeks. No exact quantity is specified; no indication is given as to how large the glass was or how much of it was filled. However, assuming a full cup volume of 250 mL and a patient weight of 70 kg, the dose would be 3.6 mL/kg. The NOAEL of the animal studies is 22 times greater than the ingestion rate of this patient, and the clinical study high dose is three times more. Not only are all reported doses in these cases well within the highest doses of the controlled studies, where no liver effects were observed, but were also sufficiently low to assume a large margin of safety. If there is any true causal link, it is likely to be only idiosyncratic in nature.

As a pretext for implicating noni juice in liver toxicity, the authors of both reports cite publications containing only limited information, including similar case reports for the herbal laxative drugs Senna (*Cassia augustifolia*)[5] and Cascara sagrada (*Rhamnus purshianus*)[6]. The laxative effects of these herbal preparations are due to large quantities of a specific class of anthraquinones[7] (different than those in the noni plant).

In these cases, the patients had ingested large quantities of the herbs for an extensive time. Consequently, the investigators propose a potential involvement of anthraquinones. A similar assumption is made in the few case reports of other herbs cited by the authors of these two publications[8-10]. In these instances, however, the role of the anthraquinones directly isolated from these herbs, and linked to the patients' liver dysfunction was not supported by any additional experimental evidence. In fact, support for these assumptions is based on limited information from experimental studies of sennosides[11] and luteoskyrin[12], which do not occur in the noni plant.

The suggestion of an anthraquinone involvement in the three Austrian cases is not based on solid data. The first argument against such a causal link is a quantitative one. Until very recently, investigators had been unable to identify or isolate anthraquinones from noni fruit[13]. However, two recent publications have reported the presence of anthraquinones in noni fruit, at very low concentrations. The first report describes 48.3 mg of isolated material, distributed amongst six anthraquinones, from 1.3 kg of dried noni fruit from Indonesia[14]. On a dry weight basis, the total concentration is 37×10^{-6}. In the juice form, the concentration would be approximately 3×10^{-6}. The second publication describes isolating a few micrograms of anthraquinones from 9 kg of dried fruit[15]. The anthraquinone concentration in this study was less than 1×10^{-6}. Such low yields and concentrations are responsible for the inability of earlier researchers to identify anthraquinones in the fruit.

In comparison to Senna and Cascara sagrada, the total anthraquinone content of noni fruit is insignificant. The European Pharmacopoeia describes Senna leaf as containing no less than 2.5% (25×10^{-3}) anthraquinones; the standardized extract is to contain no less than 5.5%. Cascara sagrada is described as having a minimum anthraquinone content of 8% (80×10^{-3}). These concentrations are many thousands of times higher than that in noni juice. Where a large quantity of Senna and Cascara is required to induce liver toxicity, it is unreasonable to assume a barely detectable quantity of anthraquinones in noni juice can have the same effect.

Beyond the minute quantity of anthraquinones in noni fruit juice is a second issue of chemical structure. Anthraquinones do not have the same universal biological effects. Differences in bioactivities, toxic or otherwise, are seen amongst variants of other types of compounds as well. Thus, it is not reasonable to assume that one category of anthraquinones will have the same exact toxic action as another. The anthraquinones present in the laxative herbs, linked to the previous cases of hepatotoxicity, are 1, 8-di hydroxyanthraquinones (1, 8-DHA's). On the other hand, those that occur in *M. citrifolia* are substituted 9, 10-anthraq uinones[16,17]. These structural differences result in different modes of action. The 9, 10-anthraquinones can not be reduced in biological systems to form anthrone radicals, while 1, 8-DHA's can[18]. It is the formation of anthrone radicals that is required to produce tissue damage[19].

In summary, human and animal studies of high doses of TAHITIAN NONI® Juice reveal no adverse liver effects. Further, anthraquinones in noni fruit are of insufficient quantities and fail to possess the necessary chemical structures to cause liver tissue damage. The available data demonstrates that noni juice is not directly toxic to the liver

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 6-10 key words that could reflect content of the study mainly from *Index Medicus.*

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included.

Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Abstract

Primary biliary cirrhosis (PBC) is a well-known but uncommon chronic liver disease that is presumed to be of autoimmune etiology. Recently, investigations in British Columbia (BC), a province of Canada situated along the Pacific North-West of North America, have suggested that PBC is not a rare disease amongst BC's Aboriginal (i.e. First Nations) communities. Geographically, BC is adjacent to South East Alaska, an American state that has also reported an increased prevalence of PBC amongst its Aboriginal communities. In this article, the medical evidence supporting a hypothesis of increased risk of PBC amongst BC's First Nations communities is reviewed. Evidence suggesting that autoimmune hepatitis is also more likely amongst BC's First Nations communities is also presented.

INTRODUCTION

Primary biliary cirrhosis (PBC), autoimmune hepatitis (AIH) and primary sclerosing cholangitis (PSC) constitute a triad of liver diseases that are widely accepted to be of autoimmune etiology with differing targets of immunologic attack. In PBC, it is the microscopic intra-hepatic bile duct that is the immunologic target, whereas in PSC, both intra- and extra-hepatic bile ducts are involved and in AIH, the antigenic target is located on the hepatocyte. Aside from the fact that all three diseases will result in end-stage cirrhosis, resulting in morbidity and premature mortality unless rescued by an increasingly scarce liver transplant, there are similarities between all these three liver diseases. Overlap syndrome, in which a patient may have features of both PBC and AIH[1] or PSC and AIH[2], is well recognized to occur and is often seen by clinicians. Occasionally, patients have been reported to have overlap with PBC and PSC as well as all three[3]. Furthermore, it is well recognized that patients with PBC and AIH can have many associated extra-hepatic autoimmune disease, especially rheumatologic conditions[4,5]. PSC, although classically occurring in the context of ulcerative colitis, is also reported to be associated with an increased likelihood of co-existent extra-intestinal, extra-hepatic autoimmune diseases compared to those with ulcerative colitis alone[6]. Recently, we have reported evidence that suggests that the Aboriginal population of British Columbia (BC), Canada (i.e. part of Canada's First Nations) has a significant burden of PBC[7-9] and possibly AIH[10,11]. It is commonly accepted by the gastroenterology community of BC that inflammatory bowel disease is extremely rare amongst its First Nations peoples, a fact that most likely explains the rarity of PSC in the First Nations population.

The finding of an increased rate of PBC and AIH in BC's First Nations community has clinical, epidemiologic, anthropologic as well as socio-political implications. First Nations of Canada, also referred to as American Indians or Native Americans in the United States, are the original inhabitants of the continent and pre-date, by millennia, the subsequent European colonizers. In Canada, the First Nations peoples constitute about 4% of the population. In British Columbia, with a total population of close to 4 million people, about 170 000 are First Nations in demographic background. Often plagued by socioeconomic injustice, it is well recognized in recent years that the global health of Canada's First Nations communities is disproportionately worse than the rest of Canadian society. Chronic health problems, including diabetes mellitus, obesity, coronary artery disease, etc, are over-represented in our First Nations communities[12,13]. Excessive alcohol consumption remains a problem amongst some within the First Nations communities[14], however, the stereotypic generalization that all chronic liver diseases amongst First Nations are a result of alcoholic liver disease more likely

reflects societal bias or arises from clinical encounters in poor urban inner city areas. Within our own studies[7-9], we found that some PBC patients were initially misdiagnosed as suffering from alcoholic liver disease. The potential for accidental perpetuation of this stereotype remains in BC, since according to National Vital Statistics, all deaths from chronic liver disease are collected under the category of "alcohol-related" under a separate category of "Digestive Diseases"[15], the distinction between the two being unclear.

PRIMARY BILIARY CIRRHOSIS AND THE FIRST NATIONS COMMU-NITIES OF BRITISH COLUMBIA

Prior to the work formally studying the question of PBC amongst BC's First Nation Community, there had been indirect evidence suggesting that autoimmune liver disease was relatively common in this community. The British Columbia Vital Statistics Report[15] from 1991-1999 reported that deaths from chronic liver disease amongst First Nations women were five times higher than that in non-Aboriginal women, an interesting finding since both PBC and AIH are overwhelmingly afflictions amongst women. Furthermore, a study of the racial demographics of solid organ transplantation in British Columbia noted that organ recipients of First Nations background were significantly more likely to receive a liver allograft than any other transplanted organ (i.e. kidney, heart, lung)[16]. Lastly, anecdotal reports amongst BC's gastroenterologists[17] suggested that PBC was common amongst the province's First Nations community. The first direct evidence that PBC may be more common amongst BC's First Nations community came from the referral database of the BC Transplant Society's Liver Transplant Program[7]. It was discovered that of all patients referred for liver transplant assessment with a diagnosis of PBC, regardless of whether transplantation occurred or not, 25% were First Nation in demographic background. This was statistically significant compared to the 3.8% demographic proportion of First Nations Aboriginal's within BC's population as a whole. Not surprisingly, over half of all liver transplant recipients, who were First Nations in background, had a pre-transplant diagnosis of PBC[7]. A subsequent review of the BC Transplant Society referral database, performed a few years later, again confirmed that the trend of PBC referrals amongst the First Nations population was disproportionate to the expected[8], with a population odds ratio calculated at 8.3 with a 95% confidence interval between 5.6-12.21. The discovery, independent of the BC Transplant Society database, of an extended First Nations family with seven PBC cases in three sibships, related via common great grandparents led to a formal medical genetics population-based study of PBC in this community. This study[9] found a family history of PBC in 33% of PBC First Nations patients. A segregation analysis, which included five multiplex families, calculated the recurrence risk for PBC for all first-degree relatives, for first-degree relatives over the age of 21 years and for females over the age of 21 years as 4%, 4% and 10%, respectively. A calculation of the risk ratio (λ), an estimate of genetic effect in complex traits based on the frequency in families, compared to the population prevalence, yielded a λ for siblings of 1500, if one used a PBC population prevalence of 22 per million as previously reported in Ontario, Canada[18], and 100 if one used a PBC population prevalence of 289 per million as reported in the state of Alaska[19] which is geographically adjacent to BC. Considering that most autoimmune diseases have a λ between 8 and 20[18], a strong genetic predisposition of PBC amongst BC's First Nations population is implied.

We note that no other Canadian province has reported the finding of an increased prevalence of PBC in its First Nations community. In fact, the most well-known Canadian epidemiological study of PBC, based in the province of Ontario[19], did not report a significant association of PBC amongst First Nations. This leads to the question of whether an association of PBC in BC truly exists or whether the association is a spurious false positive one. Of importance, the First Nations communities of Canada do not constitute one homogeneous entity. From an anthropologic perspective, geographic distribution of the First Nations peoples of North American follows different temporal waves of migration from Asia. Culturally and linguistically, similarities exist within geographically linked communities and disparities exist when comparing geographically removed First Nations communities. It may not be surprising that BC's First Nations community differ in medical disease predisposition compared to Ontario's communities. Our studies have suggested that the distribution of PBC amongst BC's First Nations communities is not geographically uniform throughout the province and the predilection appears strongest amongst the communities along the Pacific Coastal areas as opposed to the non-coastal interior of BC[8,9]. We note that the American Indians of Southeast Alaska have also been reported to have an increased prevalence of PBC[20]. Southeast Alaska (i.e. the Alaskan Panhandle) is geographically adjacent to the Pacific Coast of BC where most of our First Nations patients with PBC are located. Moreover, there are cultural and anthropologic similarities between these Alaskan and BC coastal communities that appear to share a predisposition to PBC. Furthermore, it is interesting that the First Nations communities of BC' s Pacific Northwest and Southeast Alaska have both been long recognized to suffer a disproportionate burden of rheumatologic diseases[21-23] including lupus and arthritis. In general, similar rheumatologic diseases are well-known to be associated with PBC[4], suggesting that the independent reports of PBC and rheumatologic diseases within geographically proximate First Nations communities may not be spurious.

AUTOIMMUNE HEPATITIS AND THE FIRST NATIONS COMMUNITIES OF BRITISH COLUMBIA

Studies on AIH in BC's First Nations communities are still preliminary, however, there is a suggestion that this population may also be at risk for AIH. Two separate and independent database reviews have yielded similar proportions of First Nations patients amongst the BC AIH population. The first database review was of the BC Transplant Society's liver transplant candidate referrals[10] and the second was of the BC Children's Hospital AIH

Database[11]. Despite the fact that both database reviews looked at separate populations of AIH patients (i.e. adult *versus* pediatric), the proportion of First Nations with AIH was strikingly similar, approximately 17% in both. Since AIH is, in most cases, readily treated with corticosteroids and other immunosuppressive medications, unlike the situation of PBC where definitive cirrhosis-preventing treatment is not available, reviewing transplant centre and quaternary centre databases may be more prone to selection and referral bias. The discovery of classic PBC and classic AIH in a First Nations mother-daughter pair[24], although anecdotal, dramatically suggests that these autoimmune diseases are both related and associated with BC's First Nations community.

CONCLUSION

In closing, the story of PBC in BC's First Nations community underlines several important points. The first is that North American's First Nations people may have a genetic predisposition to autoimmune disease. Non-genetic factors, including recent changes in nutritional/dietary habits, environmental change/contamination, infectious agents, *etc*, may also be co-factors that interact with a genetic predisposition to produce phenotypic disease. For researchers, the reasons for disease association remain to be determined and should be the subject of further epidemiologic, basic science and clinical research. In order to accomplish this, however, researchers must be sensitive to the needs and concerns of the First Nations community. If the community is to be expected to participate, then it is a reasonable expectation that the community will, in the long-term, derive some benefit from its participation. For clinicians, a high index of suspicion is required when encountering members of an at-risk population group as is the case of chronic liver disease and BC's First Nations community. Secondly, the First Nations communities across North America are not homogeneous from a cultural anthropologic perspective and the same may also be true with regards to disease predisposition. Lastly, the dynamic interaction between medical culture and medical research can not be down-played. Currently in BC, when encountering a First Nations patient with chronic liver disease, screening for PBC and AIH is considered mandatory and alcoholic liver disease is a diagnosis of exclusion. The same may not have been true in the past.

Abstract

The human leucocyte antigen (HLA) complex on chromosome 6p21.3 is the most extensively studied genetic region in Inflammatory bowel disease (IBD). Consistent evidence of linkage to IBD3 (6p21.1-23), an area which encompasses the HLA complex, has been demonstrated for both Crohn's disease and ulcerative colitis, and a number of replicated associations with disease susceptibility and phenotype have recently emerged. However, despite these efforts the HLA susceptibility gene (s) for IBD remain elusive, a consequence of strong linkage disequilibrium, extensive polymorphism and high gene density across this region. This article reviews current knowledge of the role of HLA complex genes in IBD susceptibility and phenotype, and discusses the factors currently limiting the translation of this knowledge to clinical practice.

INTRODUCTION

The human leucocyte antigen (HLA) complex is a highly polymorphic, gene dense region on chromosome 6p21.3 (Figure 1). The complex spans ~4 Mb and encompasses at least 130 expressed genes[1,2]. These include the highly polymorphic classical class Ⅰ and Ⅱ HLA genes essential for normal lymphocyte function, and a number of other genes with immunoregulatory function. Since the first report of an HLA association with IBD in 1972[3], more than 100 studies have been published investigating the role of HLA genes in determining susceptibility and phenotype of inflammatory bowel disease (IBD). Early data derived from both association and linkage analyses were inconsistent, reflecting the difficulties of inadequate sample size, low resolution typing techniques, poor statistical methodology and a failure to consider disease heterogeneity. However, since the mid-1990's, advances in genotyping and computational technology, combined with improved study design, have been successfully applied to much larger, more accurately characterised cohorts of patients, and this has revealed important clues to molecular pathogenesis of IBD.

Genome-wide scans have shown consistent evidence of linkage to IBD3 (6p21.1-23), an area which encompasses the HLA complex. This has been demonstrated in several independent studies of both Crohn's disease[4-8] and ulcerative colitis[5-8], and was recently been confirmed by the IBD Consortium in a large replication study of 733 nuclear families[9]. The importance of this area was further highlighted by a meta-analysis of 10 published genome-wide scans[10]. Notably in this study, IBD3 was the only locus that met genome-wide significance, and provided stronger evidence of linkage than 16p13.1-16q12.2 (IBD1), the locus that contains the susceptibility gene CARD15. Although it is difficult to estimate the importance of this region in determining overall genetic susceptibility, calculations derived from studies of HLA allele sharing within families suggest that this region contributes between 10%-33% of the total genetic risk of Crohn's disease[11] and 64%-100% of the total genetic risk of ulcerative colitis[12].

Interest in the HLA complex in IBD has traditionally focused on association with the classical class Ⅱ HLA alleles, but recent insights into the biological function of other genes encoded within this region have led investigators to a more diverse exploration of this region.

CLASSICAL HLA CLASS II GENES

The classical class Ⅱ HLA genes encode cell-surface

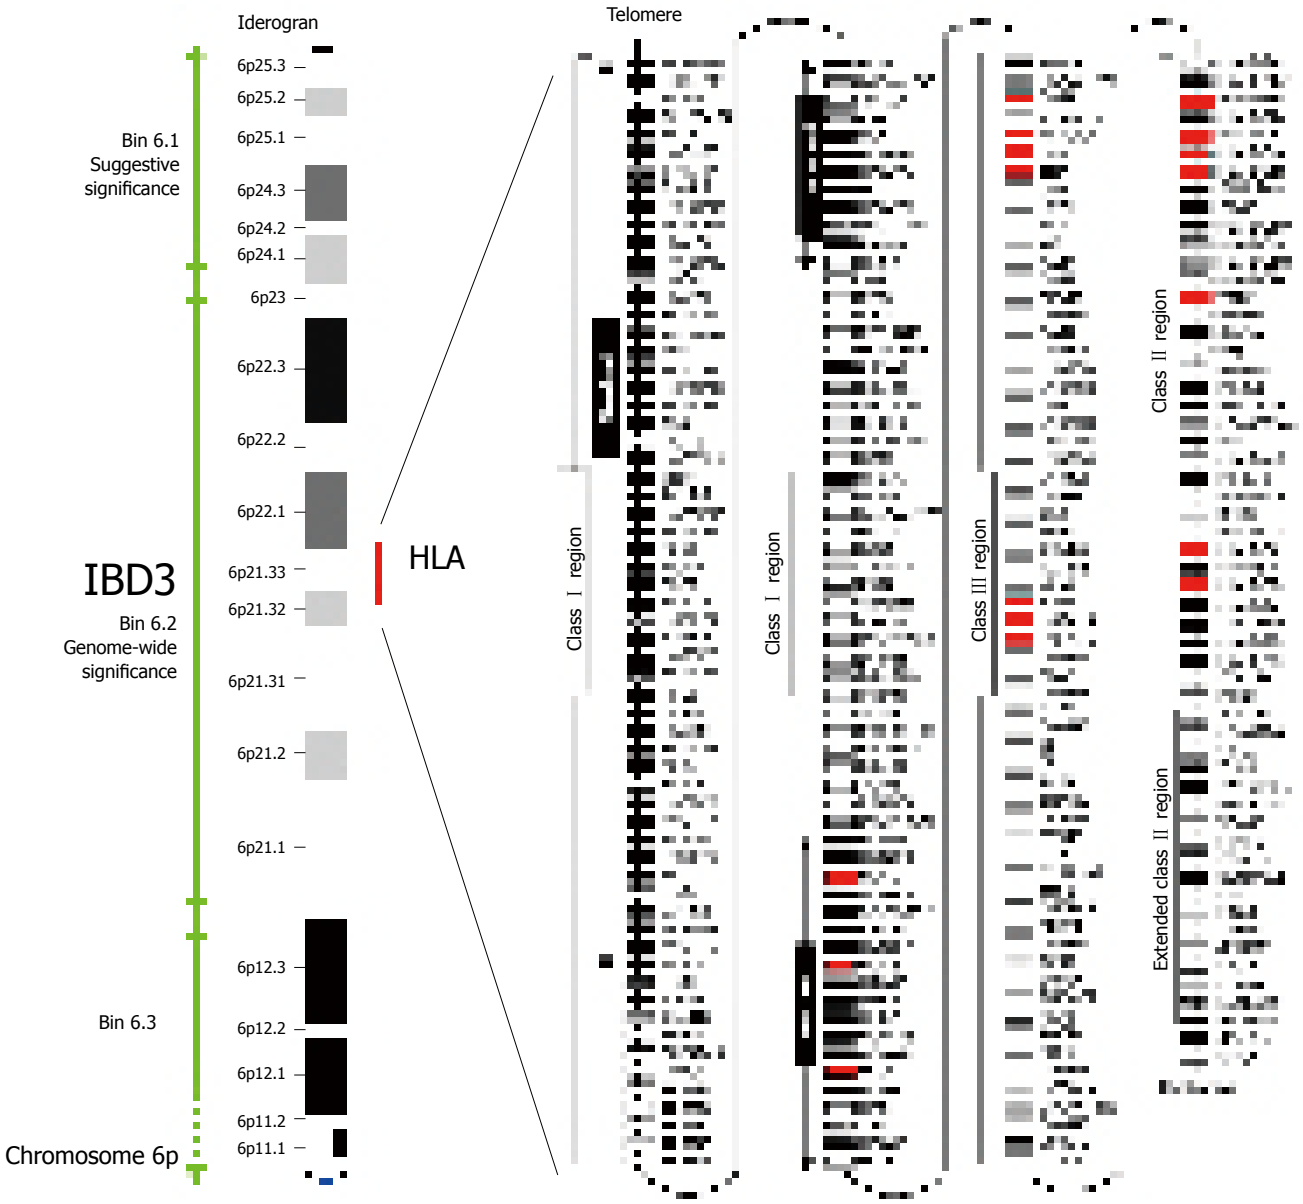

Figure 1 Crohn's disease map of chromosome 6p and the HLA region. The IBD susceptibility locus IBD3 is here defined by a 34cM chromosomal bin (6.2), which reached genome wide significance for IBD in the genome scan meta-analysis of van Heel *et al*[10]. The IBD3 region encompasses the ~ 4MB HLA region shown in detail on the right of the figure. White, grey, striped and black boxes show expressed genes, gene candidates, non-coding genes and pseudogenes, respectively. Genes with polymorphisms associate with IBD are shown in red. Modified with permission from Shiina *et al*[61].

glycoproteins which are expressed on antigen presenting cells, including dendritic cells and macrophages. Their major role is to present peptides to T cell receptors, as a prelude to T cell activation. There are three types of HLA Class Ⅱ molecules expressed by a single cell, namely HLA-DR, HLA-DQ and HLA-DP. These are each made up of αβ heterodimers: the β chains are encoded by the DRB1, DQB1 and DPB1 genes respectively, all of which are highly polymorphic. The α chains for DPA and DQA are also highly polymorphic, while the DRA gene is invariant. In addition, gene duplication events have occurred on certain haplotypes producing additional DRB3, 4 and 5 genes. When present, these are expressed at low levels in conjunction with the DRA chain.

The mechanism by which classical HLA class Ⅱ genes exert their influence in IBD is unclear, although a number of hypotheses have been postulated. Polymorphism in these molecules is concentrated around specific pockets of the binding groove that interact with critical side-chains or 'anchor' residues of a peptide. Thus different HLA molecules may bind preferentially to different peptides, or bind the same peptide with varying affinity. In IBD, cross reactivity (known as "molecular mimicry") may exist between the peptides derived from bacterial luminal flora and from self antigens present in the gut. This may lead to the generation of auto reactive T cells which contribute to disease pathogenesis through either stimulation or inhibition of the immune system. This mechanism is supported by identification of murine MHC-restricted CD4+ T cells reactive to enteric bacterial antigens that are able to induce colitis by adoptive transfer[13].

HLA-DRB1 is the most extensively studied gene in IBD. Convincing evidence of association has been described for a number of alleles, some of which confer

risk, whilst others are protective. Many of these were highlighted in a 1999 meta-analysis of 29 association studies published between 1966 and 1998[14]. Since publication of this report, more detailed genotype-phenotype analyses of this locus have been conducted in larger, accurately characterised, patient cohorts leading to the realisation that genetic variation within this region may explain some of the disease heterogeneity of IBD. The most consistently replicated associations are described below.

HLA CLASS II ASSOCIATIONS WITH CROHN'S DISEASE

*HLA-DRB1*07 and CARD15 negative ileal Crohn's disease*

The most consistently replicated association of Crohn's disease with a common HLA allele is with HLA-DRB1*07. The population frequency of this allele varies between 5%-29% in Europeans and North Americans but is less than 1% in Japanese. The 1998 meta-analysis demonstrated a weak association of HLA-DRB1*07 in unselected patients with Crohn's disease (OR 1.42, CI 1.16-1.74)[14], but three subsequent studies of well-characterised patients from the UK (n = 244)[15], Canada (n = 432)[16] and Spain (n = 210)[17] showed that this association is specifically with patients with ileal involvement (with or without colonic disease). When comparison was made in these 3 studies between patients with, and patients without ileal disease, the Odd's Ratios for ileal disease were 1.5[15], 1.9[16] and 2.6[17] respectively, which are equivalent to those observed for possession of a single CARD15 variant. Importantly the UK and Canadian studies provided evidence for genetic heterogeneity in ileal Crohn's disease, by demonstrating that the association with HLA-DRB1*07 is only present in patients who do not possess one of the three common Crohn's disease associated CARD15 variants[15,16].

Studies in other ethnic groups have not been as detailed. Few Jewish patients were included in the UK or Spanish studies, but data from the Canadian study suggested that this phenotypic association may also be present in this ethnic group, although the relatively small number included prevented this reaching statistical significance[16]. DRB1*07 appears not to be associated with Crohn's disease in the Japanese, although studies have been insufficiently powered to detect a modest effect of such a rare allele.

*HLA-DRB1*0103 and Colonic Crohn's disease*

HLA-DRB1*0103 is a rare allele with a frequency of less than 2% in European and white North American populations. It is present at a similar frequency in Jews but is absent in the Japanese. A strong association of HLA-DRB1*0103 with ulcerative colitis was identified in 1996[12], but not demonstrated in Crohn's disease until 2000[18], almost certainly a consequence of the disease heterogeneity of Crohn's disease and the low prevalence of this allele. This association has been widely replicated since, although studies in Jewish patients have been inconsistent[16,18]. Association with this allele is observed both on the DRB1*0103-DQB1*0301 and DRB1*0103-DQB1*0501 haplotypes, strongly implicating DRB1*0103 in disease pathogenesis. It is now clear that DRB1*0103 is strongly associated with colonic location, particularly isolated colonic disease[15-17,19]. The Odd's ratios for isolated colonic disease range from 5.1 to 18.5 in non-Jewish caucasoids[15-17]. Data from a recent study suggests that amongst British patients with isolated colonic Crohn's disease, DRB1*0103 is associated with the development of severe disease as defined by the requirement for infliximab or colectomy. Furthermore data from this study suggests this allele may predict time to surgery (*personal communication-Laura Hancock*). Despite the strength of these associations it should be noted that this allele was present in no more than 32% of patients with isolated colonic disease, indicating that whilst this marker has a high positive likelihood ratio, the negative likelihood ratio limits its clinical application. Association with perianal location and fistulizing behaviour, reported in two studies, probably reflects their clinical association with colonic disease, rather than an independent genetic association[15,17].

*HLA-DRB3*0301 - HLA-DRB1*1302*

The HLA-DRB3 gene is expressed in less than 50% of Europeans and white North Americans, and has not been extensively studied in IBD. However, a meta-analysis of three studies, each comprising less than 70 patients, supports a positive association of Crohn's disease with DRB3*0301 (OR 2.18, CI 1.25-3.80)[14]. This association has been replicated in a larger cohort of British patients (RR = 2.4)[15], although once again inadequate sample size has prevented investigators determining whether it is due to linkage disequilibrium with another disease associated DRB1 allele, DRB1*1302[14,15], or the HLA class Ⅰ allele Cw*0802[15]. Although stratification by disease phenotype is limited, data from this latter study, which awaits replication, suggests that this association is most marked in patients with perianal disease.

*HLA-DRB1*04 and CARD15 positive ileal disease?*

Data from the meta-analysis of seven small studies also demonstrated a non-significant increase in the common allele HLA-DRB1*04 in Crohn's disease (OR 1.62 CI 0.73-3.61)[14]. This association is particularly important in Japanese cohorts, in whom the strongest HLA associations are with DRB1*0405, *0410, and the linked DQB1*0401, 0402 alleles[20-22]. Association with DRB1*04 has not been widely observed in European and North American patients. However in the recent Canadian study, a weak association with DRB1*04 was identified in patients with ileal disease RR = 1.7 (1.1-2.5)[16]. It is interesting that this association was stronger in patients possessing one of the three common Crohn's disease associated CARD15 variants, which may indicate an epistatic interaction between this DRB1 allele and CARD15 in determining susceptibility to ileal Crohn's disease[16]. Genotype-phenotype analysis of this allele in the Japanese is awaited.

*HLA-DRB1*1501 – Crohn's disease protection*

Much confusion has surrounded associations of Crohn's disease with the serologically defined HLA allele DR2. DR2 includes the molecularly defined alleles HLA-DRB1*1501 and HLA-DRB1*1502, amongst others. The

allele frequency of DRB1*1501 varies between 6%-25% in European and white North American populations and 6%-10% in the Japanese. It is negatively associated with Crohn's disease which explains the earlier negative association reported with the serological antigen DR2 (OR 0.83, CI 0.70-0.09) highlighted in the 1999 meta-analysis[14]. This allele appears to confer protection against all subgroups of Crohn's disease, in all ethnic groups including Japanese.

HLA CLASS II ASSOCIATIONS WITH ULCERATIVE COLITIS

*HLA-DRB1*0103 and severe, extensive ulcerative colitis*

The most consistently replicated association of ulcerative colitis in European and American populations is with the rare allele HLA-DRB1*0103. Data from the Stokkers *et al*[14] meta-analysis, derived from only 3 studies, demonstrated a moderate association in unselected ulcerative colitis patients (OR 3.42 CI 1.52-7.69). Subsequent larger studies have confirmed this association in Spanish[23], North American[18], British[24]and Mexican cohorts[25]. This association is particularly strong in patients with extensive[24-27] or severe disease, as defined by the need for colectomy for failed medical therapy[24,25]. Amongst patients who require colectomy this allele may also be associated with a shorter mean time to surgery[24]. Once again, the frequency of this allele, even in the ulcerative colitis population, is too low to be clinically useful in predicting disease course.

*HLA-DRB1*1502*

HLA-DRB1*1502 is associated with ulcerative colitis in European[24], North American[18], Japanese[22,28] and Korean[29] populations. Although the background prevalence of this varies considerably, being highest in the Japanese (20%-25%) and lowest in Northern Europeans (less than 1%), the associated relative risk is similar in all populations (2-4.5). This interesting transracial concordance suggests this allele, or a nearby allele, is a true disease causing variant. This association is specifically with HLA-DRB1*1502, rather than HLA-DRB1*1501, and explains the earlier reported association with the serological antigen DR2 (OR 2.00, CI 1.52-2.63) highlighted in the 1999 meta-analysis[14]. These two alleles differ only at amino acid position 86 within pocket 1 of the peptide binding groove. At this position HLA-DRB1*1501 has a valine and DRB1*1502 (and DRB1*0103) a glycine. Limited data suggests HLA-DRB1*1502 is associated with extensive and intractable ulcerative colitis amongst Japanese[30], but not Korean patients[29].

In Japanese[31] and British UC patients[24], association has also been reported with HLA-B*52, the class Ⅰ allele found in linkage disequilibrium with HLA-DRB1*1502. However, studies have been insufficiently powered to determine which allele represents the primary association due to the highly conserved nature of this haplotype. Interestingly HLA-B*52, but not HLA-DRB1*1502, has also been shown to be associated with colonic Crohn's disease in these populations[15,32], providing further evidence of a shared genetic basis for ulcerative colitis and colonic Crohn's disease.

*HLA-DRB1*04-ulcerative colitis protection*

The common HLA-DRB1*04 allele is negatively associated with ulcerative colitis in Northern Europeans and Japanese populations, in contrast to the positive association in Crohn's disease. Data from the Stokkers meta-analysis of 15 studies demonstrated an Odd's Ratio of 0.54 (CI 0.73-3.61) in ulcerative colitis[14]. In the British population, the protective effect of this allele is confined to the most prevalent subtype DRB1*0401, and only then, when present on the two locus haplotype DRB1*0401-DQB1*0301[24]. This suggests that either an interaction between DRB1*0401 and DQB1*0301 is important for disease protection, or, and perhaps more likely, that the true protective polymorphism is found nearby on the associated extended haplotype.

HLA CLASS II ASSOCIATIONS WITH THE EXTRA-INTESTINAL MANIFESTATIONS

A number of HLA associations have been described with the extra-intestinal manifestations of IBD. The majority of data has been derived from small studies from one single centre and should be interpreted with caution until replicated. Small sample size has also hindered attempts at determining the primary association, but the most convincing associations have been described with DRB1*0103[33] in mixed studies of ulcerative colitis and Crohn's disease. Type 1 peripheral arthritis, a migratory pauciarticular large joint arthritis has specifically been shown to be associated with HLA-DRB1*0103, as well as the class Ⅰ alleles that may be found in linkage disequilibrium, namely B*27 and B*35[33]. In this study, HLA-DRB1*0103 was found in 35% of patients compared to 3% of controls. In patients with recurrent arthritis this association becomes even stronger, being found in 65% of patients[33]. In contrast, type Ⅱ peripheral arthritis, a chronic, small joint, symmetrical arthritis is associated with HLA-B*44[33]. Uveitis has also been associated with DRB1*0103 and HLA-B*27, and erythema nodosum with the TNF promoter SNP TNF-1031C[34]. However, it is important to note that an increased prevalence of extra-intestinal manifestations has previously been reported in patients with colonic Crohn's disease[35] raising the possibility that the association between DRB1*0103 and the extra-intestinal manifestations may merely reflect the replicated association with colonic disease. Further work is required to clarify this issue.

OBSERVATIONS ON HLA CLASS II ASSOCIATIONS WITH IBD

A number of important observations should be noted from the reported associations with HLA Class Ⅱ alleles described above. Firstly, the specific associations with Crohn's disease and ulcerative colitis are different, with the notable exceptions of the shared association

of ulcerative colitis and colonic Crohn's disease with HLA-DRB1*0103 and HLA-B*52. Secondly it is clear that multiple alleles, rather than a single allele, may be associated with any specific phenotype. Whilst these associations may merely reflect linkage disequilibrium with a nearby gene, this observation supports peptide presentation as an explanation for these associations, and raises the possibility of a shared disease-associated epitope, as seen in rheumatoid arthritis[36]. Some associated class Ⅱ alleles do indeed share significant residue changes in the third hypervariable region, which forms part of the antigen binding domain. However these are not shared by all of the associated alleles, suggesting this hypothesis cannot entirely explain these associations. Thirdly, it is not known whether a gene dose effect operates, such that possession of two HLA risk alleles confers additional risk. To date studies in IBD have not been sufficiently powered to conclusively answer this question. Fourthly, whilst many of the associations appear to be robust, it is clear that the penetrance of the genotype is low, and the presence of a risk allele is neither necessary nor sufficient for disease to occur. Finally the reported associations vary with ethnicity and geographical location, reflecting genetic heterogeneity, prevalence of risk alleles in the background population, and population specific patterns of linkage disequilibrium across the HLA. This illustrates the importance of studying ethnically homogenous cohorts in order to prevent population stratification.

OTHER IBD GENES IN THE HLA COMPLEX

In IBD, as with a number of other HLA Class Ⅱ -associated diseases, there is increasing evidence for more than one susceptibility locus within the HLA complex[37-41]. The evidence is accumulating faster for Crohn's disease than ulcerative colitis, reflecting the focus of recent research efforts towards Crohn's disease. Such a gene(s) might act independently of the class Ⅱ locus, or interact with disease associated class Ⅱ alleles on either the *cis* or *trans* chromosome. However, the presence of highly conserved haplotypes across such a gene-dense region has made it extremely difficult to dissect out primary associations. In Crohn's disease, it is most likely that a second disease-susceptibility locus is located between the telomeric end of class Ⅰ, and the central class Ⅲ regions. Specific associations have been identified with the class Ⅰ genes HLA-B and Cw, the non-classical MHC class Ⅰ-related (MIC) genes, MICA and MICB, and the three heat shock protein genes (HSPA1L, HSPA1A, HSPA1B). However most recent interest has focused on a cluster of immunoregulatory genes centred in the HLA class Ⅲ region, including TNF, LTA, LTB, NFKBIL and BAT1. To date most studies have investigated only a few SNPs in a single gene, chosen because of previously described associations, or for ease of genotyping, rather than their ability to 'tag' a haplotype to comprehensively survey the linkage disequilibrium across the gene. Results have generally been inconsistent, even within phenotypically defined subgroups, and as with other HLA associated diseases, very few studies have fully controlled for linkage disequilibrium with HLA-DRB1. Associations with TNF and the MIC genes are now discussed.

TNF

The most widely studied gene in the HLA class Ⅲ region is TNF, which encodes a proinflammatory cytokine that is found in increased concentrations in the mucosa, serum and stool of patients with IBD. The ΔARE[42] and $TNF^{-/-}$ mice[43] models provide experimental evidence of the importance of TNF in IBD, and convincing clinical evidence is seen in both Crohn's disease and ulcerative colitis from the dramatic response following infusion of the anti-TNFα monoclonal antibody, infliximab. A large number of TNF promoter polymorphisms have been described, raising the possibility that altered TNF expression may play a role in determining susceptibility to IBD. However the functional significance of individual polymorphisms remains uncertain as TNF regulation is highly cell and context-specific and currently available in vitro systems provide limited insight into how TNF is regulated *in vivo*.

The most consistent TNF association is with the -857C allele. This is a very common allele: 99% of the healthy caucasoid population possess at least one copy and ~85% are homozygote. A modest association with the -857C allele genotype was reported in TDT and case-control analyses from the UK. Relative risks for the homozygote TNF-857CC genotype were 2.4 (CI 1.4-4.0) in ulcerative colitis and 2.4 (CI 1.4-4.2) in Crohn's disease patients lacking the three associated CARD15 variants[44]. This association was replicated in a TDT study from Australia, but unlike the British study, evidence for epistasis was observed between TNF-857C and CARD15 variants[45]. Further evidence for an epistatic interaction was noted in a recent large TDT study from the IBD consortium, in which the TNF-857C allele was shown to be associated with Crohn's disease, but only in CARD15 transmitting families[9]. No association was found in ulcerative colitis, possibly a consequence of the smaller number of ulcerative colitis families included. At present the TNF-857CC genotype has not been found to be associated with a specific Crohn's disease or ulcerative colitis phenotype. An important confounder, which has not been directly investigated by either of these studies, is that the rare, protective -857T allele is the linkage disequilibrium with DRB1*0301[46], an allele shown by several studies to confer protection to Crohn's disease. Thus it is possible that the TNF-857C association simply reflects linkage disequilibrium within this highly complex region.

Modest associations have also been reported with many other polymorphic sites in the TNF promoter. In Crohn's disease these include TNF-1031C[47], TNF-863A[48] and TNF-308A[15,49,50]. The association with TNF-308A appears to be specifically associated with colonic Crohn's disease (with or without colonic disease)[15,49,50], however once again this finding is confounded by the tight linkage disequilibrium across the A1-B8-DR3 ancestral haplotype, the only common haplotype to contain the TNF-308A allele. In small studies TNF-308A has also been shown to be associated with ulcerative colitis[51,52] providing further evidence of shared genetic susceptibility for ulcerative colitis and colonic Crohn's disease. TNF promoter

polymorphisms may also predict ulcerative colitis phenotype: In a British study, which requires replication, homozygosity for a common promoter haplotype, defined by the common alleles at each of 6 positions, were more likely to have distal disease that remained distal throughout the period of follow-up[24].

MICA and MICB

The non-classical MHC class Ⅰ-related (MIC) genes, MICA and MICB, are expressed on the basolateral cell surface of the gastrointestinal epithelium as well as fibroblasts, endothelial cells and dendritic cells. Their expression is markedly increased in response to cellular stress including both viral and bacterial infection[53,54]. MICA and MICB bind to an activating receptor NKG2D, which is expressed on NK cells, CD8 αβ T cells, γδT cells and activated macrophages[55,56]. Interaction between these receptors may directly stimulate cell cytotoxicity as well as providing costimulation for NK and T cell activation.

Exons 2, 3 and 4 of MICA and MICB are highly polymorphic, and 54 MICA alleles have been officially designated to date. The functional significance of these polymorphisms and the nature of selective forces maintaining them are not known, but the presence of a high proportion of non-synonymous substitutions suggests that these polymorphisms are not the result of random mutation alone. Importantly, several MICA alleles have been shown to alter the binding affinity with NKG2D by as much as 30 fold, suggesting they might exert a functional effect on immune activation[57]. Studies involving unselected IBD cohorts from Europe have failed to report consistent associations with MICA or MICB polymorphisms[58-60]. However, in the Japanese, a consistent association has been reported with MICA-A6 and UC, although this does not appear to be independent of the association with the adjacent HLA-B52 allele[31]. In a phenotypically characterised cohort from the UK, MICA*010 and B*1501, which are in linkage disequilibrium, were shown to be associated with perianal Crohn's disease (RR = 2.1)[15], a finding which requires confirmation.

DOES HLA DETERMINATION HAVE A ROLE IN CLINICAL PRACTICE?

Clinical observation, supported by molecular and serological data, strongly suggests that IBD is a heterogeneous family of inflammatory disorders. Ultimately, it is hoped that more accurate clinical, serological and molecular definition of these disorders will lead to better understanding of the different biological mechanisms and complex environmental interactions specific to disease subgroups. This would assist clinicians in the prediction of disease course, prognosis, complications and response to therapy. The data reviewed in this report demonstrate that genes in the HLA are important in determining susceptibility and phenotype of Crohn's disease and ulcerative colitis. Although the specific disease causing gene(s) remain unidentified, the strength and consistency of the emerging HLA associations have confirmed the importance of classifying patients both by accurately defined clinical characteristics, and by possession of known genetic risk factors, such as CARD15 disease associated variants.

In both Crohn's disease and ulcerative colitis, the most consistently replicated associations are with the classical class Ⅱ gene, HLA-DR. In Crohn's disease the strongest associations are observed with subgroups defined by location of disease. No consistent associations have been reported with disease behaviour, a less stable phenotypic characteristic, or with age at diagnosis. At present, there is little information about HLA associations with complications or response to treatment in Crohn's disease. In ulcerative colitis, the strongest HLA associations are seen with overall susceptibility, which is consistently associated with two alleles, DRB1*0103 and DRB1*1502. These alleles vary widely in prevalence across ethnic groups. Fewer subgroup associations have been identified than with Crohn's disease, but the association with DRB1*0103 is particularly strong in patients with extensive or severe disease. However, the low sensitivity and specificity of these associations currently preclude their use as a tool in diagnosis of either Crohn's disease or ulcerative colitis. For the same reason, it is unlikely that the use of HLA markers alone will be useful in disease screening of asymptomatic, genetically high risk individuals.

In addition to the interest in using biomarkers to predict IBD susceptibility, there is also considerable interest in using molecular and serological markers to assist in the discrimination of Crohn's disease from ulcerative colitis. Currently, markers in the HLA cannot be reliably used for this purpose. Indeed the shared association of DRB1*0103 and B*52 with ulcerative colitis and colonic Crohn's disease suggests the presence of at least one shared HLA susceptibility factor, providing a tantalising clue as to the potential molecular basis for the definition of colonic inflammation. Such shared HLA factors may explain in part why both forms of IBD can coexist in a family at a frequency greater than expected by chance. The apparent differential effect of HLA-DRB1*0401, which is a susceptibility allele in Crohn's disease and a protective allele in ulcerative colitis is interesting, but weak, population specific, and neither sufficiently sensitive or specific to be clinically useful.

In the near future, knowledge of an individual's HLA genotype is likely to be most useful in the prediction of disease course in patients with an established diagnosis of Crohn's disease or ulcerative colitis. However, at present, the sensitivity and specificity of even the most robust associations limit their application in isolation in this clinical context. Integration of an individual's HLA genotype into a panel of other genetic and serological markers may improve the sensitivity and specificity, although ultimately this is likely to require the identification of the primary IBD genes within this complex region.

In common with virtually all other HLA associated complex diseases, the HLA susceptibility gene(s) for IBD remain elusive. This is a consequence of the obstacles that challenge the mapping of disease genes within this region, including the high gene density and degree of polymorphism; the complex haplotype structure and

patterns of linkage disequilibrium; the relatively small relative risks conferred by disease associated alleles; and the likely clustering of more than one IBD susceptibility gene, either within the HLA, or within the surrounding IBD3 locus.

Abstract

The MDR1 gene is an attractive candidate gene for the pathogenesis of inflammatory bowel disease (IBD) and perhaps response to therapy, with evidences at both functional and genetic levels. Its product, the P-glycoprotein (P-gp) functions as a transmembrane efflux pump thus influencing disposition and response of many drugs, some of whom (i.e. glucocorticoids) central to IBD therapy. In addition P-gp is highly expressed in many epithelial surfaces, included gastrointestinal tract (G-I) with a putative role in decreasing the absorption of endogenous or exogenous toxins, and perhaps host-bacteria interaction. Many genetic variations of MDR1 gene has been described and in some instances evidences for different P-gp expression as well drugs metabolism have been provided. However data are often conflicting due to genetic heterogeneity and different methodologies employed. Perhaps the greatest piece of evidence of the physiological importance of P-gp in the G-I tract has come from the description of the mdr1 knock-out mice model, which develops a spontaneous colitis in a specific pathogen-free environment. Studies investigating MDR1 gene polymorphism and predisposition to IBD have also shown conflicting results, owing to the known difficulties in complex diseases, especially when the supposed genetic contribution is weak. In this study we have undertaken a meta-analysis of the available findings obtained with two SNPs polymorphism (C3435T and G2677T/A) in IBD; a significant association of 3435T allele and 3435TT genotype has been found with UC (OR = 1.17, P = 0.003 and OR = 1.36, P = 0.017, respectively). In contrast no association with CD and the G2677T/A polymorphism could be demonstrated.

INTRODUCTION

The role of P-glycoprotein (P-gp), the encoded product of the MDR1 gene, has been extensively studied as a mediator of multidrug resistance phenotype associated with certain types of cancers. Constitutive expression of this transporter in normal tissues has been shown to play an important role in drug disposition and response. More recently, genetic heterogeneity in terms of single nucleotide polymorphisms (SNPs) in this transporter has received significant attention as potential determinant of susceptibility to inflammatory bowel disease (IBD), and variability in drug efficacy in this condition.

The goal of this review is to summarize the available knowledge regarding the role of P-gp in the human gastrointestinal tract and on drug disposition process, and to focus specifically on the putative effects of the MDR1 gene polymorphisms in IBD by means of a meta-analysis of the available studies.

P-GP FUNCTION

P-gp is a member of the adenosine triphosphate (ATP)-binding cassette family that is encoded by the human ABCB1 gene (ATP-binding cassette, subfamily B), also called MDR1[1]. Human P-gp is a phosphorylated and glycosilated transmembrane protein consisting of 1280 amino acids and 2 homologous and symmetric sequences, each containing 6 transmembrane domains and an ATP-binding motif. P-gp functions as a transmembrane efflux pump, thereby moving drugs from the intracellular to the extra cellular domain; it may also interact with drug molecules trapped within the cell membrane lipid bilayer. ATP hydrolysis provides the energy for active drug transport against steep concentration gradient

(like a "vacuum cleaner")[2]. P-gp was first isolated from colchicine-resistant Chinese hamster ovary cells[3]. Subsequently the gene coding for P-gp (MDR1) was identified owing to its over expression in tumour cells associated with an acquired cross-resistance to multiple cytotoxic anticancer agents[4]. In humans, two MDR genes, MDR1 and MDR3 (also called MDR2), have been described, whereas in rodents three genes mdr1a, mdr1b, mdr2, have been identified. Subsequently, P-gp was also recognized to be expressed in many normal tissues, such as the canalicular surface of hepatocytes, the apical surface of proximal tubular cells in kidneys, and the brush borders of the enterocytes[5]. In addition, P-gp is also found in the epithelium of the brain choroids plexus (where constitutes the blood-cerebrospinal fluid barrier) as well as on the luminal surface of blood capillaries of the brain (blood-brain barrier)[6]. P-gp is also expressed in other tissues known to have blood-tissues barriers, such as placenta, ovaries, and testes[7]. Moreover, P-gp has been detected in haematopoietic stem cells, peripheral blood mononuclear cells, mature macrophage, natural killer cells, antigen-presenting dendritic cells, and T and B-lymphocytes[8].

The function and especially the anatomic localization of P-gp suggest that this transporter acts as a protective barrier to keep toxins out of the body by secreting them into bile, urine, and intestinal lumen, and thereby preventing their accumulation in critical organs[9].

P-gp IN THE GASTROINTESTINAL TRACT

In the human gastrointestinal tract (GI), P-gp is found at high concentrations on apical surfaces of superficial columnar epithelial cells of the colon and distal small bowel. High levels are also found in small biliary ductules and small pancreatic ductules[5]. In the GI tract there is a regional variation in P-gp expression with a maximal expression in the epithelial cells of the ileum and a gradual decline proximally to the jejunum, duodenum, and stomach; variations across the colon are less well defined[10]. The putative role of the P-gp in the GI tract is to decrease the absorption of endogenous and exogenous hydrophobic amphipathic toxins[11,12]. A great insight into the physiological role of P-gp protein in the GI tract has derived from the phenotype of the mdr1a gene knockout mice. This model was prompted by the finding that the MDR1 gene is present in a region of the human genome (7q21.1) that may harbour a disease gene involved in susceptibility to IBD[13]. Interestingly, the mdr1a knockout mice also develop a spontaneous colitis when maintained under specific pathogen-free conditions[14]. The colitis is prevented and reversed by the administration of antibiotics, suggesting that the intestinal flora is necessary to initiate and perpetuate the inflammation. This model implies that loss of the xenobiotic efflux mechanism may promote the development of the colitis. At histology, presence of long and dysregulated crypts, crypt abscess, and superficial mucosal inflammation has been described, a picture reminiscent of ulcerative colitis. However, transmural infiltration resembling Crohn's disease has also been observed. More recently it has been described that Helicobacter bilis infection accelerated while Helicobacter hepaticus infection delayed the development of spontaneous colitis[15], thus suggesting that specific luminal bacteria may critically influence the development of colitis in genetically susceptible animals.

P-gp SUBSTRATES

The structure-activity relationship for P-gp substrates has yet to be clearly defined. Table 1 summarizes a comprehensive list of compounds that act as substrates, inhibitors or inducers of P-gp (modified from Marzolini *et al*)[9]. The range of substrates is broad and it also evident that many drugs are also substrates of the cytochrome P450 (CYP) 3A4. The overlap between CYP3A4 and P-gp is also emphasized by the genomic proximity of both genes (7q22.1 and 7q21.1 for CYP3A4 and MDR1, respectively)[16]. The co-localization of the P-gp and CYP3A4 in the small intestine and liver suggests that this transporter also plays a significant role in the oral bioavailability, distribution, and excretion of drugs. Evidence supporting such a role was obtained from animal models. A mouse strain naturally deficient in mdr1a demonstrated a marked sensitivity to the neurotoxic effects of ivermectin, an antiparasiticide[17]. Experiments with mdr1a knockout mice have revealed the P-gp limits the central nervous system entry of drugs like cyclosporine, digoxin, vinblastine[18], and the oral absorption of drug like paclitaxel[19]. Of broad clinical relevance is the interaction

between digoxin and other cardiac drugs such as verapamil, quinidine, and amiodarone[20]. Of interest, several drugs central to IBD therapy are also MDR1 substrates like glucocorticoids[21,22], cyclosporine[23] and methotrexate[24].

POLYMORPHISM IN THE HUMAN MDR1 GENE

MDR1 is located in the human chromosome 7 band p21-21.1 on a 600 kb NruI fragment[25], and the MDR1 coding region is contained on a 120 kb XhoI fragment[26]. The gene extends over more than 100 kb containing 28 introns, 26 of them interrupting the protein-coding sequence. MDR1 mRNA has a size of 4.7 kDa, thus its coding region accounts for less than 5% of the total. The first report of MDR1 polymorphism was presented in 1989[27]. To date, genetic variations of the human MDR1 gene has been extensively studied (reviewed in ref.28, 29) with 50 SNPs and 3 insertion/deletion polymorphisms reported. Moreover, several preclinical and clinical studies have provided evidence for naturally occurring polymorphisms of MDR1 gene and their effects on drug absorption, distribution, and elimination[30]. Hoffmeyer *et al* performed the first systematic screening for MDR1 polymorphisms in 2000[31]; in that study a synonymous SNP in exon 26 (C3435T) was the first variation to be associated with altered protein expression, although the SNP does not change the encoded amino acid (Ile). In addition, P-gp expression in the duodenum of individuals with the homozygous T allele (variant) was decreased when compared with individuals with the C allele (wild type). Other studies have shown that SNPs at exon 21 (G2677T/A) and at exon 1b (T129C) may also be associated with altered transport function or expressions[32,33]. However, a disequilibrium exists between SNPs in exon 26 (C3435T) and exon 21 (G2677T/A), suggesting that the observed differences in P-gp, initially attributed to the exon 26 SNP, may be the result of the associated polymorphism in exon 21[32]. Furthermore, several groups have subsequently confirmed the existence of such distinct haplotypes[34,35], with three common haplotypes found in more than 70% of individuals. It has also been recently shown that a synonymous SNP in exon 12 (C1236T) is linked to the C3435T and G2677T/A SNPs[36,37]. Available data indicate that the allele frequencies of these three main variants differ considerably in the various populations. Of note, marked differences of the C3435T SNP allele frequency have been observed with an increased frequency of the C allele (wild type) in African populations compared with Caucasian-Asian populations[38,39]. Similarly, the 2677A genotype of the G2677T/A SNP is significantly more common in Japanese subjects[40], while the variant 1236T of the C1236T SNP is significantly more frequent in Asian subjects compared to Caucasian subjects[41].

The study of Hoffmeyer *et al*[31] was the first to demonstrate a 2-fold reduction in P-gp expression in duodenal biopsy samples among healthy Caucasian subjects homozygous for the exon 26 3435T allele. Those subjects were also shown to have increased digoxin plasma concentrations after oral administration, suggesting greater drug absorption in individuals with low intestinal P-gp levels. However, the replication of this finding has been controversial with consistent[42,43] and conflicting studies[44-46]. In a study quantifying MDR1 mRNA in the duodenum, Nakamura *et al*[47] showed, in contrast to the Hoffmeyer's findings, greater levels in healthy Japanese subjects carrying the 3435T allele as compared with subjects with the C3435T allele of the exon 26. This controversy, however, is not limited to the Asian population[34], as conflicting data have been noted also for others P-gp substrates including fexofenadine[32,48] cyclosporine[49-53] and tacrolimus[36,54-57]. Similarly conflicting data have also been reported for the exon 21 polymorphisms concerning the digoxin[44,45], tacrolimus[35,54,55-57], and multiple drugs[58,59] pharmacokinetics. Furthermore, conflicting data have also been obtained when evaluating the P-gp or mRNA mucosal expression with studies demonstrating reduced[31,60,48,61], increased[47] or unchanged[33,34,36,58,62-65] P-gp function for mutant C3435T SNP. Functional studies investigating the contribution of G2677T/A polymorphism also accounted for conflicting results[32-34,36,40,58,59,63-65]. Possible reasons for such discrepancies are the existence of gene-gene interaction, linkage disequilibrium between C3435T SNP and other MDR1 SNPs, and environmental factors influencing also the CYP enzyme activity. Moreover, it should be noted that regulation of P-gp expression might significantly differ from tissue to tissue. For example, the ligand-activated nuclear receptor PXR is though to be critical to P-gp expression in the liver and intestine, whereas in sites such as blood-brain barrier, PXR is unlikely to display regulatory functions. Finally, the methodology used to measure P-gp expression widely differs between studies. In addition different substrate drugs have been used in various studies, with different route of administration and potential different extent of metabolism relative to P-gp-mediated transport. For example, cyclosporine not only is transported by P-gp but also it is a substrate of CYP3A4, thus a potential P-GP effect may be masked by CYP3A4 activity.

MDR1 AND INFLAMMATORY BOWEL DISEASE

The MDR1 gene is an attractive candidate gene for the pathogenesis of IBD and perhaps response to therapy, with evidences at both functional and genetic levels[66]. In a German case-control study Schwab *et al* investigating the C3435T polymorphism firstly reported an increase of the T allele and TT genotype frequencies in 149 patients with ulcerative colitis, but not Crohn's disease, compared with controls ($P = 0.049$, OR = 1.4; $P = 0.005$, OR = 2.1, respectively)[67]. Subsequent studies, however, have gained conflicting results: Glas *et al*[68] in a small group of 123 patients with UC found results in partial accordance with a trend towards an increased frequency of T allele compared to healthy controls, but a statistical difference was obtained only in one of two different control groups (T allele, $P = 0.018$; TT genotype, $P = 0.016$), thus suggesting the key factor of patients and controls recruitment. In a small

Greek study[69] no difference was found in both UC and CD patients, but this study has been criticized because the investigated populations were not in Hardy-Weinberg equilibrium. A large study[70] performed in a German and British cohort investigating 307 UC and 564 CD patients by using both a case-control strategy and a transmission disequilibrium test based analysis (which is more resilient to latent effects such as population stratification), failed to demonstrate an association, even after stratifying individuals on the basis of CARD15 gene variants. More recently Ho *et al*[71] confirmed the association in UC patients ($P = 0.04$, OR 1.6 for TT genotype), especially those with extensive colitis ($P = 0.003$, OR = 2.64), but in contrast completely negative findings have been reported in large studies from North America[72], Slovenia[73] and Italy[74]. In particular in the latter study from our Institution, about one thousand IBD patients have been genotyped (Tables 2 and 3) with negative results. In addition, Urcelay *et al*[75] paradoxically found a significant association of the CC3435 genotype (wild) in CD patients ($P = 0.007$), but data were not in Hardy-Weinberg equilibrium.

In a multicenter North American cohort with 444 IBD trios, Brant *et al*[72] investigated also another polymorphism of MDR1, the tri-allelic G2677T/A SNP (Ala893Ser/Thr). They found a significant association of the Ala893 variant (G2677), known to decrease transporter function, with IBD in both case-control analysis ($P = 0.002$) and the pedigree disequilibrium test (PDT) ($P = 0.0002$), especially in non-Jewish subjects. The association was confirmed by PDT analysis within the CD subset ($P = 0.001$) with a similar, non-significant trend in the small subset of UC patients. Curiously, an association with another allele (T allele, 893Ser variant) of this SNP was found in UC patients ($P = 0.029$) by Potočnik *et al*[73]. Ho *et al*[71], did not find an association between this polymorphism and IBD; however, a 2-locus haplotype (3435T/G2677) was significantly associated with UC in this study ($P = 0.03$). Urcelay *et al*[75] similarly did not found a correlation between this polymorphism and IBD, however, a trend towards an increased frequency of 2-locus 2677T/C3435 haplotype was found in CD patients. In contrast, more recently Palmieri *et al*[74] did not found any association of this polymorphism and 2-locus haplotype with IBD patients (Table 3). Reasons for this discrepancy may lie in population heterogeneity, sample size, selection of control population, incomplete phenotype description, and difficulty to replicate results in case control study when the contribution of the genetic predisposing factor under investigation is weak. Accordingly, when looking for example at the existing data on C3435T polymorphism, it is apparent that the 5%-8% difference of the "risk" allele and genotype frequencies in UC patients and their significance (P values ranging from 0.02 to 0.049) are rather modest. More importantly, there is a significant heterogeneity in patients (T allele frequency ranging from 42.3% up to 65.3% in UC) and especially control populations (T allele frequency ranging from 35.7% up to 63%).

The hypothesis that altered PGP expression in IBD patients could modify the response to medical therapy was put forward by Farrell *et al*[76]. Peripheral blood lymphocytes (PBL) from patients with active Crohn's disease (CD) and Ulcerative colitis (UC) in whom medical therapy had failed and surgical intervention had been necessary were shown to have higher expression of P-gp glycoprotein compared with those from patients who had inactive disease and required surgery for obstruction or dysplasia. Based on this observation the authors speculated that poor response to glucocorticoids in IBD might relate in part to constitutive MDR1 expression. We have recently challenged this hypothesis in a large cohort of IBD patients[74] using steroids, by evaluating both C3435T and G2677T/A polymorphisms. Allele and genotype frequencies were compared in 594 patients using systemic steroids, subgrouped in 320 responders, 76 non-responders and 198 steroid-dependent. No significant differences were found within subgroups and between subgroups and 450 healthy subjects. Moreover, 297 patients taking immunosuppressive drugs (included azathioprine, 6-mercaptopurine, methotrexate, and cyclosporine) were also evaluated. No influence of MDR1 genotypes was found with respect to response to therapy. Similarly, in a recent study by Mc

Govern *et al* in which the need for colectomy in UC patients was used as a surrogate marker for glucocorticoids resistance, no association was found with C3435T polymorphism[77].

Although the Farrell's hypothesis is attractive, data from our study strongly question the influence of MDR1 gene on response to steroid therapy in IBD patients. There are, indeed, also some caveats to the Farrell's study; firstly, circulating lymphocytes consist of different subsets of lymphocytes which express MDR1 at varying levels, since it is now established that lymphocytes homing to the gut associated lymphoid tissue are phenotypically distinct from circulatory ones. Accordingly, Yacyshyn *et al*[78] have demonstrated different level of MDR1 expression and activity in intraepithelial, lamina propria, and PBL. Overall, intraepithelial MDR1 expression and function were lower in UC compared with CD and healthy controls. Accordingly, Langman *et al* found a down-regulation of MDR1 tissue expression in UC patients[79]. Moreover, the effect of corticosteroids or other treatment used in IBD on MDR1 expression it is not fully established. It remains therefore to be evaluated whether different expression of P-gp reflects

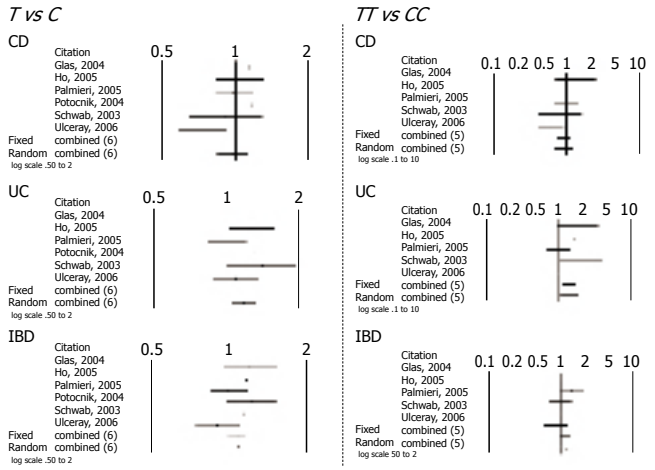

Figure 1 Schematic representation of studies included in the meta-analysis of C3435T SNP.

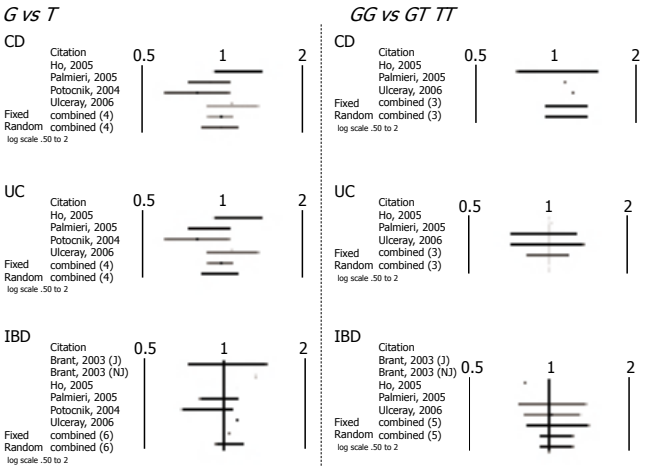

Figure 2 Schematic representation of studies included in the meta-analysis of G2677T/A SNP.

a secondary phenomenon to therapy or a primary one, influencing the response to treatment. Finally, increased expression does not necessarily imply increased function in diseased states. Based on the available evidence, the contribution of MDR1 gene on IBD predisposition and response to medical therapy, although biologically plausible is still unproven.

META-ANALYSIS

In the attempt to evaluate the potential association of C3435T and G2677T/A polymorphisms with IBD, a meta-analysis has been performed. Because case-control studies were included, the odds ratios (ORs) were employed. For each outcome, the between-study heterogeneity across all the eligible comparisons has been performed by using the chi-square based Q statistic; heterogeneity was considered significant for p lower than 0.10. Data were combined by using both fixed and random effects models; random effects are more appropriate when heterogeneity is present. Analysis was conducted by Comprehensive Meta Analysis v.1.0.23, 1999 Biostat software (www.meta-analysis.com).

In Tables 2 and 3 are depicted the characteristics of the studies included in the meta-analysis, with the allele and genotype frequencies. The study by Gazouli *et al*[69] has been excluded due to failure of Hardy-Weinberg equilibrium. The study of Croucher *et al*[70] was also excluded due to lack of data concerning allele and genotype frequencies, also upon specific request to the authors. For the study of Brant *et al*[72] data are expressed as whole IBD, since no complete information for UC and CD subgroups were available.

When comparing allele (T *vs* C) and genotype frequencies (TT *vs* CC) of the C3435T SNP in CD and UC patients, a slight but significant difference in the pooled data was found in UC patients (Table 4). More specifically a significant association with T allele (OR 1.17, CI 1.06-1.31, $P = 0.003$) and TT genotype (OR=1.36, CI 1.05-1.76, $P = 0.017$) was demonstrated. In contrast no association in CD patients was found and in IBD patients as whole. Similarly no significant difference was found after pooling data of the available studies for allele and genotype frequencies of the G2677T/A SNP (Figures 1 and 2).

Abstract

The currently accepted etiopathogenic hypothesis suggests that the chronic intestinal inflammation and related systemic manifestations characteristic of inflammatory bowel disease (IBD) are due to an overly aggressive or pathologic immune response to resident luminal bacterial constituents. Predisposing factors are genetic dysregulation of mucosal immune responses and/or barrier function, with onset triggered by environmental stimuli. These factors and their interactions may also be important determinants of disease phenotype and disease progression. The emergence of immunogenetic phenotypes lends support to the proposed hypothesis that susceptibility genes regulate distinct immune processes, driven by luminal antigens, expressed as specific immune phenotypes which in turn influence clinical phenotypes in IBD patients.

INTRODUCTION

The currently accepted etiopathogenic hypothesis suggests that the chronic intestinal inflammation and related systemic manifestations characteristic of inflammatory bowel disease (IBD) are due to an overly aggressive or pathologic immune response to resident luminal bacterial constituents. Predisposing factors are genetic dysregulation of mucosal immune responses and/or barrier function, with onset triggered by environmental stimuli. These factors and their interactions may also be important determinants of disease phenotype and disease progression. The interaction between genetic susceptibility and luminal bacteria deserves particular attention. The results from animal studies indicate that not all commensal bacterial species are identical in their abilities to induce disease in the face of a common genetic defect. For instance, HLA B27/β2 microglobulin transgenic rats raised under sterile conditions do not develop colitis. However, when colonized with normal specific pathogen-free commensal cecal bacteria, they develop aggressive disease involving the colon and gastro-duodenal area within one month[1]. On the one hand, when colonized with a single bacterial strain, *Bacteroides vulgatus*, these same genetically susceptible rats develop moderate colitis but no gastro-duodenal disease. When selectively colonized with Eschericia.coli, they exhibit neither disease nor T cell activation[2]. This data suggests that not all commensal bacterial strains trigger an abnormal immune response for a given genetic susceptibility. The same non-pathogenic bacteria, however, may induce inflammation in a different genetically susceptible host. More specifically, further research from the same group demonstrated that Escherichia coli induced only mild cecal inflammation after 3 wk of monoassociation in interleukin 10-/- mice. In contrast, Enterococcus faecalis-monoassociated interleukin 10-/- mice developed distal colitis at 10-12 wk that was progressively more severe and associated with duodenal inflammation and obstruction by 30 wk. Their results suggest that different commensal bacterial species selectively initiate immune-mediated intestinal inflammation with distinctly different kinetics and anatomic distribution in the same host[3]. These findings highlight the fact that both genetic susceptibility and luminal antigenic drive are important determinants of disease susceptibility and modification. Immune reactivity as measured by the serological expression of immune responses to specific bacteria may indeed be representative of this host gene luminal bacterial interaction. If indeed these immune responses represent the sum of a genetic and environmental predisposition to IBD, quantitative and qualitative expression of these immune responses may serve as an immunologic risk marker for IBD phenotypes.

IMMUNE PHENOTYPES

Immune responses to resident intestinal flora in humans have been reported. Duchmann *et al* demonstrated that CD patients boast reactivity to hundreds of bacterial antigens created from sonification of multiple bacterial specifies including enterobacteria, bacteriodes and bifidobacterium[4]. Immune reactivity to more specific microbial antigens has been reported in the sera of patients with IBD (Table 1).

Antibodies to *Saccharomyces cerevisiae* (ASCA) was the first CD specific immune response thought to be targeted towards microbial antigens. IgA and IgG antibodies are directed against a specific oligomannosidic epitope present on the cell wall of the yeast saccharomyces[5]. To date it remains unknown as to what the specific microbial antigen ASCA is cross reacting with and giving rise to seropositivity specifically in the sera of patients with CD. ASCA is present in approximately 60% of CD patients, yet less than 5% in UC and non-IBD patients[6-8]. The specificity of ASCA renders a positive test result accurate in differentiating CD from UC and IBD from non-IBD in cases of diagnostic uncertainty. ASCA also remains an important marker of disease severity as defined by the development of complicating disease. More recent research has resulted in the identification of 3 additional markers representative of microbial driven immune responses, antibodies to the E.coli outer-membrane porin C (OmpC), the Pseudomonas fluorescens CD related protein (anti-CD related bacterial sequence {I2}) and the CBir1 flagellin. Antibodies to OmpC, whose antigen is purified from commensal *E.coli*[9,10], are present in 37%-55% of patients with CD and 2%-11% of patients with UC, while no more than 5% of non-IBD individuals express anti-OmpC[11-13]. I2 was isolated from affected colonic mucosa yet not in the unaffected segments and thus thought to be specific to CD[9]. Immune responses to this antigen are present in up to 55% of CD patients; however the specificity of this antibody has been questioned as it has been detected in the serum of UC patients (10%) and more impressively in up to 20% of non-IBD patients (9, data on file Prometheus Labs). Given its limitation as a diagnostic marker, it is unclear as to whether this immune response will provide additional prognostic information and further studies are needed. Serologic expression cloning was used to identify an immunodominant antigen, CBir1 flagellin, to which strong immune responses (B cell and CD4T cell) occurred in colitic mice[14]. These findings were translated from the bench to the bedside and approximately 50% of CD patients had serum reactivity to CBir1 whereas UC, inflammatory and healthy controls exhibited little to no reactivity to this flagellin[15].

All of the prior immune responses are specific to CD. In contrast perinuclear anti-neutrophil antibody (pANCA) is noted for its association with UC or a UC like phenotype. This IBD-specific ANCA displays a unique perinuclear highlighting (pANCA) on immunoflourence staining and is DNAse sensitive[16]. Although it remains undefined, it has been suggested that the antigen to which pANCA is directed is a nuclear histone (H1)[17]. This antigen is clearly distinct from the proteinase 3 or the myeloperoxidase reactivity observed in those patients with vasculitic disorders. pANCA is likely an autoantibody that is representative of a cross-reactivity with a luminal bacterial antigen[10,18,19]. Despite epidemiological and methodological differences, pANCA has been shown repeatedly to be prevalent in the sera of approximately 60% and 20% of UC and CD patients, respectively[6-8,20-23]. Typically, < 5% of non-IBD patients are pANCA positive.

Table 1 Pooled frequency of immune responses in CD, UC and non-IBD

Immune Response	%CD	% UC	% non-IBD
ASCA	60	< 5	< 5
Anti-OmpC	40	< 5	< 5
Anti-I2	54	< 10	20
Anti-CBir1	50	< 10	< 10
pANCA	20-25	65	< 5

As seen with the genetic and clinical heterogeneity of CD, studies have shown immune response (immune phenotype) heterogeneity exists among CD patients. Landers et al analyzed immune response heterogeneity in 330 patients and found that ASCA was detected in 56% of patients; 55% were seroreactive to OmpC 50% were seroreactive to I2, and 23% were pANCA[9]. Eighty-five percent responded to at least 1 antigen; only 4% responded to all 4. Among microbial antigens (ASCA, OmpC, I2), 78% responded to at least 1, and 57% were double positive, but only 26% responded to all 3. The level of response was stable over time and with change in disease activity. Among patients with the same qualitative antigen-response profiles, quantitative response differed. Moreover this study demonstrated that CD patients could be clustered into 4 distinct groups depending on their immune response patterns to microbial or autoantigens. One cluster was ASCA, a second was antibodies to OmpC and I2, the third pANCA and the fourth was low or no immune response to any tested antigens.

Subsequent analyses incorporating CBir1demonstrated that antibodies to CBir1 are present in approximately 40% of CD patients negative for antibodies to specific microbial antigens (ASCA, OmpC and I2) which suggests a unique immune phenotype[14]. Immune reactivity to CBir1 may further define CD phenotypes in that anti-CBir1 expression is present in 40%-44% of pANCA positive CD patients *vs* only 4% in pANCA positive UC patients. This difference may denote a unique etiopathogenic mechanism of disease that helps to further stratify patients based on immunogenetic phenotypes.

CLINICAL AND IMMUNE PHENOTYPES

Disease phenotype is not always a static phenomenon. Retrospective studies have examined the stability of disease phenotypes over the course of disease from time of diagnosis until point of last follow-up. It appears that disease location essentially remains stable over time, yet disease behavior evolves, such that after 20-yr of follow up, at least 80% of patients with originally non-complicating disease progress to complication, either

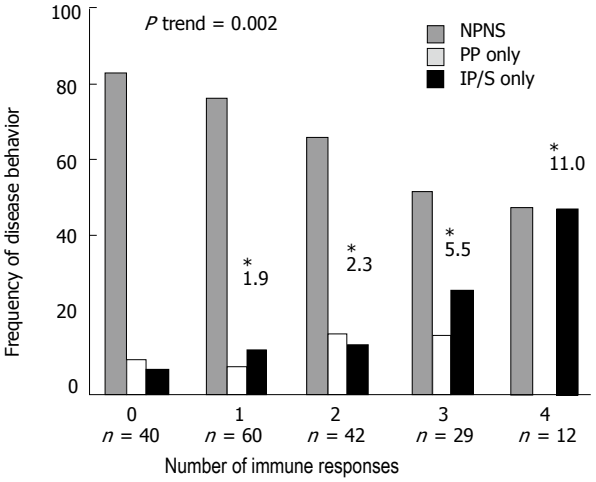

Figure 1 The frequency of disease behavior. The test for trend demonstrated a positive linear trend in the frequency of patients with IP and/or S disease as the number of positive immune responses toward I2, OmpC, ASCA and CBir1 increased (P = 0.002). The odds ratios (OR) reflect the odds of having internal penetrating and/or stricturing disease when positive for any 1, combination of 2, 3 or all 4 immune responses, as compared to those patients negative for all immune responses (baseline group).

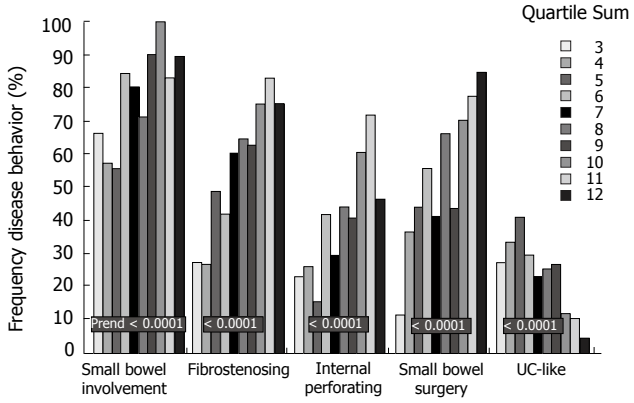

Figure 2 Association of the summed level of antibody responses towards multiple microbial antigens and disease phenotypes. Quartile sums used to reflect lowest (3) to highest titer level (12) for ASCA, anti-I2 and anti-OmpC.

penetrating or stricturing in nature[24-26].These findings suggest that non-complicating (non-penetrating, non-stricturing) disease behavior may not be a stable phenotype but just a temporary state that evolves in to one of the two complicating disease states over time.

Immune responses were first investigated as tools to differentiate UC from CD given the specificity of ASCA for CD and pANCA for UC. Advances in the sensitivity of the test characteristics lead to studies evaluating antibodies as diagnostic tools to differentiate IBD from non-IBD. Although conflicting, studies do support the use of these markers, particularly in children, to guide clinicians in cases of diagnostic uncertainty[8,27,28]. As new markers are identified and the test characteristics improve, the notion of immune responses optimizing diagnostic accuracy may become more clearer and clinically valid. It has become clear, however, that immune responses may also have perhaps a more important mechanistic implication in the pathogenesis of IBD. As alluded to above, these immune reactivities, as measured by the serological expression of immune responses to specific bacteria, may be representative of the host gene luminal bacterial interaction characteristic of IBD. Moreover if these immune responses represent the sum of a genetic and environmental predisposition to IBD, quantitative and qualitative expression of these immune responses may serve as an immunologic risk marker for IBD phenotypes. The initial immune-clinical phenotype studies demonstrated that although pANCA has been established as a UC-specific marker, approximately 25% of all CD patients also express pANCA. These CD patients are described as "UC-like" and tend to have an uncomplicated disease course[29-31]. In contrast, higher ASCA levels were shown to be associated with earlier age of disease onset, both stricturing and internal penetrating disease behaviors and need for small bowel surgery[30,31]. Further reports have found that patients with Crohn's disease who are positive for ASCA IgA, IgG, or both, may define a subset of patients with Crohn's disease at increased risk for early surgery[32]. ASCA has also been shown to be associated with a more aggressive disease course among a cohort of pediatric CD patients[33]. More recently anti-OmpC and anti-I2 have also been shown, like ASCA, to be associated with complicated disease behaviors among adult and pediatric CD patients[12,13,34]. Anti-CBir1 has also been shown to be independently associated with complicated disease behaviors in adult CD patients[14]. Of interest is that these associations were not found in a pediatric CD cohort suggesting potential differences in the mechanistic influence of CBir1 in the pediatric age group[34].

These studies also demonstrated that both the number of immune responses to the different microbial antigens expressed by a given individual as well as the magnitude (titer level) of these immune responses correlated most significantly with the presence of complicated CD phenotypes[12,34] (Figures 1 and 2). In theory, higher levels of immune reactivity may reflect the degree of loss of tolerance to specific microbial antigens rather than a global loss of tolerance. This may translate clinically to the magnitude of effect that specific bacteria have on the degree and extent inflammation resulting in more aggressive disease behaviors. Studies have demonstrated that immune responses to microbial antigens had a stronger association with the presence of complicated disease behaviors than known susceptibility genotypes, such that NOD2 was independently associated with small bowel disease location only and not disease behavior, fibrostenosing disease in particular, as previously reported[35-39]. None of these earlier phenotype correlation studies, however, took into account the assessment of multiple immune phenotypes.

IMMUNOGENETIC PHENOTYPES AND NATURAL HISTORY OF DISEASE

The prospective acquisition and determination of immune reactivity prior to the development of a disease complication is important to be able to truly evaluate the potential predictive value of immune responses in defining the natural history of IBD. It is generally agreed upon

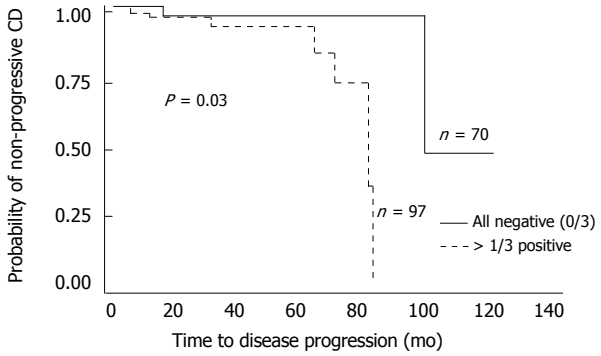

Figure 3 Kaplan Meier survival analysis. Comparison of time to progression from non-complicating to complicating disease behaviors between patients positive for 1 immune response to ASCA, I2 and OmpC (n = 97) (- - -) and those negative for all 3 (n = 70) (——).

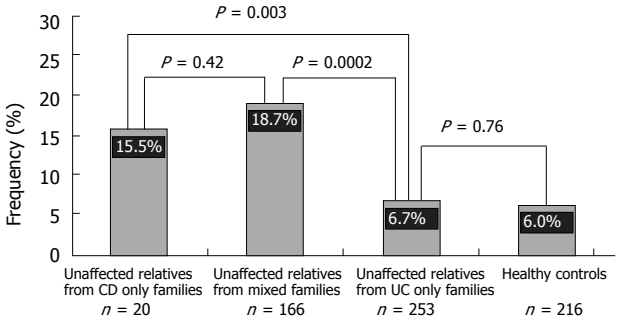

Figure 4 Frequency of anti-OmpC in unaffected relatives from CD only families, mixed families, UC only families, and healthy controls.

that the presence and level of immune responses do not change in a given CD patient[12,33]. We recently published the first prospective evaluation of the prognostic value of immune responses in patients presenting with non complicated CD[34]. This study included only those patients not presenting with internal penetrating and or stricturing disease at diagnosis and continued to be uncomplicated at the time sera was collected for immune response measurement so that it could be ascertained that the complication occurred after the antibodies were measured. Among those who developed a complication during the follow-up, the median time from diagnosis to the onset of the complication was 48 months. As of the last follow up of this cohort, 8% of the group seropositive to at least one serological marker had developed a complication *vs* only 3% in the seronegative group. Survival analysis (Figure 3) demonstrated that among those patients positive for at least one serology, more progressed to internal penetrating and or stricturing disease than those negative for all serologies. Saying it differently, those patients positive for at least one serology progressed faster that those negative for all serologies. Determining the factors that can predict the progression from uncomplicated to complicated disease states may stratify patients into at risk populations and impact the ultimate therapeutic management of patients with the goal of halting or more importantly preventing progression to complicated behaviors.

FAMILIAL EXPRESSION OF IMMUNE PHENOTYPES

There has been interest in evaluating whether immune responses are familial traits due to genetic factors. ANCA expression was the first marker to be studied. Several studies have observed an increased frequency of pANCA in unaffected relatives of UC patients but not environmental controls[40,41]. This relationship however has not been observed in all studies[42,43]. Sutton *et al* demonstrated that the quantitative and qualitative expression of ASCA was familial[44]. Another study confirmed that ASCA occur particularly frequently in CD patients, especially with the presence of a positive family history. However, they are also significantly increased in UC patients with a family history and in a considerable number of unaffected relatives of inflammatory bowel disease families, irrespective of the characteristics of their families (UC, CD, mixed, ASCA positive, and ASCA negative). The presence of ASCA in unaffected relatives might point towards a genetic predisposition to either CD or UC[45]. Studies in a twin population demonstrated an agreement in ASCA titers within concordant monozygotic twin pairs with Crohn's disease and suggested that the level of increase in ASCA reactivity(magnitude) is genetically determined[46]. None of these studies evaluated the influence of ASCA on the natural history of the affected offspring. A very recent study has shown that antibodies to OmpC have a strong familial aggregation pattern[47]. In this study, expression of anti-OmpC in unaffected family members of multiplex IBD families were compared with controls. As shown in figure 4, unaffected family members in CD only families had a similar frequency of anti-OmpC to those in mixed families. However, when comparing these two groups with healthy controls, both of them showed a much higher frequency of anti-OmpC expression. In addition, unaffected family members in these two groups displayed a greater prevalence of anti-OmpC than those unaffected from UC only families. This study also addressed whether ASCA and OmpC were co-segregating in patients and unaffected relatives. The results however suggest that anti-OmpC and ASCA may represent related but distinct immune responses in CD patients. More importantly the distinct immune phenotypes may translate into distinct clinical phenotypes.

SUMMARY

In summary, the emergence of immunogenetic phenotypes lends support to the proposed hypothesis that susceptibility genes regulate distinct immune processes, driven by luminal antigens, expressed as specific immune phenotypes which in turn influence clinical phenotypes in IBD patients. Immune responses to various microbial antigens among patients with CD may be related to different pathophyisological mechanisms of disease and a genetically susceptible host may yield distinct disease characteristics as a result of the immune responsiveness expressed by the at risk individual. Further research is necessary to validate the associations of immune responses to disease behavior and prognosis and for novel

immune responses to be identified so to provide more information on the underlying etiopathogenic mechanisms of characteristic of IBD. Advances in this field will afford clinicians the opportunity to create and implement appropriate and timely therapeutic management regimes based on the aggressiveness of the IBD subtype in order to alter and thus improve the long-term prognosis.

Abstract

In 2004, an association of genetic variation in the discs large homolog 5 (*DLG5*) gene with inflammatory bowel disease (IBD) was described in two large European study samples. The initial report of *DLG5* as a novel IBD susceptibility gene sparked a multitude of studies investigating its effect on CD and IBD, respectively, leading to controversial findings and ongoing discussions concerning the validity of the initial association finding and its role in the aetiology of Crohn disease. This review aims to summarize the current state of knowledge and to place the reported findings in the context of current concepts of complex diseases. This includes aspects of statistical power, phenotype differences and genetic heterogeneity between different populations as well as gene-gene and gene-environment interactions.

INTRODUCTION

In 2004, we described replicated association of genetic variation in the discs large homolog 5 (*DLG5*) gene with IBD and CD in two large European study samples consisting of German and UK patients[1]. The *DLG5* gene product is a member of the group of membrane-associated guanylate kinases (MAGUKs) and as such contains 4 PDZ domains, one SH3 domain followed by one guanylate kinase (GUK) domain. Additionally, this MAGUK contains an N-terminal domain of unknown function, DUF622. All of these domains are assumed to be involved in protein-protein interactions, supporting the notion of DLG5 as a multifunctional adapter and scaffold protein. DLG5 has been reported to be involved in maintaining cell shape and polarity[2] and to be located at sites of cell-cell contact[3]. The *DLG5* gene is located in a region of strong linkage disequilibrium which is independent of the surrounding genes due to substantial recombination. Analysis of the extended *DLG5* haplotype identified 4 common haplotypes, with haplotype A tagged by 8 htSNPs of equivalent genetic information content. While haplotype A was significantly undertransmitted in IBD and CD, haplotype D is significantly overtransmitted in both IBD ($\chi^2 = 8.08$, $P = 0.004$) and CD ($\chi^2 = 4.15$, $P = 0.04$). The only tagging SNP for haplotype D that allows discrimination from the underlying frequent haplotype C is the single nucleotide polymorphism 113G→A (reference SNP ID: rs1248696). The polymorphism results in the amino acid substitution R30Q in the DUF622 domain of DLG5. Comparisons with homolog proteins indicate that the R30Q variant may disturb binding to a Rab GTPase and thus is likely to have functional implications[1]. In addition, we described 5 additional rare, so-called 'private' mutations that are also likely to have functional implications but are running at a very low frequency in the general population and are thus unlikely to considerably contribute to the observed effect[1].

The initial report of *DLG5* as a novel IBD susceptibility gene sparked a multitude of studies investigating its effect on CD and IBD, respectively, unfortunately leading to discrepant findings and ongoing discussions concerning the validity of the initial association finding.

ROLE OF DLG5 IN JAPANESE PATIENTS WITH CROHN DISEASE

Shortly after the initial report, *DLG5* was analysed for its association to CD in Japanese patients[4]. The CD associated variant R30Q in individuals of Caucasian decent was absent in the Asian population. However, another variant in the *DLG5* gene, rs3758462, located in intron 15 of the *DLG5* gene, was significantly associated with CD ($P = 0.023$) in this Japanese population with an evaluated odds ratio (OR) of 1.39 confirming that *DLG5* is a susceptibility gene for CD with a moderate effect size. More important, the study by Yamazaki *et al* highlights the fact that ethnically divergent populations, although they share the same phenotype, need not necessarily share the same predisposing variants. One reason is that ethnically

divergent populations do not necessarily share the same risk genes as highlighted by the example of *CARD15* variants in ethnically divergent populations. While certain mutations in the *CARD15* gene, namely SNP8 (R702W), 12 (G908R) and 13 (1007insC), are strongly associated to CD in populations of Caucasian descent, the same mutations are completely absent in Asian populations. In fact, the *CARD15* gene is not even associated to the disease in Asian populations[5,6]; thus the finding that a variant in *DLG5* is - although modestly - associated with CD in a Japanese population implicates *DLG5* as a susceptibility gene that confers risk in populations of divergent ethnic origin. However, further studies involving additional cohorts of Asian or African origin will need to be studied to conclusively address the role of *DLG5* in ethnically divergent populations.

DLG5 AND HETEROGENEITY OF RISK VARIANTS IN POPULATIONS OF CAUCASIAN DESCENT

Daly *et al*[7] investigated the contribution of *DLG5* in three study cohorts consisting of patients from Quebec, Italy and UK. This study failed to replicate the reported undertransmission of haplotype A and suggested that the original observation could conceivably have been partially a statistical fluctuation and partially a result of LD with the observed R30Q association on haplotype D. However, they found evidence for an association of the R30Q variant with an estimated OR for R30Q of approximately 1.25, supporting the fact that *DLG5* is a moderate susceptibility gene in populations of Caucasian decent and weaker than in the initial report[1]. This finding implicates that if the true association was as modest as observed by Daly *et al* several thousand cases and controls would be required to have a > 90% power to replicate this effect with confidence ($P < 0.01$), an effort that can only be managed by a consortium effort as none of the individual investigators has a sufficiently powered study population at their disposal. Of note, Daly and colleagues[7] found evidence of replication of the *DLG5* association in only two of three of their sample collections, with the study sample from the UK failing to replicate the *DLG5* association. This observation pointed towards the possibility of either phenotypic differences between the populations studied or genetic heterogeneity within populations of Western European descent. The latter explanation was further supported by a more recent study which failed to replicate this association[8] in a Scottish population. In fact, in their study, the 113A allele was less common in IBD and CD patients than in healthy controls (11.4% in IBD *vs* 13.2% in healthy controls). The authors concluded that the observed discrepancies in allele frequencies might be explained by genetic heterogeneity within European populations. Such genetic heterogeneity has been observed even for the well established *CARD15* gene within Europe with Northern European populations exhibiting the lowest frequencies and Southern European populations exhibiting the highest frequencies of the variant alleles[9]. Accordingly, divergent association results for the R30Q variant in the *DLG5* gene may be indicative of the observed genetic heterogeneity in European populations. This finding is further corroborated by a recent study by Medici *et al*[10] who observed extreme heterogeneity for both *CARD15* and *DLG5* variants between a German and a Norwegian study sample, with a lower population attributable risk percentage for *CARD15* and *DLG5* variants in the Norwegian cohort than observed for other European cohorts. These results are consistent with an emerging pattern of a low frequency of e.g. *CARD15* variants in Northern countries where the prevalence of IBD is greatest. Interestingly, a recent study involving Greek patients with Crohn disease[11] showed that the R30Q variant was completely absent in their study population, further demonstrating the presence of extreme heterogeneity in *DLG5* variants between Northern and Southern European populations.

A recent meta analysis by Tenesa *et al*[12] combining the data from the studies reported by Stoll *et al*, Daly *et al* and Noble *et al* found substantial heterogeneity among the studies that reached statistical significance using the Cochran's Q statistic ($P = 0.0004$), and when including a fixed effect model, the R30Q variant was associated with an OR of 1.19 ($P = 0.035$)[12]. When further exploring the source of heterogeneity it became obvious that the frequencies among IBD samples tended to be more similar than between controls, an intriguing observation that will be further detailed in the following paragraphs.

ROLE OF GENDER

Environmental factors as well as gender may contribute to the complex basis of CD. While gender-specific gene effects are well documented in other complex diseases, i.e. cardiovascular diseases, gender has previously not been investigated in this context in inflammatory bowel disease. Interestingly, a follow-up study of the original genome-wide linkage study in German and UK IBD families[13] examined the data set for gender specific linkage[14] and identified the chromosomal region 10 q, harbouring *DLG5*, as a male specific CD susceptibility locus. In a recent study we investigated whether the association of the DLG5 variant R30Q to CD shows the same gender specificity as the underlying linkage signal. Using multivariate logistic regression analyses in a combined sample consisting of individuals from Germany, Italy and Quebec that were part of the studies reported by us[1] and Daly *et al*[7], we examined whether gender is a relevant factor to the association between CD and the R30Q variant in DLG5. Remarkably, our analyses revealed that the R30Q variant was associated with CD in men (OR = 2.49, $P < 0.001$) but not women (OR = 1.01, $P = 0.979$), thus establishing the DLG5 R30Q variant as a gender-specific susceptibility factor for CD[15]. This gender dependence may in part explain the divergent association studies relating to *DLG5* and IBD outlined in the paragraphs above, as gender composition of the cohorts at study may have been different, and gender was not included as an independent variable in previous analyses. Hopefully, reanalysis of the previous study data involving gender will help to further clarify the role of *DLG5* in the aetiology of IBD.

Of note, similar to the observation made by Tenesa

Table 1 Summary of genetic studies that analyzed DLG5 variants for their association to IBD or CD

	Study	Summary of results	Country of sample collection	Number of participants	Detailed results	Further sample info: gender/age
Association findings	Stoll *et al* 2004[1]	First finding of association between DLG5 variants and IBD/CD Positive association between R30Q (haplotype D tagging SNP) and IBD/CD Negative association between haplotype A and IBD/CD Positive association between P1371Q (rare haplotype) and IBD/CD Interaction between R30Q variant and CARD15 risk alleles	Germany	457 IBD trios (302 CD)	*TDT (T:U) single SNPs* R30Q IBD: 92:64, $P = 0.025$; CD: 60:42, $P = 0.075$ Haplotype A (DLG5_e26) IBD: 162:225, $P = 0.001$; CD: 108:151, $P = 0.008$ P1371Q IBD: 40:24, $P = 0.046$; CD: 24:17, NS

TDT: Transmission disequilibrium test; T:U: Transmitted alleles versus untransmitted alleles (transmissions from heterozygous parents to affected offspring); OR : Odds ratio; NS: Not significant.

et al[12], the observed difference for men and women is result of divergent allele frequencies in the healthy controls and not in the CD patients. The allele frequencies for the Q allele were almost identical among men and women affected with CD (CD males: 10.1%, CD females 10.9%) while there was a significant difference in healthy individuals (males controls: 5.2 %, female controls: 11.3%). These data suggest gender-specific genetic heterogeneity or, more likely, the presence of transmission ratio distortion (TRD) of the Q allele among healthy controls. This hypothesis was further supported by two independent population-based study samples, where similar observations were made[15]. Interestingly, one of the two study samples consisted of a study sample of newborns (Q allele: 7.1% in males *vs* 11% in females, $P = 0.036$) indicating that the observed gender-specific disparity of Q allele frequencies is in fact consequence of prenatal processes, and likely of gender-dependent transmission distortion. However, other mechanisms or a combination of all possible causes for TRD, i.e. biased meiotic segregation, gametic selection and viability selection are conceivable and the true underlying mechanisms are subject to further research. The question remains why the observed gender-dependent disparity in Q allele frequencies is offset in male CD patients. In our opinion, the increase in Q alleles in affected individuals could be either consequence of a yet unknown, disease related mechanism or result of an accumulation of the risk associated Q allele in affected men but not women. However, further studies will need to be conducted to conclusively address this question.

ROLE OF GENE-GENE INTERACTION

Prior to the identification of *DLG5* as a susceptibility gene for IBD and CD, respectively, two CD risk genes were identified, *CARD15* and the *IBD5* risk haplotype that since then have been unequivocally replicated several times[16-23]. As IBD is a polygenic, multifactorial disease, the potential gene-gene interaction between the known susceptibility variants in *CARD15, IBD5* and *DLG5* needs to be investigated to estimate the overall genetic risk. However, most of the studies on IBD genetics are hampered by the lack of statistical power to address gene-gene interactions due to small sample size, rendering such studies a challenging endeavour. This is particularly true for *DLG5*, as *DLG5* is a susceptibility gene that only confers a modest risk[7], the DLG5 R30Q risk variant is comparably infrequent (5%-10%) and subject to genetic heterogeneity[12]. Despite the before mentioned restrictions in the investigation of gene-gene interactions, we examined potential locus-locus interactions with variants of *CARD15* in our initial study describing genetic variation in DLG5[1]. Interactions between *DLG5* and *CARD15* were examined by stratifying trios in two groups on the basis of the *CARD15* genotype of the affected child. Interestingly, in CD trios, we observed a significant difference in transmissions of R30Q between the $CARD15^{risk}$ and $CARD15^{nonrisk}$ group with an increased association of the risk allele in the $CARD15^{risk}$ group, while the association was no longer seen in the $CARD15^{nonrisk}$ group. This suggested a potential interaction of the DLG5 R30Q variant with $CARD15^{risk}$ variants. Recently, Vermeire *et al*[24] reported that *DLG5* was not associated in a large Flemish IBD cohort when *DLG5* was analyzed without considering the genotype status at *CARD15*[24] variants. However, after stratification for $CARD15^{risk}$ variants in the CD patients, the R30Q frequency turned out to differ significantly in the $CARD15^{risk}$ group (Q frequency 12.2%) compared to the $CARD15^{nonrisk}$ group (Q frequency 8.7%; $P = 0.033$), providing further evidence for a potential interaction between $CARD15^{risk}$ variants and DLG5 R30Q. However, further studies involving large study samples will need to be conducted, although due to the observed genetic heterogeneity in *DLG5* variation even within Europe, a consortium effort will be difficult to conduct, and the results are likely difficult to interpret. (Table 1).

In summary, genetic variation in *DLG5* and its role in IBD is a prime example for the difficulties encountered in the dissection of the genetic basis of complex disease. Similar to many examples from other complex diseases, the primary association signal could not be unequivocally replicated in other independent study populations. However, with more and more studies emerging and the growing awareness about the complexity of multifactorial diseases in general, the picture appears to clear off - although there are still a lot of loose ends to tie. The example of *DLG5* shows for the first time that gender needs to be considered as an independent factor contributing to the genetic risk for IBD, a fact that has not been considered previously as the prevalence of IBD is almost equal among genders.

In order to further elucidate the contribution of present and emerging susceptibility genes to the aetiology and clinical presentation of IBD, there is the need to have well-characterized and homogeneous patient populations as well as appropriate controls, preferentially with standardized phenotypes to allow for comparisons between independent study cohorts. In addition, investigators need to be aware of the extreme heterogeneity in IBD disease variants among European populations and between ethnically divergent populations. Finally, the investigation of gene-gene and gene-environment interaction and its influence on disease-onset and progression will gain more importance. Due to the availability of whole genome genotyping arrays, more susceptibility variants will become available in the near future, all of which require further validation in the context of existing IBD susceptibility genes and environmental factors.

Abstract

Pharmacogenetics is the study of the association between variability in drug response and (or) drug toxicity and polymorphisms in genes. The goal of this field of science is to adapt drugs to a patient's specific genetic background and therefore make them more efficacious and safe. In this article we describe the variants in genes that influence either the efficacy or toxicity of common drugs used in the treatment of inflammatory bowel diseases (IBD), ulcerative colitis (UC), and Crohn's disease (CD) including sulfasalazine and mesalazine, azathioprine (AZA) and 6-mercaptopurine (6-MP), methotrexate (MTX), glucocorticosteroids (CSs) and infliximab. Furthermore, difficulties with pharmacogenetic studies in general and more specifically in IBD are described. Although pharmacogenetics is a promising field that already contributed to a better understanding of some of the underlying mechanisms of action of drugs used in IBD, the only discovery translated until now into daily practice is the relation between thiopurine S-methyltransferase (TPMT) gene polymorphisms and hematological toxicity of thiopurine treatment. In the future it is necessary to organize studies in well characterized patient cohorts who have been uniformly treated and systematically evaluated in order to quantitate drug response more objectively. An effort should be made to collect genomic DNA from all patients enrolled in clinical drug trials after appropriate informed consent for pharmacogenetic studies.

INTRODUCTION

Inflammatory bowel diseases (IBD) are chronic invalidating relapsing and remitting diseases of the bowel. Crohn's disease (CD) and ulcerative colitis (UC) are the two main clinical presentations. Within these subgroups there are many differences regarding disease extension, localization, behavior and the occurrence of extra-intestinal manifestations (EIM)[1,2]. The precize ethiology of IBD is unknown but bot environmental factors and a genetic susceptibility play a role. Although great advances have been made in the management of the disease with the introduction of immune-modulators and monoclonal antibodies, a curative therapy does not yet exist. Mesalazine or sulfasalazine formulations are the first-line drugs for induction and maintenance of remission in UC. Glucocorticosteroids (CSs) are added if necessary[3]. For severe acute UC cyclosporine is an option if intravenous steroids fail to induce remission [4]. Azathioprine (AZA) and 6-mercaptopurine (6-MP) are efficacious to maintain remission although the evidence is rather weak. Recently the ACT1 and ACT2 trials proved the usefulness of chimeric monoclonal antibodies to TNF-alpha (TNF-α) (infliximab) for induction of remission and maintenance therapy of therapy refractory UC[5,6]. Active CD is treated with steroids and (or) antibiotics. AZA, 6-MP or methotrexate (MTX) are added for maintenance of remission[3,7]. The role of sulfasalazine or aminosalicylates in the induction and maintenance of medically induced remission of CD is limited[8]. Infliximab has become the treatment of choice for both induction and maintenance of remission in refractory luminal and fistulizing CD[9]. A great inter-patient variability exists in efficacy and toxicity of the drugs used. There are many factors that influence response to pharmaco-therapy including disease severity and complications, environmental factors such as smoking and genetic factors. Variability in drug response is greater across a population than within the same patient or in monozygotic twins, therefore part of this difference is attributed to genetic factors. It is estimated that polymorphisms in genes can account for 20%-95% of variability in drug effects[10]. The scientific

domain studying the relation between genetic variability and variability in drug response and toxicity is called pharmacogenetics[11]. Primary candidate genes of interest include those encoding for drug receptors, metabolizing enzymes, and transporters. However, selection of optimal drug therapy may also involve disease susceptibility genes indirectly affecting drug response. Pharmacogenetics holds the promise that drugs might one day be adapted to each person's own genetic background and therefore be more efficacious and safe. In this article we describe (1) the genetic variants in genes that influence the toxicity of respectively AZA and 6-MP, sulphasalazine and mesalazine and MTX and (2) polymorphisms in genes that influence response to GCs and infliximab. Finally we will discuss the clinical usefulness of and the problems associated with pharmacogenetic studies in IBD.

VARIABILITY IN TOXICITY

The definition and diagnosis of side effects is usually less complicated than the definition of response to therapy although there are confounding factors such as the use of multiple drugs simultaneously. A study that compares the prevalence of side effects between 2 groups of patients with and without a polymorphism is relatively easy to perform. The genetic polymorphisms in the thiopurine S-Methyltransferase (TPMT) gene and its influence on AZA and 6-MP treatment is the first example of how genotyping can be used to optimize drug therapy in IBD. We also describe the relation between polymorphism in N-acetyltransferase genes (NAT) and side effects of mesalazine and sulphasalazine and variants in genes encoding MTX metabolizing enzymes.

Azathioprine and 6-mercaptopurine

Efficacy and toxicity of the drugs: Indications for the use of 6-MP or the prodrug AZA in moderate to severe CD are maintenance of remission and steroid sparing[12,13]. They are used in the treatment of fistulizing CD and recommended during infliximab treatment to reduce antibody formation and to optimize response rates[14]. The drugs are also useful in maintenance therapy of UC[15]. Approximately 40% of IBD patients do not respond to AZA therapy[12,13,15]. Ten to twenty-five percent of patients have to withdraw from AZA or 6-MP due to major (leucopenia, pancreatitis, infection and malignancy) or minor (rash, nausea, fever, arthralgias, malaise and diarrhea) adverse events[16]. Myelosuppression is dose dependent and can be lethal and occurs in 1% to 5% of the patients[12,13,17,18].

Metabolization and pharmacogenetics: AZA is a prodrug that is administered orally at a daily dose of 2.5 mg/kg. Sixteen percent to 50% of the drug are absorbed in the gut. AZA is broken down by non-enzymatic degradation to 6-MP and methyl-nitrothioimidazole. 6-MP can also be administered directly and the current dose is 1 to 1.5 mg/kg. 6-MP is converted to the nucleotide 6-thioinosine monophosphate (6-TIMP) by the enzyme hypoxanthine guanine phosphoribosyl-transferase (HGPRT). 6-TIMP is further metabolized to thioguanine mono-, di- and triphosphates [thioguanine nucleotides (TGNs)]. Alternatively 6-MP can be inactivated by xanthine oxidase (XO) into 6-thiouric acid (6-TU) or by TPMT into 6-methylmercaptopurine (6-MMP). TPMT also catalyses the methylation of the nucleotide metabolites including 6-tIMP and thioguanosine 5-monophosphate[19] (Figure 1). The relative activities of the TPMT, XO and HGPRT enzymes determine the amount of the active 6-TGN and other 6-MP metabolites. The precise mechanism of action of the drug is not completely understood. Incorporation of TGNs in DNA plays a role in immune suppression and bone marrow toxicity[20]. More recent studies suggest that TGNs may also act by inhibition of Rac1, a GTP binding protein involved in the CD28 signal transduction pathway in T cells. CD28 co-stimulation is essential for T cell activation. Through inhibition of Rac1, its target genes [e.g. mitogen-activated protein kinases, NF-kB, bcl-x(L)] are suppressed[21]. There is also evidence that methyl TIMPs inhibit the de novo purine synthesis[22].

TPMT activity: In 1980 Weinshilboum *et al* described for the first time inherited differences in TPMT activity[23]. In the mean time 2 wildtype TPMT alleles (TPMT*1 and TPMT*1S) and 16 variant alleles with low enzymatic activity (TPMT*2, *3A, *3B, *3C, *3D, *4-15) have been described[24-28]. In the Caucasian and African populations approximately 90% of individuals carry 2 wildtype alleles resulting in high TPMT enzyme activity, 10% are heterozygous and display intermediate activity and 0.3% are homozygous for low activity alleles and display no detectable TPMT activity. Heterozygosity is less frequent in Asians (2%-5%). The TPMT*2, *3A and *3C alleles account for 80% to 95% of inherited TPMT deficiency in different populations over the world[29-31]. The TPMT*2 allele contains a non-synonymous mutation at amino acid position 80 (Ala80Pro, G238C)[32]. The TPMT*3A allele contains two missense mutations, G460A (Ala145Thr) and A719G (Tyr240Cys). The TPMT*3C allele contains only the A719G missense mutation[33]. In African, African-American and Asian populations the most common low TPMT activity allele is the TPMT*3C and in Caucasians the TPMT*3A allele. The TPMT *3B (G460A) allele occurs in 1% of Caucasians. This allele is however important because PCR based assays can not distinguish between TPMT 1/*3B and *3B/*3C genotypes[34] (Table1).

TPMT genotype and hematopoietic side effects: A hundred percent of the compound heterozygous or homozygous IBD patients develop severe hematotoxicity when treated with a normal thiopurine dose[35-38]. The inverse is not entirely true as Colombel *et al* found that only 27% (11/41) of IBD patients treated with AZA who developed myelosuppression had one or more of the 3 frequent variant alleles[39]. However, in a study in patients treated with AZA for rheumatoid arthritis(RA) by Black *et al* 5 of 6 (83%) patients with leukopenia were heterozygous for a TPMT variant allele[40,41]. Some investigators suggest that thiopurine drugs should entirely be avoided in patients with low TPMT activity (heterozygous), however it seems that IBD patients with low TPMT activity (heterozygous) can mostly safely be treated with reduced doses of AZA or 6-MP provided they are submitted to close monitoring[42,43]. Homozygous or compound heterozygous patients with no TPMT activity should not receive the drug.

Table 1 Interpretation by PCR based methods of TPMT activity

Genotype		PCR	Risk of hematopoietic toxicity
238G/238G	*1/*1	238 GG	-7%
460G/460G		460 GG	
719A/719A		719 AA	
238G/238G	*1/*3A	238GG	-35%
460A/460A		460GA	
719A/719G		719AG	
238G/238G	*1/*3B	238GG	-35%
460G/460A		460GA	
719A/719A		719AA	
238G/238G	*1/*3C	238GG	-35%
460G/460G		460GG	
719A/719G		719AG	
238G/238G	*3B/*3C	238GG	-100%
460G/460G		460GG	
719A/719G		719AG	
238G/238G	*3A/*3C	238GG	-100%
460A/460G		460GA	
719G/719G		719GG	
238G/238G	*3A/*3B	238GG	-100%
460A/460A		460AA	
719G/719A		719AG	

Patients with *1/3A and *3A/*3C genotype have the same PCR results, however the risk to develop hematopoietic toxicity for patients with 2 low activity alleles is almost 100% compared to 35% only for heterozygous patients.

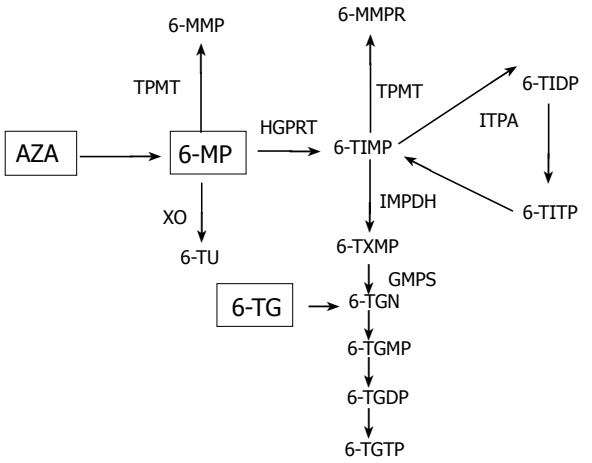

Figure 1 Simplified scheme of AZA metabolism: AZA is non-enzymatically converted to 6-MP. 6-MP is converted into the 6-thioinosine monophosphate (6-TIMP) by the enzyme hypoxanthine guanine phosphoribosyl-transferase (HGPRT). 6-TIMP is further metabolized to thioguanine mono, di and triphosphates [6-thioguanine nucleotides (TGN)]. Alternatively 6-MP can be inactivated by xanthine oxidase (XO) into 6-thiouric acid (6-TU) or by TPMT into 6-methylmercaptopurine (6-MMP). TPMT also catalyses the methylation of the nucleotide metabolites including 6-TIMP and 6-thioguanosine-5'-monophosphate to 6-methylmercaptopurine (6-MMPR). Inosine monophosphate dehydrogenase (IMPDH) and guanine monophosphate synthetase (GMPS). Inosine triphosphate pyrophosphatase (ITPA), 6-thioinosine triphosphate pyrophosphate (6-TITP).

TPMT activity and other side effects: One study has described a relation between low TPMT activity and nausea, however this has not been replicated[44]. More recently a relation between therapy refractoriness and normal or high TPMT activity has been described. Predicting response is useful especially since there is a 3 month delay before the effect of these drugs is achieved. Efficacy of treatment with 6-MP or AZA is related to red blood cell levels of the active metabolite TGN (> 235 pmol/8×10^8 RBC)[38]. Patients heterozygous for TPMT low activity alleles have lower TPMT activity and higher erythrocyte TGN levels[45] (Figure 1). One study showed a lower relapse rate in patients with low TPMT activity compared to patients with normal TPMT activity but 2 later studies failed to replicate this finding[45-47]. High levels of 6-MMP are thought to be responsible for hepatotoxicity[48]. Liver transaminase elevation has been associated with high TPMT activity and 6-MMP levels and TPMT variant alleles are very rare in patients with hepatotoxicity[48]. This finding has not been replicated.

TPMT activity from bench to bedside: Genotyping the 3 most common SNPs or measuring the enzyme activity are 2 alternative methods for predicting the risk for hematopoietic toxicity. TPMT enzymatic activity can be measured in red blood cells with a radiochemical or high-performance liquid chromatography assay, however the results are modified by recent blood transfusions[49]. TPMT activity also varies over time and is influenced by other drugs (e.g. diuretics, 5-ASA) and conditions (e.g. uremia)[50-52]. TPMT enzyme activity will identify patients with high TPMT activity that metabolize 6-MP to 6-MMP and therefore may be resistant to treatment with thiopurine drugs[48]. As described PCR based assays can not distinguish between the TPMT 1/*3B and *3B/*3C genotypes[34]. Furthermore there are problems with the correlation between enzyme activity assays and genotype, since patients with low-normal enzyme activity can have either a wildtype or a heterozygous genotype[41,55].

There is no consensus yet that TPMT genotype or phenotype should be measured before starting AZA or 6-MP treatment in IBD patients, especially since hematologic toxicity can develop in patients with normal TPMT activity. Monitoring of blood counts and liver transaminases remains therefore necessary in all patients. If TPMT enzyme activity is measured patients with normal TPMT activity (or wildtype patients) can receive 2-2.5 mg/kg AZA or 1-1.5 mg/kg of 6-MP. Patients with intermediate activity (heterozygous) should have a dose reduction of 50% and patients with low or absent TPMT activity (compound heterozygous or homozygous) should not receive thiopurine drugs at all or at very low dose (10%)[54]. One socio-economic study in IBD has proven that TPMT phenotyping or genotyping is cost effective to identify patients with low or no TPMT enzyme activity (homozygous or compound heterozygous) in order not to treat them and avoid severe hematological complications[55].

ITPA genotype and thiopurine toxicity: Inosine triphosphate pyrophosphatase (ITPA) deficiency results in the accumulation of the inosine nucleotide ITP and a methylate product (Figure 1). Sixty-two IBD patients suffering adverse drug reactions to AZA therapy and 68 AZA treated patients without side effects were genotyped for the ITPA SNP C94A by Mariniki *et al*[44]. The ITPA C94A deficiency-associated allele was significantly associated with flu-like symptoms (OR 4.7, 95% CI

1.2-18.1, $P = 0.03$), rash (OR 10.3, 95% CI 4.7-62.9, $P = 0.02$) and pancreatitis (OR 6.2, CI 1.1-32.6, $P = 0.05$). This finding was not replicated in two subsequent studies in 72 and 41 patients respectively[56,57]. The thiopurine drug 6-thioguanine (6-TG) is not metabolized by TPMT and ITPA and might therefore be efficacious for patients with AZA or 6-MP resistance and high TPMT activity or for patients with impaired ITPA activity (Figure 1). However 6-TG treatment is associated with an increased risk of nodular regenerative hyperplasia of the liver and veno-occlusive disease[58,59].

Sulphasalazine and mesalazine

Variability in drug acetylation was discovered 45 years ago in patients who were treated with isoniazide for tuberculosis. Family studies revealed that this variation was genetically controlled and that the population can be divided into slow acetylators and rapid acetylators due to polymorphisms in the N-acetyltransferase genes (NAT). Two iso-enzymes NAT1 and NAT2 that have overlapping and specific aryl-amine substrates have been identified in humans[60]. Eleven single nucleotide polymorphisms (SNPs) in the NAT2 gene result in 25 different alleles in humans[61]. More than 50% of Caucasians are NAT2 slow acetylators[62]. The slow acetylating phenotype for NAT2 (reduction of 10% to 20% of the cytosolic NAT2 protein) is a heterozygous trait and several low activity alleles have been described (Table 2)[61,63,64]. There is also an allele (NAT2*12B) associated with high NAT2 expression and a fast acetylating phenotype (Table 2). Lin *et al* found that 4 variants (191A, 481T, 590A and 857A) accounted for nearly all slow acetylating phenotypes in Caucasian, African, Hispanic and Asian populations[65]. A polymorphism in the NAT1 gene was first described in 1993 and since over 20 alleles have been identified[63,66,67]. Several variant alleles are functional and result in reduced N and/or O-acetylation in humans (NAT*14A, NAT1*14B, NAT1*17, NAT1*19 and NAT1*22) and yeast cells (NAT1*14B, NAT1*15, NAT1*17, NAT1*19 and NAT1*22)[66,68,69]. Sulphasalazine is still widely used for long term maintenance therapy in UC. Five percent to fifty-five percent of the patients treated with the drug develop hypersensitivity or intolerance. Sulphasalazine is split in the lumen of the colon into the active metabolite 5-ASA and sulphapyridine (SLP) by bacterial azo-reductases. SLP is absorbed and acetylated in the liver by NAT2 into N-acetyl-SLP. Levels of SLP above 50 mg/L are associated with most of the severe side effects (thrombocytopenia, leukopenia, liver and lung toxicity and pancreatitis) and are observed more frequently in slow acetylators[70]. Case reports suggested a relation between side effects like leukopenia and a mononucleosis-like syndrome and one of the slow acetylating genotypes in IBD patients treated with sulphasalazine[71,72]. Mesalazine exists in different targeted release preparations designed to protect 5-ASA from absorption and metabolism in the proximal digestive tract. 5-ASA is released in the distal ileum or the colon and part is systemically absorbed. 5-ASA is acetylated in the liver by NAT1 into N-acetyl 5-ASA (N-Ac-5ASA) and excreted in the urine. Side effects are less common with mesalazine compared to sulphasalazine but there is still some concern about nephrotoxicity with long term use. A retrospective study in 77 UC patients did not show an impact of NAT1 genotype on efficacy or side effects of mesalazine [73].

Table 2 NAT2 phenotypes and genotypes

Mutations	Allele designation	Phenotype
None	NAT2*4 (wild-type)	normal
T341C, C481T, A803G	NAT2*5B (r3,S1a)	Slow
C282T, G590A	NAT2*6A (M2)	Slow
T341C, C481T	NAT2*5A (M1)	Slow
T341C, CA803G	NAT2*5C (S1c)	Slow
C282T, G857A	NAT2*7B (M3)	Slow
C282T	NAT2*13 (S4)	
G590A	NAT2*6B (R2)	Unknown
G191A	NAT2*14A (M4)	Slow
A803G	NAT2*12A	Rapid

Methotrexate

MTX is efficacious for the induction of remission while weaning patients from steroids in 39% of CD patients and for maintenance of remission in 65% of CD patients after successful induction therapy with this drug[7]. A low single weekly dose of 15 to 25 mg intramuscularly or subcutaneously is used. Most pharmacogenetic studies on MTX are derived from the oncologic literature where patients receive a high dose MTX. MTX is taken up by the cell trough reduced folate carrier-1 (RFC1) and polyglutaminated by folyglutamate synthetase (FPGS)[74]. MTX polyglutamate inhibits amino-imidazole carboxamide (AICAR) transformylase, an enzyme of the de novo purine synthesis pathway. MTX also inhibits the enzyme 5, 10-methylenetetrahydrofolate reductase (MTHR) that catalyses the conversion of homocystein to methionine (Figure 2). Deficiency of MTHR and hyperhomocysteïnemia are implicated in neurological and vascular diseases[75]. Inhibition of MTHR and DNA synthesis is the primary mechanism of action of MTX in oncology. Tissues undergoing rapid cell turnover with a high fraction of the cell in the S-phase of the cell cycle are the most susceptible to its cytocidal effects. This mechanism also explains the possible severe side effects of MTX including bone marrow suppression, mucositis, gastro-intestinal toxicity and liver function abnormalities. Folic acid or folinic acid supplementation diminishes the rate of these side effects[76]. The common C677T SNP in the MTHFR gene is associated with decreased MTHFR activity and altered folate levels and has been studied extensively[77]. The 677TT genotype has been identified as a risk factor for elevated ALT values in MTX treated RA patients[77]. In patients undergoing bone marrow transplantation patients homozygous for the 677T allele had more often oral mucositis and platelet recovery was slower[78,79]. In patients with breast cancer and MTX chemotherapy neutropenia was more frequent in patients with the TT genotype[80]. The risk of side effects for patients with the TT genotype was reduced with folic acid supplementation in RA patients[76]. A second SNP in the 3'-untranslated region of the MTHFR gene is associated with higher expression

of the gene[81]. No studies are available that examine the relation between these variants and the prevalence of side effects in IBD patients treated with low dose MTX. The exact anti-inflammatory mechanism of low dose MTX therapy in RA and IBD is not clearly known. In contrast to side effects the anti-inflammatory effect is not inhibited by folic acid supplementation[76]. A possible mechanism of action is inhibition of AICAR and a subsequent rise in intracellular adenosine[74]. Polymorphisms in RFC1, thymidilate synthetase, and in AICAR transformylase have been implicated in response to therapy with low dose MTX in RA[82]. Polymorphisms in DHFR, in enzymes involved in catabolism of MTX (γ-glutamyl hydrolase) or its efflux have also been suggested to play a role in response to treatment. No data on the relation between any of these SNPs and IBD are available.

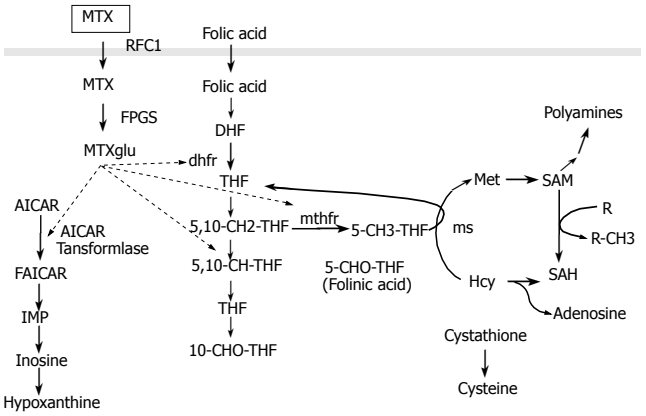

Figure 2 The dotted arrows indicate inhibitory effects of MTX methotrexate. RFC1 reduced folate carrier 1; MTXglu methotrexate polyglutamate; AICAR, 5-aminoimidazole-4-carboxamide ribonucleotide; DHF, dihydrofolate; THF, tetrahydrofolate; dhfr, dihydrofolate reductase; mthfr, methylene tetrahydrofolate reductase; 5,10-CH-THF, 5,10 methenyl THF; 5,10-CH2 THF, 5,10 methylene THF; 10-CHO THF, 10-formyl THF; Hcy, homocysteine; 5-CHO THF, 5-formyl THF; ms, methionine synthetase; Met, methionine; SAM, S-adenosyl-L-methionine; R, methyl acceptor; SAH, S-adenosyl–L-homocysteine.

VARIABILITY IN RESPONSE TO TREATMENT

Investigating genetic variants that influence the response to a specific drug is more difficult than finding factors that influence toxicity. Side effects are usually easy to define and identify. Efficacy scores are often less well defined, different scores to assess disease activity are used and scores [e.g. Crohn's disease activity index (CDAI), endoscopic scores, ulcerative colitis disease activity index] are usually constructed using a combination of clinical, laboratory (e.g. CRP, hemoglobin) and (or) endoscopic parameters[83]. Moreover, treatment response in a heterogenic disease like IBD is influenced by many confounding factors such as the duration of disease, disease behavior and disease severity. Besides polymorphisms in specific drug metabolizing enzymes or target proteins, heterogeneity in the genetic background can also influence response to treatment. Pharmacogenetic studies focusing on drug efficacy in IBD have been published for CSs and infliximab.

Glucocorticosteroids

CSs are effective in the initial treatment of most cases of moderate to severe active UC and CD. However, a retrospective population-based American study reported 28% and 22% steroid dependency in CD and UC patients and 16% steroid resistance after one year of treatment[84]. Other studies report steroid resistance in 20% to 40% of Caucasian IBD patients. A high frequency of surgical interventions is described in steroid dependent and resistant patients[84-86]. The doses of CSs, the tapering regimens and the definition of steroid refractoriness vary greatly between different publications. CSs are potent inhibitors of T cell activation and cytokine secretion and mediate their anti-inflammatory effect through binding the intracellular glucocorticoid receptor (GRα). A homodimer of 2 activated GRs is translocated to the nucleus and the complex subsequently binds to specific DNA sequences [glucocorticoid response elements (GRE)] and controls the expression of target genes [e.g. inhibition of the activator protein-1 (AP-1) gene and induction of the inhibitor kappa Bα (IκBα) gene](Figure 3). There are 3 potential mechanisms for resistance to CSs treatment in IBD. First, a decreased plasma level through over-expression of the MDR1 gene and subsequent elevated p-glycoprotein mediated efflux of the drug. Furthermore, an altered function of the GR and finally the anti-inflammatory capacity of CSs can be overwhelmed by an excessive synthesis of pro-inflammatory cytokines induced by the activation of pro-inflammatory transcription factors which may also reduce the affinity of GR for its intracellular ligands[87]. The reported refractoriness to CSs in IBD patients can not only be explained by disease severity since resistance to treatment is also seen in some mild cases[87,88]. Familial abnormalities of the GR have been described but are rare and there are no cases in the literature in IBD patients[89]. Steroid resistant asthma patients do not respond to high doses of inhaled CSs but they do develop the Cushingoid side effects of steroid treatment. In these patients reduced peripheral T-lymphocyte GR binding affinity and abnormalities of GR-AP-1 interaction and increased expression of GRβ (a truncated splice variant of the normal isoform GRα) are observed. GRβ is unable to activate CSs responsive genes. Honda *et al* reported GRβ specific messenger RNA expression in 83% of the patients with steroid resistant UC compared to only 9% in steroid responsive patients and 10% in healthy controls and chronic active CD patients[90]. The level of GRβ is, however only 0.165% of the level of GRα and has to be at least 5 to 10 fold in excess of GRα to significantly inhibit CSs mediated gene expression. Furthermore, *in vitro* data suggest that splicing and generation of the isoform of GR is induced by cytokines and CSs administration[90,91]. The MDR1 gene encodes the drug efflux pump P-glycoprotein-170 (Pgp-170) and is expressed on the surface of lymphocytes and intestinal epithelial cells. Pgp and MDR expression is significantly higher in CD and UC patients requiring surgery due to failure of medical therapy[92]. Genetic factors are suggested to play a role in the observed higher MDR expression. The MDR1 exonic SNPs C3435T and G2677T have been correlated

with activity and expression of Pgp170[92,93]. Although an association between CS refractory CD and MDR polymorphisms has been described, no randomized trials with fixed clinical endpoints studying the relation between these SNPs and response to steroids in IBD patients have been published[94]. Hirano *et al* found a relation between CSs administration and MDR expression and suggested that over-expression of MDR1 mRNA in peripheral blood monocytes of IBD patients and subsequent refractoriness to CSs therapy is not intrinsic but secondary to high-dose administration of CSs[95]. MDR1 knockout mice spontaneously develop colitis and the MDR1 gene maps to the IBD susceptibility locus on chromosome 7 making it an excellent functional and positional candidate gene for susceptibility to IBD. Recently associations between C3435T and UC and G2677C/T and IBD have been described[96,97]. The MDR1 3435 TT genotype was especially associated with extensive UC[97], An association between steroid refractoriness and the 3435 TT genotype can αtherefore be the result of disease heterogeneity and more specifically an extensive disease phenotype in UC. But the TT genotype is associated with lower expression of MDR1 and Pgp-170. Trials in large patient cohorts treated with fixed CSs doses and followed with well defined activity scores to assess response are necessary to further clarify the relation between MDR polymorphisms and Pgp expression and response to treatment with CSs.

Infliximab

Infliximab is a chimeric monoclonal IgG1 antibody against TNF-α. It is effective for the induction and maintenance of remission of refractory luminal and fistulizing CD. It was the first drug that clearly showed to induce mucosal healing[98-100]. Twenty-five percent of the patients however, did not respond to infliximab administration and in another 20%-30% the response was incomplete. Pharmacogenetic studies of response to infliximab in CD are interesting since most patients have been included in randomized placebo controlled phase Ⅲ and Ⅳ multicenter clinical trials. Most patients received the same dose (5 mg/kg) of the drug and response and remission were defined as a decrease of CDAI of 70 (or 100) points and drop below 150 respectively. DNA was collected from subcategories, by individual centers. Therefore the studies by different centers are well comparable. Infliximab reaches its effect in CD not only by blocking soluble TNF-α but also by inducing apoptosis of activated T-cells and monocytes[101-103]. The CARD15 gene on chromosome 16 was the first susceptibility gene identified for CD. In most Western populations 40% of CD patients carry at least one variant in the gene[104, 105]. The 3 CD associated CARD15 mutations alter NF-κB activation and subsequent cytokine production[106-108]. Since NF-κB signaling and TNF-α levels after stimulation are lower in cells carrying a CD associated CARD15 variant, it was hypothesized that patients carrying a mutation in the CARD15 gene might respond differently to treatment with a TNF blocking agent. Therefore CD patients receiving infliximab were genotyped for R702W, G908R and 1007InsC in CARD15, however no difference was observed in response measured by CDAI between patients with and without variants in

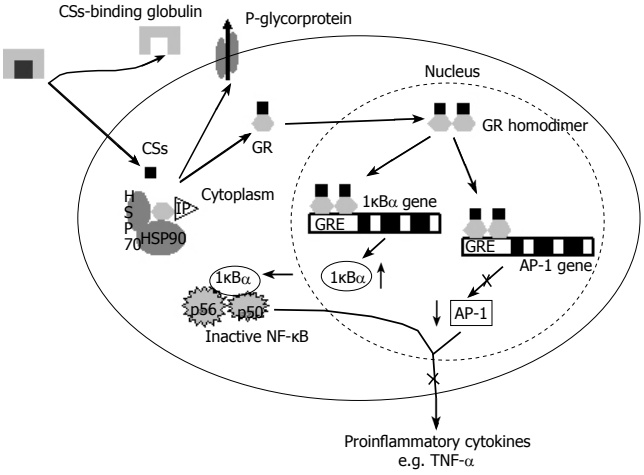

Figure 3 Anti-inflammatory mechanism of glucocorticoids (CSs). CSs enter the cell and interact with the glucocorticoid receptor (GRα) to change the GR conformation, induce formation of GR homodimers and translocation to the nucleus. GR homodimers specifically bind to glucocorticoid response elements (GRE) in target genes. HSP90, 90-kDa heat shock protein; HSP70, 70-kDa heat shock protein; IP, 56-kDa immunophilin; IκBα inhibitor kappa B alpha; NF-κB, nuclear factor kappa B; AP-1, activator protein 1.

the gene[109,110]. A possible association between SNPs in the main target molecule of infliximab TNF-α (-238, -308, -376, -857, -1031) and its receptors TNF receptor 1 (TNFR1) (-609 and +36 or P12P) and TNFR2 (168 or L56L, 587 M196A, 1663, 1690) and response to treatment in CD was studied by several investigators but no significant associations were found[111-114]. Taylor *et al* found a weak association between a haplotype spanning the TNF-α and TNF-β locus on chromosome 6p21.3 and lack of response to infliximab treatment in 75 CD patients treated with the drug. None of the individual SNPs was however associated with response to therapy[113]. Since the efficacy of infliximab in CD is partly the result of its ability to induce apoptosis of activated T lymphocytes, Hlavaty *et al* studied the effect of polymorphisms in apoptosis genes and short term clinical response in a cohort of 287 patients treated with infliximab for luminal or fistulizing CD. In luminal CD, patients carrying the Fas ligand -843 CC/CT genotypes responded in 74.7% compared to a response rate of 38.1% in patients with the TT genotype ($P < 0.01$, OR = 0.11, 95% CI 0.08-0.56). The bad outcome to infliximab in patients carrying FasL-843T could be overcome by concomitant use of AZA. Patients with the Caspase 9 93 TT genotype all responded, in contrast with 66.7% of patients with the CC and CT genotypes ($P = 0.04$, OR = 1.50, 95% CI 1.34-1.68)[115]. Binding of infliximab to membrane bound TNF-α not only induces apoptosis of monocytes and lymphocytes but probably also cell lysis by complement dependent and antibody dependent cell-mediated cytotoxicity (ADCC). The FCGR3A gene encodes FcγRⅢa, a receptor for the Fc fragment of immunoglobulines (Ig) on macrophages and natural killer cells. The non-synonymous G4985T (amino acid position Ⅴ158F) variant in the FCGR3A gene results in a different binding affinity. The FcγⅢa receptor of cells with the 158Ⅴ Ⅴ genotype have a higher affinity for the IgG Fc fragment and natural killer cells and the lysis of lymphomatous cells was more effective in patients

with this genotype treated with the TNF-α blocking agent rituximab[116,117]. Louis *et al* studied the association between this polymorphism and short term response to infliximab in 200 patients with refractory luminal or fistulizing CD. The clinical response (CDAI) was 82.9% in patients with VV genotype and 72.7% in patients with VF or FF genotypes. However, all patients with the V V genotype had a biological response (defined as a drop of CRP of at least 25% compared to baseline) compared to only 69.8% of the patients with one or more F alleles ($P < 0.01$)[118]. This study therefore suggests that there might be a better response to treatment with monoclonal antibodies against TNF-α in patient with the V V genotype.

DISCUSSION

Since the start of pharmacogenetic research 50 years ago and the identification of slow and rapid acetylators due to mutations in the NAT genes, major advances have been made. The most relevant discovery for IBD is the identification of variants in the TPMT gene and its importance for patients treated with AZA or 6-MP. To date, this is also the only test that has proven to be cost effective in clinical practice in IBD[55]. Pharmacogenetic studies of infliximab, MDR and the efficacy of CSs have contributed to understanding the mechanism of action of these drugs. There are however many problems with pharmacogenetic studies besides the normal shortcomings of association studies (i.e. low power, population stratification and multiple testing). First, pharmacogenetic data available from other diseases are not always applicable to IBD. For instance, For instance, most studies with MTX are performed in oncology patients who receive high doses of the drug during a short episode. CSs response is most extensively studied in asthma patients who are treated with inhalation therapy. Second IBD is a heterogenic disease and there are many differences regarding disease severity, location, behavior and extra-intestinal manifestations that may influence therapeutic outcome. Side effects are often rare, for instance, leucopenia and myelosuppression during AZA therapy only occurs in 1%-5% of the patients treated. This results in publications with low numbers of patients which are therefore underpowered. Multicenter studies can overcome this problem. Furthermore, exact definitions for response to therapy are necessary to replicate results in independent populations. In studies with older medications especially CSs, different doses and different tapering regimes are used. This makes the literature unorganized and comparison and meta-analyses impossible. In more recent publications however, especially those regarding biologicals and immuno suppressives, doses are calculated per kilogram body weight. Interestingly pharmacogenetic studies, in infliximab and AZA or 6-MP use strict definitions regarding therapy response. A problem especially important in patients with active IBD and an inflamed bowel is the variability of absorption of orally administered drugs. It is probably better to report drug or metabolite levels instead of the administered dose to make results comparable (e.g. TGN levels in AZA therapy). Finally, most studies investigating differences in drug response as a result of genetic polymorphisms lack explicit statements of how to translate the information for use in clinical practice. Straight clinical recommendations on how to individualize therapy based on pharmacogenetic test are essential, however the study design of most pharmacogenetic studies is inadequate to draw these sorts of conclusions. The study design of most pharmacogenetic studies is inadequate to draw these sorts of conclusions. The cost effectiveness of genotyping patients before the start of treatment should also be evaluated. We can therefore conclude that pharmacogenetics remains a promising field that already contributed to better understanding the molecular mechanisms of some of the drugs used in IBD. Until now however, the only clinical useful discovery is the relation between TPMT polymorphisms and hematological toxicity associated with thiopurine treatment. In the future it is necessary to organize studies in well characterized patients who have been uniformly treated and systematically evaluated in order to quantitate drug response and side effects more objectively. Also the prize of genotyping should be compared with the money saved by the prevention of side effects or treatment of non-responders. An effort should be made to collect genomic DNA from all patients enrolled in clinical drug trials after informed consent for future pharmacogenetic studies.

Abstract

Studies examining the inheritance of inflammatory bowel disease (IBD) within different family groups have been the basis for recent molecular advances in the genetics of IBD. The derived heritability in Crohn's disease (CD) is higher than in many other complex diseases. The risk of IBD is highest in first-degree relatives of a CD proband, but first-degree relatives of a proband suffering from ulcerative colitis (UC) and more distant relatives are also at increased risk. Disease concordance rates in IBD have been examined in multiplex families and in three large European twin studies.

INTRODUCTION

Attempts to increase understanding of genetics of inflammatory bowel disease (IBD) have greatly increased in frequency and reached a molecular level during the last decade. In fact, the initial interest to commence with molecular genetic studies was based on the data derived from epidemiological studies showing convincingly and consistently that the prevalence of IBD is increased among relatives with Crohn's disease (CD) and ulcerative colitis (UC). Quantitatively, the degree of familial clustering of disease may be expressed as the ratio of the risk of siblings to the reported population prevalence (λs ratio). Using this formulation, the genetic risk ratio for IBD is in the range of 15-42 for CD[1–5] and 7-17 for UC[4,5]. These λs values, especially for CD, are in the range or even higher than those reported for many other complex disorders, including type 1 diabetes (λs 15), type 2 diabetes (λs < 10), schizophrenia (λs < 10) and celiac disease (λs 7-30). Collectively, these data support a strong contribution of genes in the pathogenesis of CD in particular, although they do not provide information on the exact mode of inheritance.

TWIN STUDIES IN IBD

Although few in number, twin studies have constituted an important tool to identify the relative contribution of inherited and environmental factors in the aetiology of CD and UC. Should a disease be entirely due to genes, then its concordance in identical (monozygotic) twins would approach 100% and that in non-identical (dizygotic) twins 50%. If, on the other hand, the disease is fully dependent on extrinsic and acquired factors, then its concordance would be similar in both types of twins. In large European studies conducted in Sweden[6,7], Denmark[8] and UK[9], the concordance rate for CD in monozygotic twins was estimated at between 20% and 50%, whereas the concordance rate in dizygotic twins brought up in the same environment is less than 10 % (Table 1). More recently closer examination of the phenotypic characteristics of the Swedish cohort provided some evidence that in CD even the disease phenotype may be genetically determined[7]. Thus, in the monozygotic CD concordant pairs 7/9 were concordant for disease location, as determined by Vienna classification, and 6/9 were diagnosed within 2 years of each other. There was no significant concordance for disease behaviour, *i.e.* fistulizing or stricturing type, or extent of the disease.

The evidence from twin studies in ulcerative colitis also implies an important heritable component, although a weaker one than in CD. The concordance rate of UC in monozygotic twins was reportedly about 16% and that in dizygotic twins about 4% (Table 1) , i.e. figures markedly lower that the corresponding estimates in CD[6-9]. Along

Table 1 Concordance rates for CD and UC according to three large twin studies

	Monozygotic twins		Dizygotic twins	
	CD	UC	CD	UC
Halfvarsson[7]	50% (n = 18)	19% (n = 16)	4% (n = 26)	0% (n = 20)
Orholm[8]	50% (n = 10)	14% (n = 21)	0% (n = 27)	7% (n = 44)
Thompson[9]	20% (n = 25)	16% (n = 38)	7% (n = 46)	3% (n = 34)

the same line, concordance for phenotypic characteristics in twin pairs with ulcerative colitis is less consistent compared with CD.

In comparison to the general population, an IBD co-twin is also at increased risk of developing an IBD phenotype opposite to his/her twin partner[8]. The role of smoking habits to influence the risk and phenotype in IBD has also been confirmed by twin studies[6,8]. Orholm et al. reported that smoking was positively, although non-significantly, associated with CD and negatively and significantly with UC. In that study discordant smoking habit explained at least part of the disease discordance[8].

In summary, identical twins are significantly more likely to be concordant for IBD than non-identical twins. However, the concordance for homozygous twins does not reach a higher extent than 50% underscoring the important role of environmental causes in the pathogenesis of IBD.

FAMILY STUDIES IN IBD

Familial clustering of IBD has been documented in numerous studies. The rate at which patients with CD report a family history of CD varies from 2% to 14% and of any type of IBD from 5% to 16%, whereas patients with UC possess a family history of UC from 7% to 11% and any type of IBD from 8% to 14% (Table 2)[1,2,5,10-15].

However, it should be emphasized that the methodologies used by different family studies vary, and comparing the data between studies is not straightforward. For instance, published estimates may be biased as studies carried out in teaching hospital populations tend to overrepresent IBD patients with positive family history and more severe disease course compared to population-based studies. In addition, studies do not report results in a similar manner. Thus, some of the studies report risk for all relatives while some report risks to first-degree relatives only; in addition, the degree of risk may not be assigned to all phenotypes (UC, CD and/or IBD) in all studies. Furthermore, studies with longer follow-up time are more likely to include more family members with IBD. Therefore, age-adjusted figures when available give more reliable estimates of the true risk developing IBD. Despite of different methodologies used, in all studies the greatest risk is constantly seen in first-degree relatives, especially siblings, and a positive family history is more common in CD patients than in UC patients.

Risk of IBD in first-degree relatives

Strömgren's methodology has been most frequently used for assessment of age-adjusted relative risk. The calculations are based on the assumption that all patients live to age 70 years. Based on different studies in European and North-American white non-Jewish populations[5,13,15], the approximated age-adjusted life-time risk of developing IBD for first-degree relatives of a CD proband is 5 % and that of an UC proband 1.6%. The corresponding figures for Jewish patients are 8 % and 5.2%, respectively[15]. Family studies have repeatedly shown that the siblings of a proband are at highest risk of developing IBD, while parents have the lowest risk[13,15].

Accurate risk estimates for the offspring of CD and UC probands are difficult to calculate because many of them may not have reached the age at which the first symptoms of the disease should appear. One approach to overcome these difficulties is to calculate the prevalence proportion ratio which is estimated by dividing the observed number of offspring with IBD with the expected number of cases from the general population. In a Danish population-based study, the prevalence proportion ratios of CD and UC among offspring of patients with CD were 12.8 and 4.0, respectively, while the corresponding figures for patients with UC were 2.6 and 5.1, respectively[16]. If both parents have IBD, the risk of children to develop IBD is relatively high. Accordingly, under these circumstances about one third of the offspring have developed IBD before 30 years[17,18]. Estimations for the relative risk (relative to the population prevalence) of a sibling to develop the same disease as the proband have varied greatly. The λs ratio to a sibling to develop same disease has been estimated to be 15-42 for CD and 7-17 for UC[1-5]. Tobacco smoking probably is a strong environmental factor influencing the acquisition of the disease type. Sib pairs discordant for both smoking and IBD subtype almost always show CD in the smoking and UC in the non-smoking mate[19,20].

INFLUENCE OF INHERITANCE ON THE CLINICAL PHENOTYPE IN CROHN'S DISEASE AND ULCERATIVE COLITIS

The fundamental difficulty in exact comparison of the phenotypes in family studies lies in the fact that there is no agreed standard definition for a phenotype in either CD or UC. In fact, almost all family studies have been performed before Vienna classification of CD was adopted.

Crohn's disease

The age at onset of disease, location of disease, disease behaviour, the extent of extraintestinal manifestations and need for surgery are the most often studied phenotypic characteristics of CD. In these studies, familial aggregation and a high degree disease concordance have been confirmed, and the age at diagnosis and initial disease location were especially strongly related within generations of given families[13,15,21,22]. A high degree of concordance for disease location in parent-child and sibling pairs has also been demonstrated[13,14,22-24]. In contrast, most studies found no effect of a positive family history on severity and course of CD. There are no strong arguments for phenotypic differences between familial and sporadic

Table 2 Recent studies on the occurrence (in percent) of affected first-degree relatives in a proband with CD and UC

	Proband with CD		Proband with UC	
	First-degree relatives with CD	First-degree relatives with any form of IBD	First-degree relatives with UC	First-degree relatives with any form of IBD
Freeman (2002)[10]	8.7% (n = 1000)	-	-	-
Halme (2002)[11]	10.9% (n = 257)	15.6% (n = 257)	11.3% (n = 436)	13.8% (n = 436)
Carbonnel (1999)[12]	7.5% (n = 1316)	8.4% (n = 1316)	-	-
Peeters (1996)[13]	13.6% (n = 640)	14.5% (n = 640)	-	-
Bayless (1996)[14]	12.2 % (n = 554)	-	-	-
Satsangi (1994)[1]	-	11.5% (n = 433)	-	-
Probert (1993)[2]	9.4% (n = 424)	10.4% (n = 424)	7.1% (n = 469)	8.6% (n = 469)
Yang (1993)[15]	7.4% (n = 258)	14.0% (n = 258)	7.1% (n = 269)	8.6% (n = 269)
Orholm (1991)[5]	2.2% (n = 133)	5.2% (n = 133)	7.5% (n = 504)	8.1% (n = 504)

forms of IBD except for the age at onset[12,13,20,22,24]. High concordance rates of extraintestinal manifestations in CD have been shown in two studies[21,23] between affected first degree relatives, although extraintestinal manifestations were not associated more often in a familial disease type than in a sporadic one[25].

Ulcerative colitis

A high concordance rate for the presence of extraintestinal manifestations and for the extent of colon involvement has been reported in UC patients[23]. In a recent report the concordance rate for extension of the colon involvement was observed in 33% of relative pairs, in 47% of pairs for requirement of steroids and in 34% of pairs for a high relapse rate[21]. However, in UC families the concordance rates are less consistent than in CD families.

Genetic anticipation in IBD: fact or fallacy?

The term genetic anticipation is used when the disease severity increases and age at onset of an inherited disease decreases in subsequent generations. In IBD anticipation has been proposed to explain the observation that affected children are diagnosed an average of 12 to 23 years younger than their affected parents[21,23,26-28]. Anticipation was reported to be more marked in father-child pairs than in mother-child pairs[29].

On the other hand, some reports have provided strong evidence that anticipation does not occur in IBD and is merely caused by failure to make statistical corrections[27,30,31]. Thus, supporters of this assumption believe that a more rigorous screening or closer observation of the children of an affected parent simply result in earlier diagnosis in the offspring. Studies on genetic anticipation may also suffer from follow-up bias which implies situations where children, who are unaffected by IBD at the time of a cross-sectional survey, later develop disease.

CARD15 gene variants in familially occurring and sporadic forms of IBD

Three variants of the CARD15 gene are strongly associated with susceptibility to CD[32,33], although significant geographic and racial variations in their frequency have been described. In most Caucasian populations, at least one risk allele of the CARD15 gene is found in 44%-50% of CD patients[34,35]. In these populations the proportion of CD patients with or without documented CARD15 mutations were similar among familial and sporadic cases. On the other hand, a lower frequency (15.5%) of the risk alleles of the CARD15 gene has been described among the Finns, but in this population the1007fs allele frequency was higher among the familial (10.9%) than in sporadic CD cases (3.5%)[36]. Moreover, there is evidence for genetic heterogeneity also in other North European countries. Despite low prevalence of risk alleles of the CARD15 gene mutation the prevalence of CD and familially occurring IBD are similar as in countries of high frequency of CARD 15 risk alleles[37,38].

Familial clustering of variations in intestinal permeability

A genetically impaired intestinal barrier function has long been suspected to be a predisposing factor for CD. An increased intestinal permeability is found in nearly one fourth of the asymptomatic first-degree relatives, although similar figures have also been demonstrated in spouses of IBD patients, making it difficult to judge whether these alterations are due to genetic or environmental factors, or both[39,40]. Buhner et al. have recently shown that in healthy first degree relatives of CD patients a high mucosal permeability is associated with the presence of a CARD15 3020insC mutation, indicating that genetic factors may be involved in the impairment of the intestinal barrier function in families with IBD[41]. Recently, Stoll *et al*[42] described a significant linkage and association of CD with specific haplotypes of the DLG5 gene, coding for a membrane associated guanylate kinase possibly associated with maintenance of epithelial integrity. These studies also suggested an interaction between allelic variants of the CARD15 and DLG5 genes as risk determinants of CD[42]. It will be important to identify additional gene loci potentially interacting with the risk alleles of the CARD15 genes to modify the phenotypic features, including the intestinal permeability, in IBD.

CONCLUSION

The single strongest risk factor for developing IBD is having an affected relative with IBD. The highest risk

(> 30%) is observed in offspring of two affected parents. The age-adjusted risk of IBD is about 5% for siblings and 10% for offspring. A positive family history is more common in a CD proband than in a UC proband. Relatives of patients with CD have a higher risk of developing IBD than those of patients with UC. The rates for concordance among monozygotic twins are higher for CD than for UC. Collectively, all these family data suggest a stronger genetic influence for CD than UC. Studies showing that smoking shifts the predisposition from UC to CD indicate that not the genes alone but also environmental factors have an important role in disease expression.

Abstract

Investigations into the inheritance of the three risk alleles R702W, G908R and 1007fsInsC in NOD2 associated with susceptibility to Crohn's disease have demonstrated a remarkable amount of heterogeneity across ethnicities and populations, with regional variation across Europe for example, suggesting local founder effects. In non-Caucasian populations Crohn's disease continues to increase in incidence but this increase appears not to be a consequence of variation in NOD2, further advancing the accumulating evidence for other susceptibility loci. Frequencies of the known alleles are compared across populations in health and disease and evidence for additional alleles in NOD2 is reviewed. Based on its position on chromosome 16 coincident with some other autoimmune disease susceptibility localizations, research has targeted NOD2 variation as the potential cause of other autoimmune disorders. While these investigations have mostly returned negative findings, two diseases, Blau Syndrome and Graft versus Host Disease, have been shown to be caused by risk alleles in NOD2. As is frequent in complex disease investigations, some results await validation, but the identification of NOD2 and the differences within and across population raises intriguing questions about the population genetics of the variation at this locus.

NOD2 AND CROHN'S DISEASE

NOD2 (also known as CARD15) was the first gene underlying susceptibility to Crohn's Disease (CD) to be identified with three common mutations being described[1,2] and an analysis of the haplotypes carrying the three major mutations suggests that these represent three independent mutation events[3]. Two of the mutations lead to amino acid substitutions (R702W) and (G908R), while the third (L1007fs) is a single base insertion that results in a stop codon that truncates the protein. In addition, a growing number of "private" mutations that are unique to individual pedigrees have been described but supporting evidence for causality based on functional evidence is rarely reported for these rare alleles[4,5]. The majority of mutations in CARD15 that are associated with CD occur in the Leucine Rich Repeat domain-the part of the protein believed to be involved in intracellular sensing of bacterial components[4].

Each of these mutations is more properly called a "risk allele" (RA) because possessing one or more of the alleles confers an increased risk on an individual, but does not mean that disease will necessarily develop. The argument about whether the three risk alleles confer loss or gain of function remains unresolved but it is clear that the normal function of NOD2 is as a receptor for bacterially derived molecules known as pathogen associated molecular pattern (PAMP) molecules in the intestine. Our understanding of the disease processes and the link between innate and adaptive immune responses has advanced remarkably because of the identification of NOD2 in up to 50% of CD. Nevertheless carriage of risk alleles is neither necessary nor sufficient for disease.

One prediction that comes from our understanding of complex disease is that such risk alleles will occur in the healthy population albeit at lower frequencies than in disease. Allele frequencies of the three RAs in CD have been reported for many populations and are summarized in Table 1. As predicted, there is a significant elevation of the allele frequencies in CD in comparison to that in healthy controls in most populations. Since few studies report on additional mutational assessment of NOD2 in their populations, it is not possible to assess whether unique or population specific mutations exist. In a number of cases a stronger association has been reported in pediatric cohorts[5]. This result has been borne out by multivariate analysis of CD that indicates that early age of onset is significantly associated with carriage of NOD2

Table 1 Allele frequencies for the NOD2 RAs in different ethnic groups

Ethnicity /population	Frequency (patient/control) R702W	Frequency (patient/control) G908R	Frequency (patient/control) L1007fs	Other features	Reference
Greek	0.1 (0.01)	0.14 (0.03)	0.18 (0.06)	EAO	[22]

risk alleles. This enrichment is likely to be a consequence of the stronger genetic contribution to disease observed in many predominantly inherited diseases when cohorts with an early age of onset are studied. In fact the improvement in linkage and or association evidence observed in regions identified by genome wide scans when cohorts are conditioned on carriage of NOD2 may be a consequence of the effective selection for early age of onset rather than evidence for epistasis with NOD2.

Researchers in the International IBD Genetics Consortium have compared the frequency and impact of NOD2 RAs in disease groups from fourteen centers from Europe, North America and Australia (Cavanaugh *et al* in preparation) and have found a strong association between early age of onset and the NOD2 RAs, particularly for the L1007fs allele in those families. They have also noted that the P268S allele is also strongly associated with disease, but since functional assays do not support the rare variant in disease causation it is unlikely that this allele is itself disease associated[6]. Thus this variant is likely to be in linkage with other causative allele (s) whether in NOD2 itself or at some distance from the coding region. In the search for regulatory mutations the 5' region of NOD2 has been studied but have no disease associated alleles (Schreiber pers com). Nevertheless, the recent description of remote Conserved Non-Coding regions (CNCs)[7] that are implicated in disease gene expression suggests that variation that is quite distant from NOD2 may regulate its expression and potentially impact in disease.

GEOGRAPHIC AND ETHNIC DIFFERENCES

Several authors have commented on evidence for a North-South gradient in CD in Europe with a higher frequency of disease in northern Europe than southern Europe[8]. This hypothesis is extremely intriguing given the similarities already identified between multiple sclerosis and inflammatory bowel disease. Nevertheless, the frequencies of NOD2 risk alleles do not appear to underlie this gradient. Vind *et al*[9] compared Danish and Portuguese patients and controls and found no evidence to support a North - South gradient in allele frequencies. Arnott *et al*[10] have reported that NOD2 RAs are at lower frequencies in Scottish, Irish and Scandinavian CD than in England, central Europe or North America and went on to argue that these data demonstrating regional heterogeneity across Europe are suggestive of regional founder events with respect to NOD2 risk alleles. For example, allele frequencies and Population Attributable Risk (PAR) reported for NOD2 RAs in Finland are similarly low yet the incidence of disease is relatively high[11]. These data highlight the existence of other contributing susceptibility loci in CD.

Studies in disease populations from central and southern Europe confirm a consistent pattern of association between NOD2 RAs and CD (Table 1)[10]. In North America admixture probably accounts for the low frequency of NOD2 RAs in African Americans and Hispanics[5]. Bonen *et al*[6] reported a significantly higher frequency of the G908R allele in Ashkenazi jews than in non-jewish whites and that association has been conformed in other studies[12]. At the same time the frameshift mutation that is well represented in most ethnicities is at lower frequencies in Ashkenazi Jews. With the exception of Greece and Ashkenazi Jews, the G908R allele is rarely elevated in frequency disease in most disease groups (Table 1).

In a comparison of NOD2 allele frequencies in 3575 Caucasian healthy individuals from sixteen different centers from Europe, North America and Australia, Hugot et al (in preparation) described significant heterogeneity between centers with Australia and Finland having the lowest frequencies of known variants while Belgium and Canada has the highest. Those authors also note that the frequency of the RAs is highest in central and southern Europe, in good agreement with other studies.

Analyses of non-Caucasian groups has failed to identify a significant contribution from the known NOD2 RAs. In South-East Asian populations that have been studied to date, NOD2 RAs are absent from Japanese and Korean populations (reviewed in Arnott *et al* 2004) and more recently, are also absent in Han Chinese[13]. Little information is available for South American or African populations with the exception of a recent report of low

NOD2 allele frequencies in coloured South Africans of Indian descent[14]. CD in Indians is more prevalent than in Chinese or Malays and the incidence and the prevalence of inflammatory bowel diseases appears to be increasing in Asian countries though this trend is more evident for ulcerative colitis than CD[15].

The pattern that emerges from these studies both of disease groups and healthy controls suggests that CD occurs at quite variable rates across geographical regions and that in some populations where NOD2 RA carriage rates are at a high, those alleles are present in up to 50% of individuals with CD. Nevertheless the incidence of CD in populations with substantial carriage of RA eg Belgium and Canada is remarkably similar to those with lower rates, suggesting that CD occurs in those groups because of other genetic susceptibilities, raising the issue of differential genotype by environmental interaction. ie the specific agents that initiate disease process in one population may be different to those in other populations depending on the underlying genetic susceptibility. This suggests that different micro-organisms may initiate disease in different populations depending on the underlying genetic susceptibilities of that population. Such a scenario may lead to the heterogeneity, both genotypic and phenotypic, observed in inflammatory bowel disease generally. These issues will only be resolved as further research identifies other IBD susceptibility loci and functional analyses identify the microorganisms that likely underlie disease initiation.

ASSOCIATION WITH OTHER DISEASES

Interestingly, two other diseases have been associated with NOD2 mutations. The first non IBD association was with a rare disease long known to map to the pericentromeric region of chromosome 16 that has also been shown to carry mutations in NOD2 that result in the simple Mendelian inheritance of Blau syndrome[16]. Mutations that confer susceptibility to Blau syndrome occur in the nuclear binding domain (NBD) of the protein, which is believed to be independent of LRR interactions. The second association has been shown with gastrointestinal Graft versus Host disease[17]. In this case, disease course is exacerbated in the recipient if either donor or host carries any of the three risk alleles associated with CD. This increased susceptibility to rejection is probably a function of altered epithelial reactivity in the ileum leading to an impaired microbial response. Recently there has been a suggestion that NOD2 RAs may be involved in breast cancer in the individuals with first degree relatives with lung cancer[18] however this study requires validation.

OTHER AUTOIMMUNE DISEASES

In addition a number of inherited autoimmune diseases have been shown to demonstrate linkage to the pericentromeric region of chromosome 16 that houses NOD2, including rheumatoid arthritis and lupus erythematosus. As a consequence of the observation that autoimmune disease appear to cluster in specific regions of the genome[19] and might therefore share some common underlying genetic susceptibilities, a number of researchers have tested their different disease groups for the common mutations in NOD2. Diseases in which association with known NOD2 mutations have been investigated are shown in Table 2 along with evidence for linkage evidence to chromosome 16 and ethnicity of patient (and control if reported). The small subset of patients with spondyloarthropathy with chronic gut inflammation show association with NOD2 RAs and share many features with CD[20]. Those authors commented that this group of patients is likely to progress to fulminant CD. The closely related phenotypes of atopic eczema, asthma and allergic rhinoconjunctivitis[21] have been shown to have an association with NOD2 variants, although the causative alleles were not identified. With these exceptions, these studies have failed to demonstrate a fundamental association of autoimmune diseases with NOD2, nevertheless the central role that the described NOD2 RAs have in CD remains unequivocal.

Table 2 Results of association analysis between NOD2 RAs and other inherited diseases

Disease	Linkage to chromosome 16	Ethnicity	Association	Reference
Allergy and atopy	yes	German	yes[1]	[21]
Behcet's disease	yes	UK, Turkish and Arab	no[2]	[27]
Breast cancer with lung cancer FDR[3]	no	Poland	yes	[18]
Idiopathic pulmonary fibrosis	unknown	Italian	no	[28]
Necrotising enteritis	unknown	France	no[4]	[29]
Psioratic arthritis	yes	Newfoundland	yes	[30]
Psioratic arthriris	yes	UK	no	[31]
Rheumatoid arthritis	no	USA	no[5]	[32]
Sarcoidosis	no	Danes	no	[33]
Sarcoidosis	no	United Kingdom	no	[34]
Spondyloarthropathy with chronic gut inflammation	no	Belgium	yes	[20]
Systemic lupus erythematosus	yes	Spain	no	[35]
Type 1 diabetes	yes	Scandinavia	no	[36]
Wegener's granulomatosis	no	North America	no	[37]

[1]Both disease and protective associated haplotypes are described; [2]Direct sequencing to identify polymorphisms failed to identify association by case-control; [3]FDR first degree relative. The association reported occurs only in breast cancer patients who have a first degree relative with lung cancer but not in individuals without; [4]All exons and exon/intron boundaries of NOD2 were sequenced; [5]Genoyped for 3 common and a further 12 SNPs in NOD2 with no haplotype association observed.

Abstract

Crohn's disease and ulcerative colitis are inflammatory disorders of the gastrointestinal tract with a substantial heritable component. The IBD5 region on chromosome 5q31 is one of only two loci widely confirmed to be associated with Crohn's disease in multiple independent cohorts. Although many populations have demonstrated association with IBD5, there remains uncertainty as to the causal variant within the region. A recent report identified polymorphisms in *SLC22A4* (*OCTN1*) and *SLC22A5* (*OCTN2*) as being responsible for the IBD5 association, however, these findings have not been replicated. This review discusses the data evaluating the IBD5 locus and the OCTN genes and their relationship to inflammatory bowel disease. Several other genes, including *IRF1* and *P4HA2* may be equally as likely to contain the IBD5 causal variant as the *OCTN* genes.

INTRODUCTION

The pathogenesis of inflammatory bowel disease (IBD) is believed to involve exposure to an as yet unidentified environmental trigger in a genetically susceptible individual[1]. The importance of genetic factors in the pathophysiology of IBD has been repeatedly established by the substantially increased relative risk to siblings of affected individuals and higher monozygotic versus dizygotic twin concordance rates[2-6]. While the heritability of Crohn's disease (CD) seems higher than that for ulcerative colitis (UC), the available epidemiological and genetic data suggest that there are common susceptibility factors for both diseases and it is likely that gene-gene and gene-environmental interactions determine the specific phenotype[6].

Significant progress has been made in identifying genetic factors responsible for IBD with numerous replicated susceptibility loci identified. However, among the confirmed susceptibility loci identified through linkage for IBD (IBD1-IBD6)[7-12] only the susceptibility gene within the IBD1 locus has been identified[13,14]. The caspase recruitment domain-containing protein 15 (*CARD15*) gene was described simultaneously by a positional and candidate gene approach and data from numerous populations have confirmed an association between three variants within the *CARD15* (*NOD2*) gene and CD[13-15]. Sub-phenotypic analysis shows that mutations in the *CARD15* (*NOD2*) gene are particularly associated with the development of small bowel CD[15]. Despite widespread replication of the *CARD15* (*NOD2*) findings, there is still important ethnic and geographic heterogeneity. For example, despite general genetic similarity between Ashkenazi Jews (AJ) and Non-Jewish (NJ) Caucasians, the allele frequencies and odds ratios of the *CARD15* (*NOD2*) variants for AJ are slightly different when compared to those found in NJ populations and in Asian individuals affected by CD, *CARD15* (*NOD2*) variants are extremely rare and not associated with CD[15-18].

IDENTIFICATION OF THE IBD5 LOCUS

The IBD5 locus on chromosome 5q31 is the only other locus clearly demonstrated to confer increased risk for CD through association. Following an initial finding of significant linkage in a Canadian population[12], subsequent studies identified a 250 kb risk haplotype within the IBD5 locus that is significantly associated with CD[19]. As part of this effort, the region was sequenced in eight individuals and was intensively evaluated with dense genotyping in more than 250 trios which led to the discovery of long segments of complete linkage disequilibrium (LD), described as "haplotype blocks", which were separated by apparent "hotspots" of recombination[20]. This original study described 11 haplotype tagging (single nucleotide polymorphisms) SNPs in this region which were equally associated with CD. The 250 kb region has since been the subject of intensive study as a number of highly relevant potential candidate genes are located within and nearby to it. These include interferon regulatory factor 1 (*IRF1*), solute carrier family 22, member 4 (*SLC22A4*) also known

as organic cation transporter 1 (*OCTN1*); solute carrier family 22, member 5 (*SLC22A5*), also known as organic cation transporter 2 (*OCTN2*); and prolyl 4-hyroxylase (*P4HA2*) among others and there are also a number of important cytokine genes (*IL-4, IL-13, IL-5, IL-3*) located adjacent to the immediate 250 kb risk haplotype. Since the initial identification of this risk haplotype, numerous studies have replicated the association with CD and a few have demonstrated an association between IBD5 and UC as well[21-25], establishing this as one of a still limited number of *bona fide* associations in human complex disease genetics and the second in IBD specifically.

THE IBD5 SUSCEPTIBILITY GENES?

In 2004 Peltekova and colleagues postulated that functional polymorphisms, L503F (rs1050152) and G-207C (rs2631367) in the *SLC22A4* (*OCTN1*) and *SLC22A5* (*OCTN2*) genes, respectively, comprised a two locus risk haplotype that accounted for the association findings at IBD5[26]. The "TC haplotype" described was found in 54% of CD patients versus 42% of affected controls ($P = 0.0003$). Moreover, the odds ration for those homozygous for the TC haplotype was 3.43-5.14 for CD with an even higher odds ratio for those carrying the TC haplotype and a CARD15 risk allele (7.28-10.5). No association was found with ulcerative colitis. In this study, the TC haplotype was independently associated with CD as compared to the background risk haplotype where the marker IGR2078 was utilized as a tagging SNP to represent the IBD5 risk haplotype.

That functional polymorphisms in significant linkage disequilibrium with each other in adjacent, highly homologous genes may act as a functional cassette to increase disease risk would represent a novel, important paradigm in complex disorders. In particular, *SLC22A5* (*OCTN2*) transports carnitine, which plays a key role in mitochondrial transport of long chain fatty acids; furthermore, *SLC22A5* (*OCTN2*)-deficient mice develop intestinal lymphocytic infiltration. However, establishing a functional role for SNPs located within conserved elements which subtly alter gene expression can be difficult compared to establishing altered activity for amino acid polymorphisms.

REPLICATION STUDIES AND GENOTYPE PHENOTYPE STUDIES OF THE IBD5 LOCUS

As described above, there have been numerous studies to confirm the association of CD with the IBD5 risk haplotype[21-25]. These studies initially tested varying markers selected as tagging markers for the risk haplotype on chromosome 5 due to the high degree of linkage disequilibrium in the region. Statistical support for a relatively unique contribution of the two-locus *OCTN* haplotype was initially described, but not examined in large enough cohorts to confidently refine localization in the IBD5 region[27]. Further studies performed subsequent to the identification of the OCTN variants have primarily tested these markers alone although more recent reports have also tested additional SNPs within the IBD5 risk haplotype.

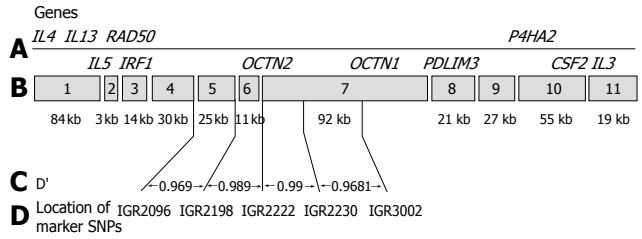

Figure 1 IBD5 map demonstrating the location of SNPs and regional candidate genes (Taken from Noble et al ref 28 - permission for reproduction being sought).

A well designed study including 374 patients with CD from Noble and colleagues in Edinburgh demonstrated that while the OCTN1 and OCTN2 variants are associated with CD, this association is not independent of the background risk haplotype in the region[28]. This study assessed not only the OCTN variants but also a number of surrounding SNPs from the list of SNPs comprising the IBD5 risk haplotype (IGR2096, IGR 2198 and IGR2230). Utilizing these SNPs they could not demonstrate independent association of the OCTN variants and suggest that the IGR2078 SNP used by Peltekova and colleagues is one haplotype block removed from the OCTN variants and therefore was not truly indicative of an independent association (Figure 1). A number of additional such reports have been presented in abstract form with similar findings (DDW 2005).

Despite the controversy that still exists over the true causal gene within the IBD5 locus, studies performed both before and after the identification of the OCTN variants have attempted to further dissect the specific phenotype associated with this region. Just as is the case for the causal genetic variant there is also inconsistent data regarding the phenotype associated. Early on, it was reported that the IBD5 locus was associated with perianal CD in a UK study[21]. This report analyzed several of the SNPs on the IBD5 risk haplotype in a case-control fashion. More recently, association of the IBD5 region has been found to be associated with markers of more severe disease such as progression to stricturing or penetrating CD and need for surgery in an Edinburgh population[28]. No association was found for any specific disease location or with UC in this report. A study from the same investigators in a pediatric population also confirms the association of the OCTN variants with CD and UC but the variants were not independently associated from the surrounding SNPs of the IBD5 risk haplotype[29]. This study also demonstrated that the OCTN TC haplotype may be a marker for more severe CD with an association with lower height, weight and body mass index (BMI) at the time of diagnosis. A report evaluating IBD patients from Italy also demonstrated IBD5 to be related to more severe CD behaviour although by multiple regression it was felt that this effect was essentially conferred by the presence of CARD15 risk alleles rather than by IBD5 loci independently[30].

A study of more than 981 IBD patients from Leuven

could not demonstrate an association of the OCTN1 and OCTN2 variants with IBD, CD or UC globally but did show an association with perianal and penetrating CD[31]. These association findings have yet to be replicated and their significance has yet to be determined. One may speculate that the IBD5 locus represents a "phenotype-determining" genetic effect, however, the lack of an overall positive association with CD in the Belgian population makes this interpretation somewhat precarious. There have been inconsistent reports describing a role of IBD5 and UC with only a few describing positive findings[22,23,32]. A study of 187 German families with UC was the first to describe an association of IBD5 with UC by family-based association testing and, in particular, the association was strongest in those individuals carrying one of the CARD15 risk alleles[22]. This potential epistatic interaction was also reported in a cohort from the UK[23]. Although these results require further investigation in larger sample sizes, it is not altogether unexpected that there may be some effect of IBD5 on the development of UC. There is an increased risk of UC developing in the relatives of those with CD and the reverse is also true suggesting there are genes which confer overlapping susceptibility[6]. In addition, the clinical heterogeneity among the two disorders could result in misspecification of disease type in those with colonic involvement. Moreover, it has been previously noted that there are subsets of CD which have a more "UC-like" appearance raising further suspicion for overlapping genetic susceptibility factors[33]. One might also speculate on the possibility of a unique "IBD5 positive", genetically and clinically unique subset of IBD patients, that would require further testing to be better characterized. As is the case with CARD15, the IBD5 region does show some variation with respect to the population studied. Studies from Asian populations show no evidence for IBD5 as a contributing factor to IBD susceptibility[34,35]. In addition, a study with a significant Jewish population report no evidence for a contribution of IBD5 to susceptibility in this high risk group[36].

In conclusions, while common alleles of modest effect play a very important role in the architecture of complex diseases and can be readily detected in some cases with modest sample sizes, it is now widely recognized that extremely large sample sizes are required in order to conclusively confirm these factors, resolve their location through fine-mapping and identify specific subphenotypes that are either preferentially associated or not-associated with disease. While the two allele risk haplotype of the *SLC22A4* (*OCTN1*) and *SLC22A5* (*OCTN2*) genes may thus far be the best candidates for the IBD5 association findings, there is as yet insufficient evidence to make concrete conclusions regarding their significance. Current data suggests that other, nearby SNPs, can be considered statistically equivalent in terms of their association to CD and the extensive linkage disequilibrium in this region suggests that caution must be exerted in asserting which of the SNPs in this region is potentially causal. Further functional evaluation of these variants is certainly warranted. In addition, the inconsistent findings in UC illustrate the importance of better powered UC genetics studies to further delineate the role of IBD5 and UC susceptibility and phenotype. In complex disorders, the IBD5 association represents one of the best replicated genomic regions, and therefore warrants comprehensive studies in large, well-phenotyped cohorts to define those population subsets and functional polymorphisms which most likely contribute to disease risk. To further advance the understanding of the IBD5 locus and its role in IBD susceptibility will require even larger population studies than those already performed, that will have adequate power to dissect the high degree of linkage disequilibrium found in this region in conjunction with functional studies that will demonstrate mechanisms. Due to the modest but important genetic relative risk of this locus, large consortia with prospectively collected, well-phenotyped cohorts will be required in order to refine the information regarding this region.

Abstract

Chronic liver diseases are very common worldwide, particularly those linked to viral hepatitis and to alcoholic and non-alcoholic fatty liver. Their natural history is variable and long-term evolution differs in individual patients. Optimised clinical management of compensated chronic liver diseases requires precise definition of the stage of liver fibrosis, the main determinant of prognosis and of most therapeutic decisions. Liver biopsy is the gold standard for assessment of hepatic fibrosis. However, it is invasive with possible complications, costly and prone to sampling errors. Many non-invasive markers of liver fibrosis have been recently proposed and assessed in the clinical setting as surrogates of liver biopsy. Direct markers are based on biochemical parameters directly linked to fibrogenesis while indirect markers use simple or more sophisticated parameters that correlate with liver fibrosis stages. Non-invasive markers of liver fibrosis have been tested in different forms of chronic liver disease and showed variable diagnostic performance, but accuracy rarely was above 75%-80%. Better results were obtained when markers were combined. On this line, we have recently proposed a set of algorithms that combine sequentially indirect non-invasive markers of liver fibrosis, reaching 90%-95% diagnostic accuracy with significant reduction in the need for liver biopsy. Based on available evidence, it can be anticipated that non-invasive markers of liver fibrosis and their combined use will soon become a most useful tool in the clinical management of many forms of chronic liver disease. However, their implementation is expected to reduce, but not to completely eliminate, the need for liver biopsy.

INTRODUCTION

Chronic infection with the hepatitis B (HBV) and C (HCV) viruses and alcoholic and non-alcoholic steatohepatitis are the main causes of chronic and progressive liver disease leading to cirrhosis, end-stage liver disease, and hepatocellular carcinoma worldwide, with a predominant role of hepatitis B in the Middle and Far East regions and of hepatitis C and steatohepatitis in the Western Countries. These different etiologic forms of chronic liver disease (CLD) have a common histopathological pathway that is the formation and accumulation of fibrosis leading to the development of progressive distortion of the hepatic architecture that is the hallmark of evolution to cirrhosis. Natural history studies indicate that advanced fibrosis and cirrhosis develop in about 20%-40% of patients with chronic hepatitis B or C and in a similar proportion of those with alcoholic or non alcoholic steatohepatitis[1-4]. Development of fibrosis is a step-by-step process starting from minimal fibrosis limited to the portal tracts, followed by more extensive fibrosis with septa expanding into the liver parenchyma, that can form bridges between two portal tracts or portal tracts and central veins, eventually ending in complete cirrhotic nodules. This type of progression may take years or decades to fully develop, and staging of hepatic fibrosis is therefore of paramount clinical importance for the prognostic assessment in the individual patient. In patients with chronic viral hepatitis precise definition of the hepatic fibrosis stage is the most important parameter to assess the risk of disease progression and to decide the need for immediate antiviral therapy. This is particularly true for those patients with chronic viral hepatitis or alcoholic or non-alcoholic fatty liver who are still in a well compensated phase and have no overt clinical or laboratory signs of cirrhosis. In these patients liver biopsy represents the gold standard for evaluating presence, type and stage of liver fibrosis. This procedure, however, is invasive, costly and difficult to standardise. In recent years there has been increasing interest in the possibility of identifying and describing liver fibrosis by using non invasive, surrogate markers measurable in the peripheral blood and many of such tests have been reported in the literature. This review is

aimed to describe the different non invasive markers and methods that have been proposed for the assessment of liver fibrosis, to discuss their advantages and limits and to suggest a rational use in clinical practice.

HISTOLOGICAL CLASSIFICATION OF CHRONIC LIVER DISEASE

The old classification of chronic hepatitis made a rough grading distinction between milder and more severe forms of liver disease. More recently, the new insights in the etiology and therapy of CLDs, particularly viral hepatitis, has led to a revised classification, aimed to describe and quantify in more details necroinflammation and fibrosis. Several semiquantitative scoring systems have been proposed to measure the activity grade of inflammation and to stage the amount and type of fibrosis in the liver. Scoring systems specifically designed for chronic viral hepatitis are the histological activity index proposed in 1981 by Knodell *et al*[5], the Ishak's score[6] and the METAVIR scoring system[7].

The histological activity index is based on the evaluation of four parameters: periportal necrosis (score of 1-10), parenchimal damage (score of 0-4), portal inflammation (score of 0-4) and fibrosis (score of 0-6). The cumulative score therefore ranges from 0 to 18 to describe the overall histological activity. The limitation of this scoring system is that necro-inflammation (grading) scores are cumulated with the fibrosis (staging) scores, while these parameters describe different lesions and clearly have different prognostic implications. The Ishak's system is a revised version of the histological activity index, and describes the activity grade and the fibrosis stage as two separate items. Liver fibrosis is here classified in absent (0), mild (1-2), moderate (3-4) and severe/cirrhosis (5-6). The METAVIR scoring system for liver fibrosis, frequently used in recent times particularly for chronic hepatitis C, is described in details in Table 1. All these scoring systems have some limits, being semiquantitative, not linear and prone to intra- and inter-observer variation and to sampling variability[8]. They have been more validated for clinical use with some but not all the different etiological forms of CLD that are characterised by progressive fibrosis leading to cirrhosis.

Table 1 METAVIR scoring system for liver fibrosis

Stage	Description
F0	No fibrosis
F1	Portal fibrosis without septa
F2	Portal fibrosis with few septa
F3	Septal fibrosis without cirrhosis
F4	Cirrhosis

Portal fibrosis is a stellate enlargement of portal tracts without any bridging fibrosis on the biopsy sample. Few septa mean at least one fibrous septa on the core biopsy. Theoretically, a fibrous septa is a bridge of connective tissue between two portal tracts, a portal tract and a centrolobular vein, or between two centrolobular veins. Septal fibrosis means that the liver biopsy is crossed by several septa; the transition between F2 and F3 begins when there is more fibrous septa than portal tracts without septa on the biopsy. Cirrhosis means that liver tissue is mutilated by nodular fibrosis that delineates hepatocytes nodules.

LIVER BIOPSY: PROS *VS* CONS

For many years liver biopsy has been considered the golden standard for the evaluation of liver fibrosis staging. Liver biopsy has the advantage of allowing to obtain information not only on fibrosis, but also on many useful parameters, such as inflammation, necrosis, steatosis, hepatic iron and so on. Furthermore, it allows to identify suspected or unexpected cofactors and comorbidities. However, liver biopsy has also a number of limitations that have to be taken into account. Many recent studies clearly indicate that liver biopsy, as it is usually taken for diagnostic purpose, is prone to sampling errors and may underestimate the amount of liver fibrosis. Several studies suggest that cirrhosis might be missed on a single blind percutaneous liver biopsy in 10%-30% of cases[9-11]. When three different liver samples were analysed, the percentage of correct diagnosis increased from 80 to 100%[12]. In more recent times, Regev and colleagues have shown that samples obtained from the right and left lobes of the liver during laparoscopy gave different fibrosis staging in one third of the cases[13]. Other studies have analysed agreement/disagreement among pathologists. Although the use of more standardised scoring systems, such as those of the Knodell's, Ishak's and METAVIR's classifications, has improved the inter-observer and intra-observer variability, there are still several factors that may significantly influence the diagnostic accuracy of a liver biopsy. The size of the liver sample is obviously very important. Colloredo *et al* have carefully analysed the importance of the sample size for a correct stadiation of liver disease in patients with chronic hepatitis C[14]. By reducing progressively the dimension of the same liver biopsy, they reported that the smaller was the sample analysed, the milder was the diagnosis made by the pathologist in relation to the stage of fibrosis. The same biopsy was diagnosed as F3-F4 when a larger part of the sample was observed and only as F1-F2 when the size of tissue was reduced in length or wideness. Other studies have reported that the type and the size of needle used is also important. The Tru-Cut needle was superior to the Menghini needle, particularly for the diagnosis of more advanced fibrosis[15-16]. A thick needle was superior to the fine needle in assessing the presence of advanced fibrosis and cirrhosis[17]. Some studies would suggest that an adequate liver biopsy sample should contain more than 5 portal tracts and be at least 15 mm in length[18-20]. However, other studies reported higher threshold for optimised accuracy. Colloredo *et al* concluded that an adequate specimen should be at least 20 mm in length with at least 11 complete portal tracts while others have recommended even bigger samples, up to 25 mm in length[14,21]. On the same line, Scheuer has recently concluded that bigger is better[22]. The need for obtaining a liver sample of adequate size is however in contrast with the patient need of a procedure causing limited pain and hemorrhagic risks. Liver biopsy may be in fact a risky procedure for some patients, particularly for those with more advanced liver

fibrosis[23-25]. A French survey which interviewed 1177 general practitioners concluded that liver biopsy may be refused by up to 59% of patients with chronic hepatitis C and that 22% of the physicians share the same concern for this invasive procedure[26]. On this line, a recent survey assessing the consensus among Italian hepatologists on when and how to take a liver biopsy in chronic hepatitis C showed great divergence in the management of the same subgroup of patients[27]. Most recently Rousselet *et al* reported that the degree of experience of the pathologist, as indicated by longer duration of practice or belonging to an academic setting, may have an outstanding impact on the diagnostic interpretation of liver biopsy, even higher than that determined by the related to sample size[28].

Another shortcoming of liver biopsy is its cost as it always requires hospitalisation for 6-18 hrs. A cost-benefit analysis showed that in US the cost of a liver biopsy is 1032 USD and it could raise to 2745 USD when complications occur[29].

PATHOPHYSIOLOGY OF HEPATIC FIBROSIS-THE CONCEPTUAL BASIS OF NON INVASIVE BIOMARKERS

The key step in the pathophysiology of liver fibrogenesis is the balance between extracellular matrix (ECM) deposition and removal. Indeed, the ECM metabolism is a very dynamic process, influenced by factors that contribute to its deposition and by others that mediate its degradation. The hepatic stellate cells (HSCs) are the major source of ECM. During liver injury, activation of quiescent HSCs to a proliferative, fibrogenic and contractile type of myofibroblasts is the dominant event in fibrogenesis. HSCs can be activated by several cytokines (e.g., tumor growth factor beta (TGF-β), tumor necrosis factor alpha (TNF-α), platelet derived growth factor (PDGF)) which are secreted in response to liver injury. On the other hand, other signals (e.g., interleukin-10 (IL-10)) promote ECM degradation. Once activated, HSCs secrete cytokines such as metalloproteinases, TGF-β1, PDGF, monocyte chemotaxis protein 1 (MCP-1), endothelin 1 (ET-1). Some of these are directly involved in fibrogenesis (TGF-β1, connective tissue growth factor), others in chemotaxis (MCP-1) and proliferation of HSCs (PDGF, ET-1) and others in matrix degradation (metalloproteinases)[30].

The pathogenesis of liver fibrosis is somehow related to the etiology of the underlying CLD. The mechanisms by which HCV and HBV induce liver fibrosis are only partially understood. In chronic hepatitis B infection the pathogenesis of hepatic fibrosis has been associated with cytokines, particularly TGF-β1[31]. HCV induces oxidative stress and recruitment of inflammatory cells, with HSCs activation and collagen deposition. In addition, several HCV proteins directly stimulate the fibrogenic and flogistic pathways of HSCs[32]. A recent "in vitro" study reported that hepatitis C virus nonstructural genes (NS3 and NS5B) are able to induce increased expression of TGF-β1 and of other profibrogenic factors in infected hepatocytes[33]. These cellular events directly mediated by HCV in infected hepatocytes could explain the occurrence of progressive liver fibrosis with minimal inflammation. The pathogenetic mechanisms acting in alcoholic (AFLD) and in non alcoholic fatty liver disease (NAFLD) also involve cytokine- and oxidative stress- mediated injury. In AFLD the main stimulus for cytokine release from Kupffer cells in the liver is portal endotoxemia, arising as a result of increased gut permeability caused by ethanol and its metabolism to acetaldehyde. Oxidative stress derives from ethanol metabolism, Kupffer cell activation and from the effect of TNF-α on hepatocyte mitochondria. The resulting activation of HSCs increases the fibrogenic and inflammatory signals[34-35]. The pathogenesis in non alcoholic steatohepatitis (NASH) is less understood and several mechanisms have been proposed and investigated. Hepatic steatosis is considered as the first of two hits in the pathogenesis of NASH, since the presence of oxidisable fat within the liver is able to trigger lipid peroxidation[36]. However, many patients with fatty liver do not progress to necroinflammation and fibrosis. The potential second hits for the development of NASH could be an increase in the expression of ethanol-inducible cytochrome P450 2E1 (CYP2E1) and in the intrahepatic concentration of free fatty acids, resulting in oxidative stress via peroxisomal oxidation[37]. It has also been hypothesised that iron, in relatively low concentrations, could synergize with lipid overload and CYP2E1 induction to trigger oxidative stress in hepatocytes[38].

All these data and concepts are of great interest for the understanding of the various factors that contribute to progressive liver fibrosis in patients with different forms of CLD. However, their complexity and interplay clearly explain the difficulties encountered in the search of a specific and sensitive marker that could be universally valid as a diagnostic and prognostic tool to measure liver fibrogenesis in clinical practice.

GENETIC POLYMORPHISMS AND LIVER FIBROSIS

The complexity of the fibrogenetic process and the high number of cytokines involved imply that several genetic polymorphisms could influence progression of liver fibrosis. To date, genetic polymorphisms linked to hepatic fibrogenesis have been investigated mainly in chronic hepatitis C and in AFLD. Table 2 describes gene polymorphisms that were reported to either favour or reduce fibrogenesis in patients with different forms of CLD. While these studies clearly indicate that many genetic factors have a definitive influence on the risk of developing a more or less active and progressive fibrogenesis, none of them have found an application as diagnostic/prognostic marker in clinical practice, due to their complexity, difficulty to test and variable behaviour in different patients populations. Better understanding of the genetic influence on liver fibrogenesis is nevertheless of paramount importance as it may lead in the near future to identification of new therapeutic targets and strategies for development of effective antifibrotic treatments.

Table 2 Gene polymorphisms described as involved in fibrogenesis

Author	Etiology of liver disease	Gene	Function of the gene product	Implicated genotype	Effect on gene product	Effect on fibrosis
Powell[39]	HCV	TGF-β1	Profibrogenic	Codon 25 (pro/arg)	Increased transcription	Increased
Powell[39] Forrest[40]	HCV	AT	Profibrogenic	-6 G/A	Increased transcription	Discordant results
Bonkovsky[41] Negro[42] Chitturi[43] Geier[44]	HCV / NASH	HFE	Iron metabolism	C282Y, H63D	Iron overload	Discordant results
Yee[45] Grove[46]	HCV /AFLD	TNF-β	Proinflammatory	-308 G/A	Increased transcription	Increased
Grove[47] Knapp[48]	HCV / AFLD	IL-10	Immune modulation	-1082 A/A; -627 C/A	Decreased transcription	Increased
Reynolds[49]	HCV	MPO	Battericide	-463 G/A	Increased transcription	Increased
Wozniak[50]	HCV	ApoE	Viral entry to cells	E4 allele	Abnormal function	Reduced
Muhlbauer[51]	HCV	MCP-1	Proinflammatory	-2518 G/A	Increased transcription	Increased
Wright[52]	HCV	Factor Ⅴ Leiden	Thrombine generation	Codon 560 (arg/gln)	Resistance to activation	Increased
Romero-Gomez[53]	HCV	SLC11A1	Macrophage function	Homozygosity $(GT)_5AC(GT)_{10}G$ (Allele 2) in the promoter region	Poor promoter	Reduced
Adinolfi[54]	HCV	MTHFR	Folate metabolism	C677T	HyperHC	Increased
Okamoto[55]	HCV	MMP	Matrix degradation	1G/2G (MMP-1), 5A/6A (MMP-3), C/T (MMP-9)	Reduced transcription	More frequent in cirrhosis than CHC
Yamauchi[56] Okamoto[57] Frenzer[58]	AFLD	CYP2E1	Ethanol metabolism	c1/c1, c2/c2 alleles	Increased activity	Discordant results
Yamauchi[56] Frenzer[58]	AFLD	ADH	Ethanol metabolism	ADH2 c1,c2,c3 alleles; ADH3 c1, c2, c3 alleles	Abnormal function	Discordant results
Yamauchi[56] Okamoto[57]	AFLD	ALDH	Ethanol metabolism	ALDH2 c2/c2 alleles	Abnormal function	Discordant results
Burim[59]	AFLD	CYP1A1	Ethanol metabolism	m2/m2 allele	Increased activity	Increased
Dixon[60]	NAFLD	AT and TGF-β	Profibrogenic	High AT and TGF-β1 producing polymorphisms	Increased activity	Increased

TGF-β = transforming factor beta; AT = angiotensinogen; HFE = hereditary haemochromatosis gene; NASH = non alcoholic steatohepatitis; TNF-β = tumor necrosis factor beta; AFLD = alcoholic liver disease; IL-10 = interleukin 10; NAFLD = non alcoholic fatty liver disease; MPO = myeloperoxidase; ApoE = apolipoprotein E; MCP-1 = monocyte chemotactic protein 1; SLC11A1 = solute carrier family 11 member 1; MTHFR = methylenetetrahydrofolate reductase; HC = homocisteinemia; MMP = metalloproteinase; CYP2E1 = cytochrome P 2E1; ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase; CYPA1 = cytochrome P A1.

SEARCHING FOR THE IDEAL NON INVASIVE MARKER OF LIVER FIBROSIS: THE HOLY GRAIL OF THE CLINICAL HEPATOLOGIST

In the last decade, many studies have been dedicated to the search of non invasive markers able to provide an accurate information about liver fibrogenesis activity and fibrosis stage in patients with chronic, potentially progressive, hepatic diseases. The ideal characteristics of such a marker are summarised in Table 3. Two main, quite different, approaches have been followed. Many studies have been dedicated to the evaluation of "direct" markers of fibrogenesis, i.e. of biochemical parameters, measurable in the peripheral blood as direct expression of either the deposition or the removal of ECM in the liver. These direct markers of liver fibrosis include several glycoproteins (hyaluronan, laminin, human cartilage glycoprotein 39 (YKL-40)), the collagens family (procollagen Ⅲ, type Ⅳ collagen and type Ⅳ collagen 7s domain), the collagenases and their inhibitors (metalloproteinases and tissue inhibitors of metalloproteinases) and a number of cytokines connected with the fibrogenetic process (TGF-β1, TNF-β). These markers and their role in fibrogenesis are described in Table 4. The potential clinical applications of such markers appear extremely interesting and innovative, as they could be used not only to stage liver fibrosis, but also and more appropriately to assess the speed of liver fibrogenesis with most relevant prognostic value, and also to estimate and monitor the efficacy of and the response to antifibrotic drugs. However, these ambitious goals have not been yet achieved and the described direct makers of fibrogenesis have been so far tested only for their performance in defining the actual

Table 3 Features of the ideal marker of liver fibrosis

Specific for fibrosis of the liver
Providing measurement of: A) stage of fibrosis, B) fibrogenesis activity
Not influenced by comorbidities (e.g. renal, reticulo-endothelial)
Known half-life
Known excretion route
Sensitive
Reproducible

Table 4 Direct non invasive markers of liver fibrosis

Author	Liver disease	Marker	Characteristics	Pathophisiology
McHutchison[61] Murawaki[62] Halfon[63] Pares[64] Suzuki[65] Naveau[66] Santos[67] Montazeri[68]	HCV, AFLD, NAFLD, HBV	Hyaluronic acid	Component of the ECM in every tissue	Synthesized by HSCs and degraded by sinusoidal endothelial cells
Santos[67] Walsh[69]	HCV, NAFLD	Laminin	Co-expressed with type Ⅳ collagen in basement membranes	Increased deposition in viral disease
Tran[70] Saitou[71]	AFLD, HCV	YKL-40	Human cartilage glicoprotein	Involved in remodelling and degradation of ECM
Sakugawa[72] Murawaki[73] Walsh[69] Saitou[71] Santos[67]	HCV, NAFLD	Type Ⅳ collagen/ 7s domain	Main collagen component of the basement membrane	Increase with severity of liver fibrosis
Guechot[74] Pares[64]	HCV, AFLD	Procollagen Ⅲ	Propeptide	Released during matrix deposition and remodelling
Boeker[75] Murawaki[62]	HCV	MMP-2	Collagenase	Correlates with fibrosis
Boeker[75]	HCV	TIMP-1	Metalloproteinase	Inhibitor of collagenase
Patel[76]	HCV	Three-marker panel	Combination of hyaluronic acid, TIMP-1, α_2M	Better accuracy by combined markers

AFLD = alcoholic fatty liver disease; NAFLD = non alcoholic fatty liver disease; ECM = extracellular matrix; HSCs = hepatic stellate cells; YKL-40 = human cartilage glycoprotein-39; MMP-2 = metalloproteinase 2; TIMP-1 = tissue inhibitor metalloproteinase 1; α_2M = alfa-2-macroglobulin.

stage of liver fibrosis, with variable results (Tables 6 and Table 7). A second and easier approach in the search of non invasive markers of liver fibrosis has been to take single or combined haematological or biochemical parameters that reflect the stage of liver disease and to assess and compare the accuracy of their diagnostic performance. This approach, that often uses routinely performed blood tests, has led to the identification of sets of markers able to define the stage of liver fibrosis with an accuracy very similar, if not superior, to that of the more sophisticated and difficult to test direct markers. The diagnostic performance of most direct and indirect markers of liver fibrosis has been investigated in all the common etiological forms of CLDs, including hepatitis C, hepatitis B and alcoholic and non alcoholic fatty liver and steatohepatitis, although some of them have been more extensively tested in patients with chronic hepatitis C.

WHAT THE IDEAL NON INVASIVE MARKER OF LIVER FIBROSIS SHOULD IDENTIFY?

Most non invasive markers of liver fibrosis described in the literature were developed with the aim of discriminating between "insignificant" (F0-F1 by METAVIR) and clinically "significant" fibrosis (≥ F2 by METAVIR) or of identifying or excluding established cirrhosis in patients with well compensated CLD. Both these aims are clinically most relevant. Presence of significant fibrosis in the liver is indeed considered as the hallmark of a progressive liver disease and a clear indication for immediate initiation of antiviral therapy in patients with chronic HCV or HBV infection, in agreement with International and National Guidelines and recommendations for the management of these conditions[1,77-78]. On the other hand, patients with F0-F1 usually do not progress or progress much slowly[79-80]. Presence of cirrhosis, even when fully compensated and still clinically occult, indicates the need for specific monitoring of complications related to portal hypertension and to the increased risk of developing hepatocellular carcinoma. Furthermore, patients with HCV or HBV related cirrhosis are less likely to respond to interferon-based antiviral therapy and at higher risk of hepatic decompensation in the case of significant ALT flares when relapsing after therapy withdrawal.

THE DIRECT MARKERS OF LIVER FIBROGENESIS

A list of direct markers of liver fibrogenesis are described in Table 4 while Table 6 and 7 report their diagnostic performance in detecting significant fibrosis (≥ F2 by METAVIR) and cirrhosis, respectively, in the different etiologic forms of CLDs in which they have been evaluated. Hyaluronic acid has been extensively studied in hepatitis C and AFLD and, in more recent years, it has also been tested in smaller cohorts of patients with NAFLD and hepatitis B. Overall, a rather good accuracy of hyaluronic acid in the different studies in discriminating significant from insignificant fibrosis has been reported, with an area under the curve (AUC) ranging from a minimum of 0.78 in NAFLD to an excellent 0.98 in hepatitis B (Table 6). However, the number of patients tested was quite low in both these patients categories, with 75 and 112 cases in two studies on NAFLD (AUC of 0.87 and 0.79, respectively)[65,72] and only 65 patients in the single study conducted in chronic hepatitis B[68]. Further studies are clearly needed, especially in hepatitis B since the accuracy reported by Montazeri *et al* was excellent (0.98 AUC) but should now be confirmed in larger studies. In chronic hepatitis C, the ability of hyaluronic

acid to differentiate minimal-mild from moderate-severe fibrosis has been tested in much larger series of patients. In various cohort studies the AUC values have ranged from 0.82 to 0.92 (Table 6). In a study conducted in 326 patients the AUC was 0.86 and the specificity was 95% for significant fibrosis while the AUC was 0.92 and the specificity was 89.4% for cirrhosis when a cut off level of 110 μg/L was used[74]. However, another cohort study with more than 400 cases has reported an AUC of only 0.73 for significant fibrosis[63]. In the same study, cirrhosis could be excluded with excellent negative predictive value and sensitivity (100%) using a cut off level of 50 μg/L. Similar results were reported in another study of 486 patients in which hyaluronic acid levels < 60 μg/L excluded cirrhosis with 99% negative predictive value[61]. In a smaller study hyaluronic acid performed less well in excluding cirrhosis, with an AUC of 0.85 and 80% negative predictive value[71]. In AFLD the performance of hyaluronic acid for significant fibrosis varied significantly[64,66] while the marker showed very good performance for cirrhosis, with an AUC of 0.93[66]. On the basis of these findings, the greatest clinical utility of hyaluronic acid might be in its ability in excluding cirrhosis. The results of a study conducted in 79 patients with NAFLD were also encouraging, as hyaluronic acid had a 0.92 AUC value for cirrhosis[65]. Further studies with larger series of cases are needed, especially in NAFLD and chronic hepatitis B.

Among the glycoproteins, laminin has been assessed as a non invasive marker mainly for significant liver fibrosis. It showed an overall accuracy of 81% in a detailed study on 243 patients with CLDs[81]. It performed better in AFLD (84% accuracy) than in viral hepatitis (77% accuracy). Another study of 37 patients with chronic hepatitis C showed slightly better performance (AUC = 0.82)[69]. In a recent study conducted on 30 patients with NAFLD laminin showed good performance, particularly when combined with type IV collagen, with 87% accuracy, 100% specificity and positive predictive value[67].

YKL-40 is a recently described glycoprotein that belongs to the chitinase family. It is strongly expressed in human cartilage and human liver. YKL-40 is a relatively new marker of hepatic fibrosis and it has been only preliminarly evaluated in CLDs. It was initially investigated in patients with alcoholic liver disease. In a cohort of 146 heavy drinkers, YKL-40 showed good specificity (88.5%) but poor sensitivity (50.8%)[70]. Better results have been reported in 109 patients with chronic hepatitis C, with 0.81 AUC, 78% sensitivity and 81% specificity[71]. In the same study the accuracy in predicting cirrhosis was however lower, with an AUC of 0.795. Further studies are needed to elucidate the value of this new non invasive marker of liver fibrosis in chronic viral hepatitis and in fatty liver diseases.

Among the collagens, type Ⅳ collagen has been extensively investigated as non invasive marker of liver fibrosis. Type Ⅳ collagen is composed of a major triple-helix, an amino-terminal triple-helix (7s domain) and a carboxy-terminal globular domain. The first two forms of type Ⅳ collagen have been used in clinical studies. Type Ⅳ collagen has been studied in hepatitis C and NAFLD and a good diagnostic performance for significant fibrosis has been reported, particularly in hepatitis C (AUC = 0.83)[69,73]. Murawaki *et al* have focused on the 7s domain and central triple helix domain and found a slightly better accuracy of the former in detecting cirrhosis, with 75% positive predictive value and 92% negative predictive value[73]. The role of 7s domain has also been investigated in 112 patients with NAFLD and its performance has been compared with hyaluronic acid[72]. The results showed a better diagnostic accuracy for type Ⅳ collagen-7s domain (0.828 *vs* 0.797 AUC, respectively). Several studies have also compared the diagnostic performance of type Ⅳ collagen with that of hyaluronic acid in hepatitis C and reported the superiority of the latter marker[62,71]. These findings would indicate no definitive advantage in using type Ⅳ collagen instead of hyaluronic acid in hepatitis C. Data on type Ⅳ collagen in NAFLD are extremely limited and need further evaluation.

Several studies evaluated a possible role of procollagen Ⅲ in hepatitis C and in AFLD. In comparative studies conducted in hepatitis C, procollagen Ⅲ performed less well than type Ⅳ collagen and hyaluronic acid[71,74]. On the other hand, a good accuracy has been described in AFLD (AUC = 0.867), but again it was slightly worse than hyaluronic acid (0.913)[64]. The superiority of hyaluronic acid and type Ⅳ collagen does not allow to recommend the use of procollagen Ⅲ as non invasive marker of liver fibrosis.

Collagenases and their inhibitors have also been proposed as surrogate markers of liver fibrosis. Those reported to have some clinical impact include metalloproteinase 2 (MMP-2) and tissue inhibitor metalloproteinase 1 (TIMP-1)[82]. In a recent study Boecker and colleagues investigated the role of MMP-2 and TIMP-1 as non invasive markers of liver fibrosis in 78 patients with chronic hepatitis C[75]. Both these proteins were measured with two different methods and their diagnostic performance was different. However, with both methods, the performance in detecting cirrhosis was very high, especially for MMP-2 (0.97 AUC). Unfortunately, it has been difficult to obtain good standardisation of the method for routine clinical use.

Measurements of serum cytokines (TGF-β, TNF-β) involved in fibrogenesis have been assessed in a limited number of studies in which cytokines were found to have somehow less value in predicting liver fibrosis compared to the ECM tests[20,83]. Several Authors have tried to combine different direct markers of liver fibrosis. In a cohort study of more than one thousand patients with CLD an algorithm combining hyaluronic acid, procollagen Ⅲ and TIMP-1 has been described[84]. The AUC was discrete for hepatitis C (0.77), good in NAFLD (0.87) and excellent in AFLD (0.94). Another combination panel of matrix markers (hyaluronic acid, TIMP-1 and α_2-macroglobulin) has been tested in a cohort of HCV patients, obtaining an AUC of 0.83 with an accuracy of 75%[76]. The diagnostic performance of this combination panel appears quite similar to those reported for some single ECM components, particularly hyaluronic acid, laminin and YKL-40. Santos *et al* have recently investigated some ECM components in NAFLD showing that a combination of laminin and type Ⅳ collagen (282 ng/mL and 145 ng/mL

Table 5 Indirect non invasive markers of liver fibrosis

Authors	Liver disease	Biomarker	Description	Rationale
Giannini[85]	HCV, NAFLD	AAR	AST to ALT ratio	AST and ALT levels increase with progressive fibro-
Wai[86] Macias[87]	HCV, HIV/HCV	APRI	AST to platelet ratio	Statistical association with liver fibrosis
Forns[88] Macias[87]	HCV, HIV/HCV	Forns' index	Combination of age, platelet, γGT, cholesterol	Statistical association with liver fibrosis
Islam[89]	HCV	GUCI	Combination of AST, INR, platelet	Statistical association with liver fibrosis
Imbert-Bismut[90] Myers[91] Myers[92] Naveau[66]	HCV, HIV/HCV, HBV, AFLD	Fibrotest	Combination of α_2M, ApoA1, bilirubin, γGT, haptoglobin	Statistical association with liver fibrosis
Sud[93]	HCV	FPI	Combination of HOMA-IR, age, cholesterol, AST, alcohol intake	Statistical association with liver fibrosis
Callewaert[94]	CLDs (mostly HCV)	Glycocirrho test	Profiles of serum protein N-glycans	Glycoproteins are produced mainly by hepatocytes

NAFLD = non alcoholic fatty liver disease; AAR = aspartate to alanine aminotrasferase ratio; α_2M = alfa-2-macroglobulin; ApoA1 = apolipoprotein A1; APRI = AST to platelet ratio index; GUCI = Goteborg University Cirrhosis Index; INR = international normalised ratio; FPI = fibrosis probability index; HOMA-IR = homeostasis model assessment of insulin resistance; CLDs = chronic liver diseases. γGT = gamma glutamil transpeptidase.

cuts off, respectively) could individuate patients with significant fibrosis with 100% positive predictive value and specificity[67]. Unfortunately, only 30 patients were included in this study. In conclusion, combination panel of ECM components may improve the diagnostic accuracy of the single markers, particularly in AFLD and NAFLD, while no clear advantage has been so far demonstrated in patients with chronic hepatitis C. Further studies are needed to validate the new combinations of markers recently proposed for AFLD and NAFLD.

THE INDIRECT MARKERS OF LIVER FIBROSIS

One of the main limitation to the clinical use of direct markers of liver fibrosis is that they are not routinely available in all hospital settings. While direct markers of liver fibrosis reflect the process of fibrogenesis, indirect markers satisfy the request for a simple and easy to perform marker. The indirect markers of liver fibrosis are described in Table 5. Their diagnostic performance in detecting significant fibrosis and cirrhosis is reported in Table 6 and Table 7, respectively. The first indirect marker of liver fibrosis were transaminases, later associated in the aspartate to alanine aminotrasferase ratio (AAR) to detect cirrhosis[85]. The strength of such marker is the simplicity and the immediate availability for every Hepatologist and Clinician. On the other side, the numerous studies conducted showed that its accuracy is highly variable[83]. Moreover, it cannot be used to differentiate between no-mild and moderate-severe fibrosis. A further evolution of this index was later introduced by Wai *et al* who combined aspartate aminotrasferase (AST) with platelet count[86]. This AST to platelet ratio index (APRI) was then assessed in several studies conducted with a cohort of patients with hepatitis C and showed a rather good diagnostic performance and reproducibility, particularly for cirrhosis (AUC range from 0.77 to 0.94)[86,95-97]. The real strength of such index is that it is based on blood tests that are routinely performed in patients with liver disease with no need for additional blood collection

or costs. Most recently, APRI has been modified by adding alanine aminotrasferase (ALT) and international normalised ratio (INR), with further improvement of the diagnostic accuracy, particularly for cirrhosis[103]. Another rather simple index has been described by Forns *et al*[88]. It derives from combination of age, cholesterol level, gamma glutamil transpeptidase (γGT) and platelet count and was developed to differentiate no/minimal (F0-F1) from significant (≥ F2) fibrosis in hepatitis C, while it gives no informations on cirrhosis. It has been suggested that Forns' index might be less accurate in patients with HCV genotype 3 that is associated with very low cholesterol levels[99]. A recent study by Macias and colleagues have tested the role of APRI and Forns' index as non invasive markers of liver fibrosis in 357 patients coinfected with human immunodeficiency virus (HIV) and HCV[87]. Overall, the markers showed a lower diagnostic accuracy than in HCV mono-infected patients. The most important limits of both APRI and Forns' index are in the fact that they leave almost half of the patients unclassified.

Another index that combines together standard biochemical serum markers such as AST, platelet count and INR has been reported[89]. It showed good accuracy for cirrhosis in hepatitis C, but without significant improvement with respect to the individual tests used alone. The most widely investigated combination set of non invasive markers of liver fibrosis is Fibrotest. This was initially proposed in 1999 by Imbert-Bismut and colleagues as fibroscore and uses a combination of five blood tests including γGT, bilirubin, haptoglobin, apolipoprotein A1, α2-macroglobulin, adjusted for gender and age[90]. Fibrotest and Fibrosure are the commercially available equivalents of fibroscore in Europe and in the US, respectively. Fibrotest-Fibrosure has the great advantage of classifying all stages of liver fibrosis and it does not leave any patient unclassified. On the other hand, it uses two rather uncommon parameters, apolipoprotein A1 and α2-macroglobulin and requires precise standardisation of the laboratory procedures[104]. To date, Fibrotest-Fibrosure is by far the most investigated and validated non invasive marker of liver fibrosis with around 20 studies reported in the literature. It has been extensively tested in chronic hepatitis C where it shows an AUC of around 0.85 for significant fibrosis. Fibrotest was also tested in chronic hepatitis B and it performed slightly worse, with an AUC of 0.78 in the only study conducted[92]. In the only study performed in HIV/HCV coinfected patients Fibrotest performed well, particularly for cirrhosis (AUC = 0.87) that could be excluded with 100% negative predictive value[91]. The same performance on AFLD was obtained in another study from Poynard's group and the accuracy for cirrhosis was particularly high, with an AUC of 0.95[66]. However, no validation study of Fibrotest-Fibrosure has been conducted in HIV/HCV coinfection, chronic HBV infection and AFLD. A recent comparative study of indirect markers of liver fibrosis conducted in our Unit on 190 patients with chronic hepatitis C tested the performance of APRI, Forns and fibrotest[97]. Fibrotest showed the best accuracy, with an AUC of 0.81 for significant fibrosis and of 0.71 for cirrhosis. The same study was also one of the few reporting data on non invasive markers of liver fibrosis in patients with persistently normal transaminases (PNALT). The three non invasive markers of liver fibrosis were tested in 65 HCV patients with PNALT and APRI showed the best accuracy, with an AUC of 0.77 (Table 8). Available data would suggest that Fibrotest-Fibrosure performs well in detecting the two extremes of the staging range of liver fibrosis (F0-1 and F4), while it might performs somehow less well in the intermediate stage (F2)[20,101]. In some validation studies Fibrotest-Fibrosure was not so accurate as described in the early studies[100]. Fibrotest-Fibrosure has also been evaluated in combination with other markers. Callewaert and colleagues have recently proposed a non invasive marker based on profiles of serum glycoproteins (Glycocirrhotest)[94]. They found that the combination of Fibrotest-Fibrosure and Glycocirrhotest allows identification of cirrhosis with 100% specificity and 75% sensitivity. Another study has recently considered the influence of metabolic factors in the development of fibrosis in hepatitis C and proposed an index that includes assessment of insulin resistance and alcohol consumption. The performance of this approach was however inferior to that of simpler markers (0.77 of AUC) and has not been yet externally validated[93]. Recently a new technology (Fibroscan) that measures liver stiffness has been proposed[105]. The rationale is based on the

correlation between liver fibrosis and stiffness. This new method of measuring liver fibrosis has been evaluated in a prospective study conducted in more than seven hundred patients with CLDs of different aetiologies obtaining an AUC ranging between 0.8 for detecting significant fibrosis to 0.96 for diagnosing cirrhosis[106-107]. Fibroscan has also been combined with Fibrotest-Fibrosure in a series of patients with hepatitis C obtaining an AUC of 0.88[108]. The limitation of this new technology is that it requires a costly device to measure liver stiffness, on the other hand it showed great accuracy for cirrhosis. A detailed description of the several studies recently published on the use of Fibroscan in assessing fibrosis in patients with CLDs is not within the purposes of this review aimed to discuss non invasive diagnosis of liver fibrosis by biochemical markers and blood tests.

CURRENT USE OF NON INVASIVE MARKERS OF LIVER FIBROSIS IN CLINICAL PRACTICE AND FUTURE PROSPECTIVES

Although several non invasive markers of liver fibrosis have been developed in the last decade, their implementation in clinical practice has been slow and is still limited. According to many experts in the field, both liver pathologists and clinical hepatologists and also to the most recent international guidelines and recommendations, inter-laboratory variability, lack of reproducibility and, most importantly, an expected rate of misdiagnosis of at least 20% do not yet allow to recommend the use of most of these methods in substitution of liver biopsy[20,78,109]. One of the major limitations may be in the lack of reliable identification and classification of the intermediate stages of fibrosis[83]. On the other hand, from a clinical and not merely statistical point of view what the hepatologist needs is a diagnostic tool that, being on one side non invasive and therefore much more acceptable by the patient compared to liver biopsy, should however ensure not to misdiagnose fibrosis and particularly not to underestimate the stage of fibrosis and presence of cirrhosis. With currently available non invasive tests, this goal cannot be achieved in all patients. The most rational way of using them is therefore that of a compromise in which non invasive markers are first used to classify those patients in which they perform with high accuracy, limiting liver biopsy to the subset in which precise non invasive staging is not possible. Obviously, the indication to take or not to take liver biopsy in the cases in which non invasive markers perform less well will also depend on the need of obtaining a more or less accurate definition of the exact stage of fibrosis and will therefore vary according to the patient's characteristics. As an example, in the elderly population with chronic HBV or HCV infection or fatty liver distinction between minimal and advanced fibrosis may be sufficient for clinical decision independently of obtaining a more precise semiquantitative staging of fibrosis. On the other hand, more precise staging may be required in other patients categories such as those with chronic HBV or HCV infection who are candidate for antiviral treatment, since the decision to start therapy and also the type of drugs to be used may be influenced by fibrosis stage.

The use in clinical practice of non invasive markers of liver fibrosis will most likely increase in the near future as they become more validated and the indication for their selective use in specific patients categories is better clarified and standardised.

SEQUENTIAL ALGORITHMS OF NON-INVASIVE MARKERS OF LIVER FIBROSIS REDUCE THE NEED FOR LIVER BIOPSY IN HEPATITIS C

Recently we have proposed new combination algorithms of non invasive markers for assessing liver fibrosis in

chronic hepatitis C[97]. This represents the first application of a panel of markers used sequentially. Three different algorithms were developed by combining APRI, Forns' index and Fibrotest (Table 8). The rationale was that each individual test has advantages and limitations. APRI and Forns' index leave many patients unclassified while Fibrotest is more expensive and uses two uncommon parameters. Furthermore, the diagnostic accuracy of these methods does not exceed 80%-85% when they are used individually. In the first algorithm, significant fibrosis (≥ F2 by METAVIR) was identified in patients with elevated transaminases with high diagnostic performance (> 94% accuracy) using APRI as screening test, followed by Fibrotest in APRI non-classified cases and restricting liver biopsy to patients classified F0-F1 by non-invasive tests. In the second algorithm excellent accuracy (95%) in identifying cirrhosis was achieved using a similar algorithm with different cut-off levels, limiting by 60%-70% the need of liver biopsy. This marked reduction in the need of taking a liver biopsy and the fact that our algorithm restrict this invasive procedure to patients with low chance of having cirrhosis (being classified as F0-F1 by non invasive markers) is particularly important since the risk of liver biopsy complications is increased in the presence of cirrhosis. We have also developed an algorithm for identifying patients with significant fibrosis among HCV carriers with PNALT. This category has not been considered in most previous studies of non-invasive markers of fibrosis. However, there is abundant evidence in the literature that around 15%-30% of them may have significant fibrosis and a definitive indication to antiviral therapy[110], particularly when considering the favourable results recently reported in such patients with PEG-interferon alfa-2a plus ribavirin combination therapy[111]. The algorithm we have developed in this specific subset of patients reduces by 50% the number of liver biopsies, and shows 93%-95% accuracy in detecting or excluding significant liver fibrosis. However, this subgroup of patients remains difficult-to-diagnose with non invasive markers and liver biopsy is still necessary in around 50% of the cases.

CONCLUSION

Many biomarkers of liver fibrosis have been recently proposed with the aim of substituting liver biopsy. The evidences of the literature on these markers are consistent in showing that: (1) the direct markers of liver fibrosis may have a value in excluding cirrhosis, particularly in hepatitis C (hyaluronic acid, MMP-2), and in predicting fibrosis in NAFLD and hepatitis B (hyaluronic acid, type collagen Ⅳ) but further studies are needed especially in the last two patients subgroups; (2) the indirect markers of liver fibrosis may have a value in excluding HCV-related cirrhosis (APRI, Fibrotest), HCV-related cirrhosis with HIV coinfection and cirrhosis related to AFLD (Fibrotest) but further studies are needed in large cohorts of patients; (3) combination panels of non invasive biomarkers may improve the accuracy of the single tests (algorithm combining hyaluronic acid, procollagen Ⅲ and TIMP-1 in patients with AFLD, combination of laminin and type Ⅳ collagen in NAFLD) but further external validation is needed; (4) a series of algorithms based on sequential combination of non invasive biomarkers have shown high diagnostic accuracy in identifying significant fibrosis and cirrhosis in patients with chronic hepatitis C with a reduction by more than 50% in the need of taking liver biopsies; (5) based on these findings, it is conceivable to anticipate that non invasive markers of fibrosis will become in the near future an important tool in clinical practice; however, implementation of these tests in the diagnostic management of CLDs is expected to reduce but not completely abolish the need for liver biopsy; (6) for future research, priority should be given to large scale validation studies of the most promising non invasive markers and of their combinations in the different forms of CLDs accompanied by progressive fibrosis. There is also an urgent need for better assessment and validation of direct fibrogenesis markers that could be implemented in the prognostic evaluation and in dynamic testing of the efficacy of antifibrotic interventions and treatments.

Abstract

The hepatocyte, the main cellular component of the liver, exhibits variable susceptibility to different types of injury induced by endogenous or exogenous factors. Hepatocellular dysfunction or death and regeneration are dependent upon the complicated interactions between numerous biologically active molecules. Platelet-activating factor (PAF) seems to play a pivotal role as the key mediator of liver injury in the clinical and experimental setting, as implied by the beneficial effects of its receptor antagonists. A comprehensive up-to-date overview of the specific functional and regulatory properties of PAF in conditions associated with liver injury is attempted in this review.

INTRODUCTION

Platelet-activating factor (PAF) (1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine) is a potent pro-inflammatory lipid mediator[1,2] presenting a very broad spectrum of biological activities, including allergic reactions, inflammatory conditions, cardiovascular and neuronal function, reproduction, ischemia-reperfusion (IR) organ injury, sepsis, shock and tumorigenesis, which are being continuously populated[3]. PAF is typically produced by several types of leukocytes (i.e. basophils, eosinophils, neutrophils, macrophages and monocytes), platelets, endothelial cells and many other types of stimulated cells and has been detected in virtually all biological fluids. PAF exerts its activity through binding to a specific receptor, PAF-R, a seven transmembrane, heterotrimeric G protein-linked membrane receptor[4]. PAF-R transduces pleiotropic functions such as cell motility, smooth muscle contraction, synthesis and release of mediators and cytokines[5]. It has also been speculated, supported by the observation that most of the synthesized PAF remains within the cell, that PAF possibly plays an intracellular role in addition to its function as an extracellular communication molecule[6]. Moreover, PAF may play a role in many pathophysiological processes as a cofactor, i.e. as a distinct component of a complex mediator network. PAF is enzymatically synthesized through two major routes, the so-called remodeling and *de novo* pathways, with the contribution of an acetyltransferase (PAF-AT) and is degraded by acetylhydrolases (PAF-AH) into its biologically inactive form, lyso-PAF[7]. The biochemical steps of biological PAF synthesis and degradation are schematically presented in Figure 1. PAF-AHs exhibit phospholipase A_2 (PLA_2)-like activity leading to hydrolysis of the *sn2* ester bond, reversing the acetyltransferase synthetic step and generating lyso-PAF and acetate. One plasma-type and two intracellular PAF-AH have been described and cloned[8]. Plasma PAF-AH is a monomeric enzyme synthesized and secreted by macrophages (and to a lesser extent in the liver) and associated with lipoproteins in plasma. Intracellular PAF-AHs are divided into types I and II, with type II PAF-AH showing a broader specificity and significant homology to the plasma-type enzyme. PAF-AHs obviously control, through elimination or inhibition, PAF activity in cases of excessive production and release of this potent mediator[9], although their precise role in normal and disease state is still poorly understood.

PAF has been suspected to play an important role in liver pathophysiology, particularly associated with inflammatory conditions. Its contribution as a mediator to the pathogenesis of liver injury in regenerating livers, through activation of multiple intermediate molecules or cofactors, has been elucidated in several experimental studies. In the liver, PAF is mainly produced and released by Kupffer cells facilitating communication and interaction between hepatic sinusoidal and parenchymal cells. The regulatory role of PAF in leukocyte recruitment, microvascular dysfunction and cytokine production associated with liver injury remains a main target of current research.

This review aims to present in a collective way the information available concerning the involvement of

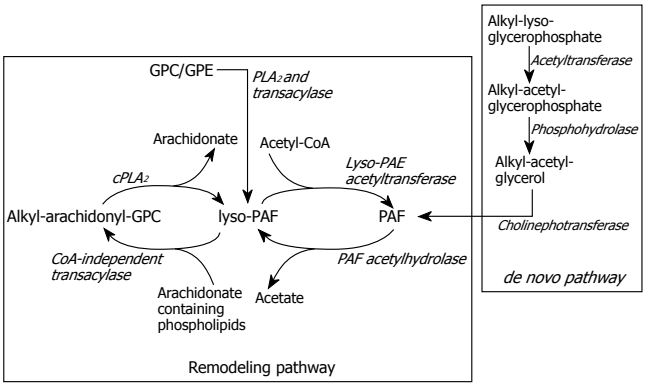

Figure 1 Remodeling and *de novo* pathways of platelet-activating factor (PAF) synthesis. GPC = Glycerophosphocholine; GPE = Glycerolophosphoethanola mine; Lyso-PAF = Alkyl-lyso-GPC; PAF = Alkyl-acetyl-GPC; $cPLA_2$ = Cytosolic phospholipase A_2.

PAF in various types of liver injury in order to reveal its crucial role in liver pathophysiology. The already reported effects of specific PAF-R antagonists on liver injury and regeneration are also mentioned.

PAF AND LIVER INJURY

PAF and hepatic ischemia-reperfusion (IR) injury

Hepatic ischemia-reperfusion (IR) injury is a common issue encountered in various clinical conditions, including systemic shock followed by hepatic failure, liver transplantation and liver resections or extensive hepatectomy due to trauma or cancer. Although hepatocellular injury does occur during the period of ischemia or hypoperfusion of the liver, there is increasing evidence that most of the hepatic cellular damage occurs during reperfusion of the ischemic liver, supporting the assumption that hepatic injury due to ischemia is accentuated after the re-establishment of oxygen flow[10]. Among the mechanisms accounting for this type of liver injury, which include oxygen-derived free radical formation, cellular energy depletion leading to cell membrane dysfunction[11], disruption of calcium homeostasis[12], activation of phospholipases[13], production and release of soluble mediators such as interleukin (IL)-1, IL-6, IL-8 and tumor necrosis factor (TNF)-α, neutrophil stimulation, chemoattraction and adhesion to activated endothelial sites resulting in microvascular injury[14-16], PAF is thought to play a major role as a mediator of the inflammatory events following hepatic IR[17]. Several experimental animal models have been used to investigate the extent of cellular disruption and the protective mechanisms involved in liver IR injury in association with PAF activity and the potentially beneficial effects of potent PAF-R antagonists. The variability of these models remains a major issue limiting the reliable assessment and comparison of their results. Studies conducted as yet can be schematically divided into two groups: *in situ* and isolated hepatic IR studies. Table 1 summarizes the features of experimental studies using PAF-R antagonists.

Liver function following hepatic IR has been initially assessed in studies using an isolated liver perfusion apparatus. In an early study[18] comparing cold liver preservation in the Eurocollins and the University of Wisconsin (UW)-lactobionate solutions, the efficacy of pretreatment with SRI-63441, a potent PAF-R antagonist, was also evaluated. Livers isolated from pretreated rats and stored in the UW solution for 24 h produced significantly more bile than livers preserved in the UW solution alone. Although the differences in other parameters of liver function evaluated in this study did not reach statistical significance, the observed beneficial effect was attributed to PAF antagonism, supporting the assumption that PAF was implicated in cold ischemic liver injury. The role of PAF and its antagonist CV-6209 in cold ischemic liver injury of similar duration has also been investigated[19]. After 24 h of cold preservation, bile flow was significantly higher in all CV-6209-treated groups at two hours of reperfusion and at specific time points with a dose-dependent recovery outcome, which also correlated with significantly lower aspartate aminotransferase (AST) levels. A tendency toward lower liver weight increase and lower perfusion pressures was also noted. Using the same isolated liver perfusion system, an experimental series of warm liver ischemia revealed better recovery of bile flow in groups which received higher doses of CV-6209 over a specific threshold of antagonism. In addition, AST level increase was significantly lower within certain dosage limits and a tendency toward lower perfusion pressures was observed. These results suggested that PAF was possibly implicated in both warm and cold ischemic liver injuries, which might be effectively diminished by a potent receptor antagonist. SRI-63441 has also been used in another series of isolated liver perfusion experimental studies[20] aiming to evaluate the pharmacologic modulation of warm postischemic hepatic function. Pretreatment with this PAF-R antagonist before the induction of *in situ* total hepatic ischemia resulted in significantly increased bile production, decreased perfusate transaminase levels and higher tissue adenosine triphosphate (ATP) content compared to ischemic non-treated controls. The degree of hepatocellular vacuolization and sinusoidal endothelial disruption due to ischemic injury revealed by electron microscopy was also less severe in the pretreatment group. These findings confirmed the dose-dependent protective effect of this antagonist against warm IR injury, thus implicating PAF as a key mediator of this type of liver injury. The direct effect of PAF on ischemic liver injury has been investigated in an *ex vivo* isolated rat liver perfusion system[21], in order to avoid the interference of other factors. Administration of high doses of PAF, expected to result in shock and death *in vivo*, did not exacerbate hepatic ischemic injury in this model after 30 or 60 min of ischemia. This finding suggested that PAF, unlike its *in vivo* action, neither causes hepatocellular injury nor enhances ischemic liver injury directly, supporting the hypothesis that PAF exerts its effects through other factors and substantially acts as a key mediator of ischemic liver injury. However, in another similar study, administration of increasing doses of PAF significantly decreased liver tissue ATP levels and oxygen consumption and significantly increased alanine aminotransferase (ALT) and purine nucleoside phosphorylase (PNP) activity in the effluent perfusate compared to control values[22]. The noted disruption of

parenchymal cells in association with the unaltered PNP/ALT ratio, used as a relative indicator of non-parenchymal cell injury, suggested that PAF might lead to functional impairment of parenchymal hepatic cells, i.e. hepatocytes, even in the absence of microcirculatory disturbance secondary to the interaction between circulating leukocytes and endothelial cells.

Experimental studies of *in situ* hepatic IR have consistently used models of total, with or without splanchnic congestion, or partial liver ischemia. Partial liver ischemia by clamping or ligation of the hilar area of the left lateral and median rat liver lobes, thereby avoiding intestinal congestion, has been extensively applied in several warm hepatic IR studies. Demonstration of the protective effects of CV-6209, in terms of improved bile flow and earlier recovery of rat liver ATP levels and energy charge after 60 min of ischemia, as well as determination of the optimal timing and dosing pattern were attained in a leading study conducted by Wang *et al*[23]. The contribution of PAF to the inflammatory consequences of hepatic IR injury, especially during the late-phase hepatic reperfusion, has been evaluated[24] by measurement of hepatic PAF levels[25] and intraperitoneal administration of the PAF-R antagonist WEB-2170. Treatment with WEB-2170 resulted in a significant decrease of plasma ALT levels and polymorphonuclear (PMN) leukocytes infiltration in liver tissue in association with impaired hepatocellular necrosis compared to the control group. Additional pharmacological interventions provided evidence that interaction between Kupffer cells and oxygen-derived free radicals led to local hepatic generation of PAF after IR. A survival study[26] using a partial hepatic IR injury model demonstrated that pretreatment with the PAF-R antagonist BN-52021 resulted in a statistically significant reduction of warm liver injury in terms of improved seven-day cumulative survival rates and histological evidence of minor hepatocellular necrosis on the first postoperative day and revealed a dose-dependent protective effect. Pre-ischemic administration of BN-52021 in a similar hepatic IR model[27] resulted in a significant reduction of hepatocellular loss of cytoplasmatic ALT and intramitochondrial glutamate dehydrogenase (GLDH) into the plasma. In this study, significantly reduced endothelial enzyme leaking (PNP), increased bile flow and liver tissue ATP content and moderately decreased malondialdehyde (MDA) levels in the pretreated reperfused livers were observed, suggesting the implication of PAF in both structural and metabolic changes induced by hepatic IR injury. Microcirculatory disruption due to hepatic IR has also been investigated[28]. Pretreatment with WEB-2170 did not result in significant recovery of postischemic liver blood flow and liver oxyhemoglobin saturation, as determined by laser Doppler flowmetry and photometry, respectively. It was therefore assumed that the involvement of PAF might be secondary in the pathogenesis of reperfusion injury or bypassed by other major contributors, such as leukocytes in this instance. Nevertheless, another contemporary study evaluating the role of PAF in microcirculatory disturbance in a similar experimental model[29] demonstrated that pretreatment with BN-52021 resulted in significant improvement of left lobular erythrocyte flux recovery, reaching nearly preischemic control values after 10 min of reperfusion. In addition, PNP leakage from hepatic vascular endothelium into plasma as a result of reperfusion was significantly attenuated by administration of BN-52021. A statistically significant reduction of postischemic hepatocellular ALT loss, accompanied by enhanced bile production and increased tissue ATP levels as well as by suppressed neutrophil infiltration in liver tissue, as indicated by reduced myeloperoxidase (MPO) activity, were also observed in the pretreatment group, suggesting that PAF might be implicated in IR-induced microcirculatory disturbance. The emerging controversy between these studies seems to have been resolved by a recent experimental evaluation of the effects of PAF and a thromboxane (Tx)-A_2 analogue

on hepatic vascular resistance distribution and liver weight in an isolated perfused animal model[30]. PAF was shown to be a potent vasoconstrictor causing a dose-dependent increase of total hepatic vascular resistance. Furthermore, it was demonstrated that PAF increases predominantly presinusoidal over post-sinusoidal resistance and influences liver weight, causing liver weight loss at low concentrations and liver weight gain at high concentrations. These findings support the presumption that PAF is involved in the induction of hepatic microcirculatory disturbance in conditions such as IR injury.

In many recent studies, total hepatic ischemia has been applied using the Pringle's maneuver, i.e. by ligation or cross-clamping of the portal triad - hepatic artery, portal vein and bile duct. The effects of pretreatment with the PAF-R antagonist E5880 on hepatic and systemic metabolism have been investigated after a relatively short period of *in situ* total warm hepatic ischemia followed by a similarly short period of reperfusion, without avoiding intestinal congestion[31]. In the pretreatment group, hepatic tissue ATP and energy charge levels were significantly increased while AMP levels were significantly decreased after 30 min of reperfusion compared to non-pretreated animals. However, no statistically significant difference was noted in parameters reflecting hepatic mitochondrial function, such as the arterial ketone body ratio (AKBR - ratio of acetoacetate to 3-hydroxybutyrate) and arterial ammonia levels, or those indicating systemic changes, such as arterial blood gas values and pyruvate and lactate levels. These data suggested that PAF exerts local effects during liver IR injury, attenuated by its antagonism, without mediating systemic metabolic changes. The effects of the specific PAF-R antagonist TCV-309, alone or in combination with a prostaglandin I_2 analogue, on total warm hepatic IR injury were evaluated in a large study[32]. After two hours of *in situ* hepatic ischemia followed by one hour of reperfusion, improvement of bile flow rate, suggesting restoration of hepatic ATP levels, a significant decrease of tissue glutathione disulfide/glutathione (GSSG/GSH) ratio and less severe midzonal liver injury and congestion were observed in groups treated with TCV-309, indicating preservation of hepatic function and attenuation of oxidative stress. Despite a significant increase in portal endotoxin levels in pretreated animals, 30 d survival rates were higher compared to non-treated groups. These results suggested that PAF was generated in the liver during warm IR leading to liver injury. Using the same PAF-R antagonist, a similar study focusing on cytokine production and neutrophil activation induced by PAF after hepatic IR was conducted[33]. Total hepatic ischemia was produced while intestinal congestion was avoided using an extracorporeal portosystemic shunt. During the reperfusion period, an increased 30-d survival rate, decreased plasma AST levels, significant suppression of plasma TNF-α and CINC (cytokine-induced neutrophil chemoattractant) levels, less severe hepatic necrosis, markedly decreased neutrophil accumulation and significantly lower O_2^- production in liver tissue were noted in the pretreatment group compared to the control group. Inhibition of TNF-α and CINC production by the specific PAF-R antagonist TCV-309 strongly suggested that PAF functions on hepatic IR injury were exerted through either direct neutrophil activation or cytokine induction. The role of this specific PAF-R antagonist in hepatic IR injury has been further evaluated in a recent survival study of total hepatic ischemia[34]. Pretreatment with TCV-309 significantly suppressed the increase in plasma levels of AST and endothelin (ET)-1, a potent vasoconstrictor derived from vascular endothelium and hepatic sinusoidal endothelial cells which leads to hepatic microvascular injury, at all selected time points after reperfusion. In addition, at 6 h after reperfusion, hepatocellular necrosis and neutrophil accumulation in midzonal and pericentral areas of the hepatic lobule were less prominent in TCV-309-treated group. Similarly, survival rates demonstrated a statistically significant improvement in TCV-309-treated animals compared to controls. The complicated interaction between PAF and ET-1 in hepatic IR injury evaluated in this study supported the hypothesis that PAF-R antagonism might exert a potential protective effect against this type of injury via indirect modulation of plasma ET-1 levels. A most recent study of total hepatic IR[35] showed that pretreatment with the PAF-R antagonist BB-882 (lexipafant) resulted in a statistically significant decrease of liver damage scores[36], the mean hepatic MDA levels (sensitive indicator of lipid peroxidation) and serum AST, ALT and lactate dehydrogenase (LDH) levels. These beneficial effects were attributed to a reduction in the inflammatory reaction and oxygen radical synthesis induced by PAF after hepatic IR injury. In order to confirm the putative etiologic relation between PAF, xanthine oxidase, reactive oxidants and leukocytes in the pathogenesis of liver injury, a modified hemorrhagic shock-resuscitation rat model based on Wigger's isobaric principle has been used[37]. In this unique study, inhibition of PAF-R binding by WEB-2170 significantly attenuated leukocyte accumulation in the pericentral areas of the hepatic lobule, both at the early inflammatory response time point and at 24 h end point, as demonstrated by total hepatic MPO activity and histochemical examination. Significantly less severe hepatic injury, evident by plasma AST and alcohol dehydrogenase (ADH) levels and histological grading of hepatocellular necrosis, was also observed in the WEB-2170-treated group, although there was no decrease in the generation of hepatic oxidant stress, as shown by hepatic reduced GSH and oxidized GSSG levels. These results, in combination with those yielded from the administration of other potentially protective factors, established an apparent etiologic relation between PAF and the aforementioned components of hepatic injury *in vivo*. In another experimental model of hemorrhagic shock, causing whole-body IR, the effects of PAF on calcium homeostasis were investigated[38]. PAF is known to use voltage- and receptor-gated Ca^{2+} influx to exert its actions in a variety of cell types[5]. In this model, hepatocellular Ca^{2+} uptake, initial rate of Ca^{2+} influx and membrane Ca^{2+} flux, determined using specific incubation techniques[39], were significantly increased in the shock group compared to sham-operated animals. Administration of the specific PAF-R antagonist BN-52021 in the shock group significantly reduced Ca^{2+} uptake, without influencing other parameters of calcium homeostasis, and largely prevented hepatocyte lipid peroxidation, determined fluorometrically[40]. These results suggested that PAF may play a pivotal

role in promoting hepatocyte Ca^{2+} overload during hemorrhagic shock, which in turn accentuates hepatic oxidative injury.

PAF and liver transplantation

In the field of clinical liver transplantation, liver injury due to cold ischemia followed by warm reperfusion, referred to as preservation-reperfusion injury (PRI) of the graft, remains one of the most critical issues affecting postoperative graft viability and ultimate survival of the recipient. It has been well established that hypothermic ischemia mainly causes sinusoidal lining cell injury which becomes fully manifest on reperfusion, leading to deterioration of the microcirculation[41]. Although the exact mechanisms have not yet been fully elucidated, PAF has been proposed as a major mediator involved in the pathogenesis of PRI and several studies have attempted to clarify the potentially protective role of PAF-R antagonists, as shown in Table 2.

A clinical study of 17 patients who underwent orthotopic liver transplantation (OLT)[42] revealed that peripheral blood PAF levels were not significantly altered during the immediate reperfusion period or during the acute rejection episodes, confirming that successful OLT normalizes blood PAF levels in cirrhotic decompensated patients and that PAF levels were probably unrelated to the onset of acute graft rejection. On the other hand, in another clinical study, PAF levels were increased after portal venous reperfusion, except for one case where veno-venous bypass was applied, suggesting that PAF was probably involved in postoperative liver graft dysfunction[43].

Experimental studies evaluating the role of PAF in liver transplantation through its antagonism have consistently used porcine or rat models. In a rat OLT model, administration of BN-52021 in the preservation solution and to the recipient prior to liver graft implantation[44] resulted in significant reduction of serum LDH and PNP levels and significant improvement of hepatic bile production after reperfusion in the treated group compared to untreated controls. A tendency toward suppressed oxygen free radical generation, as indicated by attenuation of serum conjugated dienes (CD) levels, and liver tissue-associated MPO activity was also noted in the treatment group, although the differences were not statistically significant. The potentially protective effect of the potent PAF-R antagonist E5880 on PRI of the liver graft has been evaluated in another OLT study[45]. Survival rates after 12 h of reperfusion, AKBR, an accurate marker of liver graft metabolic function, and white blood cell (WBC) count were significantly higher, whereas AST and ALT levels at 4 h and lactate levels were lower in the treatment group compared to controls. Histological examination revealed only occasional presence of inflammatory cells, mainly PMNs, in the sinusoids of the treatment group. These results confirmed the implication of PAF in PRI as well as the protective effect of its antagonism. A similar study demonstrated that treatment with WEB-2170 resulted in suppressed, though not statistically significant, postoperative elevation of hepatocellular enzymes (AST, ALT) and bilirubin levels in hepatic venous blood samples and in normalization of local tissue oxygen tension after 6 h of reperfusion, as determined by the use of a multiwire oxygen electrode on liver surface[46]. These data suggested that PAF antagonism attenuated hepatocellular injury and prevented the detrimental shifts of local tissue oxygen tension which reflects the integrity of hepatic microcirculation. The role of PAF as a mediator involved in the regulation of leukocyte adhesion after OLT has been evaluated through administration of the PAF-R antagonist WEB-2086[47]. In the treatment group, the temporary leukocyte adhesion to sinusoidal endothelial cell lining in the periportal region, determined by the method of intravital fluorescence microscopy, was significantly reduced in the early reperfusion period followed by a similar reduction of permanent leukocyte adhesion in the late one. Comparable changes in midzonal and pericentral areas were also noted. Suppression of leukocyte adhesion by this PAF-R antagonist was further reflected by an increase in peripheral blood WBC count during the early reperfusion period. These results suggested that PAF antagonism attenuated the inflammatory response in hepatic sinusoids, thus contributing to the preservation of microcirculation, whereas no protective effect on hepatocellular integrity was noted. The effects of E5880 on PRI of the liver graft in porcine OLT were further assessed in a survival study[48], in which postoperative survival of more than 12 h was significantly higher in the PAF-R antagonist treatment group. Treated animals demonstrated a slight but significant increase in WBC count at 2 h after reperfusion and at 4 h AST, ALT and lactate levels were significantly lower compared to the control group. In addition, the AKBR was significantly increased at 12 h after reperfusion, indicating better recovery of liver graft function. Histological examination by light and electron microscopy revealed less severe sinusoidal endothelial cell damage in the treatment group. Similar results were obtained in another study in which prolonged warm hepatic ischemia in non-heart-beating donors was followed by cold preservation and reperfusion[49]. Improved survival rate at 12 h after OLT, suppression of serum AST and lactate levels, attenuation of hepatocellular degeneration and significantly better energy charge recovery were noted in animals treated with E5880 compared to controls. Although most parameters

did not reach statistical significance, this was partly attributed to the small number of treated animals.

PAF and acute liver injury

Acute hepatic dysfunction, or even failure, occurs frequently in the clinical setting and is usually refractory to currently available treatment options. The pathogenesis of hepatocellular damage has been well characterized in several experimental studies of acute liver injury induced by lipopolysaccharide (LPS) compounds, chemical and pharmacological factors, bile duct ligation or hepatectomy (Table 3).

In an early study of endotoxin-induced liver injury by intravenous infusion of heat-killed *Propionibacterium acnes* and LPS[50], treatment of experimental animals with a PAF-R antagonist attenuated liver tissue damage, as indicated by the reduction of focal liver necrosis in histological examination. In addition, liver adherent cells isolated from control and endotoxin-treated mice were capable of producing PAF upon stimulation with A23187 calcium ionophore. These results suggested that the produced PAF by liver adherent cells could be involved in the induction of liver injury during endotoxemia. The effects of endotoxin and PAF in rats with secondary biliary cirrhosis were also evaluated[51] and it was suggested that the hemodynamic changes observed in cirrhosis might be aggravated during acute infections. LPS administration significantly increased heart rate and total peripheral vascular resistance and reduced cardiac index, portal pressure and renal blood flow in cirrhotic animals compared to controls. PAF infusion resulted in similar changes in the experimental group, with the exception of a sharp rise in portal pressure owing to an increase in portal territory vascular resistance. Treatment with the specific PAF-R antagonists WEB-2170 or BN-52021 largely prevented LPS-induced renal vasoconstriction and the former also restored cardiac index and peripheral resistance to near normal levels. The complicated interactions between LPS, PAF and TNF-α have been further elucidated[52]. Administration of either LPS or PAF resulted in elevated serum TNF-α levels and TNF-α mRNA production in the intestine and the liver in response to LPS was only partially inhibited by the PAF-R antagonist WEB-2086. These results suggested that LPS induces TNF-α production via both PAF-dependent and PAF-independent pathways and that these major inflammatory mediators interact through a positive feedback mechanism. LPS-associated activation and PAF-induced biochemical response of hepatic macrophages and endothelial cells have also been investigated[53]. PAF administration resulted in a rapid and transient increase in intracellular calcium content in both cell types whereas a rapid decrease in intracellular pH of hepatic macrophages only, attenuated by the PAF-R antagonist triazolam, was also noted. In addition, LPS caused a significant increase in the number of PAF-binding sites/cell and the equilibrium dissociation constant (Kd) for PAF in endothelial cells. These results revealed that the biochemical responses of these two major hepatic cell types to PAF during endotoxemia are distinct. In a unique model of LPS-induced liver injury, based on evidence that intestinal IR increases portal and systemic plasma endotoxin levels[54], the role of Kupffer cells in mediating leukocyte recruitment, impaired sinusoidal perfusion and liver tissue hypoxia via complicated interaction with PAF and TNF-α was investigated[55]. In this study, treatment with WEB-2086 effectively attenuated LPS-induced leukostasis in all segments of hepatic microvasculature, the number of nonperfused sinusoids and elevation in plasma ALT and TNF-α levels. Furthermore, the increased autofluorescence of pyridine nucleotide [NAD(P)H], an indicator of mitochondrial oxygen consumption and redox status[56], was significantly suppressed in both midzonal and pericentral areas and expression of P-selectin, an endothelial cell adhesion molecule[57], was depleted by this antagonist in the liver and the small intestine. It was also reported that excessive nitric oxide (NO) generation by hepatic cells, especially Kupffer cells, in response to LPS and inflammatory mediators, such as PAF, contributes to the pathogenesis of liver injury. In a model of rat liver-focused endotoxemia[58], pretreatment with specific PAF-R antagonists (BN-50739 or WEB-2170) reduced serum ALT and inducible nitric oxide synthase (iNOS) mRNA levels in the whole intact liver. In addition, pretreatment of cultured Kupffer cells with either of these antagonists resulted in significant inhibition of both LPS and PAF-induced iNOS mRNA and protein synthesis. Previous studies have shown that iNOS gene activation in macrophages by LPS depends on the transcription factor nuclear factor-kappa B (NF-κB), whose activation results in degradation of the α and β subunits of its inhibitor (IκB)[59]. It was shown that PAF-R antagonists attenuated the translocation of the active p65 subunit of NF-κB into the nucleus. A concomitant suppression of LPS-dependent degradation of the inhibitory protein subunit IκBα and intracellular calcium content of Kupffer cells was also noted. These results confirmed the protective effects of PAF antagonism against NO-mediated inflammatory liver tissue

injury during endotoxemia. In contrast to the results of the aforementioned studies, pretreatment of experimental animals with WEB-2086 one hour before intravenous LPS administration failed to inhibit LPS-induced sinusoidal neutrophil infiltration, evaluated by histological examination of hepatocellular necrosis and indicated by elevated plasma ALT activity, and did not significantly alter thrombocytopenia or plasma fibrinogen levels[60]. However, it has been speculated that the conflicting results might derive from variations related to the experimental models used in terms of the route of LPS administration, the degree of hepatocellular injury and temporal differences in the development of liver injury and histological evaluation. The role of PAF in alcoholic hepatitis in association with LPS administration has been studied by Murohisa *et al*[61]. Chronic ethanol administration remarkably sensitized experimental animals to the effects of LPS and severe hepatocellular injury associated with significantly elevated serum ALT, TNF-α and IL-8 levels was observed. Histological findings of liver injury included hepatocyte apoptosis and necrosis with marked neutrophil infiltration and enhanced Fas-receptor expression on hepatocytes and Fas-ligand expression on infiltrating neutrophils. Pretreatment with TCV-309 attenuated hepatocellular apoptosis and necrosis, neutrophil infiltration, Fas-receptor and Fas-ligand expression and decreased serum TNF-α levels. These protective effects suggested that PAF acts as a key mediator of endotoxin-induced liver injury in alcoholic hepatitis and possibly regulates Fas-receptor expression on hepatocytes via TNF-α, thus facilitating neutrophil accumulation and hepatocellular apoptosis. In an experimental model of liver-focused endotoxemia[62], LPS administration resulted in a significant increase in plasma-type PAF-AH mRNA and protein expression, particularly in Kupffer cells. A similar increase was noted in both circulating leukocytes and peritoneal macrophages as well as in all tissues examined. Administration of the PAF-R antagonists BN-50739 and WEB-2170 significantly inhibited the increase in PAF-AH activity in response to LPS, suggesting that PAF-R is probably involved in the upregulation of this enzyme, thereby minimizing the unfavorable hepatic and systemic effects of PAF-mediated injury. Two independent studies on D-galactosamine (D-GalN)/LPS-induced rat liver injury confirmed the protective effects of the potent PAF-R antagonist WEB-2086[63,64]. In the first study, a significant suppression of elevated transaminase levels and less severe histological changes were noted in the WEB-2086-treated animals compared to controls. Furthermore, PAF-R antagonism resulted in a significant attenuation of D-GalN/LPS-induced elevation of MDA and MPO levels and prevented the decrease of superoxide dismutase (SOD) in the liver tissue of WEB-2086-treated animals[63]. In the second study, both *in vivo* and *in vitro* effects of WEB-2086 were investigated[64]. The degree of hepatic injury and the levels of transaminases were significantly decreased in WEB-2086-treated animals after D-GalN/LPS administration and a significantly reduced number of infiltrating neutrophils was observed compared to the untreated group. *In vitro* evaluation revealed that the enhanced neutrophil adhesion to hepatic endothelial cells, either by stimulation with the sera collected from D-GalN/LPS treated animals or due to a direct effect of LPS, TNF-α or PAF, was also attenuated by WEB-2086 in a dose-dependent manner. These results strongly suggested a crucial role for PAF and PAF-R antagonists in this specific type of liver injury[63,64].

In an experimental study of acute, chemical-induced cholestasis by administration of the cholangiolitic hepatotoxicant alpha-naphthylisothiocyanate (ANIT), the role of PAF was investigated through pre- and post-treatment of study animals with WEB-2086[65]. ANIT-induced hepatotoxicity was confirmed by histological evaluation of periportal inflammation with marked neutrophil infiltration and biochemical parameters indicative of cholestasis. Treatment of the experimental group with WEB-2086 did not attenuate ANIT-induced liver injury as shown by increased plasma ALT and γ-glutamyl transferase (γGT) activities, or cholestasis, as indicated by increased plasma bilirubin concentration. These results suggested that soluble mediators other than PAF might be primarily involved in neutrophil-dependent liver injury caused by this hepatotoxic agent. In a most recent study evaluating the role of PAF in acetaminophen (APAP)-induced liver injury and regeneration[66], blood PAF levels and serum PAF-AH activity were measured in association with a biphasic pattern of APAP hepatotoxicity, as indicated by histological findings and three independent indices of liver regeneration. Blood levels of free PAF were significantly elevated during the first wave of liver injury and peak levels temporally coincided with the maximal levels of AST, ALT and ALP activity. Serum PAF-AH activity showed different time course from that of PAF and hepatic enzymes following the biphasic pattern of liver regeneration, with the first rise occurring before the elevation of PAF levels and the second rise coinciding with the second wave of regeneration, probably in response to the prior high levels of PAF. These results suggested that PAF plays a major role in the initial priming of the liver regeneration process, possibly acting as an intracellular mediator, and that PAF-AH seems to eliminate PAF-mediated liver injury mainly during the late phase of APAP-induced hepatotoxicity. The protective effects of the PAF-R antagonist BN-52021 on APAP-induced acute liver injury have been recently reported in a serial study conducted by Grypioti *et al*[67]. Intraperitoneal administration of this PAF-R antagonist resulted in a significant decrease of serum hepatic AST, ALT (indicative of necrosis) and alkaline phosphatase (ALP) (indicative of cholestasis) activities at several time points, accompanied by a remarkable elevation of serum PAF-AH activity at all time points compared to the control group. In addition, APAP-induced hepatocellular necrosis and apoptosis were significantly attenuated in BN-52021-treated animals. These results suggested that PAF might play a major role in liver injury and regeneration following acute APAP intoxication, underlying the beneficial effects of PAF-R antagonism.

In an experimental model of obstructive jaundice by bile duct ligation, a significant increase of liver tissue and plasma PAF levels was observed[68]. In another rat model of experimental obstructive jaundice of the same duration, PAF levels were significantly increased in liver tissue only, whereas no changes in plasma PAF levels were observed[69]. In this study, endotoxin was detected in portal

blood from jaundiced animals and endotoxin antagonism by neomycin plus polymyxin B significantly reduced local hepatic PAF levels. Moreover, isolated Kupffer cells from jaundiced rats demonstrated higher levels of cell-associated PAF compared to other liver cell types and spontaneous release of PAF by these resident hepatic macrophages was significantly increased compared to controls, supporting their putative role as the major source of hepatic PAF production. Pretreatment of isolated Kupffer cells with polymyxin B selectively prevented LPS-induced PAF production, implying that the interaction of Kupffer cells with portal endotoxin constitutes a potential mechanism that triggers local hepatic PAF synthesis. Treatment with PAF-R antagonists (BN-52021 or WEB-2170) partially prevented the increase in tissue levels of eicosanoids (TxB_2, 6-keto-PGF_{1a}), lipid peroxidation, as was prominent by reduced MDA production, and liver injury, evidenced by reduced plasma ALT levels. The effects of recombinant PAF-AH on tissue damage and antioxidant response have been recently evaluated in an experimental model of obstructive jaundice[70]. On the seventh postoperative day, AST, ALT, γGT, ALP, TNF-α and IL-6 levels were significantly lower in the PAF-AH treatment group compared to rats with obstructive jaundice which did not receive PAF-AH treatment, although still significantly higher compared to controls. Portal inflammation was also less severe and increased levels of antioxidant enzymes were noted in the treatment group, suggesting a protective effect of PAF-AH through PAF degradation.

Postoperative acute liver injury remains one of the most serious complications of extended hepatectomy and significantly influences postoperative morbidity and mortality. The implication of PAF in this type of injury was investigated in a rat model of 70% partial hepatectomy (PH)[71]. Post-PH, a significant rise in serum TNF-α, IL-6 and prostaglandin E_2 (PGE_2) levels was observed at 1, 3 and 6 h, respectively. No significant increase in portal venous endotoxin levels was noted. As early as 1 h post-PH, a significantly increased expression of PAF-R mRNA in Kupffer cells was noted in the group of hepatectomized rats compared to sham-operated ones. These data suggested that PAF possibly stimulated Kupffer cells leading to upregulation of PAF-R and induced acute liver injury via the release of TNF-α and IL-6 from these cells, which was subsequently suppressed by enhanced PGE_2 production. The role of PAF in LPS-induced liver injury with regenerating livers post-PH has also been investigated[72]. Treatment of experimental animals with TCV-309 before or after LPS administration resulted in significantly higher survival rates, effective suppression of plasma ALT and CINC levels and reduced liver tissue necrosis with infiltration of CINC-positive neutrophils, compared to the saline treated controls. Furthermore, attenuation of continuous CINC mRNA upregulation and NF-κB activation in the regenerating livers by TCV-309 confirmed the crucial role of PAF in LPS-induced liver injury, possibly via neutrophil accumulation and activation.

PAF and chronic liver injury

Liver cirrhosis is a terminal pathologic state induced by several biological and chemical agents capable of producing chronic liver injury. Irrespective of the exact mechanisms by which etiologic factors induce liver injury, they all trigger a common final pathway that leads to excessive fibrosis and nodular regeneration of the viable liver tissue[73,74]. PAF has been implicated as a mediator of the pathologic, metabolic and hemodynamic changes observed in cirrhosis both in humans and experimental animal models. Table 4 presents clinical and experimental studies on chronic liver injury in association with PAF synthesis and antagonism.

Table 4 PAF and chronic liver injury (cirrhosis)

Type of study	Method of cirrhosis induction	PAF levels	PAF-R antagonist used	Reference
Clinical				
	NA	↑	-	[76]

	CCl_4	↑	-	[87]
	CCl_4	↑	BN-52021	[88]

[1] Not determined; NA = Not applicable; NS = Not significant; CCl_4 = Carbon tetrachloride; TAA = Thioacetamide.

In an early clinical report, increased PAF levels were observed in serum and ascitic fluid from decompensated cirrhotic patients, while compensated cirrhotics presented lower values but still higher than controls. In addition, serum PAF-AH activity was similar in all groups, supporting the conception of an enhanced production rather than a decreased degradation of PAF in cirrhotic patients[75]. Laffi *et al* further investigated alterations of PMN leukocyte function in nonalcoholic cirrhosis[76], based on well-established evidence of defective PMN function in patients with cirrhosis of alcoholic etiology[77]. PMN leukocytes from cirrhotic patients demonstrated *in vitro* a significantly reduced capacity to produce superoxide anion, determined by the reduction of cytochrome c, and a significant suppression of PAF synthesis, measured by [^{3}H]acetate incorporation into PAF and mass-spectrometric analysis, in response to physiological (opsonized zymosan) and nonphysiological (calcium ionophore, A23187) stimuli. Impaired PAF synthesis was attributed to defective PLA_2 activity implicated in the remodeling pathway. In addition, it was shown that most of synthesized PAF from stimulated PMNs remained cell-associated rather than being secreted, supporting the hypothesis that PAF may also function as an intracellular second messenger[78]. However, it has been argued that these *in vitro* results need to be confirmed in an *in vivo* model[79], since elevated serum PAF levels in cirrhotic patients have been previously reported. In a clinical study, patients with chronic cholestasis, especially those with end-stage primary or secondary biliary cirrhosis or cholangiocarcinoma, demonstrated increased serum PAF-AH activity[80]. Normalization of liver function after liver transplantation

was accompanied by a reduction to normal or near normal serum PAF-AH levels, suggesting that the liver plays an important role in the regulation of this degrading enzyme and, consequently, PAF. Moreover, it was shown that circulating levels of PAF are not a determinant of PAF-AH release from liver tissue. The crucial role of serum PAF-AH activity in the regulation of serum PAF levels has also been evaluated in patients with hyperbilirubinemic hepatobiliary disease[81]. In this clinical study, apart from an elevated serum PAF-AH activity in all groups, a significant correlation with serum cholesterol and low density lipoprotein (LDL) cholesterol levels was also noted in patients with liver cirrhosis and/or obstructive cholestasis. These findings confirmed the hypothesis that serum cholesterol, especially the LDL fraction, is a major factor influencing serum PAF-AH activity *in vivo*[82]. Although both PAF-AH activity/cholesterol and PAF-AH activity /LDL cholesterol ratios were elevated in all types of hyperbilirubinemic liver disease, the differential alteration of these ratios following normalization of bilirubin levels in each study group indicated that factors other than serum LDL levels, such as reduced biliary excretion of PAF-AH, might also be involved in the enhancement of PAF-AH activity.

Significantly higher blood PAF levels were observed in rats with experimental cirrhosis in a study evaluating the hemodynamic effects of PAF in cirrhosis[83]. Cirrhotic animals demonstrated a hyperdynamic circulatory status, similar to that induced by systemic intravenous PAF infusion[84], with increased cardiac output (CO) and decreased mean arterial pressure (MAP) and peripheral vascular resistance (PVR). In these animals, intravenous administration of BN-52021 resulted in a significant decrease in CO, attributed to the preexisting cardiac failure becoming apparent, along with a significant increase in PVR to near normal values, whereas MAP was only slightly elevated. These results strongly suggested a possible role for PAF in the regulation of hemodynamic changes in liver cirrhosis. The response of hepatic macrophages and the effects of PAF in experimental thioacetamide (TAA)-induced cirrhosis have been studied by Noda *et al*[85]. TAA administration resulted in an increase in hepatic macrophage population and cell size, followed by a marked increase in liver tissue hydroxyproline content, an index of collagen formation and deposition, indicative of cirrhosis. Intravenous PAF infusion during fibrosis induction before the development of cirrhotic changes significantly increased hepatic portal pressure and decreased oxygen consumption in TAA-treated animals compared to controls, possibly through elevation of the portal venous resistance by PAF-related molecules. The remarkable increase in prostaglandin D_2 (PGD_2) and thromboxane B_2 (TxB_2) levels in the perfusate induced by PAF was attributed to enhanced eicosanoid production and release by the increased population of active hepatic macrophages, suggesting a possible complex interaction between these components of chronic liver injury. Moreover, PAF-induced glycogenolysis was significantly lower in the TAA-treated group, indicating the disturbance of hepatocellular function in the early stages of cirrhosis as the likely cause of suppressed glucose production. Two serial studies on experimental carbon tetrachloride (CCl_4)-induced cirrhosis have further elucidated the role of PAF and its cognate receptor in the pathophysiology of liver cirrhosis. The first study revealed a pronounced increase in both basal and ET-1-stimulated PAF synthesis in Kupffer cells from cirrhotic rats compared to controls[86]. PAF binding capacity of these cells was also doubled, owing to increased density of functional PAF-Rs, although no significant difference in the PAF-R affinity was noted. It was also shown that Kupffer cells substantially contributed to increased hepatic and circulating PAF levels in cirrhosis. Consistent with the receptor binding data, the mRNA expression of PAF-R was also significantly increased. Since previous studies have shown that PAF stimulated eicosanoid synthesis in Kupffer cells, the enhanced production of prostaglandin E_2 (PGE_2), a hepatoprotective eicosanoid, observed in this study suggested an autocrine loop of PAF action which limited liver injury. The second study confirmed and extended these results in the hemodynamics of cirrhosis[87]. Compared to control rats, cirrhotic ones presented higher hepatic and arterial blood PAF levels, elevated PAF-R mRNA transcription and protein expression levels and higher baseline portal pressure. PAF infusion caused an augmented increase in portal pressure, whereas administration of BN-52021 resulted in a significant decrease of portal pressure in cirrhotic animals, without influencing systemic arterial hypotension. In addition, increased PAF-R density was observed in the contractile perisinusoidal stellate cells from cirrhotic livers. These results suggested that elevated circulating PAF levels, derived mainly from liver tissue, largely contribute to portal hypertension which is further exacerbated by upregulation of PAF-Rs in the cirrhotic liver.

CONCLUSIONS

During the past two decades, the role of PAF in a number of physiological and pathophysiological processes has been extensively investigated and documented. The characterization of PAF-Rs and their attendant signaling pathways, involving a complex interactive network of cytokines, second messengers and autacoids, has further elucidated the extracellular and intracellular actions of this potent proinflammatory lipid mediator. Liver pathology appears to be directly related to PAF synthesis and release by local or systemic cellular sources. The implication of PAF in virtually all types of liver injury and regeneration has been well-established by numerous experimental and clinical studies. It has been explicitly shown that PAF is a major contributor to the initiation and prolongation of liver IR injury, liver graft dysfunction and various types of acute liver injury, while its involvement in cases of chronic liver injury is possibly more complicated due to interference of several other mediators. However, there remain many incompletely characterized or probably unknown aspects in regard to the crucial role of PAF in the regulation and modification of cellular responses to various endogenous and exogenous biological or biochemical stimuli. The effects of potent and specific PAF-R antagonists in experimental conditions associated

with liver injury have provided emerging evidence for their potentially beneficial use in the clinical setting. The need to establish standardized experimental, or even clinical, models for the evaluation of the role of PAF and its antagonism is imperative in order to limit the variability of current models and provide an accurate means for reliable comparisons. Moreover, the present review could ideally serve as a comprehensive basis for future reference in this intriguing field of research.

Abstract

AIM: To evaluate the treatment effect of percutaneous ethanol injection (PEI) for patients with advanced, non-resectable HCC compared with combination of transarterial chemoembolisation (TACE) and repeated single-session PEI, repeated single-session PEI alone, repeated TACE alone, or best supportive care.
