EDITORIAL

2641 Endoscopic therapies of gastroesophageal reflux disease
Iqbal A, Salinas V, Filipi CJ

2656 Reassessment of functional dyspepsia: A topic review
Chua ASB

TOPIC HIGHLIGHT

2660 Reassessment of functional dyspepsia: From the editor
Chua ASB

2661 Epidemiology of functional dyspepsia: A global perspective
Mahadeva S, Goh KL

2667 Subtypes of functional dyspepsia
Baker G, Fraser RJ, Young G

2672 Functional dyspepsia: The role of visceral hypersensitivity in its pathogenesis
Keohane J, Quigley EMM

2677 Role of *Helicobacter pylori* in functional dyspepsia
O'Morain C

2681 Central serotonergic and noradrenergic receptors in functional dyspepsia
O'Mahony S, Dinan TG, Keeling PW, Chua ASB

2688 Cholecystokinin hyperresponsiveness in functional dyspepsia
Chua ASB, Keeling PWN

2694 Drug treatment of functional dyspepsia
Mönkemüller K, Malfertheiner P

2701 Functional dyspepsia: Are psychosocial factors of relevance?
Barry S, Dinan TG

2708 Functional dyspepsia and irritable bowel syndrome, are they different entities and does it matter?
Gwee KA, Chua ASB

REVIEW

2713 Latest insights into the effects of *Helicobacter pylori* infection on gastric carcinogenesis
Murakami K, Kodama M, Fujioka T

2721 A concomitant review of the effects of diabetes mellitus and hypothyroidism in wound healing
Ekmektzoglou KA, Zografos GC

2730 Is interferon-beta an alternative treatment for chronic hepatitis C?

Abstract

The high prevalence of gastroesophageal reflux disease (GERD) in Western societies has accelerated the need for new modalities of treatment. Currently, medical and surgical therapies are widely accepted among patients and physicians. New potent antisecretory drugs and the development of minimally invasive surgery for the management of GERD are at present the pivotal and largely accepted approaches to treatment. The minimally invasive treatment revolution, however, has stimulated several new endoscopic techniques for GERD.

Up to now, the data is limited and further studies are necessary to compare the advantages and disadvantages of the various endoscopic techniques to medical and laparoscopic management of GERD. New journal articles and abstracts are continuously being published. The Food and Drug Administration has approved 3 modalities, thus gastroenterologists and surgeons are beginning to apply these techniques. Further trials and device refinements will assist clinicians.

This article will present an overview of the various techniques that are currently on study. This review will report the efficacy and durability of various endoscopic therapies for gastroesophageal reflux disease (GERD). The potential for widespread use of these techniques will also be discussed. Articles and abstracts published in English on this topic were retrieved from Pubmed. Due to limited number of studies and remarkable differences between various trials, strict criteria were not used for the pooled data presented, however, an effort was made to avoid bias by including only studies that used off-PPI scoring as baseline and intent to treat.

INTRODUCTION

Gastroesophageal reflux disease affects millions of people worldwide. The prevalence of heartburn in a randomly selected adult population is approximately 20%. It is estimated that approximately one third of the adult population in the United States suffers from heartburn[1]. Of these, approximately 7% have reflux esophagitis. The management of GERD has gained increasing attention during the past two decades due to a high prevalence in Western societies, a better understanding of the pathophysiology, new potent anti-secretory drug therapies, the advent of minimally invasive surgery and new transoral endoscopic therapies. We attempt to determine the true efficacy and benefit of these therapies. The relative advantage of one over the other is enlightened by objective comparison of study outcomes. The potential for use by clinicians in daily practice and the underlying mechanisms of action are also explored.

It is important to understand the pathophysiology of GERD although much controversy remains. The efficacy of the antireflux barrier at the GEJ is dependent upon three factors. These include the "lower esophageal sphincter complex", the geometric profile of the cardia and the changes within each as a result of gastric distension. Other factors such as gravity, intra-peritoneal pressure, esophageal motility and the mucosal barrier also play a role in reflux prevention. Reflux can be precipitated by a decrease in either the length or the pressure of the lower esophageal sphincter (LES) and/or obliteration or diminishment of the angle of His. Both these factors are present during periods of gastric distension. It is believed that transient LES relaxations (tLESR), i.e. intermittent spontaneous decreases in LESP, are responsible for reflux events in patients with a normal LES[2-5]. In the early stages of disease and in the absence of a hiatal hernia, the geometry and integrity of the cardia are normal. However, during periods of gastric distension such as after meals, gastric distension alters the anatomy and makes the sphincter incompetent due to sphincter shortening, which some term transient lower esophageal sphincter shortening (tLESS)[6]. Such patients appear to be the ideal population

[1]Recently some studies have included patients with a hiatal hernias > 3 cm and Barrett's esophagus.

Figure 1 Inclusion/exclusion criteria for endoluminal therapies of GERD.

for endoscopic antireflux procedures.

In the light of the above described pathophysiologic factors, endoscopic therapies should prevent reflux in the following ways; (1) alter the compliance of the cardia and prevent tLES shortening/relaxation, (2) increase baseline LES tone or (3) increase baseline LES length. None of the endoluminal therapies reduce the distal esophagus into the abdomen and effect a hiatal hernia repair.

The majority of patients with GERD are best treated by proton pump inhibitors (PPI's). However, symptom relapse is common after cessation of treatment[7] and lifelong therapy is often necessary. Even while on therapy, up to 33% of patients have recurrent symptoms within the first two years. Almost 50% of patients continue to exhibit objective evidence of acid regurgitation despite complete symptomatic control on PPI therapy. Although, a fundoplication is a good treatment option[8], laparoscopic anti-reflux surgery requires a general anesthetic, hospitalization, postoperative lifestyle limitations for days to weeks, is expensive and is associated with post-operative morbidity and even a mortality rate. In addition, patients may return to medical therapy[9]. These limitations created the need to develop less invasive but effective procedures. These procedures are listed here (1) Endoscopic Suturing devices: Endoluminal Gastroplication (ELGP/Endocinch); Endoluminal full-thickness plicator (NDO plicator); Syntheon ARD Plicator; (2) Radiofrequency energy delivery device: Stretta; (3) Synthetic Implants/Injections: Implantable biopolymer (Enteryx); Implantable Prosthesis (Gatekeeper); Implantable plexiglass microspheres (PMMA). Of these, 3 novel endoscopic therapies have been approved for use by the FDA. All procedures can be safely performed in an outpatient setting utilizing conscious sedation.

The general selection criteria that have been used in most trials are shown in Figure 1. In addition to this, specific patient selection, if any, is mentioned under the respective procedures.

ENDOLUMINAL GASTROPLASTY

Initially, Swain *et al* developed a mechanical aid which allowed passage of a needle and subsequent suture via the biopsy channel of an endoscope[10]. Later, the technique was modified to create plications endoscopically below and at the GEJ for the prevention of GERD.

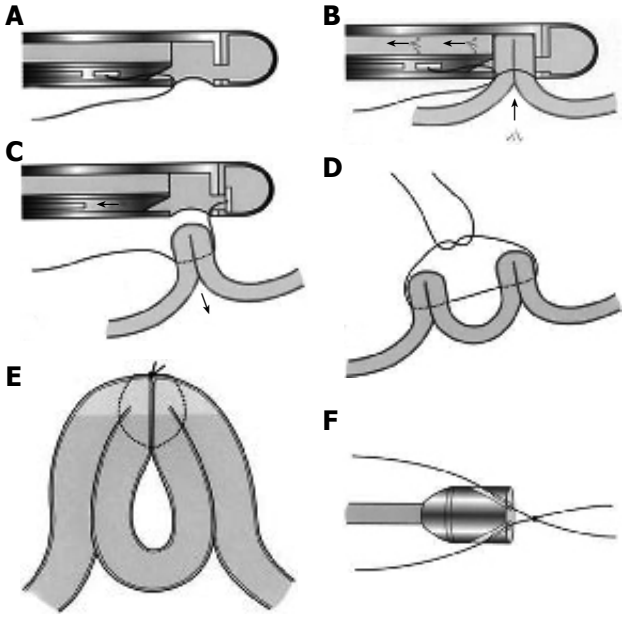

Figure 2 A: Drawing of the suturing device which is equipped with a vacuum chamber and a hollow needle in which there is a suture attached to a tag; **B:** Tissue is drawn into the chamber by suction. The needle passes through the tissue and the tag is captured in the distal chamber; **C:** The suction is then released; **D:** The procedure is repeated on an adjacent piece of tissue; **E:** On tightening the knot, the pieces of tissues are approximated; **F:** The knot, tied outside the animal, is advanced by a knot pusher which is attached to the tip of the endoscope.

Procedure

The procedure requires a suturing capsule, suture tags and an anchoring system that secures the suture and cuts the strands (Figure 2). A short, 18 mm-outer-diameter overtube allows repeated intubations (approximately 12) while avoiding trauma to the esophageal mucosa. Usually patients tolerate the procedure with conscious sedation. However monitored anesthesia or general anesthesia may be used as necessary. Two to four plications are placed either longitudinally (one above the other), radially (next to each other) or spirally within the cardia. Each plication is formed by two stitches that are placed into the gastric submucosa, approximately one centimeter apart and then pulled together. The procedure is completed within 40 to 60 minutes.

The application of cautery on opposing mucosal surfaces prior to plication may secure tissue apposition and promote long-term adherence. Its efficacy has been proved in pilot studies[11] and needs to be tested in a larger randomized controlled trial.

Efficacy

The overall results with ELGP are tabulated in Table 1. This is a pooled data obtained from 11 studies. Two multicenter trials are included in the table and will be highlighted. In the first trial 64 patients were randomized between a circumferential and a linear plication configuration[12]. All patients were dependent on anti-

[1]6 mo follow-up. None: Change not statistically significant. All results are at 1-yr follow-up except Gatekeeper. Highlighted cell indicate controversy regarding results but the results mentioned above are the ones shown by the majority of studies.

secretories and had proven reflux by 24-h pH monitoring. Manometry and endoscopy was performed to exclude patients with Barrett's esophagus, grade 3 or 4 esophagitis, large hiatal hernias and an esophageal dysmotility disorder. There was no difference found between the plication configuration groups and post-procedure manometry and endoscopy showed no improvement in LES pressure or grade of esophagitis. A significant improvement in heartburn and regurgitation scores from baseline was found but the pH monitoring results although significantly improved showed only a 30% normalization rate.

In a second multicenter study, 85 symptomatic GERD patients when off PPIs and with proven reflux on 24-h pH monitoring were included[13]. Upper endoscopy and manometry were also performed at baseline. Follow up was scheduled at 3, 6, 12, and 24 mo. Symptom scores and medication usage were assessed at each follow up and pH-metry was done at 3 mo follow up. This study was different from others with respect to their inclusion criteria as it included patients with esophagitis grade 3 ($n = 10$), hiatal hernia >2 cm ($n = 9$), Barrett' s esophagus ($n = 4$), failed fundoplication ($n = 3$) and those with pulmonary symptoms ($n = 10$). The majority of the patients had 2 plications performed (range, 1-3) and most had a circumferential plication (65%) with the remaining receiving a linear configuration (35%). Twenty-four-mo follow up data demonstrated durable functional improvement and a sustained reduction in anti-secretory medication. Heartburn scores were reduced at both 1 (94%) and 2 yr (78%) follow up. At 2 yr follow up, complete resolution for heartburn was seen in 52% of patients and 77% for patients with regurgitation. Likewise, PPI usage decreased with 69% of patients using <50% of their baseline medication and 41% were completely off PPI's at 2 yr follow up. The duration and number of esophageal acid exposures at 3-6 mo post-procedure were significantly reduced. There was no change in LES length or pressure when measured at 3 mo.

A sham-controlled, randomized, blinded single institution study ($n = 34$) is underway and 3 mo follow-up is available[14]. The study nurse and patients were blinded to the procedure performed. An overtube and 2 endoscopes were exchanged in all patients and the conscious sedation dosing was similar. Four circumferential plications were placed when performing the ELGP. At 3 mo follow up, heartburn frequency (69% *vs* 31%, $P = 0.03$) and severity (47% *vs* 17%, $P =$ NS) were improved in patients with ELGP in comparison to those with the sham procedure. A significantly greater number of patients discontinued their daily PPI/H_2B (75% *vs* 25%, $P = 0.03$) in the plication group. A significant reduction in % time pH < 4 was also observed, however, no difference was seen between groups regarding normalization of pH, median LESP or quality of life. Limitations of this study include a probable type II error, a larger than expected sham effect, inadequate follow-up length and lack of technique standardization. A randomized controlled trial of larger size with longer follow up is needed for objective evidence of durable benefit.

Other studies of note have demonstrated a markedly improved quality of life at one year follow up[15], reduction of the rate of tLESRs by 37% at 6 mo in a single-center study[16], in baboons[17] a significant increase in LES length, and Kadirkamanathan *et al* reported an increase in intra-abdominal, but not total, length of the LES after placement of three linear plications in dogs[10]. A double blind pilot study with 18 patients randomized to either ELGP alone or ELGP with cautery (10 in cautery group, 8 in no cautery group) showed numerically improved patient plication persistence, decreased esophageal exposure and improved symptoms at 1 year in the cautery group. However, the benefits were not sustained at 2-yr follow

Table 2 Procedure characteristics and complications: Pooled data

Variable		Endocinch	NDO Plicator	Stretta	Enteryx	Gatekeeper

up[11]. Plication persistence at 1 year was 37% in the cautery group *vs* 15% in the no-cautery group. Further studies are required to elucidate the efficacy of cautery with ELGP.

Changes in selection criteria

A significant improvement in symptom scores and pH study results has been observed in 19 patients refractory to medications, although, this improvement was less than that seen in other studies[18]. Short term studies suggest that ELGP can be used as an effective salvage procedure for failed surgical fundoplication[19,20], however, this indication requires further study.

Mechanism of action

The mechanism by which ELGP improves competence of the gastroesophageal junction remains unclear. Feitoza *et al* demonstrated lack of fusion between the folds when sutures were placed intra-luminally in the stomach of rabbits, irrespective of suture depth[21]. The symptomatic improvement can be explained by a lower volume of refluxate reaching the more "sensitive" proximal esophagus. The decreased volume might signify a decreased frequency of tLESR's, probably due to scar formation. Secondary scarring may also impair distensibility of the proximal stomach. This when combined with the fact that ELGP has been shown to stimulate localized circular muscle hypertrophy in both humans and animals[22] may lead to an increased basal tensile tone and increased resistance to gastric distension. This explanation does not negate, however, the deleterious effect of the acid within the distal esophagus and the chance for progression to complications such as stricture formation or even Barrett's esophagus.

Complications

Endoluminal gastroplasty is generally safe over long term follow up and free of serious immediate side effects. The major and minor complications are shown in Table 2. Esophageal perforations can occur. Two perforations have been seen so far, one of whom required a thoracotomy and the other hospitalization and antibiotics. To avoid a perforation, which is usually due to placement of a full-thickness suture within the esophageal wall, all stitches and plications should be placed below the squamocolumnar junction. If the suturing capsule needle does not retract after penetrating the tissue, the handle with pusher rod should be disassembled rather than pulling the capsule away from the esophageal wall. Occasionally, the suture loops and locks at the tissue level as the second stitch is being placed. The needle literally goes through a loop and the suture will not slide through the tissue on removal of the endoscope. In this circumstance the suture should be cut with an endoscopic scissors, however, this can be difficult and pull out may be necessary. If tissue accompanies the knot, it should be sent to pathology for frozen section analysis. If the muscularis propria is

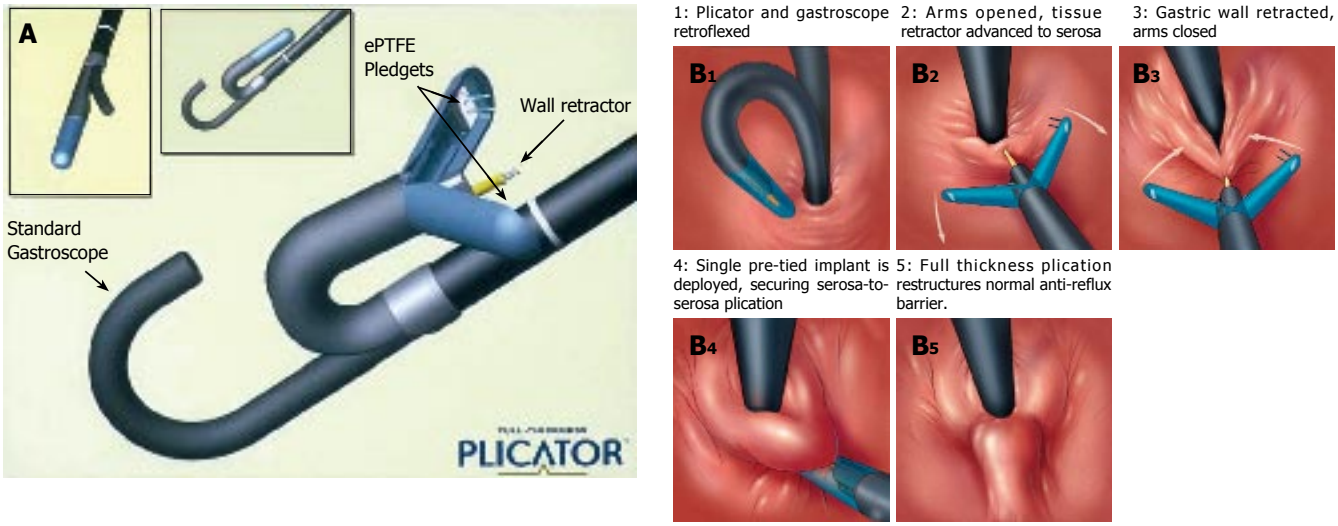

Figure 3 A: The NDO plicator mounted on a small diameter endoscope; **B:** Schematic representation of the procedure for application of a full-thickness plication by NDO plicator.

included within the specimen, an esophagram should be performed followed by hospitalization.

Procedure failure

Studies demonstrate that laparoscopic Nissen fundoplication (LNF) is feasible and effective after failed ELGP[23,24]. Patients should undergo upper GI endoscopy before surgery but suture removal is not necessary. No significant scarring or adhesions have been noted in the esophageal hiatus or inferior mediastinum at LNF. This may be due to the stitches not penetrating beyond the muscularis propria, as penetration of the serosa has been shown to induce more scarring[21]. This in itself might contribute to the lack of durability in post-ELGP results. Although the technique is initially effective, long-term symptom control has yet to be established.

Alternatively, patients who experience recurrent GERD symptoms post-ELGP may benefit from a second procedure. However, one study demonstrates a significant trend toward earlier onset of recurrent symptoms after repeat ELGP[25].

Advantages

Easy repeatability, short operative time, early discharge, no morbidity and symptomatic improvement make ELGP an attractive option. Endoscopic gastroplication has proven short term efficacy and has been demonstrated to be cost-effective for one to two years[26].

Disadvantages

The absence of objective improvement after ELGP is disconcerting. No studies have shown improvement in LES pressure or length and grade of esophagitis. pH monitoring results are mixed but the rate of normalization is only 30%-40% between studies. Several studies have compared ELGP with LNF[27-29]. Comparable improvement in symptom scores, reduction in PPI intake and QOL assessments has been seen, however, surgery is superior to ELGP in patient satisfaction and objective improvement in reflux.

Recently, Chang *et al* showed that ELGP with cautery did not improve LESP, Gastric yield volumes, pressures or GEJ compliance in a porcine model, however, limited sample size ($n = 5$) precludes definitive analysis[30]. Lack of durability is another reason for concern as shown by many authors. Lepoutre *et al* reported loss of 51% plications in 60 patients at one year follow up[31].

The optimal configuration for plications is not known. In a small and unfortunately underpowered study by Davis *et al* 22 patients with proven GERD were randomized between a helical and circumferential plication pattern. No difference in outcome was observed between configurations at 18 mo although a trend in objective results favored the helical pattern[32]. At 18-mo follow up, only 15% of patients being asymptomatic and off antisecretory medication. The prevalence and persistence of these possible advantages are currently subject to investigation. Increasing the number of plications, when using the helical pattern, did not show a significant benefit at either 6- or 12- mo follow-up[32].

ENDOSCOPIC FULL-THICKNESS PLICATOR

Current endoscopic suturing techniques usually involve submucosal suture placement, which may limit potential procedure-related complications but may also lead to early suture dehiscence and loss of long term efficacy. This problem may be theoretically solved by full thickness suturing or stapling devices, which include pledgets. Such an approach may, however, increase the risk of subsequent perforation. A novel technique of applying a full-thickness plication endoscopically has been developed and recently underwent clinical study in a U.S. multicenter trial. Selection criteria were similar to that shown in Figure 1.

Procedure

The (NDO) plicator (Figure 3A) is designed to apply a full thickness pledget reinforced U stitch tissue near the

GE junction with serosa to serosa apposition. The system consists of a reusable instrument and a single-use suture-based implant. Additionally, a proprietary endoscopic tissue retractor and a 5 mm diameter endoscope are used to perform the procedure[33]. The tissue retractor is designed to engage the deep gastric wall, allowing for creation of the serosa to serosa plication.

With the patient under conscious sedation, a gastroscope is passed into the stomach for endoscopic inspection and passage of a guidewire. The gastroscope fitted with the plication device is passed into the stomach over the guidewire. The suture applicator is retroflexed and properly positioned under endoscopic vision. The endoscopic tissue retractor is then inserted to within 1 cm of the GE junction and advanced to the level of the serosa which is judged by visible tenting of the tissues around the entry point of the retractor. The gastric wall is then retracted and instrument arms are closed upon it. The pre-tied implant is deployed to secure a full-thickness plication. The tissue retractor is removed from the greater curvature side of the GEJ, the jaws opened and entire assembly is removed from the stomach followed by removal of the overtube (Figure 3B 1-5). The approximate procedural time is 15-20 min.

Efficacy

Pooled results for NDO plicator are shown in Table 1. A multi-center study enrolled 64 patients with symptomatic GERD who were dependent on antisecretory medication and showed evidence of esophageal acid exposure (pH-metry) without an underlying motility disorder. Follow up was completed at 1, 3 and 6 mo post-procedure. It showed a significant reduction in GERD symptom scores, medication usage and esophageal acid exposure on 24-h pH-study, which persisted at one year follow up. No significant changes in esophageal manometry were noted[34]. At 6-mo follow up, there was a 63% symptom score improvement with elimination of PPI therapy in 74% and normalization of pH in 30% patients. No patient required re-treatment during the 6-mo follow up. In this initial trial, one full thickness plication was used. A pilot study on 7 patients also showed similar results but failed to show objective improvement of reflux[35]. Further studies with single *vs* multiple plications are anticipated. No sham controlled trial has yet been completed but one is being organized.

Mechanism of action

This procedure aims at inducing fusion of the opposed gastric tissue and thereby reducing distensibility at the GEJ. Feitoza *et al*[21] showed maximal fibrosis with incorporation of serosa in the plication when compared to other depths of suture plication. Theoretically, the suture retention rate and thus, durability of results should also improve. Lengthening of the intra-abdominal segment of the LES[33] is expected.

Complications

The most common complication was sore throat (spontaneously resolving within several days post-procedure).

Figure 4 Syntheon device.

One gastric perforation did occur during the multi-center trial and was managed conservatively.

SYNTHEON ARD PLICATOR

This is a promising new endoluminal suturing/compression implant device that has the capacity to place two titanium plications at once, thus, decreasing technical variability between operators (Figure 4). The distance between the two stitches is pre-determined. The plications are removable within the first 48 h. Withdrawal of the device is not necessary after each stitch which may decrease the procedure time and anesthesia related complications. Implantation is performed using a standard endoscope and no overtube is required. The mean procedure time is 21 min. Initial results show the device to be safe and time-efficient. An expanded multicenter pivotal phase I study is ongoing and will help clarify the procedure results.

Efficacy

The results of feasibility trials involving 8 patients with symptomatic GERD, abnormal pH scores, normal motility and responsiveness to daily PPI use have been published. Patients with large hiatal hernias (>2 cm), esophagitis (grade II or more) and Barretts esophagus were excluded. At 6 mo follow up, 75% were off PPI's, 68% improved GERD-HRQL score and 40% improved GSRS:GERD score. However, 24-h pH and manometry showed no significant improvement. (S1199)

Complications

Serious complications have not been encountered. Minor adverse effects seen to date are sore throat, epigastric/referred chest pain and the gas bloat syndrome.

THE STRETTA PROCEDURE

Radiofrequency energy (RFe) has been extensively utilized in medicine since 1921 and is currently being used in the treatment of benign prostatic hypertrophy, cardiac arrythmias and metastatic liver lesions. The possibility of RFe being used for GERD therapy was explored after successful treatment of snoring and sleep apnea.

Patient selection

Radiofrequency augmentation of the LES has been widely used. Over 3500 procedures have been performed in the United States alone. The indications in the past have

been confined to patients with early reflux disease. The Stretta procedure may have specific utility in morbidly obese patients, those with a previous gastric resection, a gastric bypass, after a failed LNF[36] or as an alternative to re-operation after fundoplication disruption. In a porcine fundoplication disruption model, fluoroscopic guidance improved RF lesion accuracy therefore it has been suggested that fluoroscopic guidance be utilized to ensure probe placement[37]. Patients with failed anti-reflux surgery and subsequent RF therapy have experienced non-significant symptomatic improvement (heartburn score from 3.33 pre-procedure to 2.75 post-procedure), however, patient satisfaction scores are significantly improved[38]. The role of the Stretta procedure in postoperative fundoplication patients remains unclear.

Procedure

The Stretta catheter (Figure 5A) is a flexible, handheld, disposable 20F Savary-style dilator that is used in conjunction with the Curon (Sunnyvale, California) control module. It is comprised of a balloon basket assembly, 4 nickel titanium electrodes, suction and irrigation. The balloon basket deploys 4 radially arranged electrodes into the smooth muscle of the GE junction. Tiny thermocouple temperature sensors within the electrodes provide temperature feedback to the radiofrequency generator. A target temperature is pre-selected and the power is automatically discontinued if the temperature exceeds the predetermined threshold. The needles also provide feedback on impedance which allows the operator to know if the needles are positioned correctly into the tissue.

Under conscious sedation, the catheter is placed over the guidewire into the stomach and withdrawn to the position of needle deployment. After removal of the guidewire, the balloon at the distal end of the catheter is inflated, the electrodes are deployed and RF is applied for a specific period of time while monitoring the temperature and impedance levels (Figure 5B). A first treatment ring of 8 lesions is created by rotating the catheter 45° and repeating the same. Four such antegrade rings, each with 8 lesions, are created at 0.5 cm intervals to a distance of 1cm below the GE junction. Two further gastric "pull-back" rings, of 12 lesions each (3 sets of deployment each), complete a set of thermal lesions (Figure 5C). Halfway through the procedure, an endoscope is reintroduced to verify the location of treatments with subsequent adjustment distally or proximally to prevent superimposition of lesions. Following recovery, patients continue their usual anti-reflux medication for 3 wk. A modified technique has been proposed in the presence of a large hiatal hernia (>3 cm) or a failed Nissen fundoplication[39]. The modified technique creates 6 anterograde treatment levels instead of 4, beginning 1 cm above the squamocolumnar junction with 5mm between levels and placing 2 sets of lesions at each of the 4 proximal levels and 3 sets at the distal 2 levels.

Efficacy

In the initial US open label trial[40], one year follow up showed a significant decrease in symptom scores. Gastro-esophageal reflux disease-specific quality of life satisfaction scores and distal acid exposure were significantly improved over the baseline on-medication scores as well. However, normalization of pH monitoring scores did not occur in the majority of patients. In addition, LES pressures did not increase and esophagitis did not improve significantly at 6 mo endoscopic follow-up.

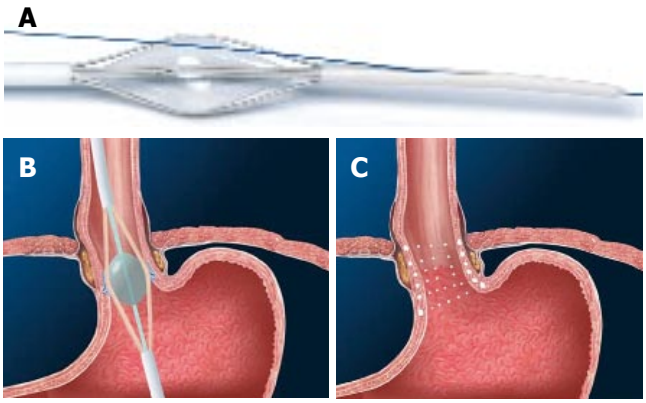

Figure 5 A: The Stretta catheter with guidewire; **B:** The balloon assembly with struts and electrodes extending into the muscularis propria; **C:** A total of 56 lesions are applied as seen in this diagram.

The sham-controlled trial[41] showed significant improvement in symptom scores and quality of life at 6 and 12 mo, but at 6 mo there was no difference between groups in medication usage. Esophagitis grade did not show improvement, and in fact grade 2 esophagitis increased in severity in both groups. Similarly, pH scores also failed to show significant improvement, unlike the previous uncontrolled studies[40,42]. The explanation for these findings may be altered sensitivity of the distal esophagus or unusual persistence of the sham effect.

In a registry series[43], 558 patients underwent the Stretta procedure and showed a significant improvement in GERD symptom control (from 50% to 90%) and patient satisfaction (from 23% to 86% at a mean follow up of 8 mo. The onset of GERD relief was in less than 2 mo in most patients (69%). The treatment effect was durable beyond 1 year and most patients (51% at one year *vs* 96% pre-procedure) were off all antisecretory drugs at follow-up. Most studies are limited to short term follow up (up to 12 mo). For the first time, Torquati *et al* reported long term results in 41 patients with 83% being highly satisfied at a mean follow up of 27 mo[44]. Proton pump inhibitor usage was discontinued in 56% patients and was significantly reduced in 87%. Similarly, Reymunde *et al* demonstrated significant and sustained improvement in anti-secretory drug discontinuation (88%), GERD symptom scores (82%) and QOL scores (44%) at more than 3 years of follow-up[45]. This is encouraging evidence and suggests that durability of results is the distinguishing attribute for the Stretta procedure.

Significant improvement in symptom scores and quality of life have also been observed in shorter term studies[40,43,46,47]. Similarly, decreased PPI use and increased patient satisfaction have been consistently seen[46,40,47]. Most studies fail to demonstrate a beneficial effect of Stretta

on esophagitis but Triadofilopoulos *et al*[42] showed an improvement in esophagitis grade, from 21% with grade 2 esophagitis to 9.3% post-procedure in 43 patients at 6 mo. The role of Stretta in improving extra-esophageal manifestations of GERD is still not clear, however, one study[36] suggests that respiratory benefit can be achieved if strict patient selection (abnormal pH study) is followed. Pooled results are shown in Table 1.

Mechanism of action

Multiple changes may be responsible for the effect seen in the Stretta procedure. First, a mechanical alteration and thickening of the LES musculature leads to diminished reflux, as shown in the canine model[48]. Secondly, progressive tissue remodeling and scar formation observed after Stretta could contribute to the decreased compliance and an increased tensile strength of the GE junction which also exerts its effect in decreasing tLESRs. This decrease in tLESRs has been shown in both animals and humans[48,49]. Histologically normal muscle with occasional focal areas of collagen deposition at 8 wk follow up has been shown in the porcine model.

The disparity between symptomatic improvement and acid exposure seen in the sham trial was surprising and might be explained by a residual sham effect on symptoms or altered visceral sensitivity[41]. The later would explain the striking dichotomy between symptom relief and minimal to moderate improvement in acid reflux profiles. A diminished sensitivity may be due to destruction of chemosensitive or mechanosensitive nerve endings[50]. However, some studies contradict this contention[44] by showing significant improvement in pH results at 27 mo in patients who had responded to therapy.

Complications

The major and minor complications are shown in Table 2. The 5 perforations and 2 deaths occurred during the learning curve and were due to poor patient selection and technical errors. No major complications were seen in the multi-center trial and subsequent studies have not shown adverse effects on vagal nerve function or gastric emptying. The complication rate after Stretta has been $<0.6\%$ since the introduction of the new technology and 0.13% in the last 12 mo.

Recommended precautions

Operators should check the position if abnormal impedance/temperatures are observed, use correct balloon pressures, control the mucosal temperature carefully, minimize balloon pull back pressure and avoid NG tube placement for one month post-procedure

Alternatives after treatment failure

In the US open label trial, 5% of the patients elected to undergo fundoplication 6-12 mo after Stretta due to incomplete or recurrent symptom response. In each case, there was no evidence of extra-esophageal tissue abnormality and the anti-reflux operation was performed in a normal manner and without difficulty. Richards *et al*[36] compared the outcome of patients who had the Stretta procedure and a laparoscopic fundoplication at 6 mo and found a comparable and significant improvement in QOLRAD, SF-12 and pH scores in both groups. However, medication usage was significantly less in patients who had surgery (97% *vs* 58% off PPI's). Both groups were highly satisfied with their procedure. A repeat Stretta procedure is not recommended.

ENTERYX

Enteryx consists of a biocompatible polymer (80 g/L EVOH with a radioopaque contrast agent dissolved in an organic liquid carrier [DMSO]). Upon contact with tissues or body fluids after injection, the solvent, DMSO, rapidly diffuses resulting in precipitation of the polymer (EVOH) as a spongy mass. It is not biodegradable and has no antigenic properties. Migration through blood vessels or lymphatics nor prosthetic contraction after injection have been observed[51].

The three components of Enteryx, ethylene vinyl alcohol polymer (EVOH), dimethyl sulfoxide DMSO, and tantalum, have been previously used together medically as a vascular embolization agent and a membrane for hemodialysis and plasmapheresis.

Patient selection

Enteryx is a treatment with promise but, like other endoluminal therapies, is lacking objective supportive data. Patients must understand that the procedure is irreversible[52]. The possible future indications for Enteryx include primary therapy for GERD in patients who respond to PPI's but prefer not to take medications daily, salvage therapy for PPI responders to reduce or eliminate daily medications and salvage therapy for surgical failures[52]. Recently, Enteryx has been attempted in pos-fundoplication patients[53].

Enteryx therapy is clearly contraindicated in any individual who does not have physiologically documented GERD by pH study or endoscopic findings. It is also contraindicated in individuals who cannot undergo or tolerate endoscopy and those who have esophageal varices. There is no reported experience with this procedure in individuals with esophageal motility disorders, prior gastric or GERD surgery, scleroderma, Barrett's esophagus, hiatal hernias >3cm, BMI >35 or patients who use anticoagulants other than aspirin[52].

Procedure

The procedure is performed in an endoscopy suite equipped with fluoroscopy under conscious sedation. A long needle catheter is filled with Enteryx after it has been flushed with DMSO, to keep it liquefied as long as it stays within the catheter. The prepared injection needle is placed into the muscularis propria at the appropriate level of the esophageal wall. The prosthesis is injected at a rate no greater than 1mL/s under combined fluoroscopic and endoscopic guidance (Figure 6). The EVOH solidifies within the esophageal wall as the generated heat causes DMSO to dissipate. The injection is stopped if either a submucosal or transmural injection is observed. Submucosal accumulation of material is seen endoscopically as a black bulge and an extramural

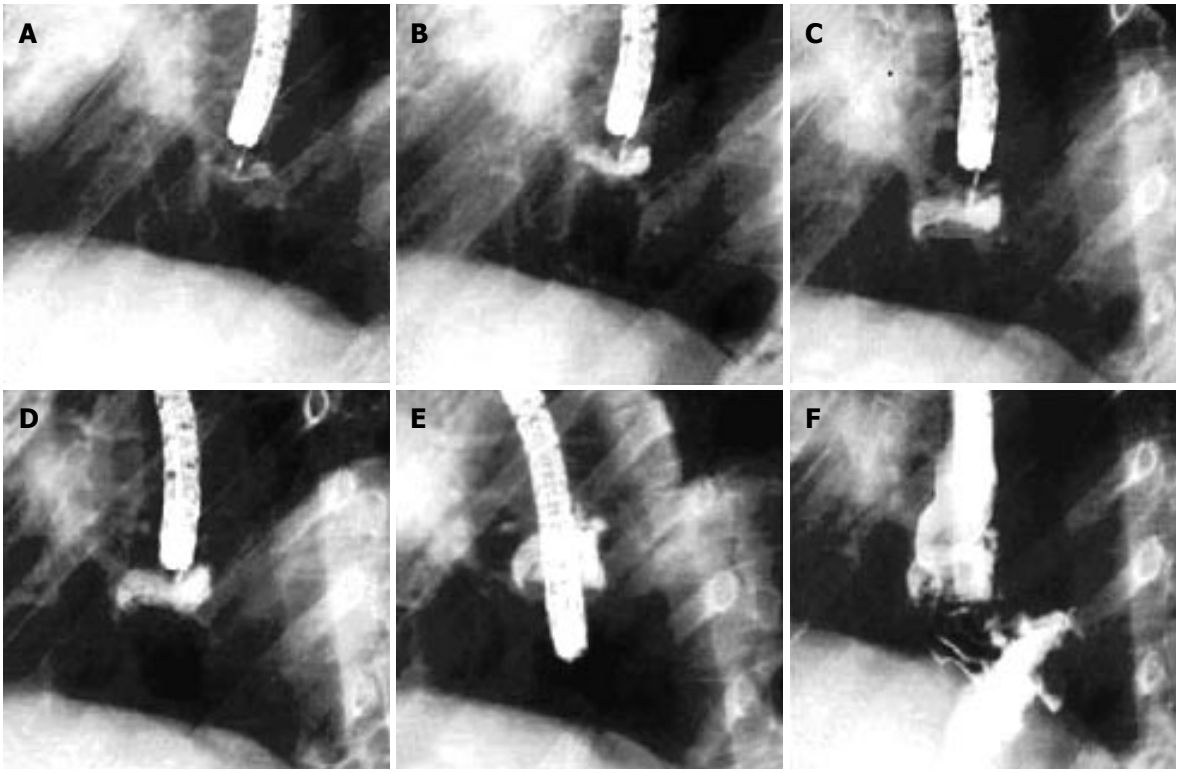

Figure 6 Enteryx injection under fluoroscopic control with a resultant prosthetic cuff.

injection is demonstrated on fluoroscopy as either flow of material beyond the muscularis into the mediastinum or the abdominal cavity, or lack of a visible deposit in the esophageal wall. If a circumlinear transverse path of material is visualized under florosocopy, the injection is completed at this stie using a total of 1 to 2 mL. The procedure is considered satisfactory if 6 to 8 mL of Enteryx is delivered to the muscularis propria circumferentially without a submucosal or transmural injection. After the injection is complete at one site, the needle remains in place for 20 s allowing the material to stabilize and solidify. This maneuver prevents leakage of the prosthesis into the esophageal lumen. Patients are usually discharged 2 to 4 h after recovery.

Robert *et al* reported Enteryx implantation in 5 pigs without the use of fluoroscopy. Enteryx was consistently deposited into the deep esophageal wall with a high degree of accuracy in a minimal amount of time. The placement was accurate in 85% and was transmural in just one instance. A human trial is underway to confirm these findings[54].

Efficacy

Enteryx implantation significantly improves the QOL scores and medication usage[51,52]. No change has been seen in the severity of esophagitis at endoscopy after Enteryx implantation. In general, the structural characteristics of the LES, including its length and pressure, are not altered significantly. Pooled results are shown in Table 1.

The 2 year follow up results of this U.S multicenter trial, which included 85 patients, were recently published[55] and showed PPI use to be eliminated in 74% of patients at 6 mo follow up. This effect was maintained in 64% of subjects at 2 years while 74% were maintained on less than half of their baseline PPI dosage. The improvement in symptom scores was 82% at 6 mo and 70% at 2-yr. Quality of life (SF-36) questionnaires demonstrated an improvement of 6% from baseline at 3 mo and 3% at 12 mo for the mental score while the improvement in the physical score was maintained at 12% at both 6 and 12 mo follow up. pH scores improved with 30% normalization and there was a small but significant LES length augmentation (1 cm) following therapy[56]. No significant change in LES pressure was observed. The absence of change in LES resting pressure contrasts with findings from the pilot study, in which a significant increase in the LES pressure was observed at 6 mo. This may have been due to the inclusion of patients with a normal LES pressure at baseline or the smaller sample size in the pilot study. Importantly, most of the decline in treatment responders during follow-up occurred between 1 and 6 mo. Between 6 and 12 mo, the proportion of treatment responders remained stable. There was no evidence that the reduction in PPI usage after the implant procedure was due to medication shifting.

The decline in residual implant volume seen after one month was attributable to sloughing of superficially implanted material until encapsulation was complete. There was no radiographic evidence of implant migration and after 3 mo, residual volume remained stable ($P > 0.1$)[57]. Twenty two percent of patients were re-treated at 3 mo follow up of which, 63% improved at 12 mo follow up with 58% completely off PPI's and 5% of patients reducing their PPI usage by more than 50% of baseline[56].

The multicenter randomized controlled sham trials with "cross-over" option starting at 3 mo post-randomization are currently underway in both Europe and the United States[58]. An interim report on 56 out of the 64 total

European patients has been announced with 3 mo follow up. An improvement in GERD HQRL was seen in 65% patients in the Enteryx arm *vs* 21% in the sham arm. The median change in symptom scores was 15 for the Enteryx group and 4 for the sham group. There was also a greater reduction in PPI usage (64% *vs* 33%) and a lower cross-over/re-treatment incidence (21% *vs* 71%) in the Enteryx group when compared to the sham group. Criteria for both cross over (for controls) and re-treatment (for the Enteryx group) were the same i.e. an off-PPI HQRL score >15[58].

Johnson *et al* reported that the likelihood of a successful clinical outcome is higher with more residual implant volume. He showed that all patients who retained $\geqslant 5$ mL of implant material eliminated or reduced PPI use by $\geqslant 50\%$ and the majority of subjects who retained >5 mL of Enteryx achieved a GERD-HRQL score of <15. Lehman *et al* reported the procedure to be equally effective irrespective of the radiologic pattern evident at the time of implantation[59]. In a study evaluating predictors of outcome for Enteryx, Deviere *et al*[60] showed there was no statistically significant difference in PPI usage or pH outcome by gender, but GERD-HRQL symptom scores were significantly more likely to improve in males (86%; 57/66) than in females (67%; 32/48) ($P=0.01$). Finally, Ganz *et al* compared the endoscopic findings of patients from the multicenter study at 1 yr follow up with their baseline values (on PPI's) and reported that treatment with Enteryx provided improvement in esophagitis scores comparable to that provided by PPI medication[61]. This finding, however, has not been supported by other studies. A pilot study determining the efficacy of Enteryx in post-fundoplication patients ($n=19$) and reported no apparent difficulty due to the distorted anatomy during the procedure. Post-fundoplication patients with refractory symptoms on high dose PPI therapy were enrolled and 'improvement' was seen in 89% of patients, however, this study primarily addressed the technical feasibility rather than the efficacy of post-fundoplication Enteryx implantation[53].

Mechanism of action

Both gross and histological examination in animals have shown that the implants persist as encapsulated, firm, smooth, slightly mobile ovoid masses, several weeks after implantation. No evidence of pathologic inflammatory changes in the surrounding tissues have been observed. However, the implants lead to a significant increase in the yield pressure and yield volume with a raised threshold for transient relaxations after implantation[6].

Fibrous encapsulation may functionally lengthen the LES. The encapsulation/scarring is the probable mechanism of effect but the exact mechanism in humans remains to be fully characterized. The "bulking" effect, seen with some injectable treatments for urinary incontinence, is not apparent for Enteryx because follow-up endoscopies reveal no evidence of luminal narrowing. Sloughing of superficially injected material may be the reason for inadequate clinical outcome and lack of durability seen in some patients[57].

Complications

The complications are shown in Table 2. Recently, one death was reported in a patient due to inadvertent injection of Enteryx into the aorta. Further details are not yet available. Two patients experienced a pericardial effusion after injection of the prosthesis and subsequently underwent a pericardial window. Two additional patients developed a pleural effusion but no other problems were recognized. Although, the cause of the effusions is not clear, extension of an inflammatory process from the esophagus to the surrounding structures namely pericardium and pleura and the possibility of an allergic or infectious process cannot be ruled out.

Recommended precautions

All operators are required to receive hands on laboratory training prior to clinical utilization. Injection techniques when using fluoroscopy are emphasized and guidelines for prostheses preparation are given. Most centers place patients on a liquid diet followed by a soft diet, the day of the procedure followed by normal diet the day after. Maintenance therapy with PPI's is continued for 10-14 d after implantation.

GATEKEEPER

Gatekeeper is a dehydrated hydrogel prosthesis implanted into the submucosa of the cardia/LES. It hydrates to 6 mm × 15 mm cylinder shaped soft pliable cushions and is removable by endoscopy[62].

Patient selection

In addition to the general selection criteria already described, patients with esophageal varices, a peptic stricture and morbid obesity were excluded from the trials for Gatekeeper.

Procedure

The Gatekeeper device consists of an overtube with separate channels for passage of an endoscope and a long delivery sheath (Figure 7). After placement of the overtube, the injection capsule is placed through the overtube to straddle the squamocolumnar junction. A vacuum is created to stabilize the device and to draw the mucosa in. The injection needle is advanced into the submucosa followed by injection of 3-6 mL of sterile saline until blanching is observed. This is followed by removal of the injection needle and advancement of the needle assembly and the delivery sheath into the mucosa, leaving the delivery sheath in the submucosal plane. After the needle assembly has been retracted, the prosthesis is inserted into the proximal end of the delivery sheath and advanced to the submucosal level using a pushrod assembly. Up to 6 hydrogel implants are placed. The implants are small and "sliver"-like when introduced but swell to full size within 24 h, when hydrated.

Efficacy

In a limited number of patients the Gatekeeper procedure has been shown to significantly decrease heartburn,

improve quality of life, 24-h pH-metry scores and decrease medication usage[63]. The success rate for implantation is 93% while the procedural success rate was reported at 98.7%[64]. Pooled results for Gatekeeper are shown in Table 1.

After completion of a 6 mo pilot study[65] with favorable results, a European multicenter study was initiated[66]. Patients underwent manometry, endoscopy, 24-hr pH-metry and symptom scoring before and after the procedure. The average number of prostheses implanted was 4.3 (2-6). Final results showed significant improvement in symptom scores (HRQL score from 24 to 5), quality of life, pH parameters (% time pH < 4, 9.1% to 6.1%) and LESP (8.8 to 13.8 mmHg) at 6 mo[64]. The prosthesis retention was 70% at 6 mo. Other studies with smaller numbers of patients have failed to show significant improvement in LESP, however, symptom scores and pH results show consistent improvement[63,66].

An international, prospective multi-center (US/European) randomized, sham-controlled Gatekeeper trial has recently commenced[67]. One hundred and forty four patients with symptomatic GERD dependent on PPI with evidence of reflux on 24-h pH study and a symptom score of > 20 off medications are being included in the study. Patients with Barretts esophagus, hiatal hernia > 3 cm, esophagitis (garde II or higher), stricture formation, varices or prior antireflux surgery will be excluded. Randomization will be attempted with a sealed envelope at a rate of 2:1 implant *vs* sham. Four implants will be placed circumferentially in the distal LES/cardia with re-treatment offered to individuals if GERD symptoms persist. Sham patients will be offered Gatekeeper therapy at 6 mo. Patients will take anti-secretory medications on a PRN basis. Outcome parameters are HRQL, esophagitis, medication use, 24 hr pH monitoring and implant persistence. To date, 52 subjects have been enrolled and randomized, 21 of whom have been implanted. Enrollment completion is anticipated in April, 2005[68].

Mechanism of action

The mechanism of action is probably similar to Enteryx in addition to bulking. The prosthesis narrows the lumen as seen at 6 mo follow-up endoscopy and is self contained.

Complications

The complications reported at 6 mo follow-up are shown in Table 2[64]. In the largest multicenter study, 2 out of 40 patients (5%) developed severe complications which included esophageal perforation caused by overtube placement and severe postprandial nausea (1 wk post-procedure) leading to endoscopic removal of the prosthesis at 3 wk[64].

Advantages

The Gatekeeper prosthesis is removable by endoscopic means. A needle knife can be used to incise over the edge of the implant which is then suctioned from its submucosal pocket[62]. Endoscopic ultrasound may be used for exact localization of the prosthesis. Of note, one of the two patients who had the prostheses removed was 7 mo post-procedure. All 3 prostheses were removed in the other patient, 3 wk post-procedure. No complication was encountered with either patient.

PLEXIGLASS

A trial of gelatinous plexiglass (polymethylmethacrylate, PMMA) microsphere implants has been published by Feretis *et al*[69]. A mean volume of 32 mL was implanted submucosally, 1-2 cm proximal to the squamocolumnar junction, in 10 patients with a 21-gauge needle. Transient dysphagia was noted in one patient due to excessive implant volume. At a mean follow-up of 7.2 mo, there was significant improvement of GERD-related symptoms and 24-h pH-studies (decreased from 24.5 to 7.2) but pH normalization was not seen. Ninety percent of patients were completely off PPI's at 6 mo follow-up. The procedure was found to be safe at short term follow-up.

Minor and self-limited complications occurred in 4 of 10 patients (40%). Transient dysphagia and the gas-bloat syndrome (10%) were thought to be due to excessive treatment with an implantation volume of 39 mL. The plexiglass injection was not associated with local or systemic complications and is not antigenic. Polymethylmethacrylate (PMMA) is highly viscous and

therefore a sigmoidoscope with a larger biopsy channel that accommodates a large caliber catheter was used for implantation. Longer follow-up studies are needed[69]. A multicenter study is currently being planned.

In addition, to these bulk-forming implants, injection therapy with sclerosing agents which induce focal necrosis and fibrosis similar have been tried. Sodium Morrhuate was used in 15 refractory GERD patients but after a year of follow up, the authors concluded that the therapy was ineffective[70].

COMBINATION THERAPIES

The use of endoscopic therapies after a failed fundoplication has been seen with ELGP, Stretta and Enteryx and their preliminary results have been discussed above. A combination of two different endoscopic therapies may be a solution to the lack of durability and objective benefit seen with these procedures. Anderson reported results of a pilot study done on 5 patients who were symptomatic and had radiological or pH probe evidence of reflux after prior ELGP procedure. These patients underwent Enteryx implantation and 3 of the 5 patients were off medication (60%) at a mean follow up of 7.6 mo. Transient dysphagia was seen after implantation in two patients but no major adverse effects were observed. Larger studies with longer follow up and objective documentation of improvement will help elucidate the efficacy of the combination approach[71].

Summary

The endpoints studied in most of the trials are GERD symptoms scores (HRQL), medication usage, manometric findings, grade of esophagitis and 24 hr pH-study results. In general, the procedures are safe with 3 deaths in 9000-10 000 cases. At present, the overall complication rate reported for ELGP, Stretta, Enteryx and Gatekeeper is 11%, 6%, 6.7% and 15% respectively[64]. All studies, to date, allow use of PPI's and most gauge success by the number of patients decreasing PPI dosage and symptomatic improvement. Meaningful conclusions cannot be made in this instance. There is evidence of symptomatic relief with decreased medication usage but with failure of an increase in LES length and pressure, healing of esophagitis and improvement in pH scores. An overview of the procedure for different endotherapies for GERD is shown in Table 2. A comparison of results in patients with Endocinch, Stretta and Enteryx at various follow-up intervals is also depicted in graphic format (Figures 8A-D).

In conclusion the scientific community needs to wait

for industry-independent trials showing endoscopic and 24 hour pH monitoring follow-up data that establishes long term efficacy and prolonged symptomatic benefit. Cost-effectiveness and post-marketing documentation of complications will better define the "true" role of these procedures in the management of GERD patients.

Abstract

Dyspepsia itself is not a diagnosis but stands for a constellation of symptoms referable to the upper gastrointestinal tract. It consists of a variable combination of symptoms including abdominal pain or discomfort, postprandial fullness, abdominal bloating, early satiety, nausea, vomiting, heartburn and acid regurgitation. Patients with heartburn and acid regurgitation invariably have gastroesophageal reflux disease and should be distinguished from those with dyspepsia. There is a substantial group of patients who do not have a definite structural or biochemical cause for their symptoms and are considered to be suffering from functional dyspepsia (FD). Gastrointestinal motor abnormalities, altered visceral sensation, dysfunctional central nervous system-enteral nervous system (CNS-ENS) integration and psychosocial factors have all being identified as important pathophysiological correlates. It can be considered as a biopsychosocial disorder with dysregulation of the brain-gut axis being central in origin of disease. FD can be categorized into different subgroups based on the predominant single symptom identified by the patient. This subgroup classification can assist us in deciding the appropriate symptomatic treatment for the patient.

Functional dyspepsia (FD) is a heterogeneous disorder of yet unknown etiology. It is commonly encountered both in the primary practice as well as the gastroenterological outpatient clinic. Though never life threatening, FD has important social and economic implications. It is an important cause of job absenteeism and a major burden on health care services. The review article by Sanjiv and Goh[1] in this topic highlights reported that 20% of patients would have consulted either a general practitioner or a gastroenterologist, 50% would be on medications most of the time, 30% would have days off work or schooling and there is a definite reduction in the quality of life. They also maintain that proper epidemiological studies on dyspepsia is plagued with problems without agreed definitions on "dyspepsia", but the recent definition based on the Rome II working committee report has helped. It is also important to distinguish between the patients who present with dyspepsia that is uninvestigated (UD) and the true functional dyspeptics. Prevalence rate of UD varies across the world depending on the definition of dyspepsia used. When Rome II criteria were used, studies showed that approximately 25% of people in the community complain of UD. For FD the rates are still quite variable depending on the geographical background, varying from 11.5% to 29.2%.

Majority of patients with a diagnosis of FD continue to be symptomatic over long period of time despite periods of remission. Approximately one-third of the patients lose their symptoms spontaneously. Only some dyspeptics present for medical care, in the United States and United Kingdom 1 in 4 will consult but the figure is higher in Australia. Severity of pain and anxiety over the possibility of serious diseases are factors associated with consulting behaviour. In their review the authors also considered various risk factors that may be associated with UD or FD. It appears that being a female and having underlying psychological disturbances will predispose one to having FD. On the other hand, smoking, caffeine intake, poor socioeconomic status and NSAID (non-steroidal anti-inflammatory drugs) ingestion placed one at risk from developing UD.

Does the ubiquitous bacterium, *Helicobacter Pylori* (*H pylori*) have any role to play in FD? Most authors will agree that the evidence is still unclear and most *H pylori* eradication trials in FD have been badly designed and gave conflicting results. However in the reviews by both O'Morain and Malfertheiner[2,9], evidence were provided of well conducted randomized control trials and meta-analysis, showing a small but significant effect in eradicating *H pylori* in dyspeptic patients. O'Morain further suggested that *H pylori* associated dyspepsia is related to acid secretion. *H pylori* infection resulted in increased fasting and post-prandial serum gastrin levels and decreased gastric mucosal levels

of somatostatin. Of more significance is the fact that these abnormalities were corrected following eradication therapy. Furthermore, an intravenous infusion of gastrin-releasing peptide causes a six-fold increase in acid secretion in *H pylori* peptic ulcer patients, a four-fold acid increase in *H pylori* FD patients and a two-and-a-half fold increase in asymptomatic *H pylori* infected individuals, compared to asymptomatic controls without *H pylori* infection.

Most authors would agree that, *H pylori* when discovered needs to be eradicated to prevent gastric ulcer and reduce the risk of gastric cancer. It will be interesting to see in the long term, if the eradication of *H pylori* does any harm. Recently it has been suggested that eradicating the bacteria in susceptible individuals, may predisposed them to develop reflux oesophagitis , which can lead to Barrett's oesophagus and oesophageal carcinoma. Whether it is cost-effective to conduct a "test and treat" or "search and treat" strategy and on which population is still debatable. A lot of it will depend on the resources available to the individual community.

Interestingly, it has also been reported that *H pylori* FD patients are less likely to show evidence of dysmotility or delayed gastric emptying. However it has consistently been shown that approximately 50% of FD patients have some kinds of gastric motility disorder, the most common of which is delayed gastric emptying. Doubts still remain as to the relationship between gastric dysmotility and dyspeptic symptoms. Symptoms may be caused as a direct result of the abnormal motility or arises secondarily from the effect of the abnormal gastrointestinal propulsion, or a combination of both.

The subdivision of dyspepsia into subsets according to symptoms clusters remain controversial but are widely practiced[3]. Two main subgroups were widely recognized: "ulcer-like dyspepsia" and "dysmotility-like dyspepsia". Ulcer-like dyspeptic patients usually complain of upper abdominal pain while dysmotility-like dyspeptic have symptoms very suggestive of impaired gastroduodenal motility. However it has now being realized that the subgroup classification according to symptom clusters suggested thus far is of no clinical utility. More recent suggestions for a new classification is based on the most bothersome or prominent symptom presented by the patient. Newer trials seem to support the existence of such grouping in that severe postprandial fullness and vomiting were independently associated with delayed gastric emptying, while impaired gastric accommodation is linked to early satiety. Furthermore response to proton-pump inhibitors was better in the subgroup of patients with epigastric pain rather than discomfort. However there is also published data that does not agree with the above mentioned observation. This new sub-grouping will need to be assessed further before it can be widely used. Patients who have heartburn as their predominant symptoms are generally accepted to have gastro-oesophageal reflux disease and not dyspepsia. They may have erosive or non-erosive oesophagitis and even "functional heartburn". Similarly patients with lower gastrointestinal symptoms probably fall in the domain of irritable bowel syndrome (IBS) rather than FD.

A "hypersensitive" gut is now considered as the main pathophysiological factor underlying the functional bowel disorders. Patients suffering from the irritable bowel syndrome (IBS) have a lower threshold for pain especially during endoscopy and digital examination. Similarly FD patients demonstrate an increased sensitivity to gastric distension at lower distending pressures when compared to normal healthy controls. Other investigators have also shown that patients with FD respond abnormally to an infusion of lipid into the duodenum. The observed abnormality was due to the effect of CCK released locally causing gastric sensorimotor dysfunction. CCK's influence is exerted either locally on CCK mucosal receptors or at a distance on CCK receptors located on sensory afferent fibers or CCK receptors located in central circuits of the CNS. However it is also conceivable that the effect of the CCK is not from the increased level of circulating CCK but rather due to an altered response of the CCK receptors. In this respect we have demonstrated that FD patients respond abnormally to an infusion of CCK octapeptide[5]. CCK infusion reproduced the dyspeptic symptoms which can be blocked by atropine and loxiglumide. End organs (sensory receptors) present in the mucosa, muscle layer or serosa may respond abnormally (hypersensitive) to an external stimuli. The enhanced sensory perception may also result from an alteration of ascending sensory afferent neurons (vagal or spinal afferents) and perhaps from central amplification of visceral signals. Interestingly the presence of CCK receptors has also been demonstrated at all the above sites.

Keohane *et al*[4] suggested in their review that apart from visceral hypersensitivity, visceral hyperalgesia and viscero-somatic referral also play important roles in FD. In viscero-somatic referral the offending stimulus will elicit pain at a site distant from the site of application. Visceral hyperalgesia is the phenomenon whereby the application of an ordinary innocent stimuli result in pain. Hyperalgesia consists of both peripheral and central components, initiation and continuance of which contribute to the observed altered sensations that is so prominent in FD. It is possible that an acute visceral insult may recruit or sensitize sensory receptors or fibers, which even after the insult has subsided, will result in long term consequences of sensory-motor disturbances so characteristic of FD. It is proposed that altered mucosal mechano- or chemoreceptor may contribute to an exaggerated response to the CNS, when exposed to the presence of normal food content. Conceptually CCK and serotonin will be released from endocrine cells in the presence of normal luminal contents, which then act on their respective receptors to generate an abnormal response which when presented to a normal functioning CNS may be interpreted as inappropriately painful.

The CNS-ENS (brain-gut axis) interaction is vital in the pathophysiology of FD. As suggested by O'Mahony *et al*[5] and Chua[6] in their review, the dyspeptic symptoms may result from altered interactions at any level of the brain-gut axis. The CNS plays a central role in conducting and processing visceral signals. Alterations in brain processing of pain, perception and affective responses may be important in the pathogenesis of dyspeptic symptoms. The finely regulated motor, sensory and secretory activities of the GI tract are coordinated by the interactive actions between the CNS, autonomic system (sympathetic and parasympa-

thetic) and the ENS. Both the central serotonergic (5HT) and adrenergic (AD) systems play important roles in this interaction.

Central serotonergic pathways are important in the control of nociception. Depending on the receptor subtype activated, the response could be pro or antinociceptive. The antinociceptive effects of serotonin are dependent on noradrenaline being release by the serotonin. Similarly central adrenergic receptors play an essential role in the regulation of gastrointestinal motility. Activation of central alpha-2 (NAD) receptors mediates the inhibition of GI function. NAD neuronal input to the paraventricular and supraoptic nuclei in the hypothalamus arises from cell groups in the brainstem, all of which receive directly or indirectly visceral sensory input from the vagus and glossopharyngeal nerves. The paraventricular nucleus has output nerves to the brainstem and spinal cord which are important in regulating feeding and GI function.

Peripherally serotonin is well recognized for its effects on GI motility and secretion. Whether central serotonergic systems play the same role remains unclear. 5HT neurons in the pons and medulla contribute to the innervations of the paraventricular nucleus which influence autonomic and neuroendocrine function. The paraventricular nucleus also projects to the dorsal motor nucleus where vagal efferent neurons that control the stomach are located. Interestingly it has been shown that hypersensitive central 5HT receptors are associated with delayed gastric emptying and an abnormal response to CCK-8 infusion in FD. Furthermore the dyspeptic symptoms in FD can be reproduced by the CCK-8 infusion. The hypersensitive CCK receptors as mentioned earlier, under physiological condition of CCK release, may be stimulated and activate a vago-vagal reflex pathway that results in GI sensory-motor dysfunction and feeding abnormality.

FD has been shown to demonstrate hypersensitive central 5HT receptors while their central alpha-2 (NAD) receptors appear to be down regulated. Serotonergic and noradrenergic pathways may have opposite effects on feeding behavior and GI sensory-motor function. NAD stimulation of the paraventricular nucleus elicits feeding behavior that can be antagonized by local pretreatment with serotonin. The anorexic effect of CCK is dependent on central serotonergic pathways. It is possible that both the serotonergic and noradrenergic pathways may mediate the CCK effect in FD in an antagonistic way, serotonergic pathways being excitatory while the noradrenergic pathways are inhibitory. The observed sensory-motor abnormalities may be the result of a final pathway that originated in the sensitized peripheral receptors and afferent vagal pathway, modulated centrally, and the efferent pathways from the dorsal motor nucleus results in perturbation of peripheral GI function.

A biopsychosocial model to explain FD has been proposed, whereby biological, psychological and social factors interact to account for patient's symptoms, behavioral response and disease outcome. The brain gut axis plays a central role in mediating this interaction. FD can then be seen as a result of dysregulation of intestinal motor, sensory and CNS activity, resulting from interruptions at some level of the brain gut axis.

Stress, a commonly seen factor in precipitating symptoms in FD, may aggravate symptoms by its effects on the CNS. Acute or short term stress may result in delayed gastric emptying or other sensory-motor disturbances which are present in FD. Psychosocial factors as suggested by Dinan *et al*[7] in this topical review may be implicated in the predisposition, exacerbation and perpetuation of functional bowel disorder (FBD) including FD. Different types of stressors may play different roles in the pathophysiology of FBD. Early life stress and acute life-threatening situations are strong risk factors for developing FBD in the genetically predisposed individual, later on in life. Other stressors occurring throughout life transiently may cause intermittent changes in the stress response so as to cause symptoms exacerbation. Conceivably, psychological stress may affect peripheral sensory-motor function through an effect on central processing circuits. Similarly physical stress such as infection and trauma may contribute to and aggravate symptoms, and in the vulnerable to perpetuate symptoms.

Corticotrophin-releasing factor (CRF) has long been believed to have a physiological role in the mediation of CNS response to stress. CRF is also involved in reactions that coordinate and modulate the autonomic, behavioral, and visceral responses of the CNS to stress. Dinan *et al* suggested that CRF may act via central connections known as the emotional motor system (EMS). Ascending monoaminergic projections and circulating glucocorticoids has a feedback control on output fibers from the EMS that modulate a peripheral response which involves the neuroendocrine, autonomic and endogenous pain control pathways.

A number of psychological factors have been linked to FD. These includes psychological stress, personality traits, social support, life-events and life-stresses including abuse and bereavement. Barry *et al* have elegantly debated through each factors and their association to FD in their comprehensive review. The suggestion that psychological morbidity and social stressors merely motivating health care seeking measures has been challenged.

Similar to patients with FD, individuals with IBS have a higher rate of psychiatric comorbidities. The two entities though regarded as separate disorders have many similarities and overlapping symptoms. Both seem to have a genetic predisposition, prior infection or inflammation may contribute to its pathophysiology, while stress, life events and history of previous abuse play important roles in the progress and manifestation of these two chronic diseases. It is relatively easy for IBS patients with upper abdominal pain to be misdiagnosed as FD. This problem seems to be greater in Asia as Asians tend to present more commonly abdominal pain, according to Gwee *et al*[8]. In his review, one important reason for differentiating IBS from dyspeptic symptoms is to avoid unnecessary surgery. In patients with concomitant FD and IBS (FD-IBS), the risk of cholecystectomy is much higher compared to either FD or IBS alone. One interesting fact highlighted by Gwee *et al* is the observation that overlapping FD is more commonly seen in IBS with constipation. Moreover delayed gastric emptying has been reported in IBS patients with concomitant FD but not in those with IBS alone. Further-

more it has been shown that dysmotility-type FD is more likely to be associated with constipation type IBS. Though impaired accommodation to a meal is as prevalent in FD alone compared to FD-IBS, visceral hypersensitivity is significantly higher in FD-IBS patients. Post infectious IBS has generally being accepted as an entity while recent reports also suggested that FD could develop post-infection with delayed gastric emptying and impaired accommodation. The infectious agent could be viral in origin while a recent study reported dyspeptic symptoms post salmonella gastroenteritis.

FD does coexist with IBS and a substantial proportion of FD patients will evolve into IBS with time. Whether it is important to differentiate between FD and IBS remain to be seen. Clinically it is common practice to use combination treatment for both, suggesting that perhaps considering them as a single disorder may be more practical.

The response to drug treatment remains variable and uncertain. Monkemuller *et al*[9] in their review suggested an approach that deals with patients' predominant symptom. If the predominant symptom is epigastric pain or presence of gastroesophageal reflux, then an acid suppressive therapy should be considered with the proton-pump blockers. If *H pylori* is present, it should be eradicated. If the main symptom suggest dysmotility type FD then prokinetic agents can be considered. Cisapride and domperidone has been widely used and quite effective, until cisapride was removed due to cardiac side-effects. Other prokinetics such as erythromycin, tegaserod and alosetron has produced inconsistent results. Newer agents including itopride hydrochloride (ganaton) and mosapride may provide better results. A recent multicentre randomized controlled trial was published in the NEJM by Holtman et al showing the effectiveness of Itopride in relieving symptoms in FD. Loxiglumide, a CCK receptor antagonist has been shown in a small study to be effective in dysmotility-like dyspepsia, but this needs to be repeated in a bigger randomized controlled study. Antidepressants like the serotonin re-uptake inhibitors (SSRI) and amitryptalline will be useful in treating FD with psychological overlays. The success of this treatment strategy may also be attributable to the effects of these drugs on central pathways. The SSRIs act on central as well as peripheral 5-HT receptors while amitryptalline effects may be *via* central alpha-2 receptors. Hypnotherapy is effective in IBS but its role in FD remains to be seen. It is not widely available and very time consuming. Most studies looking at drug therapy in FD are plagued by the high placebo response. This could be accounted for by the significantly greater attention and time given to the patient by the researchers, with the attending investigations carried out per study protocol which could alleviate to a certain degree some of the anxiety, uncertainty or fear which the patients may have.

Abstract

Dyspepsia refers to group of upper gastrointestinal symptoms that occur commonly in adults. Dyspepsia is known to result from organic causes, but the majority of patients suffer from non-ulcer or functional dyspepsia. Epidemiological data from population-based studies of various geographical locations have been reviewed, as they provide more realistic information. Population-based studies on true functional dyspepsia (FD) are few, due to the logistic difficulties of excluding structural disease in large numbers of people. Globally, the prevalence of uninvestigated dyspepsia (UD) varies between 7%-45%, depending on definition used and geographical location, whilst the prevalence of FD has been noted to vary between 11%-29.2%. Risk factors for FD have been shown to include females and underlying psychological disturbances, whilst environmental/ lifestyle habits such as poor socio-economic status, smoking, increased caffeine intake and ingestion of non-steroidal anti-inflammatory drugs appear to be more relevant to UD. It is clear that dyspepsia and FD in particular are common conditions globally, affecting most populations, regardless of location.

INTRODUCTION

Dyspepsia refers to a collection of upper gastrointestinal symptoms that is believed to be common world-wide. Despite numerous consensus meetings[1-4], a standardized international definition that is applicable to all populations remains controversial. This is partly due to the overlap with gastro-esophageal reflux disease and the fact that cultural differences remain in reporting of symptoms[5]. The generally accepted definition by most clinicians includes the presence of upper abdominal pain or discomfort with or without other upper gastrointestinal symptoms, such as nausea, belching, vomiting, etc. However, confusion over what patients interpret as abdominal pain versus discomfort continue to "muddy the waters" in this issue[6].

Regardless of its definition, the causes of dyspepsia are known to include peptic ulcer disease, gastro-esophageal reflux, and functional dyspepsia. Functional dyspepsia, otherwise known as non-ulcer dyspepsia, is clearly the commonest cause of dyspeptic symptoms in the West and increasingly in other parts of the world[7]. The latest definition of this includes the presence of "chronic or recurrent pain or discomfort centred in the upper abdomen in the absence of any known structural cause and without any features of irritable bowel syndrome"[4]. The precise pathophysiology of this condition remains unclear, but it is thought to result from a combination of visceral hypersensitivity, gastric motor dysfunction and psychological factors[8].

Functional dyspepsia is not life-threatening and it has not been shown to be associated with any increase in mortality. However, the impact of this condition on patients and health care services has been shown to be considerable. In a recent community survey of several European and North American populations, 20% of people with dyspeptic symptoms had consulted either primary care physicians or hospital specialists, more than 50% of dyspepsia sufferers were on medication most of the time and approximately 30% of dyspeptics reported taking days off work or schooling due to their symptoms[9]. Similar findings have been reported by other leading investigators in this field[10], including the fact that people with functional dyspepsia have a significantly reduced quality of life when compared to the general population[11].

This review aims to describe the epidemiology of func-

tional dyspepsia from a global perspective. Previous reviews on this subject have been based mostly on published reports from Western populations[11,12], mainly as a result of a lack of data from non-Western countries. However, there has been a growth of population-based studies from Asia in the last few years and data from these publications will be emphasised in this review.

POPULATION-BASED STUDIES

In an attempt to demonstrate the variations between populations, we have decided to compare and contrast the prevalence and epidemiology of uninvestigated and functional dyspepsia from various geographical locations. Only studies that have been published in the English medical literature have been selected for this review. Population-based surveys, as opposed to referral-based (for endoscopy) or self-reporting studies, are more representative of the general population as issues such as selection bias (of consulters *vs* non-consulters) are minimized, although not completely excluded. In situations where different population studies from similar or close geographical locations have been presented separately, but have had similar results or conclusions, data from the larger cohort only will be examined in this review.

PREVALENCE OF DYSPEPSIA

The prevalence of dyspepsia varies considerably between different populations (Figure 1). Although these may represent genuine epidemiological differences, it is also apparent that the varying definitions used in different population studies may have contributed to this discrepancy. In studies using "upper abdominal pain" as the definition, the prevalence of uninvestigated dyspepsia (UD) has varied between 7%-34.2%[13,14,22-25,31,32,36]. With this definition, the lowest UD prevalence of 7%-8% is seen in Singapore, South East Asia[31], slightly higher rates are seen amongst the Scandinavians (14.5%[22] and 18.4%)[23,24], prevalence rates of 23-25.8% are seen in the US[13,14] with populations in India (30.4%)[32] and New Zealand (34.2%)[36] having the highest rates.

When a broader definition of "upper gastrointestinal symptoms" is used to define dyspepsia, a 23%-45% prevalence of UD[16-21,26,37] is observed. Using this definition, a lower prevalence is seen in Spain (23.9%)[26], a 32% UD prevalence rate in the US is noted[16], whilst significantly higher rates of 38%-41% are noted in the UK[18-21] and 45% in Nigeria[37].

In population studies that have used the Rome I criteria to define uninvestigated dyspepsia, a prevalence between 18%-38% has been observed[15,29-30,34-35]. The lowest prevalence of 18.4% was recorded in Hong Kong[30], whilst higher rates of 26% and 27.8% were noted in US[15] and Taiwan[29] respectively, and the highest prevalences of up to 38.2% were observed in populations in Australia[34,35].

Finally, with use of the recent Rome II criteria, where symptoms of reflux and IBS are excluded, surveys have reported prevalences around 24%[28,35]. Population studies in Australia and China reported prevalence rates of 24.4%[35] and 23.5%[28] of uninvestigated dyspepsia.

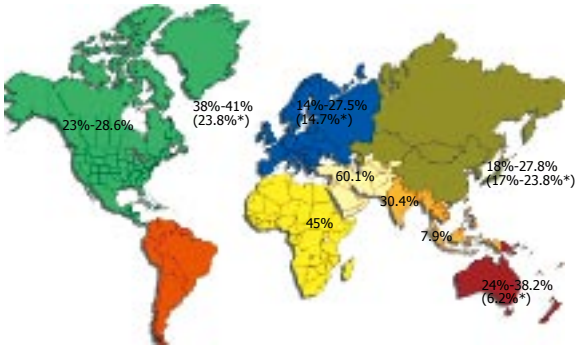

Figure 1 Global prevalence of uninvestigated dyspepsia and functional dyspepsia*.

True functional dyspepsia (FD), where organic disease has been excluded, has been difficult to determine in population studies, for obvious logistical difficulties. Nevertheless, several studies around the globe have actually undertaken this task to provide a reflection of the prevalence of functional or non-ulcer dyspepsia. In a survey of employees within a single institution in the US, Shaib and El-Serag managed to endoscope half of the survey participants and obtained a FD prevalence rate of 29.2% (with reflux symptoms) and 15% (without reflux symptoms)[16]. In the UK, two separate population surveys attempted to estimate the prevalence of FD. One fifth of 9936 subjects surveyed by Jones et al had been investigated with either a Barium meal or endoscopy, and an extrapolated FD prevalence of 23.8% was obtained[18]. Later, in a community survey of 2066 adults, 20% had undergone endoscopy in the study and FD was estimated at 11.5% of this population[19]. A 14.7% of FD was recorded in a Norwegian survey, where the majority of 2027 adults agreed to undergo endoscopy[25]. In Japan, Hirakawa et al were able to document a 17% prevalence of FD in adults undergoing a population gastric cancer screening programme[27]. Finally in Taiwan, the prevalence of FD appeared to vary, depending on criteria used. Of 2018 adults endoscoped, FD was documented at 23.8% with Rome I criteria and confusingly at 11.8% using the Rome II criteria[29].

EPIDEMIOLOGICAL FACTORS

Population-based studies determining the prevalence of dyspepsia have attempted to identify epidemiological risk factors for UD, and when relavant FD as well. Below is a brief summary of various parameters that have been studied in association with the prevalence of dyspepsia.

Age

All surveys that have been conducted have examined adults 18 years or older. While most surveys have shown that dyspepsia does not appear to be related to any particular age group, several studies have noted some trends. Peak prevalences of UD have been noted between the ages 45-54 in a Canadian survey[17], whilst FD appeared to peak in Chinese subjects 41-50 years[28] and in Japanese adults 50-59 years[27]. In the latter study, dyspepsia sub-types appeared to be associated with different age groups: reflux-like more common in middle-aged adults, dysmotility-like more

frequent in those < 59 years and ulcer-like predominant symptoms more frequently in adults < 39 years. In other populations, the prevalence of UD appeared to decrease with increasing age in British[18], Taiwanese[29] and Danish[23] surveys. In the latter survey, there was a significantly lower prevalence of UD in adults > 70 years (10%) compared to those < 60 years (18.4%)[23]. In contrast, a survey in urban Mumbai, India found that UD was more prevalent in adults > 40 years[32]. Despite these trends, age extremities has not been identified as a predictor of dyspepsia (UD or FD).

Gender

Most population studies have been able to obtain relatively equal ratios of male: female ratios and the majority of them have shown no differences in dyspepsia prevalence between genders, mostly where UD is concerned. Several studies, in different populations, however, have noted a consistent female preponderance with dyspepsia[16, 23, 26, 29,34]. Female gender was found to be the only independent risk factor for FD amongst 2018 Taiwanese health check attendees[29]. In a population-based study in Australia, female adults significantly outnumbered males in most functional GI disorders, including FD[34]. As only a few population studies have examined true FD prevalence, it is likely that the gender effect in surveys of UD have been masked due to the combination of adults with FD and organic dyspepsia.

Ethnicity

The role of ethnicity in dyspepsia has not been examined by most population studies. Most surveys have been done on populations of single/similar ethnic groups, mostly of Caucasian or Oriental background (Table 1). However, in one of the few studies involving subjects of several ethnic backgrounds from a single institution in the US, African-American race was found to be one of several epidemiological risk factors for UD[16]. In a survey of a multi-racial population in Singapore, South East Asia, the ethnic-adjusted prevalence of UD was demonstrated as follows: Chinese 8.1%, Malays 7.3% and Indians 7.5%[31]. Although the majority ethnic group in Singapore is Chinese, the authors were able to obtain prevalence based on equal representations of the three different ethnic groups. At present, little can be concluded regarding the role of ethnicity and it is clear that more data is required from future studies.

Smoking

Although a common practice world-wide, regular smoking as a risk factor has not been consistent in its association with dyspepsia. In the few population-based studies that have examined FD, smoking has not been shown to be a risk factor[25,28,29,34]. In surveys of patients with UD however, regular smoking has been identified as a risk factor in populations in US[16], Canada[17], UK[21] and India[32]. This observation may be explained by the proportion of organic disease amongst subjects with UD, as smoking has been identified as clear risk factors for diseases like peptic ulcer disease[38].

Alcohol

Regular alcohol intake, as a risk factor, has been studied and it has not been shown to be associated with dyspepsia in the vast majority of surveys. However, in the Asia-Pacific region, only population studies in India[32] and New Zealand[36] have showed definite associations between alcohol and UD.

Non-steroidal anti-inflammatory drugs

The effect of non-steroidal anti-inflammatory drugs (NSAIDs) on dyspeptic symptoms have been examined specifically in only two population-based studies. In a survey of American adults from a single institution, regular usage of NSAIDs and Aspirin, bought over the counter, were strongly associated with UD than in controls without dyspepsia[16]. In a British study of 4982 adults, NSAID usage was identified as an independent risk factor for UD and thought to be responsible solely for 4% of dyspepsia in the community[21]. Interestingly, data from the African sub-continent may correlate this fact in a study of Nigerian highlanders. "Indulgence in self-medication" amongst the subjects surveyed was found to be a significant risk factor for UD[37]. Although this was not described clearly, and probably included various types of traditional medication, it is probable that analgesics containing NSAIDs may account for a sizeable amount of this "self-medication".

Helicobacter pylori infection

To date, only one population-based study in the UK has investigated the association of *H pylori* infection with UD. Among 8047 subjects who were tested for *H pylori,* those who were infected had more dyspeptic symptoms (44%) than those who were *H pylori* negative (36%)[21]. Subsequent analysis revealed *H pylori* status to be predictive of UD and the authors concluded that *H pylori* infection had a 5% population attributable risk for dyspepsia assuming a causal association. The association of *H pylori* and FD is less clear, but this has only been examined in some detail in non-population-based studies[39].

Dietary factors

The role of diet in dyspepsia has not been studied by many, probably due to the diversity of dietary habits within individual populations. In the few studies that have attempted to examine dietary factors and their association with dyspepsia, the definitions of food types and categories do not appear to be clear. In the Chinese study examining the prevalence of FD[28], "bad dietary habits" was shown to be a significant risk factor. However, the authors fail to clarify their definition of this term. In an urban survey in India, Shah et al managed to demonstrate that no differences in dyspeptic symptoms occurred between vegetarians (29.1%) and meat-eaters (31.2%), whilst spicy, fried or food prepared outside the home contributed insignificantly to worsening of symptoms[32]. In Nigerian adults living in the highlands, the type of staple food consumed was strongly associated with UD, but no specific definitions of food types are given[37]. The effect of caffeine intake has also been examined in some population studies,

Table 1 Epidemiology of uninvestigated dyspepsia (UD) and functional dyspepsia (FD)

particularly from Western studies. Surveys in the US and Europe have reported that excessive coffee or tea intake has not been shown to be related to the presence of dyspepsia/UD[16,17,21,23,25]. However, in one of the few studies to examine its' role, a Canadian survey showed that heavy intake of cola was associated with markedly increased prevalence of dyspepsia[17]. An explanation for this observation may be due to the fact that greater quantities of caffeine in cola can be consumed more readily, or it may be a non-caffeine related compound which is responsible for dyspeptic symptoms. Clearly, more studies on the role of diet in dyspepsia are needed, but standardization in dietary terminology and habits are required before meaningful conclusions can be elicited from such data.

Socio-economic associations

Most population-based studies have examined basic socio-demographic associations in dyspepsia and the majority have not revealed any significant findings, eg between social classes and prevalence of dyspepsia. However studies examining details of socio-economic status were able to elicit associations with dyspepsia. Drossman in the US noted a strong relationship between lower household income and larger household membership with increased functional GI diseases, including FD[15]. Similarly, a Canadian survey revealed that chronic GI symptoms (UD) were more prevalent in adults with lower household income, those who were unemployed and with lower educational levels[17]. In a British survey, factors including rented accommodation, no central heating, low educational level and sharing a bed with siblings (surrogate for crowded household) were found to be predictive of UD in adults[21]. Amongst an urban population of dyspeptics in China, "dissatisfaction with financial income" was associated with FD, but this was not as significant as other psychological factors (see below)[28]. Finally, in the Nigerian study, a larger sized family together with occupational scatter was strongly associated with UD[37].

Psychological associations

In most population surveys that have studied psychological disturbances as a risk factor, definite risk associations, particularly for FD, have been elicited. Talley *et al* had previously reported in an American adult population that sexual, emotional and verbal abuse either in childhood or adulthood were significantly associated with dyspepsia[14]. This, in turn resulted in more health-care seeking behaviour amongst this group of adults. In a Danish survey, Kay and Jorgensen noted that UD was strongly associated with adults who had "experience of problems" and "psychological vulnerability"[23]. In one of the few population-based studies that managed to examine FD in some detail (by excluding structural abnormalities in most of the adults), the authors found that FD patients, as opposed to those with UD alone had a significant association with tranquiliser usage[25], probably a surrogate marker for anxiety or a neurotic behaviour. This observation is similarly observed in an Australian survey where adults with FD scored highly on anxiety and depression scales[34], and in a Chinese study which revealed "pressure from society" and "destructive living habit" as risk factors for FD[28]. Yet another survey in Hong Kong also revealed that subjects with UD had more anxiety, compared to adults with IBS, which appeared to influence health-care seeking habits[30].

Summary

Table 1 summarises the features of the epidemiology of dyspepsia from a geographical perspective. The published data to date supports the notion that dyspepsia is common in most populations of this world. The varying prevalence of UD in different populations, some even in similar geographical locations, appear to be related to the different definitions of dyspepsia used by investigators of individual surveys. The true prevalence and epidemiology of FD amongst the general population has not been evaluated as much, due to the difficulties in excluding organic disease in large numbers of people. Nevertheless, several studies[16,25,27,29] have been able to examine this in some detail. With the data that is available, the true prevalence of FD globally is estimated between 11.5%-29.2% (including symptoms of reflux) (Figure 1). Epidemiologically, it appears that risk factors for FD are different to that of organic dyspepsia and even general UD. Where this has been studied in some detail, female gender and underlying psychological disturbances have been shown to be important factors in FD[16,25,28,29,34]. In contrast, environmental/lifestyle habits such as poor socio-economic status, smoking, increased caffeine intake and NSAID ingestion appear to be more relevant to UD[17,21,28,32] . We believe this is a result of the presence of organic disease in these populations. Although a peak preponderance of dyspepsia around the middle ages (40-50 years) have been reported in some surveys[26,27], the extremities of age do not appear to be predictive of dyspepsia generally. Apart from one study from the US[16], the role of ethnicity has not been shown to be relevant. However, most of the published surveys have usually been on single/majority ethnic populations and hence this factor has yet to be refuted for certain.

Abstract

Functional dyspepsia is a common clinical condition characterised by chronic or recurrent upper abdominal pain or discomfort commonly associated with a variety of associated gastrointestinal symptoms and a normal endoscopy. To standardise research-based approaches, an initial categorisation of into sub groups was agreed to, based on clusters of symptoms. However the early expectation that these subgroups would be associated with distinct pathophysiologies amenable to specific therapy has not been realised. A classification based on the most troublesome symptom has been suggested but the utility of this is also unclear. More recent data suggest that some of the pathophysiologic dysfunctions may be associated with specific symptoms and so provide a better tool for grouping patients. But this approach remains incomplete as current insights into the pathogenesis are still too limited for this to be satisfactory. In conclusion, no classification provides for an adequate treatment-based approach to the syndrome of functional dyspepsia. As a consequence treatment remains largely empiric.

INTRODUCTION

Dyspepsia is broadly defined by predominantly midline pain or discomfort located in the upper abdomen[1]. Although the term often implies a relationship with food ingestion and majority of patients have symptoms worsened by food[2] this is no longer essential. Dyspeptic symptoms occur commonly in the general community[3] and constitute one of the most frequent reasons for referral to gastroenterologists[4]. Surveys suggest as many as 15%-20% of the population in Western countries experience dyspepsia over the course of one year[5]. During investigation of dyspepsia, three major structural causes are readily identifiable: peptic ulcer disease (10%), gastroesophageal reflux (20%)(with or without oesophagitis), and malignancy (2%)[6]. It is apparent that most (50%-70%) patients with chronic dyspepsia do not have a significant focal or structural lesion found at endoscopy. When symptoms are chronic or recurrent, but without an identifiable structural cause using standard diagnostic tests (usually endoscopy), the condition is usually labelled functional (or non-ulcer) dyspepsia[7]. Hence functional dyspepsia is a diagnosis of exclusion that implies that symptoms have been investigated without the demonstration of an organic or anatomical cause.

INITIAL APPROACHES TO CLASSIFICATION INTO SUBTYPES

To standardise research studies amongst this heterogenous population of patients, a definition of functional dyspepsia was developed by consensus amongst a group of international experts. In addition to describing the nature of reported symptoms a temporal component of persistent or recurrent for 4 wk in a 3 mo period was included[1]. This was subsequently modified to include more than 12 wk in one year[8]. As many patients with a final diagnosis of functional dyspepsia presented with symptoms suggestive of specific diseases initial efforts to subcategorise the syndrome, proposed subdividing dyspepsia into symptom-based subgroups namely reflux-like, ulcer-like, dysmotility like and non-specified[1]. The underlying expectation was that such subgroups would share common pathophysiology and might also respond to specific therapy. However, as is typical of a chronic condition, the manifestations of dyspepsia can be complex. Patients with upper abdominal discomfort frequently complain of a multiple of related symptoms. (Table 1)[9]. Indeed population-based studies indicate that patients presenting with uninvestigated dyspepsia, have at least three dyspepsia symptoms; more than 80% have at least six and approximately half have eight or more[10].

Table 1 Definitions of dyspeptic symptoms

Symptom	Description
Pain centred in the upper abdomen	A subjective unpleasant, patients may feel that tissue damage is occurring. Other symptoms may be extremely bothersome A subjective unpleasant without being interpreted as pain.
Discomfort centred in the upper abdomen	A subjective unpleasant sensation that is not interpreted as pain, which may include any of the symptoms below.
Early satiety	A feeling the stomach is overfilled soon after starting to eat, out of proportion to the size of the meal.
Fullness	An unpleasant sensation of the persistence of food in the stomach (may or may not occur post prandially).
Bloating in the upper abdomen	A tightness in the upper abdomen, this should be distinguished from true abdominal distension.
Nausea	A feeling of the need to vomit.
Retching	Heaving as if to vomit but no gastric contents are forced up.

Furthermore, symptoms often vary over time. The initial classifications were expanded to include cluster analysis of these associated symptoms.

With further intensive investigation, it has become apparent that dividing patients with uninvestigated dyspepsia empirically according to clusters of symptoms has not assisted in identifying specific gastrointestinal mechanisms for different symptom types[11]. This may well reflect the extensive overlap of symptoms within the empirically derived groupings[12] the frequent association with irritable bowel syndrome[13] and the temporal variation in symptoms[9, 12, 13]. It also became apparent that the symptom sub classification was a poor predictor of underlying structural abnormality.[14]

SUB-TYPES IN FUNCTIONAL DYSPEPSIA POST ROME II (TABLE 2)

Concerns about the lack of progress in understanding the syndrome and the overlap between various symptom clusters resulted in a refinement of these in a subsequent consensus agreement[8]. In particular the inclusion of patients with predominant symptoms of GORD was considered unwarranted as this entity should be distinguished in its own right. Thus the ROME II assessment of Functional Gastrointestinal Disorders recognised three subtypes of functional dyspepsia[8]. (1) Ulcer-like: Characterised by predominantly epigastric pain or discomfort which may worsen with hunger and improve with food or antacids. As with ulcer disease, symptoms may remit and relapse spontaneously. (2) Dysmotility-like: Contained clinical features suggestive of disturbed upper gastrointestinal motility. Thus upper abdominal discomfort aggravated by food commonly associated with nausea, vomiting, bloating and upper satiety together. Anorexia also occurred in part because of the consequences of food ingestion was also a feature and often associated with significant weight loss. (3) Unspecified: Patients with symptoms which did not fit either of the categories above.

Table 2 Categorisation of Adult Functional Gastroenterological disorders as per Rome II[1]

A: Oesophageal disorders
- Globus
- Rumination syndrome
- Functional chest pain of presumed oesophageal origin
- Functional heartburn
- Functional dysphagia
- Unexplained functional oesophageal disorder

B: Gastroduodenal disorders
- Functional dyspepsia
- Ulcer-like dyspepsia
- Dysmotility-like dyspepsia
- Unspecified (non-specific dyspepsia)
- Aerophagia
- Functional vomiting

C: Bowel Disorders
- Irritable bowel syndrome
- Functional abdominal bloating
- Functional constipation
- Functional diarrhoea
- Unspecified functional disorder

D: Functional abdominal pain
- Functional abdominal pain syndrome
- Unspecified abdominal pain syndrome

E: Biliary Disorders
- Gall bladder dysfunction
- Sphincter of Oddi dysfunction

F: Anorectal disorders
- Functional faecal incontinence
- Functional ano-rectal pain
- Levator ani syndrome
- Proctalgia Fugax
- Pelvic floor dyssynergia

As noted previously, patients with functional dyspepsia often do not fit neatly into symptom cluster classifications, in part because of the wide overlap of symptoms[13]. The attempts to subgroup patients using the Rome II modification has also not been particularly helpful in either clinical practice or research studies[11]. In addition the substantial overlap between dyspeptic groups, those with GORD and other functional gastrointestinal disorders has limited the utility of this approach (Figure 1)[15] although it has been suggested that functional dyspepsia can usually be separated from symptoms related to the lower gut (ie Irritable Bowel Syndrome) by the presence of bowel disturbance despite the fact that many patients had both dyspepsia and IBS[16]. In the light of the extensive symptom overlap and poor discriminatory value in individual patients, the value of the cluster-based symptom classification has been questioned and possibly replaced by a subcategorisation based on the most troublesome symptom. The value of this approach remains unproven[17]. Notwithstanding these restrictions, some recent data suggest that symptom clusters based around specific pathophysiologic disturbances may provide insights into the mechanisms of the functional dyspepsia[2]. These appear to have predictive value and could possibly direct approaches to the development of novel strategies.

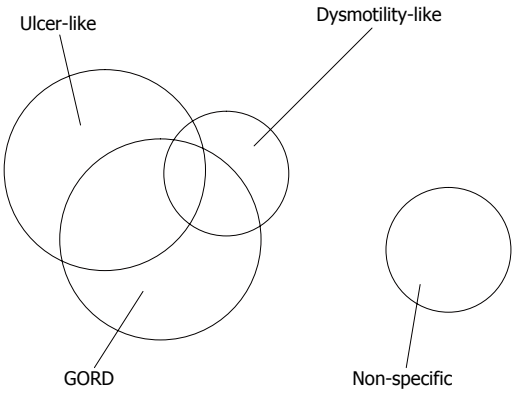

Figure 1 Schema of overlap of dyspepsia subtypes (according to Rome II) and gastro-oesophageal reflux disease[15].

GORD and functional dyspepsia

It has become obvious that it is important to discriminate between symptoms related to GORD and functional dyspepsia. A sensation of retrosternal or epigastric burning that characteristically radiates towards the throat, is precipitated by meals or the supine posture and is relieved at least temporarily by antacids, is strongly suggestive of GORD[15]. Frequent heartburn increases the likelihood of GORD as the cause of symptoms[6] although pyrhosis may be much less obvious in the older patient[18]. It is likely that the majority of dyspeptic patients with predominantly reflux symptoms have GORD, although only 50% of these patients have oesophagitis at endoscopy. As noted above, the revised criteria in ROME II did not include reflux-like dyspepsia as a sub-grouping of functional dyspepsia, and patients with heartburn as their major symptom are now generally excluded from dyspepsia studies. However it needs to be recognized that many patients with GORD have multiple symptoms[10] and a substantial number of patients with GORD also have functional dyspepsia which may be unmasked by successful treatment of GORD with PPI. A number of patients with functional dyspepsia may have heartburn as an extra symptom and the prevalence of GORD in patients with epigastric pain alone is unknown. It is also unclear whether this could represent undiagnosed or non-erosive reflux disease.

Pathophysiologically based sub-groups

The pathophysiology of functional dyspepsia is unclear and a large number of mechanisms proposed as causative[19]. These include delayed gastric emptying[20,21], visceral hypersensitivity[22], impaired gastric accommodation to meals[23], abnormal motility[24], infection with *Helicobacter pylori* (*H pylori*)[25] and CNS dysfunction. In addition, childhood abuse[26] and prior gastrointestinal infection[27] have been described as precursors to later dyspepsia. However, an association between the majority of these mechanisms and specific symptoms is lacking.

CLASSIFICATION ACCORDING TO SPECIFIC PATHOPHYSIOLOGIES ASSOCIATED WITH FUNCTIONAL DYSPEPSIA

Gastric motor and sensory dysfunction

Although it has long been recognized that gastric emptying is delayed in approximately 1/3 of patients with functional dyspepsia[20], this does not reliably predict individual patient symptoms, with the exception that there is some association with fullness and bloating[28, 29]. Gastric antral hypomotility measured by manometry is well described[24], but may well reflect the limitations of pressure recordings with non-lumen occlusive contractions. More promising are recent descriptions of the proximal gastric function, which may permit better discrimination of some symptoms related to meal ingestion[2]. Thus intolerance to gastric distension suggesting impaired visceral sensitivity has been associated with epigastric pain, and belching[22]. Similarly, impaired proximal gastric accommodation has been associated with pain, early satiety and weight loss particularly in young women[23]. Of particular interest to clinicians, are reports that these abnormalities can be evaluated with a high calorie drink test[30]. This technique potentially allows an office-based approach to address at least some symptoms in these patients, without resorting to invasive gastric barostat techniques, or expensive technology with limited availability[31-33].

Helicobacter pylori Infection

Depending on the population under study, between 30%-65% of patients diagnosed with functional dyspepsia have *H pylori*-induced gastritis[25,34]. However, a consistent causal link between *H pylori* infection and specific symptom profiles has not reliably been established[35]. *H pylori* positive individuals are as likely to have symptoms of bloating and early satiety as symptoms suggestive of peptic ulcer[17]. Suggestions that *H pylori* infection has a significant impact on gastric motility have also not been confirmed[36]. It is feasible that some of these patients could have undiagnosed peptic ulcer disease. At present, the aetiology of symptoms in *H pylori* patients without peptic ulceration is unclear[37].

Intestinal hypersensitivity

Dyspeptic symptoms are frequently worsened by food especially those rich in fat. A heightened sensitivity to both lipids[38] and acid[39] have been reported to be possible mechanisms underlying symptoms. High fat meals slow gastric emptying and hence may accentuate bloating and fullness. A similar effect may be seen with high fibre meals. These studies involved small numbers of patients and their general applicability at this stage remains uncertain.

CLASSIFICATION ACCORDING TO POSSIBLE PATHOGENESIS

The pathogenesis of functional dyspepsia is unknown and probably multi-factorial. Only a minority of patients report previous gastrointestinal infection[27] or an acute onset compatible with a post-infective aetiology. Psychological factors especially stress[40] and previous abuse[26] have been suggested to be important but direct evidence for a causative role is yet to be established. A recent description of an association between dyspeptic symptoms and a functional polymorphism of a G-protein subunit[41] has demonstrated that patients who are homozygous for the GNB3 825C subunit have a higher incidence of abdominal symptoms. The full implications of this is currently under

investigation. In the light of these uncertainties, further data are required before a meaningful classification based on potential pathogenesis can be undertaken.

THERAPEUTIC IMPLICATIONS

Given the limited understanding of the pathophysiological basis for symptoms in functional dyspepsia, there are limited options for rational treatment. It appears however unlikely that a single therapy will effectively manage all or even most patients with the condition[42]. In addition to general measures such as reassurance and avoiding obvious precipitants, the most commonly available options are: (1) Eradication of *H pylori* infection; (2) Acid reducing therapy; (3) Gastrokinetic agents

Eradication of helicobacter pylori infection

In patients where abdominal pain is the most bothersome symptom especially if ulcer-like in character, current practice frequently involves eradication of *H pylori* particularly in regions where *H pylori* infection is endemic[42]. This has the advantage of treating patients where the diagnosis of peptic ulcer has been missed as well as reducing the risk of subsequent malignancy. These patients may well be cured, although it must be recognised that the overall direct therapeutic gain from this approach in dyspeptic patients in general is small[43].

Acid-reducing therapy

Although ulcer-like symptoms would be expected to benefit from acid suppression with simple antacids, H_2 receptor antagonists or more recently proton pump inhibitors, the therapeutic benefit is small[42,44]. Some of this may derive from successful management of hidden GORD and peptic ulcer disease.

Gastrokinetic drugs

Data indicating that patients who have predominant pain are associated with hypersensitivity to gastric distension suggests that targeting modulation of gastric accommodation (such as $5HT_1$ antagonists) may have a role in the future management[2] although such approaches are at present in limited use. In patients with dysmotility-like symptoms prokinetic therapy is a rational approach especially if supported by objective evidence of delayed gastric emptying or a positive response to a satiety drinking test. Cisapride, a substituted benzamide with activity as a $5HT_4$ agonist, was arguably the most effective prokinetic agent although the evidence for an effect on symptoms is controversial[42]. The drug has been withdrawn in many countries due to rare but life-threatening cardiac toxicity. Another 5-HT_4 agonist with prokinetic activity, mosapride[45], has not been widely released. Newer agents such as tegaserod[46] and itopride[47] are currently undergoing evaluation. In patients with *H pylori* gastritis there is the theoretical possibility that gastritis-induced hypersensitivity may be ameliorated by treating the infection[35].

In conclusion, the sub-classification of functional dyspepsia is currently in transition. The early expectation that particular subtypes based on dominant symptom clusters would be associated with specific pathophysiologic disturbances has not been realised, although these descriptive terms remain entrenched in clinical practice. More recent data support a division into pathophysiologically-based patient groupings. In particular there appears to be an association between slow gastric emptying and dysmotility-like symptoms whilst hypersensitivity to gastric distension is more common in patients with post prandial pain. Eradication of *H pylori* gastritis has limited direct therapeutic gain. Patients with predominantly reflux symptoms need exclusion of GORD. Until further data are available it seems rationale to base initial therapy on the suspected pathophysiological abnormalities rather than symptoms, although well evaluated therapeutic options are limited. Further research is required to clarify the relationship between symptoms and motor and sensory dysfunction to provide an evidence-based management strategy.

Abstract

Functional, or non-ulcer, dyspepsia (FD) is one of the most common reasons for referral to gastroenterologists. It is associated with significant morbidity and impaired quality of life. Many authorities believe that functional dyspepsia and irritable bowel syndrome represent part of the spectrum of the same disease process. The pathophysiology of FD remains unclear but several theories have been proposed including visceral hypersensitivity, gastric motor dysfunction, *Helicobacter pylori* infection and psychosocial factors. In this review, we look at the evidence, to date, for the role of visceral hypersensitivity in the aetiology of FD.

INTRODUCTION

Functional dyspepsia is a common clinical condition in the community and is one of the most common disorders encountered by gastroenterologists worldwide. It forms part of the functional gastrointestinal disorders (FGID's), a spectrum that includes irritable bowel syndrome (IBS), non-cardiac chest pain, and non-ulcer or functional dyspepsia and that overlaps to a significant extent with non-erosive reflux disease (NERD)[1]. Studies of FD prevalence have provided varied rates but one study estimated that as many as 25% of Americans may be affected[2]. However not all of those affected seek medical attention for their symptoms. While the individual symptoms may be included within the concept of FD are also varied and include post-prandial fullness, bloating, early satiety, nausea, and vomiting, the hallmark of functional dyspepsia is the presence of persistent or recurrent pain or discomfort centred in the upper abdomen for which there is no organic cause. According to the most widely employed definition of FD, Rome II, this symptom should have been present for at least 12 wk within the preceding 12 mo in order to be classified as FD[3]. The advent and widespread use of the Rome criteria has facilitated clinical studies, including studies of pathophysiology, by ensuring, as far as possible, the inclusion of a relatively homogenous population within any given study. In the evaluation of any study of the role of visceral hypersensitivity, or indeed, any other factor in the pathophysiology of FD, it is critical to be fully apprised, not only of the criteria that were employed in the definition of the study population, but also of their geographic origin and the location of the study. These and other features, such as age, socio-economic status and ethnicity, can lead to tremendous variations in the relative contributions of various factors to the pathophysiology of FD, in a given population. For decades, general practitioners and specialists alike dismissed these patients as malingerers or as having some form of somatization disorder. However, it is only in the last decade or so that attempts have been made to elucidate the true pathophysiology of this heterogeneous disease. A number of putative mechanisms have been elucidated, including visceral hypersensitivity, delayed gastric emptying, impaired gastric accommodation, acid sensitivity, *Helicobacter pylori* (*H pylori*) infection and disturbed central perception of peripheral visceral events.

With regards to the relative contributions of these factors, Stanghellini *et al* found delayed gastric emptying in 33% of FD patients, and this was associated with female gender, low body weight, the presence of severe postprandial fullness, and vomiting, and the absence of pain as a dominant symptom[4]. Impaired gastric accommodation is thought to be present in approximately 40% of patients and is associated with early satiety and weight loss[5-7]. As regards *H pylori*, its role in the generation of symptoms remains controversial but certainly there is evidence to show that persistent infection may alter gastric

motor and sensory physiology; however, the benefits of eradication remains somewhat controversial[8-10]. The prevalence of hypersensitivity to gastric distension has been reported to be of the order of 30%-40%. Attempts to link mechanisms with symptoms have met with mixed results; proposed symptom associations with various pathophysiologic mechanisms are outlined in Table 1 below[11].

Method

An extensive review of the role of visceral hypersensitivity in the pathogenesis of functional dyspepsia was undertaken. For this purpose a systematic search of Pubmed databases 1966-2003 for relevant literature was performed, using the following key word combinations: functional dyspepsia or non-ulcer dyspepsia and visceral hypersensitivity. Relevant literature was reviewed and cited accordingly.

Table 1 The mechanism and associated symptoms in functional dyspepsia

Mechanism	Associated symptoms
Delayed gastric emptying	Postprandial fullness, nausea, vomiting.
Hypersensitivity to gastric distension	Epigastric pain, belching, weight loss.
Impaired accommodation	Early satiety, weight loss.
Helicobacter infection	Epigastric pain
Duodenal lipid hypersensitivity	Nausea
Duodenal acid hypersensitivity	Nausea
Unsuppressed phasic contractility	Bloating, absence of nausea
Atypical nonerosive reflux disease	Epigastric pain

VISCERAL HYPERSENSITIVITY

In order to fully understand visceral hypersensitivity we must first return to neurophysiology and understand how stimulation of the gut wall results in conscious perception. The perception of somatic pain involves a three-neuron chain, as illustrated in Figure 1. For visceral pain, a similar mechanism is operative. The signal is initiated at sensory receptors in the mucosa, muscle layer or serosa and relayed *via* intrinsic primary afferent neurons (IPAN's), vagal or spinal sensory afferent neurons to second order neurons in the enteric nervous system, brain stem or spinal cord, respectively.

Theories abound regarding potential sites of abnormal sensory signalling in FD. While most studies have involved mechanical stimuli, such as distension, there is evidence of sensitivity to other stimuli. For example, Samsom and colleagues have previously shown that FD patients are more sensitive to the introduction of exogenous acid into the duodenum[12]. Firstly, the existence of hypersensitivity, at the level of gut mechanoreceptors, has been nicely illustrated by Tack and colleagues[13]. In this experiment, they took fifty patients with documented visceral hypersensitivity by barostat studies and treated half with fundus-relaxing drugs, sumatriptan and clonidine. When re-tested, those treated with gastric relaxing drugs now demonstrated a significant reduction in gastric sensitivity, thereby, illustrating the role of the mechanoreceptor in the generation of symptoms from a hollow viscus in the gastrointestinal tract, as had been previously shown by others, in healthy volunteers[13-15].

Much of the initial work on visceral hypersensitivity involved balloon distension of the stomach. The development of the barostat allowed investigators to measure gastric tone and sensory responses accurately and reproducibly for the first time[16]. It has long been known in clinical practice that patients with irritable bowel syndrome (IBS) have a low threshold for the development of pain when subjected to certain stimuli, such as digital rectal examination, sigmoidoscopy and colonoscopy. This was confirmed some time ago by balloon inflation studies in IBS[17]. More recent studies have suggested that both visceral hypersensitivity[18], and visceral hyperalgesia[19], the phenomenon whereby innocuous stimuli become painful, are highly specific for IBS. Another related phenomenon characteristic of IBS is that of viscero-somatic referral, whereby the pain elicited by a given stimulus is experienced at a site remote from that of its application.

Similar observations have been made in functional dyspepsia, thereby, advancing the visceral hypersensitivity hypothesis in this disorder also. Several studies have looked at balloon distension of the stomach using the gastric barostat and have all found increased sensitivity to distension at lower distending pressures relative to normal healthy controls[20-25]. Mearin and colleagues nicely illustrated this phenomenon. In their study, one can clearly see the distinct difference in abdominal discomfort scores between the FD patients and the control subjects as intragastric pressure is increased[22].

Mearin's group also, rather interestingly, showed that there were no differences in terms of somatosensory responses between controls and dyspeptics thus suggesting that this was truly a visceral phenomenon. Some would even suggest that visceral hypersensitivity to distension appears to be organ specific, with the response to rectal distension being specific for IBS and that to gastric distension being similarly specific for FD. However, a subsequent study by Bouin *et al* looked at somatic sensation by hand immersion in cold water, and found that those with functional gastrointestinal disorders perceived pain earlier and had a lower pain tolerance than normal controls[26]. These findings suggest, in contrast, that hypersensitivity is not just a visceral problem, but, perhaps, forms part of a more generalised sensory dysfunction. Whether differences in patient populations or testing methodology can explain these apparently discordant results remains unclear.

Mertz and colleagues compared sensory responses in a group of FD patients with both healthy controls and a group of patients with organic cause for their dyspepsia[24]. They examined both sensory thresholds to gastric balloon distension and the nature of the symptoms perceived during gastric distension. While there was no real difference in the prevalence of symptoms between the organic and functional groups (apart from nausea as a primary complaint being significantly more common in the FD group), only those with functional dyspepsia

had lowered perception thresholds to gastric distension, 87% versus 20%. In addition, they showed, rather nicely, the presence of viscerosomatic referral in the FD patient group alone. This could explain how patients with functional dyspepsia may perceive pain at sites distant to the stomach.

THE BRAIN-GUT AXIS

Other potential sites for sensory abnormalities in functional dyspepsia are the sensory afferent neurons, the spinal cord, and the brain itself. More and more research is now focusing on the so-called brain-gut axis. Normally, most visceral sensation to the central nervous system (CNS) does not reach conscious perception but patients with FD are thought to perceive visceral stimuli in an abnormal manner[27]. Vandenberghe and colleagues demonstrated, in their study, that visceral hypersensitivity may originate at sites other than the gut wall and involve a multimodal pathway[28]. They showed that both painful and non-painful gastric distension resulted in higher symptom scores among a group of FD patients with visceral hypersensitivity, yet gastric compliance was similar to that in a group of FD patients without hypersensitivity, suggesting that altered perception was more than a gut wall phenomenon.

Research in animal models has furthered our knowledge of the visceral sensory pathways (Figure1). Previously it had been thought that nocioception was mediated by spinal afferents and the sympathetic system[29], until animal studies established the role vagal afferents played in the modulation of nociception[30,31]. The advent of functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scanning have greatly increased our knowledge of the final sensory pathways in the spinal column and the brain[32]. Two recent studies, in healthy volunteers, have demonstrated the activation of several areas of the brain in individuals subjected to gastric distension[32,33]. Some of the areas of activation included the thalamus, the insula, the left and right postcentral gyrus, and the anterior cingulate gyrus. The latter, interestingly, was previously shown to be an area of low activation, in IBS patients, in response to a painful stimulus[34]. Similarly, non-painful oesophageal balloon distension activates the primary somatosensory cortex, the insula bilaterally, and the operculum and painful stimuli activate the right anterior insular cortex and the cingulate gyrus[35,36]. These studies illustrate the complexity of central nervous system processing of visceral pain.

FOOD HYPERSENSITIVITY IN FUNCTIONAL DYSPEPSIA

Typically, and almost by definition, FD patients report the occurrence of most their symptoms in relation to food ingestion. Accordingly, studies have shown that about 60%-70% of patients with FD are hypersensitive to an infusion of lipid into the duodenum[37,38]. Another study found more dyspeptic symptoms in patients following the ingestion of high-fat versus low-fat soups[39]. It would also appear that hypersensitivity is nutrient specific as the intraduodenal infusion of an emulsion of long-chain triglycerides induced fullness, nausea, and bloating in patients with FD, whereas an infusion of glucose did not[40]. A role for fat was further illustrated in a recent study on healthy volunteers where the lipase inhibitor, orlistat, markedly reduced the perception of fullness and nausea induced by duodenal lipid infusion and gastric distension[41].

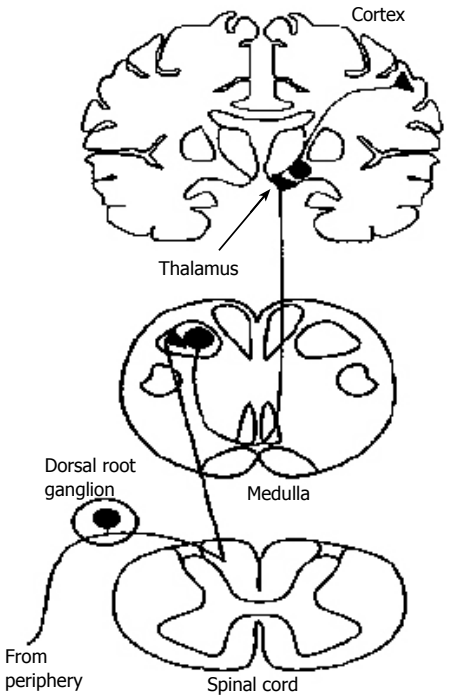

Figure 1 Sensory pathway showing one route of visceral sensation from the periphery, via a spinal sensory afferent neuron to the central nervous system.

Duodenal infusion of acid was also found by Samson and colleagues to induce nausea in FD; these patients also demonstrated impaired clearance of exogenous acid from the duodenum[12]. It is clear from these studies and others that small intestinal sensing of certain nutrients and fat, in particular, as well as the motor response in the foregut to their instillation, may play a role in the induction of symptoms in FD. In this way motor and sensory phenomena may interact and prove synergistic in symptom induction.

Helicobacter pylori

H pylori infection is purported in several studies as a possible mechanism in functional dyspepsia. However, recent large scale controlled trials and a meta-analysis failed to show any improvement in dyspeptic symptoms with *H pylori* eradication[42-44].It is unclear what role *H pylori* plays in the symptom profile of the FD patient, and whether any of the proposed pathophysiological mechanisms mentioned earlier are related to *H pylori* infection. These particular questions were addressed in a recent study by Sarnelli and colleagues[45] in which they compared the symptom profile of FD patients with and without *H pylori*, and looked at various pathophysiological mechanism including gastric emptying, sensation and accommodation.

They found no association between *H pylori* infection and the overall prevalence of symptoms or the gastric sensory-motor functions. This is in keeping with the previous observations that eradication of *H pylori* is not associated with with improvement in the dyspeptic symptoms.

In conclusion, clearly, a vast amount of knowledge regarding FD has been garnered from detailed studies of the last decade or so. The level of complexity involved in visceral sensation is only now being fully understood and therapies aimed at ameliorating the hypersensitive gut are crucial. These will involve visceral analgesics and agents that block the various neurotransmitters involved. The development of enhanced neuroimaging will allow us better understand the mechanisms of actions of some of these agents. Functional dyspepsia often leaves the clinician despondent due to the lack of clinical efficacy of many of the drugs used, but novel agents and targets of treatment offer hope for the treatment of this complex condition.

Abstract

The aetiology of dyspepsia is unknown in the majority of patients. *Helicobacter pylori* (*H pylori*) is the cause in a subset of patients. A non invasive test to assess the presence of *H pylori* is recommended in the management of patients under the age of 50 presenting to a family practitioner with dyspepsia. A urea breath test or a stool antigen test are the most reliable non invasive tests. Eradication of *H pylori* will reduce the risk to the patient with dyspepsia of developing a peptic ulcer, reduce the complication rate if prescribed non-steroid anti-inflammatory drugs and later reduce the risk of gastric cancer. The recommended treatment for non ulcer dyspepsia associated with a *H pylori* infection should be a 10-d course of treatment with a PPI and two antibiotics. Treatment efficacy should be assessed four weeks after completing treatment with a urea breath test or a stool antigen test.

INTRODUCTION

Dyspepsia or indigestion is an unsatisfactory term as it describes a spectrum of conditions. It has other limitations as there is no similar word in all languages. The patient does not volunteer symptoms and the diagnosis depends on a doctor's interpretation of the patient's complaint. Symptoms are vague and varied but for research and clinical purposes are grouped as reflux, ulcer like, motility or non specific[1].

Since the aetiology of dyspepsia is uncertain, it is not surprising that (*Helicobacter pylori*) *H pylori* has been implicated in dyspepsia. Large population studies have shown that the bacteria is found more frequently in dyspeptic patients compared to controls. Peptic ulcer relapse and remit and it is possible that at the time of endoscopy an ulcer is not present and then the patient is diagnosed with non ulcer dyspepsia as the bacteria will be present[2]. There is unequivocal evidence that infection with *H pylori* is the principal cause of peptic ulcer disease. The organism is present in 85%-95% of patients with peptic ulcer disease, and treating the infection is effective in healing these ulcers. Treatment to eradicate *H pylori* results in permanent cure of peptic ulcer disease, whereas 60%-80% of such patients relapse within a year if treated with anti-secretory drugs alone[3].

The evidence for an association between *H pylori* and non-ulcer dyspepsia is more uncertain. Many trials evaluating the efficacy of *H pylori* eradication treatment for non-ulcer dyspepsia have been poorly designed and have given conflicting results but there is a clear indication that *H pylori* eradication treatment is effective in at least a subset of patients with non-ulcer dyspepsia.

INVESTIGATING DYSPEPSIA

Patients presenting to a primary care physician with symptoms referable to the upper gastrointestinal tract are usually treated empirically with a proton pump inhibitor (PPI) or are assessed for the presence of *H pylori* by a non-invasive test. The recommended non invasive tests are a urea breath test or a stool antigen test. A serology test is considered less reliable and is not recommended. Consensus guidelines have recommended a test and treat approach to patients with *H pylori*[4,5]. This has been controversial as the response to treatment has been equivocal. In a double blind study the test and treat approach has been vindicated in non investigated dyspepsia in patients presenting to a family practitioner. In a study of 294 patients who were randomised to triple therapy of a PPI and two antibiotics, clarithromycin and metronidazole for one week or a PPI and placebo antibiotic the patients were evaluated monthly for one year[6]. The results of this randomised control led study demonstrate a significant benefit of a *H pylori* "test and treat" strategy at primary care level (Figure 1).

Endoscopy

Investigated dyspepsia describes patients who had an endoscopy and in whom no mucosal lesions are found, but are found to have an *H pylori* infection on biopsy. Systematic review of randomised controlled trials comparing *H pylori* eradication with placebo or another drug treatment has been published[7]. In this analysis the trial reports were reviewed according to predefined eligibility and quality criteria. Twelve trials were included in the systematic review, nine of which evaluated dyspepsia at 3-12 mo in 2541 patients. *H pylori* eradication treatment was significantly superior to placebo in treating non-ulcer dyspepsia (relative risk reduction 9% (95% confidence interval 4% to 14%)). One case of dyspepsia being cured for every 15 people treated. *H pylori* eradication cost £56 per dyspepsia-free month during first year after treatment. The conclusion of this comprehensive data review is that *H pylori* eradication is cost effective treatment for non-ulcer dyspepsia in infected patients.

Test and treat vs endoscopy

A number of economic models were developed suggesting that eradication models were developed suggesting that eradication of *H pylori* might be cost saving in dyspepsia. Silverstein *et al* reported that the 1 year medical charges for the initial management of an incident episode of dyspepsia were $2163 for prompt upper endoscopy versus $2123 for empirical therapy, a difference of only 2%; the decision was a toss-up across all age groups and clinical strata applying medical charges[8]. Other models support empirical *H pylori* therapy as being less costly. Fendrick *et al*[9] in a model restricted to persons with symptoms suggesting peptic ulcer disease, reported that the most expensive strategy was endoscopy and biopsy for *H pylori* at $1584, while the costs per patient treated were lowest for serologic testing for *H pylori* (and treating seropositive cases) at $894 and empirical anti-secretory therapy combined with antibiotics (for all cases) at $818. Only if an upper endoscopy cost $500 or less was an endoscopy strategy superior.

Ofman *et al*[10] in a model of *H pylori*-positive patients with dyspepsia, found that empirical treatment was less expensive ($820 *vs* $1276), largely due to less upper endoscopy (52%). They calculated that endoscopy related costs had to be reduced by 96% before initial endoscopy and *H pylori* treatment were similarly cost-effective. Other models have suggested benefits may be marginal[11] or will take at least 5 years to accrue[12]. Upper gastrointestinal radiology is still practiced in some primary care settings but was not a cost-effective alternative to a *H pylori* test and treat strategy. In another US model[13], the test and treat approach is cost effective compared to prompt endoscopy. The benefit is more apparent if there is a high prevalence of peptic ulcer and of *H pylori* infection in the population. The value of this approach decreases when the prevalence rate of the infection falls. The critical prevalence below which the test and treat is less effective although still an option is 15%[14].

The yield from endoscopy in patients being investigated for dyspepsia increases with advancing age but is low[15]. Missing early (and hence curable) gastric cancer is often of greatest concern to the clinician contemplating empirical therapy, especially in an older patient[16,17]. Fear of gastric cancer has to be taken into account when planning the management of dyspepsia. A practical approach to investigate patients with endoscopy presenting with dyspepsia should be made for alarm signs and not on the basis of age alone, reflecting the balance of benefit and harm from endoscopy. Empirical management without formal diagnosis is appropriate for most patients: reviewing the patient history, lifestyle, over-the-counter medicines, and providing a course of proton-pump inhibitors and/or *H pylori* test and treatment. Patients with ongoing symptoms require at least annual review to discuss symptoms and lifestyle, and as appropriate, encourage stepping down prescribed medication and returning to self-care. A new strategy included in the step down process is the use of therapies 'on-demand'.

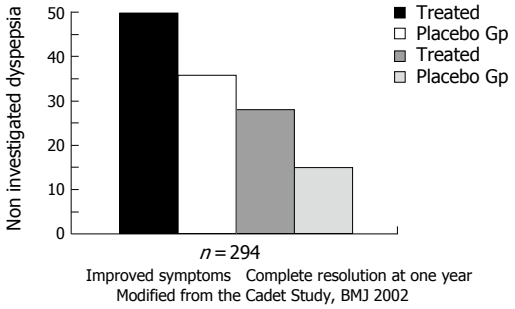

Figure 1 Significant improvements in complete resolution of symptoms in patients successfully treated of *H pylori* infection.

However, there is inconclusive evidence that patients without alarm signs will benefit subsequently from endosocpy, while investigation involves a small but real risk of harm[18].

Long term studies

The effectiveness of a test and treat strategy, is confirmed in long term studies. In two long term follow up studies of almost 7 years the benefits of eradication were still apparent[19,20]. In a short term prospective study from my unit of 90 patients with non ulcer dyspepsia, no clinical or endoscopic evidence of other peptic biliary, pancreatic or malignant disease; all had evidence of *H pylori* infection were randomised to bismuth alone, antibiotics alone or a combination of bismuth and antibiotics. Overall *H pylori* eradication was achieved in 49% of patients, although gastritis improved in those in whom the bacteria was eliminated whereas symptoms score were similar in patients where the infection persisted or was eradicated[21] when assessed at four weeks. However, a follow-up study at one year of these patients showed the patients in whom the bacteria persisted required additional treatment and in were more symptomatic compared to those who were eradicated of the bacteria.

The same patients when reviewed at a 5-yr follow up showed that patients who were successfully treated were more likely to be asymptomatic and none developed a

duodenal ulcer. Where as up to 20% developed an ulcer when the bacteria was still present (Figure 2)[22].

PATHOGENESIS

There is some evidence that *H pylori*-associated dyspepsia is caused by the effect of the bacterium on acid secretion[23]. *H pylori* infection causes increased fasting and post-prandial serum gastrin levels and decreased gastric mucosal concentrations of stomatostatin abnormalities which are corrected following eradication[24-27].

Gastrin-releasing peptide is a neuro-peptide that mimics the physiological responses of the stomach to a meal. After intravenous infusion of gastrin-releasing peptide, patients with peptic ulcers and *H pylori* infection have a six-fold increase in acid secretion and patients with non-ulcer dyspepsia and *H pylori* have a four-fold increase, whereas asymptomatic *H pylori* positive individuals have a two-and-a-half-fold increase in stimulated acid secretion, when compared to asymptomatic controls who do not have *H pylori* infection[28]. This would suggest that non-ulcer dyspepsia may represent part of a spectrum of *H pylori*-induced disease. The spectrum ranges from an asymptomatic carrier state, through an ulcer-free dyspeptic period to finally developing a peptic ulcer.

Further work from my unit suggest that mast cells are found in *H pylori* negative dyspeptic patients, compared to *H pylori* positive patients suggesting a different mechanism of symptoms in *H pylori* negative dyspepsia[29].

TREATMENT

It has been suggested that the eradication rates in patients with non ulcer dyspepsia is not as successful in patients with duodenal ulcer[30]. The possible explanation is that the bacteria colonisation is not as dense and that the gastritis is not as severe allowing poorer penetration of antibiotics. It emphasis the need for compliance. Smoking is associated with a lower success in treatment and may serve as surrogate marker for compliance. The treatment is complex and it is know that individuals who have received third level education achieve only 50% compliance to a five day course of antibiotics. Patient education is vital for successful treatment. They should be warned of possible side effects such as diarrhoea and antibiotic sensitivity. Diarrhoea is usually transient and self limiting and occasionally cases of clostridium difficile have been reported.

New options in the treatment armamentarium against *H pylori* provide hope of higher eradication rates. The use of a more prolonged 10-d course of therapy rather then the traditional 7-d course, and quadruple rather than triple therapy may lead to higher eradication rates. In a French study of 2571 patients, the use of 10-d therapy as opposed to 7-d therapy was associated with higher eradication rates- 83.9% compared with 70.6%[30]. A meta-analysis of 13 studies evaluated lengthening triple therapy beyond 7 d. Only randomised trails comparing 7-d triple therapy with either 10 or 14 d triple therapy were included. In the intention to treat analysis, pooled 10 and 14 d therapies lead to better results than 7 d schedules. However, in head-to-head comparisons, although a trend for higher cure rates was found with longer therapy, only 14-d therapies were found to be significantly better than 7-d therapy. Looking at intention-to-treat analysis, 10 d therapy compared with 7-d therapy lead to a 3% increased eradication rate-from 80 to 83% - whereas, 14-d therapy compared with 7-d therapy led to a 9% increased eradication rate from 72 to 81%[31].

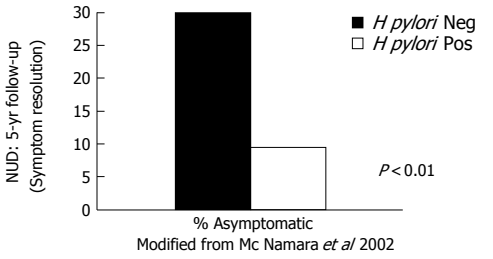

Figure 2 Patients who had *H pylori* eradicated were less symptomatic at 5 years compared to patients who had persistent *H pylori* infection.

CONCLUSION

A test and treat strategy is the preferred option for patients with dyspepsia presenting to primary carer physicians. The benefit of this are apparent in long term studies. The additional benefit of eradication of the bacteria will prevent subsequent development of an ulcer and the complication that might ensue if prescribed NSAIDs later and reduce the risk of gastric cancer. Treatment compliance is essential. The preferred treatment is a PPI based triple therapy, which should be given for a period of at least 10 d.

Abstract

Functional dyspepsia is a symptom complex characterised by upper abdominal discomfort or pain, early satiety, motor abnormalities, abdominal bloating and nausea in the absence of organic disease. The central nervous system plays an important role in the conducting and processing of visceral signals. Alterations in brain processing of pain, perception and affective responses may be key factors in the pathogenesis of functional dyspepsia. Central serotonergic and noradrenergic receptor systems are involved in the processing of motor, sensory and secretory activities of the gastrointestinal tract. Visceral hypersensitivity is currently regarded as the mechanism responsible for both motor alterations and abdominal pain in functional dyspepsia. Some studies suggest that there are alterations in central serotonergic and noradrenergic systems which may partially explain some of the symptoms of functional dyspepsia. Alterations in the autonomic nervous system may be implicated in the motor abnormalities and increases in visceral sensitivity in these patients. Noradrenaline is the main neurotransmitter in the sympathetic nervous system and again alterations in the functioning of this system may lead to changes in motor function. Functional dyspepsia causes considerable burden on the patient and society. The pathophysiology of functional dyspepsia is not fully understood but alterations in central processing by the serotonergic and noradrenergic systems may provide plausible explanations for at least some of the symptoms and offer possible treatment targets for the future.

INTRODUCTION

Dyspepsia is defined as pain or discomfort centred in the upper abdomen[1]. Discomfort specifically includes early satiety, fullness, upper abdominal bloating and nausea[2]. It is a common symptom and comprises 30 to 40% of all abdominal complaints presenting to gastroenterologists[3]. Patients treated in primary care usually have uninvestigated dyspepsia, and their symptoms may have an underlying structural cause, such as peptic ulcer disease, reflux oesophagitis, or endoscopy negative gastro-oesophageal reflux disease. However, a large number of these patients will have functional dyspepsia (FD) where there is no structural or biochemical explanation for their symptoms following appropriate investigation[3].

FD may be categorised by the predominant symptom into ulcer-like, dysmotility-like, and unspecified dyspepsia. Ulcer-like dyspepsia has pain as the predominant symptom while dysmotility-like dyspepsia has predominantly discomfort. There was another category of dyspepsia, reflux-like dyspepsia, but this is no longer included as these patients have reflux disease and are treated as such. This classification scheme was first used as an aid in the design and performance of clinical trials. Its clinical use beyond taxonomy has yet to be proven[1,2].

FD is a heterogeneous disorder which does not have a well established pathophysiology. Gastrointestinal motor abnormalities, altered visceral sensation, and psychosocial factors have all been identified as major pathophysiological mechanisms. It has become more evident recently that FD is a biopsychosocial disorder[4] in which these three major pathophysiological mechanisms interact to generate the symptoms. This view has now replaced the earlier perspective that the condition was the result of a sole motor or sensory disorder of the stomach[5]. There is much controversy whether *Helicobacter pylori* infection induces FD or not. Some studies suggest that it is implicated in a small proportion of patients with FD[6] whilst others suggest that it is not involved in the pathophysiology at all[7].

The motor, sensory and secretory activities of the

intestine occur through the coordinated bidirectional communications between the central nervous system (brainstem and cerebral cortex), the autonomic nervous system (ANS) (sympathetic and parasympathetic neuronal pathways) and the enteric nervous system[8]. These systems form what is known as the brain-gut axis[9,10]. FD symptoms may result from deregulated interactions at any level of the brain-gut axis. Recent studies emphasize the role of the central nervous system (CNS) in conducting and processing visceral signals and suggest that alterations in brain processes involving perception and affective responses might be key factors in the pathogenesis of functional gastrointestinal symptoms[10]. Familial clustering of FD has been reported[11] which suggest a genetic component. FD causes considerable burden on the affected patient and society[12].There is now evidence to support the fact that functional disorders such as FD impair the affected patients to a similar extent as a disease with well-defined structural lesions; this disorder also causes considerable loss of working time and a large financial expense for medical management[13].

There is substantial evidence to suggest that patients with FD have a higher incidence of psychological disorders than population controls[14]. Patients with unexplained gastrointestinal complaints are more likely to suffer from symptoms of neurosis, anxiety, hypochondriasis and depression than controls[15,16]. Some studies have also revealed that there are possible links between emotional factors and changes in gastrointestinal physiology which may lead to abnormal gastric secretion, gut motility and function[17].

Life stress contributes to symptom onset and exacerbation in the majority of patients with FD[18]. Acute stress affects upper gastrointestinal motility and gastric acid secretion. However, studies of acute stress in FD patients have conflicting results[19]. A longitudinal study assessed the relationship of chronic and severe life stress to subsequent symptom intensity in patients with FD. The results of this study showed that severe and chronic threat has large and consistent effects on symptom intensity over time in FD patients[18].

VISCERAL HYPERSENSITIVITY

Visceral hypersensitivity is currently regarded as the mechanism responsible for both motor alterations and abdominal pain in functional bowel disorders including FD[20]. In order to elucidate the origins of visceral hypersensitivity it is necessary to understand the neuroanatomy and physiology of visceral sensation itself. Enteroendocrine cells in the lining of the gut act as chemical and mechanical transducers for local reflexes of initiation of afferent projections to the CNS[21]. Gut afferent signals reach conscious perception through a three neuron chain[4]. The cell body of the first order neuron is in the dorsal root ganglion and this neuron terminates in the dorsal column of the spinal cord. En passant fibres project to noradrenergic neuron in the prevertebral ganglia. This reflex centre results in modulation of viscus functions such as motility. Somatic and visceral afferents converge on dorsal horn neurons and result in viscerosomatic projection or referred pain. Descending controlling fibres such as serotonergic and noradrenergic from brainstem centres alter the sensitivity of the dorsal horn neurons and therefore centrally control the intensity of perception during visceral stimulation[21].

The second order neuron projects from the dorsal horn of the spinal cord to the thalamus and reticular formation in the brainstem. The ascending pathways are found in the spinoreticular and spinothalamic tracts. Nociceptive spinal pathways have recently been identified in the dorsal column of primates. These project nociception from viscera such as pancreas, colorectum, and duodendum (the upper bowel)[22]. This was also found in studies using rats[23]. These second order neurons synapse with satiety and autonomic centres and also the third order neurons that lead to emotional responses (limbic system) and conscious perception (sensory cortex). These projections lead to alterations in pulse rate, blood pressure, appetite and emotions in response to visceral pain. The loci of projection in the sensory cortex are not fully elucidated yet[24]. At present there is a limited understanding of the cerebral processing of visceral stimuli, the pathways and mediators of visceral afferents, the role of end organ modulation of sensation and association of symptoms with sensorimotor dysfunctions. Among the neurotransmitters involved in visceral perception are serotonin and noradrenaline. Different receptor subtypes for the transmitters may also have differential effects[24].

NEUROANATOMY OF THE SEROTONIN AND NORADRENALINE SYSTEMS

Serotonin is a neurotransmitter in the CNS and in the gastrointestinal tract. There are seven known serotonergic receptors, of which 5-HT_1, 5-HT_3, 5-HT_4 receptors (and their subtypes) seem to play an important role in the gut[25]. Centrally serotonin neurons are found at most levels of the brainstem and are concentrated in the raphe nuclei. Serotonergic neurons innervate virtually all parts of the CNS. Projections from the rostral raphe nuclei reach the forebrain, providing a cortical innervation that is the densest in sensory and limbic areas. Caudal raphe nuclei provide most of the projections to the brainstem and spinal cord.

Noradrenaline systems are also located in the CNS and within the gastrointestinal tract. There are two main types of adrenoreceptors α and β. There is two of each of the receptors: α_1 and β_1 are located on the post-synaptic membrane while α_2 and β_2 are found on the pre-synaptic membrane. Noradrenergic neurons are found in the pons and the medulla of the brainstem. Most are located in an area called the locus ceruleus, a collection of pigmented cells located near the floor of the fourth ventricle. The remainder of noradrenergic neurons are found in the lateral parts of the medullary reticular formation, in some nuclei associated with cranial nerves (the solitary nucleus and the dorsal motor nucleus of the vagus). Collectively these neurons innervate nearly the entire CNS. Ascending fibres reach the thalamus, hypothalamus, limbic forebrain structures and the cerebral cortex. All areas of the cerebral cortex receive some noradrenergic innervation with

the somatosensory cortex receiving a particularly dense innervation. Descending fibres project to other parts of the brainstem and to all spinal levels as well as the cerebellum[26].

INTERACTION OF SEROTONIN AND NORADRENALINE SYSTEMS

Central serotonergic pathways have been implicated in the mechanisms of nociception. Conflicting results have been published because serotonin administered intrathecally is seen to either inhibit or stimulate nociceptive responses. This may depend on the dose and the species studied[20].

While both supraspinally and spinally projecting serotonin pathways are involved in the modulation of nociceptive transmission, it is the pathways originating in the brainstem and projecting to the dorsal horn of the spinal cord that have been studied the most. This is due to the proposal of an endogenous pain-suppressing system using serotonin[27]. The actions of serotonin depend on the receptor subtype being activated and the response may be pronociceptive or antinociceptive[28]. Activation of spinal 5-HT_{1B} and 5-HT_3 produces an antinociceptive effect while activation of 5-HT_{1A} receptors has a pronociceptive effect. Activation of 5-HT_2 receptors produces antinociception which may be preceded by pronociceptive responses[29]. Serotonin interacts with other brainstem projection pathways including noradrenaline[28].

Studies were undertaken by Sawynok *et al* (1996), in order to investigate the interactions between serotonergic and noradrenergic systems in the modulation of pain in the rat. They provide evidence that the spinal antinociceptive effects of serotonin are dependent on noradrenaline. This is true as the antinociceptive effect of intrathecal (it) serotonin is reduced by depletion of noradrenaline in the spinal cord after the administration of the neurotoxin 6-hydroxydopamine[30]. The nature of the serotonin-noradrenaline interaction was investigated using pharmacological agents that interact with adrenergic mechanisms in different ways. Serotonin agonists produced a dose-related antinociception. This action was blocked by the administration of a non-selective antagonist for noradrenlaine and an antagonist selective for α_2 receptors but not by the α_1 and α_{2a} antagonist. But this observation is not definitive as α adrenoceptor antagonists could block the action of serotonin and related agonists by a number of mechanisms. Such mechanisms may include serotonin causing the release of endogenous noradrenaline by perhaps a receptor mediated reaction[31]. Serotonin could also interact synergistically with endogenous noradrenaline. The adrenergic system is tonically active within the spinal cord[32] and serotonin may depend on such tonic activity for expression.

In order to determine which serotonin receptors were involved in the interaction a number of serotonin agonists each selective for a different serotonin receptor were administered to rats. Pre-treatment with 6-OHDA produced a marked depletion in noradrenaline levels in the spinal cord (>80%) and reduced antinociception by serotonin and by most of the 5-HT_1 agonists but not the 5-HT_3 or 5-HT_2[28]. The agents that were inhibited by 6-OHDA were potentiated by a systemic pre-treatment of desipramine (blocks the reuptake of noradrenaline). This data presents several possibilities: (1) serotonin releases endogenous noradrenaline from the spinal cord through a receptor mediated action. This indicates that the action of serotonin is augmented by desipramine. This is consistent with a serotonin receptor mediated release of noradrenaline and augmentation resulting from a blockage of the reuptake of noradrenaline. (2) The serotonin receptor involved in this interaction appears to be a 5-HT_1-like receptor[28] as depletion of noradrenaline reduced the antinociception of the 5-HT_1 agonists and not others.

ACTION OF CENTRAL NORADRENALINE AND SEROTONIN RECEPTORS ON GASTROINTESTINAL MOTILITY

Gastrointestinal motility and secretions are modulated by cerebral nuclei via autonomic efferents in a coordinated manner. The sympathetic division of the ANS is important in the control of gastrointestinal function both in the basal and under stressful conditions[33]. Noradrenergic α_2 receptors in the hypothalamus form an important part of this network and research has demonstrated that these receptors have a significant influence on intestinal motility and transit time.

In several species, including humans, the sympathetic nervous system exerts a primarily α_2 mediated tonic inhibitory effect on gastrointestinal motor function[33]. α_1 and β_2 agonists also reduce colonic contractile frequency in non-human primates[34].

Noradrenaline (10 nmol) administered intracisternally (i.c.) significantly decreased gastric motility while yohimbine and not prazosin abolished this decrease pointing towards the involvement of the α_2 receptor in noradrenergic regulation of gastric motility[35]. The α_2 agonist clonidine acting centrally produces a dose dependent decrease in intestinal motility[36]. These studies indicate that central noradrenergic receptors play a role in the modulation of gastrointestinal motility and that alterations in this system may lead to motility symptoms seen in FD patients.

Peripheral serotonin and its receptors effects on gastrointestinal motility have been well established but the control of central serotonergic receptors has been somewhat overshadowed. This may be due to the fact that the majority of serotonin is present in the gut and only 5% exists in the CNS. Some treatment studies suggest that centrally acting serotonergic agents alleviate motility symptoms in FD patients. But it is not clear whether this is due to central or peripheral effects of these drugs. Serotonin is present in enterochromaffin cells (EC) and enteric neurons in the gastrointestinal tract. Release of serotonin from EC cells act as chemical and mechanical transducers for the initiation of local reflexes (peristalsis) and for activation of projections to the CNS[37].

ALTERATIONS IN VISCERAL SENSATION AND POSSIBLE CAUSES

Patients with FD have an increased perception of physiological or minor noxious stimuli in both the fasting and postprandial states[38]. When compared to normal healthy controls, FD patients are hypersensitive to isobaric or isovolumetric balloon distension of the proximal stomach. In view of normal gastric wall compliance in these studies, increased sensation during gastric distension suggests abnormal afferent function or the "irritable stomach syndrome"[39]. This enhanced perception of visceral stimuli may be due to greater sensitivity of visceral afferent pathways or a central amplification of visceral afferent input[40]. Visceral afferent input is modulated by a variety of mechanisms operating between the gastrointestinal tract and the CNS, and dysfunction of these regulatory systems could distort gastrointestinal perception[41]. The ANS which regulates gastrointestinal function is thought to modulate visceral sensitivity. Increased sympathetic tone is known to increase the level of perception of gastrointestinal stimuli without affecting the reflex responses[42]. Alterations in sympathetic modulation of visceral sensitivity may therefore play an important role in FD[41]. Since noradrenaline is the principal neurotransmitter and receptor system involved in the sympathetic nervous system, it may be fair to speculate that there is an abnormality in this system in FD patients. This may be present as an alteration in sensitivity or regulation of the noradrenergic receptor system.

Hypersensitivity of the dorsal horn neurons or altered supraspinal processing of visceral afferent function has been implicated in the increase in visceral sensation[5]. This hypersensitivity may develop in response to descending influences from the brainstem. With regard to the clinical characteristics and the concept of central hypersensivity, a model has been proposed by which abdominal pain in FD could develop by multiple mechanisms either alone or in combination[21]. Stress is involved in the exacerbation of symptoms in FD. Stress induced analgesia is modulated by descending pain inhibitory pathways that are partially mediated by serotonergic systems. This stress induced somatic hypoalgesia can be accompanied by a stress induced visceral hyperalgesia[43]. This may be due to both pain facilitatory and inhibitory systems being activated simultaneously by stress, with the net effect being determined by the contribution of each system[44].

If there is a dysregulation of the descending pain inhibiting serotonergic system, then this would at least partially explain the visceral hyperalgesia of FD patients. Stress is associated with the onset and exacerbation of symptoms in these patients. It may provoke an increase in visceral hyperalgesia in individuals who are vulnerable due to the inability to inhibit the pain facilitatory mechanisms due to a dysregulation of their central serotonergic systems.

ALTERATION IN MOTILITY AND POSSIBLE CAUSES

FD is associated with gastrointestinal motor abnormalities such as delayed emptying[45], impaired initial distribution of a meal within the stomach[46], impaired accommodation[38] antral hypomotility, gastric dysrhythmias (tachygastrias, bradygastrias and mixed dysrhythmias) and altered duodenojejunal motility[5]. The occurrence of dyspeptic symptoms after food digestion suggests a disturbance of postprandial gastric motility which leads to slowed gastric emptying accompanied by sensations of prolonged gastric distension, bloating, and nausea. It was Coffin *et al*[47] that initially suggested that patients with FD may have abnormal motor function of the proximal stomach. Usually, after a meal the proximal stomach relaxes in order to act as a reservoir and to enable an increase in gastric volume without a significant increase in gastric pressure. This impaired accommodation is a disturbance of the "diastolic" function of the stomach and is a frequent finding in FD patients[5].

The underlying mechanism for this impairment of gastric motor is not fully understood. But it has been proposed that there may be a dysfunction of the ANS[48]. Noradrenergic modulation of synaptic vagal transmission in the nucleus tractus solitarus can be assumed to play a role in the modulation of vagovagal reflexes. These include regulation of gastric accommodation, regulation of spontaneous transient lower oesophageal sphincter relaxation and duodenogastric reflexes[40]. Therefore, alterations in this noradrenergic receptor system can lead to abnormalities of motor function and accommodation.

As mentioned, stress plays a role in the onset and exacerbation of symptoms in functional gastrotintestinal disorders such as FD and chronic stress leads to overactivity of these systems. A downregulation of autoreceptors (α_2 and 5-HT_{1A} receptors) was observed in an animal model of social stress[49] and in patients with posttraumatic stress disorder[50] which results in an enhanced release of noradrenaline and serotonin respectively. This enhanced release may lead to a downregulation of postsynaptic receptors (such as β adrenergic and α_1 receptors)[49]. These neuroplastic alterations would initially increase noradrenaline release (presynaptic) but ultimately decrease postsynaptic target neurons. Also excessive release of transmitters could result in depletion of serotonin or noradrenaline further decreasing postsynaptic neuron activation[40].

Stress among other factors can lead to alterations in central aminergic networks involving serotonin and noradrenaline. These alterations may result in changes in the functioning of the ANS and therefore may have an impact on gastrointestinal functions such as motility.

TREATMENT OF FD

Although treatment of FD is expensive, the agents are rarely used in a systematic manner: the majority of treatments are empirical and the results are short lived once the therapy ends. To a degree, this is due to lack of consistent pathophysiologic markers which is why treatment of FD is symptom driven. Eradicating *Helicobacter pylori*, if present, is a first-line strategy. Patients with upper abdominal pain (ulcer-like) as the predominant symptom can initially be treated with proton

pump inhibitors. Those that suffer from dysmotility-like symptoms can be treated with acid suppressive therapy, prokinetic agents or 5-HT_1 agonists. The use of prokinetics is limited due to availability issues[51]. Some studies suggest that 5-HT_1 agonists are effective in the treatment of impaired accommodation[2].

Many patients with FD also suffer from psychiatric disorders including anxiety, mood and somatoform disorders[52] so that the expanding field of psychologic therapies provide a promising area of treatment. Psychoactive agents such as antidepressants and anxiolytics with serotonergic activity have been widely used in the treatment of patients with FD. But it is unclear if these medications improve symptoms through central or peripheral mechanisms[53].

Nonpharmacological interventions have also been employed with two studies having reported a favourable outcome with psychotherapy in FD[53,54]. A Cochrane review on psychological interventions (such as psychotherapy, cognitive behavioural therapy and hypnosis) in FD patients reported beneficial results of such therapy[3].

STUDIES

At present, an integrated disease model that adequately explains the broad variety of symptoms seen in FD, as well as the association with extra-intestinal syndromes and psychiatric disorders is lacking. A number of receptors may be involved in symptom production in FD patients. One study suggests that there is an increased sensitivity of central serotonin receptors in these patients[55]. The authors examined the functional activity of central serotonin by means of a neuroendocrine challenge. The release of the hormone prolactin is partially under serotonin control. The anxiolytic buspirone was used to stimulate the 5-HT_{1A} and increase prolactin release. Although not entirely specific for serotonin receptors (it also acts on dopamine receptors) there is enough evidence to indicate that its mediation of prolactin release is via serotonin receptor as this action can be blocked with the serotonin antagonist methysergide[56]. Dopamine responses in FD were examined using bromocryptine as a probe drug and prolactin decrease as the response. The response of the FD patients was not any different from that of the controls. So it was concluded that buspirone provided an acceptable method of serotonin-stimulated prolactin release. When FD patient were administered the dose of buspirone the response was 200% greater than in healthy controls. This indicates that patients with FD have a supersensitivity of central 5-HT_{1A}[55].

FD is sometimes referred to as upper irritable bowel syndrome (IBS) due to the overlap of symptoms[57]. A down regulation in the noradrenergic α_2 receptors has been implicated in IBS[58]. This may apply to a subgroup of FD patients. The function of these receptors was assessed using a neuroendocrine test. The test was based on the fact that the monoamine reuptake inhibitor desipramine acts on central α_2 receptors to bring about the release of growth hormone[59]. This effect is blocked by the α_1 and α_2 receptor antagonist phentolamine but not by the α_1 antagonist prazosin[60]. IBS patients displayed blunted growth hormone response to a challenge with desipramine at 1 mg/kg body weight. Similar blunted growth hormone responses are seen in depressed patients[61] but this does not account for the blunting here. All patients in this study were assessed by a consultant psychiatrist and while five out of the total 13 were diagnosed with depression both the depressed and the non depressed patients displayed blunted responses[58]. Also it may be argued that delayed gastric emptying and slowed absorption of desipramine might explain the findings. But this was not the case as no further elevations in growth hormone were noted in samples taken later. These results are due to the central action of the α_2 receptors. These findings indicate that the abnormal functioning of these receptors may be important in IBS and a subset of FD and may offer new treatment options[58].

A dose response study using nitroglycerin and clonidine demonstrated that gastric relaxation and antinociception have different effects on the perception of visceral stimuli in humans[38]. Both of these drugs caused relaxation of the fasting stomach without impeding normal postpradial accommodation of the proximal stomach. The gastric balloon distension test was used to measure the antinociceptive effects. Perception scores were reduced with clonidine but not with nitroglycerin. The nitroglycerin actually increased bloating despite significant relaxation. This data suggests that relaxation alone is insufficient to reduce sensation in response to distension in humans[38]. This study suggests that central α_2 receptors are involved in the perception of visceral stimuli and that activation of these receptors produces an analgesic effect in FD patients. This suggests that these patients may have some abnormality of the α_2 receptors that may influence the hypersensitivity seen in FD patients.

In summary the main symptoms of FD are alterations in motor function and abdominal pain. The mechanisms involved in the modulation of these functions include central serotonergic and noradrenergic receptor systems. Both human and animal studies indicate that there are abnormalities in these systems in FD which may account for the symptoms of FD.

Abstract

Functional dyspepsia (FD) is a common disorder of yet uncertain etiology. Dyspeptic symptoms are usually meal related and suggest an association to gastrointestinal (GI) sensorimotor dysfunction. Cholecystokinin (CCK) is an established brain-gut peptide that plays an important regulatory role in gastrointestinal function. It inhibits gastric motility and emptying via a capsaicin sensitive vagal pathway. The effects on emptying are via its action on the proximal stomach and pylorus. CCK is also involved in the regulation of food intake. It is released in the gut in response to a meal and acts via vagal afferents to induce satiety. Furthermore CCK has also been shown to be involved in the pathogenesis of panic disorder, anxiety and pain. Other neurotransmitters such as serotonin and noradrenaline may be implicated with CCK in the coordination of GI activity. In addition, intravenous administration of CCK has been observed to reproduce the symptoms in FD and this effect can be blocked both by atropine and loxiglumide (CCK-A antagonist). It is possible that an altered response to CCK may be responsible for the commonly observed gastric sensorimotor dysfunction, which may then be associated with the genesis of dyspeptic symptoms.

INTRODUCTION

Functional dyspepsia (FD) is a heterogeneous condition of uncertain etiology. It is a common disorder frequently encountered, both in the primary care and specialist clinics. FD in the current Rome II criteria refers to, persistent upper abdominal pain or discomfort with or without symptoms of fullness, bloating, early satiety and nausea, with no identifiable organic cause. Excluded are patients with reflux symptoms and lower gastrointestinal (GI) symptoms. It also stipulates that symptoms must be present for at least 12 wk which need not be consecutive, in the preceding 12 mo[1]. The symptoms patients complain of are variable, occasionally very disabling and associated with a reduced quality of life, which is determined by symptom severity. The dyspeptic symptoms are usually meal related, however the temporal relationship between dyspeptic symptoms and meal intake need to be studied further. Symptoms are usually intermittent and can be aggravated by food[2] and stress[3]. Depending on the symptom clusters, patients may be categorized into different subgroups. Dysmotility-like dyspepsia describes a group that, on symptoms alone, appears to have GI sensorimotor dysfunction. The other two subgroups include Ulcer-like dyspepsia and mixed group. Studies have implicated among others GI dysmotility, gastric hypersensitivity, abnormality of accommodation and an altered brain-gut communication as important pathophysiological correlates of FD. It can be thought of as a biopsychosocial disorder, in that there is an underlying GI sensorimotor dysfunction with an important input from the psyche[4].

Cholecystokinin (CCK) is an established brain-gut peptide that plays an important regulatory role in gastrointestinal function. CCK is involved in the control of food intake in both man and animals[5-7]. It inhibits gastric motility and emptying via capsaicin-sensitive vagal pathways in rats[8]. In human studies, CCK mediates gastric emptying under physiological conditions[9]. It also inhibits food intake and increase satiety in humans[10]. CCK appears to be involved in the gastric response to the presence of several intestinal stimuli, including fat and protein. In humans, CCK pathways modulate sensations induced by gastric distension[11]. It has also been hypothesized that CCK plays an etiologic factor in panic disorder and anxiety[12], factors that may be important in precipitating or aggravating symptoms in FD patients. CCK plays an important role in the brain-gut axis, allowing peripheral signals from the gut to modulate central pathways and vice-versa. An altered CCK function in terms of response to food intake, abnormal central response to stressors or

even disturbed effect on gut sensorimotor functions may be responsible for the dyspeptic symptoms in FD and involved in the pathophysiology of this common disorder.

SYMPTOMATOLOGY IN FD

The correlation between symptoms and proposed impaired GI function is still unclear. Stanghellini investigated the relationship between symptom severity, demographic features and gastric dysmotility in a large series of FD patients[13]. They were able to identify two main subgroups, the first has predominant epigastric pain, male gender and normal gastric emptying, while the second group is characterized by predominantly nonpainful symptoms, female gender, a high association with irritable bowel syndrome (IBS) and delayed gastric emptying. The same group also reported that postprandial fullness and severe vomiting were independently associated with delayed gastric emptying of solids. These findings were confirmed by Sarnelli *et al* who studied the relationship between FD and delayed gastric emptying of solids or liquids and discovered that delayed gastric emptying of solids was constantly associated with postprandial fullness and vomiting. While delayed emptying of liquids was associated with early satiety and postprandial fullness[14]. However the above findings were disputed by Talley *et al* who found no predictive value using specific symptoms to identify alterations of gastric emptying[15].

Studies have suggested that in FD, gastric accommodation is normal during fasting but is impaired after a meal, due to failure of proximal stomach relaxation[16,17]. Other reports suggested that impaired accommodation is associated with symptoms of early satiety and weight loss. Furthermore restoring gastric accommodation with fundus relaxing drugs, 5HT1 agonists sumatriptan and buspirone[18], Tack *et al* were able to improve the symptom of early satiety. The above findings however, were contradicted by Boeckxstaens *et al* who could demonstrate no difference between postprandial symptoms and proximal stomach function[19]. Hypersensitivity to gastric distension has previously been reported in FD[20], but it is present only in a subset of patients. The relevance of this particular characteristic observation was studied by a group from Belgium[21] who discovered that gastric hypersensitivity is associated with symptoms of postprandial epigastric pain, belching and weight loss. Similar observations were reported by Salet *et al* who reported that gastric visceral hypersensitivity plays an important role in the pathogenesis of upper gastrointestinal symptoms especially nausea, abdominal bloating and pain[22].

More importantly FD patients were known to report symptoms after a meal, including fullness, bloating, epigastric pain, nausea and vomiting. Based on symptoms alone, this seems to suggest an underlying gastric sensorimotor disorder. However the temporal relationship between symptoms, meal ingestion and gastric dysmotility has not been truly examined. Ingestion of a fatty meal in FD patients will result in the induction of dyspeptic symptoms[2]. The presence of nutrients in the small intestine slows gastric emptying and suppresses appetite and food intake which is mediated in part by CCK[23,24]. CCK has also been implicated in the induction of nausea in healthy subjects[25,26]. It relaxes the proximal stomach[27] and delays gastric emptying. Thus CCK may play an important role in symptoms production in patients with FD.

CCK AND GI HYPERSENSITIVITY

Prevalence of hypersensitivity to gastric distension in FD has previously been reported[20,28,29]. Gastric distension is perceived as painful at smaller distending volumes and lower pressures compared to a group of healthy controls. The observed hypersensitivity to gastric distension is associated with epigastric pain, belching and weight loss. There is also evidence of sensitivity to other stimuli including acid and digestive products of fat and protein. Furthermore we have previously demonstrated that FD patients responded differently to an infusion of CCK octapeptide (CCK-8), compared to a group of healthy and disease controls[46].

Response to CCK-8 was assessed by an intravenous CCK-8 infusion (6 ng/kg per minute) in a double-blind, cross-over fashion using normal saline solution as placebo infusion. The test was deemed positive when the infusion reproduced part or all of the patients' symptoms. The severity of the response was evaluated on a simplified visual analog scale (VAS). The VAS allowed us a reproducible method of assessing symptoms and a crude form of grading patients' responses. It also provided a means of analyzing severity of symptoms and allows us to grade individual's responses to the CCK-8 infusion. Furthermore we can also determine the efficacy of atropine and loxiglumide in alleviating symptoms.

The most common reproducible symptom in the CCK challenge test is that of upper abdominal pain. This is usually associated with a feeling of abdominal bloating and satiety. Other symptoms included borborygmia, nausea, vomiting, light-headedness and occasional heartburn. The test is negative if the infusion fails to precipitate any symptoms or only an occasional mild discomfort. In some cases the precipitated symptoms were so severe that the infusion had to be discontinued due to patients' distress. Majority of FD patients had a positive response to the CCK-8 challenge. In all the responders, the symptoms produced were quite marked and there was little doubt about the diagnosis. None of the healthy controls reported any significant symptoms to the CCK-8 infusion. The few that experienced minor epigastric discomfort or nausea can be explained by the physiological action of CCK. None of the subjects reported any sensation from the saline infusion.

It was also demonstrated that the response to CCK-8 can be blocked by atropine in a dose dependent fashion. Atropine also managed to prevent recurrence of symptoms to further CCK-8 infusion. The CCK-8 challenge test, likewise can be attenuated using the CCK-A antagonist loxiglumide.

Scintigraphic gastric emptying was also determined in the FD group of patients using radiolabelled technetium and solid phase gastric emptying was shown to be significantly delayed in this group of patients compared to

a group of healthy controls.

Katchinski demonstrated that sham feeding in healthy volunteers brought about a stimulation of gastrointestinal motility implying a cephalic stimulation of GI motility. He also showed that the peripheral acting cholinergic antagonist atropine completely abolished antral activity and consequently coordinated antroduodenal motor activity, while Loxiglumide inhibits cephalic stimulation of antral contractions[30]. Furthermore, atropine completely blocked the changes in gastric function induced by stimulation of the nucleus raphe obscurus[31]. Similarly, the dyspeptic symptoms produced by the CCK infusion were completely abolish by atropine, indicating the importance of the vagal efferent pathways in mediating this response. The suppression of response by atropine may occur also at the level of the peripheral muscarinic receptors, at the junction of the gastric musculature or the secretory glands.

Hypersensitivity to CCK may explain the abnormal response to CCK infusion in dysmotility-type FD patients. The exaggerated response to CCK in this group of patients may be the basis of the pathophysiology of the condition and also account for the observed dyspeptic symptoms. Exogenous CCK may act on primary afferent neurons that are also gastric mechanoreceptors and there follows activation of a vago-vagal reflex pathway, which leads to relaxation of the body of the stomach[8,32-34]. Early satiety and post-prandial fullness may be mediated via the afferent sensory pathways or through central CCK interconnections. Meanwhile, abdominal discomfort, pain, distension, nausea and vomiting may result from excessive fundal relaxation mediated via the motor limb of the vago-vagal reflex, activated by CCK, gastric distension or possibly a combination of both. This reflex results in the inhibition of gastric emptying which is a predominant feature of FD. Any abnormalities which up-regulate sensory signals anywhere within the central nervous system and enteral nervous system (CNS-ENS), could induce hypersensitivity leading to pain and discomfort which characterise FD. Over stimulation of the afferent limb of the multiple sensorimotor reflexes anywhere from the GI tract to the CNS could trigger a motor response. Depending on the pathway stimulated, a different response will be obtained.

CCK CHALLENGE TEST AS A DIAGNOSTIC TEST

FD is a diagnosis of exclusion, though a positive diagnosis can be made based on the symptoms[1], efforts should be made to exclude organic diseases if there were presence of "alarm signs or symptoms". The CCK-8 challenge test may be used as a diagnostic tool to positively identify dysmotility type FD. For it to be effective the challenge test should be safe, able to reproduce patients symptoms, response should be reproducible and dose dependent and blocked by the antagonist and most importantly specific to the disorder. We have shown that the test is safe and can precipitate the patients' symptoms which can be blocked by Atropine and Loxiglumide (CCK antagonist). The CCK-8 challenge test is dose dependent, in that no response was seen with 2 ng/kg per minute, moderate response seen with 4 ng/kg per minute and best response identified with the 6 ng/kg per minute. The test is reproducible in that in 10 patients when the test was repeated on a separate day, there was no significant difference in the reported symptom severity (on the VAS), score of 35 (5) *vs* 36 (7) [mean (SD)]. However the test needs to be tested further in other functional disorders especially in Irritable Bowel Syndrome (IBS) patients or patients with Non-erosive reflux disease. Thus more work need to be done before the CCK-8 challenge test can be reliably used as a diagnostic test.

FOOD SENSITIVITY AND CCK IN FD

CCK is released by the duodenum in the presence of digestive products of fats and proteins in the intestine[35]. We have previously seen that physiological CCK relaxes the stomach, constricts the pylorus[36,37] and inhibits gastric emptying,[38] and thereby increases gastric distension. This effect of CCK is mediated via gastric vagal afferents[10]. Furthermore in healthy subjects, the combination of duodenal lipid and gastric distension induces meal-like fullness and nausea. Duodenal lipid reduces gastric tonic and phasic activity during distension, and this can be partially block by loxiglumide[39]. This signifies that CCK-A receptors are implicated in the cause of nausea and postprandial fullness, associated with duodenal lipid infusion. The increased gastric distension induced by the delayed gastric emptying may be the method by which CCK reduces food intake[5,38].

Similarly in FD the presence of certain nutrients especially fat, in the intestine can generate dyspeptic symptoms, including nausea, bloating, pain and fullness[40-43]. Feinle *et al* demonstrated that in the FD patients, duodenal infusion of lipid aggravates the hypersensitivity to gastric distension. This effect is specific for fat, and evidence suggests the participation of CCK[44]. The fat induced dyspeptic symptoms can also be abolished by dexloxiglumide (CCK-A antagonist) signifying an involvement of CCK-A receptors[42]. The underlying mechanism is probably due to hypersensitivity to CCK. We postulate that it is CCK that enhances the distension effect, rather than distension enhancing the effects of CCK. Furthermore recordings from the afferent vagal nerve indicates that mechanoreceptors sensitive to gastric stretch respond more strongly in the presence of CCK[45].

Endogenous CCK released in response to lipid infusion acts in a paracrine fashion to stimulate CCK-A receptors. The information is then transmitted to the CNS via vagal afferent nerves. This pathway is involved in the feedback inhibition of gastric tone and motility which could indirectly gives rise to the observed symptoms[42,46]. However CCK may not be the only factor involved in the above vagal reflex pathway. It is more common indigestion, trying to eat when we are emotionally stressed[5]. Psychological and physical stress has been shown to cause slowing of gastric emptying in animals. Furthermore, excitation of the sympathetic nervous system by stressors increases visceral sensitivity[47,48].

ROLE OF CENTRAL SEROTONERGIC AND NORADRENERGIC RECEPTORS

Stress also plays an important role in precipitating or aggravating symptoms in FD. Central serotoninergic (5HT) receptors are important in mediating the stress response. Utilizing the Buspirone Neuroendocrine challenge test, we have previously shown that FD patients have hypersensitive central 5HT receptors functioning[49]. The release of prolactin from the anterior pituitary is under the inhibitory control of dopamine and stimulatory control of 5HT. Buspirone, an azaspirodecanedione, stimulates central 5HT1A receptors and causes prolactin release in a dose dependent manner, and the extent of prolactin release post stimulation can be used as an index of central 5HT receptors function. Prolactin release following Buspirone challenge was reported to be significantly greater in FD patients. 5HT plays an important role in the control of GI function both peripherally at the ENS and also centrally at the CNS. Similarly, we have also shown that the observed hypersensitivity of the central 5HT receptors were highly correlated with delayed gastric emptying[50].

Central noradrenergic pathways are also important in the mediation of the stress response. α-2 receptor activation mediates inhibition of a number of gastrointestinal functions including intestinal motility. Its activation also inhibits acetylcholine release from the vagal nerve. Previously we have shown that the central α-2 receptors are hyposensitive in patients with delayed gastric emptying[51] using the desipramine neuroendocrine challenge test. In this test, subjects were challenge with desipramine, a monoamine reuptake inhibitor, which blocks the reuptake of noradrenaline when given orally. This indirectly stimulates growth hormone release by acting on central α-2 receptors situated in the hypothalamus.

In fact FD patients who have an abnormal response to the CCK-8 challenge test, have been shown to have hypersensitive central 5HT receptors (as evidenced by an exaggerated prolactin response to buspirone challenge) and hyposensitive central α-2 or noradrenergic receptors (as evidenced by a blunted growth hormone response to Desipramine challenge). Gastric emptying was also shown to be delayed in this group of patients[52]. Kendrick established that injections of CCK stimulated significant increase of noradrenaline and serotonin in the paraventricular and supraoptic nucleus. Both hypothalamic nuclei receive noradrenergic and serotonergic inputs and are important in the regulation of feeding and control of GI motility. The principal action of systemically administered CCK centrally is via the nucleus tractus solitarius (NTS) which projects directly or indirectly to the paraventricular nucleus (PVN) and supraoptic nucleus (SON) and the dorsal motor nucleus of the vagus (DMV). In the PVN, systemic injections of CCK activate neurons which influence feeding behaviour and affect gastric motility[7,33].

CCK AND PSYCHOLOGICAL STRESS

Both depression and chronic tension can present with abdominal symptoms[53,54]. Studies have shown that patients with FD have increased levels of anxiety. Gomez and Daly reported that 22% of their FD patients had chronic tension and a further 15% demonstrated hysterical symptoms[55]. Mangi *et al* reported that two thirds of 30 consecutive outpatients with FD met DSM-III criteria for anxiety disorders[56]. The neurotransmitter CCK can be found in abundance in the brain. Two receptor subtypes (A and B) have been identified within the CNS. CCK-B receptors are more numerous and widely distributed in the CNS[57-59]. CCK or CCK receptors are discovered in areas of the brain involved with cognitive or emotional aspects of behaviour[58,60]. It is known to interacts with other neurotransmitters in the CNS (monoaminergic, serotonergic, GABAergic) known to be involved in anxiety and affective disorders[61-63]. Chronic treatment with imipramine, which inhibits noradrenaline and 5HT reuptake, could antagonize the panic causing effects of CCK-4 in panic disorder patients, indicating that these monoamines may be important in interacting with CCK in promoting panic symptoms. Thus CCK-B receptor plays an important role in anxiety states and panic attacks[12,64,65]. CCK-B receptors can modulate activity within the hypothalamic-pituitary-adrenal (HPA) axis[65,66], which is involved in the stress response.

Psychological stress is widely believed to precipitate exacerbation of symptoms in FD. Inhibition of gastric emptying and stimulation of colonic transit is the most consistent motility response of the GI tract to acute stress. An organism's response to stress is generated by a complex integration of neurons in the CNS. Main output of this integrated central network to the periphery (which is activated in response to various stressors, both physical and psychosocial) includes autonomic and neuroendocrine responses together with modulation of pain. Present evidence strongly suggests that acute stress affects visceral sensitivity in humans. Whether chronic stress plays the same role remain to be seen. Early life stress and trauma, in the form of abuse, neglect, or loss, play a major role in the vulnerability of individuals to develop functional GI disorders. It is proposed that in the genetically predisposed individual, both early life stress and severe life-threatening stress can result in permanent alteration in central stress circuitry and predisposes the individual to the development of functional disorders later in life.

LOXIGLUMIDE IN THE TREATMENT OF FD

If CCK plays an important role in the pathophyphysiology of FD then the use of Loxiglumide (CCK-A receptor antagonist) should be effective in the control of the symptoms. A randomized, double-blind, parallel group, placebo-controlled trial was conducted in 28 symptomatic FD patients (8 male, 20 female, aged 19-59 years, mean age 33). All patients satisfy the Rome II criteria for the diagnosis of FD. They all have normal endoscopy, normal abdominal ultrasonography, a positive CCK provocation test (symptom appearance after CCK-8 6 ng/kg iv infusion) and delayed (half emptying time > 60 min for the solid phase) gastric emptying of a radiolabeled, mixed solid-liquid meal of about 400 Kcal. Patients were randomly assigned to placebo or

Loxiglumide 400 mg three times daily for 8 wk. Response to treatment was evaluated on a Visual Analogue Scale to generate a Cumulative Symptom Score (CSS). Despite an expected high rate of placebo response, a quicker, more pronounced, and sustained symptomatic relief was observed during treatment with loxiglumide. There were 11 of 12 responders on Loxiglumide compared to only 6 of 11 on placebo ($P = 0.04$ Chi-square test). Loxiglumide also showed an acceleration of solid phase gastric emptying whereas placebo did not show any effect. However there was no correlation observed between increased gastric emptying and clinical improvement. Thus Loxiglumide is effective in the treatment of symptoms of FD and has a prokinetic effect. However, we need further studies on a larger population of patients to confirm the findings[67].

In summary, the discomfort, pain and altered sensations (to intraluminal stress) that characterize FD are considered to represent visceral hyperalgesia. Mechanisms by which functionally disordered visceral receptors, respond abnormally to normal everyday stimuli remain unknown. However, it is also possible that an aberrant input to the CNS or altered CNS pathways (5HT, Noradrenergic and central CCK) could contribute to the observed visceral hyperalgesia and dysmotility. Hypersensitive visceral CCK receptors may be modulated by central pathways primed by stress or trauma. The receptors will then respond inappropriately to normal stimuli, activating efferent pathways via a vago-vagal reflex pathway to cause perturbation of peripheral sensorimotor functions. This may be the basis for the genesis of the symptoms encountered in FD.

Furthermore, the CCK-8 challenge test may also be a useful tool for the diagnosis of Dysmotility type FD, but this will need further evaluation.

Abstract

Symptomatic improvement of patients with functional dyspepsia after drug therapy is often incomplete and obtained in not more than 60% of patients. This is likely because functional dyspepsia is a heterogeneous disease. Although great advance has been achieved with the consensus definitions of the Rome I and II criteria, there are still some aspects about the definition of functional dyspepsia that require clarification. The Rome criteria explicitly recognise that epigastric pain or discomfort must be the predominant complaint in patients labelled as suffering from functional dyspepsia. However, this strict definition can create problems in the daily primary care clinical practice, where the patient with functional dyspepsia presents with multiple symptoms. Before starting drug therapy it is recommended to provide the patient with an explanation of the disease process and reassurance. A thorough physical examination and judicious use of laboratory data and endoscopy are also indicated. In general, the approach to treat patients with functional dyspepsia based on their main symptom is practical and effective. Generally, patients should be treated with acid suppressive therapy using proton-pump inhibitors if the predominant symptoms are epigastric pain or gastroesophageal reflux symptoms. Although the role of *Helicobacter pylori* (*H pylori*) in functional dyspepsia continues to be a matter of debate, recent data indicate that there is modest but clear benefit of eradication of *H pylori* in patients with functional dyspepsia. In addition, *H pylori* is a gastric carcinogen and if found it should be eliminated. Although there are no specific diets for patients with FD, it may be helpful to guide the patients on healthy exercise and eating habits.

INTRODUCTION

Symptomatic improvement of patients with functional dyspepsia with current drug therapy is left with many unmet needs. This is because functional dyspepsia is a heterogeneous disease and a uniform response to drug treatment can therefore not be achieved. There are many possible factors to explain the difficulties achieving adequate symptom relief these patients[1-3]. The issues to be addressed when treating patients with functional dyspepsia: (1) Definition and classification of dyspepsia (Rome I, Rome II); (2) Associated upper and lower GI symptoms; (3) Predominant symptom (e.g. reflux, abdominal pain); (4) Number of symptoms; (5) Presence of alarm features (anemia, weight loss, dysphagia); (6) Co-morbidities; (7) Drug interactions; and (8) *Helicobacter pylori* (*H pylori*) status. One of the main factors that warrants clarification is the definition of dyspepsia. Although great advance has been achieved with the consensus definitions of the Rome I and II criteria, there are still some aspects about the definition of functional dyspepsia that require clarification. The Rome criteria explicitly recognise that epigastric pain or discomfort must be the predominant complaint in patients labelled as suffering from functional dyspepsia. However, this strict definition can create problems in the daily primary care clinical practice, where the patient with functional dyspepsia presents with many complex rather one simple symptom because on the average, patients with dyspepsia seen in primary-care settings report 5.5 abdominal symptoms, which also may vary over time[4,5]. In addition, patients with functional dyspepsia presenting to the primary care doctor are different than patients being evaluated at tertiary medical centres[1,2,6-9]. Before starting drug therapy it is recommended to provide the patient with an explanation of the disease process and reassurance. Ruling out an organic cause of their disease by endoscopy can lead to improved acceptance of the disease process. In general, the approach to treat patients based on their main symptom is practical and effective. The general approach is to treat patients with

acid suppressive therapy with proton pump inhibitors if the predominant symptom is epigastric pain or if there are gastroesophageal reflux symptoms present. The role of *H pylori* in functional dyspepsia continues to be a matter of debate. Nevertheless, recent data indicate that there is a modest but significant benefit in eradication of *H pylori* in functional dyspepsia. Although there are no specific diets for patients with FD, it may be helpful to guide the patients on healthy exercise and eating habits.

PROBLEMS WITH THERAPEUTIC TRIALS

The literature is full of reports on drug therapies for functional dyspepsia and the list of drugs used to treat functional dyspepsia is long[10-30] (Table 1). One of the most frustrating aspects about therapies in functional dyspepsia is that most medical treatments available to date have been shown to be of no or only limited efficacy. Furthermore the results of most of these studies do not apply to our current standards anymore. First, the definition of functional dyspepsia has changed over time. Second, most studies are difficult to interpret because of lack of rigorous design criteria, either because of small sample size, poor design, not blinded or not placebo-controlled. Smaller studies tend to show more efficacy than well-controlled larger ones. Abraham *et al* has demonstrated that the quality of trials has an impact on the efficacy estimates of treatment[31]. The authors performed a systematic review of randomized controlled trials of dyspepsia investigated using endoscopy from 1979 to 2003 using the Jadad score and Rome II guidelines[31]. They found that poor quality trials suggested a benefit of prokinetic therapy, which was not confirmed in high quality trials. Also there was a marked benefit of H2-receptor antagonist therapy in poor quality trials, but a marginal benefit in good quality trials. Two high quality trials suggested a limited benefit with the use of proton pump inhibitors, with no poor quality trials to provide a comparison[31] are (1) Setting where study was conducted (primary care, tertiary centre); (2) Size of study; (3) Duration of recruitment; (4) Duration of therapy; (5) Clinical endpoint: complete response versus partial response to therapy; (6) Short versus long-term response; (7) Follow-up after finishing therapy; (8) Quality of meta-analysis or systemic review (i.e. inclusion of abstract, contact of primary author, use of effective therapies to eradicate *H pylori*, etc); (9) Good clinical practice standards; (10) Publication bias (negative studies are less likely to be published); and (11) Publications before 1992 (definitions of dypspesia have changed, older studies were too small or used drugs that are not current any more). The issues to be addressed when interpreting trials of drug therapy in functional dyspepsia. In order to clarify issues, meta-analyses of various approaches to treat functional dyspepsia have been conducted. Interestingly, even meta-analyses performed in the same period have yielded completely opposite results[32,33]. Third, it is also very important to remember that functional dyspepsia tends to be a chronic condition[6,34]. In most studies therapy has been only given for short periods of time. There are essentially no studies evaluating chronic therapies for functional dyspepsia. And finally, the placebo effect in patients with functional dyspepsia is high. Therefore, most studies comparing a new therapy to no therapy will likely show a marked benefit for the treatment arm. But on the other side, clinicians treating patients with dyspepsia are many times confronted with the option of no therapy and any form of therapy, and will likely choose to give some form of therapy, because of the possibility of achieving a symptom response (similar or slightly better than placebo) in a significant percentage of patients.

Table 1 Drug therapies used in the therapy of functional dyspepsia

Acid suppression therapy
Proton pump inhibitors[1]
Omeprazole
Lansoprazole
H2 blockers
Cimetidine
Ranitidine
Famotidine
Simethicone
Herbal therapies
Iberogast (Iberis, peppermint, Camomille)
Artichoque leaf extract
Xinwei decoction
Ganaton (itorpide hydrochloride)
Capsaicin
Motility agents
Cisapride
Domperidone
Mosapride
Erythromicin
H pylori eradication
Antidepressants
Serotonin reuptake inhibitors (SSRI)
Amitryptiline
Placebo

[1]Other PPI such as esomeprazole, rabeprazole and pantoprzole are also used to treat functional dyspepsia, but the largest and most significant trials reported to date have used either omeprazole or lansoprazole.

CLINICAL PREDICTORS OF TREATMENT RESPONSE

In functional dyspepsia it has been suggested that there are associations between pathophysiologic mechanisms and symptoms (i.e. clinical presentation)[1-3,5]. These mechanisms include gastroesophageal reflux, delayed gastric emptying, impaired gastric accommodation to a meal, hypersensitivity to gastric distension, altered response to duodenal lipids or acid, abnormal duodenojejunal motility or central nervous dysfunction[1]. Therefore, it seems logical to hypothesize that the clinical presentation of patients with functional dyspepsia can guide therapy and even predict the response to therapy. The problem is that there is much overlap and interaction of these mechanisms, and their relevance for the individual patient is uncertain, especially because of the variability of symptoms over time[34]. Meineche-Schmidt *et al* showed that patients with functional dyspepsia usually have a combination of symptoms and the predominant symptom may vary over time[6]. Nonetheless, there are some studies which tried to address response to therapy based on the predominant symptom[35-37]. In a random

starting day trial including 301 patients with functional dyspepsia, Bytzer *et al* found that this sort of trial may be a valuable tool to identify response to acid suppression in dyspeptic patients[35]. In this study the only predictor of response was symptoms suggesting gastroesophageal reflux[35]. In another similar trial, Madsen *et al*[36] also found that response to therapy was more in patients with associated symptoms of gastro-oesophageal reflux[36]. Nonetheless, the same authors later showed that reproducibility of this study design was imperfect, mainly because of the strict criteria used to evaluate response and overall low response rates[37]. Lack of symptom stability in patients with functional dyspepsia further impairs the value of the random-starting-day trial and only patients with frequent and stable symptoms should be evaluated in this design[37].

H pylori ERADICATION

Although, the aim of our article is aimed mainly at describing drug therapies for functional dyspepsia, the role of *H pylori* therapy in patients with functional dyspepsia deserves a comment. Today it is clear that *H pylori* is the main cause of peptic ulcer disease but its role in non-ulcer dyspepsia is not well known. The effect of *H pylori* eradication on the symptoms of non-ulcer dyspepsia show somewhat conflicting results[2] Until the mid-nineties most studies evaluating *H pylori* eradication in the therapy of functional dyspepsia did not meet adequate methodological criteria. Since then there have been few well done prospective, randomized double-blind, placebo controlled trials of adequate size that evaluate the efficacy of *H pylori* eradication in functional dyspepsia[2,38-43] (Table 2). The ELAN study (European multi-centre trial) and a single-centre trial from Scotland suggested modest superiority of eradication therapy versus acid suppressive therapy with PPI alone[38,39]. The ELAN study further suggests that if patients were classified as responders (dyspepsia score of 1) or non-responders, there was a higher proportion of responders (44%) in patients with successful eradication compared to patients without eradication (36%)[38]. In the Scottish study it is likely that the high response occurred because of high prevalence of peptic ulcer disease[39]. The other studies evaluating elimination of *H pylori* in functional dyspepsia have had negative results[40-43] (Table 2). But recent well done meta-analysis and Cochrane Database systematic reviews show that there is a small but significant benefit of eliminating *H pylori* in patients with dyspepsia[44,45]. In the most comprehensive and thorough systematic review published to date, Moayyedi *et al* identified through electronic searches of the Cochrane Controlled Trials Register (CCTR), MEDLINE, EMBASE, CINAHL and SIGLE all randomized controlled trials evaluating *H pylori* eradication in functional dyspepsia and concluded that *H pylori* eradication therapy has a small but statistically significant effect in *H pylori* positive non-ulcer dyspepsia[44]. As demonstrated by Moayyedi *et al*[45], other systematic reviews have included trials that used drug regimens known to be ineffective for *H pylori* eradication, have failed to include recent trials, have not contacted authors for further information, have included abstracts, and have assumed that dropouts were treatment failures.

Table 2 Role of *H pylori* eradication in functional dyspepsia

ACID SUPPRESSIVE THERAPY

H2 receptor antagonists

Several studies and a large meta-analysis have demonstrated a slight advantage of H2-blockers over placebo or motility agents for treating functional dyspepsia[2,10-18]. In the large meta-analysis 22 studies met the inclusion criteria, 15 of which reported H2-blockers to be superior to placebo. Although many of the analyzed studies suffered from sub-optimal study design the odds ratio in favor of H2-blockers was 1.48 (95% confidence interval (CI): 0.9-2.3), for global assessment of dyspepsia symptoms, 2.3 (95% CI: 1.6-3.3) for improvement of epigastric pain, and 1.8 (95% CI: 1.2-2.8) for complete relief of epigastric pain. In most studies standard doses of H2-blockers were used but the duration of therapy was not longer than 8 wk[18]. Larger studies evaluating higher doses of H2-receptor antagonists and of longer duration may be necessary to determine the exact effect of H2-blockers on functional dyspepsia, but because PPI have been shown to be superior to placebo or H2-blockers in the therapy of functional dyspepsia, it is likely that we will not see major H2-blocker studies for the therapy of dyspepsia in the future[19-27].

Proton pump inhibitors

In a large primary care study, Meineche-Schmidt showed that in patients with presumed acid-related un-investigated dyspepsia, a standard dose of omeprazole 20 mg/d was significantly more effective than placebo in treating their self-worded main dyspepsia complaint[19]. In this study, 9% of the patients had sole reflux-like symptoms while the rest had other accompanying symptoms and would be considered to have dyspepsia. In fact, patients had on average more than five symptoms. As no initial endoscopic investigations were made, patients could have had a variety of possible diagnoses such as gastroesophageal reflux disease, ulcer disease, or functional dyspepsia. The recent CADET-PE study showed that if patients had endoscopic abnormalities (i.e. esophagitis), these were findings that predicted an appropriate response to acid suppression therapy[20].

The largest studies evaluating PPI for the therapy of functional dyspepsia are: the CADET-HN, OPERA,

Table 3 Role of acid suppression using PPI in functional dyspepsia

Author	Name of study	Year	Type of study	PPI	No pts	Follow-up	Response
Bolling-Sternevald	PILOT	1996	Multicenter	Omeprazole *vs* placebo	197	2 wk	Yes
Jones		1997	Multicenter	Lanzoprazole *vs* ranitidine	432	4 wk	L better than R
Talley	BOND	1998	Multicenter	Omeprazole *vs* placebo	642	4 wk	Yes
Talley	OPERA	1998	Multicenter	Omeprazole *vs* placebo	606	4 wk	No
Meineche-Schmidt	ENCORE	1999	Multicenter	Omeprazole *vs* placebo	567	3 mo	Yes
Peura		2004	Singlecenter	Lanzoprazole *vs* placebo	921	8 wk	Yes
Veldhuyzen	CADET-HN	2005	Multicenter	Omeprazole (O), ranitidine (R), cisapride(C), placebo	512	4 wk	O better than R, C or placebo

BOND, PILOT, ENCORE and lansoprazole studies[21-26] (Table 3). In the CADET-HN study, 512 *H pylori* negative patients were randomised to omeprazole, ranitidine or cisapride for 4 wk. The proportion of patients who were responders at 4 wk and 6-mo was significantly greater for those receiving omeprazole (31%), compared with cisapride (13%) or placebo (14%), and ranitidine (21%, $P=0.053$). In the BOND and OPERA multi-center trials 1262 patients with functional dyspepsia were randomized in a double-blind, placebo-controlled design in two studies with identical protocols to omeprazole 20 or 10 mg a day or identical placebo for 4 wk[21,22]. Complete symptom resolution was observed in 38% of patients taking omeprazole 20 mg/d, 36% on omeprazole 10 mg/d and 28% of patients on placebo. The Scandinavian Pilot study was a double blind, randomized, placebo controlled trial that evaluated the effect of gastric acid inhibition using omeprazole 20 mg twice daily in 197 patients recruited from gastroenterology practices in Bolling-Sternevald E *et al*[23]. Patients were excluded if they had a known gastrointestinal disorder, predominant symptoms indicating GERD, or the irritable bowel syndrome, as were patients with heartburn/regurgitation as their only symptom. Complete symptom relief was achieved in 32% of patients treated with omeprazole 20 mg/d compared with 14% of patients on placebo[23]. The ENCORE study addressed the consequences of relieving symptoms in patients with functional dyspepsia once they are off therapy[24]. In this study 567 patients from the OPERA study were followed for as additional three months during which time treatment was given at the discretion of the investigator. Responders had fewer clinic visits than non-responders (1.5 *vs* 2.0 mean visits) and fewer days on medication (mean, 9 d *vs* 23 d) over the 3-mo period (both, $P<0.001$). The quality of life in responders was better at study entry and persisted over 3 mo (all, $P<0.001$) Two large studies using lansoprazole have been published[25-26]. Jones *et al* performed a double-blind, parallel group, randomized, multi-center study in 32 general practices in the UK[25]. The investigators randomized 213 patients with symptoms of reflux-like or ulcer-like dyspepsia to receive lansoprazole 30 mg daily, and 219 to receive ranitidine 150 mg b.i.d. for 4 wk. After 2 wk 55% of the lansoprazole patients and 33% of the ranitidine group were symptom-free ($P=0.001$) with corresponding 4-wk figures of 69% and 44%, respectively ($P=0.001$). In the lansoprazole group, at 4 wk, 80% of patients were free of daytime heartburn and 81% of night-time epigastric pain, compared with 55% ($P=0.001$) and 65% ($P=0.01$) in the ranitidine group[25]. Peura *et al*[26] compared the efficacy of lansoprazole with placebo in relieving upper abdominal discomfort in 921 patients with functional dyspepsia in a blinded-randomized trial and moderate upper abdominal discomfort on at least 30% of screening days[26]. In contrast to the study of Jones *et al*, none of the patients had predominant symptoms suggestive of gastroesophageal reflux or endoscopic evidence of erosive or ulcerative esophagitis, or gastric or duodenal ulcer or erosion. Patients were assigned randomly to receive lansoprazole 15 mg ($n=305$), lansoprazole 30 mg ($n=308$), or placebo ($n=308$) daily for 8 wk. At wk 8, significantly greater mean reductions in the percentage of days with upper abdominal discomfort were reported in patients treated with lansoprazole 15 mg (35%) or 30 mg (34%) compared with those treated with placebo (19%) ($P<0.001$). Similarly, more patients treated with lansoprazole 15 mg (44%) or 30 mg (44%) reported complete symptom resolution at 8 wk than did placebo-treated patients (29%, $P<0.001$). Improvement of upper abdominal discomfort, however, was seen only in patients who had at least some symptoms of heartburn at enrollment[26].

Prokinetic agents

Although delayed gastric emptying is considered a major pathophysiological mechanism in functional dyspepsia, the efficacy of prokinetic drugs to treat this dyspepsia has not been clearly established[1-3]. Problems with studies evaluating prokinetic agents include small sample size, patient heterogeneity, and poor quality design. Nevertheless, prokinetic agents such as metoclopramide, cisapride, mosapride citrate, itopride hydrochloride and domperidone continue to be widely used for the therapy of functional dyspepsia worldwide[1,2,27-30,46-48]. Due to its severe cardiac side effects, cisapride is not currently available in most of Europe and North America. Recent reviews and meta-analyses suggest that domperidone and cisapride are more effective than placebo[49-51]. Veldhuyzen *et al*[49] performed a meta-analysis to determine the efficacy of cisapride and domperidone in functional dyspepsia in placebo-controlled trials that included more than twenty patients[49]. For cisapride, 17 studies met the inclusion criteria. For all outcome measures, there was a statistically significant benefit in favor of cisapride: global assessment of improvement by the investigator or patient, epigastric pain, early satiety,

abdominal distension, and nausea. There were insufficient data to determine whether there is a relationship between improvement in gastric emptying and response to treatment. For domperidone, four of eight studies could be used for the analysis of global assessment of improvement by the investigator. This showed an OR of 7.0 in favor of domperidone. Although both cisapride and domperidone appear to be efficacious in the treatment of functional dyspepsia, this conclusion was largely based on global assessment by the investigator, which is not an optimal outcome measure. The effect of other prokinetic drugs, such as erythromycin, alosetron and tegaserod on functional dyspepsia have been inconsistent[52,53].

Antidepressants

Antidepressants have been only marginally explored in functional dyspepsia. Serotonin re-uptake inhibitors (SSRI) have the potential of relieving functional dyspepsia because they increase the availability of synaptically released 5-HT (pro-motility) not only at the central nervous system, but also at the level of the enteric nervous system[1-3]. Amitryptilline and 5-HT-3 receptor antagonists have been investigated mainly in IBS and the few studies performed in functional dyspepsia have provided conflicting results[54-56]. Also, kappa-opioid receptor agonists might be useful for functional dyspepsia because of their antinociceptive effects, but available results in functional dyspepsia are inconclusive. Other receptors that represent potential clinical targets for antagonists include purinoceptors (i.e., P2X2/3 receptors), NMDA receptors (NR2B subtype), protease-activated receptor-2, the vanilloid receptor-1, tachykinin receptors (NK(1)/NK(2)) and cholecystokinin (CCK)(1) receptors[1,2].

Herbal Medications

Among the herbal medications, one of the best evaluated in prospective studies is Iberogast®[57,58]. Iberogast® is a combination of herbal medicines, which include Iberis, peppermint, and chamomile[58]. Meta-analysis of double-blind, randomized clinical studies that evaluated the efficacy of the herbal preparation Iberogast® in patients with functional dyspepsia demonstrated a clear and highly significant overall therapeutic effect of Iberogast® in the treatment of functional dyspepsia[57,59]. All studies had the same duration and used the same dosage of active treatment and the same primary outcome measure, a dyspepsia-specific gastrointestinal symptom score. Of the 592 trial participants, 196 were treated with Iberogast® and 192 with placebo or cisapride (positive control). The individual studies all showed a substantial improvement of symptoms with Iberogast® but varying results regarding its statistically significant superiority to placebo[57]. There are many other herbal medications used in the therapy of functional dyspepsia[59-61]. These include the traditional chinese herbal medicine Xinwei Decoction, ganaton (itorpide hydrochloride), capsaicin (red pepper) and artichoke leaf extract (ALE)[59-61]. It is paradoxixal to consider red pepper as a potential therapy for FD, but capsaicin, through its desensitation of gastric nociceptive C-fibers may alleviate dyspeptic symptoms[61]. Nonetheless, most studies using herbal medications are too small to allow us to reach conclusions regarding their efficacy to treat functional dyspepsia.

Hypnotherapy

Hypnotherapy was shown to be effective in irritable bowel syndrome, with long-term improvements in symptomatology and quality of life[62]. In another study aimed to evaluate the efficacy of hypnotherapy in functional dyspepsia, the data demonstrate an advantage of hypnotherapy over placebo and medical treatment[62]. Although hypnotherapy is time consuming and requires intense involvement by both physician and patient, it is an option that deserves further evaluation in future studies.

In summary, functional dyspepsia is a heterogeneous disease with variable response rates to therapy Although the main aim of therapy is to obtain complete and long-lasting relief of symptoms, in many patients there is only partial relief or the relief is only of short-term duration. Long-term improvement with drug therapy occurs in a minority of patients. Before starting drug therapy it is recommended to provide the patient with an explanation of the disease process and reassurance. Ruling out an organic cause of their disease by endoscopy can lead to improved acceptance of the disease process. In general, the approach to treat patients based on their main symptom is practical and effective. The general approach is to treat patients with acid suppressive therapy with proton pump inhibitors if the predominant symptom is epigastric pain or if there are gastroesophageal reflux symptoms present. The role of *H pylori* in functional dyspepsia continues to be a matter of debate. Nevertheless, recent data indicate that there is a modest but significant benefit in eradication of *H pylori* in functional dyspepsia. The overall data indicates that symptomatic improvement of patients with functional dyspepsia with current drug therapy is left with many unmet needs. Thus, more studies are needed to better understand this condition as well as to study more therapeutic possibilities.

Abstract

The pathogenesis of Functional Dyspepsia (FD) remains unclear, appears diverse and is thus inadequately understood. Akin to other functional gastrointestinal disorders, research has demonstrated an association between this common diagnosis and psychosocial factors and psychiatric morbidity. Conceptualising the relevance of these factors within the syndrome of FD requires application of the biopsychosocial model of disease. Using this paradigm, dysregulation of the reciprocal communication between the brain and the gut is central to symptom generation, interpretation and exacerbation. Appreciation and understanding of the neurobiological correlates of various psychological states is also relevant. The view that psychosocial factors exert their influence in FD predominantly through motivation of health care seeking also persists. This appears too one-dimensional an assertion in light of the evidence available supporting a more intrinsic aetiological link. Evolving understanding of pathogenic mechanisms and the heterogeneous nature of the syndrome will facilitate effective management. Co-morbid psychiatric illness warrants treatment with conventional therapies. Acknowledging the relevance of psychosocial variables in FD, the degree of which is subject to variation, has implications for assessment and management. Available evidence suggests psychological therapies may benefit FD patients particularly those with chronic symptoms. The rationale for use of psychotropic medications in FD is apparent but the evidence base to support the use of antidepressant pharmacotherapy is to date limited.

INTRODUCTION

Dyspepsia, an umbrella term for a number of gastrointestinal symptoms, is common with prevalence rates estimated at 26%-41%[1]. The spectrum of dyspeptic symptoms may be defined as those arising from the upper digestive tract unrelated to colonic function[1]. Potentially caused by a variety of underlying conditions, most often, no overt cause is elucidated. In such cases, in the absence of demonstrable organic abnormality using available diagnostic measures, the term functional dyspepsia (FD) is employed. Non-ulcer dyspepsia (NUD) and essential dyspepsia are used synonymously. This syndromal diagnosis, according to the 'Rome II' Consensus Report, is defined by 12 wk in the past 12 mo, of persistent or recurrent pain or discomfort in the upper abdomen, in the absence of organic disease and no association with bowel habit. Using these guidelines, patients may also be categorised as ulcer-like dyspepsia, motility-like dyspepsia or unspecified dyspepsia[2]. Though highly prevalent, the underlying pathogenesis is incompletely elucidated, seems diverse and is thus, inadequately understood.

Some investigators object to the separation of functional gastrointestinal disorders (FGID's) into different clinical entities, and indeed, there is considerable overlap between FD and the oft more studied irritable bowel syndrome (IBS)[3]. In at least 40% of patients presenting to gastroenterologists this overlap in symptomatology is sizeable[4,5]. In fact, it has been suggested that the current evidence is insufficient to determine whether the two syndromes are indeed two distinct processes or simply different manifestations of a single, broad-spectrum condition[3]. Data in relation to the role of psychosocial factors in IBS is bountiful but as yet, there is less available pertaining to FD. Even so, as with IBS, psychosocial factors have long been implicated in the predisposition, precipitation and perpetuation of this syndrome.

Review of the literature clearly reveals an association between psychosocial factors and FGID's including FD[6-9]. However, the precise role of psychosocial variables in FD remains elusive. To explain this observation, one could espouse a number of hypotheses, none of which are likely to be mutually exclusive: Psychosocial variables are intrinsic to the aetiopathogenesis of FD; Psychosocial difficulties arise secondarily to chronic digestive symptoms; FD is a physical manifestation of unconscious psychological conflict or distress; Psychosocial factors motivate increased help-seeking and medical consultation; Psychosocial factors influence symptom experience.

Perhaps the most clinically useful way of conceptu-

alising a role for psychosocial factors in FD is within the biopsychosocial framework of disease as suggested by Drossman[10]. In this model, functional gastrointestinal disorders are seen as having mulitfactorial, bi-directional, rather than unicausal, unidirectional aetiology. This integrative view of illness, adopts the understanding that biological, psychological and social factors interact and said interaction accounts for the symptoms experienced, the patient's behavioural response and the outcome of the disorder. Many investigators now consider the 'Brain-Gut Axis' (BGA) to be the anatomical substrate, mediating this interaction[11]. At the very least, it provides a rough neurobiological framework for reciprocal connections between the brain and the gastrointestinal tract[12]. As a concept, it has emerged consequent to a convergence of research into brain-gut interactions and the effect of stress on such exchanges. The BGA is central to the biopsychosocial model in FD. To elaborate briefly, this axis is bi-directional and integrative with input from sensory sources (sight, smell, etc.) and somatosensory/viscerosensory sources, modified by cognitions and affects, and a neural circuit in the central nervous sysytem (CNS), the spinal cord, the autonomic nervous system (ANS) and enteric nervous system (ENS)[11]. Using this paradigm, chronic functional gastrointestinal symptoms can be seen as a result of dysregulation of intestinal motor, sensory and CNS activity, resulting from disturbance at some level of the BGA.

EVIDENCE TO SUPPORT AN ASSOCIATION BETWEEN PSYCHOSOCIAL FACTORS AND FUNCTIONAL DYSPEPSIA

A myriad of psychosocial factors have been examined in the literature in relation to FD. These include psychological distress, personality traits, social support, life-events and life-stresses including abuse and bereavement. The issue of Psychiatric Disorder co-morbidity is often addressed within the same context. The associations between a number of these variables and FD are outlined below.

Psychological morbidity

Studies have demonstrated a high prevalence of Psychiatric Disorder in patients with dyspepsia of unknown origin. In the midst of the debate concerning the significance of this relationship, speculation as to the potential for a shared pathophysiology has arisen[12]. The most common psychiatric co-morbidities in patients with functional dyspepsia are Anxiety Disorders, Depressive Disorders and Somatoform Disorders[6,13]. In a clinic based study, findings showed that 87% of patients with FD, compared to 25% of patients with organic dyspepsia, had a psychiatric diagnosis[13]. A larger study, utilising semi-structured psychiatric interview and psychometric tools, revealed that 34% percent of the FD patients versus 15% of the duodenal ulcer patients had a psychiatric diagnosis. Anxiety Disorders were again most common. A mere 1% of the healthy controls met criteria for a psychiatric diagnosis[6]. These findings are not consistent across studies but conflicting results may be explained by use of different sample populations. Interestingly, in contrast to the latter findings, an earlier study demonstrated no statistically significant difference between essential dyspepsia and duodenal ulcer patients on various psychometric test scores. However, elevated levels of neuroticism, anxiety and depression were demonstrated in FD patients compared to controls. No explanation was offered for lack of difference between the DU and FD patients[14]. Similarly, the results of a study examining psychosocial variables in organic dyspepsia and IBS, illustrated that the prevalence of formal psychiatric disorder did not differ significantly in both patient groups. The inclusion of chronic treatment resistant patients, who may account for the higher levels of psychopathology seen in other studies, was minimised by use of consecutive general practitioner referrals[15].

In a recent study, investigators sought to characterise relevant psychosocial variables and quality of life in a population of patients with functional dyspepsia, primarily referred from a primary care clinic, and in addition sought to correlate these variables with specific dyspeptic symptoms. It was hypothesised that if dyspeptic symptoms represented the physical manifestations of various aspects of psychological distress, a correlation should be evident between specific symptoms, measures of somatisation (the tendency to express emotional dysphoria as physical symptoms) and specific psychosocial variables. Self-report measures were used to evaluate symptomatology and psychological parameters. Results showed that, compared with healthy patients, patients with FD had significantly greater scores for dyspeptic symptoms, significantly greater psychiatric distress and significantly poorer quality of life. However, symptom severity and psychological distress did not correlate strongly. Thus, because of the lack of correlation, the authors concluded that digestive symptoms at that level of care are unlikely to represent physically manifested emotional distress. Instead, it would appear that dyspeptic symptoms are occurring against a background of psychiatric morbidity[16]. Studies, in addition to demonstrating greater psychiatric co-morbidity, have also revealed a greater tendency towards multiple extra-intestinal somatic complaints in FD patient groups[6]. This, together with overlapping symptoms in the various functional syndromes, contributes to the argument of proponents of a unitary somatisation syndrome[17].

Further studies have lent support to the notion that psychological distress, not necessarily warranting a psychiatric diagnosis, is involved in the causative pathway. Patients with NUD, at a clinic level, report more psychological distress than healthy controls[6,18]. However, a number of studies have demonstrated no psychological differences between people with functional bowel disorders who have not consulted a physician compared to community-based healthy controls[19]. This has engendered the assertion that psychosocial factors are not implicated in the aetiopathogenesis of FD and IBS, but rather serve to motivate health-care seeking i.e. act as confounding factors. More recently, in contrast to this dogma, elevated levels of psychological distress across all domains (except phobic anxiety) of the SCL-90-R, a measure of psychological state, have been demonstrated in a population-based study of subjects with functional GI disorders inclusive of both

consulters and non-consulters[9].

Life events

Life-events are changes in a person's life that require adjustment and where the demands associated with such events exceed resources available, stress is the result. The association between FD and stress in life has often been suggested, though yet again in a minority of studies, inconsistent results have been reported[20,21]. Severe life stress has been found immediately before the onset of functional bowel disorders[22] and may precede consultation with a general practitioner in dyspepsia sufferers[23]. It has been suggested however, that there is a lack of community studies that have carefully evaluated whether stress is linked to disease or merely to health-care seeking[9].

In a retrospective study using semi-structured interview and a number of psychometric tools, authors looked at the occurrence and perception of life events, personality factors and psychopathology of patients with FD, compared with DU patients and healthy controls. Results demonstrated that patients with FD experienced more life-events than both DU patients and controls. In addition, DU patients experienced more than controls. These findings were accounted for by differences in stressful life-events[7]. Moreover, the most prevalent types of severe events in all groups were changes in social activity, changes in job situation and illness in the family. Though, evaluation of stress is influenced by psychiatric co-morbidity, and indeed higher psychopathology scores were seen in the FD group, one could also argue conversely that the life-events precipitated the psychopathology. The authors suggest that the difference in perception of life-events may relate to an imbalance between stressors and coping abilities and that this may indirectly mediate gastric motor disturbances and abdominal discomfort. Similar findings were established in a clinic-based study which showed that highly threatening chronic difficulties were significantly more evident in the non-ulcerative dyspepsia group than controls, as were acute life-events which remained highly threatening one week after their onset[24].

A population based study, looked at a number of psychosocial variables, life-event stress inclusive, and their association with FGID's. Using the *life experiences survey*, it was demonstrated that subjects with higher negative change scores and greater total change scores were more likely to have a FGID. When the comparison was then limited to NUD patients only, subjects with higher positive change scores (indicating change with a positive impact) and higher total change scores were more likely to have NUD. Life-threatening events, in contrast to the latter study, were not associated with NUD[9].

Personality and coping style

In one study examining personality, investigators hypothesised that patients with FD would have more nervous symptoms and a different personality pattern than healthy control subjects[25]. Interesting findings were illustrated. Using a personality inventory, the patient group reported a lower *detachment* score than the control group, the *detachment scale* relating to the individual's need for social distance and coldness in social relations. This finding would indicate a greater need for attachment, which could conceivably lead to frustration. Female patients scored lower *socialisation* and higher *suspicion* than female controls. The authors suggest their findings may reflect a relationship between personality and development of gastrointestinal symptoms. Higher levels of introversion and suspicion may hinder adequate coping with stress.

Previous personality studies, showed significantly more symptoms of anxiety and tension and higher scores for trait tension and hostility for FD patients compared with peptic ulcer disease patients[18]. Others would suggest that personality differences are minimised when IBS co-morbidity is excluded. It has been shown that individuals with FD, without IBS, have higher scores of anxiety, neuroticism and depression, than paired community controls, but the differences are relatively small[14]. Where IBS is an accepted co-morbidity the differences are more significant[26]. Neuroticism, characterised by an individual' s tendency to have an exaggerated responsiveness to physiological changes, may theoretically exert an influence on the recognition and reporting of symptoms[27].

Coping response is another psychological factor that has proposed relations to FD symptoms. With regard to the relationship between coping behaviours and well being, FD patients may adopt a distinct coping pattern that is related to their heightened level of anxiety[28]. It has been shown that a non-discriminative, action orientated coping pattern was found to be characteristic of FD regardless of stressor controllability. Consistent use of this coping strategy under all circumstances may not be useful in mitigating distress, may provoke anxiety, may not be useful in altering outcome and may prove costly in terms of psychological strain.

Abuse

Studies suggest that abuse, both past and current, is an important risk factor for functional GI symptoms. It has been found that women outpatients with functional, as opposed to organic bowel disease, were nearly twice as likely to report sexual abuse[29]. Clinic-based studies may carry potential selection bias. However, a population based cross-sectional study, using a self-report questionnaire, has shown that subjects with an abuse history, in childhood or adulthood, were significantly more likely to report a history of dyspepsia or heartburn and that this association could not be explained by confounders for which the analysis accounted[30]. An interview-based study examining the prevalence of FGID's in women subject to ongoing abuse revealed that 71% had a FGID-67% having FD. This group also had higher levels of psychological distress[31].

These observations do not imply causality and the role of confounding co-morbidities to which the individual may be predisposed by virtue of the abuse, may be an issue[32]. It has also been observed that there is a high frequency of abuse history in other chronic pain conditions. Abuse may not be implicated in the aetiology of FGID but may be associated with a tendency to communicate psychological distress through physical symptoms[33].

Psychosocial factors and health-care seeking

Aetiological issues aside, it is reasonable to hypothesise

that psychosocial factors may also exert their effect in FD through an influence on health-care seeking. Health-care seeking is determined by a plethora of factors including symptom severity, personality, coping skills, social support, sociodemographics, psychological morbidity and health-care availability[34]. Illness behaviour, which may be defined as how one perceives, evaluates and acts upon symptoms[35], is also critically involved in the decision to seek medical consultation. Intrinsic to this process are illness beliefs and attitudes. It has been suggested that the observed association between FD and psychosocial factors is in fact mediated through increased help-seeking prompted by elevated levels of psychosocial distress. This theory is derived from the findings by some investigators, in volunteer studies, identifying no differences across psychological parameters between healthy controls and FD patients who have not sought medical advice[36,37].

A number of studies have demonstrated elevated levels of psychosocial distress amongst consulters recruited at clinic, in comparison with non-consulters, with functional dyspeptic symptoms. One such study showed that the former have more worries about cancer and heart disease than the latter. Consulters interviewed also had experienced more stressful or threatening life-events over the previous 6 mo[38]. These are factors that may potentially motivate health-care seeking to ameliorate concern and gain reassurance. More recently, a critical review of the literature pertaining to predictors of health-care seeking for both IBS and FD, was undertaken. Authors concluded that psychosocial factors including life-event stress, psychological morbidity, personality, abuse, and abnormal illness attitudes and beliefs have been found to characterise those that seek help versus those that do not[34]. In a study that sought to examine the differences in behavioural and perceptual characteristics between non-consulters and consulters with FD in a Chinese population, it was found that non-consulters were distinguishable by their perceptual style, coping behaviours and psychological symptoms. Moreover, investigators found levels of anxiety and depression to be highest in consulters compared to non-consulters and healthy controls[39].

Others refute the generalisability of these findings. The results of a recent community based study, suggest that psychosocial factors are significantly associated with functional GI disorders in both consulters and non-consulters, at population level[9]. The debate thus clearly remains unresolved.

ABNORMALITIES OF FUNCTION IN FUNCTIONAL DYSPEPSIA

Though the pathophysiology underlying FD is incompletely elucidated and seems heterogeneous, several mechanisms to explain symptom manifestation have been proposed. Motor abnormalities of the upper gut have been demonstrated including delayed gastric emptying, antroduodenal dysmotility and altered gastric compliance[40,41]. So too has gastric sensory dysfunction in the form of visceral hypersensitivity[42,43]. Infective and inflammatory processes have also been proposed which may involve *Helicobacter pylori* and acute gastric infection[44-46]. Different types of inflammation throughout the gut can leave a legacy resulting in abnormal function in apparently histologically normal organs, by means of proposed mechanisms including: defective resolution of inflammation, changes in mucosal function and persistent changes within the ENS[44]. In a review of the molecular basis of FGIDs, it has been suggested that mediators or regulators of mucosal inflammation, including cytokines, may trigger events that ultimately result in the manifestation of functional gastrointestinal disorders[47]. Abnormalities of receptor function, including central serotonin receptors have also been implicated[48,49].

Influence of psychosocial factors on abnormalities of function

Using the brain-gut interaction construct, how then do psychosocial factors ultimately influence FD symptomatology? Stress is a characteristic shared by the various psychosocial factors that have a demonstrated association with FD. From a psychological perspective, stress is emergent when demand exceeds resources. More broadly, it is defined as 'any threat to the homeostasis of an organism, be it real or perceived, which may be posed by events in the outside world or within[50]. In recent times, the biological substrates of the stress response, in health and disease, have been recognised. In brief summary, centrally, interoceptive (systemic) stressors employ subcortical circuits, while exteroceptive (psychological) stressors engage pathways in the limbic forebrain, hippocampus and amygdala. Both circuits activate hypothalamic effector neurons. Corticotrophin releasing hormone (CRH), not only secreted in the hypothalamus, is an important mediator of the central stress response. The latter is generated by a network of integrative brain structures, in particular subregions of the hypothalamus, amygdala and periaqueductal grey. Mayer refers to this central circuitry as the 'emotional motor system' (EMS), which is under feedback control via ascending monoaminergic projections and circulating glucocorticoids. Outputs from the EMS play a role in mediating the peripheral response[50]. Neuro-endocrine systems are heavily implicated and include the hypothalamic-pituitary-adrenal (HPA) axis[51]. The autonomic nervous system and endogenous pain modulation system are also involved[50]. It is generally recognised that early life-trauma and chronic severe stress in adulthood can cause long-lasting, potentially irreversible, changes in the stress response system[52]. It is possible therefore that in vulnerable individuals the neurobiological substrates of stress, or maladaptive states thereof, operating on the BGA, form part of the link between psychosocial factors and FD.

Approximately one in three FD patients have a definable gastric motor abnormality[53]. In patients with FD, the effect of stress on antro-duodenal activity has been studied, revealing findings contrary to those seen in healthy controls[54]. In an experimental design, it was shown that antro-duodenal motility was diminished by stress in healthy controls. This was not the case in dyspeptic patients suggesting that FD may arise from the effect of stress on upper gut motility in susceptible individuals. The autonomic nervous system has been proposed as the

mediating mechanism for this effect. In an earlier study, antral motility and autonomic function in FD patients and healthy controls were investigated[55]. The effect of mental stress on antral motility was also examined. Findings confirmed autonomic dysfunction, specifically low vagal tone, in functional GI disorders. At baseline, post-prandial antral motility was on average reduced in FD patients compared to controls. Moreover, acute mental stress diminished post-prandial antral motility in healthy subjects but not in dyspeptics. In fact, some patients demonstrated increased motility. Subsequently, it was proposed that poor vagal tone may represent a mediating mechanism for the causal effects of personality on antral motility and related FD symptoms[56]. The relationship among a number of psychological factors, antral dysmotility and dyspeptic symptoms in FD patients were examined. Specifically, it was asked if any such relationship depends on vagal activity, by examining the relationship between these psychological factors and vagal tone. Findings showed that psychological predictors explained a substantial amount of the variance in task-related dyspeptic symptoms, vagal tone and gastric antral dysmotility. FD patients had lower scores on vagal tone and motility index in addition to the expected higher scores on epigastric discomfort. Symptoms appeared to be predicted by trait anxiety, depression and neuroticism and poor vagal tone was associated with neuroticism.

Several studies have established that patients with FD have enhanced sensitivity to gastric distension thus potentially allowing physiological stimuli to induce symptoms[43,57]. The mechanisms underlying visceral hypersensitivity are not fully clarified but there are several sources of evidence for a role of the central nervous system. Studies in experimental animals indicate that acute psychological stress seems to facilitate increased sensitivity to visceral stimuli[40]. Conceivably, psychosocial stressors may affect visceral sensation through an effect on central processing and/or modulation of afferent visceral information or on central cortisol receptors. With reference to the latter, a thorough characterisation of the HPA axis in FGID has not been reported. However, it has been demonstrated that chronic stress may result in HPA axis overactivity and thus hypercortisolaemia[52]. Brain regions involved in visceral sensation, and indeed mood regulation, express cortisol receptors and abnormal levels of cortisol can causes changes in these structures ultimately resulting in abnormal visceral sensation, affective disorders or both[12,50]. Imaging research has revealed considerable overlap between brain regions involved in processing visceral sensation and those important for emotional regulation[12,58,59]. From animal research, neonatal maternal separation in rats, a model of early-life stess, predisposes them to develop visceral hyperalgesia in response to psychosocial stress[60]. It is felt that this is probably CRH mediated.

Approximately 25% of FD cases develop acutely after an acute infectious illness often characterised by vomiting and fever[46]. It is well recognised that stress plays a role in immunological modulation[61]. Chronic stress renders individuals more vulnerable to intestinal infection and inflammation, which can be an important pathophysiological mechanism in post-infectious FGID[62].

PSYCHOSOCIAL FACTORS AND MANAGEMENT OF FUNCTIONAL DYSPEPSIA

The association between psychosocial stressors and FD and the high rates of psychiatric co-morbidity in FD, clearly have implications for effective management. Taking a psychosocial history may help reduce return visits in IBS patients and this may also apply to other FGIDs[63]. Depression and anxiety have been shown to adversely affect outcome in IBS[64] as have pronounced health worries and poor psychosocial support. Overt psychiatric illness should respond to conventional treatment and if suspected, or if there is evidence of somatisation in other systems leading to multiple consultations across specialities, referral to a mental health profession may be considered[8]. As with IBS, treatment in FD is symptom driven. In reducing the likelihood of invalidating the patient's symptoms (secondary to lack of organic pathology) it may help to explain the mechanisms underlying brain-gut interactions. Acknowledging the relevance of psychosocial factors will no doubt meet with some resistance in certain patients.

If the role of psychosocial factors in FD remains to be fully clarified, then the role of psychological therapies is similarly undetermined. However, patients with FD may benefit from psychological treatments. This is particularly true of those with chronic symptoms unresponsive to conventional medical approaches. Psychotherapy has been defined as an interpersonal process designed to bring about modifications of feelings, cognitions, attitudes and behaviour, which have proved troublesome to the patient seeking help from a trained professional[65]. There are wide ranges of interventions that can be described as psychotherapeutic including cognitive-behavioural therapy (CBT), psychodynamic psychotherapy and group therapies. Psychodynamic therapies focus on how maladaptive ideas and behaviours have emerged whereas cognitive behavioural work concentrates on how maladaptive ideas and belief systems are maintained by the patient's environment and behaviour[66].

A systematic review to establish the effectiveness of psychotherapy and hypnosis in FD, revealed a paucity of randomised controlled trials investigating psychological intervention in FD[66]. The data available suggest that these techniques benefit FD but the authors conclude that the evidence is insufficient to confirm their efficacy. One particular study randomised patients to psychodynamic-interpersonal psychotherapy or supportive therapy, which consisted of sympathy and support for the same duration of time as the intervention arm. Patients recruited had chronic symptoms and a history of failed response to conventional pharmacological therapy. After 12 wk of treatment the intervention group were significantly better across parameters but after 12 mo, the symptom scores were similar between groups[67]. CBT has been found to be effective in the treatment of depression, anxiety disorders and of patients with medically unexplained symptoms[68]. A study comparing the outcome of cognitive therapy (attempts to change dysfunctional thoughts and behaviour

by cognitive restructuring, behavioural modelling and role-play) and a control group intervention (bimonthly therapist visits), in patients with FD, demonstrated significantly greater improvement in the former[69].

The rationale for using psychotropic medication rests in the level of psychiatric co-morbidity seen in patients with FD as mentioned earlier. Additionally, there is data to support the use of antidepressants in the relief of chronic pain[8]. A meta-analysis of the treatment of functional gastrointestinal disorders with antidepressant medications, identifying 3 randomised controlled trials evaluating FD, suggested that antidepressants (predominantly tricyclics) might reduce the symptoms of FGIDs. Of note, the majority of studies included, used antidepressant doses that are essentially sub-therapeutic for treatment of depression. The authors thus suggest that it is unlikely that the benefit observed is due entirely to the antidepressant effect of these drugs[70]. There is little data available on the use of selective serotonin reuptake inhibitors. It seems reasonable that choice of drug is tailored to the individuals dominant symptom pattern whilst remaining cognisant of side-effect profiles. Essentially, if used, psychotropics should be regarded as complimentary to an overall multi-component plan.

In conclusion, functional dyspepsia is a heterogeneous disorder in which the role of psychosocial factors continues to be the subject of debate. The suggestion that psychological morbidity and social stressors serve to motivate physician consultation, rather than possessing an aetiological role in symptom pathogenesis, has been challenged. Despite inconsistent findings, it is evident that there is a high level of psychiatric co-morbidity with FD and that anxiety disorders predominate. Individuals with FD appear to experience a greater number of life-events, which are not limited to those of negative impact, compared to healthy controls. A recent or remote history of abuse is a non-specific risk-factor for symptoms of FD. The speculation that functional gastrointestinal disorders and psychopathology share common pathophysiology is interesting and warrants further examination. The evolving appreciation and delineation of brain-gut interactions and CNS processing continues to enhance our understanding of the complex mechanisms underlying symptom generation, interpretation and presentation.

Abstract

A high prevalence of overlap between functional dyspepsia and irritable bowel syndrome has been consistently and universally reported. Recent studies demonstrating shared common pathophysiological disturbances including delayed gastric emptying and visceral hypersensitivity involving more than one region, suggest that these patients have a generalised rather than regional, disorder of the gut. Furthermore, a study of the natural history of dyspepsia suggests that with time, a substantial proportion will evolve into IBS. The recognition of IBS in dyspeptic patients has potentially profound therapeutic importance. It could help to reduce the risk of unnecessary cholecystectomy in IBS patients. The ability to appreciate the extent of involvement could allow us to address the disturbances more comprehensively, and thereby achieve greater patient satisfaction with their treatment.

INTRODUCTION

Many patients with functional dyspepsia (FD) will also fulfil the criteria for irritable bowel syndrome (IBS). Functional dyspepsia (FD) may coexist with irritable bowel syndrome (IBS) for several reasons. The association may be a chance occurrence simply because both FD and IBS are so common. IBS patients with upper abdominal pain may be mistakenly labelled as FD. Both conditions could share common pathophysiological disturbances.

PREVALENCE OF FD-IBS OVERLAP

In population-based studies, the estimated prevalence of IBS among dyspeptic subjects, ranges between 13% and 29%, while the prevalence of FD among IBS subjects ranges between 29% and 87%[1-3]. These figures are higher than the corresponding figures in the general population, where the prevalence of IBS and FD are estimated to be about 10% and 20% respectively. This would suggest that the overlap is not simply the chance occurrence of two extremely common human conditions. In patient-based series, as opposed to community series, the prevalence of overlap appears to be even higher, with between 26% and 46% of FD patients having concomitant IBS and as many as 87% of IBS patients having concomitant FD[4-8]. This observation would appear to suggest that the coexistence of these two sets of symptoms increases the likelihood of a subject seeking medical attention. There is some support for this from a study by van Bommel *et al* who found in a survey of primary care patients consulting for dyspeptic complaints, that those who had concomitant IBS were most likely to be referred for specialist assessment[9].

In Asia the figures are similar. In a population-based study from Mumbai, India, the prevalence of dyspepsia was 30%, while among subjects with IBS, the prevalence of dyspepsia was 58%[10]. Similarly, the prevalence of IBS among subjects with dyspepsia at 14% was greater than in the general population where it was 7.5%. In a community study from Xi'an in northwest China, Wang *et al*[11]found that significantly more subjects with GERD symptoms also experienced constipation (22%), and diarrhoea (14%) than subjects without GERD symptoms (10%, 5% respectively). In the Guangdong province of south China, Chen *et al* reported that 22% of 473 FD patients attending gastroenterologists had concomitant IBS, whereas the prevalence of IBS in this population was estimated to be 7%[12]. In the Zhejiang province of China, the prevalence of FD among 662 consecutive IBS patients consulting gastroenterologists, was 64%[13].

IBS MISDIAGNOSED AS FD

It is conceivable that IBS patients who present with upper abdominal pain may be mislabelled as FD. Colonic distension studies have clearly demonstrated that in IBS patients, pain from the colon can be referred to the upper abdomen. In a classical experiment, Swarbrick *et al* provoked abdominal pain in 48 IBS patients by using an attached balloon to distend the colon at various regions during colonoscopy[14]. Distension of the mid transverse colon induced pain in the epigastrium in 10 patients.

There are several reasons why doctors may mislabel IBS patients as having dyspepsia and overlook the association with bowel disturbances. Past diagnostic criteria for IBS have tended to focus on the bowel disturbances and lower abdominal pain. Even the Rome II criteria did not consider the association of pain with a meal as a possible symptom of IBS. And yet, a study by Ragnarsson *et al* suggested that about 50% of IBS patients would experience postprandial pain[15]. Foods that are commonly implicated in dyspepsia include spicy foods such as chilli, fatty foods and coffee. In a study of chronic upper abdominal pain, Kang *et al* found that as many IBS patients as FD patients reported precipitation of pain by fatty foods (28%, 19%), chilli (45%, 47%) and coffee (41%, 36%)[16]. A study by Simren *et al* has demonstrated that lipid infusion into the duodenum increased the area of referred pain in IBS patients such that more patients were experiencing pain in the upper abdomen during distension of the sigmoid colon[17].

One important reason for differentiating IBS from dyspeptic symptoms, is to avoid the risks of unnecessary surgery. Several recent studies have highlighted the risks of unnecessary surgery in IBS[18-20]. Based on statistics from studies in the USA population an estimated 8% of IBS patients will undergo unnecessary cholecystectomy in a lifetime[20]. It is possible that in some of these IBS patients undergoing cholecystectomy, their IBS symptoms could have been mislabelled as dyspeptic symptoms. In a study of 22 patients with chronic right upper quadrant pain, their pain was reproduced by distension of the jejunum in 15, ileum in 12 and right colon in 9, and 16 had symptoms consistent with IBS[21]. And yet, prior to their referral these patients had never received a diagnosis of IBS. On the contrary, they had been subjected to an average of 3 pancreatobiliary investigations each, 10 of them had been subjected to cholecystectomy without obvious improvement, even in the 5 who proved to have gallstones. The risk of cholecystectomy could be particularly greater among subjects with FD-IBS. In a community survey Talley *et al* found a cholecystectomy rate of 19% in FD-IBS subjects compared with only 6%-8% for subjects with either FD alone or IBS alone, no different from subjects with neither IBS nor FD[1].

The mislabelling of IBS as dyspepsia is likely to be a greater problem in Asia than in the west. IBS patients in Asia appear to present more commonly with upper abdominal pain[22]. In numerous studies from India, more than half of their patients complained of upper abdominal pain, whereas in western series only about a quarter do so. In a recent study from Taiwan, Lu *et al*[23] looked at 481 patients with FD by Rome criteria, and found more than half had IBS criteria. When they looked at these patients with FD criteria and IBS criteria, they found that in about a third of these patients, their upper abdominal symptoms could be attributed solely to IBS alone. In a study from the same centre in Taiwan, IBS subjects were observed to have twice the rate of cholecystectomy of the non-IBS subjects[24].

In the east, another possible reason for misdiagnosing IBS as dyspepsia could be the milder degree of defecatory and stool disturbances. In a community study from Singapore, more than half of IBS subjects reported pain in the upper abdomen[25]. Despite the fact that 50% fulfilled criteria for chronic constipation and 25% for chronic diarrhoea, when these people were asked to describe their bowel pattern, 77% thought that they had a normal bowel habit.

SHARED COMMON PATHOPHYSIOLGICAL DISTURBANCES

Pathophysiological processes implicated in FD such as altered gastric emptying and visceral hypersensitivity, have also been demonstrated in IBS patients. Post-infectious IBS is a well recognised entity. A recent study suggests that FD could also arise post-infection.

Delayed gastric emptying

Although early studies failed to demonstrate delayed gastric empyting among IBS patients, recent studies employing greater number of patients suggests that it exists in about 30% of IBS patients, particularly in those with constipation-predominant IBS[26-32]. Van Wijk *et al*[29] studied 16 patients with constipation predominant IBS and found slower gastric emptying of solids compared with healthy controls. Evans *et al*[30] studied 44 IBS patients and observed delayed gastric emptying in 9 of 22 (41%) C-IBS and 8 of 22 (36%) D-IBS patients. Caballero-Plasencia *et al*[31] studied 50 IBS (30 C-IBS, 20 D-IBS) patients and found evidence of delayed gastric emptying of both solids and liquids compared with healthy controls. IBS patients with constipation had slower gastric emptying of solids compared with diarrhoea-predominant IBS.

Recently Stanghellini *et al* studied gastric emptying in a large cohort of IBS patients[32]. In 146 IBS patients, majority IBS with constipation, overlapping FD was present in 96 patients (66%). Gastric emptying was delayed in patients with concomitant FD but not in those with IBS alone. In particular, postprandial fullness and nausea were independently associated with delayed gastric emptying. In another large study involving 309 FD patients, Corsetti *et al* using the gastric emptying breath test, found evidence of delayed gastric emptying to solid meal in 23% of patients with FD-IBS and 19% of patients FD alone[8].

Visceral hypersensitivity

In the study by Corsetti *et al*[8] using the gastric barostat, impaired accommodation to a meal was found to be as prevalent in FD-IBS patients (31%) as in FD patients (35%). However, significantly more FD-IBS patients were found to have hypersensitivity to gastric distension than patients

with FD alone (44% *vs* 28%). On the other hand, testing of visceral sensitivity in other regions of the GI tract has not shown any significant differences between FD and IBS subjects. Holtmann *et al* tested sensitivity to distension in the third part of the duodenum and demonstrated hypersensitivity in patients with FD alone, IBS alone and FD-IBS, with no significant differences observed between the groups[33]. Trimble *et al*[34]demonstrated hypersensitivity to distension of the rectum and the oesophagus in both IBS and FD patients compared to healthy controls. However, patients had normal pain thresholds to electrocutaneous stimulus applied to the finger.

Post-infection sensitization

The development of IBS following an episode of acute gastroenteritis has been documented in prospective studies[35-36]. Retrospective studies had previously suggested that FD could also develop post-infection, and that this form of FD was associated with delayed gastric emptying and impaired accommodation[37]. While post-infectious IBS has been largely associated with bacterial infections such as salmonella and campylobacter, post-infectious dyspepsia was presumed to be of viral origin. Recently however, a large prospective study of a well documented single source out-break of salmonella gastroenteritis demonstrated the development not only of IBS, but also for the first time, of dyspepsia[38]. The three most common dyspeptic symptoms were pain, bloating and fullness. Prolonged abdominal pain and vomiting during the acute episode were found to be positive predictors. In patients who developed IBS, there was a 62% overlap with FD at 12 mo post-infection. In patients who developed FD, there was a 46% overlap with IBS.

SYMPTOMATOLOGY OF FD-IBS

The type of symptoms that appear to predominate among FD-IBS subjects, as well as the substantial flux between FD and IBS populations observed in longitudinal studies, lends further support to the hypothesis for a shared common pathophysiology between FD and IBS.

In a Swedish community-based study Agreus *et al* found that the greatest overlap was between IBS and dysmotility-like dyspepsia[3]. In Italy Stanghellini *et al* studied a series of 483 patients with FD, and found that patients with predominantly non-painful symptoms such as post-prandial fullness, nausea and vomiting, were more likely than patients with predominantly epigastric pain to be associated with IBS[6]. Similarly in Singapore, Gwee *et al*[39]studied a consecutive series of 224 patients with FD, and found that 33% had concomitant IBS, with dysmotility type symptoms predominating in the FD-IBS group.

Patients with constipation predominant IBS (IBS-C) appear to be more prone to FD than diarrhoea predominant IBS (IBS-D), and their dyspeptic symptoms appear to be of the dysmotility type. Schmulson *et al*[40] found that IBS-C patients had more upper GI symptoms, in particular early satiety and postprandial fullness, than IBS-D. Similarly, Talley *et al*[7] reported that more patients with IBS-C had upper abdominal pain, and in particular, had significantly more bloating and early satiety than IBS-D. In China, there was a trend for a greater prevalence of FD among IBS-C patients (70%) than IBS-D patients (62%)[13]. A cologastric brake has been proposed by Tjeerdsma *et al* as one mechanism through which constipation could give rise to upper abdominal symptoms[41]. Delayed gastric emptying was recorded in a study of healthy volunteers who had suppressed defecation for 3 d.

The available literature suggests that FD-IBS patients could have more severe symptoms, and it is possible that IBS could be a predictor of consultation seeking behaviour. Talley *et al* reported that community subjects with FD-IBS subjects had made more physician visits for abdominal pain and for disturbed defecation than subjects who had either FD or IBS alone[1]. Furthermore, while the rates of appendicectomy and cholecystectomy among subjects with FD alone or IBS alone were no different from subjects with neither FD nor IBS, the rates were two to three times greater for subjects with FD-IBS. In a study of patients consulting their general practitioners for dyspepsia, it was also found that those who had IBS along with their dyspeptic complaints were most at risk of being referred for specialist assessment[9]. Corsetti *et al*[8] reported that FD-IBS was associated with higher symptom severity scores.

Evolution of Symptoms

In a one year study of symptom turnover by Agreus *et al* 87% of subjects with IBS also fulfilled Rome I criteria for dyspepsia[13]. When these IBS subjects were surveyed one year later, 50% still fulfilled IBS criteria. However, 22% appeared to lose their IBS, but changed their symptom profile to one of dyspepsia. Among subjects who were categorised as dyspepsia, 43% retained this diagnosis, while 16% converted to IBS. By comparison, among subjects who were symptomless at the beginning of the survey, 80% remained asymptomatic, while only 1% developed IBS and 3% developed dyspepsia. When this study was extended to 7 years Agreus *et al*[42] observed that dyspepsia appeared to decrease with advancing age, the prevalence in their cohort declined from an initial 11.7% to 8.1%, whereas IBS increased in prevalence from 8.9% to 13.6%. Of all subjects with dyspepsia on the first survey, only 30% could still be classified as dyspepsia after 7 years, 17% became asymptomatic, while 18% evolved to IBS. With IBS, 55% remained as IBS, 13% became asymptomatic, and only 8% evolved to dyspepsia. Whereas substantial symptom fluctuation and symptom profile flux was observed between IBS and dyspepsia, the prevalence of GERD remained relatively stable, and only a minority (<10%) of GERD evolved to dyspepsia or IBS, or vice-versa. Thus, while patients with GERD appear to form a distinct population from FD or IBS, separation between the latter two blurred with time.

In conclusion, in view of the high degree of symptom overlap it has been suggested that the separation of functional GI disorders into FD and IBS may be inappropriate[3]. Given the shared pathophysiology, some have suggested that patients with FD-IBS have an irritable gut[3,34]. With the substantial flux between FD and IBS, and the observation that a greater proportion of dyspeptic patients

evolved into IBS than the reverse, it is tantalizing to speculate that FD could be a precursor of IBS, and eventually all FD could evolve into IBS. At the end of the day, the key consideration is whether the division of patients into FD and IBS has led to improved treatment outcomes. The experience with sub-classification of FD suggests that this is not the case. Perhaps it is now time to lump again rather than split, and also in our research to return to the old approach of examining combination treatments. After all, combination treatment is the reality of clinical practice.

Abstract

There appears to be the strong association between *Helicobacter pylori* (*H pylori*) and gastric cancer. We reviewed the latest evidences about the effects of *H pylori* infection on gastric carcinogenesis, classified into epidemiology, dynamics of gastric mucosal changes, DNA damages, virulence factors, host factors, and source of gastric malignancy. Through the considerable progress made in research into virulence factors resulting from differences between *H pylori* strains, such as *cagA* positivity, as well as into host factors, such as gene polymorphisms, a diverse spectrum of *H pylori*-associated diseases, including gastric cancer, is beginning to lend itself to elucidation. The impact of the novel hypothesis advanced by Houghton *et al* proposing bone-marrow derived stem cells (BMDC) as a potential source of gastric malignancy on evolving research remains to be seen with interest. Further progress in research into *H pylori* eradication as a viable prophylaxis of gastric cancer, as well as into the mechanisms of gastric carcinogenesis, is to be eagerly awaited for the current year and beyond.

INTRODUCTION

By now, there appears to be no doubt about the strong association between *Helicobacter pylori* (*H pylori*) and gastric cancer, and the focus of current research interest has now shifted to the mechanism of gastric carcinogenesis associated with *H pylori* infection, long regarded as a black box, which is now beginning to be unraveled thanks to the considerable progress made in this area through the clarification of various aspects including *cagA*. Difficult as it is to cover the full spectrum of papers accumulated on *H pylori* and gastric cancer even in the last few years, in what follows, we propose to provide a review of the literature, while drawing on selected papers of interest on this topic.

EPIDEMIOLOGY

In the beginning of 2004, Wong *et al*[1] reported on the results of a randomized controlled trial investigating the association between *H pylori* eradication and prophylaxis of gastric cancer in 1630 patients with *H pylori* infection (of whom 988 patients were found to have no precancerous lesions, such as atrophy of gastric mucosa, intestinal hyperplasia, or atypical epithelium) allocated to either the eradication arm or placebo arm and followed up for 7.5 years. Of the patients who developed gastric cancer during follow-up, 7 had had *H pylori* eradicated, and 11 had received placebo, and there was no significant ($P=0.33$) difference in the incidence of gastric cancer between the two arms. However, a subset analysis of patients without precancerous lesions in both the treatment and placebo arms revealed that the incidence of gastric cancer was 6 in the placebo arm *versus* 0 in the treatment arm ($P=0.02$), suggesting that *H pylori* eradication significantly inhibited the incidence of gastric carcinogenesis in patients without precancerous lesions.

In another randomized, double-blind, placebo-controlled trial in 248 patients, of whom 122 received eradication, and 126 received placebo, Ley *et al*[2] reported in their follow-up ranging from 6 wk to 1 year that there was no significant improvement with *H pylori* eradication in the consensus "worst biopsy" diagnosis, while there was improvement in the weighted index score, and concluded that the study results do not prove that eradication of *H pylori* decreases cancer risk. However, these inconclusive

results may be attributable to the short-term follow-up of the study.

The Japan Collaborative Cohort (JACC) Study Group for Evaluation of Cancer Risk reported that women with a family history of gastric cancer and infected with *H pylori* were associated with a 5.10-fold risk for gastric cancer compared to women without a family history of gastric cancer and *H pylori* infection[3]. In contrast, family history and *H pylori* infection were not found to be significant risk factors for gastric cancer in male patients in their report, where the investigations of *H pylori* infection were performed using only *H pylori* antibodies.

Matsuhisa *et al*[4] investigated the ratio of corpus gastritis to antrum gastritis (C/A ratio) in *H pylori*-positive Chinese, Thai and Vietnamese adult populations compared to the Japanese population by evaluating the degree of neutrophil activity in the corpus and antrum of these patients. The C/A ratio was found to be significantly higher in the Japanese population compared to the other populations, where corpus-predominant gastritis was characteristic of aged Japanese and Chinese (Fuzhou), while, in contrast, gastritis in Chinese (Beijing), Thai and Vietnamese was found to be antrum-predominant, which is considered to be related to the low incidence of gastric cancer in Thai and Vietnamese.

Brenner *et al*[5] demonstrated in a case-control study that after excluding those who met the exclusion criteria (blood sample taken more than 90 d after gastrectomy, advanced (T4) gastric cancer, and *cagA* positivity in Western blot analysis despite a negative result in anti-*H pylori* immunoglobulin G enzyme-linked immunosorbent assay), as well as those who had borderline levels in immunoglobulin G enzyme-linked immunosorbent assay, the odds ratio for noncardia gastric cancer was increased from 3.7 to 18.3 in those with any *H pylori* infection, and from 5.7 to 28.4 in those with *cagA*-positive *H pylori* infection. The authors therefore concluded that *H pylori* infection might even be a (close to) necessary condition for the development of nocardia gastric cancer.

In a multi-center trial evaluating 2 503 patients with histologically confirmed gastric cancer *versus* 6 578 control subjects, Kato *et al*[6] demonstrated that *H pylori* infection was strongly associated with the development of gastric cancer ($OR = 2.47$), while there were no significant differences in the prevalence of *H pylori* infection, histological subtypes of gastric cancer (intestinal type *vs* diffuse type), or sites of gastric cancer occurrence (antrum, corpus and cardia) between the gastric cancer and control subjects.

Shiotani *et al*[7] demonstrated that *H pylori*-positive patients with pruritic skin diseases may be at increased risk for the development of gastric cancer. Leung *et al*[8] reported the results of a randomized trial on *H pylori* eradication, demonstrating that *H pylori* infection ($OR = 2.13$), 45 years of age or greater ($OR = 1.92$), alcohol intake ($OR = 1.67$) and drinking water from a well ($OR = 1.74$) are risk factors that predict the progression of intestinal metaplasia as precancerous lesions.

Camargo *et al*[9] investigated the prevalence and the age of acquisition of *H pylori* infection in children aged 1 to 8 years old residing in Pasto, Colombia, which is associated with a high prevalence of gastric cancer as compared to those in children living in Tumaco, Colombia. They found that there were no significant differences between children in Pasto and Tumaco in the prevalence and age of acquisition of *H pylori* infection, suggesting that the risk for gastric cancer is associated with the bacterial virulence of the *H pylori* strains involved.

DYNAMICS OF GASTRIC MUCOSAL CHANGES

Kato *et al*[10] investigated the sex differences in mucosal response to *H pylori* infection and found that atrophy and intestinal metaplasia scores in the corpus with *H pylori* infection were more severe in men than in women, particularly in elderly patients. They also reported that while there were no differences between the sexes with regard to interleukin-8 mRNA induction, cyclooxygenase-2 (COX-2) mRNA expression was higher in men than that in women, concluding that these differences in response between men and women may account for the 2-fold difference in the incidence of gastric cancer between the sexes.

Shiotani *et al*[11] demonstrated that the gastric nitrate and pH levels were progressively increased from patients with histological normal diagnosis to those with antral-predominant gastritis to those with pangastritis, and then on to those with corpus-predominant gastritis, suggesting that the gastric pH level is one of the prognostic markers for corpus-dominant gastritis and probably for patients at high risk of developing gastric cancer.

Of the reports that addressed post-eradication changes in the mucosa, a study by Fichman *et al*[12] demonstrated that there was improvement in acute and chronic inflammation scores, the number of lymphoid follicles, as well as an increase in the number of gastric glands, while there was no change in intestinal metaplasia over time, during a mean follow-up of 23.15 mo after *H pylori* eradication in 89 patients. They further demonstrated that the Ki67 labeling index significantly decreased after eradication, while the MUC5AC and MUC6 expressions increased. Of the numerous reports published on post-eradication changes in the gastric mucosa, many reported improvement of intestinal metaplasia with eradication of *H pylori*, suggesting the potential role of *H pylori* eradication in the prophylaxis of gastric carcinogenesis[13-15].

Iijima *et al*[16] also reported that *H pylori* infection showed a stronger inhibitory effect on acid secretion in males than that in females. Ohata *et al*[17] demonstrated in a longitudinal cohort study in 4 655 healthy subjects with a mean follow-up of 7.7 years that 45 subjects subsequently developed gastric cancer. In this study, *H pylori* infection was established by serum-specific antibodies and the presence of chronic atrophic gastritis was confirmed by measurement of serum pepsinogen I and II. They also demonstrated that *H pylori* infection and gastric mucosal atrophy were both strongly implicated in gastric carcinogenesis and that *H pylori*-negative patients in whom there was no evidence of gastric atrophy did not develop

gastric cancer. Furthermore, they concluded that while *H pylori* infection is not directly associated with gastric carcinogenesis, it is indirectly implicated in it by promoting gastric atrophy, and severe gastritis with extensive intestinal metaplasia is a major risk factor for gastric cancer.

Suzuki *et al*[18] provided evidence that *H pylori* eradication exerted an inhibitory effect on the proliferation of epithelial cells as shown by the tissue content of hepatocyte growth factor (HGF) and Ki67 labeling index. Our previous study also demonstrated that *H pylori* eradication led to a decrease in the expressions of *p53* and multiple double minute 2 (MDM2) in the epithelial cells, which had been elevated prior to eradication[19] .

DNA DAMAGE

Ladeira *et al*[20], using the comet assay or single-cell gel electrophoresis, investigated the status of DNA damage in gastric epithelial cells from the antrum and corpus in *H pylori*-infected patients with gastritis of varying degrees, and demonstrated that the level of DNA damage in *H pylori*-infected individuals was significantly higher (8.4-fold) than that in non-infected individuals, with the levels of DNA damage significantly higher in those aged 50 years or more.

The DNA repair enzyme human oxoguanine glycosylase 1 (hOGG1) is known to be responsible for the repair of the 8-hydroxy-deoxyguanosine (8-OHdG) region. Of the hOGG1 polymorphisms identified, a Ser→ Cys polymorphism at position 326 was found to interact with atrophic gastritis, but not with antioxidant dietary or nutrient intakes, likely making patients with atrophic gastritis who also have the hOGG1 Cys allele more susceptible to gastric cancer[21] .

The concentrations of 8-OHdG, inducible nitric oxidative synthase (iNOS), nuclear factor κB (NF-κB), myeloid cell leukemia-1 (Mcl-1) and inhibitor of apoptosis protein (IAP) were reported to be significantly higher in patients with *H pylori* infection, in cancer tissues, and in stage 3 and 4 gastric cancer patients, pointing to the pivotal role that oxygen-free radical-mediated DNA damage due to *H pylori* infection plays in the development of gastric carcinoma from chronic gastritis[22].

VIRULENCE FACTORS

CagA proteins and gastric carcinoma

H pylori virulence factors include the cytotoxin-associated gene A antigen (CagA), the vacuolating cytotoxin (VacA), urease, and blood group antigen-binding adhesin (BabA). After the year 2000, much has been clarified about the behavior of CagA proteins, where *H pylori* could directly deliver the CagA protein into the host epithelial cell cytoplasm via the *cag* PAI-coded type IV export system[23]. Inside the epithelial cells, the CagA protein undergoes tyrosine phosphorylation by the host Src family protein tyrosine kinases, and the CagA protein binds an Src homology 2 (SH-2) domain-containing tyrosine phosphatase SHP-2, and stimulates the division and proliferation of gastric epithelial cells[24] .

Twenty percent of the tyrosine-phosphorylated CagA also binds carboxyl-terminal Src kinase (Csk) with 80% of the tyrosine-phosphorylated CagA binding SHP-2. The CagA-Csk interaction activates Csk and inactivates the Src family kinases, thereby bringing about a decrease in CagA tyrosine-phosphorylation as well as in CagA-SHP2 interactions as a feedback mechanism[25]. Through this mechanism, chronic infection with *cagA*-positive strains persists, thus causing the host damage.

There are two subtypes of the CagA proteins reported, namely the Western CagA and East Asian CagA[26] . Due to the presence of polymorphisms in tyrosine phosphorylation sites, the East Asian CagA proteins were reported to have a significantly higher SHP-2-binding affinity than the Western CagA proteins, whereas the Western CagA proteins with repeated EPIYA motifs are associated with greater CagA phosphorylation, and higher SHP-2-binding affinity, and greater induction of the hummingbird phenotype than the Western CagA proteins without repeated EPIYA motifs[26]. However, the East Asian CagA proteins, with a different amino acid sequence downstream of the third EPIYA motif, are reported to exhibit even greater activity than the potent Western CagA proteins.

Argent *et al*[27] also reported that the more EPIYA motifs present in the CagA proteins, the higher the degree of CagA tyrosine-phosphorylation and the level of CagA biologic activity in inducing human gastric epithelial (AGS) cell elongation (hummingbird phenotype), and the more likely they are to be associated with gastric cancer.

In the host cell, the tyrosine-phosphorylated CagA protein induces rearrangements of the actin cytoskeleton. The tyrosine-phosphosphorylated CagA inhibits the catalytic activity of Src family kinases and induces tyrosine-dephosphorylation of several host cell proteins, one of which has been identified as ezrin. Ezrin is a component of microvilli, and makes up the ezrin-radixin-moesin (ERM) family of proteins as a linker protein between actin filaments and membrane proteins, and thus is deemed responsible for the adhesion and division of molecules as well as for intracellular signaling. This suggests that ezrin dephosphorylation may be implicated in the mechanism of gastric carcinogenesis[28].

Given the well known fact that the incidence of gastric cancer in Okinawa Prefecture, Japan is quite low, Azuma *et al*[29] compared the *H pylori* strains prevalent in Fukui and Okinawa Prefectures, and found that, of the strains examined, those found in Fukui were all of the East Asian CagA subtype; and, of the 42 strains associated with gastritis in Okinawa, 6 strains (14.3%) were *cagA*-negative, 8 strains (19.0%) were of the Western CagA subtype, and 28 strains (66.7%) were of the East Asian CagA subtype; and all strains associated with gastric carcinoma were of the East Asian CagA subtype. The degree of inflammation, activity of gastritis, and gastric mucosal atrophy observed in the East Asian *cagA*-positive strains were significantly more advanced than that in the Western *cagA*-positive or -negative strains, suggesting that infection with East Asia *cagA*-positive *H pylori* strains is strongly associated with gastric atrophy and cancer.

Furthermore, Azuma *et al*[30] compared the distribution of CagA polymorphisms in the world and analyzed the

relationship between the CagA distribution and associated mortality rate of gastric cancer. In this report, they noted that no East Asian CagA proteins were found in the West, while all CagA proteins reported in Asia were of the East Asian CagA subtype, with the prevalence of the East Asian CagA subtype found to be correlated well with the mortality rate from gastric cancer, thus concluding that searching for CagA polymorphisms rather than mere *H pylori* infection may be of greater value in identifying patients at increased risk of developing gastric cancer.

Azuma *et al*[31] also reported on several genes in a pathogenicity island (PAI) known as *cag* PAI, of which the *cagA* gene is one. According to their report, the *cag* PAI can be classified by their polymorphisms into the Japanese and Western clusters, and their diversity is associated with the *vacA* and *cagA* genotypes; and all strains with the *s1c vaA* genotype as well as with the East Asian *cagA* genotype are found in the Japanese cluster. They also noted that patients infected with strains found in the Japanese cluster were associated with high grade gastric mucosal atrophy and that while nearly all patients with *H pylori* infection are found to be *cag* PAI-positive, of all *cag* PAI polymorphisms, the Japanese cluster-genotypes appear to be predominantly associated with advanced gastric atrophy and increased gastric cancer risk.

Kauser *et al*[32] investigated the chromosomal integrity or lack of the *cag* PAI across different populations by evaluating the biogeographical distribution of strains carrying the fully integral *cag* PAI. According to their report, the *cag* PAI was well conserved in the East Asian clinical isolates and most highly conserved in the Japanese clinical isolates, but least conserved in the majority of the European and African clinical isolates. They also found that the *cagE* and *cagT* genes were less often rearranged (18%) compared to the *cagA* gene, and the differing *cag* PAI rearrangement patterns were related to varying disease outcomes, with the *cagA* promoter and the left end of the *cag* PAI frequently rearranged or deleted in clinical isolates associated with severe pathology.

AI-Marhoon *et al*[33] proposed a model on the association between *cagA*-positive *H pylori* infection and distal gastric cancer, explaining how *cagA*-positive *H pylori* infection is associated with greater PGE_2 production, increased mucus thickness and hydrophobicity, which serve to protect and keep intact bacterial colonization and increase gastritis, and is therefore associated with the risk of distal gastric cancer.

Ladeira *et al*[34] showed that *cagA*, *vacA*, and *iceA* genotypes were associated with significant DNA damage in both the gastric antrum and corpus, indicating that they may serve as biomarkers for the risk of extensive DNA damage and possibly for gastric cancer.

Toward the end of 2003, Huang *et al*[35] performed a meta-analysis of the relationship between *cagA* seropositivity and gastric cancer in a total of 2284 patients with gastric cancer *versus* 2770 control subjects, demonstrating that *H pylori* infection and *cagA* positivity increased the risk for gastric cancer by 2.28-fold and 2.87-fold, respectively. They also reported that among *H pylori*-positive patients, *cagA* positivity further increased the risk for gastric cancer by 1.64-fold, and that for non-cardia gastric cancer by 2.01-fold, whereas the gastric cancer at the cardia was not associated with *H pylori* infection or *cagA* positivity, thereby concluding that *cagA* positivity is associated with a greater risk of developing gastric cancer than *H pylori* infection. Furthermore, Held *et al*[36] investigated the association between *cagA*-positive *versus cagA*-negative status and gastric cancer in a case-control study and found that *H pylori* antibody positivity was associated with a greater risk of gastric cancer than *H pylori* antibody negativity, and that cag*A* antibody positivity further increased the risk, while cag*A* antibody-negative *H pylori* infection was associated with a significantly greater risk for gastric cancer than *cagA* antibody- and *H pylori* antibody-negative status.

There are several reports, however, that tend to negate the role of *cagA* as a risk factor for gastric cancer, while acknowledging its importance. Hirata *et al*[37] reported on the functional variability of the *cagA* gene in 36 clinical strains isolated from Japanese patients with various gastric diseases. They demonstrated that while delivery of the CagA protein into the host epithelial cell cytoplasm in the majority of Japanese patients with *H pylori* infection is ensured via the type IV export system, and tyrosine-phosphorylation of the CagA protein is promoted, the intensity of CagA phosphorylation as well as the activation of the serum response element (SRE) vary greatly among the *cagA*-positive strains, with those associated with gastric cancer, MALToma and chronic atrophic gastritis found to be slightly higher than those associated with gastroduodenal ulcers. They also noted that while the *cagA* polymophisms and the number of EPIYA motifs repeated should account in part for the variety of resulting diseases, the association between *cagA* status and disease outcome might not be too strong.

Bachert *et al*[38] performed a functional analysis of the *cag* PAI in 25 *H pylori* strains each isolated from patients with gastritis, peptic ulcer disease, and gastric cancer, and demonstrated that *cagA* expression, translocation and tyrosine-phosphorylation were high but similar among all patient groups examined, suggesting that while the *cag* PAI-dependent processes remain an important *H pylori*-associated virulence factor, the determination of disease outcome may be highly complex and involve multiple bacterial and/or host factors. Similarly, Nishiya *et al*[39] investigated the role of the *cag* PAI by performing an analysis of 39 *H pylori* strains each isolated from Japanese patients with gastric cancer and chronic gastritis, respectively, where the presence of *cagA*, *cagE*, and *VirD4* homologue was studied. They reported that almost all patients were found to be *cagA*-positive, and there were no differences between patients with gastric cancer and chronic gastritis with regard to the expression of *cagA*, *cagE* and *VirD4*, thus concluding that the structure of the *cag* PAI might not be associated with the development of gastric cancer in Japanese patients.

Apart from this, while the interaction between *H pylori* infection and gastroesophageal reflux disease (GERD) has long been under debate, Ye *et al*[40] showed in a large population-based case-control study in Sweden that *H pylori* infection might prevent the development of GERD and reduce the risk of esophageal adenocarcinoma,

whereas gastric atrophy and infection with *cagA*-positive stains of *H pylori* might increase the risk for esophageal squamous cell carcinoma.

OTHER VIRULENCE FACTORS

In an analysis of gene expression profiles using gastric cancer cells, Yuan *et al*[41] reported that VacA affects cytoskeleton-associated genes, thereby disrupting cytoskeletal architecture; it also causes damage to cell cycle-related genes, and breaks the balance between cell proliferation and cell death, while at the same time inducing inflammatory responses.

In a comparison of the *hrgA* gene thought to encode a restriction enzyme in *H pylori* using clinical isolates from East Asian and Western countries, the prevalence of *hrgA*-positive strains was reported to be significantly higher in the Western countries (49%) compared to the East Asian countries (20%). However, the prevalence of the *hrgA* gene was not found to be related to disease specificity or to other important putative virulence factors (*i.e.,* CagA, VacA)[42].

Gastric mucosal interleukin 8 (IL-8) levels are related to the presence of both the *cag* PAI and the outer inflammatory protein (OipA)[43]. Yamaoka *et al*[44] examined the upstream IL-8 signal transduction pathway including the *H pylori*-associated IL-8 promoter and gene transcription region using *oipA*, *hepZ*, *cagE* gene knockout cultured cells. Maximization of *H pylori*-induced IL-8 gene transcription requires the presence of binding sites for ISRE-like element, NF-κB, and AP-1. Both the OipA and *cag* PAI are implicated in the process in which the interferon regulatory factor (IRF)-1 becomes activated by binding the interferon-stimulated responsive element (ISR)-like element, while the *cag* PAI, and not the OipA, is implicated in the activation of AP-1 and NF-κB. Again, the OipA, and not the *cag* PAI, is implicated *in vitro* and *in vivo* in the phophorylation of signal transducers and activators of transcription 1 (STAT1) as an upstream signal transduction pathway. Thus, while both the OipA and *cag* PAI are required for the full activation of the IL-8 promoter region, each acts via a different pathway that becomes distinct upstream of the IRF-1, with only the OipA implicated in the STAT1-IRF1-ISRE pathway. Gastric mucosal inflammatory processes are complex and involve different pathways centered on the IL-8 promoter region.

HOST FACTORS

In an experiment using gastric epithelial (AGS) cells, *H pylori* infection was found to increase the expression of plasminogen activator inhibitor (PAI)-2, suggesting that PAI-2 may play a role in influencing the progression to gastric cancer[45].

Nardone *et al*[46] demonstrated that in patients with up-regulation of COX-2 or microsomal PGE-synthase 1 (mPGES1) expressions by *H pylori* infection, the expressions of the anti-apoptosis marker *Bcl-x1* or the multi-drug resistance 1 gene (*MDR-1*) product P-gp were also increased, suggesting that this *H pylori*-induced process may contribute to gastric carcinogenesis and resistance to therapy.

It is reported that *H pylori* infection increases the mRNA expression of the apoptosis-regulating proteins Bid, Bax and Bcl-2[47], and that the tumor suppressor protein Bax translocates to the mitochondaria which subsequently undergoes fragmentation[48], suggesting that a loss of control over these apoptosis-regulating genes potentially leads to gastric carcinogenesis. Of note, these genes were found to be more markedly expressed in *cagA*-positive *H pylori* strains[47].

Of the IL-10 gene polymorphisms identified, the IL-10-1082G/-819C/-592C alleles (GCC haplotype) are reported to be associated with the highest mucosal IL-10 mRNA expression, and carriers of the GCC haplotype are associated with colonization by more virulent *cagA*, *vacAs1*, and *babA2*-positive *H pylori* strains[49], suggesting that cytokine gene polymorphisms may be implicated in the development of gastritis and gastric cancer.

The pro-inflammatory cytokine IL-1 is implicated in host susceptibility to *H pylori*-associated diseases, and recent studies have further suggested that this susceptibility may be under genetic control. Hartland *et al*[50] prospectively investigated the relationship between selected polymorphisms in three of the major IL-1 gene clusters for association with *H pylori* infection and/or gastric cancer, and reported a significant difference in the genotype frequencies for the *IL1R1 HinfI* SNP in those with current or previous evidence of *H pylori* infection as compared with those without (GG, 53% *vs* 75%; GA, 40% *vs* 19%; AA, 7% *vs* 6%; $P=0.0079$). They concluded that the relationship among IL-1 gene polymorphisms, *H pylori* and disease outcome is more complicated than previously proposed, and may not be associated with the development of gastric cancer. Polymorphisms of the IL-1 gene cluster (IL-1A, -B, and -RN) have been associated with advanced gastric cancer. In early-stage gastric cancer, Glas *et al*[51] investigated the role of host genetic susceptibility and concluded that the genotype *IL-1 RN*2/2* is associated with early-stage gastric cancer, where, in contrast to advanced disease, further pro-inflammatory cytokine polymorphisms are not implicated independently, but may act in combination to play a role in early stages of gastric carcinogenesis, while the role of *H pylori* infection in this process remains unclear. In addition, Chen *et al*[52] demonstrated in a case-control study of 142 gastric cancer patients and 164 control subjects that the carriage of *IL-1RN*2*, male gender, old age, and *H pylori* infection were associated with increased risk for gastric cancer, concluding that *H pylori* infection and *IL-1RN*2* are independent risk factors for gastric cancer, and *H pylori* testing and host genotyping may combine to help target the eradication of *H pylori* to high risk individuals.

Basak *et al*[53] investigated the role of *H pylori* lipopolysaccharide (LPS) in IL-1β gene expression and the signaling pathways leading to LPS-induced IL-1β secretion, and demonstrated that activation of the mitogen-activated protein (MAP) by LPS resulted in activation of the immediate downstream C/EBP β and the C/EBPβ-binding elements of the IL-1 promoter, thus leading to the expression of the IL-1β. Of note, they also reported that

LAP-induced activation of the Rac1/PAK1 signaling plays a role in activation of caspase-1 required for maturation of the pro-IL-1β.

Osawa *et al*[54] investigated the effect of *H pylori* infection on ghrelin, a novel peptide expressed in the gastrointestinal tract conferring potent protection against gastric mucosal inflammation[55], in 110 *H pylori*-positive and 50 *H pylori*-negative patients, and demonstrated that impaired gastric ghrelin production associated with atrophic gastritis induced by *H pylori* infection accounts for the decrease in plasma ghrelin concentration.

SOURCE OF GASTRIC MALIGNANCY

It is well accepted that epithelial cancer originates from transformation of tissue stem cells. However, this view was recently challenged by Houghton *et al*[56] in 2004, who proposed a new intriguing theory regarding gastric carcinogenesis. In their theory, it is advanced that bone marrow-derived cells (BMDC) may represent a potential source of malignancy, while they are usually recruited to sites of tissue injury and inflammation. In their experiments, C57BL/6 female mice were infected with *Helicobacter felis*, irradiated, and transplanted with galactosidase- and green fluorescent protein (GFP)-labeled bone marrow cells from male mice. At wk 20, the level of apoptosis was elevated in the infected mice, and galactosidase- and GFP-positive glands appeared. After 1 year of infection, these mice developed gastric carcinoma *in situ* or gastrointestinal intraepithelial neoplasms (GIN), which were found to be galactosidase- and GFP-positive. Houghton *et al*[56] noted that while acute injury or inflammation does not lead to a recruitment of BMDC, chronic infection of C57BL/6 mice with *Helicobacter* induces a repopulation of the stomach with BMDC, and these cells progress through metaplasia and dysplasia to intraepithelial cancer. This new hypothesis appears to have far-reaching implications for future research in gastric carcinogenesis.

H PYLORI ERADICATION AND GASTRIC CANCER

In the current review, we have addressed issues surrounding *H pylori* infection and gastric carcinogenesis. Not only long-term morphological but also genetic studies will be required to clarify whether or not improvement in gastric atrophy and intestinal metaplasia after *H pylori* eradication would lead to prophylaxis of gastric cancer or when would be the "point of no return" for such prophylaxis in the course of patient follow-up. Further long-term research into the morphological changes associated with *H pylori* eradication is also required to explore strategies for the prevention of gastric cancer with *H pylori* eradication.

Abstract

This paper reviews the negative impact of diabetes mellitus or hypothyroidism on wound healing, both in experimental and clinical settings. Since both are metabolic disorders of great clinical importance, special attention is given, not only to their pathophysiology, but also to their biochemical and histological effects on tissue integrity and regeneration. Also, special focus is awarded on wound healing of the gastrointestinal tract, i.e. in intestinal anastomosis, and how these disorders can lead to wound dehiscence. Since diabetes mellitus and hypothyroidism can coexist in clinical settings, more research must be directed on their influence on wound healing, considering them as one clinical entity.

INTRODUCTION

Wound healing is an integral part of recovery of critically ill patients[1]. They often are at risk for impaired healing because of their compromised body systems and multiple risk factors. Disruption of healing may result in delayed healing, dehiscence, infection, and death. Understanding healing and the factors that may impede it provides the physician with the foundation on which care is planned to facilitate wound healing.

IMPEDIMENTS TO WOUND HEALING

The treatment of chronic wounds presents a challenge to physicians, caregivers, and patients[2]. A familiarity with the factors that impede healing is necessary if treatment of chronic wounds is to be effective. These wounds often heal in a short period of time if the factors inhibiting wound healing are adequately identified and managed. Recombinant growth factor therapy may provide an additional stimulus to healing in certain types of chronic wounds. However, there remains no substitute for a physiologic environment conductive to tissue repair and regeneration, without which the efficacy of growth factor therapy is questionable. Some of the most commonly encountered and clinically significant impediments to wound healing include tissue hypoxia, infection, presence of debris and necrotic tissue, use of anti-inflammatory medications, a diet deficient in vitamins or minerals, or general nutritional deficiencies, tumors, environmental factors, and metabolic disorders such as diabetes mellitus. Treatment of chronic wounds should be directed against the main etiologic factors responsible for the wound. Moreover, factors that may impede healing must be identified and corrected for healing to occur if possible.

Especially, regarding diabetes mellitus, there have been numerous experimental and clinical studies, not only establishing its negative impact on wound restoration but also studying its metabolic pathophysiology in comparison with every stage of wound healing. This is not only because diabetes mellitus is one of the most common clinical entities found, but also because it coexists with other metabolic disorders, such as hypothyroidism. While hypothyroidism alone, or as part of a clinical condition, like myxedema, is a well established disease, little research has been made to determine its exact effect on tissue healing and the biomechanical profile of wounds in hypothyroid patients.

COMPLICATIONS OF DIABETES MELLITUS

The long term complications of both types of diabetes mellitus are usually categorized into macrovascular, microvascular, and neuropathic diseases[3]. Macrovascular complications are associated with an accelerated rate of atherosclerosis and an increased propensity for peripheral vascular disease, myocardial infarction, and cerebrovascular accidents. Microvascular complications include retinopathy

and nephropathy and are associated with thickening of the capillary basement membrane. Also, the current suggestion by investigators states that microcirculatory damage is apparent in the skin and subcutaneous tissue, leading to impaired wound healing. An intact microcirculation is required for tissue nutrition, removal of waste products, inflammatory responses and temperature regulation therefore, logically any defect in microvascular function adversely affects tissue repair. One undisputed structural change that occurs in people with diabetes is thickening of the basement membrane, the extracellular matrix (ECM) bellow the cells lining the vessels. This is a consistent finding in the capillaries and arterioles of people with diabetes[4]. Studies have demonstrated that in early diabetes, microvascular blood flow is increased with prolonged exposure to hyperglycemia[5]. This is explained by increased production of nitric oxide by the endothelial cells as a result of vessel wall damage and heightened viscosity of the blood due to glycosylation of hemoglobin[6]. Hyperemia and capillary hypertension ensue. Precapillary resistance is reduced and further vasodilatation occurs in response to increased metabolic demand and oxygen requirements of damaged tissue. In turn, shear stress on the vascular wall increases leading to accumulation of ECM and the protein fibronectin in response to this chronic injury. Further basement membrane thickening occurs, altering membrane charge and as a result affecting capillary permeability. Microangiopathy-capillary disease has progressive pathology, particularly affecting cells in which glucose transport and metabolism are independent of insulin, such as endothelial cells[7]. Persistent hyperglycemia encourages the conversion within the endothelial cells of glucose to sorbitol. Cellular edema occurs, as sorbitol cannot diffuse across the cell membrane. This results in metabolic alterations, membrane function alteration and basement membrane thickening. It is also thought that hyperglycemia leads to increased protein synthesis, deposition of abnormal ECM proteins and further basement membrane thickening. However, there is a lack of human experimental evidence to support this[6]. As microvascular disease progresses usually in parallel with the duration of diabetes, impaired vascular reactivity and limited hyperemia result in the loss of normal autoregulatory function[4]. Homeostatic balance relies on the microvascular circulation maintaining a constant blood supply despite fluctuations in perfusion pressure. However, a thickened and rigid basement membrane restricts the normal hyperemic response to tissue damage and hypoxia ensues. Skin tissue breakdown inevitably occurs.

Neuropathic complications include damage to sensory, motor, and autonomic nerves.

WHY BLOOD GLUCOSE AFFECTS HEALING

Patients with diabetes often have wounds that are difficult to heal[8]. The initial barrier to healing is an increased blood glucose level, which causes the cell walls to become rigid, impairing blood flow through the critical small vessels at the wound surface and impeding red blood cell permeability and flow. Impairment release of oxygen by hemoglobin results in oxygen and nutrient deficits in the wound. A less optimal immune function also contributes to poor wound healing in patients with diabetes. When blood glucose levels are persistently elevated, chemotaxis and phagocytosis are compromised. Chemotaxis is the process by which white cells are attracted to the site of infection, while phagocytosis is the ingestion of bacteria by white cells. Both processes are important in controlling wound infections. Diabetic infections take a longer time to heal because of delayed macrophage introduction and diminished leukocyte migration, which causes a prolonged inflammatory phase in the wound healing cascade.

Protein-calorie malnutrition and the resultant body composition changes are an additional consideration in wound healing. Patients with diabetes often have a progressive loss of lean body mass, which is replaced with a metabolically inactive fat mass.

The absence or deficiency of insulin in diabetes mellitus causes impaired metabolism of carbohydrates, fat and proteins, which are necessary for cellular activities and tissue synthesis in wound healing[9]. Insulin is required for glucose to enter cells as to provide a source of energy for uptake of amino acids to synthesize proteins and for inhibition of adipose tissue lipolysis. Glucose is also needed to supply energy for fibroblastic and polymorphonuclear (PMN) activities during wound healing. Altered glucose metabolism, as seen in diabetes mellitus, leads to defective metabolism of these nutrients and reduces fibroblastic/PMN activity, causing impaired wound healing.

Altered protein metabolism

Protein is essential for the synthesis of collagen structures that establish wound tensile strength. Without adequate tensile strength of collagen structures, dehiscence and evisceration can occur. Protein deficiencies also impair formation of new capillaries, fibroblastic activity, and the bactericidal activity of PMNs. Insulin, which is lacking in diabetes, is the anabolic hormone that stimulates protein synthesis, so to promote wound healing, both insulin and protein need to be provided in adequate amounts for protein tissue rebuilding.

Altered lipid metabolism

Without insulin and glucose for energy, fat is the primary source of body fuel. So, when fatty acids, which are used to form cell membranes, are used for energy, as in poorly controlled diabetes mellitus, healing is impaired, since there is delayed cell membrane synthesis.

Decreased chemotaxis, phagocytosis, bacterial killing[10,11], decreased heat shock protein expression[12], less antioxidant synthesis , and increased oxygen free radical generation[13,14] during the early phase of wounding healing all have been implicated in impaired diabetic healing. Additionally, growth factor depletion[15,16], increased glucocorticoid concentration[17], decreased cell proliferation[18], and up-regulation of apoptosis[19] characterize the later phases of diabetic healing resulting in poorer granulation tissue formation. Diabetes mellitus lowers extracellular matrix synthesis following wounding[20].

While the relation of diabetes mellitus to wound healing is well elicited in numerous other studies and

papers[21-25] demonstrating that it is a complex metabolic disorder whose components have several direct and indirect effects on the healing of wounds, Komesu *et al*[26] evaluated the healing process during early phases of experimental diabetes on rat skin and found that not only the initial healing phase has a slow beginning and tends to last longer, but also that healing areas show lower density of neutrophils after surgery, and in addition, after three days, when the neutrophils leave the healing area and are replaced by macrophages, diabetic animals show a higher number of neutrophils. The principal conclusion is that although diabetes is a chronic progressive disease, acute diabetes can be associated to subclinical alteration, and is considered responsible for deficiencies in defense cells and in repair tissue failures.

METABOLIC PATHOPHYSIOLOGY OF DIABETES MELLITUS

There are three possible ways that hyperglycemia contributes to the metabolic pathophysiology of diabetes-related complications[27].

The first hypothesis is that abnormal glucose levels alter the actual control of cellular Na^+/K^+ ATPase activity[28]. Hyperglycemia leads to increased polyol pathway activity, which leads to a depletion of myo-inositol stores. This involves the biochemical pathway in which glucose is converted to sorbitol by aldose reductase. Because the conversion of sorbitol to fructose (by sorbitol dehydrogenase) is slow, sorbitol tends to collect in cells. The end-product of the sorbitol to fructose is NADH. The increased conversion to fructose leads to decreased NADPH and increased risk for oxidative stress. The increased levels of sorbitol may increase the osmotic load in the cells. Sorbitol inhibits myo-inositol uptake, which in turn leads to the alteration in Na^+/K^+ ATPase activity.

A second metabolic abnormality that results from hyperglycemia may be related to the activity of protein kinase C (PKC). Diabetes appears to increase the synthesis of diacyl-glycerol, which in turn leads to increased PKC activity. PKC is a key signaling receptor for many cellular activities including proliferation, contraction, calcium influx and others.

Thirdly, hyperglycemia also leads to the production of pathologic by-products. Hyperglycemia leads to 'advanced glycosylation end products' (AGEs), which are large aggregates of aldoses covalently bound to reactive amino groups. AGEs may lead to increased oxidative stress and activate a key transcription factor, nuclear factor (NF)-κB. NF-κB is involved in many cytokine-related cell responses. For instance, AGEs appear to induce the production of platelet-derived growth factor (PDGF), tumor necrosis factor-α, and interleukin-1α. AGES may also lead to collagen cross-linking and inhibit normal collagen degradation.

Fahey *et al*[29] examined leukocyte infiltration and the appearance of tumor necrosis factor-α (TNFα) and interleukin-6 (IL-6) in wound chambers implanted in normal and streptozotocin-induced diabetic mice. The data suggest that delayed healing on diabetes is associated with altered leukocyte infiltration and wound fluid IL-6 levels during the late inflammatory phases of wound healing. These observations suggest that while the initial inflammatory response is intact, diabetes can impair the late inflammatory response to wound healing, data that corroborate previous reports from Goodson and Hunt[30-32] that implicate a defective inflammatory response to wounds in the pathophysiology of delayed wound healing are associated with diabetes. They have shown that obesity, insulin resistance, hyperglycemia, and depressed leukocyte function interfere with collagen synthesis and thus impair wound healing. Their studies of skin and subcutaneous wounds in diabetic mice showed that the granulocyte influx is slow and is associated with depressed synthesis of protocollagen and collagen. Hennessey *et al*[33] postulated that altered collagen metabolism seen in experimental diabetes could be related to the presence of increased tissue levels of advanced glycosylation end products. Others, like McMurry[34] suggested that impaired leukocyte function may contribute to the impaired healing in diabetes based on abundant evidence that neutrophil chemotaxis and phogocytosis are inhibited by hyperglycemia and poorly-controlled diabetes mellitus[35]. Robson *et al*[36] have addressed the issue of wound infections in diabetic patients by evaluating the relative growth of various bacteria in the presence of hyperglycemia, and found that gram-positive bacteria thrive in hyperglycemic serum and that Gram-negative bacteria grow less well in hyperglycemic serum, which could partially explain the clinical observation that diabetic patients are prone to staphylococcal infection.

Additionally, defects in wound healing of experimental diabetes may be corrected, at least in part, by administration of large amounts of vitamin A[37] or zinc[38].

Last but not least, uremia is another factor that alters healing[39]. Patients with diabetes mellitus are prone to silent or overt renal disease. Increased urinary protein loss in these diseases predisposes the patient to edema, which contributes to impaired tissue repair. In addition, uremia is another factor that independently contributes to the altered healing.

WOUND HEALING AND GROWTH FACTORS

Recent advances in wound treatment include topical growth factor therapy, which has been successful in diabetic wounds. Platelet-derived growth factor (PDGF), fibroblast growth factor, and epidermal growth factor have been shown to accelerate tissue repair in an experimental wound model. Insulin is one of the primary anabolic hormones in the body, and numerous studies have shown beneficial effects of insulin therapy on wound healing. Insulin increases wound tensile strength and stimulates protein anabolism in skin and muscle. One possible reason for their success is the relative deficiency of growth factors in chronic wound fluid due to decreased supply, increased binding, or increased degradation of the naturally occurring growth factors. A study[40] was performed to examine the level of the insulin-degrading enzyme (IDE) in diabetic wound fluid and to relate this to glucose control [hemoglobin A_{1c} (HbA_{1c}) levels]. An excess of this enzyme could contribute to reduced levels of growth factors in

wound fluid. The authors showed that insulin-degrading activity is present in human wound fluid, and that the activity is higher in subjects with diabetes. The biochemical properties of the wound fluid insulin-degrading activity are consistent with the properties of the insulin-degrading enzyme (insulysin). Insulin-degrading activity correlates with HbA_{1c} levels, suggesting a mechanism for the relationship between glucose controlling and wound healing. Improvement in glucose control is a critical factor in wound healing, but a reduction in wound fluid insulin-degrading activity is also a potential therapeutic approach.

PDGF levels have been examined by radioimmunoassay in wound tissue of normal and diabetic rats, while immunohistochemical analysis can be utilized to localize and characterize PDGF immunopositive cells at the wound site of normal and diabetic animals[41]. The findings suggest that absence of an initial increase in PDGF may play an important role in poor wound healing observed in diabetic animals, and that the reduction in PDGF could be related to decreased cellular PDGF production rather than lack of PDGF-producing cells. The authors concluded that perhaps the diabetic state inhibits cellular PDGF gene expression signaled by wounding or interferes with normal PDGF expression at the wound site.

To examine the effects of recombinant growth factors *in vivo*, impaired wound healing has been studied in genetically diabetic C57BL/KsJ-db/db mice[42]. Large full-thickness skin wounds, made on the backs of these mice, exhibited significant delays in the entry of inflammatory cells into the wound, the formation of granulation tissue, and in wound closure, when compared to their nondiabetic littermates. Recombinant human platelet-derived growth factor (rPDGF-BB), recombinant human basic fibroblast growth factor (rbFGF), or combinations of both were applied topically to the wounds for five to fourteen days after wounding. Combinations of rPDGF-BB and rbFGF improved all parameters of healing but not to a greater extent than either growth factor alone.

Numerous other studies have held to elucidate the effect of growth factors in the process of healing of diabetic wounds. Hennessey *et al*[43] studied the interactions of topically applied insulin and epidermal growth factor (EGF) in diabetic rats. The EGF and insulin promoted a 202% increase over controls in collagen synthesis after fifteen days, while diabetic rats receiving EGF or insulin alone had significantly less collagen than controls. The individual effects of insulin and EGF added synergistically for a net gain in wound collagen content are a gain that has not been observed with either EGF or insulin alone. Bitar *et al*[44] have proved that diabetes induces not only a marked reduction in insulin-like growth factor-I (IGF-I) levels both in wound fluid and serum of diabetic rats, but also a reduction in the levels of IGF binding proteins and transforming growth factor-β (TGF-β) in diabetic wound fluid. The investigators reported that the diabetic wound fluid increased levels of extracellular matrix gelatinases, and that a single dose of TGF-β partially reversed the diabetes-related decrease in the tensile strength of standardized incisions.

Furthermore, elevated levels of glucose have been shown to affect insulin signaling in various ways. Hyperglycemia can alter glucose-induced insulin secretion, a phenomenon referred to as glucose toxicity. Glucose is known to affect insulin action as well by regulating the expression of several genes, including the IGF-I receptor (IGFR) and insulin receptor (IR) genes, at both the transcriptional and translational levels[45]. Moreover, hyperglycemia can inhibit insulin action. This inhibition is thought to be a result of serine phosphorylation through a PKC-mediated mechanism as well as by activation of protein tyrosine phosphatases, which deactivates the IR function. In addition to its possible involvement in inducing complications of chronic diabetes, glucose down-regulates its own transport and metabolism. In this study, the authors investigated the relative roles of hyperglycemia, insulin, and IGF-I, all of which are abnormal in diabetes, in primary murine skin keratinocytes. The results showed that in the presence of high glucose (20 mmol/L), the glucose transport rate of primary proliferating or differentiating keratinocytes was downregulated, whereas at 2 mmol/L glucose the transport rate was increased. These changes are associated with changes in the GLUT1 expression and in the affinity constant (km) of the transport. Exposure to high glucose is associated with changes in cellular morphology, decreased proliferation and enhancement of Ca-induced differentiation of keratinocytes. Furthermore, in the presence of high glucose, ligand-induced IGF-I receptor, but not insulin receptor (IR) autophosphorylation, is decreased. Consequently, in high glucose, the effects of IGF-I on glucose uptake and keratinocyte proliferation are inhibited. Interestingly, lack of IR expression in IR-null keratinocytes abolishes insulin-induced glucose uptake and partially decreases insulin- and IGF-I-induced proliferation, demonstrating the direct involvement of the IR in these processes. The results demonstrate that hyperglycemia and impaired insulin signaling might be directly involved in the development of chronic complications of diabetes, like wound healing, by impairing glucose utilization of skin keratinocytes as well as skin proliferation and differentiation.

CONFLICTING RESULTS

In a recent retrospective study though[46] that was designed to assess the contribution of several factors that could be incriminated in the occurrence of abdominal wound dehiscence in major abdominal operations, diabetes mellitus was found not to be a significant risk factor, in contrast with advanced age (> 65 years), emergency operation, cancer, haemodynamic instability, intra-abdominal sepsis, wound infection, hypoalbuminemia, ascites, obesity, and steroids. The mortality and the possibility of dehiscence seem to correlate directly with the number of those risk factors.

HISTOLOGICAL, HISTOCHEMICAL AND BIOCHEMICAL STUDY OF DIABETIC WOUNDS

Prakash et al[47,48] have studied surgical wounds in albino rats. Uncontrolled diabetics, controlled diabetics and

normal hypoglycemic rats were used for study and compared with normal control animals. The parameters of histology, histochemistry and biochemistry were assessed. Healing was delayed in the uncontrolled diabetic group and was significantly ameliorated by the administration of insulin, but not to an extent as to be better than normal controls. More specifically, the uncontrolled diabetic group showed a more marked and prolonged inflammatory response. The first appearance of scar was after seven days as contrasted at five days in the other groups, while at the end of fifteen days the scar was significantly more vascular and cellular in the uncontrolled diabetic rats. Histochemically, the precollagen (reticulin) fibers were present in moderate amounts on the 5th post-operative d, increasing up to the 10th d, after which a decline was obvious. As a contrast, practically no stainable reticulin was seen on the 5th d in the diabetic group. It appeared on the 7th d and increased till the 15th d. The reticulin fibers in that group were sparse and poorly staining. The uncontrolled diabetic group showed delay in the appearance of collagen, increasing up to the 15th d, when it was less deeply staining and less dense, in contrast with the other groups where collagen was present in minimal amounts on the 5th d. The acid and neutral mucopolysaccharides were also under study. Traces were present on the second day after which there was an increase till the seventh day. A decline in stain of this substance was present thereafter. This response was observed in the other three groups. The uncontrolled diabetic group differed by showing the presence of mucopolysaccharides till the 15th d, indicating activity of the healing processes. The hydroxyproline content was seen to register a fall on the second day after wounding as compared with the first day. Subsequently, a steady rise was seen up to the 7th d. In the uncontrolled diabetic rat group there was a rise obvious from the 5th d onwards after which there was a steady gain in hydroxyproline content, to values lower than in the other three groups.

INFLUENCE OF DIABETES ON GI WOUND HEALING

While it is widely accepted that changes in the extracellular matrix, particularly due to collagen metabolism and related disturbances like diabetes mellitus, are a prognostic factor for anastomotic leakages[49,50], Gottrup *et al*[51] have investigated the influence of experimental diabetes on the healing of incisional wounds in stomach and duodenum. Experimental diabetes impaired the mechanical strength of healing wounds in stomach and duodenum. The reduction was most pronounced for breaking energy, while only duodenum showed a decrease for breaking strength of the tissues, an impairment that became more pronounced by increasing healing time. The investigators showed that there is a relation between mechanical strength and total collagen content and that insulin treatment prevents these retardations.

The influence of diabetes on the healing of HCL-induced gastric lesions and the healing promoting effect of basic fibroblast growth factor (bFGF) on these lesions under diabetic conditions induced in rats by streptozotocin has been reported[52]. Diabetic conditions could not affect the development of HCI-induced gastric lesions but could significantly delay the healing of these lesions. Daily administration of insulin could return high blood glucose levels to normal ranges and significantly antagonize the delayed healing of these lesions. The delayed healing in diabetic rats could also be significantly promoted by recombinant human basic fibroblast growth factor without any effect on blood glucose level. The mucosal bFGF levels in streptozotocin-diabetic rats are significantly lower under basal conditions before HCI treatment and do not increase after injury, yet such dysregulation of bFGF production could be partially restored by insulin treatment. These results suggest that diabetic conditions have deleterious influences on the healing of acute gastric lesions in both an insulin- and bFGF-sensitive manner, and that the administration of exogenous bFGF antagonizes the delayed healing of gastric lesions observed in diabetic animals.

Verhofstad and Hendriks[53] demonstrated in an experimental study in rats that diabetes indeed lower bursting strength in both ileal and colon anastomosis. However, this effect is not secondary to decreased collagen deposition bur rather due to increased abscess formation around the anastomosis. Incubation of fibroblasts isolated from ileum or skin of nondiabetic rats with diabetic and nondiabetic serum only affects collagen synthesis in skin fibroblasts, suggesting that fibroblasts from different organs are distinctly affected by diabetes[54]. Postoperative restoration of blood glucose by insulin[55] or islet transplantation[56] only partially restores bursting pressure. Enhanced matrix metalloproteinase activity has been shown to be present in diabetic colon anastomosis, possibly explaining the weaker breaking strength. In contrast to dermal healing, diabetic anastomoses are characterized by an elevated number of neutrophils, which could serve as a source of matrix metalloproteinases[57].

Martens *et al*[58], studying the postoperative changes in collagen synthesis in intestinal anastomosis of the rat, investigated the differences between small and large bowel. The results showed that the ileum responds more quickly and strongly to wounding than the colon, at least as far as the production of new collagen is concerned. Possibly, this phenomenon contributes to the lower failure rate apparent for anastomoses in the small bowel.

Verhofstad *et al*[59] have studied the cellular and architectural parameters of anastomotic healing, this time in diabetic rats. The results showed that although anastomotic necrosis, edema, and epithelial recovery are not affected by diabetes, in diabetic rats, the number of polymorphonuclear cells and macrophages is significantly increased, both in ileal and colonic anastomosis. Repair of the submucosal-muscular layer in colonic anastomoses from diabetic rats is impaired, but in ileal anastomoses no difference is found. In the anastomotic area, collagen deposition remains unaffected by diabetes, thus proving that experimental diabetes leads to alterations in cellular components involved in the early phase of repair of intestinal anastomoses, but not to a reduced accumulation of wound collagen.

Most recently, Onodera *et al*[60] studied anastomotic

leakage in diabetic rats. The purpose of the study was to determine whether collagen synthesis was correlated with the anastomotic strength in diabetic animals in special reference to collagen type differences. The investigators showed that although there is no statistical significance between the control and diabetic groups in hydroxyproline concentrations and that although the expressions of mRNA of collagen type III in both groups are not statistically different, the expression of collagen type I in the diabetes group merely increases and is clearly less than that of the control group. The increase of type I collagen is much more pronounced and long-lasting than that of type III collagen. Brasken *et al*[61] suggested that type I collagen synthesis is enhanced for at least 2 wk after anastomosis whereas type III collagen synthesis is increased only during the first week. Taken together with previous experimental results, the weakness of anastomotic healing with diabetic rats is not attributed to the total contents of collagen but to changes of newly formed collagen, i.e. mainly the blockage of the type I collagen synthesis.

CONFLICTING RESULTS

Although, other investigators like Witte and Barbul[62] and Wagner and Egger[50] have recognized that colon healing is a structured cascade of different phases that can be affected by a multitude of local (infection, ischemia) and systemic (diabetes, malnutrition, anemia, hypothermia, trauma) factors, a recent retrospective study done to identify the risk factors for anastomotic leakage after left-sided colorectal resections with rectal anastomosis, showed that diabetes is a non-significant variable[63].

HYPOTHYROIDISM AND WOUND HEALING

Hypothyroid patients have long been thought to have a higher risk of surgical morbidity and mortality[64,65]. Thyroid hormone deficiency does cause derangements of cardiovascular[66], pulmonary[67], renal[68] and central nervous system functions[69], and alters drug metabolism[70] in ways that could predispose to surgical complications. Surgery in hypothyroid patients is associated with an increased risk of minor perioperative complications, which should be anticipated and preemptively managed in the course of their anesthetic and surgical care[71], a conclusion which was validated by Ladenson PW *et al*[72], who reported that postoperatively, hypothyroid patients more commonly have, among others, gastrointestinal and neuropsychiatric complications than control patients.

Since collagen is the only protein in the body containing hydroxyproline in significant amounts, urinary excretion of hydroxyproline has been considered an index of collagen metabolism since the 60's[73]. Hormones concerned with body growth and protein metabolism particularly affect collagen metabolism[74]. Thyroid hormone can stimulate hydroxyproline excretion and correct the reduction of hydroxyproline excretion in hypothyroidism[75].

Kowalewski and Yong[76] have shown a significant increase of a saline-extractable, and total soluble hydroxyproline, and a reduction of insoluble fraction in the normal wound. This might be due to vigorous biosynthesis of collagen. In contrast, no evidence of the synthesis of new collagen has been found in the wounds of hypothyroid rats. Insoluble fractions are higher in the wounds of hypothyroid rats than in normal control animals, suggesting that biosynthesis, solubility, and overall metabolism of collagen in hypothyroid rats are deficient.

Experimental work by Lennox and Johnston[77] has shown that wound healing is accelerated by a mean of 2.5 d in a hyperthyroid group of rats and delayed by a mean of 2.0 d in the hypothyroid group as compared with control rats. Mehregan and Zamick[78] demonstrated that T_3 has a beneficial effect on the healing of deep dermal burns in rats. There is better organization of collagen bundles, fewer retraction spaces, and smoother scars. Another experimental study by Herndon *et al*[79] showed that levels of thyroid hormone have a profound effect on the rate of healing of burn wounds in thyroidectomized guinea pigs. They showed that epithelization is inhibited at low and high doses of levothyroxine sodium. However, administration of levothyroxine sodium at the intermediate dose of 30 μg/kg results in improved wound closure relative to euthyroid control subjects. This finding is consistent with the results of Kivirikko *et al*[80], who showed that the rate of collagen synthesis is decreased both in hyperthyroidism and hypothyroidism**.** On the other hand, there are clinical reports of kelloid development during the healing process of wounds of patients with hyperthyroidism[81], but no change in wound healing with euthyroid hamsters receiving ip T_4[82]. A retrospective study[83] concluded that the conditions of patients with laryngeal tumors treated with surgery or surgery and radiation should be evaluated for hypothyroidism. When patients become hypothyroid, they should be treated promptly. Treatment of thyroid dysfunction can accelerate healing in patients with complications such as flap edema, flap necrosis, or fistula. Cannon[84] reported in an experimental study that although hypothyroidism alone, occurring in patients undergoing treatment for head and neck neoplasms, has no significant unfavorable impact on wound tensile strengths or flap survival, when combined with preoperative radiation, there are statistically deleterious effects on both wound tensile strengths and flap survival. Histologically, collagen fibers within the wound appear shorter and thinner, which probably account for decreased wound tensile strengths. It is recommended that thyroid function tests should be done routinely before and after therapy in all patients with head and neck cancer undergoing combined surgery and radiation.

Another study also demonstrated that the hormonal replacement therapy in hypothyroidism cases is beneficial with regard to wound healing and the results are more satisfactory if zinc is added to the therapy[85]. A decrease in serum zinc level in hypothyroidism has been reported in many clinical and experimental studies[86]. As noted above, experimental and clinical studies on hypothyroidism have shown that L-thyroxine replacement therapy has a positive effect on wound healing, which is generally delayed in this disorder. Elevation of wound breaking strength is one of the most important phenomena observed during the wound healing. In addition, the important factors

for the increase of breaking strength are the amount of collagen of the wound and the increase in intramolecular-intermolecular cohesive bounds of collagen present in the wound (cross-linking), the later being most important[84]. Lysyl oxidase, a copper-dependent enzyme, is responsible for the development of covalent bounds during collagen aggregation, in the activation process of which, it was recently shown that zinc has an important function[87]. However, there are some studies suggesting that zinc has no effect on the amount of collagen synthesis during wound healing[88]. Zinc given alone to the hypothyroid animals provides a small rise in tissue hydroxyproline level (not significant). These findings, consistent with the current recognition of collagen metabolism mentioned above, point out that zinc probably does not have a direct effect on the amount of collagen synthesis, but rather affects more directly the cross-linking of formed collagen.

Natori *et al*[89], in order to analyze the relationship between hypothyroidism and wound healing, induced a state of severe hypothyroidism in rats by surgically resecting their thyroid glands, and then assaying the levels of hydroxyproline and procollagen peptide (types I and III), which are the precursors of collagen (type IV: 7S) in wounds. The results of the assay of collagen and hydroxyproline in wounds indicate a significant decrease in type IV collagen and hydroxyproline in the surgical hypothyroidism rat group during the inflammatory phase and extending to the proliferative phase. These findings suggest that thyroid hormone is associated with the proliferation and secretion of fibroblasts in the process of wound healing. In the state of hypothyroidism, it appears that the suppression of thyroid hormone secretion causes a disturbance in the metabolical activation in tissues and the synthesis of collagen extending from the inflammatory phase to the proliferative phase.

In vitro, keratinocyte proliferation is retarded in T_3-deficient medium relative to T_3-replete medium[90]. *In vivo*, topical T_3 stimulates epidermal proliferation[90,91] and topical triac, the mild TH analog, thickens skin[92]. The keratin genes encode the intermediate filaments, making about 30% of the protein of the epidermis. Some associations between the keratin genes and specific phases of skin growth have been made[93,94]. Fox example, K6a, K16, and K17 are associated with epidermal proliferation and wound repair. In K6a knockout mice[95], the absence of K6a results in diminished superficial wound healing, but no change in full thickness wound healing. When K16 is over-expressed in cultured human keratinocytes, proliferation is enhanced[96]. However, human K16 overexpressed in mice results in delayed wound healing in the transgenic animals[97]. *Ex vivo* investigation suggested that the K16 overexpression inhibits keratinocyte migration. Although TH stimulates expression of K6a both *in vivo* and *in vitro*[98], only negative TH response elements have been identified for the keratin genes associated with proliferation[99].

The following investigation has been undertaken to ascertain the need for TH in optimal wound healing and to clarify the effect of TH on the expression of wound healing-associated keratin genes[98]. The study showed that K6a, K16, and K17 gene expressions are decreased in T_3 deficient keratinocytes. To determine whether the *in vitro* T_3-mediated keratin gene expression could be reproduced *in vivo*, and whether that pattern is associated with significantly poorer wound healing, the investigators contrasted the impact of surgical hypothyroidism on wound healing and proliferation-associated keratin gene expression. The result showed that hypothyroid mice have indeed retarded wound healing, suggesting that T_3 is necessary for optimal wound healing. T_3 exerts its influence by stimulating the proliferation of cytokeratins 6a, 16, and 17.

CONCLUSION

It is well established that both diabetes mellitus and hypothyroidism are considered to have a negative impact on wound healing, not only as part of complex metabolic disorders, but also as clinical entities. Especially for the diabetic part, numerous studies have been undertaken, not only to provide explanations in regards to its metabolic pathophysiology, but also to provide evidence for its effect on wound integrity and dehiscence. As for the hypothyroid status and its exact role in wound healing, much more studies are still needed, so as to enlighten its close relationship with collagen, and therefore wound leakage or not, but also as clinical entities, as previous studies of impaired blood flow and its relationship to wound healing, using various suturing techniques[100], and of the evaluation of adhesion formation among different types of intraperitoneal catheters used in surgical practice[101], have proven.

Abstract

The treatment of chronic hepatitis C (CHC) is still far from optimal, particularly for those subpopulations that do not respond to the standard combination therapy with Interferon-α (IFNα) plus ribavirin. Although in some cases the use of higher doses or longer treatment periods may be effective, these approaches are generally associated with a higher incidence of adverse events, which may either lead to a reduction in patient compliance or require drug withdrawal. IFNβ could represent an interesting alternative for treating CHC patients. Controversial data about IFNβ efficacy in CHC exist, the main reason being that many results stem from pilot studies with small cohorts of patients. However, promising results have been obtained in some subgroups of patients that fail to respond to IFNα. Additionally, the good tolerability of IFNβ represents an important advantage of the drug. The rates of dropouts in controlled clinical trials, as well as the need for dose reductions or treatment discontinuation are very low. It might be worth assessing the value of IFNβ plus ribavirin in randomized studies with a larger cohort of patients, not eligible or not tolerating standard therapy, and for non-responders.

INTRODUCTION

In the absence of antiviral treatment, chronic hepatitis C (CHC) is a liver disease characterized by the development of necroinflammatory changes and progressive liver fibrosis leading to cirrhosis, end-stage liver disease and hepatocellular carcinoma. CHC represents a significant public health problem[1,2]. The objective of treatment is to eradicate infection and prevent progression to cirrhosis and associated complications of end-stage liver disease. According to the latest NIH Consensus Development Statement for the management of CHC, all patients with CHC are potential candidates for antiviral therapy[2]. The therapeutic strategy to be followed is currently well defined, mainly due to the significant progress that has occurred since the initial availability of Interferon-α (IFNα). The approval of ribavirin in combination therapy regimens with IFNα has dramatically improved therapy. Another advance was the introduction of pegylated IFNα, which allows a once-weekly subcutaneous administration and shows more favourable pharmacokinetics and greater efficacy. The highest sustained virological response (SVR) rates are attained with pegylated IFNα in combination with ribavirin[3]. Large randomised trials have shown efficacy of this combination in approximately half of the patients[4,5]. In spite of these advances, a number of patients do not respond to treatment with IFNα, or discontinue treatment due to the occurrence of adverse events associated with therapy.

IFNβ represents a potential therapeutic alternative for treatment of chronic viral hepatitis. In fact, in some countries, mainly in Japan, IFNβ already plays a role in therapeutic protocols. IFNβ belongs to the same family of glycoproteins as IFNα. Although both cytokines present different physicochemical and biological properties in many respects, IFNβ shares with IFNα some of the pharmacological characteristics thus indicated for treatment of chronic hepatitis C infection[6,7].

Three different types of IFNβ are available[8]: (1) Natural human IFNβ (nIFNβ) is produced by human fibroblasts, and is currently used in Japan for treating CHC; (2) Recombinant human IFNβ-1a (rhIFNβ-1a) is produced by mammalian cells and is identical to the IFNβ that occurs naturally in humans; (3) Recombinant human IFNβ-1b (IFNβ-1b) is produced by *E-coli* and has its cysteine at position 17 substituted by serine. RhIFNβ-1a has been reported to be less immunogenic and more potent than the other forms of IFNβ[9]. IFNβ can be administered

intravenously (iv), intramuscularly (im) or subcutaneously (sc). Pharmacokinectic and pharmacodynamic studies[10] have shown that the extent and duration of the clinical and biologic effects of IFNβ are independent of the route of administration.

In this article we review the data currently available on the efficacy and safety of IFNβ for the treatment of CHC. A number of clinical trials have been conducted worldwide. However, many of them are pilot studies with small cohorts of patients targeting different subpopulations, thus frequently leading to controversial results. As a result, one has to be cautious when extracting conclusions. Distinct factors have been reported to influence efficacy of IFNβ in hepatitis C virus (HCV) infection, including the dose, frequency of administration, the dynamics of HCV clearance in the initial phases of treatment, patient age, pre-treatment viral load, HCV genotype and route of administration.

Several studies have been conducted to investigate the most appropriate doses and regimens of IFNβ for CHC showing, in general, that the highest doses did not have the greatest efficacy and result in poorer tolerability[11-14]. Generally, the intravenous administration achieved better SVR rates than subcutaneous route (Figures 1 and 2); furthermore, intravenous IFNβ obtains better results than recombinant IFNα monotherapy in CHC patients with genotype 1[12,15-36]. Similarly to other therapies with recombinant IFNα, patients infected with HCV genotype no-1 obtain higher SVR rates (Figures 1 and 3)[17,18,21-23,37]. In a randomized study with 92 CHC patients, a better biochemical response was observed in CHC patients treated with 6 million units (MIU) nIFNβ three times a week for 12 mo than in those administered 3 MIU (21% *vs* 4.5%, respectively)[12]. The frequency of administration also seems to play a role in the effects of IFNβ. Shiratori *et al* treated 22 CHC patients with high viral load and HCV subtype 1b with two different regimens of IFNβ: 6 MIU once a day, or 3 MIU twice a day[13]. The efficacy of the drug was higher with twice daily administration: negativity for HCV-RNA occurred in 18%, 73% and 89% of patients at 1, 2 and 3 wk, respectively, in the twice-a-day group, in contrast

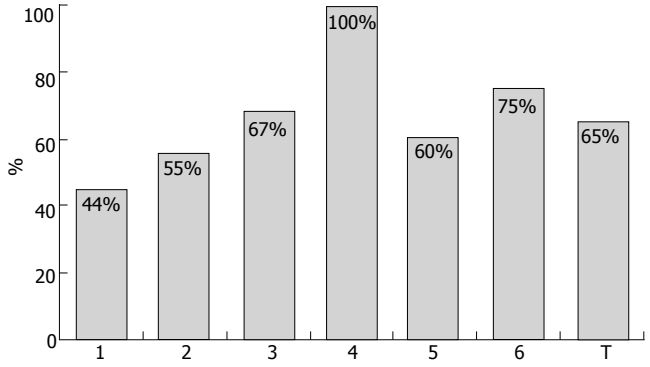

Figure 3 Sustained virological response rates in chronic hepatitis C naïve patients infected by genotype no-1: studies with intravenous IFN-β. 1: Fukutomi *et al*[17]. 2: Kurosaki *et al*[18]. 3: Shiratori *et al*[21]. 4: Nakamura *et al*[37]. 5: Mochizuki *et al*[22]. 6: Kakizaki *et al*[23]. T: total [mean of studies].

to 0%, 0% and 18% in the once-a-day group. However, the incidences of (a) reduced platelet counts and albumin levels; (b) increased serum ALT/AST; and (c) renal toxicity, were higher for the twice-a-day group. A similar outcome in terms of efficacy and safety was observed by Fujiwara *et al* in a randomized trial with 54 patients, treated either with 6 MIU every 24 or with 3 MIU every 12[14]: serum HCV-RNA disappeared in 95% of the patients on the twice-daily regimen, as compared with 74% in the once-daily injection group. Tolerability to IFNβ (in terms of proteinuria, thrombocytopenia and serum ALT levels elevation) was worse in patients receiving 3 MIU every 12 h. At the same time, in an other study, no differences between twice-daily and once-daily administrations were observed: Suzuki *et al* randomized 20 CHC patients with genotype 1b and high HCV-RNA level to receive either twice-daily 3 MIU IFNβ (group A) or once-daily 6 MIU IFNβ for 4 wk (group B)[24]. All patients then received a daily dose of 6 MIU IFNβ for 12 wk, followed by IFNα three times weekly for 16 wk; the treatment of group A was not superior to that of group B in terms of sustained responses, while adverse effects were more frequent and pronounced in group A.

The mechanisms underlying the possible enhanced an-

tiviral efficiency of frequent dosing of IFNβ were investigated in another study: serum HCV dynamics and double-stranded RNA-activated protein kinase (PKR) and MxA mRNA levels were monitored in peripheral blood mononuclear cells (PBMC) of 140 CHC patients randomized to receive twice daily 3 MIU IFNβ or once daily 6 MIU/d IFNβ[38]. The twice-a-day administration reduced the expression level of peak PKR and MxA gene expression in the first phase (4 h after single administration), although it was higher in the second phase. Furthermore, this regimen induced greater rates of HCV decline in the second phase. This enhanced clearance of HCV- infected cells probably represents the basis for the improved efficacy of frequent administration of IFNβ.

Fukutomi *et al* also studied the relation of HCV clearance during the initial phases of treatment with IFNβ with efficacy of treatment[39]. They showed that the decay slope calculated from HCV-RNA levels determined at 0 and 24 after the initiation of IFNβ treatment of CHC patients correlated with the proportion of sustained responders. Based on these findings, the authors proposed that the decay slope of viral clearance could be used as a predictor of the efficacy of therapy. However, further mechanistic data may be needed to confirm this possibility. Additional factors influencing sustained response to IFNβ have been identified[17]: in a study with 52 patients treated with 6 MIU/day IFNβ for 8 wk, the factors predicting efficacy of the treatment were primarily younger age and low pre-treatment viral load, and secondarily, HCV genotype 2a or 2b. The influence of low viral load in the outcome of therapy was further documented in a study in which 112 CHC patients received 6 MIU/d intravenous natural IFNβ for 12 wk[21]. In this trial, 88% of patients presenting a low pre-treatment viral load ($< 6.3\times10^5$ copies/mL), experienced a virological sustained response, as compared with only 22% patients that had a high viral load (in spite of the latter having the chance to receive an additional administration of IFNβ three times weekly for subsequent 14 wk at the patients' request).

Recently, Mochizuki *et al* have studied the effect of "*in vitro*" IFNβ on HCV in PBMC analysing whether this effect was associated with clinical response to IFNβ[22]. Twenty-seven patients with CHC were enrolled into this study. They were given intravenous administration of 6 MIU IFNβ daily for 6 wk followed by three times weekly for 20 wk. PBMC collected before IFNβ therapy were incubated with IFNβ and HCV-RNA in PMBC was semi-quantitatively determined. Eight patients (32%) had sustained loss of serum HCV-RNA with normal serum ALT levels after IFN therapy. Multiple logistic regression analysis revealed that the decrease of HCV-RNA amount in PBMC by IFNβ was the only independent predictor for complete response ($P<0.05$). The authors proposed that the effect of *in vitro* IFNβ on HCV in PBMC reflects clinical response and would be taken into account as a predictive marker of IFNβ therapy for CHC.

The route of IFNβ administration might also influence the outcome of treatment. Reports can be found in the literature describing intramuscular[12,29,30,32], subcutaneous[28,35,40] and intravenous injections[17,21,22,41-45]. Since there are no trials directly comparing the results of one route *vs* the other, no clear recommendations exist. The most appropriate route shoud be selected in each case to grant sufficient bioavailability, reduced toxicity, comfortable administration and adequate patient compliance.

Studies comparing the efficacy of IFNβ vs IFNα.

A number of studies have evaluated the performance of IFNβ *vs* IFNα in CHC patients[30,32,34,41,42,46,47]. Generally, IFNβ has led to poorer outcomes than IFNα, particularly when IFNβ was administered either through the intramuscular route[31,32] (probably due to low bioavailability or to insufficient dose levels), or with a once-daily regimen[46]. Only one small study reported a similar efficacy of IFNβ and IFNα when both were given subcutaneously, at a dose of 3 MIU, three times weekly for 6 mo[3]. However, the good tolerability of IFNβ in all studies suggests that further trials aimed at improving its clinical efficacy might produce interesting results. Asahina *et al* investigated the reason underlying the differences in clinical efficacy between both interferons by assessing HCV dynamics in serum and PBMC of patients treated with IFNα (alone or in combination with ribavirin) and IFNβ (twice-a-day or once-a-day administration)[31]. Although improved viral clearance dynamics were observed with combination or twice-daily dosing regimens (leading to increased rates of sustained eradication of HCV), no dramatic effects in the slopes of HCV decline or in HCV half-lives in the second phase were seen between IFNα and IFNβ.

IFNβ for patients not responding to IFNα

An interesting opportunity for IFNβ is its use as an alternative in patients not responding to IFNα. A randomized study with 200 clinically nonresponding CHC patients analysed the efficacy of intravenous IFNβ, in comparison with combination of IFNα and ribavirin for 12 wk[42]. The short-term treatment outcome showed a biochemical and virological response in 42% of patients treated with IFNβ *vs* 22% in patients treated with combination therapy. Sustained response (as documented after a further 48 wk) was seen in 21% and 13% of patients, respectively. These data indicate that, at least as a short-term therapy, IFNβ may offer a chance for sustained response in a subset of IFNα non-responders.

Cheng *et al* have evaluated the efficacy of IFNβ-1a in the treatment of CHC patients unresponsive to IFNα in a multicentre, randomized study[48]. A total of 267 patients were randomized to one of four groups: subcutaneous IFNβ-1a 12 MIU (44 μg) or 24 MIU (88 μg) administered 3 times weekly or daily. Patients were treated for 48 wk and then followed up for an additional 24 wk. There was a tendency towards a dose-response relationship regarding virological and biochemical response. Overall, 22 patients (8.3%) had a virological response at the end of treatment; 9 patients (3.4%) had a sustained virological response (SVR). Strikingly, 21.7% (5/23) of Chinese patients achieved SVR. Univariate analysis revealed that race was the only variable related to SVR (odds ratio 16.6; 35% CI 4.1 = 67.3; $P < 0.0001$). The authors concluded that IFNβ-1a

provided considerable clinical benefit in Chinese patients with CHC unresponsive to IFNα.

A few more pilot studies (with cohorts of between 10 and 30 patients) have been conducted to evaluate the efficacy of IFNβ in CHC non-responder patients[40,43,44,49]. Although these have confirmed that some patients may benefit from IFNβ therapy in terms of early biochemical and viral responses (between 20% and 40%, depending on the doses and regimens), sustained responses have been very seldom observed. None of the studies has shown a clear advantage for patients infected with any particular HCV genotype. Pellicano *et al*[40] treated 30 non-responders with 12 MIU subcutaneous IFNβ, three times weekly for 3 mo. Patients responding were given 12 MIU IFNβ for a further 3 mo, and those showing no biochemical and viral improvement had their dose increased to 18 MIU for the same 3 mo. While 20% of patients exhibited a response at the end of treatment, only one patient presented a sustained virological response at the end of post-treatment follow-up. In relapser patients after IFNβ monotherpay, few studies exist. Nomura *et al* treated 43 relapser patients genotype 1 CHC after IFNβ monotherapy, with 6 MIU of IFNβ, achieving a sustained virological response of 21%. Authors also found that better results were obtained when therpay with IFNβ was given near relpase[50]. In summary, trials with IFNβ monotherapy for CHC patients resistant to IFNα have shown conflicting results. Tolerability was good in most cases, but further investigation on strategies to improve efficacy of the drug are clearly needed.

Combination therapy: IFNβ plus ribavirin

There is limited information about the efficacy of IFNβ in combination with ribavirin for the treatment of CHC patients. In a pilot study, 27 patients were randomized to receive either 800-1000 mg/d ribavirin or IFNβ alone (3 MIU, three times weekly), or combination of the two for 24 wk[31]. No significant differences in terms of sustained viral response were observed between patients treated with IFNβ monotherapy or in combination with ribavirin (2 of 9 patients, respectively). Tolerability was good in all groups. The limited number of patients included in the study hampers reaching conclusions about the benefits of combination therapy. Pellicano *et al*[41] randomized 102 naïve CHC patients to receive 6 MIU of recombinant human IFNβ-1a subcutaneously every day for 24 wk alone or in combination with ribavirin (1000 mg/d in patients < 70 kg and 1200 mg/d in patients > 70 kg).The end-of-treatment virological response rate was 29.4% for monotherapy and 41.2% for combination therapy. After an additional 24 wk follow-up period, the sustained virological response rate in both groups was 21.56% and 27.45%, respectively. Tolerability was good, without major differences between groups (except for 2 patients in the combination therapy group who had to stop therapy due to drug-related adverse events). These results suggest an improvement of efficacy by combination therapy with respect to monotherapy. Other associations with IFNβ (amantadine, adelavin-9) do not obtain better results than those reached with ribavirin[36,51,52].

Clinical trials of IFNβ in special subpopulations of patients

Acute hepatitis C. Several studies and case reports dealing with the efficacy and safety of IFNβ in patients with acute hepatitis C have been published[45,53,54]. Omata *et al* randomized 25 acute non-A, non-B hepatitis patients to receive or not an average of 52 MIU IFNβ for 30 d, and in those showing elevated serum aminotransferase concentrations after one year, a second course of IFNβ was administrated[53]. Ten out of 11 treated patients showed normalized serum aminotransferase and negative HCV RNA at 3-years follow-up, as compared with 3 out of 14 untreated patients. Tadano and cols. Treated 97 non-A, non-B hepatitis cases with different regimens of IFNβ, reporting a resolution rate of 32% among patients with positive HCV RNA[54]. The dose of 336 MIU produced the highest resolution rate (83%; 10/12 of patients treated with this schedule). Lower doses of IFNβ induced resolution rates of 0% to 38%. These data suggest that IFNβ may prevent the progression of acute non-A, non-B hepatitis to chronically by eradicating HCV.

Cirrhosis. According to the currently available data, IFNβ is not efficacious for the treatment of patients with HCV-related cirrhosis. Sixty-one patients were randomized to receive or not 6 MIU IFNβ twice-a-week for 6 mo followed by 3 MIU/tiw for 6 mo, and followed-up for 5 years[33]. End-of-treatment biochemical and virological responses were observed in 13% and 11% of treated patients. At long-term follow-up, 16% of treated and 17% of untreated patients presented normalized serum alanine aminotransferase levels, whereas only 5% and 4% respectively, presented a virological response. Additionally, no significant reduction of cirrhosis-related clinical events (variceal bleeding, ascites, hepatic encephalopathy, progression to hepatocellular carcinoma), was associated with treatment.

IFNβ for other chronic liver diseases. IFNβ might also represent an appropriate therapy for chronic hepatitis B patients not responding to IFNα. In a pilot study, Muñoz *et al* treated 29 such patients with 6 MIU IFNβ, five times a week for 24 wk, and followed-up the patients for 48 wk[55]. End-of-treatment biochemical and virological response was obtained in 38% of patients and sustained virological response occurred in 21% of patients. The therapy was well tolerated and safe. The results were particularly positive for patients with HbeAg-negative/HBV DNA-positive chronic hepatitis B.

Safety of IFNβ

As already mentioned throughout this review, IFNβ generally presents a good tolerability, even in combination with ribavirin. This constitutes one of the main strengths of this drug as an alternative to other CHC therapies. The fact that IFNβ is the treatment of choice for relapsing-remitting multiple sclerosis, a chronic disease requiring high doses and frequent administration for years, has resulted in the availability of abundant information on this drug's safety. Severe side effects are unfrequent and several clinical studies in CHC patients report no requirement for treatment discontinuation and/or dose modifications. The

adverse effects most frequently encountered during IFNβ therapy are flu-like syndrome, fever, fatigue and injection-site reactions. The drug seems to be equally well tolerated by responders and non-responders. The frequency of adverse events is also similar among subpopulations such as patients with genotype-1b HCV hepatitis unresponsive to IFNα treatment or with HCV-related cirrhosis and patients with acute viral hepatitis. The interested reader is referred to a recently published review updating the available information about safety of IFNβ treatment for CHC[56].

SUMMARY

HCV infection remains an important health problem. Although the therapeutic options have experienced dramatic improvements during recent years, treatment of the disease is still far from optimal, particularly for those subpopulations that do not respond to the standard combination therapy with IFNα and ribavirin. Although in some cases the use of higher doses or longer treatment periods may be effective, these approaches are generally associated with a higher incidence of adverse effects, which may either lead to a reduction in patient compliance or require drug withdrawal. IFNβ could represent an interesting alternative for treating CHC in these patients. A review of the literature shows controversial data about IFNβ efficacy in CHC, the main reason being that many results stem from pilot studies with small cohorts of patients. However, promising results have been obtained in some subgroups of patients that fail to respond to IFNα. Additionally, the good tolerability of IFNβ represents an important advantage of the drug. The rates of dropouts in controlled clinical trials, as well as the need for dose reductions or treatment discontinuation are very low. All these data suggest that it might be worth assessing the value of IFNβ in randomized studies with larger cohorts patients, with special emphasis on the combination with ribavirin. IFNβ may represent an efficacious and safe second-line therapy for those populations of patients not eligible or not tolerating standard therapy, as well as for non-responders.

Abstract

AIM: To investigate the interaction between portal hypertension, splanchnic hyperdynamic circulation and splanchnic vasculopathy by observing splenic arterial and venous pathological changes and the ro1e of extracellular matrix in the pathogenesis of portal hypertensive vasculopathy by measuring the expression of type I and type III procollagen mRNA in splenic venous walls of portal hypertensive patients.

METHODS: Morphological changes of splenic arteries and veins taken from portal hypertensive patients ($n = 20$) and normal controls ($n = 10$) were observed under optical and electron microscope. Total RNA was extracted and the expression of type I and type III procollagen mRNA in splenic venous walls of portal hypertensive patients ($n = 20$) was semi-quantitatively detected using reverse transcription-polymerase chain reaction (RT-PCR).

RESULTS: Under optical microscope, splenic arterial intima was destroyed and internal elastic membrane and medial elastic fibers of the splenic arterial walls were degenerated and broken. Splenic venous intima became remarkably thick. Endothelia1 cells were not intact with formation of mural thrombus. The tunica media became thickened significantly due to hypertrophy of smooth muscles. Fibers and connective tissues were increased obviously. Under electron microscope, smooth muscle cells of the splenic arteries were degenerated and necrotized. Phenotypes of smooth muscle cells changed from constrictive into synthetic type. Red blood cells and platelets accumulated around the damaged endothelial cells. Synthetic smooth muscle cells were predominant in splenic veins and their cytoplasma had plentiful rough endoplasmic reticulum ribosomes and Golgi bodies. Along the vascular wall, a lot of collagen fibers were deposited, the intima was damaged and blood components accumulated. There was no significant difference in the expression of type I procollagen mRNA in splenic venous wall between the patients with portal hypertension and those without portal hypertension ($P > 0.05$), but the expression of type III procoagen mRNA was significantly stronger in the patients with portal hypertension than in those without portal hypertension ($P < 0.01$).

CONCLUSION: Type III procollagen and collagen might be important extra-cellular matrix resulting in neointimal formation and vascular remodeling in the pathogenesis of portal hypertensive vasculopathy. The pathological changes in splenic arteries and veins exist in portal hypertension patients. There might be an interaction between portal hypertension, splanchnic hyperdynamic circulation and splanchnic vasculopathy.

INTRODUCTION

With the elevation of portal pressure, obvious pathological changes in splanchnic vessels occur, such as extensive formation of porto-systemic communicating branches, remodeling of splanchnic great arteries and veins, which are defined as portal hypertensive vasculopathy (PHV). PHV is compensation of splanchnic vessels for hyperdynamic circulation, but also aggravates the portal pressure. PHV is one of the direct causes of variceal hemorrhage[1,2]. In this study the splanchnic vessels in portal hypertensive patients were observed under optical and electron microscope in order to explore the interaction between portal hypertension, splanchnic hyperdynamic circulation and splanchnic vasculopathy. The expression of types I and III procollagen mRNA in the splenic venous wall was detected by RT-PCR in the patients with portal hypertension in order to explore their ro1e in the pathogenesis of portal hypertensive vasculopathy.

MATERIALS AND METHODS

Patients

From June 2002 to October 2002, 20 patients including 15 males and 5 females with a mean age of 41 years with portal hypertension were selected from Center of Hepatic Surgery of Tongji Hospital and Caidian Schistosomiasis Prophylactic therapeutic Institution. Among them 14 belonged to Child class A and 6 to Child class B. Endoscopic examination revealed that all patients had moderate or serious gastroesophageal varices accompanied with hypersplenism and splenomegaly. Pathologically, there were 12 cases of schistosomial hepatic cirrhosis and 8 cases of post-hepatitis hepatic cirrhosis. Eight cases had a history of one or more episodes of massive upper digestive tract hemorrhage. Eight cases received splenectomy in combination with esophagogastric devascularization and twelve cases splenectomy. The control group I included 10 patients (6 males and 4 females with a mean age of 38 years) with traumatic spleen rupture without liver cirrhosis and all were subjected to emergency splenectomy. A piece of splenic arteries and veins near the hilus of the spleen was removed during the operation under laser scanning confocal microscope (Germany). PCR device (PTC-200 type) was the product of MJ Research Inc., (USA). UVP gel imaging analysis system was the product of UVP Company (England). M-MLV reverse transcriptionase, Oligo(dT)15 primer, DNTP, TaqNa polymerase were the products of Promega Company(USA). PCR marker was the product of Dalianbao Bioengineering Company.

Observation under optical and electron microscope

The vascular specimens were fixed with 40 g/L neutrally buffered formaldehyde, routinely embedded with paraffin, cut into 5μm thick sections and stained with H&E. The sections were observed under microscope. The fresh vascular specimens were cut into 1mm x 1mm x 1mm senctions, put into 25 mg/L glutaraldehyde within 1 min for pre-fixation for 2h, washed with phosphate buffer (pH 7.4), post-fixed with 10g/L osmic acid at 4℃ for 2h, then dehydrated with ascending concentrations of alcohol and acetone, embedded with epoxy resin Epon812, and finally cut into ultrathin sections. The sections were double stained with plumbum and observed under a transmission electron microscope (Opton EM l0C Model). After dehydration with alcohol, the sections were dried at a critical point, sherardized in vacuum, then examined and photographed under a Nikon scanning electron microscope(S-520 model).

Expression of type I and III procollagen mRNA

RT-PCR primers were designed according to Primer 5.0 version [human (a1) type I proco1 1agen (GenbankZ-74615): upstream primer 5' -ACCGCAAACCTTTCTACTTC-3' and downstream primer 5'-AAGGCGAGTAGGAGCAGT-3', 465 bp; human (al) type III procollagen (GenbankX-14420): upstream primer 5'-ACCGCAAACCTTTCTACTTC-3' and downstream primer 5'AAGGCGAGTAGGAGCAGT-3', 384 bp; human GAPDH (Genbankm 33197) served as house-keeping gene internal reference; upstream primer 5'-GGATTTGGTCGTATTGGG-3'and downstream primer 5'-GGAAGAGGTGAGGGATT-3', 384 bp]. The total RNA from splenic veins was extracted by Trizol one-step method. In each sample containing 5 mg RNA, DEPC was added to a volume of 27 μL following addition of 15 μL (1 ug) o1igo (dT). After degeneration of RNA by incubation at 70℃ for 5 min, 5×8 μL buffer, 4×2 μL dNTP, 1 μL RNAase inhibitor, 2 μL MMLV (400U) were added. In a total vo1ume of 40 μL, reverse transcription was performed at 42℃ for 1h fo11owed by denaturation at 95℃. A total volume of PCR mixture contained 10×5 μL Buffer, 3 μL 25 mmo1 $MgCl_2$, 4 x 1 μL dNTP (10pmol/mL), 5 μL upstream (10pmo1/L), 5 μL cDNA, 1 μL Taq enzyme (3 U), 33 μL DEPC. PCR conditions were 30 cycles of annealing at 52℃ for human type I and III pro collagen, 30 cycles of annealing at 51℃ for GAPDH. The PCR amplified products (10mL) were spotted and electrophoresed on 15g/L gel at 5V/cm. The results were observed under ultra-violet light. UVP gel imaging analysis system (England) was used to analyze the density of electrophoresis bands of PCR products. The targeting gene expression intensity = targeting gene RT-PCR product A÷GAPDH RT-PCR product A

Statistical analysis

All data were expressed as mean ± SD. Homogeneity test of variance, ANOVA and t test were performed by SPSSll.0 statistical software. $P < 0.05$ was considered statistically significant.

RESULTS

Morphology

As compared with the patients without hepatic cirrhosis, spleen of the patients with hepatic cirrhosis was significantly enlarged, splenic arterial and venous walls were obviously thickened, vascular caliber was increased and elasticity was decreased. Under optical microscope, intima of the normal splenic arterial walls was smooth, endothelial cells were intact and no subintimal smooth muscle cells were seen. In the tunica media, multiple layers of smooth muscle cells were separated by collagenous and elastic fibers. In the patients with hepatic cirrhosis, intima of the splenic artery was significantly thickened, endothelial cells were not intact, internal elastic membrane was broken and smooth muscle cells in tunica media were disturbed (Figures 1A and 1B). Intima of the normal splenic veins was intact and endothelial cells were not destroyed. In the patients with hepatic cirrhosis, intima of the splenic vein was locally thickeried, endothelial cells were not intact, intima was damaged and mural thrombus formed (Figures 1C and 1D). Under electron transmission microscope, smooth muscle cells of the normal splenic artery were fusiform and nuclei were long-circular in shape. In cytoplasma, there were myofilaments, mitochondria, endoplasmic reticulum ribosomes, Golgi bodies and gluycogenic granula. In the patients with hepatic cirrhosis, endothelial tissue of the splenic artery was damaged, internal elastic membrane was broken and elastic fibers were ruptured. In the tunica media, smooth muscle cells increased and migrated into subintima. Partial smooth muscle cells had atrophy and degeneration. Local

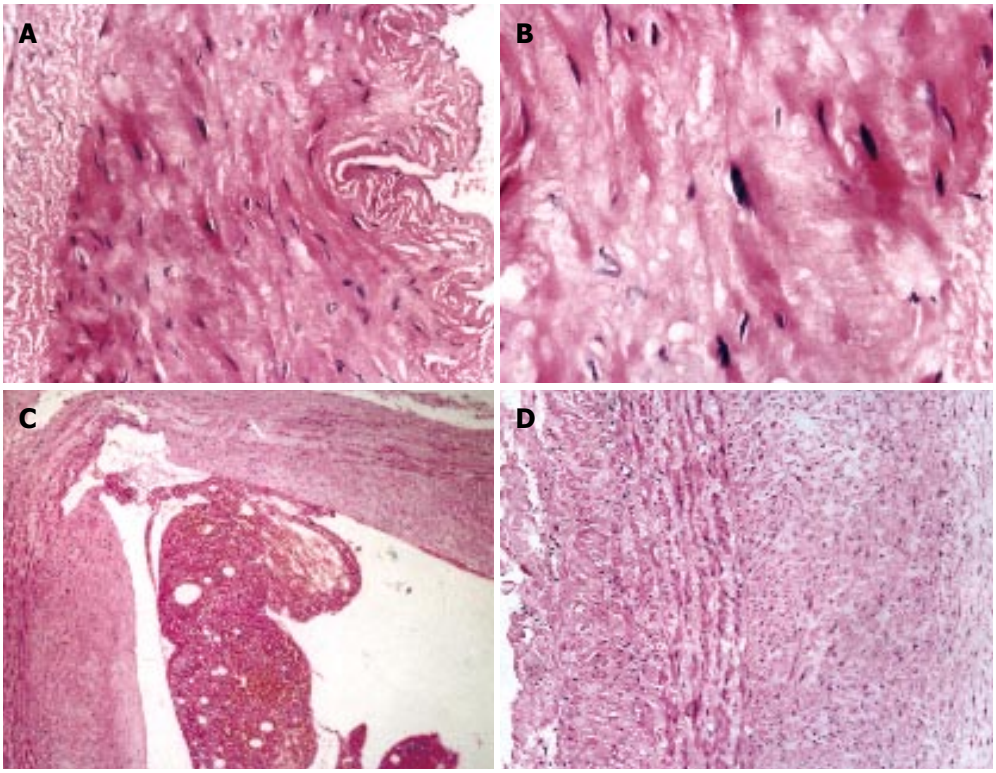

Figure 1 Changes of splenic arteries (**A**, **B**) and splenic veins (**C**, **D**) in patients with portal hypertension.

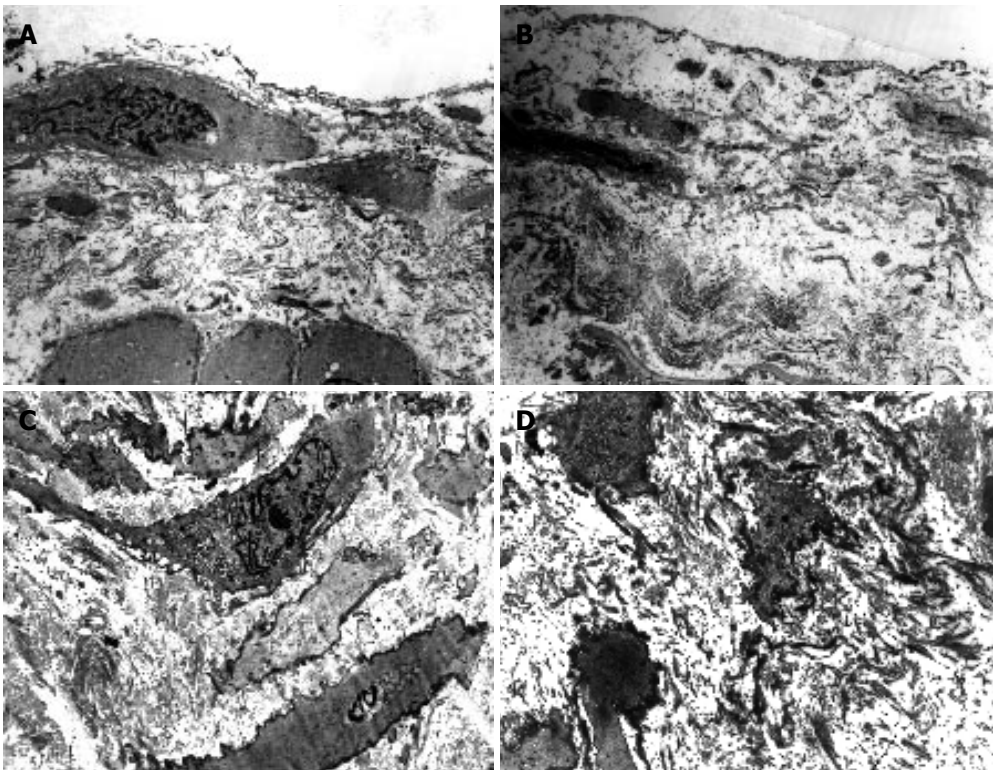

Figure 2 Ultrastructure of splenic artery (**A**, **B**) and splenic vein (**C**, **D**) in patients with portal hypertension.

cytoplasma was necrotized and formed vacuoles. The number of mitochondria was increased, their cristae disappeared and vacuoles formed. Collagenous fibers along the vascular wall were obviously increased and arranged disorderly. In some smooth muscle cells, rough endoplasmic reticulum, ribosomes and Golgi bodies were increased while myofilaments reduced, indicating that phenotypes of smooth muscle cells were changed from constrictive to synthetic type (Figures 2A and 2B). Intima of the normal splenic vein was smooth and endothelial cells were not damaged. In the patients with hepatic cirrhosis, intima of the splenic vein wall was damaged and vascular smooth muscle cells of synthetic type were predominant. Cytoplasma of the smooth muscle cells had plentiful rough endoplasmic reticulum and Golgi bodies. Along the vascular wall, a lot of collagenous fibers were deposited and disorderly arranged (Figures 2C and 2D). Under scanning electron microscope, intima was smooth

and endothelial cells were intact in the normal splenic vein (Figure 3A). In the patients with hepatic cirrhosis, intima of the splenic vein was damaged, endothelial cells were not intact, blood components accumulated, surface of the endothelia was irregular(Figures 3B and 3C). In the normal splenic artery, intima was intact and endothelial cells were not destroyed (Figure 4A). In the patients with hepatic cirrhosis, intima of the splenic artery was damaged and red blood cells and platelets accumulated around the damaged area (Figures 4B and 4C).

Expression of type I and III procollagen mRNA

In splenic vein wall of the patients with portal hypertension, the expression intensity of type I procollagen mRNA was 0.3868 ± 0.0358, while that in the patients without hepatic cirrhosis was 0.3642 ± 0.0332 with no significant difference ($P > 0.05$). In portal vascular wall of the patients with portal hypertension, the expression intensity of type III procollagen mRNA was 1.1855 ± 0.2140, while that in the patients without hepatic cirrhosis was 0.1095 ± 0.1558 with significant difference ($P < 0.01$, Figures 5, 6)

DISCUSSION

Serious damage to the intima in patient with portal hypertension results from increased portal pressure and blood flow. It has been reported that phenotype of vascular smooth muscle cells changes from normal constrictive to synthetic type[3,4] due to increased cytokines[5,6], growth factor[7], shearing force[8,9], oxygen stress[10]. The expression of constrictive proteins in vascular smooth muscle cells is inhibited, and a plentiful of extra-cellular matrix (ECM) is produced and migrates into subintima. In this study, under optical microscope, the tunica media was thickened, which is an adaptative compensatoty response of vessels to the increased pressure. Smooth muscle cells in tunica media of the splenic artery were degenerated and became shrunk and their phenotype changed from constrictive to synthetic type, which is attributed to the ischemic vascular wall injury by insufficient blood supply due to compression of nutrient vessels resulting from the increased pressure

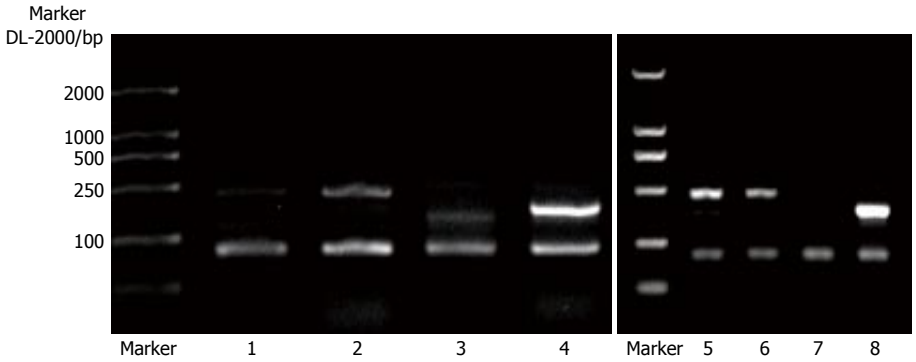

Figure 6 Expression of type III procollagen mRNA of splenic vein wall in patients with portal hypertension. Bands 1, 3, 5 and 7: control samples from patients without portal hypertension; Bands 2, 4, 6 and 8: samples from patients with portal hypertension.

and flow. Under scanning electron microscope, damage to intima of the splenic artery was seen, which is associated with the portal system involvement. In addition, under optical microscope, internal elastic membrane of the splenic artery was broken due to the following causes, such as splanchnic hyperdynamic circulation, increased blood flow and velocity, increased wall pressure and shear stress on vascular wall, long-term vascular congestion and dilation, thus resulting in endothelial exfoliation and rupture of elastic membrane. The broken internal elastic membrane contributes to the decreased ability of vascular wall to resist the blood flow attack. When the blood flow is increased, the vessels are not constricted and the blood flow is not regulated by elastic membrane, which is beneficial to the development of hyperdynamic circulation.

Collagen is an important vascular extra-cellular matrix and can maintain the flexibility and intensity of vascular wall. In this study, expression of type III procollagen mRNA in the splenic vein wall was about 5-6 times higher in patients with portal hypertension than in those without portal hypertension ($P<0.01$), while there was no significant difference in the expression of type I procollagen mRNA between the patients with and with portal hypertension ($P>0.05$). We believe that the high expression of type III porcollagen mRNA in patients with portal hypertension might be an important factor promoting vascular remodeling. At present, it is unclear about the modulation mechanism of type I and III procollagen gene expression. It has been reported that many factors, such as FGF[11], Ang-II[12] can up-regulate type I and III procollagen mRNA in vascular smooth muscle cells.

In conclusion, type III porcellagen and collagen may be an important extracellular matrix resulting in vascular remodeling in patients with portal hypertension. Splenic vasculopathy exists in patients with portal hypertension, while intrahepatic blood flow obstruction resulting from hepatic cirrhosis is the initial factor responsible for the development of portal hypertension. On the one hand, portal hypertension can promote the formation and development of splanchnic hyperdynamic circulation and splanchnic vasculapathy. On the other hand, splanchnic vasculapathy can enhance the formation and development of portal hypertension, as well as promote splanchnic hyperdynamic circulation. These three factors play an important role in the pathogenesis of cirrhotic portal hypertension and are involved in variceal hemorrhage.

Abstract

AIM: To evaluate the bioequivalence of ranitidine and bismuth derived from two compound preparations.

METHODS: The bioavailability was measured in 20 healthy male Chinese volunteers following a single oral dose (equivalent to 200 mg of ranitidine and 220 mg of bismuth) of the test or reference products in the fasting state. Then blood samples were collected for 24 h. Plasma concentrations of ranitidine and bismuth were analyzed by high-performance liquid chromatography and inductively coupled plasma-mass spectrometry (ICP-MS), respectively. The non-compartmental method was used for pharmacokinetic analysis. Log-transformed C_{max}, $AUC_{(0-t)}$ and $AUC_{(0-\infty)}$ were tested for bioequivalence using ANOVA and Schuirmann two-one sided *t*-test. T_{max} was analyzed by Wilcoxon's test.

RESULTS: Various pharmacokinetic parameters of ranitidine derived from the two compound preparations, including C_{max}, $AUC_{(0-t)}$, $AUC_{(0-\infty)}$, T_{max} and $T_{1/2}$, were nearly consistent with previous observations. These parameters derived from test and reference drug were as follows: C_{max} (0.67 ± 0.21 *vs* 0.68 ± 0.22 mg/L), $AUC_{(0-t)}$ (3.1 ± 0.6 *vs* 3.0 ± 0.7 mg/L per hour), $AUC_{(0-\infty)}$ (3.3 ± 0.6 *vs* 3.2 ± 0.8 mg/L per hour), T_{max} (2.3 ± 0.9 *vs* 2.1 ± 0.9 h) and $T_{1/2}$ (2.8 ± 0.3 *vs* 3.1 ± 0.4 h). In addition, double-peak absorption profiles of ranitidine were found in some Chinese volunteers. For bismuth, those parameters derived from test and reference drug were as follows: C_{max} (11.80 ± 7.36 *vs* 11.40 ± 6.55 μg/L), $AUC_{(0-t)}$ (46.65 ± 16.97 *vs* 47.03 ± 21.49 μg/L per hour), T_{max} (0.50 ± 0.20 *vs* 0.50 ± 0.20 h) and $T_{1/2}$ (10.2 ± 2.3 *vs* 13.0 ± 6.9 h). Ninety percent of confidence intervals for the test/reference ratio of C_{max}, $AUC_{(0-t)}$ and $AUC_{(0-\infty)}$ derived from both ranitidine and bismuth were found within the bioequivalence acceptable range of 80%-125%. No significant difference was found in T_{max} derived from both ranitidine and bismuth.

CONCLUSION: The two compound preparations are bioequivalent and may be prescribed interchangeably.

INTRODUCTION

Ranitidine is a very common histamine H_2 receptor antagonist. It exerts most prominent effect on basal acid secretion and less profound effect on acid production[1,2]. Bismuth potassium citrate has mucosal protective effects by blocking pepsin activity, retarding hydrogen-ion back-diffusion and stimulating prostaglandin synthesis. In addition, it has an inhibitory effect on *Helicobacter pylori* (*H pylori*)[3-6]. Thus, ranitidine and bismuth potassium citrate have a synergistic effect and are usually concurrently prescribed in poly-therapy regimens for gastroduodenal ulcers and *H pylori* infection. Especially, the availability of ranitidine bismuth citrate and compound preparation of ranitidine and bismuth potassium citrate in market makes administration more conveniently and increases medication compliance in ulcer patients[7,8].

The pharmacokinetics of ranitidine has been described previously[9-11]. After oral administration 50% of ranitidine is absorbed, resulting in the peak serum concentration of 2 ± 3 h after dosing, followed by elimination with a half-life of 2.5 ± 3 h. Ranitidine is metabolized to a small extent, primarily via flavin mono-oxygenases[12]. It is eliminated through kidney, with approximately 70% of the systemically available dose recovered in urine as unchanged drug. Bismuth is only minimally absorbed and its bioavailability ranges 0.16%-0.28%, but the median peak bismuth concentration occurs 30 min (range 15-105

min) post-dosing[13,14]. The concentration of bismuth in kidneys is high and it is also retained there for a long time. Elimination from blood displays multi-compartment pharmacokinetics[15].

Comparative bioavailability of different mono-preparations of ranitidine hydrochloride or colloidal bismuth sub-citrate in healthy volunteers or patients has been described previously[16-20]. However, to our knowledge, there is no report on the pharmacokinetic and bioequivalence evaluation of compound preparations containing these two drugs.

MATERIALS AND METHODS

Drugs and reagents

Ranitidine reference substance (purity> 99.5%) was provided by Shuguang Pharmaceutical Factory (Beijing, China). Bi_2O_3 reference substance (purity> 99.999%) and TlCl reference substance (purity> 99%) were provided by ALDRICH Chemical Company (USA). Nitric acid was of MOS grade. Ultra pure water was obtained from Milli-Q Academic (Millipore Co., USA). Acetonitrile was of HPLC grade. Potassium dihydrogen phosphate and perchloric acid were of analytical grade. Test preparation was compound ranitidine tablet (lot 041201, expiracy: 12/2006) from Chongqing Pharmaceutical Factory (Chongqing, China). Reference preparation was compound ranitidine capsule (lot 041002, expiracy: 9/2006) from Nuode Pharmaceutical Factory (Jiangsu, China). Each tablet or capsule contained ranitidine hydrochloride (equivalent to 100 mg of ranitidine) and bismuth potassium citrate (equivalent to 110 mg of bismuth).

Study subjects

After approval by the Ethics Committee of the 2nd Affiliated Hospital (School of Medicine, Zhejiang University), 20 male healthy Chinese volunteers (age, 24±1 years; weight, 63.8±6.1 kg; BMI, 22.1±1.7 kg/m^2) gave their written informed consent to participate in the study and all of them completed the study. All volunteers were considered to be in good health on the basis of physical examination, electrocardiogram (ECG), and laboratory tests including complete blood count, blood biochemistry testing and urinalysis. Each volunteer was required to be 18-40 years old, a nonsmoker, and to have a BMI between 19 and 25 kg/m^2. Participants were excluded for the following reasons: any significant medical history, history of any localized or systemic infection within 4 wk before admission, use of prescription or over-the counter medication or alcohol within 2 wk before enrollment, history of alcohol or drug abuse, donation of blood within the past 2 mo.

Study design

The study had an open-label, randomized, two-period crossover design, with 1 wk washout between periods. All volunteers were not allowed to take any medications 2 wk before and during the study period. After fasting for l2 h overnight, the volunteers received a single oral dose (equivalent to 200 mg of ranitidine and 220 mg of bismuth) of the test or reference products with 200 mL water in a crossover fashion. No food was allowed until 4 h after dose administration. Water intake was allowed after 2 h of dose. Water, lunch and dinner were given to all volunteers according to a time schedule. The volunteers were under direct medical supervision at the study site. Blood samples (4 mL) were drawn into Vacutainer™ tubes containing K_2EDTA from a forearm vein using an indwelling catheter before drug intake and at 0.17, 0.33, 0.50, 0.75, 1.0, 1.5, 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, 10.0, 12.0, 24 h for the two phases after dosing. Blood samples were centrifuged at 3000 r/min for 10 min, and plasma was separated and stored at -80 ℃ until assay. ECG, biochemical and hematological laboratory tests were performed for each volunteer to record any clinically abnormal finding.

Analytical procedure

High performance liquid chromatography (HPLC) assay method for ranitidine was developed in our laboratory. In brief, 50 μL of perchloric acid solution (2.5 mol/L) was added to 200 μL plasma in the eppendorf tube (1.5 mL). The mixture was vortexed for 20 s and then centrifuged at 36 670 r/min for 10 min. The supernatant was transferred to vial on the rack of autosampler and 50 μL was injected onto the column. The HPLC injection sequence was as follows: calibration standards of 0.02, 0.05, 0.1, 0.2, 0.5, 1.0, 2.0 mg/L, volunteers' plasma samples and quality-control samples of 0.04, 0.4 and 1.5 mg/L throughout all sequences.

The assay method for bismuth was as follows: plasma samples (0.5 mL) were added to Tl (internal standard) working solution and diluted to a volume of 5 mL with super pure water, followed by direct measurement in a PQ3 ICP-MS system (Thermo Electron Corporation, USA). The assay sequence was as follows: calibration standards of 0.2, 0.5, 1.0, 5.0, 10.0, 30.0, 60.0, 100.0 μg/L, volunteers' plasma samples and quality-control samples of 0.30, 8.00, 20.0, 80.00 μg/L throughout all sequences.

The two assay methods were validated according to international guidelines[21].

Chromatography

Chromatography for ranitidine was performed on a Beckman SYSTEM GOLD® liquid chromatography system (USA) consisting of a 125 solvent module, 508 auto-sampler, 166 UV detector and AT-330 column oven (Medilab). The software package 32 Karat 5.0 was used to control the chromatographic system and produce UV-spectrometric data. Analytical column used was Kromasil C18 ODS (Sweden, 250×4.6 mm ID, 5 μm, particle size), protected by a security guard cartridge C18 ODS 4×3.0 mm ID (Phenomenex Inc, USA). The mobile phase consisted of 0.02 mol/L KH_2PO_4-acetonitrile (86:14, V/V). The flow rate was 1.0 mL/min. Column oven was kept at 25 ℃. Auto-sampler was set at 4 ℃. The UV detective wavelength was 320 nm.

Working condition of ICP-MS

ICP-MS measurements were carried out under the following operation conditions. The forward power was 1350 W, the coolant and auxiliary and nebulizer gas

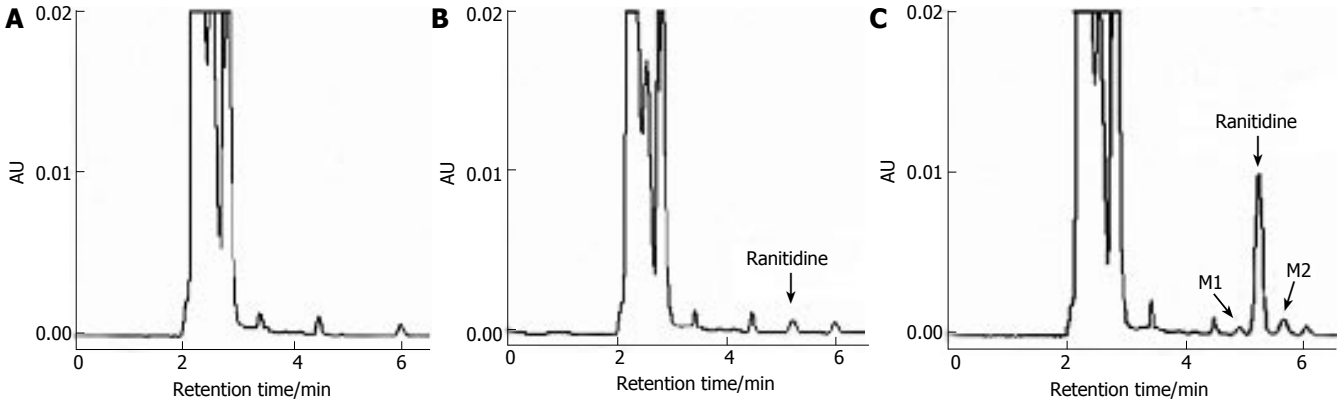

Figure 1 Chromatograms of spiked plasma sample (**B**), plasma samples of patients before (**A**) and after (**C**) the administration of 200 mg ranitidine. M1 and M2 are metabolites of ranitidine.

flow rate were 13, 0.70, and 0.73 L/min, respectively. Sample uptake flow rate was 1.2 mL/min. Mass-to-charge ratios detected (m/z) were 205 (^{205}Tl) and 209 (^{209}Bi). Sweep mode was peak hopping. Dwell time was 10 ms. Number of sweeps per run was 60. Uptake time was 60 s. Acquisition duration was 4 s.

Statistical analysis

Pharmacokinetic parameters were calculated by non-compartmental method. Bioequivalence evaluation was performed by the software BAPP2.0 (Center of Drug Metabolism & Pharmacokinetics, China Pharmaceutical University, Nanjing, China). Maximal plasma concentrations (C_{max}) and the time points at which they occurred (T_{max}) were determined by inspection of the plasma concentration-time profile. The terminal elimination rate constant (λ_z) was determined by linear regression of the terminal portion of the log concentration-time profile. The elimination half-life ($T_{1/2}$) was calculated as $0.693/\lambda_z$. Area under the plasma concentration-time curve (AUC) was determined by trapezoidal rule and extrapolated to infinity by calculation of C_t/λ_z. F=[$AUC_{(0\text{-}t)}$ (T)/$AUC_{(0\text{-}t)}$ (R)]×100%. Log transformed C_{max}, $AUC_{(0\text{-}t)}$, $AUC_{(0\text{-}\infty)}$ were analyzed using ANOVA analysis and Schuirmann two-one sided t-test. T_{max} was analyzed by the non-parametric test and Wilcoxon's test. A P value of less than 0.05 was considered statistically significant. Data were reported as mean ± SD. If the two preparations were bioequivalent, 90% confidence intervals (CI) for test/reference ratios of C_{max}, $AUC_{(0\text{-}t)}$ and $AUC_{(0\text{-}\infty)}$ should fall within the range of 80%-125% [22, 23].

RESULTS

Validation of the assays

Typical chromatograms of spiked ranitidine plasma samples, plasma samples of patients before and after the administration of compound ranitidine preparation are shown in Figure 1. The retention time for ranitidine was 5.1 min. Under the chromatographic condition described, ranitidine and its metabolite were well resolved. Endogenous plasma components did not show any interfering peaks. The assay was linear from 20.0 to 2000.0 μg/L for ranitidine in plasma samples. The mean absolute recovery was about 97.2%, while the intra- and inter-day coefficients of variation and percent error values of the assay method were all lower than 8%. The limit of quantification (LOQ) was found to be 20.0 μg/L, with a precision of less than 20% (n=5) and an accuracy of ±20% (n=5). Ranitidine was stable in plasma samples at different storage conditions: immediately after 3 h at ambient temperature, after perchloric acid treatment and being on the auto-sampler at 4 ℃ for 24 h, after two freeze/thaw cycles and after 1 mo storage at -80 ℃.

Table 1 Pharmacokinetic parameters of ranitidine and bismuth after a single oral dose of compound ranitidine preparation (equivalent to 200 mg of ranitidine and 220 mg of bismuth) in 20 Chinese volunteers (mean ± SD)

Component	Parameters	Test	Reference
Ranitidine	T_{max} (h)	2.3±0.9	2.1±0.9
	C_{max} (mg/L)	0.67±0.21	0.68±0.22
	$T_{1/2}$ (h)	2.8±0.3	3.1±0.4
	$AUC_{(0\text{-}t)}$ (mg/L per hour)	3.1±0.6	3.0±0.7
	$AUC_{(0\text{-}\infty)}$ (mg/L per hour)	3.3±0.6	3.2±0.8
Bismuth	T_{max} (h)	0.50±0.20	0.50±0.20
	C_{max} (μg/L)	11.80±7.36	11.40±6.55
	$T_{1/2}$ (h)	10.2±2.3	13.0±6.9
	$AUC_{(0\text{-}t)}$ (μg/L per hour)	46.65±16.97	47.03±21.49
	$AUC_{(0\text{-}\infty)}$ (μg/L per hour)	55.38±21.27	57.81±23.31

The ICP-MS assay was linear from 0.2-100.0 μg/L for bismuth in plasma samples. The mean absolute recovery of bismuth from quality control samples was about 100.5%, while the intra- and inter-day coefficients of variation and percent error values of the assay method were all lower than 8%. LOQ was found to be 0.2 μg/L, with a precision of less than 10% (n=30) and an accuracy of ±15% (n=30).

The validity study demonstrated that the HPLC assay was reliable for quantification of plasma ranitidine and the ICP-MS assay was reliable for determination of plasma bismuth levels. The specificity, sensitivity, accuracy and precision all met the requirement for PK study.

Concentration-time curves and PK of ranitidine

The average concentration-time curves are shown in Figure 2. The main PK parameters including C_{max}, $AUC_{(0\text{-}t)}$, $AUC_{(0\text{-}\infty)}$, T_{max} and $T_{1/2}$ are given in Table 1. The variation

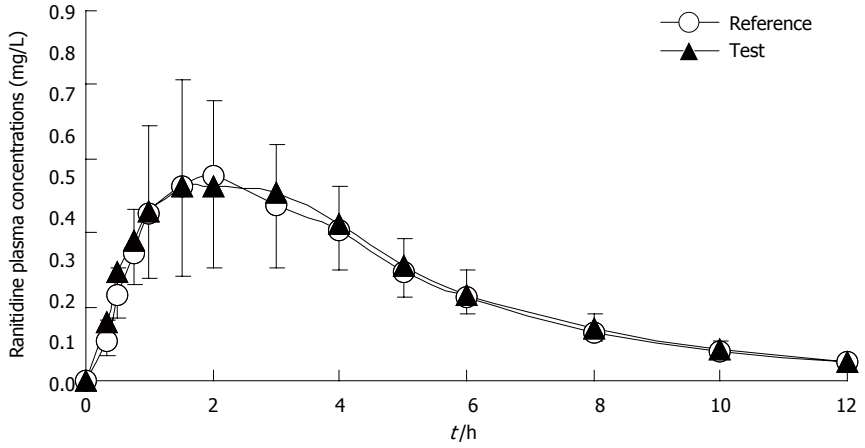

Figure 2 Concentration-time curves of ranitidine in 20 Chinese volunteers after oral administration of two compound preparations. $n = 20$. Mean ± SD. Bars indicate standard deviations (lower bars for test drug and upper bars for reference drug).

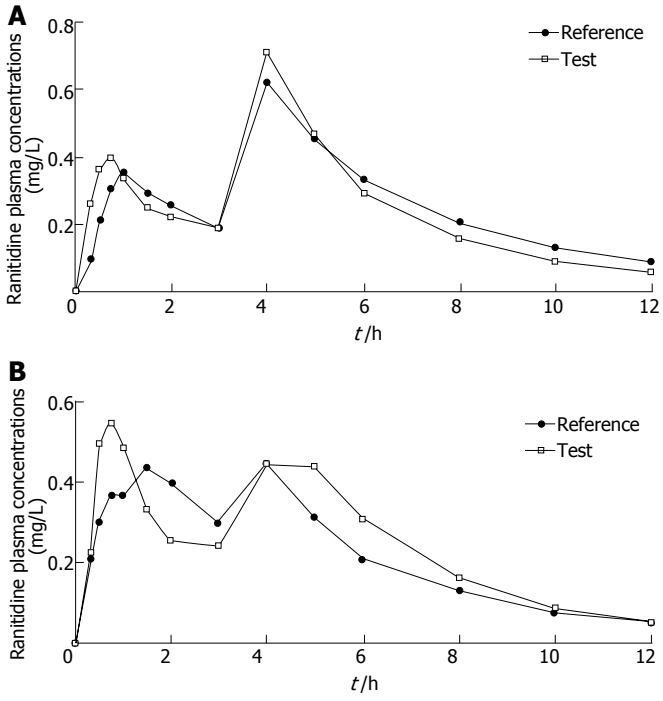

Figure 3 Typical double-peak plasma profiles of ranitidine in two Chinese volunteers (№14 and №16) after oral administration of two compound preparations.

sources of *P* values and 90% CI for the parameter ratios are presented in Table 2. No statistically significant formulation or period effect was encountered, with *P* value greater than 0.05. Inter-subject differences were the main source of variability in log-transformed $AUC_{(0\text{-}t)}$ and $AUC_{(0\text{-}\infty)}$. The 90% CI for the ratio of C_{max} (86.7%-113.6%), $AUC_{(0\text{-}t)}$ (96.0%-113.4%), and $AUC_{(0\text{-}\infty)}$ (95.3%-112.5%) values for the test and reference products was entirely within the FDA acceptable range of 80%-125%. The data indicated that the 2 preparations were bioequivalent with respect to ranitidine. In addition, no significant difference was obtained in T_{max}.

Interestingly, double-peak plasma profiles of ranitidine were observed in some volunteers receiving either test drug or reference drug. Typical double-peak plasma profiles of ranitidine in two volunteers (№ 14 and № 16) after oral administration of two compound preparations are shown in Figure 3.

Table 2 ANOVA for assessment of the drugs, subjects and period effects, and 90% CI for the test/reference ratio of C_{max}, $AUC_{(0\text{-}t)}$ and $AUC_{(0\text{-}\infty)}$, using logarithmic transformed data, after administration of two compound ranitidine preparations (equivalent to 200 mg of ranitidine and 220 mg of bismuth) to 20 Chinese volunteers ($\alpha = 0.05$).

Component	Parameters	ANOVA (*P*-value)			90% CI (%)
		Variation source			
		Drug	Subjects	Period	
Ranitidine	C_{max}	0.9191	0.0686	0.7679	86.7-113.6
	$AUC_{(0\text{-}t)}$	0.3917	0.0153	0.8366	96.0-113.4
	$AUC_{(0\text{-}\infty)}$	0.4733	0.02118	0.9064	95.3-112.5
Bismuth	C_{max}	0.65695	0.51515	0.39551	89.8-120.0
	$AUC_{(0\text{-}t)}$	0.66066	0.11347	0.71245	88.1-124.0
	$AUC_{(0\text{-}\infty)}$	0.75149	0.15804	0.87169	85.3-111.5

Concentration-time curves and PK of bismuth

The average concentration-time curves are shown in Figure 4. The main PK parameters including C_{max}, $AUC_{(0\text{-}t)}$, $AUC_{(0\text{-}\infty)}$, T_{max} and $T_{1/2}$ are given in Table 1. The variation sources of *P* values and 90% CI for the parameter ratios are presented in Table 2. No statistically significant formulation or period effect and inter-subject differences were encountered, with *P* value greater than 0.05. The 90% CI for the ratio of C_{max} (89.8%-120.0%), $AUC_{(0\text{-}t)}$ (88.1%-124.0%), and $AUC_{(0\text{-}\infty)}$ (85.3%-111.5%) values for the test and reference products was also entirely within the FDA acceptable range of 80%-125%. In addition, no significant difference was obtained in T_{max} ($P > 0.05$).

Safety

The two preparations were well tolerated by the volunteers. Unexpected incidents that could have influenced the outcome of the study did not occur. There was no drop-out and all volunteers participating in the study continued to the end. Post-study clinical laboratory tests revealed normal results.

DISCUSSION

The assay methods we developed for ranitidine and bismuth are reliable and applicable in bioavailability study. With respect to HPLC assay for ranitidine, direct

injection of the plasma samples after deproteination using perchloric acid warranted high sensitivity, good accuracy and precision and least time for sample preparation. Most literature on ranitidine determination in plasma involves solid-phase extraction (SPE)[24-26] or liquid-liquid extraction (LLE)[27-29]. However, the methods employing LLE not only consume large time for sample preparation but also give highly variable and relatively low recoveries. The SPE techniques are quite good, but they still involve several steps and need several hundred cartridges. With respect to the ICP-MS assay we developed for bismuth, sample preparation method is more simple and has less matrix effect than the method provided by Mauras Y *et al*[30].

The PK of ranitidine derived from ranitidine bismuth citrate is consistent with observations for ranitidine administered alone[31]. However, literature on PK of ranitidine derived from compound preparation is not yet available. Wen *et al*[32] showed that. C_{max} and $AUC_{(0-\infty)}$ derived from a single 300 mg dose of ranitidine alone are 0.91 mg/L and 4.78 mg/L per hour, respectively. However, when 300 mg colloidal bismuth sub-citrate capsules are co-administered, the two parameter values are significantly decreased by 41.8% and 33.7%, respectively. No significant differences have been observed with respect to T_{max} and $T_{1/2}$ under the two different circumstances, suggesting that ranitidine granules are partially enwrapped by colloidal precipitation as presented by Wen *et al*[32], which can explain the loss in ranitidine absorption. Ranitidine is characterized by a dose-proportional PK. So C_{max} and $AUC_{(0-\infty)}$ for ranitidine mono-preparations are both standardized to dose (200 mg), ranging 0.60-1.20 mg/L and 3.0-4.5 mg/L per hour, respectively[16-19,33]. The mean C_{max} and $AUC_{(0-\infty)}$ values for ranitidine derived from combined formulation in our study were 0.67 mg/L and 3.1 mg/L per hour, respectively, falling within the above range for ranitidine administered alone. If significant loss exists at absorption phase of ranitidine derived from test compound formulation and the decreased percentage is similar with the results of Wen *et al*[32]. C_{max} and $AUC_{(0-\infty)}$ values for ranitidine mono-preparation would be estimated to be 1.15 mg/L and 4.7 mg/L per hour, respectively, still being within/or near the mean range. Thus, the possible effects of bismuth potassium citrate on ranitidine absorption could not be excluded, thus more relative studies are needed to confirm the results presented by Wen *et al*[32]. Moreover, it would be useful to investigate the difference between the bioavailability of ranitidine in the compound preparation relative to the administration of two mono-preparations that are ingested simultaneously, although compound preparation has advantages such as more convenience in administration and better medication compliance in ulcer patients. However, the main purpose of this study was to confirm whether the two compound preparations can be prescribed interchangeably by bioequivalence evaluation.

The PK of oral drugs exhibiting double peaks cannot be adequately described by conventional compartmental models[34]. So we used non-compartmental method. The double-peak phenomenon of ranitidine plasma profile in several volunteers is consistent with previous reports[34,35,38]. However, this PK profile has not been revealed in Chinese. The proposal mechanism responsible for the existence of secondary peaks, presented by Yin *et al*[34] and Schaiquevich *et al*[35], includes enterohepatic recirculation and the existence of multiple sites of absorption along the gastrointestinal tract.

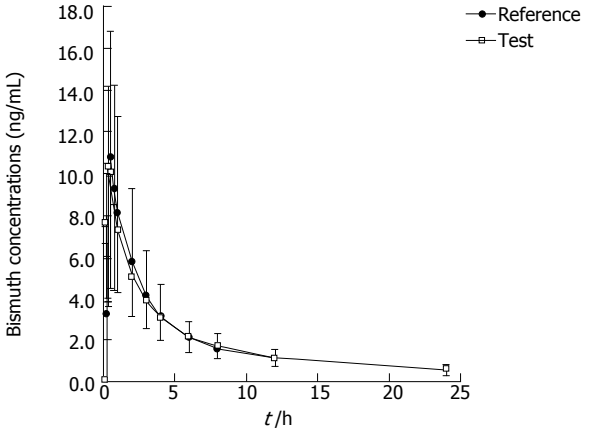

Figure 4 Concentration-time curves of bismuth in 20 Chinese volunteers after oral administration of two compound preparations. $n = 20$, mean ± SD. Bars indicate standard deviations (lower bars for test drug and upper bars for reference drug).

The mean T_{max} value for bismuth derived from compound preparations in this study was 0.50 h, indicating that bismuth is rapidly absorbed by Chinese volunteers. The result is similar with those presented by Nwokolo *et al*[13] and Benet *et al*[14]. Peak bismuth plasma concentrations in our study ranged 3.24 μg/L-27.50 μg/ L, the mean C_{max} value was 11.60 μg/L, suggesting that bismuth neurotoxicity is not associated with steady-state concentrations of 50-100 μg/L. The mean terminal half-lives for bismuth derived from the test compound preparation (equivalent to 220 mg bismuth) in this study was 10.2 h, which is nearly similar with the mean values of 9.1 h derived from a single dose of 350 mg ranitidine bismuth citrate capsules for 10 Chinese health volunteers[36]. Benet *et al*[14] considered that the intermediate half-life of 5-11 d derived from colloidal bismuth sub-citrate represents most of the clearance and elimination. Moreover, the plasma terminal half-lives averaging 21 d are derived from oral doses of 800 mg ranitidine bismuth citrate, twice daily for 28 d[31]. These different results are suggestive of possible ethnic differences in bismuth elimination or indicate that multiple-dose administration of bismuth may result in its prolonged elimination. In this way, further investigations should be carried out.

A placebo-controlled crossover study showed that daily oral administration of 40 mg omeprazole for 1 wk increases the systemic availability of 240 mg bismuth derived from tripotassium dicitrate bismuthate. The explanation by Treiber *et al*[37] is that absorption of bismuth may be dependent on intragastric pH which is elevated by omeprazole. However, the mean $AUC_{(0-t)}$ of bismuth derived from test compound preparation (equivalent to 200 mg of ranitidine and 220 mg of bismuth) in our study was 46.65 μg/L per hour, which is nearly similar with the value of 46 μg/L per hour derived from mono-preparation of tripotassium dicitrate bismuthate (equivalent to 220 mg of bismuth)[37]. Thus, additional experiments are also

needed to address whether ranitidine increases the systemic availability of bismuth.

The most important objective of bioequivalence testing is to assure the safety and efficacy of generic formulations. Two drugs are considered to be bioequivalent and thus therapeutically equivalent if they are pharmaceutical equivalents (i.e., similar dosage forms made, perhaps by different manufacturers) or pharmaceutical alternatives (i.e., different dosage forms) and if their rates (C_{max}) and extents of absorption (AUC) do not show a significant difference when administered at the same molar dose of the therapeutic moiety under similar experimental conditions[39]. Interpretation of T_{max} is difficult in some oral bioequivalence studies, because of the occurrence of multiple peaks. Comparison between the formulations is based on the overall C_{max}, T_{max}, and AUC. Therefore, the presence or absence of a double peak can not affect the accuracy of measurements[40].

It is generally accepted that the standard equivalence range is 0.8-1.25 for basic pharmacokinetic characteristics, such as AUC and C_{max}[22,23]. For ranitidine derived from the two compound preparations in this study, no significant difference was obtained in T_{max} ($P>0.05$) and 90% CI for the test/reference ratio of C_{max}, $AUC_{(0\text{-}t)}$ and $AUC_{(0\text{-}\infty)}$ was found within the range 80%-125%. Therefore the two compound preparations can be expected to be equally effective with respect to the action of ranitidine. To support equal clinical efficacy of compound preparations, it is necessary to show the equivalent gastric availability (local effect) of the bismuth component. Its effect for a large part is determined by the pharmaceutical form in which this component is delivered. Coghill *et al*[20] have developed a novel means of comparing the bioequivalence of the two preparations of tripotassium dicitrate bismuthate (De-Noltab) in patients attending a gastroscopy clinic by examining duodenal biopsies with electron microscopy. However, this method is invasive, thus lacking applicability. We performed a comparative bioavailability study to reflect the equal gastric availability indirectly. The results have confirmed the equivalent rates and extents of absorption of bismuth derived from the two compound preparations. Thus, we consider that these two compound preparations have equal clinical efficacy with respect to bismuth.

In conclusion, the 2 compound preparations are bioequivalent with respect to both ranitidine and bismuth and can be prescribed interchangeably.

Abstract

AIM: To evaluate the chemopreventive effects of aqueous *Azadirachta indica* (*A indica*) leaf extract (AAILE) against benzo(a)pyrene [B(a)P]-induced forestomach tumorigenesis in Balb/c mice.

METHODS: Female Balb/c mice were divided into four groups of 10-12 animals each. For induction of forestomach tumors, starting from d 14 of the experiment, mice of B(a)P and B(a)P+*A indica* groups were given intra-gastric instillations of B(a)P (40 mg/kg), twice a week for four weeks. Mice of *A indica* and B(a)P+*A indica* groups were orally administered with AAILE (100 mg/kg), two weeks prior to B(a)P instillations till the end of the experiment. After 22 wk of the first B(a)P instillation, mice were sacrificed and the forestomachs were analyzed for development of tumors, scanning electron microscopy (SEM) and histopathology.

RESULTS: Tumor incidence was observed to be 100% in mice that received only B(a)P. However, treatment with AAILE reduced the tumor incidence by 58.4% as observed in mice of B(a)P+*A indica* group when compared to that of B(a)P group. Similarly, the tumor burden and multiplicity were seen to decrease by 87.3% and 69.6% respectively in mice of B(a)P+*A indica* group when compared to those of B(a)P group. Scanning electron microscopy analysis showed that AAILE treatment itself did not cause any abnormalities on the surface architecture of forestomach epithelium. In tumorous forestomach, surface disruption was observed. Over the forestomach tumors of B(a)P group of mice certain rounded structures were seen in addition to closely placed tongue-shaped squamous cells. Interestingly, these rounded structures were not observed in B(a)P + *A indica* group of mice. Histopathalogically, the tumors were identical and diagnosed to be papillomas. Mice from control and *A indica* groups of mice did not develop any forestomach tumors and showed normal histo-architecture.

CONCLUSION: The present data suggest that *A indica* exerts chemopreventive effects against B(a)P-induced forestomach tumors in murine model. Because of lack of toxicity and ubiquitous bioavailability, *A indica* may play a promising role in future drug discovery and development as far as chemoprevention of cancer is concerned.

INTRODUCTION

Recent estimates show that gastric cancer is the fourth most frequent type of cancer and the second most prevalent cause of cancer deaths worldwide[1]. Human beings are exposed to a multitude of carcinogens in their environment, and majority of the cancers are considered to be chemically-induced[2]. Polycyclic aromatic hydrocarbons (PAHs) are environmental carcinogens present in the atmosphere from combustion sources such as diesel exhaust, cigarette smoke, residential heating processes, refuse burning, industrial coke production, volcanic eruption, and oil contamination by effluents and oil spills[3]. They can also be generated by the pyrolysis of amino acids, fatty acids and carbohydrates during cooking process[4]. After inhalation, ingestion is the second most important exposure route for PAHs to enter the human body[5]. Stomach is the organ where engulfed/ingested materials come into prolonged contact with gastro-intestinal (GI) mucosa[6]. So it is quite reasonable to assume that stomach has high risk of developing cancer from carcinogens entering the GI tract. Benzo(a)pyrene

[B(a)P], a potent pro-carcinogen employed in initiating stomach cancer, is the prototypical and best characterized member of PAHs family of chemical carcinogens[7]. It has been shown to induce tumors of skin, lung, mammary glands and forestomach tissues of various experimental animals[8]. Since B(a)P is an omnipresent environmental pollutant and is believed to be a risk factor for human chemical carcinogenesis, it is important to identify the naturally occurring/synthetic agents that could modulate B(a)P-induced tumorigenesis[9].

In experimental studies as well as pre-clinical systems, several drugs have been discovered to combat cancer, but are not much in use because of their undesirable toxic side effects[10]. Moreover, most of the synthetic chemotherapeutic drugs available today are cytotoxic, immuno-supressants and may cause a variety of side effects in the normal organs of the body[11]. Prevention is an effective strategy to control the incidence of cancer. Recent progress in molecular biology and pharmacology enhances the likelihood that cancer prevention will increasingly rely on chemoprevention[12]. The later is a means of cancer control, in which the occurrence of disease as a consequence of exposure to carcinogen can be slowed, blocked or reversed by the administration of one or more naturally occurring or synthetic compounds[13]. Chemoprevention also deals with the chemotherapy of pre-cancerous lesions, which are called pre-invasive neoplasia, dysplasia or intra-epithelial neoplasia depending on the organ system[14]. It has been observed that the synthetic chemopreventive agents produce toxic side effects, which have limited their extensive use[15]. Plants, vegetables as well as medicinal herbs used in the folk and traditional system of medicine have been accepted currently as one of the main source of cancer chemopreventive drug discovery and development[16]. Ayurveda, the Indian traditional system of medicine, which dates back many centuries, uses many herbal extracts to cure a variety of diseases including cancer[17]. There is a growing interest in evaluation of chemopreventive efficacy of plants used in Ayurveda and one of such plants is *A indica* commonly called Neem.

A indica leaf extract has been reported to be non-toxic, non-mutagenic and possesses immuno-stimulant, hepato-protective, anti-oxidant, anti-genotoxic and anti-cancer activities[18]. The anticancer activities of *A indica* leaf extract have attracted much of the attention of research community in last few years. Subapriya *et al*[19] have observed chemopreventive activity of ethanolic *A indica* leaf extract against N-methyl-N-nitro-N-nitroso-guanidine-induced gastric carcinogenesis in rats. Dasgupta *et al*[9] have reported the chemopreventive effects of ethanolic *A indica* leaf extract against DMBA-induced TPA promoted skin and B(a)P-induced forestomach papillomagenesis. AAILE has been shown to ameliorate 4-nitroquinoline 1-oxide-induced oral tumorigenesis in male Wister rats[20] and 7-12 dimethylbenz(a)anthracine (DMBA)-induced buccal pouch carcinogenesis in Syrian hamsters[21]. Inhibitory effect of AAILE against DMBA-induced skin carcinogenesis in mice has recently been reported from our research laboratory[22].

Keeping in view the above mentioned reports, the present study was designed to evaluate the modulatory effects of AAILE, if any, on B(a)P-induced forestomach tumorigenesis in Balb/c mice. Tumor incidence, burden and multiplicity were taken as an index for chemopreventive tumor response. In addition to histopathology, scanning electron microscopy (SEM) of forestomach tumors was also done in an attempt to examine the surface morphology of tumorous forestomach. To the best of our knowledge the SEM of tumorous forestomach of Balb/c mice has not been reported yet.

MATERIALS AND METHODS

Materials

B(a)P was obtained from Sigma Chemical Co. (St. Louis, MO, USA). Olive oil used as a vehicle for B(a)P, and all other chemicals utilized were obtained from reputed local firms (India) and were of the highest purity grade. Capsules containing 100 mg of spray dried AAILE were obtained from a recognized herbal company (Dabur India Ltd). The contents of the capsules were dissolved in double-distilled water immediately before its oral administration to the mice in order to attain the required doses as described by Balasenthil *et al*[21]. The solution obtained after dissolving AAILE was covered with dark paper in order to protect the same from direct exposure to light.

Animal experiment

Random-bred virgin female Balb/c mice (6-8 wk old) procured from Central Animal House, Panjab University, Chandigarh were housed in polypropylene cages bedded with sterilized rice husk. All the mice were allowed to have free access to clean drinking water and standard animal pellet diet formulated on scientific backgrounds (Ashirwad Industries, Tirpari, Kharar, Distt. Ropar, Punjab) throughout the experiment. All the experimental protocols were approved by the Institutional Ethics Committee (Panjab University, Chandigarh, India) and conducted according to the Indian National Science Academy Guidelines for the use and care of experimental animals. Before the commencement of various treatments, mice were kept for acclimatization to experimental conditions for one week and the final day of their acclimatization period was considered as day 0 of the experiment. Mice were randomly divided into four groups (10-12 mice per group) namely control group, B(a)P group, *A indica* group and B(a)P + *A indica* group. Mice of B(a)P and B(a)P + *A indica* groups were given B(a)P for induction of forestomach tumor as described by Wattenberg *et al*[23], with minor modification. Briefly, each mouse received intra-gastric instillations of 40 mg B(a)P/kg in 0.2 mL olive oil, twice a week for four weeks from d 14 to d 42 of the experiment (a total of eight B(a)P instillations per mouse). Also, the animals of control and *A indica* groups received 0.2 mL of only olive oil in the same schedule. Mice of *A indica* and B(a)P + *A indica* groups were orally administered (using blunt tipped canula and a syringe) with AAILE at a dose of 100 mg/ kg thrice a week on alternate days throughout the experiment as described by Balasenthil

et al[21]. Mice from all the groups were observed for alterations in body weight and diet and water consumption. After 22 wk of the first B(a)P instillation, mice from all the groups were sacrificed by cervical dislocation under light ether anesthesia. The stomachs were carefully removed and processed for different parameters.

Chemopreventive tumor response

The stomachs were kept in expanded state by injecting them with 40 g/L buffered formaldehyde solution. Twenty-four hours later, the stomachs were split longitudinally and the forestomachs were carefully observed under the dissecting microscope for the presence of tumors. Forestomach tumors (1 mm in diameter) were counted/recorded for each mouse. The chemopreventive tumor response was assessed on the basis of tumor incidence, burden and multiplicity that were calculated as follows: tumor incidence: percentage number of animals having tumors; tumor burden: total number of tumors counted/total number of mice; tumor multiplicity: total number of tumors counted /number of tumor bearing mice.

Scanning electron microscopy

For SEM studies, the forestomachs from all the groups of mice were fixed in 4% gluteraldehyde prepared in 200 mmol/L phosphate buffer (pH 7.2) for two hours followed by two washings in phosphate buffer. After this, the tissues were dehydrated in ascending grades of acetone, i.e. 30%, 50%, 70%, 90% and absolute acetone (for 30 min per grade). Tissues were then immersed in a mixture of acetone and amyl acetate (1:1, V/V) followed by amyl acetate alone (30 min each). Following this, the tissues were subjected to critical point drying (CPD) to get rid of remaining water. After CPD, the tissues were pasted on metallic stubs and further trimmed as per requirement. The stubs were placed inside the sputter for gold coating (15 min). These were then viewed under scanning electron microscope of Jeol 2601, installed at Regional Sophisticated Instrumentation Center, Panjab University, Chandigarh.

Histopathology

Formalin fixed tissues were processed for HE staining using the conventional laboratory procedure. Briefly, the tissues were dehydrated through ascending grades of alcohol, cleared in benzene and embedded in low melting point paraffin. Sections of 5 micrometer thick were cut, placed serially on clean glass slides and then deparaffinised through descending grades of alcohol. Three contiguous sections were made from each forestomach tissue and stained with HE for evaluation under light microscope. The slides were coded, so that the particular sample identity was not known while performing assessment.

Statistical analysis

Statistical significance of differences for tumor burden and multiplicity was analyzed by Student's *t*-test. Comparison was carried out between B(a)P and B(a)P + *A indica* groups.

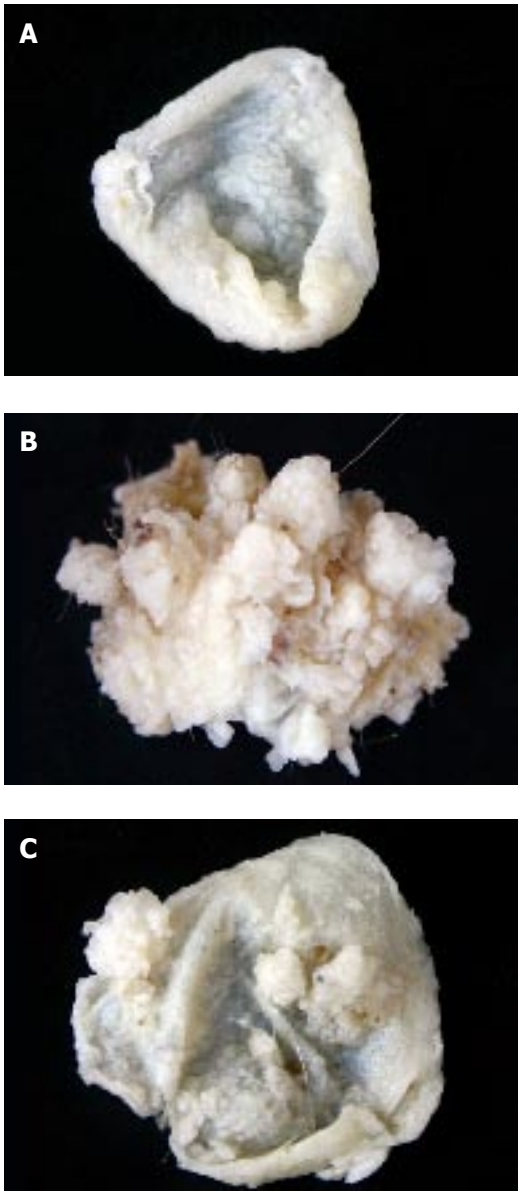

Figure 1 Gross anatomy of forestomach showing normal surface (**A**), tumorous surface in mice that received only B(a)P (**B**), and lesser number of tumors in mice that received AAILE along with B(a)P (**C**).

RESULTS

In the present study, it was noticed that the diet and water consumption by the mice in all the groups studied was approximately same during the entire experimental span (data not shown). Mice from all the groups showed normal body growth and gained weights when compared to their respective initial body weights (Table 1). It was observed that the mice from B(a)P and B(a)P + *A indica* groups developed forestomach tumors, whereas none of the mice from control & *A indica* groups developed forestomach tumors (Figures 1A-C). Tumor incidence was observed to be 100% in B(a)P group of mice. However, the tumor incidence was found to be 41.6% in the mice of B(a)P + *A indica* group, i.e. the mice that received AAILE treatments along with B(a)P instillations. This experiment clearly

Table 1 Modulatory effects of AAILE on B(a)P-induced forestomach tumorigenesis in Balb/c mice

Groups	Body mass (g)		Tumor incidence	Tumor burden	Tumor multiplicity	No. of Tumors (Min-Max)
	Initial	Final				
Control	22.1±1.51	27.6±1.64	0 % (0/10)	-	-	-
B(a)P	22.6±1.68	26.5±2.24	100 % (12/12)	7.25±2.80	7.25±2.80	5-14
A indica	22.4±1.78	27.8±1.94	0 % (0/10)	-	-	-
B(a)P+*A indica*	22.3±1.64	27.1±1.64	41.6% (5/12)	0.92±1.24[b]	2.20±0.84[b]	0-3

[b]$P<0.001$ *vs* B(a)P.

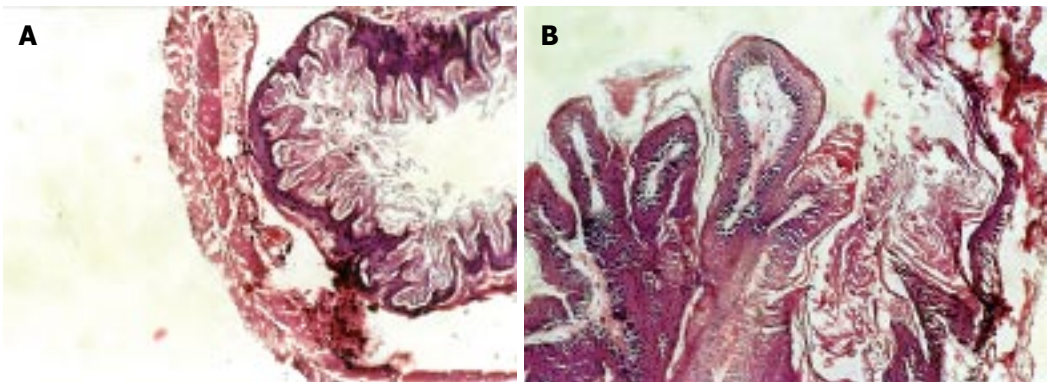

Figure 2 Histo-micrograph of forestomach. **A**: Control mice showing squamous mucosa, sub-mucosa and muscular layers X 20; **B**: Papillary projections, disrupted submucosa and muscular layers X 20.

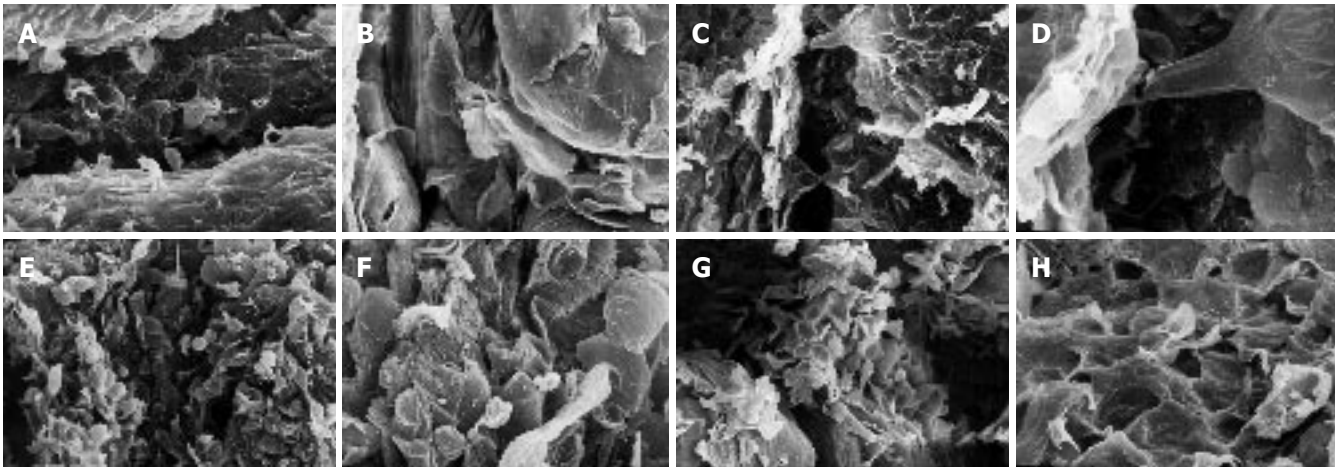

Figure 3 SEM of forestomach of mice. **A**: Control mice showing grooves and ridges X 200; **B**: Control mice showing tongue-shaped squamous epithelium X 600; **C**: Mice treated with only AAILE showing grooves and ridges X 200; **D**: Mice treated with only AAILE showing squamous epithelial cells X 600; **E**: Mice received only B(a)P showing ruptured surface X 200; **F**: Mice received only B(a)P showing certain rounded structures in addition to tongue-shaped squamous epithelial cells X 600; **G**: Mice received AAILE along with B(a)P instillations showing surface rupturing X 200; **H**: Mice received AAILE along with B(a)P instillations showing tongue shaped squamous epithelial cells X 600.

demonstrated that AAILE potentially reduced the tumor incidence by 58.4 %. The tumor burden was observed to decrease significantly (approximately 7.88 fold) upon AAILE treatment when the mice of B(a)P+*A indica* group were compared to that of B(a)P group. Similarly, the tumor multiplicity was observed to decrease (approximately 2.59 folds) upon AAILE treatment as seen in mice of B(a)P + *A indica* group when compared to that of B(a)P group (Table 1). In another similar investigation, Dasgupta *et al*[9] reported that the administration of ethanolic neem leaf could reduce the tumor incidence by 39% during B(a)P-induced forestomach tumorigenesis in Swiss albino mice.

Forestomach of control group as well as *A indica* group of mice showed normal surface morphology with distinct grooves and ridges (Figures 3A and 3C). Mucous sheath at certain places and tongue-shaped keratinized squamous epithelial cells arranged in layers like tiles were observed[24] (Figures 3B and 3D). These observations suggested that AAILE treatment itself could not cause any abnormalities over the epithelium. In forestomach of tumor bearing mice, surface disruption was observed at the sites of tumor development (Figures 3E and 3G). In forestomach tumors of the mice that received only B(a)P, within the closely placed squamous epithelial cells, in addition to tongue-shaped cells certain rounded to irregularly shaped structures were seen (Figure 3F). The observed rounded structures could be transformations

of tumorous cells. However in tumors of the mice that received AAILE treatments along with B(a)P instillations, such structures were not seen (Figure 3H). Their absence in the forestomach tumors of B(a)P + *A indica* group of mice could be attributed to the different cytotoxic effects of the phytochemical components present in AAILE.

Histopathological analysis showed that forestomach of mice from control and *A indica* groups depicted normal histoarchitecture with distinct muscular layers, sumucosa and squamous mucosa (Figure 2A). The tumors developed in B(a)P and B(a)P + *A indica* groups were observed to be similar and diagnosed as papillomas with endophytic growth in the form of papillary projections having fibro-vascular core lined by stratified squamous epithelium (Figure 2B). Though the tumors developed in B(a)P as well as in B(a)P + *A indica* were similar histopathologically, our observations clearly suggested the chemopreventive effects of AAILE against B(a)P induced forestomach tumorigenesis.

DISCUSSION

Stomach cancer is the second most prevalent malignancy in the world and chemoprevention has evolved as an effective strategy to combat this dreadful disease[25]. Fruits, vegetables, vitamins, common beverages and several medicinal plants/herbs with diversified pharmacological properties have been shown to be a rich source of cancer chemopreventive agents[26]. *A indica*, one of the most versatile traditional medicinal plants, has been known to possess a wide spectrum of medicinal properties and is used in Ayurveda to cure several ailments including cancer. In the present piece of research work, an attempt was made to evaluate the modulatory effects of AAILE against B(a)P-induced forestomach tumorigenesis.

B(a)P, an extremely potent pro-carcinogen, is metabolized by biotransformation enzymes to a variety of metabolites that are responsible for initiating tumorigenesis[27]. Biotransformation enzymes have broadly been divided into two categories namely phase-I and phase-II biotransformation enzymes. The former constitutes cytochrome P-450 based mono-oxygenase system which is responsible for initiating conversion of pro-carcinogens to several of their metabolites including ultimate carcinogens. Glutathione-S-transferase (GST) is a major phase II detoxifying enzyme that primarily functions in catalyzing the active carcinogenic metabolites to endogenous ligand-reduced glutathione (GSH) favoring their elimination from the body of the organisms[28]. The balance between the phase I carcinogen-activating enzymes and the phase II detoxifying enzymes is critical to determining an individual's risk for cancer[29]. There is substantial evidence that chemopreventive agents including medicinal plants exert their anti-carcinogenic effects by modulation of phase I and phase II xenobiotic biotransformation enzymes[30]. A significant reduction in the activity of cytochrome P450 and cytochrome b_5 (phase I enzymes) in hepatic tissue of mice upon AAILE treatment has recently been reported from our laboratory[31]. Ethanolic *A indica* leaf extract can exert down-regulatory effect on the activity of cytochrome P450 and cytochrome b_5 in some organs like liver, kidney and forestomach of mice[9]. Maintaining rats on diets containing neem flowers has been reported to decrease the activity of cytochrome P-450 in hepatic tissue that have been correlated with inhibition of aflatoxin B-1- and DMBA-induced liver and mammary gland carcinogenesis respectively[32]. *A indica* leaf extract can also enhance the activity of GST as well as GSH contents (phase II components) in different tissues of a number of experimental animal models[9,21,31]. These observations suggest that the AAILE treatment decreases the metabolic activation with simultaneous increase in the detoxification of B(a)P. Therefore the chemopreventive effects of AAILE observed in the present study could be ascribed, at least in part, to its ability to modulate certain components of carcinogen biotransformation system.

Reactive oxygen species (ROS) are widely generated in biological systems either by normal metabolic pathways or as a consequence of exposure to chemical carcinogens leading to oxidative stress that may further result in membrane dysfunction, protein inactivation, DNA damage ultimately contributing to the process of carcinogenesis[33]. For protection against the deleterious effects of these ROS, organisms have developed a sophisticated antioxidant defense system which has enzymatic as well as non-enzymatic components. The antioxidant defense system includes enzymes like glutathione peroxidase (GPx), catalase, glutathione reductase (GR), GST and superoxide dismutase (SOD), whereas non-enzymatic components include non-protein thiol GSH, uric acid, some trace metals and certain vitamins such as ascorbic acid and alpha-tocopherol, *etc*[34]. *A indica* leaf extract has been shown to enhance the activities of all the above mentioned antioxidant defense enzymes and GSH contents in various tissues of mice and rats[9,19]. Increased antioxidant defense upon AAILE treatment could lower the ROS-mediated damage at the initiation as well as progression/promotion phase of the process of tumorigenesis.

Nimbin is the first phyto-chemical compound that has been isolated from *A indica* seed oil[35] and now approximately 140 different phytochemicals have been identified and isolated from various parts of this plant[36]. The anti-carcinogenic effects of this tree are also attributed to its antioxidant phytochemicals such as flavonoids[37]. Quercetin and kaemferol are the flavonoids present in neem leaf that have been documented to retard carcinogenesis at initiation, as well as promotion phases of carcinogenesis by virtue of their radical scavenging properties[38,39]. Although we did not carry out quantitation and characterization of individual components from AAILE in this study, the contribution of antioxidant phytochemicals of AAILE in reducing the extent of tumorigenesis can not be ruled out.

Yadav *et al*[40] showed that mitotic activity can be inhibited by *A indica* leaf extract. Baral *et al*[41] reported that the growth of Ehrlich carcinoma and B16 melanoma cells is reduced significantly after administration of *A indica* leaf extract. Limonin 17β-D-glucopyranoside, a limonoid found in neem, can inhibit DMBA-induced oral carcinogenesis[42]. Azadirone 1, a limonoid constituent of *A indica* possesses cytotoxic activity against breast, melanoma and prostate cancer cell lines[43]. Cytotoxicity of azadirachtin A has been reported in human glioblastoma cell lines by

Akudugu *et al*[44]. Nimbolide and 28-deoxonimbolide have been identified as cytotoxic constituents of *A indica* leaves[45]. Intra-peritoneal administration of some isolated polysaccharides from *A indica* is active against sarcoma -180 ascites tumor cells in mice[46]. In another investigation Petit *et al*[47] reported that some active components of *A indica* show cytotoxic effects against murine P_{-388} lymphocytic leukemia. In the present study, since AAILE was given throughout the experiment, the cytotoxic effects of its active constituents against pre-cancerous / tumorous cells could not be denied.

In *in-vivo* experiments, it has been observed that *A indica* leaf extract treatment does not alter the activity of cellular lactate dehydrogenase (an indicator of cell damage) in the hepatic tissues, suggesting that the leaf extract itself does not exert any adverse effects[9]. Also, it is generally believed that the crude therapeutic preparations are more effective and less toxic than the isolated active components[48] or their respective synthetic counterparts because they contain the total family of medicinal compounds (known and unknown) just as they are found in their natural source and hence offer less risk of side effects. In crude preparations, perhaps, the other components present in addition to the active components may affect the effects of the active components. These known and unknown components might act as synergists for the therapeutic effects and antagonists for the side effects of the active components as well as the other toxic components in the crude preparation[49].

The present data together with reports available in literature, suggest that *A indica* has immense chemopreventive potentials as far as B(a)P-induced forestomach tumorigenesis is concerned. *A indica*-based therapeutic preparations have already been used in the Indian traditional system of medicine for several ailments. Previous experimental investigations along with the present study support the rational use of these preparations for chemoprevention of certain types of cancers. Because of lack of toxicity and ubiquitous distribution of this plant in nature, *A indica* seems to be a valuable plant source for use in modern chemopreventive drug discovery and development.

Abstract

AIM: To compare ecabet sodium and cimetidine in relieving symptoms of functional dyspepsia.

METHODS: We performed a multi-center, prospective, randomized, double-blinded controlled trial to compare the clinical efficacy of ecabet sodium and cimetidine in patients with functional dyspepsia. Two-hundred and seventy-two patients with dyspeptic symptoms fulfilling the Rome-II criteria were enrolled from 7 centers. In the study group (115 patients), 1.5 g ecabet sodium was given twice a day. In the control group (121 patients), 400 mg cimetidine was given twice a day. Symptoms and parameters of quality of life were analyzed at baseline, 3, 14, and 28 d after initiating the treatment.

RESULTS: Two-hundred and thirty-six patients completed the clinical trial. After 4 wk of treatment, the rates of improvement in patients with dyspeptic symptoms were not different between two groups (77.4% in the ecabet group and 79.3% in the cimetidine group, respectively, $P > 0.05$). Likewise, the rates of symptomatic improvement were not different at 3 d and 14 d. The parameters of quality of life did not change significantly during the study period in both groups. There was no clinically significant adverse event in both groups.

CONCLUSION: In patients with functional dyspepsia, ecabet sodium has similar clinical efficacy with cimetidine.

INTRODUCTION

Functional dyspepsia is defined as persistent or recurrent abdominal pain or abdominal discomfort centered in the upper abdomen which cannot be explained by structural or biological abnormalities[1,2]. Discomfort refers to unpleasant sensations that the subject does not interpret as pain and may be characterized by upper abdominal fullness, early satiety, bloating, belching, or nausea. For the diagnosis of functional dyspepsia, there should be no relationship between dyspeptic symptoms and bowel movements (i.e., irritable bowel syndrome does not explain the symptoms), and patients with predominant heartburn should be excluded.

At present, the pathophysiology of functional dyspepsia is not fully elucidated. Several mechanisms have been suggested to explain the development of dyspeptic symptoms, including delayed gastric emptying[3], impaired gastric accommodation to a meal[4], hypersensitivity to gastric distention[5,6], *Helicobacter pylori* (*H pylori*) infection[7], and central or peripheral nervous system dysfunction[8].

However, there is growing evidence that functional dyspepsia is in fact a very heterogeneous disorder and different subgroups can be identified based on different demographic, clinical, and pathophysiologic features[2].

Pharmacological treatment for patients with functional dyspepsia remains unsatisfactory. The results of studies with H_2-receptor antagonists have been conflicting[9,10]. Proton pump inhibitors appear to be superior to placebo, but not in dysmotility-like dyspepsia[11]. Cisapride has also been demonstrated to be effective[12], but it has been reported that cisapride is not superior to placebo[13]. Therefore, it seems likely that acid-suppressing agents and prokinetic agents are, at best, only effective in some subgroups of dyspeptic patients.

Ecabet sodium (ES), a 12-sulfodehydroabietic acid monosodium salt, is a novel non-systemic anti-ulcer agent[14-16] and belongs to the category of gastroprotective agents[17]. The utility of ES in clinical setting has been demonstrated in various clinical trials for patients with peptic ulcer, ulcerative proctosigmoiditis, and *H pylori* infection[18-21]. In this prospective randomized controlled study, we attempted to assess the efficacy and safety of ES in patients with functional dyspepsia.

MATERIALS AND METHODS

Patients

From October 2003 to September 2004, this trial was performed at 7 centers in Korea. A total of 272 patients with functional dyspepsia according to Rome-II criteria were enrolled. Upper gastrointestinal endoscopy was performed to exclude a structural cause of the symptoms. All patients understood the purpose and method of this study and agreed to this clinical trial with written informed consent.

Exclusion criteria included age under 18 years or over 75 years, pregnancy or lactation, regular use of steroids or NSAIDs, an experience in administration of any drug for treating the subject disease, including gastric acid secretion inhibitors (proton pump inhibitor, H2-blocker, etc.) within 4 wk of enrollment. Patients demonstrating gastric ulcer or duodenal ulcer on upper gastrointestinal endoscopy, were excluded from this study. Other exclusion criteria included gastroesophageal reflux disease with typical symptoms like heartburn or acid regurgitation, malignant diseases, and serious hepatic, cardiovascular, renal, or hematological diseases. Patients who were unable to answer the visual analogue scale question due to poor intellectual power were also excluded.

Methods

A prospective, double-blinded, randomized, comparative trial was performed in 7 centers. Patients were randomized to receive either ecabet sodium (1.5 g p.o, bid) or cimetidine (400 mg p.o, bid) for 4 wk. All medications were given within 30 minutes after breakfast and just before going to bed.

At screening, upper gastrointestinal endoscopy, complete blood cell counts, blood chemistries and serology for *H pylori* infection were performed. If the result of upper gastrointestional endoscopy within 3 mo of the enrollment was not significant, repeat endoscopic examination was not performed. At the beginning of the study, patients were required to give written informed consent and to answer the questionnaire for the evaluation of the quality of life and for individual dyspeptic symptoms. Assessment of the quality of life using the same questionnaire was repeated at the end of the treatment.

The symptoms were evaluated 4 times (baseline, 3, 14, and 28 d) using index of dyspepsia symptoms-Koreans (IDS-K) questionnaire validated in Korea[22]. This questionnaire format was designed to evaluate 12 typical upper gastrointestinal symptoms using 10-cm visual analogue scale. In addition, patients were asked to judge the global improvement of symptoms as significant improvement, somewhat improvement, no change, somewhat worsen, and severely worsen. In order to measure the overall efficacy of the medication, treatment effect was categorized into 2 groups. Significant improvement and somewhat improvement were judged as improved, while no change, somewhat worsen and severely worsen were judged as not improved.

For the evaluation of the quality of life, FD-QoL questionnaire was completed in coordinator's interview before and at the end of the treatment. The questionnaire was consisted of 21 items of 4 dimensions (5 questions for the eating status, 4 questions for the liveliness status, 6 questions for the psychologic status, and 6 questions for the role-functioning status). Higher scores indicated better quality of life. The sum of scores was calculated and compared to assess the quality of life before and after the treatment. Safety of the medication was evaluated by the assessment of significant adverse events. At the end of the treatment, complete blood cell counts and blood chemistries were repeated.

Statistical analysis

Efficacy data analyses were performed based on per-protocol analysis set. Clinical characteristics of target patients were summarized with technical statistics. Consecutive variables were described with mean ± SD and the categorical variables with proportion. With respect to the global improvement of symptoms, effective group and non-effective group were classified and compared using χ^2-test. With respect to the quality of life, a paired *t*-test was used to compare the difference of the sum of scores by each dimension between before-treatment and end-of-treatment. Additionally, subgroup analyses of the symptom score and the score of quality of life were conducted according to age, infection of *H pylori* and sex.

RESULTS

Patient characteristics

A total number of 272 patients (133 patients in ecabet group, 139 patients in cimetidine group) with functional dyspepsia were enrolled. In both groups, there was no significant difference in demographic characteristics including age, sex, weight, height, rate of smokers, and rate of alcohol intake (Table 1). Thirty-six patients (18 patients in ecabet group, 18 patients in cimetidine group)

Table 1 Demographic characteristics of the enrolled patients

Group	Ecabet group (n = 133)	Cimetidine group (n = 139)	P
Gender (male:female)	47:86	47:92	NS
Age (yr)	45.0±12.9	47.5±12.5	NS
Weight (kg)	59.6±10.0	58.5±9.0	NS
Height (cm)	162.7±8.0	161.8±7.7	NS
Smoking (%)	23 (17.3)	16 (11.5)	NS
Alcohol intake (%)	47 (35.3)	38 (27.3)	NS

Table 2 Prevalence of *Helicobacter pylori* infection

Group	Positive (%)	Negative (%)	Undetermined (%)
Ecabet group (n=120)	44 (36.7)	45 (37.5)	31 (25.9)
Cimetidine group (n=128)	40 (31.3)	60 (46.9)	28 (21.9)

Pearson's chi-square test; P=NS.

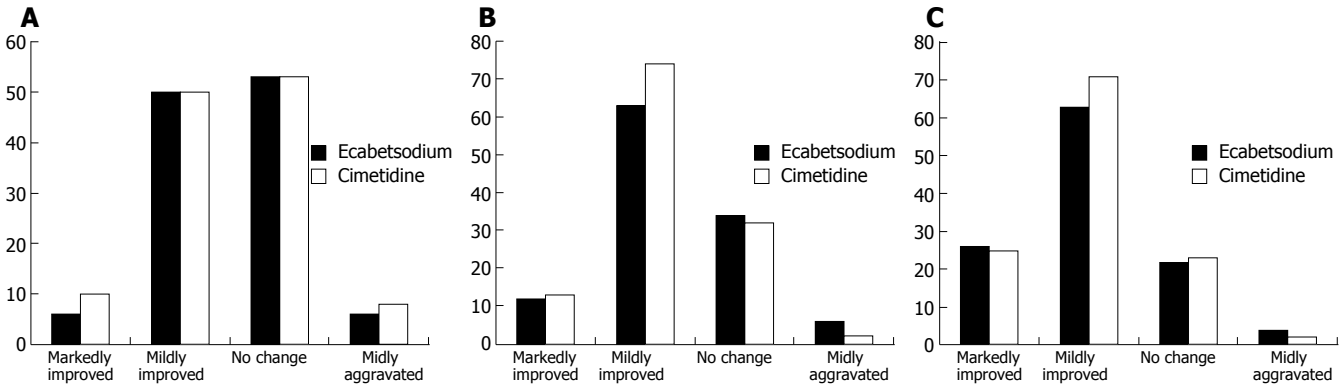

Figure 1 Comparison of the rate of the symptomatic improvement in both groups at 3 d (**A**), 2 wk (**B**) and 4 wk (**C**) of medication.

Table 3 Global assessment of symptomatic improvement after 4 wk of medication

Group	Ecabet group (n = 115) (%)	Cimetidine group (n = 121) (%)
Improved	89 (77.4)	96 (79.3)
Not improved	26 (22.6)	25 (20.7)

Pearson's chi-square test: P=0.71.

of them were dropped out. A total of 236 patients (115 patients in ecabet group, 121 patients in cimetidine group) were included in the per-protocol analysis. There was no significant difference between two groups in medication compliance 2 and 4 wk after administration. There was no significant difference between treatment groups with the respect to the proportion of patients with *H pylori* infection (Table 2).

Improvement of symptoms

For the measurement of the overall rate of improvement, a question for global symptomatic assessment was used. The result of evaluation of symptoms at baseline, 3 d, 14 d and 28 d after treatment demonstrated no significant difference between the groups (Figures 1A-C). However, both groups showed significant improvement of symptoms at 2 and 4 wk compared to the baseline (Figures 1B, IC).

When significant improvement and somewhat improvement were considered as improved, and no change, somewhat worsen, and severely worsen as not improved, the rate of improvement at 4 wk was not different between ecabet group and cimetidine group (Table 3) (P=0.53). The sum of 12 symptom scores of both groups was not different at 3 d, 2 wk and 4 wk (P=0.84).

Quality of life

The parameters of quality of life were categorized into eating status, liveliness status, psychological status, and role-functioning status. In both groups, the sum of quality of life scores in each category did not change significantly after treatment (Table 4).

Change of laboratory results

After treatment, there was no significant change in laboratory parameters such as WBC count per mm^3, ESR, and CRP in both groups.

Subgroups analysis: H pylori status, age and sex

The patients were grouped by serologic result with *H pylori*-positive group and -negative group. With the respect to the global improvement of symptoms, there was no significant difference between two groups regardless of *H pylori* infection (Table 5). In the subgroups by the age, categorized with less than 50 years old and equal/over 50 years old groups, there was no difference in the global symptom improvement in both groups (Table 6). In the subgroups by the gender, there was also no difference in the global symptom improvement in both groups (Table 7).

Adverse effects

There was no severe adverse event during the study period. Three patients among 133 patients in the ecabet group reported mild adverse events, such as diarrhea, rash

Table 4 Comparison of quality of life scores before and after treatment (mean ± SD)

Status	Before treatment			After treatment

and abdominal pain. However, the events were treated with simple symptomatic treatments. Two patients among 139 patients in the cimetidine group complained of mild diarrhea. In the chemistry at 4 wk, mild transient elevation of transaminases occurred in 1 case in the ecabet group and 1 case in the cimetidine group, respectively.

DISCUSSION

Functional dyspepsia is a symptom complex characterized by postprandial upper abdominal discomfort or pain, early satiety, nausea, vomiting, abdominal distention, bloating, and anorexia in the absence of organic disease. In this study, we used the Rome-II criteria for the exact identification of patients with functional dyspepsia[1].

The major pathophysiological mechanisms responsible for functional dyspepsia include psychosocial factors and alterations in motility and visceral perception. Approximately 50% of patients with functional dyspepsia have motor disorders, such as impaired fundic relaxation, antral dilatation and/or hypomotility, gastroparesis. It is also observed that symptoms of functional dyspepsia are related to or worsen by several psychological factors, such as negative feelings as anxiety and/or depression, abnormal stress response, dependence personality, change of coping strategy, *etc*[2-4]. The important mental element related with patients with functional dyspepsia is stress of daily life. At present, administration of antidepressants has been found to be useful for only a few patients, control of psycho-sociable element is not assessed yet[2].

Ecabet sodium (ES) is a newly developed anti-inflammatory/anti-ulcer agent and belongs to the category of gastroprotective agents[14-16]. Proposed mechanisms of action include improved blood flow in the gastric mucosa, increased gastric mucin, increased gastric mucosal PG E2, and decreased activity of pepsin[15,19]. It was reported that ES increases the eradication rate of Helicobacter pylori in dual therapy with lansoprazole and amoxicillin[18]. In patients with gastric ulcer treated with cimetidine, additional use of ES significantly accelerates rates of ulcer healing and symptomatic relief[19]. Maintenance therapy with a combination of ranitidine and ES prevents ulcer relapse in Helicobacter pylori-positive patients[20]. Interestingly, ES enemas have been proved to be a safe and potentially useful adjuvant therapy in patients with mildly to moderately active ulcerative proctosigmoiditis[21].

There are only a few clinical studies examining the effect of mucosal protective agents in patients with functional dyspepsia. A double-blind placebo-controlled multicenter study examining the effect of rabamipide in patients with functional dyspepsia reported that there is no significant improvement of individual symptom scores in rebamipide group compared to placebo group[23]. However, the efficacy of ES for patients with functional dyspepsis has never been reported in the literature. In this study examining the efficacy of ES in patients with functional dyspepsia, ES showed equivalent outcomes in most clinical indexes compared to a representative H_2 receptor antagonist (cimetidine). Rates of improvement of global symptoms were not different at 3 d, 14 d, and 28 d after starting treatment (Table 3). At the end of the 4-wk treatment, 77.4% of patients in ecabet group and 79.3% of patients in the cimetidine group reported improvement of global symptoms ($P > 0.05$). In the analysis of 12 individual symptoms, there was no significant difference

in both groups. In the subgroup analysis by age, gender and *H pylori* infection status, we could not find any factors affecting the rate of improvement.

Health-related quality of life is becoming increasingly recognized as an important outcome for patients with chronic diseases[24]. Patients with functional dyspepsia can experience significant levels of abdominal pain that interrupt daily activities, so quality of life is impaired[25]. In patients with functional dyspepsia, therefore, the impact of treatment on the quality of life can be a good measure of treatment outcome. For the evaluation of the quality of life, we used the IDS-K questionnaire, which was recently developed and validated in Korea[22]. Despite improvement of dyspeptic symptoms during the treatment period, we could not find any significant change in any dimension of our questionnaire before and after the 4-wk treatment (Table 4). One possible reason for this discrepancy may be that the duration of 4-wk treatment may be too short to document a significant change in quality of life. Longer-term treatment may be necessary for the exact evaluation of the impact of treatment on the quality of life in dyspeptic patients.

The major limitation of the present study is the lack of treatment arm using placebo. In this study, we could see a significant improvement of symptoms in both ecabet group and cimetidine group. The reported response rates of cimetidine for patients with non-ulcer dyspepsia are quite variable. Nyren *et al*[26] reported that the mean reduction in pain intensity after three weeks is less than 30% in both placebo and cimetidine group. In a meta-analysis of placebo-controlled studies for non-ulcer dyspepsia, the mixed response rate for cimetidine treatment is 67.3% (272/404)[27]. In the present study, the response rate of ecabet group was 77.4%, and that of cimetidine group was 79.3% (Table 3). The rate of improvement in this study seemed to be a little bit higher than that in the previous studies. In our opinion, differences in the patient population and the definition of improvement may be possible explanations. In the present study, there was no arm for the placebo, so we could not exclude the possibility that the outcome of this study might be a placebo effect. In the previously mentioned meta-analysis, however, the mixed response rate for placebo is 49.1% (183/372)[25]. In order to determine the efficacy of ES for functional dyspepsia more exactly, long-term randomized clinical trial with placebo arm is mandatory.

In conclusion, 4-wk treatment with ES demonstrates equivalent symptom improvement compared to a representative H_2-receptor antagonist (cimetidine) in patients with functional dyspepsia.

Abstract

AIM: To explore the influence of angiostatin up-regulation on the biologic behavior of gallbladder carcinoma cells *in vitro* and *in vitro*, and the potential value of angiostatin gene therapy for gallbladder carcinoma.

METHODS: A eukaryotic expression vector of pcDNA3.1(+) containing murine angiostatin was constructed and identified by restriction endonuclease digestion and sequencing. The recombinant vector pcDNA3.1-angiostatin was transfected into human gallbladder carcinoma cell line GBC-SD with Lipofectamine 2000, and paralleled with the vector and mock control. The resistant clone was screened by G418 filtration. Angiostatin transcription and protein expression were examined by RT-PCR, immunofluorescence and Western-blot. The supernatant was collected to treat endothelial cells. Cell proliferation and growth *in vitro* were observed under microscope.

RESULTS: Murine angiostatin cDNA was successfully cloned into the eukaryotic expression vector pcDNA3.1 (+). After 14 d of transfection and selection with G418, macroscopic resistant cell cloning was formed in the experimental group transfected with pcDNA 3.1(+)-angiostatin and vector control. But untreated cells died in the mock control. Angiostatin was detected by RT-PCR and protein expression was detected in the experimental group by immunofluorescence and Western-blot. Cell proliferation and growth *in vitro* in the three groups were observed respectively under microscope. No significant difference was observed in the growth speed of GBC-SD cells between groups that were transfected with and without angiostatin. After treatment with supernatant, significant differences were observed in endothelial cell (ECV-304) growth *in vitro*. The cell proliferation and growth were inhibited.

CONCLUSION: Angiostatin does not directly inhibit human gallbladder carcinoma cell proliferation and growth *in vitro*, but the secretion of angiostatin inhabits endothelial cell proliferation and growth.

INTRODUCTION

Gallbladder carcinoma is the most common malignant tumor of the biliary tract and a particularly high incidence is observed in Chile, Japan, and northern India. After common treatment, the prognosis of gallbladder carcinoma patients is poor[1].

A large body of work by a number of laboratories in the past 3 decades has provided both direct and indirect evidence that tumor growth and metastasis are accompanied with the growth of new blood vessels[2].

As previously reported, angiostatin is a potent antiangiogenic endogenous protein[3]. In the present study, we constructed a mammalian expression vector that was cloned as an angiostatin gene. Following stable transfection of this vector into human gallbladder carcinoma cell line GBC-SD, we observed the expression of angiostatin and its antiangiogenic effect by evaluating the influence of cultured human umbilical vein endothelial cells (ECV-304).

MATERIALS AND METHODS

Cell lines and reagents

The human gallbladder carcinoma cell line GBC-SD and the endothelial cell line ECV-304 were purchased from

China Center for Type Culture Collection. EcoRI, XbaI, PmeI, HindIII, XbaI and PvuIwere purchased from Bioson Corporation. Lipofectamine™ 2000 and G418 were purchased from Gibco Company. Recombinant eukaryotic expression vector pcDNA3.1(+)-angiostatin and rabbit anti-HAtag multiclonl antibody were presented by Dr. Jicheng Zhang. Trizol reagent, reverse transcriptase, and Taq DNA polymerase were purchased from Life Technologies, Inc. FITC was purchased from Boster Biological Technology Co.

Cell culture

Gallbladder carcinoma cells and endothelial cells were cultured in RPMI1640 (Gibco) supplemented with 10% fetal bovine serum (FBS) (Sijiqing, Hangzhou, China), penicillin (100 units/mL) and streptomycin (100 mg/mL) in a humidified atmosphere containing 5% CO_2 at 37 ℃.

Recombinant eukaryotic expression vector pcDNA3.1(+)-angiostatin construction

Mouse angiostatin cDNA fragment encoding for the NH2-terminal secretory signal sequence(SS) and kringle1-4(K1-4) regions of mouse plasminogen, fused with an antigenic epitope tag HA(HA tag) to the COOH terminus of kringle 4, was inserted into enkaryotic expression vector pcDNA3.1(+). The structure of the recombinant vector pcDNA3.1(+)-angiostatin was confirmed by restriction endonuclease digestion and sequencing. Recombinant clones were identified by HindIII, XbaI and PmeI digestion. Positive clones were further confirmed by sequencing.

Transfection of pcDNA3.1-angiostatin into GBC-SD

Gallbladder carcinoma cells (GBC-SD) in logarithmic growth phase were plated on 24-well plates at 2×10^5 cells/well, and approximately 80% confluence was obtained after overnight incubation. Cultured GBC-SD cells were divided into three groups: transfected with recombinant pcDNA3.1-angiostatin (group A), pcDNA3.1 (+) vector (group B) and without pcDNA3.1 (+) vector(group C). Transfection was performed according to the instructions of Lipofectamine TM2000 reagent kit (Gibco). The cells were then cultured in complete medium containing G418 (50 mg/L) for 14 d. G418-resistant pooled cells were subjected to further studies. Then the isolated resistant cell clones were selected and amplified. Cell growth curve was also plotted.

Analysis of angiostatin transcript by RT-PCR

Total RNA was isolated from GBC-SD cells using Trizol reagent. Reverse transcription was performed with 1 ug of total RNA in a total volume of 20 μL containing reverse transcriptase. The PCR reagents, including 0.5 units of Taq DNA polymerase, were added to a final volume of 25 μL. A 35-cycle amplification profile consisted of denaturation at 94 ℃ for 1 min, annealing at 56 ℃ for 1 min, and extension at 72 ℃ for 1 min. Primers used in PCR were designed according to the reported angiostatin cDNA sequence. The primer sequences were as follows: 5'end: 5' -CCCAACATGGACCATAAGGAAGT-3' and 3'end: 5' -TGTGGGCAATTCCACAACACTC-3'. Human-actin primers were used as positive controls. Negative controls without RNA and reverse transcriptase were also assessed. The PCR products were identified by 1% agarose gel electrophoresis.

Analysis of angiostatin protein by Western blot and immunofluorescence cytochemistry

GBC-SD cells with pcDNA3.1(+)angiostatin in logarithmic growth phase were implanted into 6-well plates. After 24 h, the glass flake was taken out and imunofluorescence cytochemistry was carried out. For immunofluorescence, cells on glass flake were fixed for 15min in 3.7% formaldehyde in PBS containing 1mM EGTA at room temperature. After fixation, the cells were made permeable by incubating with 0.2% Triton X-100 in PBS for 15 min, and then washed with PBS. After being blocked with PBS including 1% BSA, antibodies were applied and incubated for 1h at 37 ℃. The cells were then stained with secondary antibodies. After being washed with PBS, the expression was detected under fluorescent microscope.

The cells in the three groups were cultured in conditioned media for 5 d. Cell supernatant was mixed with lysine-sepharose and incubated at 4 ℃ overnight. The resin was washed with Tris-HCl (pH8.0) and protein was eluted. Protein concentration was determined by bicinchoninic acid assay (BCA) with bovine serum albumin as standard. Equal aliquots (40 μg) of protein from cell supernatants were subjected to electrophoresis on 10% sodium dodecyl sulfate (SDS)-polyacrylamide gel. Proteins were transferred onto PVDF membranes (mMillipore) using the transfer buffer for 2 h. The membranes were then blocked for 1.5 h using 5% nonfat dried milk in phosphate-buffered saline containing 0.1% Tween 20 (PBS-T), washed with PBS-T, and incubated at 4 ℃ overnight in the presence of anti-rabbit HA-tagged antibody.The membranes were washed with PBS-T and incubated with secondary peroxidase-conjugated anti-rabbit immunoglobulin G for 1 h. Following washing with PBS-T, immunoreactive bands were visualized by the enhanced chemiluminescence system (Amersham Life Science).

Viable cell number counting and growth curve

In logarithmic growth phase of the three groups of gallbladder carcinoma cells (GBC-SD), the supernatant was collected. Endothelial cells (ECV-304) were plated onto 24-well plates at 1×10^4 cells/well and ECV-304 cells were treated with supernatant separately for 7 d (supernatant/medium=1/9). Viable cells were counted under microscope everyday and growth curves were plotted.

Statistical analysis

Data were analyzed by statistical software of SPSS 10.0. Differences between groups were examined by Student's *t* test. $P<0.01$ was considered statistically significant.

RESULTS

Identification of recombinant plasmid pcDNA3.1(+)-angiostatin

The recombinant plasmid was released by restrictive digestion with HindIII, XbaI and PmeI. As shown in electro-

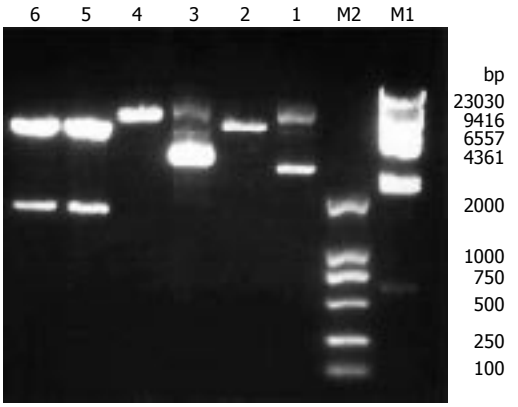

Figure 1 Identification of angiostatin cDNA insertion in pcDNA3.1(+)-angiostatin. phoresis, the linear recombinant plasmid was about 7.0kb, being a fragment of 1.4kb, suggesting that angiostatin fragment was inserted into the pcDNA3.1 (+) vector, named recombinant plasmid pcDNA3.1- angio (Figure1). The sequence obtained was the same as the reported sequence of angiostatin cDNA, indicating that the murine gene was successfully cloned into the eukaryotic expression vector pcDNA3.1 (+).The recombinant plasmid was linearized by *pvu* I(Figure 2).

Vector-mediated expression of angiostatin in vitro

Gallbladder carcinoma cells (GBC-SD) transfected with the corresponding vectors were selected by G418 for 14 d. The transfected pcDNA3.1-angiostatin and vector control groups formed macroscopic cell clones (Figure 3), but the mock group of cells was completely dead after 8 d of selection.

Angiostatin expression in transfected cells

GBC-SD cells transfected with pcDNA3.1- angiostatin were prepared. Total RNA was extracted and used as the template. A band was detected at 1.4 kb with PCR using angiostatin primers, indicating the presence of angiostatin cDNA in the GBC-SD cancer cells (Figure 4).

Angiostatin protein expression in vitro

Immunofluorescence showed signals of angiostatin in the experimental group of cell clones genetically engineered but not in the controls (Figure 5A). Supernatants of cultured cells in three groups were collected and analyzed by Western blotting. A band in a molecular mass of 58 000 kb was detected with rabbit anti-HA-tagged antibody from the cells transfected with pcDNA3.1-angiostatin, but no band was detected in mock control group or vector control group (Figure 5B).

Biological activity of angiostatin protein expression in vitro

To detect the biological activity of encoded angiostatin *in vitro*, tumor cells transfected with or without the corresponding vectors were cultured for 7 d to plot cell growth curve (Figure 6A). Under microscope, no obvious difference was observed in the cell morphology of the three groups of cells. Cell growth curves indicated no change in cell growth speed and doubling time in the three groups. These results indicate that up-regulated angiostatin expression could neither directly inhibit cell growth and proliferation nor affect cell cycle *in vitro*. But the biological activity of cells treated with supernatant of GBC-SD/ pcDNA3.1(+)-angiostatin and cell growth were obviously inhabited. The cell growth curve of the vector and mock control groups was similar (Figure 6B). These results indicate that angiostatin expression could directly inhibit endothelial cell growth and proliferation *in vitro*.

DISCUSSION

Angiogenesis refers to the formation of new blood vessels. Since Dr. Folkman[15] raised the hypothesis of tumor angiogenic dependence, experimental evidence has validated that tumor growth companies new blood vessel growth. At the prevascular stage, tumor is unable to grow to a size beyond 2-3 mm^3 and remains in its dormant state. However, once the angiogenic phenotype of tumor is switched on, tumor growth rate changes from linear to exponential[4-6]. Infiltration of new blood vessels in tumors not only supplies nutrients and oxygen for tumor cells, but also removes the waste products produced by tumor cells. In addition, endothelial cells can communicate directly with tumor cells by producing tumor growth promoting factors.

Angiogenesis begins when a fibrin clot forms on the adventitial surface of an existing blood vessel[7], which is followed by sprouting of new capillaries. The initial phase begins with increased vascular permeability and local degradation of the vessel wall. Endothelial cells enter the tumor stroma and proliferate. At this time, the cells may be most vulnerable to agents that interfere with their proliferation, since they lack protection from other cell types[8]. The next step in vessel formation is recruitment of pericytes, followed by smooth muscle cells.

It appears that a switch to the angiogenic phenotype requires a local change in the balance between angiogenic factors and inhibitors[9]. Among the angiogenic factors, fibroblast growth factor (FGF)[10] and vascular endothelial growth factor (VEGF)/vascular permeability factor (VPF)[11] are most commonly expressed in tumors. Others are inhibitors such as angiostatin[12], thrombospondin-1[13], 16-kd prolactin fragment[14], interferon-α and β[15], and endostatin[16]. Because cancer cannot grow or spread without the formation of new blood vessels[17], scientists are trying to find ways to stop angiogenesis.

Tumor angiogenesis is often the consequence of an angiogenic imbalance in which pro-angiogenic factors predominate over anti-angiogenic factors[5]. Furthermore, angiogenesis is essential for growth and metastasis of most solid cancers[18]. Gallbladder carcinoma is not a grossly vascular tumor, but is related to angiogenesis[19]. Antiangiogenic treatment may be necessary and potential for gallbladder carcinoma.

Angiostatin is an internal fragment of plasminogen and may contain either the first three (K1-3) or four (K1-4) kringle domains[20]. A similar activity has been reported for kringle 5 (K-5) of plasminogen[21]. Three receptors of angiostatin on endothelial cells have been reported to date. Adenosine triphosphate (ATP) synthase is one of the receptors. The presence of this typically mitochondrial enzyme on the endothelial cell surface is somewhat surprising[22]. Two other potential target receptors of angiostatin are angiomotin[23] and integrin alpha(v)beta(3)[24]. These receptors on the surface of endothelial cells may be located at sites so proximal to one another that angiostatin may be able to interact with more than one simultaneously[25]. Alternatively, multiple targets could be implicated in binding to different kringles of angiostatin as a function of receptor and peptide presentation[26].

Although angiostatin is a potent inhibitor of angiogenesis and tumor growth[27], the need for high doses, repeated injections and long-term administration of this protein

have made it less attractive for clinical trials[28]. In order to develop alternative strategies for therapy, we have investigated the possibility of angiostatin gene therapy. When mouse angiostatin cDNA was transfected into human gallbladder carcinoma cell line GBC-SD and endothelial cell line (ECV-304), angiostatin cDNA was present in cancer cells, and a secreted form of angiostatin was established by immunofluorescence and Western-blot. Although angiostatin had no direct effect on gallbladder carcinoma cell growth *in vitro*, the supernatant of ECV-304 cells inhibited the growth of endothelial cells *in vitro*. Xu *et al*[29] engineered a recombinant adeno-associated virus (AAV) vector encoding mouse angiostatin and found that it suppresses metastatic liver cancer in mice. In our study, similar results were achieved using Lipofectamine 2000 for transfection. These results support that angiostatin-gene therapy is a potential strategy in the treatment of gallbladder carcinoma.

In conclusion, angiostatin has no direct effect on gallbladder carcinoma cell growth *in vitro*, but inhibits the growth of ECV-304 cells *in vitro*.

Abstract

AIM: To investigate the effect of long-lasting somatostatin analogue octreotide (Oct) injected into the third cerebral ventricle (TCV) on gastric acid secretion in rats.

METHODS: TCVs were cannulated in male Wistar rats anesthetized with sodium pentobarbital. One week later acute gastric lumen perfusion was carried out and gastric acid was continuously washed with 37℃ saline by a perfusion pump. Gastric perfusion samples were collected every 10 min and titrated by 0.01 moL/L NaOH to neutral. On the basis of subcutaneous (sc) injection of pentagastrin (G-5, 160 μg/kg), Oct (0.025 μg, 0.05 μg, 0.1 μg, $n = 12$ in each group) or vehicle (pyrogen-free physiological saline, $n = 10$) was injected into the TCV. Before and after the TCV injection, 1 h total acid output (TAO) was determined and experimental data were expressed in change rate (%) of TAO.

RESULTS: Oct (0.025, 0.05 and 0.1 μg) injected into the TCV resulted in change rate of 1.56% ($P > 0.05$), 20.21% ($P < 0.01$) and 37.82% of TAO ($P < 0.001$), respectively. Moreover, comparison in change rate of TAO among these 3 doses showed $P < 0.05$ between 0.025μg and 0.05 μg, $P < 0.01$ between 0.025 μg and 0.1μg, and $P < 0.05$ between 0.05μg and 0.1 μg. However, sc injection of 0.05 μg Oct had no effect on G-5 stimulated gastric acid secretion.

CONCLUSION: Octreotide injected into the third cerebral ventricle inhibits gastrin-induced gastric acid secretion in a dose-dependent manner.

INTRODUCTION

Somatostatin, a brain-gut peptide, distributes widely in brain tissue, gastrointestinal tract, pancreatic islets, etc and plays a diversified role in biological activities[1]. Due to its short half life, its application in basic research and clinical work is limited. Octreotide (Oct) is a long-lasting somatostatin analogue with a plasma half life of 45 min[2]. Clinically it is used in the treatment of acromegaly[3], gastrointestinal hemorrhage[4] as well as in the diagnosis and management of some tumors[5]. In the aspect of basic research on gastric acid secretion there have been few reports concerning the central administration of somatostatin and its analogues. Some results are contradictory. Such discrepancy may result from differences in animal species, experimental models and methods, types, doses and injected route of the drugs used. Of note, previous studies[6,7] strongly suggested that the site of injection of Oct into the brain could largely influence its effect on gastric acid secretion. Up to now there is no report regarding the effect of somatostatin and its analogues into the third cerebral ventricle (TCV). In the present study Oct was injected into the TCV of the rats via a chronically implanted cannula and its effect on gastrin-induced gastric acid secretion was observed in the process of acute gastric lumen perfusion.

MATERIALS AND METHODS

Animals

Male Wistar rats weighing 180-280 g were used. The

Table 1 Effect of sc injection of G-5 or TCV injection of saline on gastric acid secretion (n = 10, mean ± SE)

Index	sc G-5		TCV saline	
	1st time	2nd time	before	after

[a]P < 0.05 *vs* group 2 or group 4.

animals were deprived of food for 24 h, but allowed free access to water prior to anesthesia.

Animal models

The rats were anesthetized with a single intraperitoneal injection of sodium pentobarbital (50 mg/kg). Intra-TCV implantation and acute gastric lumen perfusion were carried out as described previously[8]. Gastric perfusion samples were collected every 10 min and titrated by 0.01 moL/L NaOH to neuter (using phenol red as a volume marker). The acid output per 10 min was calculated as previously described[9]. The anus temperature of rats was kept at 37℃ by electric light during the experiment. Sufficient pentobarbital was given sc before G-5 was injected. By referring to the previous report, G-5 (160 μg/kg) was chosen to achieve the maximal acid output[10]. After basal gastric acid secretion was kept stable for 30 min, G-5 (Sigma Company, USA) was injected sc, followed by collection of gastric perfusion samples at 10 min intervals for 1 h. Gastric acid secretion increased 10 min after the injection, reached its peak at 20 min, then declined gradually to the basal level 1 h after the injection. After the gastric acid secretion was kept stable at the original basal level for 30 min, the same dose of G-5 as the first time was given sc and gastric perfusion samples were collected for another 60 min. The experimental drugs were administered into TCV 10 min before the second injection of G-5. In brief, 2.5 μL of pyrogen-free physiological saline or various doses of Oct (Sandoetatin Norvartis, Basel, Switzerland) were given by a syringe pump (with the constant speed of 2.5 μL/2 min) in a silicon tube, which was equally long and connected with the implanted cannula. In order to prove the cannula was in TCV[9], 5 μL gentian violet was injected via the implanted cannula at the end of the experiment, and the rat was immediately killed. The brain tissue was removed and cut to see whether TCV was stained by gentian violet. TCV staining signified that the cannula was correctly placed in TCV and the injected drug successfully reached TCV. Therefore, the result was accepted only when TCV was stained. In this experiment, only data arising from the two rats in saline-injected group were excluded because their TCVs were not shown on gentian violet staining.

Statistical analysis

Experimental data was expressed in percent age of TAO change, which was calculated as follows: change of TAO (%) = (E2-E1)/E1×100%, in which E1 and E2 represent 1 h TAO (μmol/L) after the first and the second sc injections of G-5, respectively. The data were expressed as mean ± SE. Significance was assessed by unpaired t test for comparison between two groups while paired t test for comparison between pre-treatment and post-treatment in each group.

RESULTS

Effect of sc injection of G-5 or TCV injection of saline on gastric acid secretion

The effect of sc injection of G-5 (160 μg/kg) two times on basal gastric acid secretion was observed in the same rat without cannulization in TCV (Table 1). The result showed that there was no significant difference in G-5 stimulated TAO between the first and second injections (P > 0.05). The effect of pyrogen-free physiological saline (2.5 μL) given into TCV on G-5 induced gastric acid secretion in the rat cannulated in TCV, revealed that TAO was almost identical between pre- and post-treatment of TCV-injected saline (P > 0.05, Table 2). Moreover, comparison in change of rate of TAO between these two groups demonstrated an insignificant difference (P > 0.05). This strongly suggested that the experimental animal model was so stable that it could be employed in study of the effect of TCV-administered drugs on gastric acid secretion in rats.

Effect of sc injection of Oct on G-5 induced gastric acid secretion

In 10 rats without cannulation in TCV, each received two injections of sc G-5. Saline (0.20 mL) or Oct (0.05 μg/0.20 mL) was given sc 10 min before the first or the second G-5 stimulation, respectively. TAO was 34.41 ± 3.75 μmol/h after saline administration and 33.49 ± 3.98 μmoL/h after Oct treatment, which had no significant difference between them (P > 0.05).

DISCUSSION

Injection of brain-gut peptides (*eg*, somatostatin, neuropeptide Y, corticotropin-releasing factor, bombesin) into the central nervous system can influence gastric acid secretion[11-13]. As a long-lasting somatostatin analogue Oct, intracisternal injection (ic) induces a dose-related (100-300 ng) and long-lasting stimulation of gastric acid output in pylorus-ligated conscious rats[6]. Four years later, the same researchers reported that Oct injected into the different regions of the brain displayed its effect on gastric acid secretion[7]. Interestingly, they found that Oct (7, 15, 30 and 60 ng) injected into the dorsal vagal

complex (DVC), increases pentagastrin-stimulated gastric acid secretion of urethane-anesthetized rats in a dose-dependent manner. Whereas, Oct injected into the lateral ventricle (100, 200, 300 ng), paraventricular nuclei (PVN) or lateral hypothalamus (LH) (7.5, 15, or 30 ng) also inhibits pentagastrin-stimulated gastric acid secretion in a dose-dependent manner. Oct (30 ng) injected into the area surrounding the PVN or LH does not modify the acid secretion response to pentagastrin. These results strongly suggest that the injection sites of Oct in the central nervous system influence their effect on gastric acid secretion. The current study, for the first time, explored the effect of intra-TCV injection of Oct on gastric acid secretion in rats and showed that Oct (0.025, 0.05, 0.1 μg) injected into TCV inhibited pentagastrin-induced gastric acid secretion of pentobarbital-anesthetized rats with chronically implanted cannula in a dose-dependent manner.

Without no doubt, somatostatin and its analogues peripherally inhibit gastric acid secretion[14]. There is evidence that somatostatin-14 injected into the lateral cerebral ventricles at 3-6 nmoL/rat induces massive hypersomatostatinemia resulting from leakage into the peripheral circulation of rats[15]. Our present study revealed that gastric acid output was suppressed by TCV-administrated Oct through a chronically implanted cannula. Whether Oct injected into TCV is absorbed into blood via the capillaries of subarachnoid space, choroid plexus and cerebral parenchyma to function peripherally is unknown, but Oct is unlikely to enter blood directly due to acute damage to the blood vessel. However, sc injected Oct at the dose of 0.05 μg in our study did not have any effect on G-5 induced gastric acid secretion, thus excluding the peripheral action of Oct. Moreover, it was reported that somatostatin could not pass through the intact blood brain barrier in humans[16].

Hypothalamus plays an important role in the central regulation of gastric acid secretion[17]. Somatostatin distributes in hypothalamus with the highest concentration. The somatostatinergic nerve fibers arising from hypothalamus end in dorsal nuclei of vagus to inhibit their activities, thus regulating gastric acid secretion[13]. TCV is adjacent to hypothalamus and has complicated uptake mechanisms on its wall[18]. These morphological characteristics provide the evidence that TCV-injected Oct exerts central inhibitory effect on gastric acid secretion.

Oct injected into TCV of the rat could suppress gastric acid secretion induced by G-5 at the dose of 0.05 μg other than 0.025 μg (Table 2). As the dose increased to 0.1 μg, such inhibition was increased, suggesting that the inhibitory effect of TCV-administrated Oct on the gastric acid secretion is dose-dependent.

Moreover, Pless *et al*[19] used ^{125}I-Tyr^{3}-Oct to investigate the distribution pattern of the central somatostatin receptors and found that the results are similar to those observed using ^{125}I-Tyr^{11}-somatostatin, suggesting that non-specific combination of Oct in the brain does not exist. Based on the above evidence, it is concluded that the central inhibition of gastric acid secretion by TCV-administered Oct is likely to be specific.

In conclusion, Oct injected into the TCV inhibits gastrin-induced gastric acid secretion of rats in a dose-dependent manner. The exact mechanism underlying this effect needs to be further investigated.

Abstract

AIM: To study the association of colorectal serrated adenomas (SAs) with invasive carcinoma, local recurrence, synchronicity and metachronicity of lesions.

METHODS: A total of 4536 polyps from 1096 patients over an eight-year period (1987-1995) were retrospectively examined. Adenomas showing at least 50% of serrated architecture were called SAs by three reviewing pathologists.

RESULTS: Ninety-one (2%) of all polyps were called SAs, which were found in 46 patients. Invasive carcinomas were seen in 3 out of 46 (6.4%) patients, of whom one was a case of familial adenomatous polyposis (FAP). A male preponderance was noted and features of a mild degree of dysplasia were seen in majority (n=75, 83%) of serrated adenomas. Follow-up ranged 1-12 years with a mean time of 5.75 years. Recurrences of SAs were seen in 3 (6.4%) cases, synchronous SAs in 16 (34.8%) cases and metachronous SAs in 9 (19.6%) cases.

CONCLUSION: Invasive carcinoma arising in serrated adenoma is rare, accounting for 2 (4.3%) cases studied in this series.

INTRODUCTION

There has been a steadily increasing interest in serrated adenomas (SAs) of the colorectal mucosa since one of their earliest descriptions by Urbanski *et al*[1] in 1984 and later by Longacre and Fenoglio-Preiser in 1990[2]. As currently understood, SAs have characteristics combining those of hyperplastic polyps and adenomatous polyps. Architecturally, they resemble hyperplastic polyps with a characteristic "saw-toothed" or serrated morphology but their lining epithelium is dysplastic with varying grades of dysplasia (mild, moderate and severe) as seen in adenomatous polyps[3]. Earlier studies have focused on assessing not only their morphology[4-9] and progression[8-12] to carcinomas but also cytogenetic abnormalities which may occur within them[13-16]. This has given rise to the concept of a 'serrated neoplasia pathway' which refers to a pattern of progression of serrated adenomas to carcinomas[4]. The aim of this paper was to study the clinical significance of colorectal SAs with respect to their association with invasive carcinoma, local recurrence, synchronicity, and metachronicity.

MATERIALS AND METHODS

Materials

An archival series of 4536 polyps spanning an 8-year period (1987-1995) were examined retrospectively. To date, this is the largest series of polyps evaluated for serrated adenomas. The adenomas were selected from the St Marks' s database using a computer search for cases which were diagnostically coded as 'colorectal polyps'. The lesions represented polyps from a series of 1096 patients including endoscopically resected polyps and those from resected colons of patients undergoing surgery for carcinoma, FAP, inflammatory bowel disease or diverticular disease.

Methods

The slides (H & E staining) were reviewed by three pathologists (AC, AC & ICT) and all polyps were recorded as hyperplastic polyps, and tubular, tubulovillous, villous adenomas as well as invasive carcinoma. Degree of dysplasia of all polyps was also recorded as being mild, moderate or severe. The histologic diagnosis of serrated adenoma was based on the criteria described by Longacre and Fenoglio-Preiser[2]. In brief, histologic confirmation

Table 1 Details of the 4536 polyps studied

Types of adenoma	*n* (%)
Tubular adenoma	
Mild	3582 (78.8)
Moderate	114 (2.5)
Severe	18 (0.4)
Tubulovillous adenomas	
Mild	87 (1.9)
Moderate	32 (0.7)
Severe	5 (0.1)
Villous adenomas	
Mild	5 (0.1)
Moderate	0 (0)
Severe	0 (0)
Hyperplastic adenomas	600 (13.5)
Serrated adenomas	91 (2)
Invasive carcinoma	14 (1.3)

of a serrated glandular pattern simulating hyperplasia, the presence of goblet cell immaturity, upper crypt zone mitosis, and the prominence of nuclei were the criteria for inclusion. Adenomas showing at least 50% of these features were recorded as SAs. Case notes for patients with SAs were reviewed to record their age, sex, clinical presentation as well as the site, size, number of SAs and their clinical follow-up. All preceding and subsequent polyps were reviewed for the presence of synchronous and metachronous SAs, local recurrence and association with invasive carcinoma. Coexisting diseases were noted, including familial adenomatous polyposis (FAP), hereditary non-polyposis colon cancer (HNPCC), inflammatory bowel disease (IBD), diverticular disease, family history of sporadic colorectal cancer and presence of other polyps. Unlike an earlier study[3], patients with known malignant potential (FAP, HNPCC) and inflammatory bowel disease were not excluded from this study as we wanted to draw attention to SAs arising in these conditions.

RESULTS

SAs were seen to comprise 2% of all polyps ($n=91$) in this series involving 46 (4.2%) patients. Details of the different types of polyps encountered in this study are shown in Table 1.

It was interesting to note that a significant proportion ($n=14$, 15.4%) of SAs were originally reported as tubulovillous adenomas with the majority ($n=75$, 83%) showing a mild degree of dysplasia. There was a male preponderance (70%), with the average age at diagnosis being 65.5 years for males and 67 years for females. The most common presenting complaint was bleeding per rectum. Clinical associations with other diseases in patients with SAs are shown in Figure 1. As seen in the figure presence of previous polyps, FAP and colorectal carcinoma were the conditions which are most frequently associated with SAs.

The most common site of occurrence was the rectum (33%) followed by sigmoid colon (20%). The size of the SAs was seen to vary between 0.1cm and 5.5 cm. The

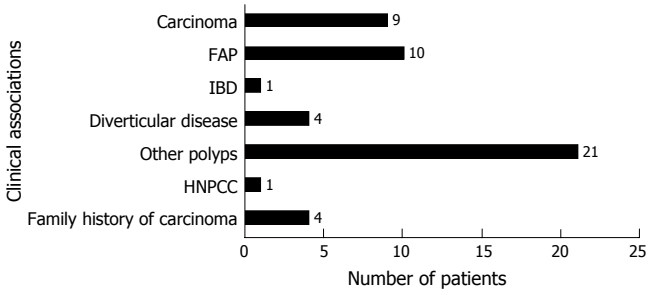

Figure 1 Clinical association of other conditions with serrated adenomas.

total number of synchronous SAs seen per patient varied between 1 (52%, $n=24$) and 8 (2%, $n=1$). Two SAs were seen in 8 (17%), 3 in 9 (20%) and 4 in 4 (9%) patients, respectively.

The mean time of follow-up was 5.75 years (range 1-12 years) with two patients being discharged from follow-up. Five patients died in the course of the follow-up of which 2 were from a FAP-related carcinoma and the remaining 3 were from unrelated causes.

Nine out of 46 (19.6%) patients with SAs had coexisting invasive carcinoma. In 3 (6.4%) cases, invasive carcinoma was seen to arise in SAs. Of these cases, 2 (4.3%) were sporadic and 1 (2.1%) was in a case of FAP. The remaining 6 (13.2%) carcinomas were presented discrete from SAs. The sporadic carcinoma in one of the above two patients was arising in a focus of severe dysplasia within SAs. The lesion was completely excised locally. There was also a synchronous SA in this patient. There was no recurrence at follow-up for 7 years in 2000. In the other patient, the invasive carcinoma arising in SAs was diagnosed in 1994. Local recurrences of invasive carcinoma were seen in 1995 and 1996 after which the patient was lost to follow-up.

All preceding and subsequent polyps retrieved from patients with SAs were reviewed with regard to metachronous SA and local recurrence. Twelve out of 46 (26%) cases showed either a recurrence or metachronicity. In 3 out of the 46 cases (6.5%) there was local recurrence, 2 of these within 1 year. In the remaining 9 cases of the 46 patients (19.6%) with SA, there were metachronous lesions seen. The time interval ranged 1-15 years with a mean time of 6.4 years and a median time of 6 years. Synchronous lesions were seen in 16 out of 46 patients (34.8%) with up to 5 synchronous lesions being present in one case.

DISCUSSION

Our interest in SAs was to evaluate clinically relevant information with respect to their association with invasive carcinoma, local recurrences and metachronicity. The prevalence of SA in our large random sample was 2% which is in the same range with other similar studies where the prevalence was noted to be 1.3%-7%[3,5-7,10] which is lower than 0.5% as originally quoted by Fenoglio-Preiser[2].

Recurrences of SA were seen in 3 cases (6.5%) and probably related to incomplete excision, as dysplastic epithelium was present at the margins of excision histologically. This is however lower than that for other

colorectal polyps which are estimated to be 21%-41% with an average follow-up time of 5-10 years[17]. It must be borne in mind that the apparent difference in the recurrence rates may reflect the difference in the incidence of SA and other polyps. Interestingly, all 3 recurrences were associated with large rectal SAs (3.5 cm and 5 cm in diameter) and took place within 1 year. Synchronicity was noted in 34.8% ($n = 16$) of the cases which are comparable to 20%-61% seen with other adenomas[17] and metachronous SAs were seen in 9 cases (19.6%) which are lower than that quoted for other polyps (32%-55%)[17]. Nevertheless, it implies the real possibility of further SA present in a patient with a histologically confirmed SA. We found serrated adenomas in 10 cases of FAP, 4 cases of IBD and 1 of HNPCC. Though SA may be a feature of FAP, it is not characteristic of the attenuated phenotype with only a few cases being reported in the literature[18].

Progression of SA to frank carcinoma has been suggested in individual cases, but the prevalence of carcinoma originating from serrated adenomas and their cytogenetic characteristics are not fully understood[11,12]. There are a few immunohistochemical studies linking different genetic mutations and oncogene expression in SA[6, 13-15], which may help to reinforce the concept of a "serrated neoplasia pathway"[4].

Inspite of the large number of polyps reviewed in our study, the number of cases in which sporadic cancers were seen to arise remains very small (2 out of 46, 4.3%). The prevalence of invasive carcinoma arising in SA in our study was lower than that in tubular adenomas (4.8%), tubulovillous adenomas (22.5%) and villous adenomas (40.7%) as reported in an earlier series from St Mark's[17]. This prevalence (4.3%) shares some similarity to a large Finnish series which looked at specimens of 466 invasive colorectal carcinomas and found that 27 cases (5.8%) are associated with an adjacent SA[11].

In conclusion, the behaviour of carcinomas arising in SA cannot be reliably differentiated from those arising in other adenomas, given their small number in this series and further work both at identifying morphological features and genetic similarities to carcinomas is needed. SAs do not differ significantly from other adenomas with respect to patient demographics and synchronicity, however they have a lower but a definite incidence of metachronous lesions. Though the prevalence of invasive carcinoma arising in SA was lower than that in tubular, tubulovillous and villous adenomas in our study, further evaluation of this is needed, both of histological and of cytogenetic characteristics. It would be interesting to study SAs in other settings (IBD and polyposis) to shed further light on their behaviour particularly in view of growing evidence of a 'serrated pathway'. The existence of such a distinct pathway of colorectal carcinogenesis has implication most notably for pathologists but at the same time for clinicians who need to recognise the entity of serrated adenomas and its associated potential for neoplastic progression.

Abstract

AIM: Platelet-activating factor (PAF) is a pro-inflammatory and angiogenic lipid mediator. Here we aimed to investigate levels of PAF, lyso-PAF (the PAF precursor), phospholipase A_2 (PLA_2, the enzymatic activity generating lyso-PAF), acetylhydrolase activity (AHA, the PAF degrading enzyme) and PAF receptor (PAF-R) transcripts in cirrhotic liver and hepatocellular carcinoma (HCC).

METHODS: Twenty-nine patients with HCC were enrolled in this study. Cirrhosis was present in fourteen patients and seven had no liver disease. Tissue PAF levels were investigated by a platelet-aggregation assay. Lyso-PAF was assessed after its chemical acetylation into PAF. AHA was determined by degradation of [^{3}H]-PAF. PLA_2 levels were assessed by EIA. PAF-R transcripts were investigated using RT-PCR.

RESULTS: Elevated amounts of PAF and PAF-R transcripts 1 (leukocyte-type) were found in cirrhotic tissues as compared with non-cirrhotic ones. Higher amounts of PAF and PAF-R transcripts 1 and 2 (tissue-type) were found in HCC tissues as compared with non-tumor tissues. PLA_2, lyso-PAF and AHA levels were not changed in cirrhotic tissues and HCC.

CONCLUSION: While the role of PAF is currently unknown in liver physiology, this study suggests its potential involvement in the inflammatory network found in the cirrhotic liver and in the angiogenic response during HCC.

INTRODUCTION

Platelet-activating factor (PAF) is a potent pro-inflammatory lipid mediator that sparks a wide range of immunoregulatory actions[1]. A phospholipase A_2 (PLA_2)-dependent process on membrane alkyl-acyl-glycerophosphocholines generates the lyso-PAF precursor, and its subsequent acetylation results in the PAF molecule[2]. Tissue PAF concentrations are physiologically down-regulated by a specific PAF acetylhydrolase activity (AHA)[2]. PAF acts through specific PAF-receptors (PAF-R) present on the membrane of responsive cells[3]. Several experimental animal models have highlighted that the liver PAF content was elevated by various types of injury, including endotoxin exposure[4,5], ischemia-reperfusion[6], hemorrhagic shock[7], and carbon tetrachloride (CCl_4)-induced cirrhosis[8,9]; results of all these animal studies leading to the conclusions that PAF is a potent vasoconstrictor and systemic vasodilator. While animal models have reported the involvement of PAF in experimental cirrhosis, no clinical study has directly investigated its values in the human cirrhosis liver.

Several *in vitro* studies have highlighted the potential involvement of PAF in carcinogenesis. Thus, PAF acts on the growth of various human tumor cell lines [10,11], increases adhesiveness of tumor cells to vascular endothelia[12], enhances oncogene expression[13], and can contribute to tumor development by enhancing cell motility and by stimulating the angiogenic response[14,15]. Clinical studies have reported elevated PAF amounts in human breast[16], and colon carcinoma[17,18]. However, PAF was not found in higher amounts in lung[19], and thyroid carcinoma[20], suggesting that over-expression of PAF is not necessarily a universal event in carcinogenesis but may be tumor-specific. At present, to our knowledge,

no study has investigated PAF levels in hepatocellular carcinoma (HCC). HCC is a hypervascular tumor. Several angiogenic factors, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF) and angiopoietins, have been reported to promote angiogenesis in HCC[21]. Of interest, PAF is known to mediate the effect of these angiogenic growth factors in several *in vitro* and *in vivo* models[22-24], suggesting a putative involvement of PAF in HCC.

To improve our knowledge concerning the role of PAF in the human liver, we investigated the levels of PAF and lyso-PAF, the enzymatic activities implicated in PAF production (i.e., PLA_2) and degradation (i.e., AHA) and the presence of PAF-R transcripts in human cirrhotic and HCC tissues.

MATERIALS AND METHODS

Subjects

The procedure of the present study followed the general rules edited by the French National Ethics. Between January 1999 and December 2004, 29 consecutive patients (27 men and 2 females; mean age 62.5 years (range 30-78 years), median age 68 years) with HCC underwent resection in the Department of Surgery of Limoges' CHU. Resectability was preoperatively assessed by ultrasonography, computed tomography and/or magnetic resonance imaging. Intraoperative ultrasonography was performed in all patients. The operative procedures included 4 wedge resections, 10 segmentectomies, 7 left hepatectomies, 6 right hepatectomies and 2 total hepatectomies before liver transplantations. A curative resection, defined as an operation in which all the tumors were macroscopically resected during surgery, was performed in 21 patients (72%). The mean margin from the edge of the tumor was 7.5 ± 1.5 mm. The mean and median tumor size was 7.79 ± 4.6 cm and 8.2 cm, respectively. Twenty tumors (69%) were solitary. Cirrhosis was present in 14 patients (48%), with the cause being alcoholism in 46%, hepatitis C in 35%, hepatitis B in 5%, alcohol and hepatitis in 7%, and unknown in 7%. Two patients had liver fibrosis without cirrhosis, 6 had steatosis, and 7 had no liver disease. Histologically, there were 10 well differentiated HCC (34%), 14 moderately differentiated HCC (48%), 4 poorly differentiated HCC (14%), and 1 fibrolamellar carcinoma, according the histopathologic criteria cited by Kojiro M[25]. Thirteen HCC (44%) had a fibrous capsule that was invaded in 68%. Vascular invasion was present in 19 cases (65%) and 8 HCC presented a high mitosis index. According to pT staging[26], there were 2 pT1, 8 pT2, 13 pT3 and 6 pT4 HCCs. Specimens for the pathologic tissue and the control tissue close to the pathologic one were obtained during the surgical procedure. Specimens were frozen at -80 ℃ until used.

Platelet-activating factor assay

Tissue samples were ethanol-extracted (80% final), purified using thin layer chromatography (TLC), and assayed for PAF activity by aggregation of washed rabbit platelets as previously reported[17-20]. The aggregating activity of samples was measured using a calibration curve obtained with 2.5 to 20 pg of synthetic PAF (Novabiochem, Switzerland). Results were expressed as picograms of PAF per mg of tissue. The lipid compound extracted from blood was further characterised on the basis of its aggregating activity in the presence of 0.1 mmol/L BN 52021 (Tebu, Le Perray-en-Yvelines, France), a specific PAF receptor antagonist and its retention time during TLC.

Assay of lyso-PAF

Lyso-PAF was measured in ethanolic biopsy sample after its chemical acetylation into PAF as previously described[17-20]. Briefly, ethanolic samples were dried, mixed with 200 μL of pyridine and 200 μL of acetic anhydride, and kept overnight in the dark at room temperature. After evaporation of the reagents and removing of the traces of pyridine with chloroform, the dried samples were retrieved with 100 μL of 600 mL/L ethanol, and PAF was bioassayed as described before. The amount of lyso-PAF was established as the difference between the quantity of PAF measured before and after acetylation of the samples. Results were expressed as picograms of PAF per mg of tissue.

Acetylhydrolase assay

Frozen biopsy specimens were pulverised and homogenised in 1 mL of AHA buffer (140 mmol/L NaCl, 3 mmol/L KCl, 4 mmol/L HEPES, 22 mmol/L EDTA). After centrifugation, supernatants were used for AHA and PLA_2 determinations. AHA was assessed as previously described[17-20]. Briefly, 10^5 dpm of [^{3}H]acetyl-PAF (10 Ci/mmol, NEN), 0.1 mmol/L PAF, AHA buffer (pH 8) in a final volume of 450 μL, and 50 μL of tissue extract supernatants were incubated for 30 min at 37 ℃. The reaction was stopped with addition of 100 μL of bovine serum albumin (100 g/L) and 400 μL of trichloracetic acid (200 g/L). Samples were centrifuged at 1500 g for 15 min, and supernatants were counted in a liquid scintillation counter. Results were expressed as fentomoles of PAF degraded per min per mg of tissue as means of duplicate assays. Variation between duplicates was less than 7%.

PLA_2 activity assay

PLA_2 levels were assessed by enzyme-linked immunosorbent assay (ELISA) according to the manufacturer's instructions (R&D Systems Europe, Oxon, UK) and as previously described[17,18,20]. Results were expressed as international unit (IU) per mg of tissue as means of duplicate assays. Variation between duplicates was less than 6%

Reverse-transcriptase polymerase chain reaction (RT-PCR) of PAF-R transcripts

Total RNA from tissue samples extracted with RNAwiz (Ambion, Austin, TX) was reverse-transcribed and the complementary DNA (cDNA) was amplified by PCR as previously described[17,18,20]. The human PAF-R transcript 1 sense primer was 5'-GACAGCATAGAG

GCTGAGGC-3', the transcript 2 sense primer was 5' -CCTGAGCTCCCCGAGAAGTCA-3' and the antisense primer was 5'-TAGCCATTAGCAATGACCCC-3. The sense and anti-sense primers of glyceraldehyde-3-phosphate dehydrogenase (GADPH, a positive control of PCR amplification) were 5' -GGCTGAGAACGGGAAGCTTG-3' and 5'-GGATG ATGTTCTGGAGAGCC-3', respectively. PCR products were electrophoresed on a 20 g/L agarose gel (Gibco, France) and visualised by ethidium bromide staining. Expected sizes of amplified products were: PAF-R transcript 1225 bp; PAF-R transcript 2269 bp; spliced variant of PAF-R transcript 2351 bp; and GAPDG, 439 bp.

Statistical analysis

Differences between groups were assessed using the Mann-Whitney *U*-test. A paired student's *t*-test was used to analyse intragroup differences. $P < 0.05$ was considered statistically significant.

RESULTS

PAF and human cirrhosis

A 4-fold increase of PAF levels was found in the cirrhotic tissue (1.61 ± 0.43 pg/mg, $n = 14$) as compared to the non-cirrhotic one (0.39 ± 0.39 pg/mg, $n = 7$) (Figure 1A). In contrast, the AHA levels (the PAF degrading enzyme) were unchanged ($P = 0.33$, Mann-Whitney *U*-test) in the cirrhotic tissue (3.93 ± 0.38 fmol/(min.mg), $n = 14$) as compared to the non-cirrhotic tissue (5.00 ± 0.53 fmol/(min.mg), $n = 7$) (Figure 1B). Similarly, PLA_2 levels (the enzymatic activity that generated the lyso-PAF precursor) were unchanged ($P = 0.23$, Mann-Whitney *U*-test) in the cirrhotic tissue (1.35 ± 0.17 U/mg, $n = 14$) as compared with non-cirrhotic one (1.76 ± 0.24 U/mg, $n = 7$) (Figure 1C). In agreement with these latter results, amounts of the lyso-PAF were similar ($P = 1$, Mann-Whitney *U*-test) in the cirrhotic tissue (1 934.0 ± 556.9 pg/mg, $n = 14$) as compared to the non-cirrhotic one (1 488.9 ± 331.0 pg/mg, $n = 7$) (Figure 1D).

PAF-R and human cirrhosis

The PAF-R gene produces three different species of mRNA [i.e., transcript 1 (leucocyte-type), transcript 2 (tissue-type) and an elongated form of the transcript 2]; both transcripts ultimately yield the functional PAF-R. As shown in Figure 1 (lower panel), RT-PCR experiments showed the presence of PAF-R transcript 1 but not transcript 2 in the cirrhotic tissue.

PAF and human HCC

A significant ($P = 0.0002$, *t*-test for paired data) increase of PAF levels was found in tumor tissues (1.69 ± 0.34 pg/mg, $n = 21$) as compared to the non-tumor ones (1.20 ± 0.33 pg/mg, $n = 21$) (Figure 2A). This increase was significant ($P = 0.0044$, student *t*-test for paired data) for cirrhotic patients (1.88 ± 0.41 pg/mg *vs* 1.61 ± 0.43 pg/mg for tumor and non-tumor tissues, respectively) and also ($P < 0.05$, student *t*-test for paired data) for non-cirrhotic patients (1.29 ± 0.62 pg/mg *vs* 0.39 ± 0.30 pg/mg for tumor and non-tumor tissues, respectively). For HCC patients, PAF values were not significantly different ($P = 0.52$, Mann-Whitney *U* test) according to the tumor status (1.85 ± 0.49 pg/mg *vs* 1.62 ± 0.44 pg/mg for six T1/T2 patients and fifteen T3/T4 patients, respectively). Only tumor PAF levels were affected in HCC tissue. Indeed, the enzymatic activities implicated in PAF production and degradation were not changed. Thus, the AHA levels (the PAF degrading enzyme) were unchanged ($P = 0.24$, *t*-test for paired data) in the tumor tissue (4.72 ± 0.52 fmol/(min.mg), $n = 21$) as compared to the adjacent tissue (4.29 ± 0.32 fmol/(min.mg), $n = 21$) (Figure 1B). Amounts of the lyso-PAF were unchanged ($P = 0.48$, *t*-test for paired data) in the tumor tissue (1 588.9 ± 377.9 pg/mg, $n = 21$) as compared to the non-tumor one (1 616.8 ± 373.7 pg/mg, $n = 21$) (Figure 1D). Moreover, PLA_2 levels (the enzymatic activity that generated the lyso-PAF) were unchanged ($P = 0.26$, *t*-test for paired data) in HCC tissue (1.28 ± 0.27 U/mg, $n = 21$) as compared with non-tumor one (1.49 ± 0.14 U/mg, $n = 21$) (Figure 1C).

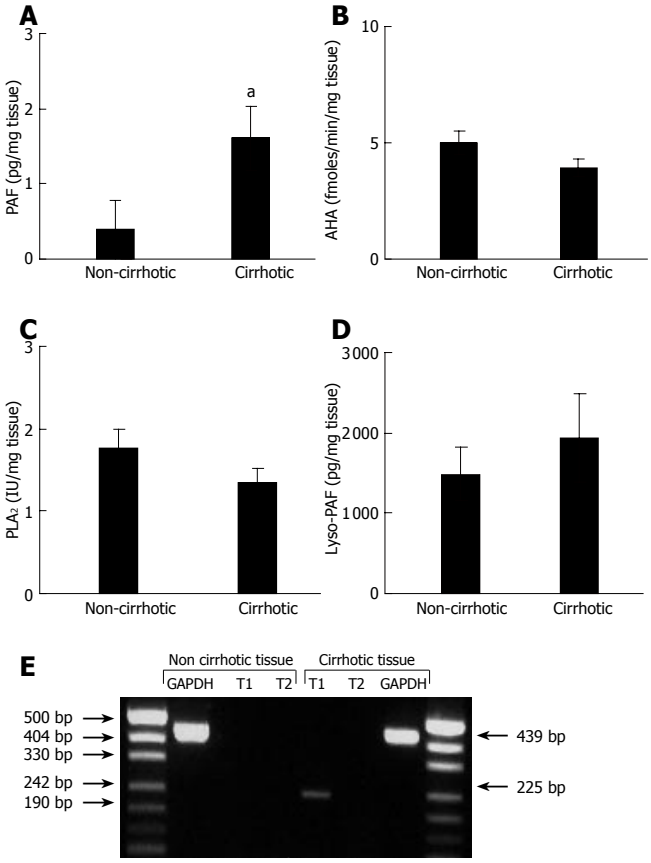

Figure 1 PAF, lyso-PAF, AHA, PLA_2 levels and PAF-R transcripts in cirrhotic and non-cirrhotic liver tissues. *Upper panel* shows the specimens of cirrhotic ($n = 14$) and non-cirrhotic tissue ($n = 7$) obtained during the surgical procedure. **A**: PAF determined by a platelet-aggregation assay, $^aP < 0.05$ *vs* non-cirrhotic; **B**: AHA determined by investigating the degradation of [^{3}H]-PAF, ($P = 0.33$); **C**: PLA_2 assessed by enzyme-linked immunosorbent assay, ($P = 0.23$); **D**: Lyso-PAF measured after its chemical acetylation into PAF, ($P = 1.00$). Results are expressed as mean±SE. Statistical analysis was performed using the Mann Whitney *U*-test. *Lower panel* shows PAF-R transcripts determined by RT-PCR. Expected sizes of amplified products were 225 bp (PAF-R transcript 1), 269 bp (PAF-R transcript 2), 351 bp (spliced variant of PAF-R transcript 2), and 439 bp (GAPDG). Sizes of PCR products and DNA size ladder are indicated by arrows. All experiments were performed in triplicate.

PAF-R and human HCC

As shown in Figure 2 (lower panel), RT-PCR experiments indicated the presence of PAF-R transcripts 1 and 2 in HCC tissues. The spliced variant of PAF-R transcript 2 was not detected.

DISCUSSION

Elevated PAF levels were found in the cirrhotic tissue as compared to the non-cirrhotic one, confirming, for the first time in human, the results obtained in experimental models of liver cirrhosis[8,9]. Elevated levels of PAF can result from a higher PAF production or a lower PAF degradation. Arguing against the latter hypothesis, the AHA levels (the PAF degrading enzyme) were unchanged in the cirrhotic tissue as compared to the non-cirrhotic tissue. Thus, the elevated PAF levels in cirrhotic tissue might be due to an elevated PAF synthesis. Kupffer cells which are a well known source of PAF[27] might be an appropriate candidate for these elevated tissue PAF levels. Strengthening this hypothesis, Kupffer cells from cirrhotic rat was found to produce more PAF than kupffer cells of control rats[8]. Confirming a previous study[28], PLA_2 levels (the enzymatic activity that generated the lyso-PAF) were unchanged in the cirrhotic tissue. In agreement with these latter results, amounts of the lyso-PAF were similar in the cirrhotic tissue as compared to the non-cirrhotic one. PAF acts as a local cell-to-cell mediator. Thus, an elevated PAF synthesis is only of relevance if PAF-R can be detected at the site of PAF production. The PAF-R gene produces three different species of mRNA (i.e., transcript 1, transcript 2 and an elongated form of the transcript 2); both transcripts ultimately yield the functional PAF-R[3]. Leucocytes produce PAF-R transcripts 1, while PAF-R transcripts 2 are found in organ extracts. Thus, PAF-R transcripts 1 and 2 are also named "leukocyte-type" and "tissue-type", respectively. RT-PCR experiments indicated the presence of PAF-R transcript 1 in the cirrhotic tissue. These PAF-R transcripts from the "leukocyte-type" fit well with the previous study that showed higher hepatic levels of PAF-R mRNA in CCl_4-induced liver cirrhosis[8], with cirrhotic kupffer cells as cellular source of these PAF-R mRNA. Thus our present study concludes that PAF and PAF-R transcripts are present in the human cirrhotic liver. PAF may have pathophysiologic functions and might account, at least in part, in the inflammatory response occurring in the cirrhotic liver. On the one hand, PAF might act directly by stimulating the production of humoral mediators including peptide leukotrienes (LTC_4, LTD_4, LTE_4)[29], prostaglandin E_2 (PGE_2)[30], and nitric oxide[31], which can affect cell proliferation and gene expression. On the other hand, and with respect to its potent immunoregulatory actions[1,32], PAF might act indirectly on stellate cell-immune cell interactions by promoting leukocyte chemotaxis and adherence, by influencing leukocyte activation and by affecting their cytokine secretions.

Previous clinical studies have reported the elevated PAF levels in breast and colon carcinomas[16-18], but not in lung and thyroid carcinomas[19,20], suggesting that over-expression of PAF is not necessarily a universal event in carcinogenesis, but may be tumor-specific. Increased PAF levels were found in HCC tissues. In contrast to colorectal cancer patients[17], tumor PAF level did not change according to the tumor status. As suggested above, the elevated PAF levels in HCC tissue might be due to elevated PAF synthesis by Kupffer cells. In contrast to that found in colon carcinoma[17], only tumor PAF levels were affected in HCC tissue. Indeed, the enzymatic activities implicated in PAF degradation (i.e., AHA) and production (i.e., PLA_2) were not changed; these latter results fitting well with the data reporting no differences in phospholipids composition (including phosphatidylcholine one) between human hepatoma homogenates and normal regions outside the tumors[33]. Few clinical studies had focussed on PAF-R levels in cancer tissue. Levels of PAF-R transcripts were not modified in colorectal, lung and thyroid carcinoma[17,19,20], while PAF-R (tissue-type) levels were increased in liver metastasis of colorectal cancer[18]. PAF-R transcripts 1 (leukocyte-type) and 2 (tissue-type) were found in the HCC tissues. Kupffer cells might be the cell source for the elevated levels of PAF-R

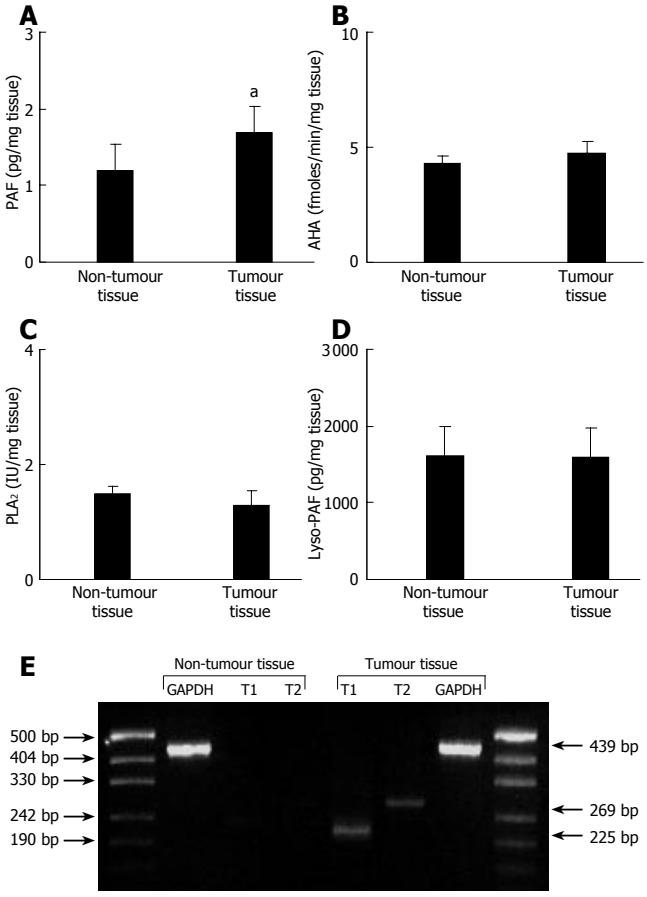

Figure 2 PAF, lyso-PAF, AHA, PLA_2 levels and PAF-R transcripts in HCC and non-tumour tissues. *Upper panel* shows specimens from 21 HCC patients obtained during the surgical procedure. **A**: PAF, $^aP < 0.05$ *vs* non-tumour tissue; **B**: AHA ($P = 0.24$); **C**: PLA2 ($P = 0.26$); **D**: Lyso-PAF ($P = 0.48$). Statistical analysis was performed using the Students' t-test for paired samples. Results are expressed as mean ± SE. *Lower panel* shows PAF-R transcripts determined by RT-PCR. Expected sizes of amplified products were 225 bp (PAF-R transcript 1), 269 bp (PAF-R transcript 2), 351 bp (spliced variant of PAF-R transcript 2), and 439 bp (GAPDG). Sizes of PCR products and DNA size ladder are indicated by arrows. All experiments were performed in triplicate.

(leukocyte-type) transcripts. Thus, transforming growth factor beta (TGF-β) and PAF stimulated PAF-R mRNA synthesis in monocytic/macrophagic cells[34,35]. Elevated levels of TGFβ[36] and PAF (Figure 2A) are found in HCC tissues. PAF-R transcript 2 (tissue-type) has also been reported to be up-regulated in HCC tissue. Such an up-regulation of PAF-R transcripts 2 has been previously reported in endometrial cells in response to estradiol[37]. Interestingly, locally elevated estrogen formation has been reported in HCC tissues[38], and estrogen enhances angiogenesis through a pathway involving PAF in a mouse Matrigel model *in vivo*[39]. Thus, whatever molecular signals implicated in these elevated PAF-R transcript levels, the current data argue for a pathophysiological role of PAF in HCC tissues.

In conclusion, PAF is a potent pro-inflammatory compound that acts as a local cell-to-cell mediator. Since PAF can generate biological responses detectable at levels of 10 fmol/L, regulating PAF levels is important since elevated levels of PAF might result in biological effects. To the best of our knowledge, this clinical study, for the first time, reports an increase in PAF and PAF-R transcripts in cirrhotic liver tissue and HCC tissue, suggesting a pathological role for PAF in liver cirrhosis and HCC. In cirrhotic tissue, PAF might act on stellate cell-immune cell interactions by influencing leukocyte activation and chemotaxis, and by altering the local cytokine network. An angiogenic role of PAF might be suggested in HCC.

Abstract

AIM: To evaluate the novel anti-endomysium (anti-EMA) detection based on ELISA.

METHODS: Anti-EMA IgA was measured by a novel ELISA in 196 patients with gastrointestinal symptoms and suspected mal-absorption. Data were compared with those obtained by the conventional IF test.

RESULTS: A good concordance of 98% was found between these two assays. In sera of 161 patients (82%) both assays tested negative whereas in sera of 31 patients (16%) both assays tested positive for the presence of anti-EMA antibodies. Discrepancies between EMA-ELISA and EMA-immunofluorescence (IF) were found in only 4 patients (2%).

CONCLUSION: This ELISA can replace IF for the detection of anti-EMA antibodies and provide clinicians with an excellent tool to screen for celiac disease in patients with gastrointestinal complaints.

INTRODUCTION

Celiac disease (CD) is the most common cause of intestinal malabsorption in the Western world with a recently described incidence of 1:100 to 1:300. Gastro intestinal damage is the result of gluten-dependent change in villous morphology and/or signs of immunological activation in the lamina propria, which is reversible on a strict gluten-free diet[1]. A biopsy from the proximal small intestine is essential for diagnosis. The number of biopsies however, can be dramatically reduced by using an objective, reliable, and easy to perform serologic screening. The antibodies most commonly detected in clinical routine are anti-tissue-transglutaminase IgA (anti-tTGA) and anti-endomysium IgA (anti-EMA)[2]. Anti-tTGA in combination with anti-EMA antibodies accounts for almost 100% sensitivity and specificity[3,4]. Anti-EMA antibody detection is at present performed with an immunofluorescence (IF) technique on cryostat sections of monkey oesophagus. Anti-tTGA antibody detection is based on an enzyme linked immunosorbent assay (ELISA). Disadvantages of IF are the qualitative results, the high costs, the need for extensively trained personnel and the ethical disapproval[2,3].

Anti-EMA antibody detection based on ELISA overcomes the disadvantages of IF. In this study we evaluated a new ELISA for the detection of anti-EMA antibodies and compared these data with the anti-EMA results obtained by IF.

MATERIALS AND METHODS

The study population consisted of 196 patients (male 35%, female 65%) with gastrointestinal symptoms and suspected mal-absorption, visiting the Department of Internal Medicine or the Department of Pediatrics of the Diaconessenhuis in Leiden or the Albert Schweitzer Hospital in Dordrecht, respectively, between November 2002 and May 2005. Total IgA was determined by immunoturbidimetric assays on the Hitachi-917 (Roche Diagnostics Corporation, Indianapolis, IN, USA) or the Beckmann-immage autoanalyser (Beckman-Coulter, Mijdrecht, the Netherlands).

Detection of anti-EMA antibodies by IF was performed by using cryostat sections of monkey oesophagus as an antigen substrate (The Binding Site,

Table 1 Comparison of the results of anti-EMA antibody detection by IF and ELISA in 196 patients

EMA-IF	EMA-ELISA	*n* (%)	
-	-	161 (82)	no biopsy results

- = negative results; + = positive results; *n* = the number of patients.

Birmingham, UK) according to the manufacturer's instructions. All slides were scored by two independent observers and a definite result was obtained by consensus.

Anti-EMA antibodies were also detected with an ELISA (Medipan Diagnostica, Selchow, Germany) according to the manufacturer's instructions (www.genericassays.com). Microplate strips coated with purified human endomysium autoantigens (90-300 kDa) were incubated with 100 μL 1:50 diluted serum, a positive control and a 4-point calibrator curve were included in each run. The strips were incubated for 1h at 37 ℃ and washed six times with 300 μL washing buffer and 100 μL horseradish peroxidase-conjugated anti-human IgA was added. After 30 min incubation at 37 ℃ the plates were washed 6 times, 100 μL of substrate solution containing 3, 3', 5, 5' tetramethylbenzidine was added and the reaction was stopped after 10 min at ambient temperature in the dark with 100 μL 0.25 mol/L H_2SO_4. The absorbance was measured at 450 nm. A standard curve was established by plotting the optical density of each calibrator with respect to the corresponding concentration value in U/mL. From the OD of each sample the corresponding antibody concentration expressed in U/mL could be determined. The cut-off value for positivity was 20 U/mL. Patients who tested positive for serologic tests, underwent a small intestinal biopsy.

RESULTS

None of the patients included in this study showed an IgA deficiency. Sera of 161 patients tested negative for anti-EMA antibodies with both IF and ELISA (Table 1). In sera of 31 patients anti-EMA antibodies were detected with both IF and ELISA and the diagnosis of CD could be confirmed by histological results. In sera of 4 patients discrepancies were found in anti-EMA results between IF and ELISA. In sera of 3 patients the presence of anti-EMA antibodies was only detected with IF. No histological data were available for these 3 patients. In serum of 1 patient the slightly increased anti-EMA concentration (22 U/mL) was only detected with ELISA, and CD could not be confirmed by histological results.

DISCUSSION

To the best of our knowledge, this is the first anti-EMA assay based on endomysium antigens from human origin. The detection of anti-EMA antibodies by an ELISA has been described before[5,6]. This EMA-ELISA however is based on endomysium antigens purified by affinity chromatography from primate liver and is not commercially available anymore.

We compared the EMA-ELISA and the EMA-IF by assaying 196 patients with gastrointestinal symptoms and suspected mal-absorption. A good concordance of 98% was found between both these assays. In sera of 161 patients (82%) both assays tested negative whereas in sera of 31 patients (16%) both assays tested positive for the presence of anti-EMA antibodies and the diagnosis of CD was confirmed by histological results. Discrepancies between EMA-ELISA and EMA-IF were found in only 4 patients (2%). In sera of 3 of these patients the presence of anti-EMA antibodies was detected by IF but not by EMA-ELISA, however in these sera anti-tTGA antibodies were absent (results not shown), suggesting the absence of CD. Since no histological data were available the diagnosis of CD could not be excluded or confirmed. In serum of 1 patient the presence of anti-EMA antibodies detected by ELISA could not be confirmed by IF and anti-tTGA antibodies were absent. The slightly increased anti-EMA antibody concentration (e.g. 22 U/mL) appears to be false positive since the biopsy results were not indicative for CD.

Quantitative results obtained by EMA ELISA are easy to interpret in contrast to qualitative results obtained after IF, providing the clinicians with an excellent tool to screen for CD in patients with gastrointestinal complaints in the absence of IgA deficiency.

In conclusion, this ELISA can replace IF for the detection of anti-EMA antibodies. In daily practice, testing for anti-EMA antibodies is frequently performed in conjunction with testing for anti-tTGA antibodies since this combination accounts for almost 100% sensitivity and specificity[3, 4].

CONCLUSION: Scoring the AWR during colorectal distensions can assess the intensity of noxious visceral stimulus. Flatting of abdomen (AWR 3) to CRD as the visceral pain threshold is clear, constant and reliable. This pain model and its behavioral assessment are good for research on visceral pain and analgesics.

Abstract

AIM: To establish a visceral pain model *via* colorectal distension (CRD) and to evaluate the efficiency of behavioral responses of CRD by measuring the score of abdominal withdrawal reflex (AWR) in rats.

METHODS: Thirty-eight male SD rats weighing 180-240g were used to establish the visceral pain model. The rat was inserted intra-anally with a 7 cm long flexible latex balloon under ether anesthesia, and colorectal distensions by inflating the balloon with air were made 30 min after recovering from the anesthesia. Five AWR scores (AWR0 to AWR4) were used to assess the intensity of noxious visceral stimuli. It was regarded as the threshold of the minimal pressure (kPa) for abdominal flatting was induced by colorectal distension.

RESULTS: A vigorous AWR to distension of the descending colon and rectum was found in 100% of the awake rats tested. The higher the pressure of distension, the higher the score of AWR. The distension pressures of 0, 2.00, 3.33, 5.33 and 8.00 kPa produced different AWR scores ($P < 0.05$). The pain threshold of AWR was constant for up to 80 min after the initial windup (first 1-3 distensions), the mean threshold was 3.69 ± 0.35 kPa. Systemic administration of morphine sulfate elevated the threshold of visceral pain in a dose-dependent and naloxone reversible manner.

INTRODUCTION

Visceral pain is produced by diseases[1]. It has not yet been studied more than the somatic pain due primarily to the lack of a reliable, stable model of visceral pain. The mechanisms of acute and chronic visceral pain have been extensively studied since the reports from Ness *et al* in 1998[2-4]. But implantation of the electrode in the abdominal muscle to record the electric muscle graph is complicated, and disturbs the movement of the awake experimental animals and increases the somatic hypersensitivity[5]. The practicability of the model is therefore limited. Al-Chaer *et al*[5] have established the abdominal withdrawal reflex (AWR) scores in a model of chronic visceral hypersensitivity in rats. We used AWR scores of the acute colorectal distension to establish a visceral pain model in rats. The minimal pressure for flatting of abdomen induced by CRD was regarded as the threshold for the assessment of the reliability and stability of the model and its behavioral reaction.

MATERIALS AND METHODS

Experiment animals

Male Sprague-Dawley (depurator grade) rats ($n = 38$) weighing 180-240g were obtained from the Experiment Animal Center of Soochow University.

Establishment of CRD

The colorectal distension balloon was made from a latex glove finger attached to an 8# rubber urethral catheter (7 cm in length and 2.5 cm in diameter).

Rats were randomly grouped for the experiment. Rats were deprived of food but had free access to water 24 h before the experiment. The prepared colorectal distension balloon covered with lubricant was totally inserted into the descending colon and rectum under ether anesthesia. Rats were put into a 20 cm×15 cm×15 cm glass box for the experiments 30 min after they were fully recovered from the anesthesia. The tube of balloon was connected *via* a Y connector to a air pump and a sphygmomanometer. The balloon that was inserted into the rat coloratura was inflated with air at a speed of 0.133 kPa/s(1 kPa = 7.5 mmHg), and the pressure inside the balloon was continuously monitored. The distension duration and intervals between two distensions were selected.

Behavioral study

Five abdominal withdrawal reflex (AWR) scores (AWR0 to AWR4) were used to assess the intensity of noxious visceral stimuli: AWR0: remarkable behavior changes; AWR1: immobility of the rat body or occasionally clinches of the head; AWR2: mild abdominal muscle contraction; AWR3: lifting the abdomen off the box platform or flatting of abdomen; AWR4: body arching or lifting pelvic structures off the platform[5]. The cut-off pressure to avoid the rectum injury was set at 13.33 kPa.

The pain threshold was defined as the minimal pressure (kPa) inside the balloon when the rat showed flatting of abdomen (AWR 3) during the colorectal distension (CRD).

Pharmacology study

To observe the effect of morphine on the abdominal withdrawal reflex, 24 rats were divided into 4 groups ($n = 6$ in each group and giving morphine s.c. 1 mg/kg, 2 mg/kg, 4 mg/kg and 8 mg/kg, respectively). Each received colorectal distension once per 5 min. The mean score of the 4th and 5th distension was regarded as the basic value. The pain thresholds at 10, 15, 20 min after morphine administration were recorded. The maximal possible effect (MPE) was used to compare the effect of morphine[6]. Percent maximal possible effect (%MPE) = (post drug value - baseline value)/(cutoff value - baseline value) × 100%[7].

Statistical analysis

Data were presented as mean ± SD. The statistical significance tested by analysis of variance ($P < 0.05$) and *post hoc*. LSD (with comparable variance) or Tamhane's T2 (with incomparable variance) method was selected. All the analyses were performed using SPSS 10.0 software.

RESULTS

Stepping increased pressure of colorectal distension

The scores of abdominal withdrawal reflex were recorded in 8 rats receiving the colorectal distension every 4 min with stepping increased pressures of 0, 2.00, 3.33, 5.33, 8.00 kPa respectively and lasted for 30 s. The mean value of 3 times of abdominal withdrawal reflex was adopted. All the rats showed the abdominal withdrawal reflex to the colorectal distension (Figure 1). The higher the pressure, the higher scores of the abdominal withdrawal reflex. There were statistically significant differences among the five pressure grades.

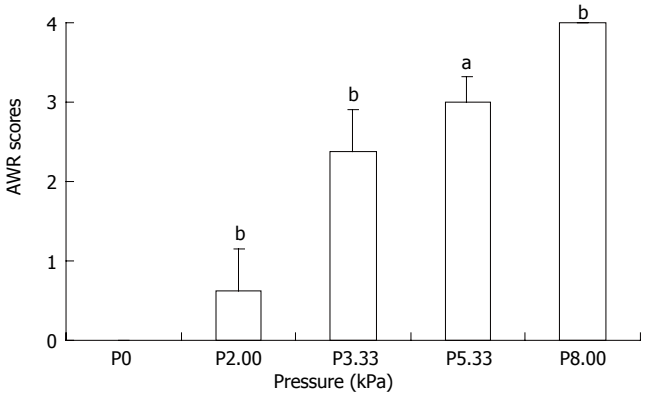

Figure1 AWR scores under stepping increased pressure of colorectal distension $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* the basal pressure.

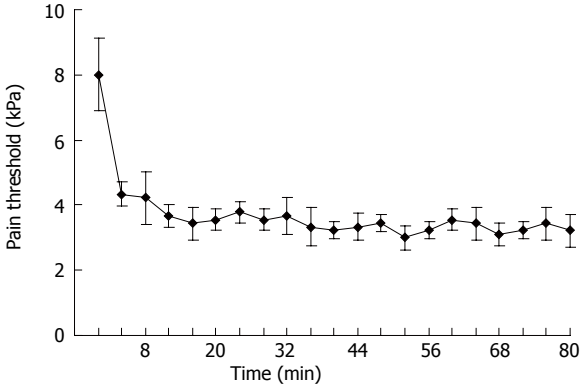

Figure 2 Repeated observations of pain thresholds after CRD at different times. The threshold was higher at the first distention, and then declined. It became stable after 3 trials. The mean pain threshold was 3.69 ± 0.35 kPa.

Repeated observation of pain thresholds after CRD at different times

The pain threshold was measured in 6 rats receiving a colorectal distension per 4 min. The results showed (Figure 2) that the threshold was higher at the first distention and then declined. It became stable after 3 trials. The mean pain threshold was 3.69 ± 0.35 kPa. The pain thresholds were measured on d 5 and 10 after the procedure in the same rats, and the mean thresholds were 3.59 ± 0.22 kPa and 3.63 ± 0.31 kPa with no significant difference among them.

Effect of mophine-naloxone on AWR to CRD

Subcutaneous administration of morphine increased the pain threshold in a dose-dependent manner. The pain thresholds of the rats that received respectively, 2 mg/kg, 4 mg/kg, 8 mg/kg of morphine were significantly higher compared to the basal values ($P < 0.01$). The duration of antinociceptive effect produced by 8 mg/kg morphine

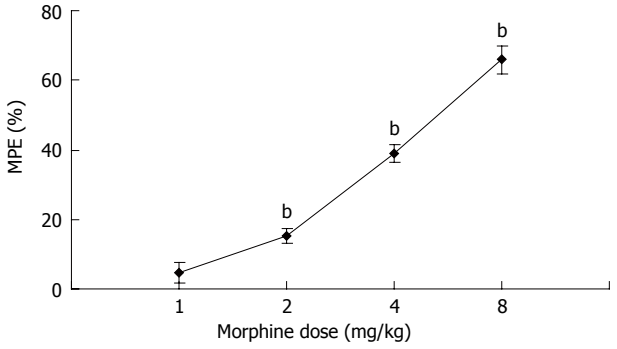

Figure 3 Effect of morphine on AWR to CRD. The pain thresholds of the rats that received 2 mg/kg, 4 mg/kg, 8 mg/kg of morphine respectively were significantly higher than the basal values ($P<0.01$). $^bP<0.01$ *vs* the basal values.

lasted for more than 2.5 h (150.45±22.50 min, Figure 3). Naloxone (0.5 mg/kg, i.p.) 20 min after 4 mg/kg morphine administration increased the movement of rats and the analgesic effect of morphine was totally antagonized. Five min after administration of naloxone, the pain threshold decreased to the basal level.

Anatomic observation

After the distension experiment, rats ($n=6$) with the balloon remained in the coloratura and the pressure inside the balloon kept at 8.00 kPa (AWR 4) were anesthetized with chloral hydrate. Shaped like column, the balloon occupying the whole descending colon and rectum was found in the left hypochondria region after opening the abdomen. The distended balloon was 8.94±1.20 cm in length and 1.20±0.21 cm in diameter. Inflating the balloon at a speed of 0.133 kPa per second, the pressure causing rupture of the colon was 19.80±1.38 kPa. Although the length of the whole colon in rats was 16.90±2.52 cm, the site of the rupture was always in the descending colon.

DISCUSSION

Visceral noxious stimulus similar to the somatic noxious stimulus contributes to the false effective responses in animals, including agony behavior, bray, and response of the circulation and respiration system, muscle contraction, escaping, *etc*. The ideal visceral noxious stimulus with less effect on surrounding tissues should be controllable and repeatable[8,9]. The chemical[10], electrical stimuli[11]on the visceral afferent fibers are the most commonly used methods in research of visceral pain, but the responses to chemical or electrical stimuli are instable and nonspecific[2].

The quantified EMG of abdominal muscles[2], cardiovascular response[2], latency of step-down[12] and abdominal musculature contractions[6] have been adopted for assessment to the stimulus and response intensity, yet these indexes are easily interfered with multi-factor. Behaviors such as immobility of rat body, anus distension, abdominal muscle contraction, back arching, testis lifting, hind leg spreading with gradually increasing the pressure in colorectalregion have been found in rats. If the pressure is persistent such behaviors can last for a longer time. Therefore, the responses to colorectal distension meet the nociceptive pain standards in animal experiment. CRD seems to mimic the pathological mechanisms of pain in humans[9].

The abdominal withdrawal reflex (AWR) is a semi-quantitative, autonomic motor reflex that is similar to visceromotor response (VMR). The reflex arc of abdominal withdrawal reflex involves the supraspinal mechanisms. The scoring of AWR is based on the enhancement of the abdominal muscle contraction, which is free of the direct abdominal muscle stimulation by the electrodes, so the somatic hypersensitivity during the study of visceral pain is eliminated[5]. In the present study, all the rats showed the abdominal withdrawal reflex to the colorectal distention, suggesting that the AWR scores reflect the visceral pain to some extent.

Since the observation of rat body or head movement (AWR 1) and the initiation of abdominal muscle constriction (AWR 2) are difficult, we consider that AWR 3 (lifting the abdomen off the box platform or flatting of abdomen) and AWR4 are more reliable responses of the animals to the visceral pain. The animal's performance of flatting of abdomen (AWR 3) is most clear and exact in response to CRD. If the distention pressure in the balloon does not change, the performance of flatting of abdomen is stable within a few minutes and no significant variations in pain threshold among individuals are noticed. Therefore, the minimal pressure (mmHg) inside the balloon is the most eligible index of the pain threshold when the rat shows flatting of abdomen（AWR 3）during CRD.

In this study, morphine (sc) inhibited the responses to CRD in a dose-dependent manner and this inhibitory effect of morphine could be antagonized by naloxone, demonstrating the stability and reliability of the visceral pain model produced by CRD in rats.

Ness and Gebhart[2] reported that the VMR threshold is 22.4±0.9 mmHg(2.99±0.12 kPa), which is similar to the values of the AWR 2 in the present study. The pain threshold in our study was 3.69±0.35 mmHg (AWR3), which was much lower than that reported by A1-Chaer *et al*[5] [53.5±2.8 mmHg(7.13±0.37 kPa)]. This difference may be due to the different species of the animals and the length of the balloon used. The relationship between the length of balloon and the threshold of distention pressure suggests a possible mechanism of "spatial summation" in visceral pain[9].

In the present study, the visceral pain threshold at the first distention was higher, which might be attributed to the "windup" effect induced by the initial noxious stimuli on visceral fibers[2]. We found that the threshold after the initial 2-3 trials became more stable in the actual visceral pain experiment. It is better to wait 1 or 2 min before the next CRD is given. The feces in the coloratura interfered with the insertion of the balloon and affected the pressure in the colorectum, thus the animals should be deprived of food intake before experiment. The pressure causing the rupture of colon was 16.67 to 21.33 kPa, averaged 19.80± 1.38 kPa. To avoid the injury of the colon during the CRD, the cut-off pressure should be 13.33 mmHg when a 7 cm long balloon is used.

In conclusion, using colorectal distension to establish a model of visceral pain in rats is simple and reliable. The scores of abdominal withdrawal reflex (AWR) to CRD are

good for quantitative behavior assessment. This model can be used in experiments with free movement of animals. It provides a good animal model for study of the mechanism of visceral pain and the effects of different drugs on visceral pain.

Abstract

AIM: To generate a SV40Tag transgenic tumor animal model and to study the mechanism underlying tumorigenesis.

METHODS: A mammary gland expression vector containing SV40Tag DNA was generated. Transgene fragments were microinjeted into fertilized eggs of FVB mice. The genetically manipulated embryos were transferred into the oviducts of pseudo-pregnant female mice. PCR and Northern blot analysis were used for genotype analysis of F1 and F2 mice. Transgene expression was detected by RT-PCR and immunohistochemistry.

RESULTS: SV40Tag gene was detected in two lines of transgenic mice. One of them delivered the transgene to F1 and a tumor was found in the pancreas of these mice. RT-PCR and immunohistochemistry showed that SV40Tag gene was expressed in the tumor. Pathological characterization of the transgenic mice demonstrated that the tumor belonged to pancreatic cystic neoplasm.

CONCLUSION: SV40Tag transgenic mouse model can be successfully established. The transgenic mice develop a pancreatic tumor, which can be used for investigation of the molecular mechanism of tumorigenesis *in vivo*.

INTRODUCTION

Pancreatic cancer is one of the most common malignant diseases threatening human life. The survival rate of pancreatic cancer patients is among the lowest in all kinds of cancer patients. The 1- 3- and 5-year survival rates have been reported to be 16%, 5% and 4%, respectively[1]. Early diagnosis and effective therapeutic intervention are essential to improve the situation. Animal models of pancreatic cancer should provide important tool for the identification of biomarkers for early detection and molecular mechanism studies of the pathological procession of pancreatic cancer.

Simian virus 40 T antigen (SV40Tag) is a virus oncogene encoded by simian virus 40 (SV40). SV40Tag protein is a multifunctional regulatory protein that binds to and inactivates tumor suppressor genes, including P53 and Rb. It has been shown that interaction between SV40Tag and tumor suppressor proteins stimulates DNA duplication, thus facilitating cell proliferation and inducing cell transformation[2,3]. A number of tumor transgenic animal models have been established, including pancreatic cancer[2,3], bone sarcoma[4], urinary bladder carcinoma[5] and liver cancer[6]. In this report, we described the generation and characterization of a SV40Tag transgenic mouse model for pancreatic cancer. The animal model may be useful for molecular mechanism studies on this disease.

MATERIALS AND METHODS

Experimental animals

FVB and CD-1 mice were provided by Center of Comparative Medicine of Yangzhou University. Mice were maintained in standard laboratory conditions in a 12h light/12h dark cycle.

Expression vectors

A 2482-bp SV40Tag DNA fragment was generated by PCR using COS-1 genomic DNA as template. The PCR

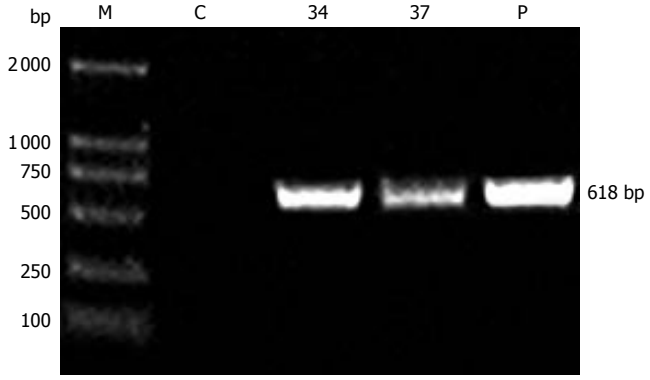

Figure 1 PCR results of transgenic mice. M: DL 2000 marker; C: Non-transgenic mouse concrol; P: pBC-SV40Tag plasmid; 34 and 37: the number of gene positive mice.

product containing the entire SV40Tag coding region and a 346 bp intron with two Xho I sites at both ends was purified, digested with Xho I and then cloned into pBC-1 vector to generate the transgenic construct pBC-SV40Tag.

Preparation of transgenic mice

An 18.2 kb pBC-SV40Tag fragment was purified from agarose gel (Qiagen, CA, USA) and adjusted to a final concentration of 2 μg/mL in PBS. FVB female mice were hormonally super-ovulated and mated with FVB male mice. The fertilized eggs were collected from the oviduct 24 h later. Transgene pBC-SV40Tag in PBS was microinjected into the pronuclei of fertilized eggs. Finally, the injected fertilized eggs were transplanted into the oviduct of pseudo-pregnant CD-1 mice.

Genotype of transgenic mice

Founder (G0) mice were identified by PCR and Southern blotting analysis. Genomic DNA was isolated from the tails of transgenic mice using a standard method. For PCR, a pair of primers spanning SV40Tag introns was designed (forward: 5'-ACTTTGGAGGCTTCTGGGAT-3' and reverse: 5'-GGTGTAAATAGCAAAGCAAGCA-3'), which would produce a 618 bp fragment for genomic DNA template and a 272 bp fragment for cDNA template. PCR using genomic DNA as template was performed under the following condition: 35 cycles at 94℃ for 1 min, at 60℃ 45 s, at 72℃ for 50 s. PCR products were detected by electrophoresis on 1.0 % agarose gels. After PCR screening, transgenic mice were further confirmed by Southern blot analysis. Genomic DNA was digested overnight with Nde I and subjected to electrophoresis on a 0.8 % agarose gels. DNA was transferred onto nylon membrane (Millipore Co., Ltd). The 1 kb fragment of plasmid pBC-SV40Tag digested with Nde I was used as a probe. Southern blot analysis was performed according to ECLTM direct nucleic acid labeling and detection system (Amersham).

Morphology and anatomy examination

Transgenic mice were examined every day. Mice with bulgy belly and showing listlessness were anatomized and photographed. Various organs and tumors were dissected from the transgenic mice and fixed in 10 % formalin. Sections were obtained from paraffin-embedded tissue samples, stained with hematoxylin-eosin, and examined under a microscope and photographed.

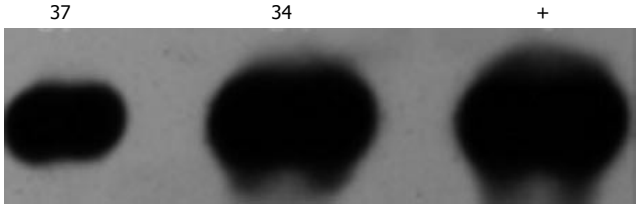

Figure 2 Southern blotting of transgenic mice. +: pBC-SV40Tag plasmid positive control; 34 and 37: the number of gene positive mice.

Expression of transgene

Total RNA was isolated from tumor and other tissues with TRIzol reagent (Invitrogen) according to the manufacturer's instructions. First strand cDNA was synthesized using reverse transcriptase (Promega). RT-PCR was performed using the SV40Tag primers described above. PCR was performed for 35 cycles at 94℃ for 1 min, at 60℃ for 45 s, and at 72℃ for 50 s. The PCR products were analyzed by electrophoresis on 1.0 % agarose gels.

Immunohistochemistry analysis

Tissues expressing SV40Tag were collected and fixed in 10 % formalin. Paraffin-embedded tissue samples were cut into 5μm-thick sections. For immunohistochemistry, tissues were de-waxed and treated with newly diluted 3 % H_2O_2 for 15 min to destroy internal peroxidases. Tissues were incubated with normal goat serum at room temperature for 20 min, then incubated with polyclonal antibody of SV40Tag (Santa cruz biotechnology, sc-20800, 1∶400) at 37℃ for 120 min, and finally with goat anti-rabbit secondary antibodies at 37℃ for 30 min. The samples were stained with DAB using SABC kit (Boster). The nuclei were counterstained with hematoxylin. Slices were observed under microscope and photographed (Olympus).

RESULTS

Establishment of pBC-SV40Tag transgenic mice

pBC-SV40Tag was generated and confirmed by restriction enzyme map and DNA sequence analysis. A total of 39 mice were analyzed for production of transgenic mice. Two mice, one male and one female, were identified as transgenic mice by PCR (Figure 1). The serial numbers of the positive mice were line 34 (female) and line 37 (male). These transgenic mice were confirmed by Southern blotting analysis using Nde I digested SV40Tag DNA fragment as a probe (Figure 2). The line 34 developed a tumor at early stage (about 4 wk). Line 37 produced F1 off-springs by mating with normal FVB female mice.

Tumorigenesis of pBC-SV40Tag transgenic mice

Line 37 mice and positive off-springs developed tumor. At age of 10 wk, the mice showed a palpable abdominal mass and became gradually depressed and moribund (Figure 3A). After the skin of abdomen was dissected,

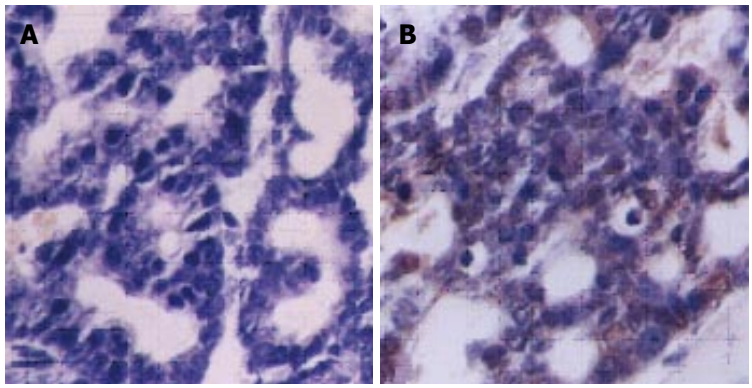

Figure 6 SV40Tag expression in tumor tissue detected by immunohistochemistry without anti-Tag antibody (**A**) and with anti-Tag antibody (**B**).

tumor tissue in the abdominal cavity was observed across peritoneum. In addition, a multilocular cystic tumor was identified in the abdominal cavity (Figures 3B and 3C). The diameter of the cysts ranged from 2 mm to 2 cm. The cystic cavities were filled with wine fluid (Figure 3D). Additionally, the spleen and kidney became swollen, and the kidney showed obvious pathological changes. No other obvious pathological changes were observed in other organs (data not shown). The cystic spaces were lined by multi-layer epithelium cells (Figures 4A-4C).

SV40Tag expression in tumor tissue

To examine whether the transgene was expressed in multiple tissues and tumor of transgenic mice, we performed RT-PCR for SV40Tag. A 272 bp PCR product was generated from tumor cDNA (Figure 5) by using SV40Tag specific primers, but not in other tissues. Furthermore, immunohistochemical analysis detected SV40Tag protein expression in tumor tissues of transgenic mice (Figure 6).

DISCUSSION

The early region of simian virus 40 (SV40) encodes a tumor antigen (Tag), a multifunctional regulatory protein responsible for the alterations of cellular processes is

required for viral infection[7]. SV40 Tag forms complexes with and inactivates the key cell cycle regulatory proteins, such as p53 and retinoblastoma (Rb) tumor suppressor gene product[7-10]. Loss of these functional tumor suppresso gene products is often associated with human cancer. SV40 Tag expression under the control of tissue specific promoters has been used to generate a variety of transgenic models for human cancers[11-14]. We have used breast-specific β-casein promoter for SV40 Tag transgenic models. Since the β-casein promoter can specifically drive the expression of SV40 Tag in the breast, we expected to generate a breast cancer transgenic mice. Surprisingly, the transgenic mice failed to produce breast cancer but developed pancreatic neoplastic lesions. One possible explanation is that the transgene has been integrated into a particular location of the mouse genome and leads to the expression of SV40 Tag in the pancreas. Another possibility is that the regulated element of the expression vector has been activated in the pancreas. In addition, the transgenic female mice developed a pancreatic tumor and died before lactation. Thus we have no way to know whether SV40 Tag is expressed in the galactophore of the transgenic mice.

Cystic pancreatic neoplasms comprise a heterogeneous group of pathologic entities. Although the incidence rate and lethality of the cystic pancreatic neoplasm are not as high as that of the pancreatic adenocarcinoma, some of the cystic pancreatic neoplasms can develop into metastatic pancreatic adenocarcinoma. The most common cystic pancreatic neoplasms are mucinous cystic neoplasm and serous cystadenoma. These two entities account for more than 75% of the cystic pancreatic neoplasms. Other less common cystic pancreatic neoplasms include papillary cystic tumor (also known as solid and papillary tumor), cystic neuroendocrine tumor, acinar cystadenocarcinoma, cystic teratoma, lymphangioma, hemangioma, and paraganglioma[15]. Due to the low incidence and recent nosographic arrangement, the natural evolution and the clinical development of these neoplasms are not well known. It is, therefore, difficult to identify all types of these cystic lesions. Pancreatic cancers are rarely observed spontaneously or induced by carcinogen administration in the laboratory mice. However, genetic engineering has been shown to effectively generate mice with germline oncogenic lesions similar to human pancreatic adenocarcinomas[16]. We have generated a transgenic animal model with classic features of human cystic pancreatic cancer. This model provides a tractable genetic system to dissect the complexities of evolving cancers in a physiological context. We believe that the mouse model is helpful for the identification of early disease markers and effective therapeutic targets for the disease.

Abstract

AIM: To study the variabilities of serum proteomic spectra in patients with gastric cancer before and after operation in order to detect the specific protein markers that can be used for quick diagnosis of gastric cancer.

METHODS: Proteomic spectra of 46 serum samples from patients with gastric cancer before and after operation and 40 from normal individuals were generated by IMAC-Cu protein chip and surface-enhanced laser desorption/ ionization time of flight mass spectrometry.

RESULTS: Fourteen differentially expressed proteins in serum were screened by analysis of proteomic spectra of preoperative patients and normal individuals. We obtained 4 proteins (heat shock protein 27, glucose-regulated protein, prohibitin, protein disulfide isomerase A3) making up marker pattern which was able to class the patient-team and normal-team. These marker patterns yielded 95.7% sensitivity and 92.5% specificity, respectively. The proteins over-expressed in serum of preoperative patients were obviously down-regulated.

CONCLUSION: Specific protein markers of gastric cancer can be used for the quick diagnosis of gastric cancer and judgment of prognosis. SELDI-TOF-MS is a useful tool for the detection and identification of new protein markers in serum.

INTRODUCTION

Gastric cancer is a common fast growing malignant tumor and takes the first place of the malignant tumors of digestive canal. About 160 000 deaths of gastric cancer patients occur every year in China[1]. It threatens people' s health in our country. The clinical diagnostic methods of gastric cancer are usually physical and pathologic diagnosis, which can only generally find the patients with intermediate stage. The technologies are complex and the patients wait a final diagnosis for a long time. We can only detect the specific protein markers expressed in gastric cancer by biochemical method to achieve early, quick diagnosis. But so far, no marker is completely specific to gastric cancer. Since the sensitivity and specificity of clinical diagnostic method of gastric cancer are not high, it is urgent to explore and set up an early gastric cancer diagnostic method which is easier, quicker and has a higher sensitivity and specificity.

We utilized surface-enhanced laser desorption/ ionization time of flight mass spectrometry (SELDI-TOF-MS) protein chip technology to contrast and analyze the changes of serum proteomic spectra in patients with gastric cancer before and after operation in order to screen the specific protein markers that could be used for diagnosing gastric cancer and judgment of prognosis.

MATERIALS AND METHODS

General documents

We chose 46 patients with gastric cancer from Department of Oncosurgery of our hospital in 2003 and 2004. Of the 46 patients, 5 were early cases, accounting for 10.9% of the total, and 41 were in intermediate and advanced stage, accounting for 89.1% of the total. The proportion of men and women was 2.2:1.0, the average age was 51 years. Forty healthy people served as the control group, the proportion of men and women was 2.1:1.0, their average age was 49 years. Before and after 15d of operation 5mL axenic venous blood was drawn from each patient on an empty stomach in the early morning and stored at -80 ℃. All the samples were provided by oncosurgery Department

Table 1 Seven over-expressed proteins in gastric cancer

Protein No.	Average molecular weight (kDa)	Protein identified
1	22.33	Heat shock protein 27
2	22.59	Transgelin
3	28.42	Glucose-regulated protein
4	29.90	Prohibitin
5	35.72	NSP3
6	42.46	Unnamed protein product
7	56.77	Protein disulfide isomerase A3

in our hospital. There was not statistical difference in sex proportion and age between the patient and control groups, and there was no relevant disease that could change serum protein content in the two groups.

Materials

Urea, acetonitrile, cibacron blue, 3-gryethylamine-1-propanesulfonic acid (CHAPS), trifluoroacetic acid (TFA), sinapinic acid (SPA) were all bought from Sigma Company. SELDI-TOF-MS, K30 size selection spin column and IMAC3 protein chip were produced by Ciphergen Company in USA.

Serum sample preparation

The samples stored at -80 ℃ were deliquesced at common temperature, cibacron blue and K30 size selection spin column were used to remove albumin in the samples. Then we used IMAC buffer solution (100 mmol/L Na_3PO_4 +250 mmol/L NaCl, pH 7.0) to dilute 20 μL serum sample.

Preparation of IMAC3 protein chip

We installed the IMAC#3 chip onto the bio-processor, added 50 μL of copper sulphate (l00 mmol/L) into every hole, spun it at 4 ℃ with the rotation speed at 200 per minute for 5 min, made copper ion combined with active surface of the chip. The remaining blotted copper sulphate was used to flush the chip in deionized water. Fifty μL of acetic acid sodium (100 mmol/L, pH 4.0) was added and spun to elute un-conjugated copper ion. The liquid was discarded and 150 μL balanced solution (50 mmol/L HEPES, pH 7.0) was added into every hole. Then 50 μL sample was added and incubated at 4 ℃ for 1 h. Excess liquid was discarded and 150 μL HEPES balanced solution flushing 3 times was used to elute the protein or peptide pieces that did not combine with the surface of the chip. Then we used PAP hydrophobic pen to draw the sample hole surrounding the chip and air dried it. After that, we added 0.5 μL SPA solution twice in every hole.

Data reading and result analysis

The prepared chip was analyzed by the analytic equipment of protein chip. Data were obtained by using Ciphergen Proteinchip software. Before the data were obtained, angiotensin peptide was used to correct the equipment to make the mass deviation of system less than 0.1%. The parameters of the data reading were as follows. Laser intensity was 175, detection sensibility was 8, grading-up molecular weight limit was 1500-100 000 Da, best focal setting centre was 6000, parameter limit of data collection was 20-80. Biomarker Wizard software was used to process the obtained data, the proteinic wave crest intensity was calculated, which had the same e/m. Different degrees were indicated by *P* value.

Statistical analysis

Data were analyzed using Biomarker Wizard software and Biomarker Patten software. $P < 0.05$ was considered statistically significant.

RESULTS

Distributed results of serum proteomic spectra between patients with gastric cancer before operation and normal control

Peak detection The protein molecular weight limit detected in the samples from 46 patients with gastric cancer before operation and 40 healthy people was set between 1500 and 100 000 Da. The proteins or peptide pieces less than 1500 Da were precluded, because between 0 and 1500 Da there were many agent compositions, SPA and other chemical compositions which could influence data analysis. The IMAC#3 array was analyzed by the analytic equipment of protein chip. The proteins obtained were expressed as spectrum and 54 126 wave crests were obtained.

Peak alignment and proteomic spectrum analysis Spectra obtained were analyzed by using Biomarker Wizard software. The content of most proteins in samples was generally identical in the preoperative and control groups, but 33 proteins were still differentially expressed in the two groups, 14 proteins of which were significantly differentially expressed in the 33 proteins in the two groups ($P < 0.05$). In these 14 proteins, seven proteins were over-expressed in the 46 patients with gastric cancer before operation, the average molecular weight of them was 22.33, 22.59, 28.42, 29.90, 35.72, 42.46 and 56.77 kDa (named gastric cancer over-expressed serum proteins 1-7), respectively. Compared with control group, seven proteins were under-expressed, the average molecular weights of them were 17.16, 22.02, 30.77, 46.73, 53.40, 77.07 and 80.02 kDa (named gastric cancer under-expressed serum proteins 1-7), respectively. Fourteen proteins were identified, the result showed that the seven over-expressed proteins were heat shock protein (hsp) 27, transgelin, glucose-regulated protein, prohibitin, NSP3, unnamed protein product and protein disulfide isomerase A3 (Table 1). The seven under-expressed proteins were p20, nucleoside diphosphate isomerase A, apolipoprotein A-1, alpha 1 antitrypsin, desmin, serotransferrin and serum albumin (Table 2).

Screening for gastric cancer serum protein markers and establishment of diagnostic pattern The data of the differentially expressed proteins were used to establish a database. Using Biomarker Pattern intellective statistical analysis software to select corresponding conditions, we analyzed the data obtained from preoperative and control groups and obtained the specific proteinic markers of gastric cancer. The results showed that using the pattern

Table 2 Seven under-expressed proteins in gastric cancer

Protein No.	Average molecular weight (kDa)	Protein identified
1	17.16	P20
2	22.02	Nucleoside diphosphate isomerase A
3	30.77	Apolipoprotein A-1
4	46.73	Alpha 1 antitrypsin
5	53.40	Desmin
6	70.07	Serotransferrin
7	80.02	Serum albumin

composed of heat shock protein 27, glucose- regulated protein, prohibitin, protein disulfide isomerase A3 could exactly distinguish gastric cancer patients from healthy people. Using these markers, we established the taxonomic tree pattern of gastric cancer diagnosis, which has two layers and three nodes and could exactly distinguish 95.7% of gastric cancer patients from 92.5% healthy people. The study results showed that these marker patterns yielded 95.7% sensitivity and 92.5% specificity, respectively.

Variabilities of serum proteomic spectra in patients with gastric cancer before and after operation

The sera of patients with gastric cancer after operation were analyzed by using IMAC#3 protein chip and Biomarker Wizard software with the same condition and parameters. The results were compared with those in the preoperative and control groups. The results showed that the expression of heat shock protein 27, glucose-regulated protein, prohibitin, unnamed protein product and protein disulfide isomerase A3 (namely: gastric cancer over-expressed serum proteins 1, 3, 4, 6, 7) decreased obviously in postoperative group compared with control group. The five proteins had significantly different expression. When compared with the preoperative group, the five proteins had significantly different expression ($P < 0.05$). NSP3 and transgelin (namely: gastric cancer over- expressed serum proteins 2, 5) were not obviously down-regulated after operation and still over-expressed. When compared with the preoperative group, they were not significantly expressed. When compared with control group, they were significantly expressed ($P < 0.05$) (Table 3). Compared with the preoperative and control groups, the results of serum proteomic spectra in postoperative group showed that serum proteomic spectra had some variabilities and the expression of some proteins with heavier molecular weight was different from that in the above two groups.

Table 3 Variabilities of gastric cancer serum over-expressed proteins before and after operation

Proteins	Molecular weight (kDa)	Expression preoperation	Expression postoperation
Heat shock protein 27	22.33	Over-expressed[a]	Normal[c]
Transgelin	22.59	Over-expressed[a]	Over-expressed[a]
Glucose- regulated protein	28.42	Over-expressed[a]	Normal[c]
Prohibitin	29.90	Over-expressed[a]	Normal[c]
NSP3	35.72	Over-expressed[a]	Over-expressed[a]
Unnamed protein product	42.46	Over-expressed[a]	Normal[c]
Protein disulfide isomerase A3	56.77	Over-expressed[a]	Normal[c]

[a]$P < 0.05$ *vs* control group; [c]$P < 0.05$ *vs* preoperative group.

DISCUSSION

Gastric cancer is a frequently encountered malignant tumor in clinic. Gastric cancer possesses a natural bacterial drug resistance to many chemotherapeutics. The current situations of gastric cancer in our country are high case fatality, low early diagnosis rate, low exairesis rate and low five-year survival rate. The method to diagnose gastric cancer is very complex. Pathogenesis of gastric cancer is a long process. Multiple factors determine genetic predisposition, which refers to bacterial infection, abnormal changes of many oncogenes and anti-oncogenes, including activation of oncogene, inactivation or absence of anti-oncogene, genic mutation, etc. It was reported that infection with *helicobacter pylori* could result in gastric epithelial hyperplasia and apoptosis[2]. Decrease of folacin in cells reduces the methylated level of some DNA fragments, including certain oncogenes[3]. Some scholars believe that the lower the methylated level of genes is the poorer the differentiation of the cancer cell[4]. The deletion of nm23 gene may relate with the transfer process of gastric cancer. It is necessary to find a new, effective and quick diagnostic technique which has a high sensibility and specificity to diagnose gastric cancer.

Before pathological change is discovered, the component and quantity of intracellular proteins may have corresponding changes in the disease. Through dynamic observation of proteins, pristine disease signs can be discovered. Proteomic technology has made the screening possible and can establish a new molecular diagnostic technology for clinical disease diagnosis, especially for tumor diagnosis[5]. Proteomic studies could lead to molecular characterization of cellular events associated with cancer progression, signaling and developmental stages[6,7]. Cancer-specific protein markers are the basis for developing new methods for early diagnosis of gastric cancer and its progression[7-10]. Genes work at protein level. Since the proteomic results can express both the intrinsic genetic effect on cells and the impact of its environment, it is very valuable to determine biomarkers of tumor. In the past, the main technologies used in protein research are 2D electrophoresis (2DE), high performance liquid chromatography (HPLC), mass spectrum, etc. Because information obtained is not enough, the development of proteomics is confined[11,12]. SELDI-TOF-MS protein chip technology is a new proteomic technology and can be used in high-flux analysis. Because the protein chip system based on this technology is widely used to screen early diagnostic markers of tumor, significant results have been achieved. Eggeling *et al*[13] have obtained the proteomic spectral variation of renal cancer by using this technology. Paweletz *et al*[14] investigated the proteomic spectral variation of liquid drawn from nipple and showed that

the proteomic spectra in patients with mammary cancer are significantly different from those in healthy people. Vlahou *et al*[15] have screened out five specific markers of bladder cancer from urine of patients with bladder cancer. These findings indicate that SELDI-TOF-MS protein chip technology is one of the main technologies of proteomics, especially suitable for screening the specific markers of tumor.

The results of our study showed that 33 proteins were differentially expressed in preoperative and control groups, 14 proteins of which were significantly expressed ($P<0.05$). In these 14 proteins, seven proteins were over-expressed and seven proteins were under-expressed. Through the identification of the 14 proteins, the seven over-expressed proteins were heat shock protein 27, transgelin, glucose-regulated protein, prohibitin, NSP3, unnamed protein product and protein disulfide isomerase A3, while the seven under-expressed proteins were p20, nucleoside diphosphate isomerase A, apolipoprotein A-1, alpha 1 antitrypsin, desmin, serotransferrin and serum albumin. The data of differentially expressed proteins were used to establish the database. The Biomarker Pattern intellective statistical analysis software was used to analyze the data in the database. We established a diagnostic pattern composed of heat shock protein 27, glucose-regulated protein, prohibitin, protein disulfide isomerase A3, which can exactly distinguish gastric cancer patients from healthy people. If these markers are used to diagnose early gastric cancer, they are able to yield a 95.7% sensitivity and a 92.5% specificity, respectively.

The serum proteomic spectra also changed in patients with gastric cancer after operation. The five formerly over-expressed proteins, namely heat shock protein 27, glucose-regulated protein, prohibitin, unnamed protein product and protein disulfide isomerase A3, were obviously down-regulated. When compared with control group, the five proteins were not significantly expressed ($P>0.05$), but the two proteins, namely transgelin and NSP3, were not obviously down-regulated. When compared with control group, the two proteins were over-expressed ($P<0.05$). The results of our study suggest that using the diagnostic pattern composed of the above four proteins to diagnose gastric cancer, can obtain a high sensibility and specificity and it can be widely used for clinical diagnosis of gastric cancer. But because the cases in early stage accounted for a small proportion of the samples in our research, the technology can only be used to diagnose gastric cancer. Before we give a conclusion whether the technology can be used to screen early gastric cancer, we must collect more cases of early gastric cancer.

In a word, using the diagnostic pattern composed of heat shock protein 27, glucose-regulated protein, prohibitin, protein disulfide isomerase A3 to diagnose gastric cancer can obtain higher positive rate, higher sensibility and specificity. It can be used to diagnose gastric cancer quickly and exactly.

In conclusion, SELDI-TOF-MS protein chip technology has lots of advantages and is a new effective technology for study of proteins.

Abstract

Constitutive activation of KIT receptor tyrosine kinase is a critical factor in the pathogenesis of gastrointestinal stromal tumors (GISTs). But there is little information on whether combination of imatinib mesylate (IM) and surgical treatment can prolong survival in the cases with unresectable multiple liver metastases. We report a case of postoperative recurrence of GIST treated by the tyrosine kinase inhibitor IM and surgical treatment. The initial complete response (CR) to treatment continued for 18 mo, but single liver metastasis showed regrowth in the left hepatic lobe during IM treatment. After partial resection of the recurrent tumor, postoperative course was uneventful and the patient has survived without recurrence for 24 mo. Currently, imatinib is the first-line therapy for non-resectable GISTs, but a single agent therapy often leads to tumor resistance. Even if tolerance to imatinib occurs, a combination of imatinib and surgical treatment can prolong survival in some cases as reported here. However, further studies on a large number of cases of recurrent GIST are necessary to evaluate the effectiveness of IM treatment combined with surgery.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are a group of mesenchymal neoplasms that arise from Cajal cells which are pacemaker cells of the gastrointestinal tract[1]. These tumors occur predominantly in middle-aged and older persons, and approximately 70% of the tumors are found in the stomach, 20%-30% are found in the small intestine, and less than 10% elsewhere in the gastrointestinal tract[1,2]. Recent studies have shown that cells GISTs express a growth factor receptor with tyrosine kinase activity termed c-kit[2]. This gene product appears to be the most specific diagnostic criterion for the diagnosis of GISTs[3]. The ligand for the c-kit receptor is the stem-cell factor, also known as the steel factor or c-kit ligand[4]. Mutations of c-kit that cause constitutive activation of the tyrosine kinase function of c-kit are detectable in most GISTs and appear to play a central part in their pathogenesis[2,5]. These mutations result in ligand-independent tyrosine kinase activity, autophosphorylation of c-kit, uncontrolled cell proliferation, and stimulation of downstream signaling pathways, including those involving phosphatidylinositol 3-kinase and mitogen-activated protein kinases. GISTs are notoriously unresponsive to conventional chemotherapy, and there is no effective therapy for the advanced, metastatic stage of this disease[6]. In this study, we used imatinib (STI571 or Glivec, Novartis, Basel, Switzerland)[7], an inhibitor of the tyrosine kinase activity of c-kit, for a patient with a GIST with multiple liver metastases.

CASE REPORT

In January 2003, a 37-year-old, previously healthy man, presented with mild abdominal discomfort and a large mass in the upper abdomen. Examination with upper gastrointestinal tract led to removal of the tumor in the

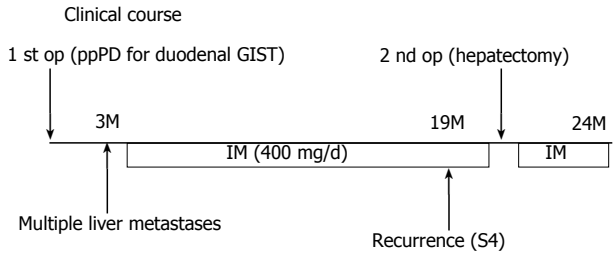

Figure 1 Clinical course of the patient illustrating the operations (pancreaticoduodenectomy for duodenal GIST and partial resection of recurrence tumor) and IM treatment.

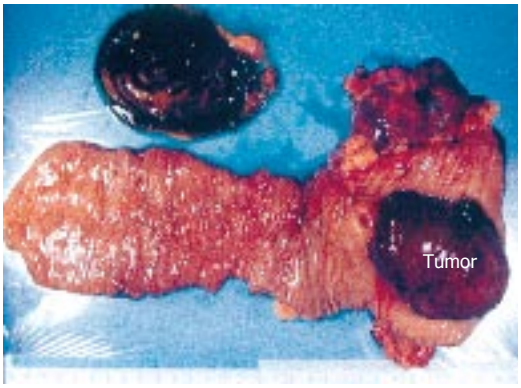

Figure 2 Surgical specimen obtained by pancreaticoduodenectomy of the duodenal GIST.

second portion of the duodenum by means of pancreaticoduodenectomy (PD). Clinical course of the operations (pancreaticoduodenectomy for the duodenal GIST and partial resection of recurrence tumor) and IM treatment are illustrated in Figure 1. The resected specimen is shown in Figure 2. In the second portion of the duodenum, a tumor of 5 cm in diameter was observed. Immunohistochemistry showed the tumor cells to be c-kit-positive, CD34-positive, SMA-negative, and S100-negative (Figure 3), indicating the tumor as a GIST. Histologic examination of the specimens revealed more than 20 cells per 10 high-power fields undergoing mitosis and identified the masses as a GIST. The diagnosis was confirmed by immunostaining for CD117, and c-kit mutation consisting of point mutation in exon 11 was detected in tumor DNA amplified by polymerase chain reaction[8]. Three months later, in April 2003, multiple recurrent tumors in the liver were detected by magnetic resonance imaging (MRI) and PET (Figures 4 and 5).

The patient was then treated with imatinib after his written informed consent had been obtained. Treatment with four 100 mg capsules of imatinib once daily was started in May 2003. This dose was based on evaluations of the safety and tolerability of imatinib for patients with chronic myeloid leukemia[9]. Toxicity was assessed at follow-up visits every two to four weeks, and blood cell counts and blood chemistry were examined every one to two weeks. The response to treatment was assessed with dynamic MRI and PET with ^{18}F-fluorodeoxyglucose as a tracer.

When measured as the sum of the products of the two

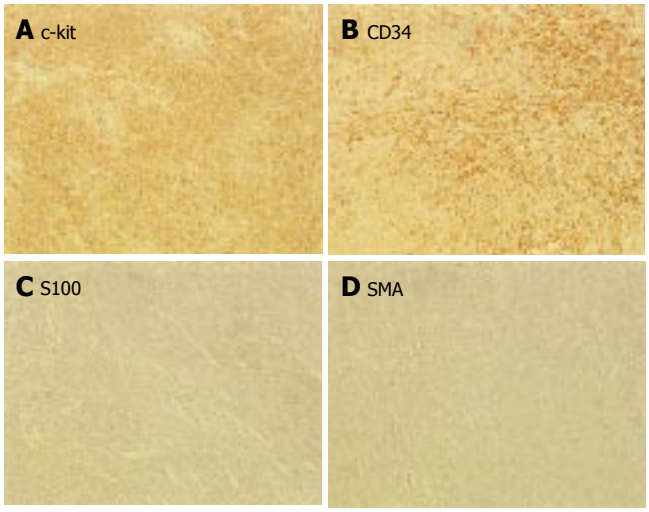

Figure 3 Immunohistochemical analysis of the duodenal GIST. **A:** c-kit; **B:** CD34; **C:** S100; **D:** SMA.

perpendicular axes of each of six large liver metastases, the size of the tumor one day before the start of imatinib treatment was 42 cm^2, but subsequent MRI scans showed that the size of the tumor had been reduced to 1 cm^2. No enhancement was seen on dynamic MRI obtained during the treatment, and many of the metastases became hypodense. Until October 2004, the tumors at all sites had continued to respond to the treatment, and the patient had remained clinically well. Multiple liver metastases and increased accumulation of ^{18}F-fluorodeoxyglucose were observed on the first PET obtained 4 d before the treatment with imatinib was started. One month after the treatment, PET scan showed no abnormal uptake of ^{18}F-fluorodeoxyglucose in the liver. On the PET scan obtained after two months of the imatinib treatment, cold areas with less uptake of ^{18}F-fluorodeoxyglucose than in the surrounding liver parenchyma were seen at the sites of liver metastases.

Although the response to treatment was initially CR and continued for 16 mo, single liver metastasis showed regrowth in the left lobe of the liver (S4) during the imatinib treatment. Other sites remained hypodense and no sign of recurrence was seen (Figure 6). Partial resection of recurrent tumor resulted a satisfactory postoperative course and the patient remains still alive without recurrence for 24 mo since the initial treatment with IM. The effect of IM treatment on other liver metastases besides the lesion of left hepatic lobe continued (Figures 6 and 7).

Mutation analysis of c-kit in exons 7, 11, and 13 was performed in the primary tumor as well as recurrent tumor as previously described[9]. Primary tumor showed the c-kit mutation at exon 11 codon 567-576 (AAT TAT GTT TAC ATA GAC CCA ACA CAA CTT → GAA), and an additional mutation was observed at exon 17 codon 820 GAT(Asp) to GGT(Gly) in recurrent tumor in the liver.

DISCUSSION

There is no effective therapy for unresectable or metastastic GIST, which is invariably fatal. The management of

unresectable or metastatic GISTs has been difficult because they are resistant to conventional chemotherapy and radiation.

Imatinib, a phenylaminopyrimidine derivative, is a small molecule that selectively inhibits the enzymatic activity of several tyrosine kinases, including ABL and the BCR-ABL fusion protein of chronic myeloid leukemia and Philadelphia chromosome-positive acute lymphoblastic leukemia. This selective activity of imatinib suggests that its inhibition of the constitutively active mutant c-kit tyrosine kinase seen in GIST can be an effective therapy for these tumors. Our patient had a rapidly progressive metastatic GIST. He showed a complete metabolic response within one month after the start of imatinib treatment, as shown by negative findings on PET, which indicated reduced tumor viability. In this case, histopathological evaluation and serial MRI analysis could not be performed soon, but dramatic shrinkage of the metastastic liver tumors was observed within two months. The close relation between clinical outcome and the findings on ^{18}F-fluoro-2-deoxy-D-glucose PET scanning indicates that such scanning is a useful complement to standard anatomical imaging with CT or MRI for monitoring the therapeutic effect of imatinib in patients with GISTs. Side effects of imatinib include nausea, diarrhea, edema, leukocytopenia, GI tract bleeding, liver dysfunction and so on[10]. In our case, however, only mild liver dysfunction was observed, and treatment with imatinib could be continued safely. This effect continued for more than 16 mo and there has

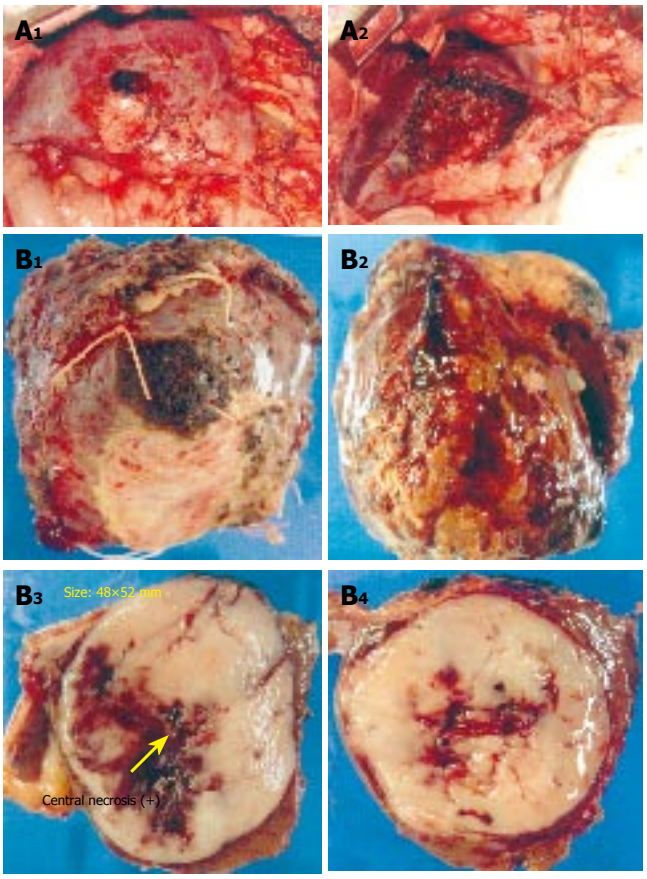

Figure 7 Surgical specimen of partial hepatectomy for GIST recurrence. **A:** Operative findings; **B:** Resected specimens.

been no sign of the recurrence. However, recurrence was subsequently detected and partial resection of recurrent tumor was performed.

It has been reported that the initial phase II study of imatinib treatment for metastatic GIST reported long-lasting responses in patients who followed up for 13 mo. However, it has become evident with extended follow-up that tumor progression can occur despite initially positive responses to imatinib therapy. The median duration of the responses was 19 mo for a series of patients with 2-year progression-free survival rate of 38%, which is a substantial drop from 90% at a 1 year[11]. Similar to previously reported cases, our case showed recurrence 16 mo after initial treatment with IM in one of six metastatic lesions. Resectability was confirmed and hepatic resection of the recurrence was successfully performed. The combination of IM and surgical treatment can prolong survival as shown in our case. Therefore, if the recurrent tumor is resectable, a second operation combined with adjuvant therapy with IM should be performed. If tumor re-growth occurs, surgical treatment should thus be considered.

Several studies have reported the relationship between c-kit mutation and imatinib sensitivity[11-19]. Although the mechanism of tolerance to imatinib is still unclear, screening of kit mutation may be useful for prediction of the imatinib sensitivity and recurrence. Many kinds of c-kit mutations related to IM resistance have been reported[11,13-19]. In our case, a mutation in exon 11 of KIT was initially noted. After interruption of the treatment, an additional point mutation arose in exon 17 that caused resistance to imanitib. It has been postulated that the emergence of c-kit mutations that are resistant to imatinib-targeted therapy may account for these late treatment failures, and investigation into the biologic phenomena of imatinib resistance is an area of current research. As the mechanisms of recurrence and resistance to imatinib in GIST remains unclear, they should be investigated in detail from both the clinical and molecular biological point of view.

Imatinib is a recent and very promising treatment modality for the GIST, but complete surgical extirpation remains the only curative treatment of malignant GIST, as evidenced by our patient, who became disease-free only after resection. Even then, however, significant risk of recurrence remains, despite successful resection and imatinib treatment. Our patient's favorable response to imatinib supports the concept that specific inhibition of tyrosine kinase is a clinically useful therapeutic intervention for tumors in which aberrant kinase signaling is critical. Depending on individual circumstances, we should choose the most desirable treatment modality, and the combination of surgical extirpation and imatinib therapy should help to improve the prognosis of GIST patients in some cases. Further studies are necessary to clarify the various mechanisms involved.

Abstract

A 23-year-old man with post-traumatic hepatic artery pseudo-aneurysm and subphrenic liver abscess was admitted. He underwent coil embolization of hepatic artery pseudo-aneurysm. The pseudo-aneurysm was successfully obstructed and subphrenic liver abscess was controlled. Super-selective trans-catheter coil embolization may represent an effective treatment for hepatic artery pseudo-aneurysm combined with subphrenic liver abscess in the absence of other therapeutic alternatives.

INTRODUCTION

Hepatic artery pseudo-aneurysm is a rare complication of blunt abdominal trauma. Diagnosis is frequently delayed and made by splanchnic angiography. Most of the indications for surgical treatment may disappear after selective catheterization and embolization. We report a case of a 23-year-old man with a history of hepatic trauma. Subphrenic abscess formation after laparotomy and right hepatic artery pseudoaneurysm were diagnosed by enhanced computer tomography (CT). The lesion was confirmed by arteriography and managed with trans-catheter embolization.

CASE REPORT

We report a case of a 23-year-old man with a severe blunt abdominal trauma caused by a car accident. An immediate laparotomy was performed due to a severe collapse upon admission and a liver fracture was observed. He gradually recovered and a subphrenic abscess occurred on day 10 after operation. Abdominal CT scanning revealed a complex subphrenic abscess and a pseudo-aneurysm of the right hepatic artery (Figure 1). Selective angiography confirmed the diagnosis of right artery pseudo-aneurysm (Figure 2) and the aneurysm was occluded by trans-catheter embolization. This was accomplished uneventfully with placement of two 5mm coils into the aneurysm and right hepatic artery was unblocked (Figure 3). The 14-F drainage catheters containing semi-solid necrotic material were placed into these collections. Eventually, recovery was complete. The classical embolization could avoid surgical treatment with a high morbidity.

DISCUSSION

The liver is the largest solid abdominal organ with a relatively fixed position, which makes it prone to injury. The most common cause of liver injury is blunt abdominal trauma, secondary to motor vehicle accidents in most instances. In the past, most of these injuries were treated surgically. However, surgical literature indicates that as high as 86% of liver injuries have stopped bleeding at the time when surgical exploration is performed, and 67% of operations performed for blunt abdominal trauma are non-therapeutic[1-2].

As a result of this high mortality rate, emergency surgery is frequently indicated in patients with hepatic injury in the past. However, with better monitoring facilities and imaging techniques, most patients with blunt abdominal trauma are now treated conservatively. Pseudoaneurysms are better depicted by spiral or multi-section CT because of the ability to image during peak contrast enhancement[3].

Complications of liver trauma occur in approximately 20% of patients, including delayed rupture (very rare), hemobilia, arterio-venous fistula, pseudo-aneurysm, biloma and abscess formation[4]. There are many potential causes of liver abscesses, such as appendicitis, diverticulitis, or

Figure 1 Axial contrast-enhanced CT scan revealing a vascular mass lesion in the right lobe of liver.

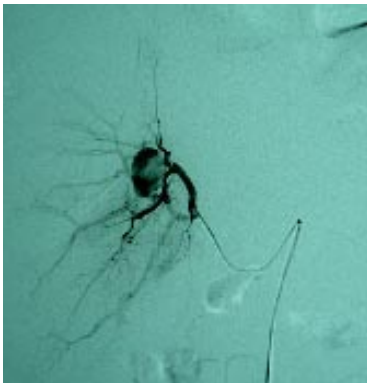

Figure 2 Selective celiac arteriogram showing a hepatic artery pseudo-aneurysm in the right hepatic artery.

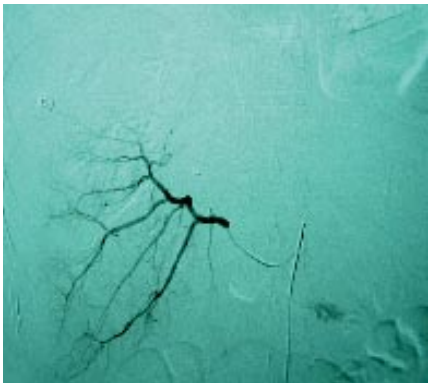

Figure 3 Post embolization selective arteriogram showing disappearance of the right hepatic artery pseudoaneurysm in the right lobe of liver.

a perforated bowel, infection in blood, infection of the biliary (liver secretion) tract, or trauma with bruised liver infection[5].

The most common bacteria that cause liver abscesses are escherichia coli, klebsiella, enterococcus, and bacteroides. The death rate is 10%-30% in treated patients, and higher in those with multiple abscesses. Life-threatening sepsis can develop. The treatment usually consists of surgical or percutaneous (through the skin, with a needle) drainage of the abscess. This is accompanied with a prolonged antibiotic therapy. Sometimes antibiotics alone can cure the infection. Occasionally, patients with blunt abdominal trauma do well initially, but subsequently develop a liver abscess, presumably due to unrecognized liver damage. These patients have signs and symptoms of deep-seated infection[6-7].

A dynamic angiographic study may demonstrate the site of active bleeding and the sac of pseudoaneurysms. Trans-catheter embolization may be the only treatment required. Superselective catheterization should be performed as far as possible. Both afferent and efferent vessels of pseudo-aneurysms or aneurysms should be occluded to prevent their retrograde filling[8]. Initially, the surgeon may control the hemorrhage by temporary perihepatic packing. Recurrent liver parenchymal bleeding can be treated successfully with trans-catheter embolization, and placement of an intravenous stent can control bleeding from a major hepatic vein[9].

Embolization can be performed for the control of persistent arterial hemorrhage which may occur due to stab wounds of the liver, and for the occlusion of pseudo-aneurysm. Trans-catheter arterial embolization may reduce transfusion requirements and allow healing of hepatic injuries without surgery. Because hepatic arteries are not the end arteries, occlusive devices should be deployed distal to the lesion to prevent collateral backdoor filling. The entire hepatic artery may be occluded if required, as long as the portal vein is patent. If the portal vein is occluded, only selective embolization can be performed to prevent liver infarction due to the presence of intrahepatic collaterals[10].

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *Helicobacter pylori, H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of change.

Perception of stimuli in the gastrointestinal physiology and new methods: From the editor

This special issue of *World Journal of Gastroenterology* contains a number of reviews on physiology and perception of stimuli in the gastrointestinal tract. Pain is probably the most prevalent symptom in medicine and characterization of pain is of major importance in the diagnosis and choice of treatment. Consequently, understanding and characterization of the physiology behind gut pain is one of the most important issues in the diagnosis and assessment of organ dysfunction. Research leading to a better insight into pain mechanisms in the gastrointestinal tract will invariably improve the treatment of the patients. Experimental pain models have been used frequently in animal studies. However, animal experiments can only to some degree reflect the experience of clinical pain in humans. Because of these factors, experimental human pain models are advantageous to assess basic pain mechanisms and to investigate abnormal pain responses in functional and organic diseases of the GI system. Using these models, the investigator can control the experimentally induced pain and provide quantitative measures of the responses. Recently, techniques to assess the gastrointestinal anatomy and function have improved dramatically. Imaging with ultrasound combined with endoscope, functional luminal imaging and advanced modeling of the luminal structures with assessment of the mechanical properties of the tissues may be a new cornerstone in experimental and clinical gastroenterology. The key to the progress in these developments have been the interdisciplinary collaboration between doctors, biomedical engineers and mathematicians. In the future the new methods will undoubtedly lead us into a new area bridging the understanding of basic physiology, symptom assessment and daily clinical practice. The reader is referred to the papers in this issue of WJG for information on these important aspects of gastrointestinal function.

Abstract

Methods related to experimental human pain research aim at activating different nociceptors, evoke pain from different organs and activate specific pathways and mechanisms. The different possibilities for using mechanical, electrical, thermal and chemical methods in visceral pain research are discussed with emphasis of combinations (e.g., the multimodal approach). The methods have been used widely in assessment of pain mechanisms in the esophagus and have contributed to our understanding of the symptoms reported in these patients. Hence abnormal activation and plastic changes of central pain pathways seem to play a major role in the symptoms in some patients with gastro-esophageal reflux disease and in patients with functional chest pain of esophageal origin. These findings may lead to an alternative approach for treatment in patients that does not respond to conventional medical or surgical therapy.

INTRODUCTION

Pain is probably the most prevalent symptom in medicine and characterization of pain is of major importance in the diagnosis and choice of treatment[1]. Abdominal pain is frequently occurring, even in the normal population[2], and abdominal discomfort and pain are among the most common symptoms responsible for patients consulting the health care system[3]. Consequently, understanding and characterization of gut pain is an important issue in the diagnosis and assessment of organ dysfunction. Research leading to a better insight into pain mechanisms in the gastrointestinal (GI) tract will invariably improve the treatment of the patients[1]. However, in practice, assessment of clinical pain is difficult as the symptoms of the underlying diseases confound the description of pain. These confounders may include complaints relating to psychological, cognitive and social aspects of the illness, as well as systemic reactions such as fever and general malaise[4]. Treatment with analgesics may also cause sedation and other side effects. Finally, abdominal pain is much more diffuse than somatic pain with autonomic symptoms, referred pain and hyperalgesia in remote somatic tissues. These factors will invariable bias the clinical evaluation. For example in the evaluation of analgesics the patients often tend to interpret other effects of the medication-such as an effect on the anxiety and depression relating to the disease-as a relief of pain[5]. To encompass these bias experimental pain models are increasingly used, especially in animal studies. In these experiments, the neuronal nociceptive activity can be recorded or behavior can be assessed[6]. However, neuronal recordings or reactions do not reveal all aspects of pain being the net effect of complex multidimensional mechanisms that involve most parts of the central nervous system[7]. Furthermore, major species differences in pain mechanisms often influence the findings. Therefore, although nociceptive reflexes or electrophysiological recordings from selected pathways in the animal nervous system are important in basic research, the central pain mechanisms and associated complex reactions are typically suppressed. Thus, animal experiments can only to some degree reflect the experience of clinical pain in humans. Because of these factors, experimental human pain models are advantageous to assess basic pain mechanisms and to investigate abnormal pain responses in functional and organic diseases of the GI system. Methods related to

experimental human pain research aim to activate different nociceptors, evoke pain from different organs and activate specific pathways and mechanisms. Assessment of the output from these pain models can be based on psychophysical or neurophysiologic methods[8]. Using these models, the investigator can control the experimentally induced pain (including the nature, localization, intensity, frequency and duration of the stimulus), and provide quantitative measures of the psychophysical, behavioral, or neurophysiologic responses. Methods for imaging can also be added and some studies used a combination of these assessments. In this paper, however, the focus will be the methods for pain induction. The reader is referred to[4] for further detail regarding assessment of GI pain

EXPERIMENTAL PAIN MODELS

The ultimate goal of advanced human experimental pain research is to obtain a better understanding of the mechanisms involved in pain transduction, transmission, and perception under normal and pathophysiological conditions. Experimental approaches can be applied in the laboratory for basic studies and in the clinic to characterize patients with sensory dysfunction and/or pain in organic and functional diseases[4,9]. Depending on the experimental model, different central mechanisms and conditions mimicking pathological pain such as increased sensation to normal physiologic/non-painful and painful stimuli (allodynia and hyperalgesia) can be studied. However, most previous studies have relied on relatively simple mechanical or electrical stimuli. These methods are easy to apply but as discussed below they have special considerations and limitations. Therefore, new controlled and reproducible models and protocols are highly warranted.

The ideal experimental stimulus to elicit gut pain in man should be natural, minimally invasive, reliable in test-retest experiments and quantifiable. Preferably the pain should mimic the observations in diseased organs by evoking phenomena such as allodynia and hyperalgesia[10,11]. The different methods for pain stimulation of the human GI tract are described below and in Table 1. Some of the existing stimulation methods seem to fulfill the above requirements but most laboratories use their own stimulation paradigms, often without the necessary standardization.

Table 1 The different methods for pain stimulation of the human GI tract

Stimulation modality	Stimulated structures	Advantages	Limitations
Electrical	Nerve fibers primarily in mucosa and muscle layers dependent of the stimulation intensity (not a specific activation of the nociceptors)	Excellent for repeated stimulation, suitable for neurophysiologic assessments of the pain	The electrical threshold depends on the fiber diameter, i.e. small-diameter nerves cannot be excited without exciting others. May induce arrhythmias in areas near the heart
Mechanical	Mechanoreceptors located in different layers	Imitates a bolus, reproducible stimulus	Problems with estimating the transmural pressure and change in circumference
Thermal	Thermal sensitive receptors preferentially in the luminal layers	Activation of unmyelinated afferents in the mucosa selectively	Temperature stimuli in the range that can be felt are normally only relevant for sensation in the upper GI tract.
Chemical	Chemo-sensitive receptors, primarily in the mucosa	Resembles clinical inflammation, chemical stimuli activate predominantly unmyelinated C-fibres	Require a relative long latency time to the onset of effects, and that they are often not reproducible when repeated

Electrical stimulation

Depolarization of the nerve afferents by electrical current has been widely used as an experimental stimulus in humans for many years-for review see[9]. The electrical stimuli have proved to be safe in all parts of the gastrointestinal system[12-15].Various electrical stimulator devices connected to electrodes applied to the mucosa of the gut can evoke electrical stimulation. Stimulator devices can deliver different stimulation patterns, e.g., different waveforms, frequencies, and duration of the stimulus. This activates with some selectivity different afferents and nervous structures, and hence evokes different kinds of pain[7]. The electrical stimulus intensity to evoke pain as well as the size of the referred pain area is reliable and reproducible[12,13,16,17]. The well defined onset and offset of the stimulation eliminates the latency to stimulation of the afferents seen with other methods[7] and makes it suitable to study pain mechanisms related to time[16,18]. Thus, the method is very suitable for neurophysiologic assessments of the pain[18-20]. Furthermore, the stimulation field is usually not as large as in other models, and diseases with localized pathology such as ulcers may better be mimicked[13,18]. Central integration or temporal summation, being a human correlate to the initial phase of "wind-up", is a potent mechanism for generation of referred visceral pain and can easily be evoked by electrical stimulation[16,18]. The major shortcomings are that electrical stimulation bypasses the receptors and activates the nerve fibres directly, and the method is not a specific activation of the nociceptors. The electrical threshold is related to the fiber diameter and one cannot usually excite small-diameter nerves without additionally exciting others. Furthermore, electrical stimuli may induce arrhythmias when areas near the heart are stimulated[18,21] and therefore bipolar stimulation where the electrical field is more localized may be recommended.

Previous methods have suffered from problems with insufficient contact between the electrodes and the gut, and in some studies pain was not evoked in all

subjects. We have improved the method by integrating the electrodes on the biopsy forceps for the endoscopes, which makes it possible to stimulate well defined areas in the esophagus, stomach, duodenum, terminal ileum and colon[13,14,16,18]. Recently we used a 6 mm nasal endoscope for the stimulations. Apart from a little unpleasantness associated with the intubations, all subjects were able to lie comfortably and none complained of unpleasantness due to the endoscope for up to 4 h. An example of stimulation of the esophagus is shown in Figure 1. The advantage of this modification is that the position of the electrodes is controllable and can be changed in case of stimulation of nearby somatic structures and nerves. The contact with the organ wall is secured and evoked motor phenomena such as secondary contractions can be studied. However, endoscopic stimulation demands special equipment and facilities and improvement of methods for "blind stimulation" is highly warranted.

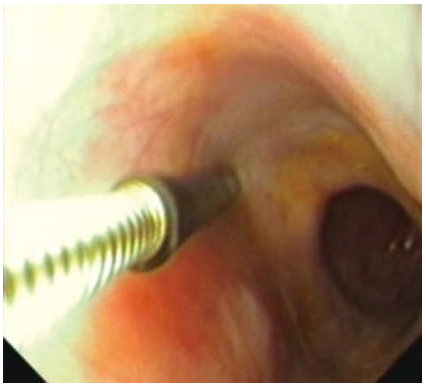

Figure 1 The stimulation electrode visualized in the distal esophagus using the nasal endoscope.

Mechanical stimulation

In the last decade several studies have addressed the mechanical and sensory function of the GI tract by means of mechanical distension. The mechanical properties of the GI tract are important for its function as a digestive organ and the gut contains mechanoreceptors at various locations in the wall, mainly in the muscle layers[6]. Mechanical GI tract stimulation, in particular balloon distension, has been widely used also to study GI smooth muscle tone[22-24], distensibility[22,25,26], peristaltic reflex responses[27], functional and organic disorders[28-32], referred pain and cerebral activation patterns[33] and the screening of new analgesics in healthy subjects and in patients with gut disorders[30,34-37]. There are several ways to stimulate the GI tract mechanically. Simple and physiological methods for distension of the gut such as ingestion of well-defined meals may be useful in clinical studies[38]. Balloon distension is, however, much more used than ingestion as mechanical stimulation method and easier to control. Therefore, the following sections will focus on controlled balloon distension methods used to evoke non-painful sensations and pain in the gut.

Most recent studies have used a method of measuring changes in volume of air in a balloon at constant pressure levels named "the Barostat". Several protocols and stimulation paradigms have been recommended for the Barostat, such as for example "phasic and tonic distensions". The stimulation paradigms have been thoroughly discussed recently and will not be described here-for review see[30,39]. The great advantage of the Barostat system and similar pressure-volume based methods are the relatively low cost, especially if the system is self-made. Furthermore, they are easy to use for routine purposes. Such systems have been used for determination of sensory and pain thresholds, and under different conditions attempts have been done to calculate the compliance and tension of the organs[26,30,39,40]. However, there are drawbacks with these simple methods. For example using the Barostat device, the data must be corrected for compressibility of air. The four major concerns, however, relate to (1) elongation of the balloon during distension; (2) the use of very long balloons; (3) the use of erroneous assumptions; and (4) the improper use of distension protocols. In more detail: (1) Balloon distension in a tube will cause the balloon to elongate to some degree due to the resistance to deformation in radial direction[41]. Volume is therefore not an accurate measure for the distension of the organ; (2) The use of long balloons is problematic because phasic contractions can be misinterpreted as muscle tone[42]. In addition relaxation in one end of the balloon and simultaneous contraction in the other end may not be registered as a change in volume at all; (3) Most previous studies have not validated the assumptions the data were based on. The most obvious and common mistake is to consider the fundus of the stomach to be spherical. From an anatomical and geometric point of view the stomach is not spherical and the wall structure with muscle layers in various directions indicates complex (anisotropic) properties. Distending a balloon in the fundus will deform the balloon into the corpus and antrum, resulting in a highly complex geometry; (4) No previous pressure-volume studies have considered the strain softening effect[43] and therefore it is highly questionable whether the results are reproducible. The tissue needs to be preconditioned before proper testing

The first three of the points mentioned above makes it impossible to compute the radius from the measured volumes. Consequently, estimation of wall tension using Laplace's law and computation of deformation in terms of strain measures will be invalid. It has also been a common mistake in gastrointestinal distension studies to consider the mechanoreceptors to be pressure receptors, volume receptors or tension receptors. Circumferential strain or stress are more likely candidates as the direct receptor stimulus, because the tensile stress and strain in distensible biological tubes are largest in the circumferential direction during distension[44]. Considering mechanical and receptor kinematic properties, strain is a more relevant parameter than stress (and tension). This is partly due to the fact that strain is a non-dimensional parameter that is independent of the original size of the organ and directly associated with tissue deformation. Recent studies clearly demonstrated that circumferential strain is an important determinant of mechanoreceptor mediated responses[45-48]. Correspondingly, studies providing tension calculations from Barostat studies have shown conflicting results, e.g.

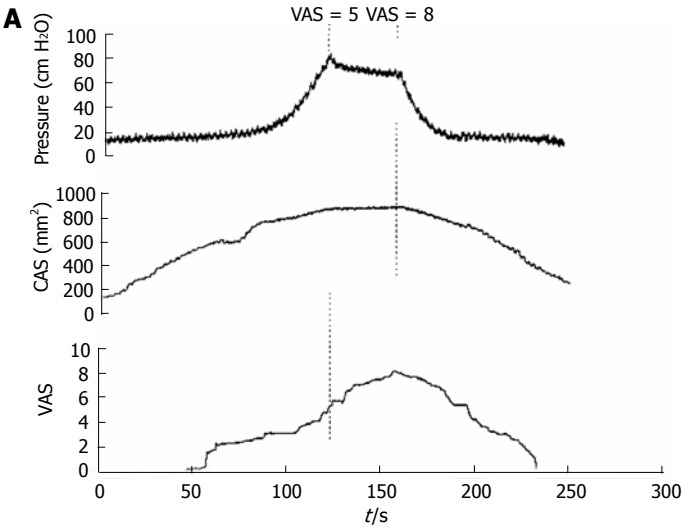

Figure 2 Top corner: The impedance planimetric probe for mechanical stimulation of the gastrointestinal tract. l and d denote infusion side for filling the balloon and the distance between two detection electrodes. Left: Recordings in the small intestine using the impedance planimetric probe with pressure, cross-sectional area (CSA) and VAS response as function of time during a ramp distension of the balloon up to the pain threshold where the bag volume is kept constant. It appears that the pressure decreased, the CSA was constant whereas the pain continued to increase.

in a recent study of the stomach the estimated tension seemed to correlate with the sensation[26,49], whereas another study[35] showed a highly inter-individual variability in the sensation score to the applied tension, suggesting that other factors than wall tension influence the sensation. However, uncertainties in the assumptions given above, and lack of proper geometric and biomechanical considerations can also explain these findings[41].

Newer methods based on impedance planimetry (Figure 2) allows recording of the luminal cross-sectional area directly and estimation of the radius in the distended segment of the esophagus or intestine[17,45,47,48,50,51]. From the radius it is possible to compute the circumferential wall tension and strain with more accuracy than from volume measurements[44]. Circularity must be assumed but this assumption has often been validated[44]. Finally, mechanical distension combined with ultrasound methods may offer the possibility for a better anatomical characterization and computation of stress in the GI tract[52]. For the stomach and other organs with complex geometry, imaging methods that provides data on the surface curvatures (3D-ultrasound, multislice CT-scanning or MR-scanning) in the whole organ may be used together with numerical mechanical analysis such as finite element analysis.

Thermal stimulation

In the skin rapid heating activates first myelinated Aδ-fiber, where the evoked sensation corresponds to the "first pain felt within 0.4 s after the heat stimulus. The first pain is followed by a C-fiber mediated second pain which is less well localized and of longer duration, being described as 'throbbing, burning or swelling'[53]. Slow heating gives a preferential activation of the unmyelinated C-fibers and the best evaluation of second pain[54]. Short lasting thermal stimuli have also been used in the human GI tract. Here they are believed to activate unmyelinated afferents in the mucosa selectively as opposed to mechanical and electrical stimuli, which activate afferents in both the superficial and deeper layers[6]. Thermosensitive mucosal afferents throughout the gut have been demonstrated in animal studies[6], and in the human esophagus, stomach and rectum[6,17,55-57]. The major limitation of these models is that temperature stimuli in the range that can be felt are normally only relevant for sensation in the upper GI tract. On the other hand, although temperature receptors may have less clinical relevance, characterization of the response to stimuli in the most superficial layers of the gut may be of major importance to develop a comprehensive sensory evaluation[4]. In recent studies the temperature of re-circulating water was continuously measured inside a balloon positioned in the esophagus[17,58]. The temperature stimuli showed a nearly linear stimulus-response relationship, demonstrating the validity of the receptor activation.

Chemical stimulation

Chemical stimulation of the GI tract more closely resembles clinical inflammation and is believed to approach the ideal experimental visceral pain stimulus[9]. Such stimuli have successfully been applied to the skin and muscles[11,59,60]. In contrast to electrical stimuli, chemical stimuli activate predominantly unmyelinated C-fibres[61] and this may be an advantage in basic studies of differentiated nerve populations. Acid stimulation of the esophagus is the most used method to sensitise the gut[59,62-65] but chemical stimulation of the gut with alcohol, bradykinin, glycerol, capsaicin and hypertonic saline were also done in humans[18,55,58,66-69]. For details see[4]. The major disadvantage of chemical stimuli is that they require a relative long latency time to the onset of effects, and that they are often not reproducible when repeated[9]. Thus, although chemical stimulation may evoke pain, the major relevance of the model is in sensitization of the visceral afferents to subsequent experimental stimulation.

Ischemic stimulation

Ischemia has been widely used for induction of muscle pain. Ischemia is important in many diseases such as mesenteric ischemia and ischemic colitis. Ischemia has been used in animal models of visceral pain[9]. Such studies are not acceptable in humans and unfortunately no human experimental gut models exist. However, distension of the gut may result in diminished blood flow. Accordingly, Öhman *et al*[70] observed a significant drop in blood supply during distension of balloons in the small intestine in rats.

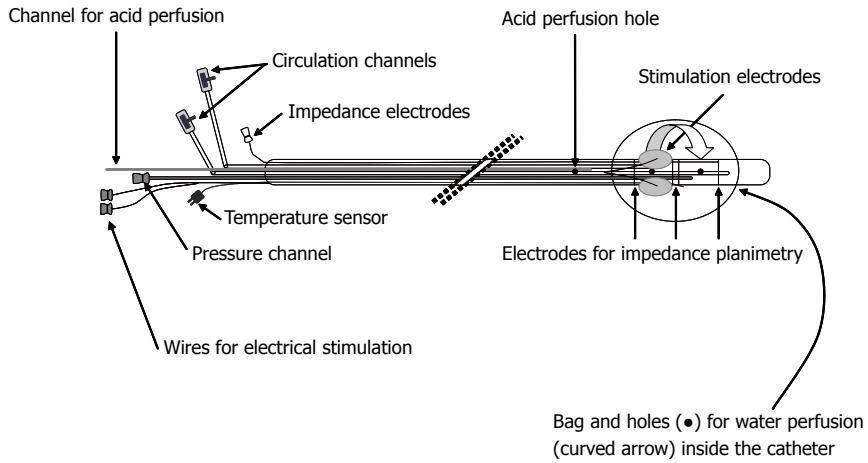

Figure 3 Schematic illustration of the probe used for multi-modal (electrical, mechanical, cold and warmth stimuli) of the esophagus. The stimulations can be combined with sensitization using acid perfusion of the distal esophagus.

Very recently, Hoff and coworkers presented a multimodal probe that selectively was developed for differentiation between mechanical and ischemic pain mechanism[71].

Multimodal stimulation of the GI tract

As pain is a multidimensional perception it is obvious that the reaction to a single stimulus of a given modality can represent only a limited fraction of the entire pain experience. The possibility for combining different methods for stimulation and assessment will approximate the clinical situation where many different nerves and pathways are activated. Thus, the method will give a more comprehensive and differentiated information about the nociceptive system compared to stimuli using single or a few modalities[72]. For comprehensive experimental studies mimicking the clinical situation, a multimodal testing approach must therefore be used, where the test battery will increase the probability for activation of a range of relevant nervous mechanisms. Such sophisticated methods will be able to select the best test procedures to explore different basic aspects of pain as well as pharmacological modulations. Multimodal models have shown their value in somatic pain models, where single modality models have been inadequate to test for example pathophysiological changes and effects of specific drugs[73,74]. Especially if the stimulation includes modalities known to evoke peripheral as well as central sensitization, the likelihood that a model will mimic clinical pain is high despite the non-harmful nature of the stimulation[73,75]. In somatic models it is possible to give many different stimuli and evoke central phenomena (e.g. central integration of summated stimuli) of clinical relevance (for review see[11,59]). In the GI tract, however, difficulties with access to the organs and technical limitations of the currently available models have until now made such a multimodal stimulation approach difficult. Some authors have combined mechanical and electrical stimuli[12,75,76] or mechanical and chemical stimuli[77,78], and in a recent study in the esophagus mechanical and electrical stimuli were combined with sensitization to acid[79]. We recently introduced a multimodal model with combined mechanical, electrical, cold and warmth stimuli of the esophagus together with acid sensitization[17,58] (Figure 3). The multimodal approach gives the possibility for a differentiated stimulation of receptors in the superficial and deep layers of the gut. The possibility for induction of hyperalgesia with e.g., acid perfusion and evoking central phenomena such as summation, allodynia and referred pain makes the model clinically relevant with respect to increase the knowledge of peripheral and central pain mechanisms[64,65,80]. The pain assessment should ideally also be multimodal and for example include quantitative and qualitative sensation, assessment of referred pain and neurophysiologic measurements. For details see[4]. However, is will typically not be feasible with too many stimulation and assessment parameters.

METHODS FOR AMPLIFICATION OF THE CENTRAL NEURONAL RESPONSE

Chronic pain is characterized by modifications of the central nervous system such as central sensitization[81]. Hence, decreased thresholds to normal stimuli such as stools and air in the GI tract seem to contribute to many of the symptoms reported by patients with inflammatory and functional diseases in the gut[82,83]. Phenomena relating to sensitization of the central nervous system (CNS) are enhanced responses to repeated stimulation, allodynia/hyperalgesia and increase in the referred pain area[4]. Repeated electrical or mechanical stimuli to the small and large intestine[16,84,85] may cause integration of the neuronal response and thus pain, and this may be used as a model for enhanced central gain (Figure 4). Munakata *et al* showed the importance of central mechanisms in functional gut disorders[86]. In their study the patients developed rectal hyperalgesia following repetitive sigmoid distensions. Induction of hyperalgesia in one area of the GI tract following conditioning of the more proximal parts most probably results from central sensitization. Chemical stimulation may also evoke sensitization. Acid stimulation of the esophagus has been used as a chemogenic stimulus by several authors[76-79,87]. Increased response to mechanical, electrical and thermal stimuli after the chemical sensitization have been demonstrated[58,76,78,79], although previous studies using latex balloons were not as consistent. This may be related to methodological problems using latex balloons, where the distension data need to be corrected for the balloons intrinsic mechanical properties *etc*.[44,78]. Sarkar *et al*[79] demonstrated the relevance

of central mechanisms in the gut, as acid exposed to the esophagus not only resulted in local allodynia, but also sensitized the proximal, non-acid exposed part of the organ to electrical stimuli. Capsaicin also increases the sensation in the esophagus to acid reflux[88,89] and when capsaicin was applied to the small intestine, consistent hyperalgesia to mechanical stimuli was seen[18]. Lipid infusion in the duodenum has also been shown to induce allodynia and increase the referred pain area to distension in functional disorders[90,91]. As fat is a natural stimulus to the gut, such studies may increase the understanding of the postprandial symptoms in these patients.

EXPERIMENTAL PAIN AND GASTRO-ESOPHAGEAL REFLUX DISEASE

Gastro-esophageal reflux disease (GERD) is defined as chronic mucosal damage or typical symptoms, which reduce quality of life by the abnormal reflux of gastric contents into the esophagus. GERD is very common in the population with up to 30% of the European population reporting heartburn and/or acid regurgitation during the previous 12 mo[92]. Recent studies revealed that up to 70% of the GERD patients have non-erosive reflux disease (NERD) according to endoscopy, 24-h pH profile and symptom-reflux association indices. However, in patients with NERD, the quality of life impairment is comparable to that in patients with erosive esophagitis[93]. The symptoms in reflux disease are highly variable and poorly understood. Thus, in patients with GERD no simple relation seems to exist between the symptoms and severity of the disease[94-96]. Although treatment with proton pump inhibitors (PPI) is very effective, many patients continue to have symptoms despite treatment[97,98], and in a recent study 50% of the patients continue to have pathologic reflux despite effective symptom control with PPI[99]. Furthermore, it is estimated that 30%-60% of patients with NERD will have normal ambulatory 24-h esophageal pH monitoring and thus no effect of PPI treatment[93]. Although some of these patients may have reflux of non-acid gastric contents, it is still not clear what causes the symptoms in many patients.

Experimental pain methods have contributed to the understanding of the symptoms in reflux disease. In an animal study Garrison *et al*[100] demonstrated that spinal neurons in the cat receiving input from the distal esophagus also received convergent input from the thoracic wall and the heart. When the esophagus was sensitized with turpentine, the neurons responded to a smaller mechanical stimulus from the different sites. Such data gives evidence that central mechanisms may explain the symptoms in a substantial proportion of the patients. In humans, however, relative few studies have been done to explore the pain mechanisms in reflux disease.

Non-erosive reflux disease

Peripheral pain mechanisms: Assessment of mechanosensitivity using intra-esophageal balloon distension has yielded contradictory results. In NERD patients Rodriguez-Stanley *et al*[101] reported a decrease in sensation and pain thresholds to distension compared with a historic control group. Trimble *et al*[102] studied NERD patients without excessive reflux and found that these patients were most sensitive to esophageal balloon distension, whereas patients with excessive reflux had a level of sensitivity similar to that of healthy control subjects. In another study using esophageal balloon distension delivered by an electronic barostat, patients with NERD and patients with erosive esophagitis did not demonstrate an increase in mechanosensitivity when compared to normal controls[87]. The previous experimental pain studies used mechanical stimulations based on recording of volume and pressure. As stated above these studies may lead to errors relating to the deformation field and erroneous conclusions[47]. Is has been suggested that chronic esophageal exposure to excess acid affects chemosensitive but not mechanosensitive afferent pathways[87] and that the key abnormality in NERD patients is that they are hypersensitive to acid reflux. Recently we conducted a study in patients with NERD where 50% had a positive 24-h pH measurement. Furthermore a multimodal approach was used. Our data showed that the patients had hyperalgesia to heat stimulation, whereas they were hyposensitive to mechanical stimulations. There was a difference in the NERD subgroups as patients with a pathological pH profile exhibited hyposensitivity to mechanical stimulations compared to both controls and patients with normal pH monitoring (Figure 5). Taken together with the above findings the results reflect that patients with pathological acid reflux may be less sensitive to mechanical stimulation and more sensitive to heat. The selective sensitization to heat may be related to specific receptor activation. Recently, we showed that acid perfusion of the esophagus in healthy subjects differentially sensitizes the esophagus to heat, but not cold stimuli[80]. The VRI receptor may be important for our findings. The receptor can be activated by a variety of stimuli, including acid (protons) and increases in temperature that reach the noxious range. Thus, it can be hypothesized that in patients with NERD the acid reflux and resulting peripheral sensitization

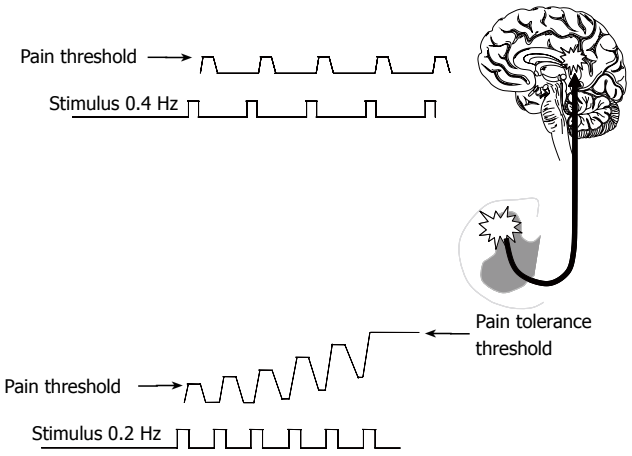

Figure 4 Central integration of repeated stimulation is seen when the stimulation frequency exceeds 0.3 Hz (bottom picture), whereas slower stimulation does not change the central gain (top picture).

results in a significant change in the sensation to heat stimuli working on the same receptor as the acid. Further studies need to explore whether the VRI receptors are up-regulated as seen in patients with erosive disease of the esophagus[103]-see below.

Central pain mechanisms: In the studies described above we also found an increase in the referred pain areas for both mechanical and heat stimulation in NERD patients. Previously we showed that acid perfusion of the distal esophagus in healthy subjects resulted in an increase in the referred pain area to differentiated esophageal stimuli[58]. This is most likely related to central neuronal hyperexcitability after acid perfusion, and subsequent opening of latent connections between converging neurons from visceral and somatic structures in the CNS[81]. Thus, the larger and widespread localization of the referred pain area is thought to represent central hyperexcitability. Consistent with these findings Penagini *et al*[104] showed that patients with NERD had increased sensitivity to distension of the proximal stomach. This viscero-visceral hyperalgesia is also considered a central phenomenon[105]. Experimental acid perfusion of the esophagus in healthy subjects has also been shown to increase the amplitude of the polysynaptic nociceptive reflex working at the spinal level[58]. Sarkar *et al*[79,106] demonstrated that acid perfusion of the distal esophagus resulted in allodynia and shorter latencies of the evoked brain potentials to electrical stimulation of a more proximal segment of the esophagus. Accordingly, we recently found a backward shift of the early activity in the cingulate gyrus to esophageal pain stimuli after acid perfusion of the organ[107]. Thus, there is substantial evidence that exposure of acid in the esophagus such as in some NERD patients may result in central neuroplastic changes at spinal and supraspinal levels.

Erosive GERD

Peripheral pain mechanisms: Patients with erosive disease of the esophagus may have a more severe disease than NERD patients, although erosive disease may also be a distinct entity[108]. In a study comparing patients with esophagitis with controls, Fass *et al*[87] demonstrated enhanced perception to acid perfusion, but the response to mechanical stimulation was normal. Such findings may point towards a differential effect on mechano-sensitive and chemo-sensitive pathways in esophagitis. Recently, we compared the sensory response in patients with grade B esophagitis and healthy controls using the multimodal approach described above. The patients had hyposensitivity to the mechanical stimulations, but had hyperalgesia to heat. These findings were comparable to those in NERD patients with abnormal pH profile and indicate that the pain mechanisms may be the same whenever erosions occur or not. A recent paper suggested that abnormal tissue resistance to acid may explain both the hyperalgesia and motor abnormalities seen in many patients with GERD and NERD[109]. In our studies the patients showed hyperalgesia to heat (but not cold) stimuli[110]. We believe that VR1 receptors sensitized by the acid reflux are important, and VR1 receptors have recently been shown to be up-regulated in esophagitis[103].

Central pain mechanisms: Central changes are also believed to be important in erosive disease. Although Fass *et al*[87] found a normal location of the referred pain we recently showed that the size of the referred pain area was larger than in controls. Thus, there is substantial evidence that exposition of acid in the esophagus in patients with esophagitis results in central neuroplastic changes. One can speculate that the reason for specific hyposensitivity to mechanical stimulations in patients with erosive disease may be related to well functioning counter-regulatory neural mechanisms acting from the brain stem at the spinal cord level. These may prevent the development of long-lasting sensitization of mechanosenstive afferent pathways[111]. The central pain modulating systems rely on a balance between facilitatory and inhibitory descending pathways and intrinsic spinal circuits and is not predictable in the individual patient[112,113]. Studies on animals have shown that the system is an important mechanism in the modulation of visceral stimuli[114] and these neuroplastic changes may result in increased referred pain on the one hand and dampening of the activity from mechanosensitive pathways on the other. In general chronic tissue injury and pain has been associated with higher thresholds to mechanical stimulation in different regions of the gastrointestinal tract. For example, chronic inflammation of the small bowel[115] in patients with inflammatory bowel disease is not associated with mechanical hyperalgesia of the rectum. This is contrasted by the pain in functional visceral disorders where hyperalgesia and allodynia to mechanical stimuli of the gut are typically found[86,115-118]. Hence, it can be speculated that a difference in the balance between noxious control systems arising in the brainstem may explain the findings in the different patient groups.

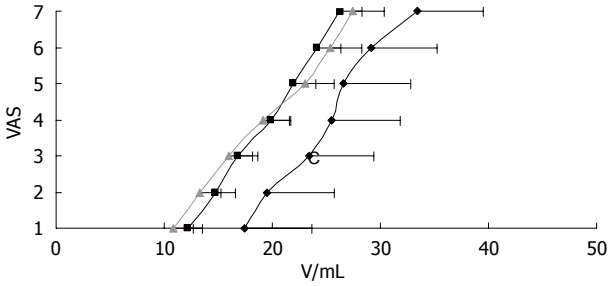

Figure 5 Stimulus-response function (mean ± SEM) to mechanical stimulation in patients with non-erosive gastro-esophageal reflux disease (NERD). The controls (■, *n* = 15) and patients with a normal 24-h pH-profile (▲, *n* = 7) had similar response to the mechanical stimulation, whereas patients with pathological pH-profile (◊, *n* = 6) showed hypoalgesia to the stimulations. The x-axis shows the volume of the balloon in the distal esophagus and the y-axis denotes the pain response on a visual analogue scale (VAS) with 5 as the pain threshold.

Non-cardiac chest pain

Non-cardiac chest pain (NCCP) was a term invented by the cardiologists. It was defined as "angina-like" chest pain without demonstrable abnormalities in the coronary vasculature. The more broad term "unexplained esophageal chest pain" is probably a better definition in gastroenterology, and may be defined as chronic chest pain, which is most likely of esophageal origin, but where

conventional tests for cardiac, esophageal, pulmonary (pain can be evoked from the pleura only) and musculoskeletal disorders are negative. The pain can be angina-like, but can also mimic other chest pain disorders such as gastro-esophageal reflux disease and musculoskeletal disorders. However, in the following the term NCCP will be used as it is the most common description of the syndrome. NCCP is very common especially in the younger age groups and the prevalence ranged from 22%-30% in the general population[119,120]. However, many persons have only modest and intermittent complaints and such cases must be classified as intermittent chest pain that is of no major burden, and a rough estimate would be that severe symptoms are seen in 2%-3% of the population.

If the patients describe "heartburn" and "acid regurgitation" they are typically classified as having GERD. However, burning pain may also be evoked by e.g., experimentally distension or electrical stimulation of the stomach[121] and the value of the subjective description of chest pain is up to discussion. GERD is also the most frequent cause of NCCP[122,123]. In this case the chest pain is no longer unexplained and the overlap invalids the diagnostic criteria for NCCP. The reason for heartburn in GERD is also up to discussion. Fass *et al*, have demonstrated that acid is not the only visceral stimulus that leads to heartburn[87], and recently Balaban *et al*, suggested that longitudinal muscle contractions of the esophagus as detected by high frequency intraluminal ultrasound, may be the motor equivalent of heartburn sensation[124]. Thus there is major overlap between the symptoms relating to the different chest structures.

The origin of chest pain

The symptom description is consistent with the organization of the nerves supplying the esophagus and the chest. The visceral afferents converge on a large scale with neurons that receive input from superficial and deep somatic tissue as well as other viscera[105]. Accordingly, in the thoracic spinal cord more that 75% of all neurons receive both somatic and visceral information, being contrasted by the actual number of visceral afferents (5%-15% of the inflow) entering the dorsal roots[6,125]. The visceral afferent terminals are widely distributed in the spinal cord and some organs have a wide spinal representation spreading to several segmental levels. For example the esophagus is innervated craniocaudally from the mid-cervical to the second lumbar segments[6]. Therefore a few visceral afferent fibers can activate many central neurons. Through the extensive functional convergence of somatic and visceral nerves on the same central neurons this wide activation of the CNS may explain the diffuse and unpleasant nature of visceral pain together with referred pain to somatic structures and other viscera[126]. In the clinic the above considerations typically leads to a very diffuse and heterogeneous description of the symptoms and experimental pain models may shed light over the pathogenesis of NCCP and related symptoms.

Peripheral pain mechanisms

Experimental pain studies in patients as outlined in the Introduction section have the possibility to control the stimulus and assessment parameters, and thus explore the abnormal pain system in further detail. Most studies found that the sensation and pain detection thresholds to distension, electrical and acid stimuli of the esophagus were lower in NCCP patients compared with thresholds found in healthy subjects[76,79,127-132]. However, the reliability of the test for diagnosing NCCP has been questioned[4], and in some experiments only few patients had abnormal sensation[133]. There are, however, severe methodological problems relating to these studies. Early balloon distension studies were based on simple volume and pressure measurements using latex balloons. As stated in the section above "Mechanical stimulations" this caused large errors due to the deformability of latex and lack of control of the stimulation field. There are also limitations and sources of error with the systems based on volume and pressure. The use of methods based on impedance planimetry has encompassed many of these limitations. Rao *et al*[134] used impedance planimetry and showed that patients with NCCP suffered from esophageal hyperalgesia. Furthermore the esophagus was more "irritable" than in controls, as the distensions resulted in more vigorous contractions at lower pressures. In more recent studies hyperalgesia was also found after relaxation of the smooth muscle with atropin[135], and there was evidence that the lower segments of the esophagus exhibited a higher level of sensory dysfunction compared to higher segments[136]. These studies were based on phasic distensions, which did not take the strain softening effect into account. Hence, we recommend to preconditioning the tissue by several distensions until the stress-strain relationship becomes reproducible[17,45,47].

Central pain mechanisms

Paterson *et al*[137] showed that repeated distensions conditioned the esophagus in NCCP resulting in higher pain scores. The effect of repeating stimulations has also been demonstrated in patients with irritable bowel syndrome, and probably this is a phenomenon relating to central hyperexcitability[86]. In a recent study we used a ramp distension protocol to distend the distal esophagus in patients with NCCP before and after sensitization with acid[138]. Patients with NCCP did not seem to be more vulnerable to develop esophageal hyperalgesia to the slowly increasing mechanical distensions as compared to controls. However, there was evidence for abnormal central pain processing as there was an increased and widespread referred pain area to the mechanical stimulations (Figure 6) and the patients were sensitive to repeated mechanical stimulation. Furthermore, after acid perfusion (believed to evoke hyperexcitability of central pathways mainly) there was a major sensitization to the distensions. Thus, it was concluded that NCCP patients showed facilitated central pain mechanisms, which may explain the character of their symptoms. This may have important implications for the diagnosis and treatment in these patients, where drugs with central effects should be used in the treatment.

Several studies have focused on brain activation to experimental pain stimuli in NCCP. The

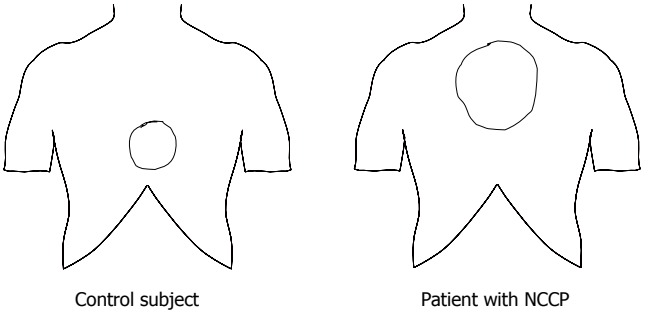

Figure 6 The localization and size of the referred pain area to mechanical stimulations of the distal esophagus in a typical control subject and a patient with non-cardiac chest pain (NCCP). The patient had and increased size and abnormal localization of the referred pain.

electroencephalography monitors the brain activity to external stimuli directly in real time. When a repetitive stimulus is applied and the cortical electrical activity is averaged (time-locked to the stimulus), the stimulus evoked cortical potential (EP) can be extracted from the background electrical activity and is shown in shape of a waveform with different peaks. Each peak in the EP represents a synaptic event associated with the transmission of afferent information from one group of neurons to another. The early peaks are supposed only to be influenced by the stimulation rate, intensity and localization, and they reflect to a major degree the brain loci that process the pain intensity and localization[139,140]. Three studies showed lower EP amplitudes to esophageal electrical and distension stimuli in patients with NCCP compared with healthy subjects[127-129]. Furthermore, Hollerbach *et al*[128] found shorter latencies of the EP peaks to electrical esophageal stimulation and more pronounced changes of the outflow of the autonomic nervous system in NCCP patients. Frobert *et al*[141] stimulated additionally the sternal skin (referred pain area) and showed shorter latencies and lower amplitudes of the EP to skin stimulation in NCCP patients. These findings suggest an increased central nervous system response to visceral stimuli in patients with NCCP comparable to those found in other groups with functional bowel disorders, e.g. patients with irritable bowel syndrome. Recently, Hobson and Aziz [142] suggested that different subgroups of patients with NCCP may exist: (1) Those with short latency of the early EP components having sensitization of gastrointestinal afferent pathways, and (2) those with long latencies and enhanced late responses reflecting hypervigilance and increased affective processing.

CONCLUSION

Pain is the most prevalent symptom in gastroenterology but yet poorly understood. This is reflected in the treatment of visceral pain that is often very difficult and highly challenging. Methods to evoke and assess experimental pain in the GI tract have recently been improved and used to explain the pain mechanisms in health and disease. In diseases relating to the esophagus these methods have contributed to our understanding of the symptoms reported in these patients. Especially does abnormal activation and plastic changes of central pain pathways seem to play a major role. These findings may lead to an alternative approach for treatment in patients that does not respond to conventional medical or surgical therapy, and probably analgesics with effect on the central nervous system such as tricyclic antidepressives, serotonin reuptake inhibitors, ion-channel blockers or opioids with additional effect on the N-methyle-D-aspartate (NMDA) receptor or kappa- opioids receptors should be used. Phase II trials where the experimental methods are used to evaluate these drugs will be a feasible way to obtain more knowledge, before more expensive large scale phase III studies in the clinic are initiated.

Abstract

Despite its role in disease there is still no definitive method to assess oesophago-gastric junction competence (OGJ). Traditionally the OGJ has been assessed using manometry with lower oesophageal sphincter pressure as the indicator. More recently this has been shown not to be a very reliable marker of sphincter function and competence against reflux. Disorders such as gastro-oesophageal reflux disease and to a lesser extend achalasia still effects a significant number of patients. This review looks at using a new technique known as impedance planimetry to profile the geometry and pressure in the OGJ during distension of a bag. The data gathered can be reconstructed into a dynamic representation of OGJ action. This has been shown to provide a useful representation of the OGJ and to show changes to the competence of the OGJ in terms of compliance and distensibility as a result of endoluminal therapy.

INTRODUCTION

The oesophago-gastric junction (OGJ) is located between the oesophagus and the stomach. Its dynamic action is dependant upon the intrinsic and extrinsic effects of its own anatomical structure and its position with respect to the surrounding organs in this region of the body. Despite its relationship to diseased states of the oesophagus, no objective measurement technique has been developed to quantify the normal or abnormal functioning of the OGJ. It is generally accepted that sphincters divide the gut into functional segments. They are characterized by a resting tension, generally known as muscle tone which is greater than in the two adjacent segments. It is common nowadays to give the term sphincter a functional meaning rather than its original anatomical meaning[1]. The sphincter at the lower end of the oesophagus, the lower oesophageal sphincter (LOS), forms part of the OGJ structure. At the OGJ the oesophagus opens into the stomach at the cardia. It is important that backflow of stomach secretions into the oesophagus is controlled at the OGJ. The OGJ guards against gastric acid moving up into the oesophagus, opening only transiently to allow passage of the swallowed food into the stomach. Swallowing is a demanding reflex activity[2]. The diaphragmatic hiatus, through which the oesophagus passes just at the OGJ, has a role in this valvular mechanism[3].

Several other structures are important in maintaining a barrier in the OGJ against the back flow of food and the stomach acids into the oesophagus, known as the anti-reflux barrier. The intrinsic muscles of the distal oesophagus and the sling fibres of the proximal stomach make up the internal mechanism of the LOS[4]. The muscles of the diaphragm that connect to the OGJ make up the crural diaphragm and this constitutes the external LOS mechanism. The tissue that connects the distal oesophagus to the crural diaphragm is known as the phreno-oesophageal ligament[5].

The OGJ can be distinguished from the body of the oesophagus by its behaviour pattern characteristics. There is an increase in the tone of the circular muscle in this region. The sphincter relaxes in response to a swallow and this usually precedes the arrival of a contraction wave travelling down the oesophagus. This phase of relaxation is followed by a short-lasting elevation of pressure above resting values[6]. In recent years it has been identified that the sphincter sometimes relaxes even when a swallow does not occur. These relaxations are know as transient lower oesophageal sphincter relaxations (tLOSRs)[7]. Other factors contribute to the role of the OGJ in controlling the flow of solids, liquids and gases between the oesophagus and the stomach. Pressures in the abdominal and thoracic cavities are involved as well as the exact intra-abdominal

location of the junction. Time and posture are also important factors.

THE ROLE OF THE OGJ IN DISEASE

Disorders of the OGJ in general relate to two diseased states. Conditions where the disease may be related to an OGJ not closing normally are generally referred to as gastro-oesophageal reflux disease (GORD) and conditions where the OGJ fails to relax or open, which is referred to as achalasia.

Gastro-oesophageal reflux disease

GORD symptoms are very common in the general population affecting up to 44% of the US population at least once a month and 20% of the population once a week[8,9]. It has been shown that patients suffering from GORD have a lower health related quality of life than patients with angina and mild heart failure[10]. There is solid evidence that incompetence or dysfunction of the OGJ is a primary determinant of GORD. Three mechanisms at the OGJ lead to an increased number of acid reflux events associated with GORD: tLOSRs, free reflux during periods of low LOS pressure or deglutitive relaxation of the LOS[7,11-13]. Much more needs to be learned about the dynamic action of the OGJ if we are to fully understand its role in GORD. Current treatment of GORD is with acid suppressing drugs such as proton pump inhibitors but for those refractory to pharmacological treatment surgery is often recommended. The surgery of choice for GORD is the laparoscopic Nissen fundoplication[14].

Achalasia

Achalasia is an oesophageal disorder of unknown cause characterized by aperistalsis of the oesophageal body and impaired relaxation of the lower oesophageal sphincter[2,15]. It is a relatively rare disease and in Western countries the annual incidence is in the range 0.5 to 8 cases per 100 000 people[16]. It can be difficult to make a diagnosis in some patients because of vague symptoms. Symptoms can emerge slowly and patients adapt. The diagnosis can be confirmed by endoscopy and manometry[17]. Developing a device that can profile the OGJ will contribute greatly to the understanding of this disorder, which often manifests as a permanently constricted or toned sphincter. Surgical performance of an oesophageal myotomy is the treatment of choice for some severe cases of achalasia[18]. Currently the laparoscopic oesophageal Heller-Nissen procedure is commonly used[19].

BIOMECHANICS OF THE OGJ

Biomechanics are the laws of mechanics applied to biology[20]. There is an increasing recognition of the importance of tissue biomechanical properties for function, e.g. organ geometry, resting conditions and elasticity is determinants of flow in the organ and sensory responses in the neural circuits. When dealing with biological tissues, solid mechanical parameters such as the relation between forces (membrane stress resultant, tension) and deformation (often expressed as a strain) are important to evaluate. The mechanical properties of the OGJ are important determinants of its distensibility and competence. In vitro studies have shown potential in measuring biomechanical parameters in the OGJ[21-25]. Very few methods exist for assessment of mechanical properties in the GI tract *in vivo*. One method is impedance planimetry from where the cross-sectional area (CSA) and pressure data can be gathered and the wall tension and strain in the organ can be estimated[26]. Other methods rely on the combination of bag distension and manometry with high resolution imaging techniques such as 3D-ultrasound of the gastric antrum[27] or MRI of the rectum[28]. Manometry is of course a simple biomechanical measurement. Its use will be mentioned again later.

METHODS OF EVALUATING OGJ FUNCTION

In 1964 Mann *et al*[6] suggested that the zone separating the lower end of the oesophagus from the stomach can be recognized in two different ways, by its distinguishing anatomic features and its unique patterns of behaviour. A huge amount of knowledge about the anatomy of the OGJ has been assembled over the last 40 years, but much of our limited understanding of the behaviour has been related to manometric studies using single or multiple pressure recordings or a sleeve placed in the OGJ. While manometry provides useful information on motility within the lumens of the digestive tract, it may be more restrictive in what it can tell us about sphincteric regions such as the OGJ and their dynamics. Harris and Pope found that sphincters do not necessarily need to squeeze or contract tightly to be competent and therefore resistance to distension by measurement of radial force should be the prime determinant of sphincteric strength[29]. Measurement of luminal pressure, however, is not a direct measure of muscle tone and tension. It is merely a proxy of changes in force generated by the surrounding tissues[27,30].

No clinically acceptable quantitative method exists to directly measure OGJ mechanical function. Intraluminal pressure recordings is the only objective measurement technique for determining the competence of the LOS, but it is usually the more indirect method of measuring acid reflux in the oesophagus which is the key determinant of failure of the OGJ to inhibit flow. Thus, pH-metry rather than manometry is the recommended test for GORD[31].

Usually in medicine dynamic diagnostic imaging methods can be used to visualize and evaluate anatomical structures similar to the OGJ. Currently none of these methods give sufficient dynamic detail to contribute to the routine diagnosis and treatment of diseases of the OGJ. Recent developments in material sciences and technology have allowed the OGJ's resistance to distension to be studied using parameters such as distensibility, opening patterns and dimensions and flow rate[32-34]. It is becoming apparent that these measurements may be useful in determining the success of therapeutic interventions such as surgery[35]. However what is needed is a technique with high spatial and temporal resolution for determination of sphincter geometry and mechanical factors.

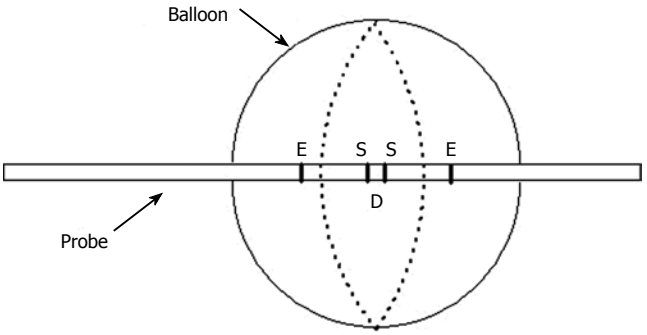

Figure 1 Sketch of a conventional impedance planimetry probe with a single set of excitation (E) and sensing (S) electrodes for the measurement of cross-sectional area in the middle of the bag. D is the distance between the sensing electrodes.

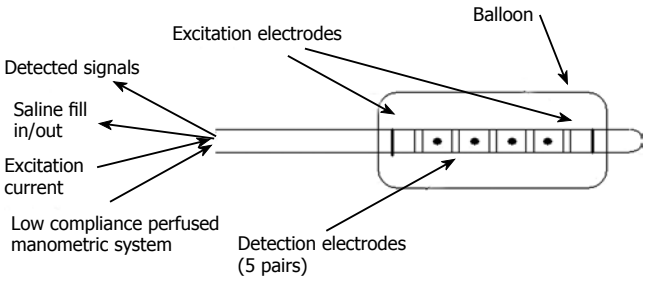

Figure 2 Diagram showing multi-electrode probe by Andersen et al for measuring 5 CSAs in the porcine rectum.

Impedance planimetry

Principle of Impedance Planimetry: Impedance planimetry (IP) is a technique established by Gregersen and coworkers for performing bag distensions in the GI tract (Figure 1). It has been used extensively to provide a single measure of CSA together with bag pressure in animal and human studies using electrical measurements inside the liquid filled bag[36]. Hence the term impedance planimetry. If we fill a polyurethane bag with saline and pass a constant current through it, the CSA is inversely proportional to the voltage across the sensing electrodes. If all other parameters are kept constant then the impedance becomes related to the CSA of the bag between the sensing electrodes.

$$V\alpha \frac{1}{CSA},$$

Many studies have shown the usefulness and reliability of IP in the oesophagus of healthy volunteers and patients[37-54]. Rather than analyzing distension data based on pressure-volume relationships as is the case with the "Barostat", IP enables data on the CSA of the bag during distension to be gathered. CSA shows a better relationship to the diametrical changes in the alimentary lumen than volume[27]. However, by far most studies have been done using a single CSA recording inside the bag rather than obtaining a series of CSAs. Due to previous limitations, it has only been used in a few studies in sphincter regions[55,56]. These limitations related to the difficulties placing the measurement electrodes at the point of most interest and the fact that distending a bag in a high-pressure zone tends to displace the bag during the measurements.

Multiple measurements: A recent pilot study in the porcine rectum demonstrates how an IP probe placed in the rectum with 5 sensing electrode pairs with 2mm between pairs and 2cms between sets can detect contractile events at different levels along the longitudinal axis of the gut (Figure 2)[39,57]. This multi-electrode technique demonstrated how a balloon with a conducting liquid and a constant current source set up across two excitation electrodes can measure multiple CSAs by measuring the voltage across multiple electrode pairs within the electric field.

There are a number of potential sources of error in multiple measurement IP systems. Electrodes placed too close together will interfere with each other. The number of wires required to make the electrical connections goes up and therefore the potential for interference, liquid leaking into the probe and bad electrical connections is much.

Manometry

Manometry has been used for more than 50 years to monitor motility in the gastrointestinal tract. Since 1977 reliable methods have been available to obtain accurate measurements of force of closure of the lumens of the intestine when contracting. These system often use reliable perfused hydraulic-capillary systems where pressure at a sensor outside the body can be used to accurately measure pressure at a point along a catheter via a low flow rate perfused channel[58]. This system has been used extensively to measure force via a pressure measurement in lumens and in liquid filled balloons. Errors in manometric readings can be caused by air bubbles in the capillary lines, occlusion of the measurement site and the compliance of the recording system but in general if well set up they produce accurate readings. In more recent years catheters with solid state transducers are becoming more popular for pressure reading and these overcome some of the measurement problems.

Using manometry to determine the competence of sphincteric or valvular regions in the lumens of the digestive tract is however dubious. Dent recognized the problem of positioning the measurement point 30 years ago and proposed a solution[59] and others tried to follow suit[60]. But pressure is a measurement of force over area and this may not be a proper measure of the function of a valvular region. As suggested by Pope and Harris we cannot assume that just because a sphincter is closed that it has a contract force or in the terminology of manometry that if it has a high lower oesophageal pressure it is deemed to be competent.

Calculation of wall tension

Law of laplace: For a membraneous cylinder with transmural pressure P and radius r the circumferential tension T can be given by :

$$Pr = T$$

Use of Laplace's law is based on the assumption that the geometry of the segment is circular and cylindrical and that the wall thickness is very small.

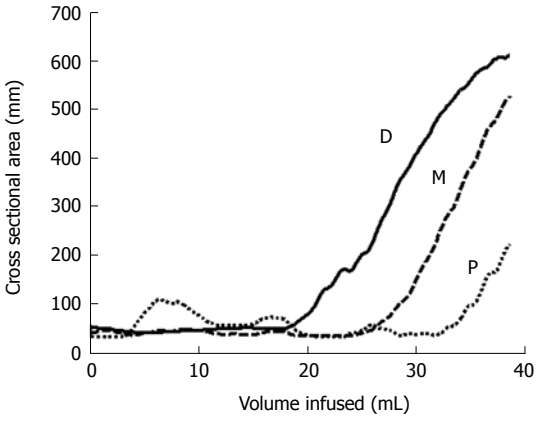

Figure 3 Plot showing the changes in the CSAs at the proximal (P), middle (M) and distal (D) electrode pairs as the balloon is distended at a constant flow rate indicated by the increase in volume.

Measurements using multi-electrode Impedance planimetry in the oesophagogastric junction

We have demonstrated that a multi-electrode probe with a cylindrical bag mounted and filled with saline can be placed in the OGJ and that data on a number of CSAs in this area can be measured[49]. Figure 3 shows results of 3 CSA measurements 8 mm apart measured from distension of a bag in the OGJ of a healthy volunteer. The plot shows how the most distal CSA (D) measurement increases more rapidly than the middle CSA (M) as a constant volume of saline is filled in to the bag. For the most proximal CSA (P) the converse is true. This suggests that distally the OGJ is more compliant than proximally. This work also demonstrated for the first time how wall tension in the OGJ can be estimated from simple distension measurements. This preliminary version of the multi-electrode technique demonstrated that a probe can be placed in the OGJ and that data can be successfully collected. However, there were limitations such as the fact that there were only three measurements made. A narrowing region such a sphincter can not be profiled very well with three CSA measurements unless the exact position of the sphincter is located and maintained. Another limitation is the outer diameter of the catheter on which the bag is mounted. In this case it was 4.5 mm. If the sphincter is to be distended from as close to the closed position as possible then a smaller catheter needs to be used.

Figure 4 shows how a probe capable of measuring 8 CSAs could be used to profile a sphincter region. It is quite obvious that a larger number of sensing pairs could be more useful in providing a geometric profile. Consequently a more elaborate probe for measurement of up to 8 CSAs in the region of the oesophago-gastric junction was developed. This probe can measure CSAs at 4 mm intervals through the OGJ thus spanning a measurement range of 28 mm.

Figure 5 shows the data from the 8 CSAs during a bag distension at a fixed flow rate of 40 mL/min to a volume of 60 mL. The information in this format can be difficult to decipher. A probe to make these measurements has been validated and test in a healthy control subject[57]. Since the OGJ is such a dynamic organ it is its functional activity which can be more of interest. Hence it is possible to generate an illustration of the geometric changes in the OGJ.

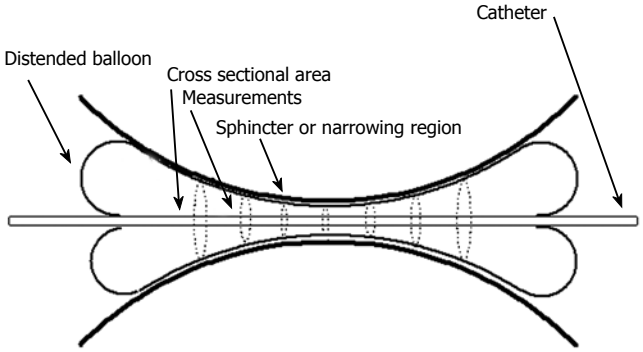

Figure 4 An example of how a probe which can measure 8 CSAs could profile the geometry of the narrowing region of a bodily sphincter.

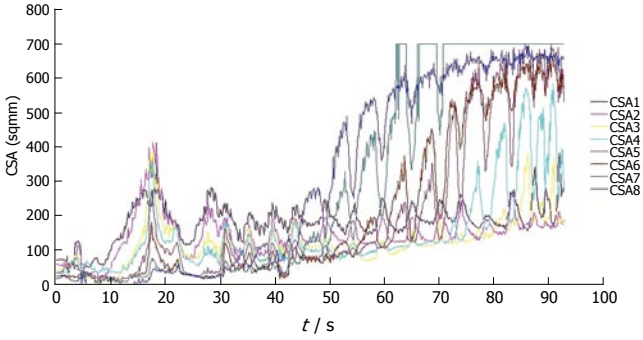

Figure 5 Plot showing changes in the 8 measured CSAs during bag distension at 40 mL/min. CSA1 is the most distal and CSA8 is the most proximal.

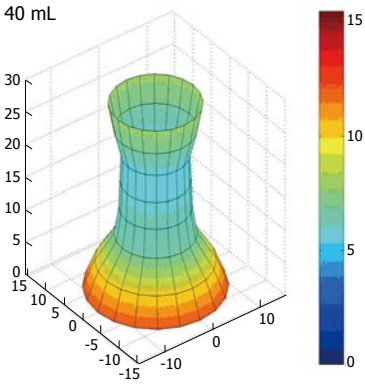

Figure 6 Three dimensional reconstruction of the OGJ geometry in a human volunteer after distension in to a volume of 40 mL. All dimensions are in millimeters. Colour change is indicating increased radius.

If we introduce the idea of demonstrating the CSA changes dynamically as reconstructed data we introduce a new concept known as the functional lumen imaging probe (FLIP). The concept suggests that by gathering data on the dynamic changes in the geometry of the OGJ during normal physiological changes we can represent these changes by recreating the geometry in a three-dimensional image. The FLIP technique can be used to monitor geometric changes in the behaviour of the OGJ during bag distension as can be seen in Figure 6. Here the dynamic data is reconstructed demonstrating the effect of the balloon distension on the amount of OGJ opening.

FLIP can quantify changes in compliance of the OGJ after endoscopic suturing at the OGJ in a pig model[61]. Figure 7 indicates how the geometric reconstruction can be used to indicate changes in the profile of the OGJ after endoscopic plication. The pressure is higher, the CSA is smaller and subsequently the wall tension has increased after the plications are inserted. These measurements indicate that the OGJ becomes less compliant after plication. No direct measure of the effects of these therapies on the OGJ has been demonstrated before. Recent studies have expressed concerns about the efficacy and durability of these procedures[62-65]. FLIP may in fact reveal new information on the mechanism of action behind these new reflux therapies. In effect it suggests that endoscopic suturing augments the compliance of the OGJ to make it less compliant. Perhaps patients could now be selected better for these procedures if their compliance can be confirmed to be abnormal in the first place and maybe the success of the procedure could be determined directly at the time of the procedure so for example more stitches can be added if necessary.

Since GORD patients are such a large group perhaps this is the most important area for FLIP to be developed. The probe can distinguish between patients for reflux surgery and normal controls. These are of course the extreme group of patients. Further studies are of course necessary on larger cohorts of patients and controls.

We have recorded with the FLIP the compliance of the OGJ intra-operatively during oesophageal myotomy for achalasia (as yet unpublished findings by the authors). FLIP offers a more sensitive and possibly a better tool than manometry and may be used for evaluating effects of surgery during the procedure as opposed to using manometry more as a blunt instrument before and after as used by Arain *et al*[66]. FLIP could provide a valuable new tool for the oesophageal surgeon.

Summary

Work already carried out shows for the first time that CSA and pressure measurements in the OGJ can be used to measure distensibility by an entirely new technique. It demonstrates how the already established technique of impedance planimetry can be used to measure geometry in vivo in the human oesophagus. It also shows that there is validity of these new measurements, their appropriateness for use in sphincteric regions in the body and their comparable accuracy has been shown with ultrasound. It has been indicated how the measurement could be used practically. Safety and efficacy has been demonstrated. The work also demonstrates how this new measure could be used as a functional imaging technique. Preliminary studies have shown potential applications of the probe. It could prove to be a very valuable tool in endoscopic therapies. It can distinguish between normal and a stitched OGJs in live pigs.

As a resistance to distension test this better describes the sphincteric action of the OGJ than tonic contraction. Even advanced manometry uses such as volume vector analysis, the Dent Sleeve or the Sphinctometer all rely on the principal that there is a force of contraction always present when the sphincter is closed[59,60,67-70]. With FLIP this assumption is not made and it presents more of a challenge test to the sphincter. The technique also represents a more direct technique to evaluate the OGJ using opening patterns with manometry and intraluminal impedance[71].

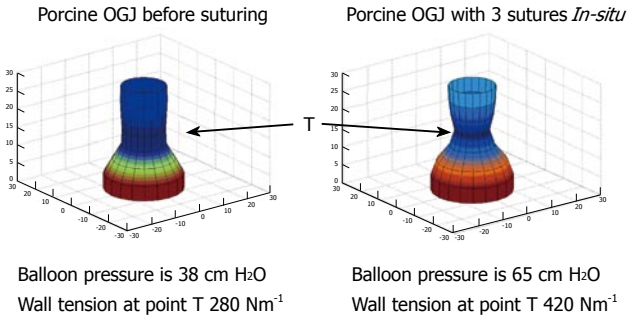

Figure 7 Geometric profile of the porcine OGJ before and after the placement of 3 sutures in the OGJ. T indicates the point where wall tension was measured.

Some other techniques for measurement of resistance to distension by other investigators are promising and confirm that the principals describe here have great potential for merit. However these other approaches are limited in a number of ways. The technique described by Pandolfino, although it is similar in its measurement design to FLIP, it requires fluoroscopic imaging[32,33,35]. It also depends on the pressure being controlled. Pressure control is difficult to achieve by increasing and reducing volume through a narrow catheter. Using pressure-volume data from the barostat to quantify distensibility does not a good basis in the application of the physical sciences. The bag on a barostat can expand in all directions we cannot be sure that an increase in the volume is reflected by a change in the geometry of the OGJ. This suggest that using this technique is of limited use[34]. Our findings in patients with achalasia confirmed this.

Perspectives

FLIP represents the first validated data on a probe capable of measuring OGJ compliance in a simple and time-saving procedure. It represents the opportunity to define the exact role of the OGJ in dysmotility and disease. As a new technique rather than representing a completed work it opens up a new door and perspectives on the junction whose function has been the subject of debate for many years. Future work and improvements in electronics and material sciences will mean that the resolution of the FLIP can be increased dramatically. Design materials have been carefully chosen to minimize signal error. The lower oesophageal sphincter or the oesophagogastric junction are often cited as being the prime causes of reflux disease, yet despite this very few research groups are investigating new ways to evaluate this dynamic structure in the gastrointestinal tract[32,34].

Much work has been done in extending manometric measurements enhancing pH measurement techniques to further evaluate the effects of acid in the oesophagus[72] and developing new techniques for measuring bolus transit

both down to the stomach and back up into the oesophagus using intra-luminal impedance[71]. However, none of these techniques have overcome the fundamental question of how the OGJ function can be quantified.

FLIP may provide the answer to this question. In a way trialing the probe in the OGJ was probably the most challenging and perhaps experiments in another sphincteric region would have been more straight-forward where the dynamic activity would be slower. FLIP may have a role in determining biomechanically the root cause of diseases. It can be used for evaluating therapy for example endoscopic and surgical therapy for reflux. It may be possible to use it intra-operatively during Nissen fundoplication, for example where the tension of the wrap is extremely important. It may also be possible to explore other sphincters in the body with FLIP so that the relationship between their biomechanical properties and their relationship to disease can be further defined.

Abstract

Gastric accommodation is important for the understanding of the pathophysiology in functional dyspepsia and is also relevant for symptom generation in other disorders. The term gastric accommodation has at least three different meanings: The accommodation *process*, the accommodation *reflex*, and the accommodation *response*. The gastric accommodation *process* is a complex phenomenon that describes how the size of the gastric compartment changes in response to a meal. The electronic barostat is considered the gold standard in assessing gastric accommodation. Imaging methods, including MRI, SPECT, and ultrasonography may also be used, particularly in patients who are stress-responsive, e.g. functional dyspepsia patients, as a non-invasive and less stress-inducing method is favourable. Ultrasonography satisfies these criteria as it does not by itself distort the physiological response in stress-responsive individuals.

INTRODUCTION

Gastric accommodation has become a key mechanism for the understanding of the pathophysiology in functional dyspepsia[1,2] and may also be relevant for symptom generation in other disorders[3-6]. Several methods can be used to assess gastric accommodation[7]. The electronic barostat is considered to be the gold standard method for measuring proximal gastric accommodation[8,9]. By applying the barostat, gastric tone is estimated by recording variations in the volume of air within an intragastric bag that is maintained at a constant pressure by the instrument. Accommodation of the proximal stomach is supposed to be reflected in changes of gastric tone. However, the method is invasive, bothersome and affects normal gastric motility[10]. The bag may also alter intragastric distribution and emptying of the meal the direct stimulus imposed by the bag itself on the stomach wall results in increased antral distension[11]. Therefore, non-invasive methods as MRI, SPECT, and ultrasonography are warranted for the study of gastric accommodation.

MRI is a safe and accurate technique to image the entire stomach with detail[12]. After ingestion of a test meal labelled with gadolinium as an MRI marker, images of the gastric region are acquired, typically using a Spin Echo T1-weighted sequence. The MRI technique permits three-dimensional reconstruction of the stomach, enabling total gastric volume measurements during fasting and postprandially. The ratio of these measurements is used to quantify the accommodation response. Single Photon Emission Computed Tomography (SPECT) uses ^{99m}Tc uptake into the gastric mucosa for visualisation and volume estimation of the gastric compartment[13]. Comparison of SPECT data with barostat measurements showed that SPECT is able to detect changes in intragastric volume but unable to detect changes in gastric tone and hence accommodation[14].

GASTRIC ACCOMMODATION

Conceptually, the process of gastric accommodation has been explored for over 100 years, evaluating relaxation of the proximal stomach[15]. Receptive relaxation has been defined as a vagal reflex, which dilates the corpus-fundus region of the stomach in response to swallowing, oesophageal stimulation, or vomitation[16-18]. Adaptive relaxation is a intrinsic vagovagal reflex that enables the stomach to increase its volume markedly without a corresponding increase in pressure[19,20]. Adaptive relaxation enables the stomach to maintain a low balanced pressure and to continuously adapt its volume to its content.

However, the term gastric accommodation is too

complex to embrace in one definition, mainly because it is utilized in at least three different meanings in the literature: The accommodation *process*, the accommodation *reflex*, and the accommodation *response*. In addition, the term is often used in an everyday language expressing that "the stomach accommodates a meal". Similarly, it was also used by Paton and Vane in 1963 to describe gastric "expansion to accommodate the fluid"[21]. The gastric accommodation *process* is a complex phenomenon that describes how the size of the gastric compartment changes in response to a meal[22]. It involves both intra- and extragastric reflexes. The extragastric reflexes comprises both receptive relaxation and intestino-gastric reflexes elicited by balloon distension or nutrient infusion in the duodenum[8,23]. The intragastric reflexes embrace at least adaptive relaxation and relaxation of the proximal stomach induced from antral reflexes[24-26].

Kelly[27] described the accommodation *reflex* when he demonstrated how intragastric pressure was regulated by gastric "accommodation to distension". The accommodation reflex is elicited when continuous volume expansion of the proximal stomach reaches a certain level, thus inducing relaxation of smooth muscles of the gastric wall in order to prevent further increase in pressure. This physiological phenomenon is a reflex arc consisting of a mechanoreceptor in the gastrointestinal wall, a neuro-muscular pathway through ENS with a reflex centre, and a well-defined response in the effective organ. The reflex is probably vagally mediated but local axon reflexes may also be involved[20]. The term accommodation *response* is the effect of the *reflex* or the result of the *process* and this is a precise notion for what we intend to measure with different methods.

IMAGING METHODS

A crucial question is whether imaging methods, as MRI, SPECT or ultrasonography, actually can be compared to the measurements made by the barostat. In our opinion, imaging methods and the invasive barostat method do not measure the same aspects of the gastric accommodation *process*. Thanks to its close contact with the gastric wall the barostat bag adjusts to changes in proximal gastric pressure by changing the intrabag volume. Thus, changes in volume are believed to reflect changes in muscle tone of the wall. However, the quantitative change in volume seen during barostat examinations is only valid during barostat studies using exactly the same equipment and positioning technique. Imaging methods, however, visualize directly the size of the gastric compartments, thus giving an indirect measure of relaxation and contraction. The volume change seen using imaging can thus be explained by additional secretion, air retention or most probable changes in gastric emptying.

The gastric meal accommodation *process* has two components: Passive meal distension of the gastric compartments and active muscle relaxation of the gastric wall. The first component is best measured with imaging methods whereas the barostat is best suited for studying the second component. Imaging methods at this stage, do not distinguish between enlargements of the stomach due to reflex relaxation or due to meal-induced distension; it just measures the totally accommodated volume. Accordingly, it may not be adequate to compare imaging methods to the barostat for validation of gastric accommodation. Gastric accommodation depends on neuromuscular factors and hence it is also a matter of evaluation of the mechanical properties of the stomach. In this sense the barostat merely detects the existence of change in wall tone, but cannot as the imaging methods, provide data on the distribution of the volume and the normal behaviour of the gastric wall. In biomechanics, it is essential to understand the geometry of the organ and the forces and deformation in different directions in order to better understand the active-passive muscle function and mechano-sensation in health and in diseases such as the functional disorders. This warrants 2D and 3D image analysis of the gastric compartments.

The different imaging methods exhibit different spatial and temporal image resolution, and these factors strongly influence accuracy in volume calculation. MRI and in particular SPECT imaging have poor spatial and temporal resolution compared to ultrasonography. Ultrasonography can provide temporal resolution above 100 fps, if necessary, and a spatial resolution on sub-millimetre level. Also, the "stress-factor" of the imaging methods should be considered in this context because dyspeptic patients in general and vagal reflexes in particular are very sensitive to psychological stress. Everyone who has been inside a narrow, noisy MR scanner knows how frightening this can be. Naturally, the stress-factor is also substantially involved in studies using the barostat. Simply because functional disorders are so strongly associated to psychological factors, the examination should be performed in a quiet and relaxing atmosphere with a minimum of distress. Ultrasonography satisfies these criteria as it is non-invasive and does not by itself distort the physiological response in stress-responsive individuals. Moreover, due to gravity playing a central role in the propulsion of gastric content, the study of meal accommodation should preferably be performed in a "natural position" such as sitting in a chair. Therefore, methods that enable patients to be seated have an advantage over methods requiring patients to be in supine position during the examination.

Ultrasonography

Ultrasonography, a clinical method that is widely available, has shown applicability and validity for the study of gastric accommodation[28]. The 2D method developed by Gilja *et al*[29] has been used to study gastric accommodation in functional dyspepsia[1,30], diabetes[4], in patients with reflux oesophagitis[5], in liver cirrhosis[31], and in children with recurrent abdominal pain[6]. This 2D method has also been applied to study pharmacological intervention[32] and the effect of a barostat bag in the stomach[11]. Another advantage with 2D ultrasonography is its clinical applicability; it can easily be performed bedside and repeated numerous times in the same subject. At Haukeland University Hospital we have for 20 years used The Ultrasound Meal Accommodation Test (U-MAT) for the work-up of patients with dyspepsia (Table 1). Our mainstream clinical protocol consists of a standard soup meal (500 mL), ultrasound

Table 1 The ultrasound meal accommodation test

Time	Protocol
Fasting	Ordinary ultrasound examination of the liver, gallbladder, biliary tract, spleen, pancreas, kidneys, and large vessels.
Fasting	Evaluation of symptoms by VAS.
Fasting	Assessment of motility pattern (phase 1-3) by observing the pattern of contractility in the antrum.
Fasting	Measurement of area of the distal stomach (AA).
Fasting	Visualisation of the proximal stomach to explore whether it has content.
Meal ingestion	500 mL of preheated meat soup is ingested in 4 min at a constant speed.
2 min pp.	Measurement of the sagittal area (SA), the oblique frontal diameter (OFD), and the antral area (AA).
5 min pp.	Postprandial symptom evaluation.
10 min pp.	SA, OFD, and AA measurement.
20 min pp.	SA, OFD, and AA measurement.
30 min pp.	SA, OFD, and AA measurement.

The ultrasound meal accommodation test (UMAT) was developed at Haukeland University Hospital on the basis of close interaction between scientific and clinical work in patients with dyspepsia. Before entering the protocol, the patients have been carefully worked-up with history, physical examination, blood tests, testing for H pylori, and upper endoscopy. In some cases, additional examinations are performed to rule out organic causes for their symptoms. The protocol presented here is the mainstream clinical protocol. In scientific studies other elements are often added. A 500 mL liquid meal of commercial meat soup (Toro × clear meat soup, Rieber & Søn A/S, Bergen, Norway) containing 1.8 g protein, 0.9 g bovine fat, and 1.1 g carbohydrate (83.68 kJ) is ingested over a period of 4 min. The soup is preheated and then cooled to 37 ℃ to improve imaging quality by reducing the amount of air bubbles. Psychometric evaluation is also performed.

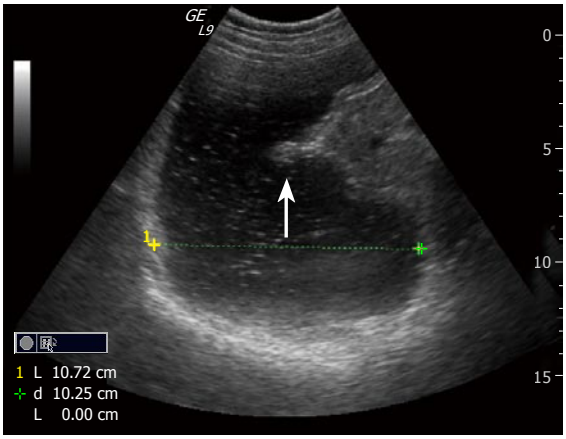

Figure 1 Ultrasonogram showing an oblique frontal section of the proximal stomach in a patient with dyspepsia referred for Ultrasound Meal Accommodation Test (UMAT). The transversal diameter is measured indicating the size of the postprandial proximal stomach and hence indirectly degree of accommodation. Interestingly, one can also observe a gastric contraction (white arrow) in the posterior angular part and progressing towards the antrum.

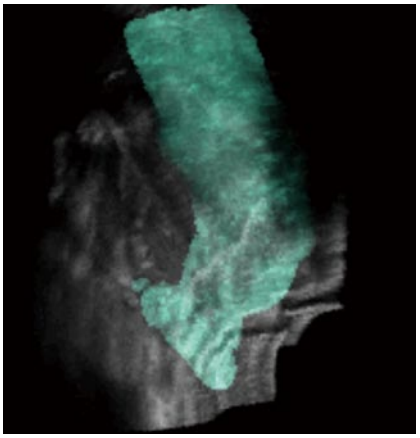

Figure 2 3D image reconstruction based on ultrasound acquisition with a magneto-based position- and orientation measurement system (POM) using GE Logiq 9. The 3D image is overlayed the ordinary gray scale values of ultrasonograms.

scanning of the proximal and distal stomach using predefined scan sections (Figure 1), calculation of size and volumes of the gastric compartments, evaluation of symptoms and psychological assessment. In our experience, ultrasonography used in this context adds valuable clinical information to the management of these patients.

There are few methods that are capable of measuring all parameters of gastric motility simultaneously. However, many authors have demonstrated that ultrasonography can be used to study not only gastric accommodation, but also gastric emptying[33-39], gastric configuration[40-42], intragastric distribution[43], antral motility[44-46] and distensibility[47,48], transpyloric flow[44,49-51] and strain of the gastric wall[42,52,53]. Of the present available methods, we would argue that ultrasonography is the method that has been shown to estimate most parameters of gastric motility, many of these also simultaneously. Furthermore, we claim that ultrasonography has the strongest potential as a clinical tool compared to MRI, SPECT, and scintigraphy, and particularly in patients with functional disorders.

3D ultrasound

For better visualization of the total stomach and improved calculation of gastric volumes, 3D ultrasound imaging of the gastric compartments was developed[43,54,55] It is important that validation of an imaging method to study gastric accommodation also include evaluation of its accuracy and precision in volume estimation. In our lab, we have utilized two different systems for acquisition of 3D ultrasound images and both systems have been validated *in vitro* and *in vivo*. First, we developed a mechanical system with the advantage of an accurate motorized movement of the ultrasound transducer in a tilting fashion. This 3D system demonstrated excellent accuracy and precision *in vitro*[56,57] and good agreement with MRI *in vivo*[58]. Subsequently, we applied a magneto-based system (Bird sensor, Ascension Technology Corp., Burlington, VT, USA) that enabled greater flexibility during scanning and larger volumes like the total gastric compartment to be captured (Figure 2). The Bird system also showed excellent accuracy *in vitro*[43,59-61] and in volume measurement of a thin-walled fluid filled bag in the human stomach the agreement with true volumes was excellent[62]. Accordingly, 3D ultrasonography delivers high resolution, is accurate in volume estimation and is a well-suited tool to monitor volume changes of the stomach during the *process* of accommodation. However, we acknowledge its limitations: impairment of image quality with air in the GI tract, mainly for use with liquid meals, and scanning of very obese subjects (fortunately dyspeptics are not often obese).

Abnormalities of gastric accommodation are a significant finding in several patients groups, not only in patients with functional disorders. Comprehension of gastric geometry, the forces and deformation during meal accommodation, and the active-passive muscle function is important in functional diseases[63]. Of the present available methods, we would argue that ultrasonography is the method that has been shown to estimate most parameters of gastric motility, many of these also simultaneously[64]. Furthermore, we suggest that ultrasonography has the strongest potential as a clinical tool, particularly in patients with functional disorders.

Abstract

The pathophysiology of IBS is complex and still incompletely known. Both central and peripheral factors, including psychosocial factors, abnormal GI motility and secretion, and visceral hypersensitivity, are thought to contribute to the symptoms of IBS. Several studies have demonstrated altered GI motor function in IBS patients and the pattern differs between IBS subgroups based on the predominant bowel pattern. Few studies have so far addressed GI secretion in IBS, but there are some evidence supporting altered secretion in the small intestine of IBS patients. Visceral hypersensitivity is currently considered to be perhaps the most important pathophysiological factor in IBS. Importantly, several external and internal factors can modulate visceral sensitivity, as well as GI motility, and enhanced responsiveness within the GI tract to for instance stress and nutrients has been demonstrated in IBS patients. Today IBS is viewed upon as a disorder of dysregulation of the so-called brain-gut axis, involving abnormal function in the enteric, autonomic and/or central nervous systems, with peripheral alterations probably dominating in some patients and disturbed central processing of signals from the periphery in others.

INTRODUCTION

Irritable bowel syndrome (IBS) is characterized by abdominal pain and/or discomfort related to abnormal bowel habits[1]. It is probably the most common disorder encountered by gastroenterologists[2] and also the most common gastrointestinal disorder seen in primary care[3]. A problem in the management of IBS is that there are no structural or biochemical disease markers for these patients. Therefore, various diagnostic criteria have been used to define IBS in clinical practice and, more importantly, in research settings[1]. In the Western world, IBS appears to affect up to 20% of the population at any given time[4-6], although the prevalence figures vary substantially depending on the definition of IBS[7,8]. Due to its high prevalence and, for many patients, chronic nature and incapacitating symptoms the cost of IBS to society is substantial[9].

Despite being very common, the pathophysiology of IBS is far from understood. IBS has for a long time been considered a disorder of disturbed gastrointestinal motility, although uniform motility patterns in IBS have been hard to define. Moreover, motility findings have been difficult to relate to symptoms, especially abdominal pain[10,11]. Beginning in the early 1970s, but progressing rapidly in the 1990s were theories that visceral hyperalgesia independent of enhanced motility could explain the painful symptoms of IBS[12]. More recently, a more integrated model of brain-gut interactions proposes that the central and enteric nervous systems interact and modulate enhanced motility, abnormal sensation and autonomic reactivity: the brain-gut axis. In context with this model, psychosocial factors, rather than being a cause of IBS, are regarded as contributing to the predisposition, precipitation and perpetuation of IBS symptoms, and affect the clinical outcome[13]. However, despite the increasing knowledge of the pathophysiological and clinical aspects of IBS, there are a substantial number of unresolved issues.

During recent years the interest in finding relevant alterations in patients with IBS in the function of the gastrointestinal tract, as well as in the central and autonomic nervous system has increased. The trend is now that there is less focus on pure gastrointestinal alterations and instead more focus on interactions between exacerbating factors and gastrointestinal function, as well as on interaction between different parts of our nervous system and the gastrointestinal tract. This article will review the literature

on findings in IBS patients supporting disturbed function in the gastrointestinal tract as well as its interaction with the central and autonomic nervous systems.

ALTERED GASTROINTESTINAL MOTILITY

Esophageal and gastric motility

Most studies of motility in functional bowel disorders have focused on the large and small bowel, although there are also reports on disturbed motility in the esophagus and the stomach. Patients with IBS demonstrate, for instance, lower pressure in the lower esophageal sphincter and more esophageal contraction abnormalities than healthy subjects[14]. Furthermore, patients with contraction abnormalities in the esophagus often report symptoms compatible with IBS[15]. There are several studies of gastric emptying in patients with IBS. These have come to somewhat different conclusions, with some of the older studies being unable to detect an abnormality[16-18], whereas some of the more recent studies found abnormal gastric emptying in at least a subset of IBS patients[19-22]. Moreover, the presence of gastroparesis in IBS was found to be related to small bowel dysmotility[23]. In a recent large-scale study, delayed gastric emptying was found in IBS patients with overlapping dyspepsia, but not in those without dyspeptic symptoms[24]. Some studies have also used electrogastrography (EGG) in patients with IBS finding a nice correlation between lack of increased postprandial EGG amplitude and delayed gastric emptying in a subset of IBS patients[25], whereas another study found EGG abnormalities only in IBS patients with concurrent dyspeptic symptoms[26]. The conclusion of these studies seems to be that altered esophageal and gastric motor function is more related to the presence of upper GI symptoms than to IBS per se, even though a significant overlap between upper GI symptoms and IBS exists[27].

Small intestinal motility

The motor patterns of the small bowel in man are rather well characterized[28], but marked inter- and intraindividual variations make interpretation difficult[29,30]. In the late 1970s technological advances made it possible to accurately record small bowel motility in man. Thompson and co-workers, using a radiotelemetry capsule system, reported abnormal small-bowel motility in a patient with "irritable colon"[31], but a follow-up study using a similar recording system failed to confirm this[32]. Subsequent studies have focused on the periodicity of the migrating motor complex (MMC) (i.e. the interval between successive MMC cycles), as well as finding specific motor patterns in IBS and relating these patterns to symptoms. In diarrhea prone subjects, the periodicity of the MMC during daytime has been found to be shorter[33,34], but longer in IBS patients with predominant constipation[35], although these are not consistent findings[36,37]. Increased frequency of clustered activity has been found in some[33,34,38], but not all studies[36,37,39]. Of more interest perhaps, are correlations between symptoms in IBS patients and certain motility patterns, such as clustered activity (e.g. "discrete clustered contractions") and prolonged propagated contractions[33,34], but likewise, these findings have been partly[37] or totally[36] rejected by others. Furthermore, IBS patients have been found to have enhanced perception of physiological intestinal motility, such as the activity front[40]. There also appears to be a relationship between heightened sensitivity to distension of the small intestine and postprandial jejunal motor abnormalities in IBS patients[41]. An increased contraction frequency postprandially has been demonstrated in diarrhea and constipation predominant IBS[42], and in a study by Schmidt et al diarrhea prone IBS patients had more aborally propagated contractions in phase II and postprandially than the controls[37]. The contraction amplitude has, if anything, been shown to be increased in IBS patients with diarrhea[37] and reduced in those with constipation[35,42]. Our group has used high-resolution manometry in the small intestine with closely spaced recording points to evaluate the propagation pattern of individual pressure waves[43]. A study in IBS patients and healthy controls disclosed a higher proportion of duodenal individual pressure waves that propagated in a retrograde direction in IBS, especially in the postprandial phase. Moreover, when combining this high-resolution analysis with more conventional manometry analysis, abnormal findings were found in the majority of IBS patients[38].

Motility disturbances of the small bowel have also been demonstrated indirectly in transit studies, with rather uniform findings of accelerated transit through the small bowel in diarrhea predominant IBS[44,45] and delayed transit in constipation predominant IBS[18,44]. Small intestinal bacterial overgrowth (SIBO) is a condition caused by an abnormal number of bacteria in the small intestine, which is a common complication of severe small intestinal motor dysfunction[46,47]. Recently, provocative studies, using the lactulose hydrogen breath test[48], have proposed that SIBO is present in approximately 80% of IBS patients[49] and that this alteration responds favourably to antibiotic treatment with symptom improvement[50]. Moreover, the presence of SIBO in IBS patients has been proposed to be related to small intestinal motor abnormalities[51]. However, contradictory results exist and the relevance of SIBO in IBS is still open to debate[52-54].

To conclude, there is evidence of disturbed small bowel motility in IBS patients as a group, but no uniform motility pattern has been found and a consistent correlation between motility findings and symptoms has been difficult to demonstrate. Whether the observed motility abnormalities of the small intestine in IBS are due to factors related to the enteric or the central nervous system is not clear, but there is evidence to suggest that both may be true[35,39,55].

Colonic motility

Considerable effort has been made to find a specific abnormality in the myoelectrical and/or motor patterns of colon in IBS. However, a primary role for colonic dysmotility in the pathophysiology of IBS has been hard to demonstrate. Some of these difficulties may be explained by the fact that myoelectrical and motor events from the colon are less predictable and less well studied than corresponding events elsewhere in the gastrointestinal tract[56,57]. In the 1970s Snape and colleagues reported on

abnormal colonic myoelectrical activity in IBS (3 cycle/min pattern)[58,59], but subsequent studies failed to confirm this pattern to be specific for IBS[60,61]. Instead, since this pattern was demonstrated to be equally common among psychoneurotics without gastrointestinal symptoms it was suggested that this abnormality represented a colonic response to stress rather than being related to IBS[62]. Other techniques have focused on colonic spike patterns and demonstrated variations in the incidence of these[63], but whether these findings simply represent a non-specific response to diarrhea is not clear, since appropriate non-IBS controls have not been studied.

Several studies of basal colonic motility with intraluminal pressure recordings have not been able to demonstrate an abnormal pattern in IBS as compared to appropriate controls or differences between IBS patients with different symptomatology[17,64], but this has to some extent been contradicted in recent studies of colonic motility[65,66]. Some of the earlier studies were, however, able to detect frequent sigmoid contractions with high amplitude in association with pain reports from some of the IBS patients studied ("spastic colon"), although no group differences in rectosigmoid motility between IBS patients and controls could be detected[67]. Also, some recent studies have found an increased frequency of high-amplitude propagating contractions (HAPC) in the colon in non-constipated IBS patients[65,68,69], and more interestingly an association between pain episodes and HAPCs[65,70], possibly related to the presence of visceral hypersensitivity in IBS. Somewhat more consistent has been the finding that IBS patients seem to have an exaggerated and prolonged postprandial myoelectrical and motor response than healthy volunteers[17,65,71,72], even though negative studies also exist[66,73].

The normal motor response in the colon after nutrient administration is an increase in phasic motor activity and a progressive increase in tone as well[74]. At least two studies have failed to detect an abnormal colonic tone response after meal intake in IBS patients[66,75]. However, there are some recent data supporting altered gastrointestinal reflex activity in IBS patients, by demonstrating abnormal recto-sigmoid tone response following a low-caloric meal[76], or as an attenuated rectal tone response to colonic distension ("the colorectal tonic reflex")[77,78]. Hopefully these interesting studies will be followed by other investigations evaluating gastrointestinal reflex activity within the gastrointestinal tract, thereby providing new important information regarding neuromuscular function within the gastrointestinal tract in IBS patients. As in the small intestine motility alterations have also been demonstrated using transit studies. Transit through the colon influences the bowel habit of the patient[79,80], and differences exist in colon transit between IBS subgroups based on the predominant bowel habit[44,81].

To conclude, there is some evidence to suggest a disordered colonic motility in IBS, even though no uniform colonic motor pattern of this patient group is evident. Of great relevance to the symptomatology is probably the exaggerated colonic motor response to physiological stimuli such as food and, perhaps also stress and emotions in IBS[61,82], which together with an enhanced visceral sensitivity might be deleterious for these patients. Alterations in gastrointestinal reflex activity in IBS patients seem plausible, but follow-up studies are needed.

ABNORMAL GAS HANDLING

In patients with IBS complaints of "too much gas" causing abdominal pain and bloating is very common, and this has been proposed to be secondary to disordered intestinal motility in combination with an abnormal GI sensitivity, rather than caused by abnormal volume or composition of intestinal gas[83]. However, an abnormal colonic fermentation in IBS has been demonstrated in one study[84], but needs to be repeated by other groups. Of great interest, patients with IBS complaining of bloating has been found to have impaired transit of exogenous gas loads, and the following gas retention reproduced their symptoms[85]. Importantly, this abnormality can be modulated by nutrients[86, 87], physical activity[88] and body posture[89]. In follow-up studies using scintigraphy the small intestine seemed to be responsible for the ineffective gas propulsion in patients complaining of bloating[90], and altered gastrointestinal reflex activity in IBS patients might also be involved in the abnormal gas handling[91].

These findings tell us that IBS patients do not necessarily need to produce more gas in order to have gas related symptoms, but these may instead be due to motor dysfunction, resulting in a transport problem, and an enhanced visceral sensitivity.

ALTERED GASTROINTESTINAL SECRETION

Few studies have so far addressed GI secretion in IBS, partly due to methodological problems in assessing gastrointestinal secretion. However, there are some evidences supporting altered secretion in the small intestine of IBS. An old study demonstrated that patients with IBS have enhanced intestinal secretion in response to perfused bile acids in the ileum, relative to controls[92]. Our group has used potential difference measurements in the small intestine as an indirect measure of secretion in the small intestine[93], and in preliminary studies found an enhanced reactivity of the secretory component of the MMC in the small intestine in diarrhea-predominant IBS and to some extent also in constipation predominant IBS[94]. Ongoing studies will further evaluate the importance of secretory abnormalities in patients with IBS and the relevance for symptoms.

VISCERAL HYPERSENSITIVITY

Since James Ritchie in 1973 demonstrated colonic hyperalgesia by inflating balloons in the sigmoid colon in patients with "the irritable colon syndrome"[95] numerous reports on visceral hypersensitivity in IBS have appeared. Lowered perception thresholds for balloon distension in IBS patients have not only been demonstrated in the rectum[96] and colon[97], but also in the esophagus[98,99], stomach[100] and the small intestine[101,102]. These findings support a generalized enhancement of gastrointestinal sensitivity in IBS patients. However, a recent investigation has implicated that the hypersensitivity seems to be pan-intestinal for

those with multiple sites of their symptoms, whereas it was restricted to a specific organ in those with more localized symptoms[103]. Whether IBS patients have a general hypersensitivity remains debatable since divergent results exist regarding somatic sensitivity[104-106]. Patients with IBS also show an altered viscerosomatic referral pattern as another indicator of disturbed processing of viscerosensory information[107]. However, visceral perception is not abnormal in all patients with IBS[100,108] and there is a considerable overlap in colonic pain thresholds between IBS patients and healthy controls [109]. Moreover, the relationship to the symptom profile of the patient is controversial[108,110-112].

In an attempt to find a biological marker for IBS, Mertz et al evaluated different aspects of rectal perception in a group of IBS patients. They found that 94 percent of patients showed altered rectal perception in the form of lowered thresholds for aversive sensations (discomfort), increased intensity of sensations or altered viscerosomatic referral[96]. Also, a more recent study has come to the same conclusion and proposed that rectal sensitivity testing is useful to confirm the diagnosis of IBS and to discriminate IBS from other causes of abdominal pain[113]. The proposal that altered rectal perception is a biological marker for IBS has, however, been questioned and the importance of psychological factors in visceral perception has been stressed instead[114]. Psychological factors might certainly be of great importance in studies dealing with visceral sensations, and response bias[115] may influence results from balloon distension studies. A different conclusion can be drawn from a study by Corsetti *et al*, who showed that there was no difference between patients and healthy controls in identifying regular balloon inflations mixed with sham distensions, suggesting that the increased frequency of sensations often reported by IBS patients are not due to psychological response bias[116]. On the other hand, Whitehead and co-workers found that thresholds were correlated with psychological measures of anxiety and somatization[117]. However, in that study sexual abuse, reported to be associated with IBS[118], did not contribute significantly to the rectal pain sensitivity, which has been confirmed recently[119]. One explanation for these somewhat discrepant results may be that IBS patients demonstrate two different perceptual alterations: hypersensitivity to rectal distension, which is proposed to be largely due to peripheral alterations, and hypervigilance towards labeling a wide range of visceral stimuli in negatively affective terms, which is more related to psychological alterations[120].

A drawback with many of the studies assessing visceral perception in IBS is that they are made under fasting and non-stimulated conditions, under which patients normally do not report severe symptoms. However, it has been shown that repetitive sigmoid distensions - thought to imitate increased colonic motility after food intake[17], emotions[82] and stress[61] - resulted in hyperalgesia and increased viscerosomatic referral during rectal distensions in IBS patients. These findings were proposed to reflect a central sensitization of the dorsal horn neurons[121]. These data fit well with findings from studies evaluating the effects of rectal distension on spinal transmission of nociceptive signals, using a somatic cutaneomuscular flexion reflex (RIII reflex)[122], where IBS patients have an altered response[123]. Whether this is designated to changes in electrophysiological properties of the spinal nociceptive neurones or failure in the inhibition of nociceptive signals in spinal nerves is yet to be answered.

Patients with IBS often describe a correlation between their symptoms and stress, and they seem to be more susceptible to stressful events of daily life[124]. Using different methodologies, several studies now exist that demonstrate an altered visceral perceptual response in IBS patients relative to control subjects after and during stress[125-127], which might be of relevance for stress-related symptoms in IBS patients. Postprandial worsening of symptoms, as well as adverse reactions to one or more foods is common in IBS patients[128]. The effects of nutrients on colorectal sensitivity have been investigated in healthy volunteers and rectal sensitivity increases after nutrient ingestion[129]. Fat is also the main stimulus for this sensory component of the gastrocolonic response[130]. Recently we demonstrated enhancement of the colonic sensitivity in IBS patients after duodenal lipid administration as compared with healthy controls[75]. This finding has thereafter also been reproduced by other groups assessing the effect of duodenal lipid administration on rectal sensory function[131,132], making it fair to state that patients with IBS seem to have an exaggerated sensory component of the gastrocolonic response.

Visceral hypersensitivity may also be affected by motor characteristics and biomechanical properties of the gut, but studies assessing for instance rectal compliance have come to somewhat inconclusive results[108,133,134]. Moreover, a study using impedance planimetry found no clear evidence of altered biomechanical properties in the rectum in patients with IBS and hypersensitivity[135]. However, more studies assessing the relationship between sensory and motor characteristics and biomechanical properties of the gastrointestinal tract in IBS patients are needed.

To conclude, visceral hypersensitivity is currently considered to be perhaps the most important pathophysiological factor in IBS. Importantly, several external and internal factors can modulate visceral sensitivity. The link between visceral hypersensitivity and specific symptoms in IBS deserves further studies.

DYSREGULATION OF THE BRAIN-GUT AXIS

The brain-gut axis is a model describing bidirectional pathways linking emotional and cognitive centres in the brain with visceral afferent sensation and intestinal function. Several observations have led to the hypothesis of a dysfunctional brain-gut axis in the pathophysiology of IBS[136-138]. Brain imaging techniques such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) have been used to investigate brain response during visceral stimulation with rectal distensions. Despite contradicting results, several studies indicate differences between IBS patients and healthy controls in activation of different pain processing regions such as the anterior cingulate cortex (ACC), thalamus, insula and prefrontal cortex (PFC)[139].

Using PET, Silverman et al initially reported that painful rectal distension in IBS patients resulted in reduced

ACC activity but enhanced activity in the PFC during anticipation of rectal pain suggesting a hypervigilance towards the stimulation and a failure to activate endogenous pain inhibition systems[140]. However, Mertz et al later published an fMRI study showing increased activity in the ACC indicating a normal activation pattern but a heightened sensitivity of the brain-gut axis[141]. Several brain imaging studies have been published thereafter with somewhat divergent results, with reports of increased activity in the insula, PFC and thalamus[142,143], as well as in the cingular cortex[142,144,145], but also decreased activity in the insula, amygdala and striatum[146]. The discrepancies in results are probably explained by factors such as small study populations and pooling of results from heterogeneous groups, as well as the use of different methodologies[147]. It has for instance been demonstrated that male and female IBS patients show differences in activation of brain regions[148,149], just like the activation pattern differs between IBS subgroups based on the predominant bowel habit[150]. The psychological state of the patient is also important since emotional status has been shown to modulate brain activation patterns[151]. Interestingly, changes in some brain regions have also been associated with treatment response in IBS[152]. In addition to brain imaging, IBS patients have also shown different results than healthy controls in studies using electroencephalography (EEG)[153,154] and evoked potentials[155,156].

Central nervous system communication with the gut is mediated through the parasympathetic and sympathetic pathways of the autonomic nervous system (ANS) by modulation of the enteric nervous system. Several studies have reported autonomic dysfunction in IBS[157-161]. The results are inconsistent, but increased sympathetic and decreased parasympathetic activity in IBS patients compared with healthy controls are the most frequently reported differences[162-166]. Again, the contradictory results may partly be due to varying experimental designs with differences in study populations. Anxiety and depression influences autonomic function in IBS[167], and there also seem to be discrepancies between different subgroups of IBS patients[162,165,168]. Recently Tillisch *et al* also showed gender differences in ANS response to visceral stimulus, with more prominent alterations in male IBS patients[169].

Another important system in the communication between the brain and the gut is the hypothalamic-pituitary-adrenal (HPA) axis, with important effects on GI motility, sensation and immune function[170]. Activation of this system takes place in response to both physical and psychological stressors[171]. Since patients with IBS often report stress-related symptoms[124], it has been a logical step to evaluate the HPA axis and its effect on GI function in IBS. Also here results are divergent with investigations reporting attenuated[172], normal[125] and enhanced reactivity[127,173] of the HPA-axis in IBS patients in response to various stressors. Again, different study designs, patient characteristics and other factors might be the explanation for the somewhat heterogeneous results[174].

To conclude, there appears to be alterations along the brain-gut axis and in autonomic nervous function in patients with IBS. However, there are discrepancies between existing studies, and in future studies standardization of the methodology, as well as strict inclusion criteria and evaluation of larger patient groups will enhance our understanding of the interaction between the gut and different parts of our nervous system.

CONCLUSION

The pathophysiology of IBS is complex and still incompletely known. Both central and peripheral factors, including psychosocial factors, abnormal GI motility and secretion, and visceral hypersensitivity, are thought to contribute to the symptoms of IBS. However, in order to be able to find new treatment alternatives for this big patients group more knowledge about the pathophysiology of IBS is needed.

Abstract

The aim of this paper was to describe functional biliary syndromes and methods for evaluation of the biliary tract in these patients. Functional biliary symptoms can be defined as biliary symptoms without demonstrable organic substrate. Two main syndromes exist: Gallbladder dysfunction and sphincter of Oddi dysfunction. The most important investigative tools are cholescintigraphy and endoscopic sphincter of Oddi manometry. In gallbladder dysfunction a scintigraphic gallbladder ejection fraction below 35% can select patients who will benefit from cholecystectomy. Endoscopic sphincter of Oddi manometry is considered the gold standard in sphincter of Oddi dysfunction but recent development in scintigraphic methods is about to change this. Thus, calculation of hilum-to-duodenum transit time and duodenal appearance time on cholescintigraphy have proven useful in these patients. In conclusion, ambient methods can diagnose functional biliary syndromes. However, there are still a number of issues where further knowledge is needed. Probably the next step forward will be in the area of sensory testing and impedance planimetric methods.

INTRODUCTION

Evaluation of the biliary tract is of importance in physiological, pathophysiological, and clinical settings. Clinical investigations in patients with well-defined, organic diseases such as gallstones, is outside the scope of this review, where focus is directed towards patients with functional biliary symptoms. Investigations aiming at morphological alterations in the biliary tract are thus not discussed in this paper.

The value of different investigative methods is often fluid: Some methods are used to render probable or document a correlation between symptoms and measurable abnormalities. Others are, or later become, real tools in the diagnostic process of patients with functional biliary symptoms. The methods can roughly be subdivided into two subgroups: Motility investigations, and methods for the evaluations of the sensory conditions. Motility comprises direct measurement of the biliary tract as well as intraluminal transport. A further evaluation of wall characteristics, e.g. by means of impedance planimetry, has, so far, only been conducted in animal experiments[1].

The present review will start with a physiologic background section, followed by a description of patients with functional biliary symptoms and evaluation methods in these patients.

PHYSIOLOGIC BACKGROUND

The function of the biliary tract is to store, concentrate, and transport bile from the liver into the duodenum. In order to accomplish this function the extrabiliary tract is composed of a ductal system, a gallbladder, and a sphincter (Sphincter of Oddi) at the termination of the common bile duct. Previously it was believed that there was an additional sphincteric structure at the junction site of the gallbladder and the cystic duct but studies have failed to prove this supposition. Smooth muscles are present in the gallbladder and in the Sphincter of Oddi (SO). Unlike previous belief, no-or only insignificant-

musculature is seen in the ducts. Active contractility is therefore only possible in the gallbladder and the SO. Bile flow into the duodenum occurs after food intake, and late in the interdigestive phase II of the duodenum[2]. The main initiator of biliary secretion-apart from bile production of the liver-is the release of the peptide cholecystokinin (CCK). This peptide relaxes the SO and contracts the gallbladder. The effect of CCK on the SO is brought about by a stimulatory action on inhibitory neurons. This effect overrides a direct stimulatory action of CCK on the SO muscles[3]. In addition to the CCK effect, a reflex relationship exists between the gallbladder and the SO, i.e. pressure increase within the gallbladder leads to relaxation of the SO (Figure 1)[4,5]. This implies that gallbladder contraction, e.g. after food intake, allows bile to run from the gallbladder into the ductal system, and further into the duodenum through the relaxed SO. Conversely, when the gallbladder is empty, the gallbladder pressure is low, and the SO actively contracts, thus allowing bile to divert into the gallbladder. A similar reflex relation is seen between the common bile duct and the SO[6]. This is important in post-cholecystectomy patients.

The gallbladder receives nerve fibres from the sympathetic and the parasympathetic systems. In addition there are a number of neurones containing peptides, e.g. CCK, vasoactive intestinal polypeptide (VIP), nitric oxide (NO), and motilin. The sympathetic nerves arise at the Th8-9 level and are relayed in the celiac plexus, with second order fibres travelling along the vascular system to the gallbladder. The parasympathetic innervation arises from both the anterior and posterior vagal trunks and reaches the gallbladder in a similar way as the sympathetic fibres, with the exception that branches from the anterior vagal nerve do not pass through the celiac plexus. Vagal activity stimulates gallbladder contraction directly, and enhances the contractile effect of CCK on the gallbladder. Sympathetic activity has the opposite effect on gallbladder motility. The sympathetic system also transmits sensory inputs to the central nervous system leading to pain. Pain is enhanced by inflammation. The ductal system and the sphincter of Oddi (SO) are innervated in a similar way as the gallbladder, with the highest neural density in the SO.

FUNCTIONAL BILIARY PAIN

Biliary pain is mainly characterized according to the symptomatic presentation of gallstone attacks. As in many other gastrointestinal disorders this is not simple, as a variation in symptomatic presentations can be seen in some patients[7]. Nevertheless, according to the existing literature, and the experience of experts, functional biliary pain was defined as absence of demonstrable organic substrate, and[8]: Episodes of severe steady pain located in the epigastrium and right upper quadrant. A number of additional criteria are outlined. One of these is that the pain attack should last at least 30 min. This seems substantiated in patients where the symptoms are derived from the gallbladder. However, if symptoms originate in the SO, this criterion will still await validation. Two types of functional biliary pain syndromes have been described: Gallbladder dysfunction and sphincter of Oddi dysfunction (SOD). The symptomatic presentation seems rather similar, but obviously patients with gallbladder dysfunction still have the gallbladder in situ, whereas SOD dysfunction most often-albeit not unequivocally-is seen in post-cholecystectomy patients.

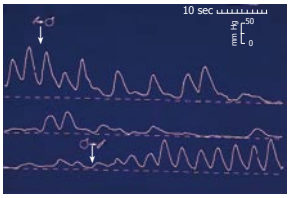

Figure 1 Sphincter of Oddi manometry in a dog during gallbladder distension (upper tracing), and gallbladder emptying (lower tracing). Distension of the gallbladder-mimicking gallbladder contraction -leads to relaxation of the sphincter of Oddi thus permitting free flow of bile into the duodenum. (After reference 5 with permission).

Gallbladder dysfunction

Gallbladder dysfunction denominates a condition where the gallbladder empties insufficiently in a patient with biliary symptoms, without demonstrable organic substrate, such as gallstones. The prevalence of biliary-type pain without gallstones was found to be 2.4%[9]. Other population studies have found prevalences as high as 7.6% in men[10] and 20.3% in women[11]. Per definition patients with gallbladder dysfunction have impaired gallbladder emptying. Later in this paper the methodology is described. The mechanism of pain is rather obscure: Generally it is believed that some kind of functional obstruction at the transition zone between the gallbladder and the cystic duct exists, leading to gallbladder pressure increase. Possibly, a combination with inflammation amplifies sensory firing. Primary hypersensitivity can also not be ruled out and central neuroplastic changes may be responsible for visceral hypersensitivity. Nevertheless, in a randomised controlled investigation[12], it was shown that patients with gallbladder dysfunction would benefit from cholecystectomy. A number of other papers have supported this finding[13,14]. However, there are still a number of critical issues to be addressed[15].

Sphincter of Oddi dysfunction

Sphincter of Oddi dysfunction (SOD) denominates patients with biliary-type pain and dysfunction of the Sphincter of Oddi. The condition is most often seen in post-cholecystectomy patients. The prevalence of symptoms suggesting SO dysfunction is about 1.5% after cholecystectomy, being more frequent in women[16]. SO dysfunction can be subdivided into three groups according to clinical presentation, laboratory results, and ERCP findings[17]: (1) Patients with type I SO dysfunction have biliary-like pain, elevated liver function tests documented on two or more occasions, delayed contrast drainage (more than 45 min, (Figure 2), and a common bile duct diameter equal to or greater than 12 mm at ERCP; (2) Type II patients present with biliary-like pain, and only one or two of the above mentioned criteria; (3) Type III patients only have biliary-like pain, and none of the above mentioned criteria. The mechanism of pain is also rather obscure in this group of patients. From a theoretical point of view SO abnormalities could give rise to pain due to impeded flow, ischemia arising from spastic contractions, and hypersensitivity of the papilla or the common bile duct.

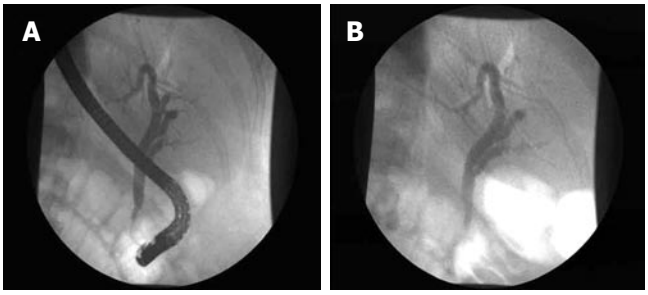

Figure 2 Endoscopic cholangiogram during investigation, and 45 min after contrast injection in a patient with complete contrast retention.

These mechanisms may solely or in combination explain the genesis of pain[18]. In a prospective randomised study it was shown that pain could be alleviated by endoscopic sphincterotomy[17].

EVALUATION METHODS

Quantitative hepatobiliary scintigraphy

Quantitative hepatobiliary scintigraphy (QHBS) is a non-invasive scintigraphic method where it is possible not only to assess the patency of the biliary system but also to measure the rate of bile flow (Figure 3). 99mTc-N-2,6-dimethylphenylcarbamoylmethyliminodiacetic acid (99mTc-EHIDA) and numerous of its analogues, such as 2, 6-diisopropyliminodiacetic acid (DISIDA) and 2, 4, 6-trimethyl-3-bromoiminodiacetic acid (mebrofenin) are the tracers most widely used for hepatobiliary imaging. After (iv) injection, these 99mTc agents bind loosely to serum proteins and are then rapidly taken up by the hepatocytes and excreted into the bile. This uptake mechanism is similar to that of bilirubin, and hyperbilirubinaemia therefore has an inhibitory effect. After excretion by the hepatocytes, the bile continues to flow into the bile canaliculi, the bile ducts and the gallbladder, and then empties into the duodenum through the SO.

Patients should be fasted for a minimum of 4 h prior to the investigation. The gamma-camera is positioned over the right upper abdomen of the supine patient. After an iv bolus injection of 140-180 MBq 99mTc-IDA derivative, gamma-camera images are acquired on a computer (1 frame/min) for 90-120 min. If needed, analogue images can also be obtained every 10 min for the first hour, with delayed images if required (first image 500 000 counts, and then subsequent images for the same length of time). The analogue pictures should be examined for liver radiotracer uptake, size, shape and homogeneity. Under normal circumstances the liver uptake of 99mTc-IDA compounds is rapid, with little if any tracer in the blood pool by 5 min. In most normal fasting subjects, radioactivity appears in the gallbladder (GB) and in the small bowel by 1 h after its administration. The extent of visualisation of the hepatic ducts is variable but the left duct tends to be more prominent than the right. In patients without extrahepatic

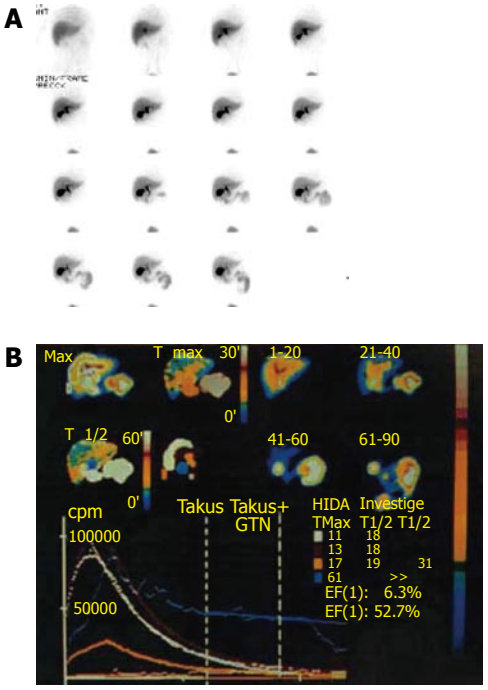

Figure 3 Hepatobiliary scintigraphy. **A:** Pictures at different time windows; **B:** Time activity curves are shown for different regions of interest.

bile duct obstruction, the level of radioactivity of the common bile duct (CBD) reaches its maximum before 45 min. Excretion of radioactivity into the duodenum occurs by 60 min in 81% of patients with the GB *in situ*. In the remaining 19% of patients without bowel activity at 60 min, duodenal visualisation is always present after exogenous CCK administration[19].

Gallbladder phase imaging

The GB contraction after consumption of a meal or administration of an exogenous CCK analogue (CCK octapeptide or caerulein) can also be measured by means of QHBS. These data can be acquired in a separate study between 60 and 90 min after the initial isotope administration. QHBS combined with administration of a meal or an exogenous CCK analogue is a validated and accurate method for the measurement of GB motility, with satisfactory reproducibility of both parametric variables and emptying patterns. The method of measuring GB is to place a region of interest (ROI) over the GB with a ROI over the liver background (adjacent to the GB), then to generate a time-activity curve for the GB and to calculate the GB ejection fraction (EF) via the following formula: EF% = (GBmax-GBmin)/GBmax × 100. The degree of GB emptying is CCK dose-dependent, and therefore the mode of administration has a critical effect on the net GB contraction. The GB EF increases as the dose of CCK is increased from 0.5 to 3.3 ng/kg per minute. Then begins to decrease when larger doses are infused, especially when CCK is given as a rapid iv bolus. A large non-physiological dose produces a low EF in association with abdominal pain, even in normal subjects. It has become clear that the GB EFs obtained depend on the procedure used but a

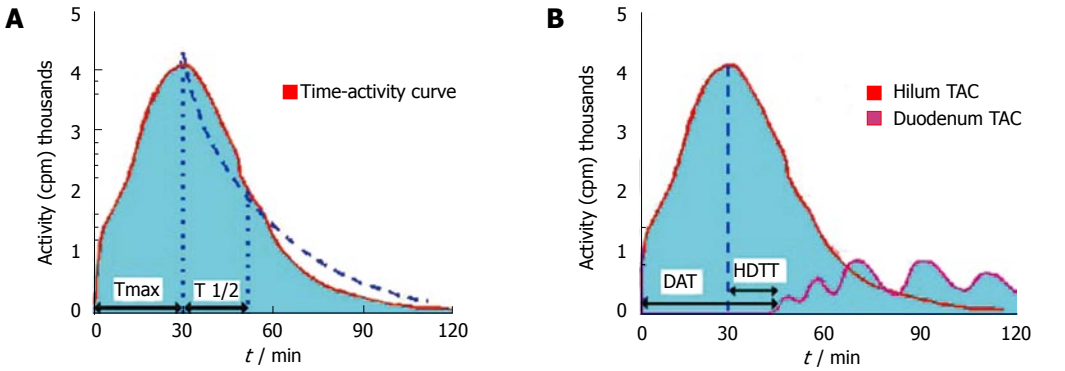

Figure 4 Hepatobiliary scintigraphic activity curves of regions of interest in sphincter of Oddi dysfunction.

GB EF over 35%[12,20,21] can be regarded as indicative of a normal GB function if it is evoked by a total infusion dose of 10 ng/kg CCK, administered during 3-10 min.

Scintigraphic features of gallbladder dysfunction

In clinical practice, the distinctive feature of a GB dysfunction is impaired GB emptying. A GB EF under 35% is a sensitive test for the identification of patients with chronic cholecystitis or GB dysfunction[12,20,21]. However, there is a considerable overlap in EF values[15]. Many of the patients experience a reproduction of biliary pain during CCK infusion. Administration of nitro-glycerine before CCK infusion can abolish biliary pain and normalise the GBEF in a subset of patients with gallbladder dysfunction.

Scintigraphic features of sphincter of Oddi dysfunction

The scintigraphic signs in SOD depend upon the presence or absence of a GB in situ, albeit the latter is rare. In patients with SOD and GB in situ, an intact GB serves as a low-pressure reservoir by compensating the increased bile flow that is diverted into it by the tight and hypertonic SO. Therefore, the CBD does not dilate and the rate of emptying of the isotope from the CBD is usually in the normal range. After CCK administration to patients with a functional SOD, the SO relaxes (except in SOD patients with a paradoxical response to CCK, which is a relatively rare phenomenon) and, if the GB function is intact, the GB EF remains normal. In cholecystectomized subjects with a normal liver function, the flow of the bile from the liver to the duodenum is mainly regulated by the motor activity of the SO. HIDA compounds, which are taken up and secreted by the liver into the bile, can therefore be used as markers to measure the rate of bile flow and indirectly to assess the patency of the SO. In asymptomatic cholecystectomized patients with a normal SO function, HIDA excretion and transit from the liver into the duodenum is rapid, and the time-activity curves are exponential, exhibiting only minor patient-to-patient variations[19]. In cholecystectomized patients with SOD however, cholescintigraphy reveals a prominent bile stasis within the intra- and extrahepatic bile ducts, and a marked delay in the transpapillary isotope transit[22-24]. Retention of a 99mTc-IDA tracer after 120 min in the visually prominent bile ducts on static images of the planar HBS was noted to be a good predictor of an abnormal biliary drainage. Quantitative cholescintigraphic parameters may afford valuable numerical information on the bile flow impairment in the presence of a SOD, thereby increasing the sensitivity (Figure 4). Unfortunately, it is not clear, which scintigraphic variable is optimal to express SOD. We recently compared the sensitivities of these parameters in cholecystectomized patients with SOD diagnosed by manometry, which showed that HDTT was the best predictor of SOD, followed by DAT, and then the $T_{1/2}$ parameters of the hepatic hilum and CBD Madacsy). The quantitative parameters of the CBD seem to be relatively insensitive, which is probably due to the disturbing influence of other factors, such as the CBD diameter and the duodenal motility phase during the study. In fact, we found that the SO basal pressure relative to the CBD pressure exhibited the best correlation with the QHBS parameters. CCK administration increases the hepatic bile secretion and relaxes the SO; it therefore washes out the bile stasis from the ducts if there is no anatomic obstruction. A differentiation between a fixed anatomic obstruction (organic SO stenosis, bile duct stricture or stones, *etc.*) and a functional obstruction (SO spasm) can also be made by amyl nitrate or nitro-glycerine administration during QHBS. In order to measure SO relaxation after the administration of a smooth muscle relaxant in patients with SOD, after the baseline evaluation of the QHBS parameters, at 60 min amyl nitrate was administered and the $T_{1/2}$ parameter of the CBD was recalculated. A reversible biliary obstruction on the QHBS (an obstructive pattern relieved after amyl nitrate) indicates a functional SOD, i.e. an SO spasm, whereas a persistent accumulation of the isotope in the biliary tree (during the baseline condition and after amyl nitrate) suggests a fixed organic obstruction[25]. A differentiation between stenosis and dyskinesia of the SO may be important from a clinical point of view, and it might modify the therapeutic strategy, since endoscopic sphincterotomy is of great benefit in patients with a persistently elevated basal SO pressure and SO stenosis. To summarise, QHBS may be regarded as a useful method for study of the bile flow dynamics in patients with postcholecystectomy syndrome and suspected SOD. QHBS may be applied not only as a simple and non-invasive screening test before SO manometry but also as a reliable diagnostic method during the evaluation and follow-up of patients with suspected SOD.

Ultrasonography

US has become a widely used method for visualisation

of the abdominal organs. As it is a non-invasive method without radiation exposure, it has also become a popular method for the investigation of motility disorders of the GB and the SO. US methods are relatively cheap and widely available and they also afford excellent reproducibility and sensitivity. However, their diagnostic accuracy is appreciably investigator-dependent and also influenced by the different forms of methodology.

Ultrasonographic measurement of GB contraction

The GB contraction induced by exogenous CCK or CCK analogue (caerulein) administration can be measured by means of either US or QHBS, but methods involving QHBS are currently regarded as the gold standard. QHBS offers the advantage over US of allowing simultaneous visualisation of the bile ducts, together with non-geometrical measurement of the GB contraction. However, the lack of radiation exposure is a favourable feature of the US methods, because it can be repeated several times in the same patient, which is extremely important in motility studies if normal physiology is investigated. US is also able to determine the approximate volume of the GB, which may be of some importance in the pathophysiology of GB motility. Different formulae are known for calculation of the GB volume. The most widely used is the sum of cylinders method, or Dodd' s formula. With this method, the GB volume (GBV) can be calculated if one multiplies the three axes together and then by Pi/6[26]. The GB EF is calculated from the fasting and post-stimulation GBVs via the well-known formula: GBEF (%) = GBVmax - GBVmin/GBVmax. The refilling of the GB is another characteristic feature of GB motility, which can be calculated as a percentage of the ratio between the GBV in the most contracted state and at the maximum after refilling. The two main types of stimuli, which can be used to evoke GB contraction, are food intake and administration of CCK or a CCK analogue.

Ultrasonographic bile duct imaging

Bile duct imaging with US is more difficult than visualisation of the GB. Most investigators use the right anterior oblique view to visualise the common hepatic duct within the porta hepatis, where the surrounding liver parenchyma gives a good acoustic window. Visualisation of the pancreatic duct in the body of the pancreas may be problematic in a number of patients, because the presence of gas in the stomach and in the intestines above it means that an acoustic window is not available. Moreover, exact determination of the pancreatic duct diameter necessitates its measurement in two different part of the pancreas. The upper limit of normal diameter of the common hepatic duct (also termed hepatocholedochus, because it is not possible to differentiate between common hepatic duct and CBD by US) is less than 8-10 mm, and of the pancreatic duct is less than 2-3 mm.

Ultrasonographic assessment of sphincter of Oddi dysfunction

Ultrasonography has been reported as a method for diagnosing SO dysfunction. The authors measured the bile duct diameter before and after CCK infusion or ingestion of a fatty meal[27,28]. However, these methods have not gained acceptance, probably because of low reproducibility.

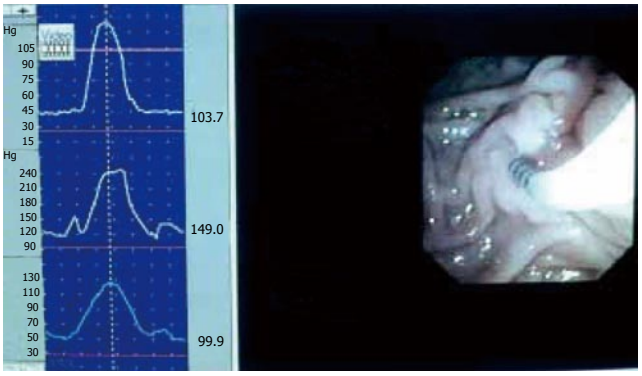

Figure 5 Combined video- and manometric recording in the sphincter of Oddi during endoscopy.

Sphincter of Oddi manometry

SO manometry can be done during endoscopic retrograde cholangio-pancreatographic (ERCP) investigation. A triple lumen catheter with sideholes spaced 2 mm apart is introduced into the common bile duct, and then withdrawn until positioned in the SO segment. The catheter is slowly perfused from a hydraulic capillary infusion pump, and external transducers are connected with a computer for direct reading of the manometric tracing. Additionally the readings are stored for later analysis[29,30]. The SO is a high-pressure zone with an elevated baseline and superimposed phasic contractions. The readings may suffer from periodic superimposed artefact patterns. Usually these are easily recognised, but simultaneous endoscopic videorecording may be helpful in separating SO activity from artefact phenomenon (Figure 5)[31]. The parameters measured are baseline pressure and phasic wave amplitude, duration, frequency, and propagation mode. Baseline pressure is measured with the duodenal pressure as zero reference. The amplitude is measured with baseline pressure as zero reference. When evaluating the propagation modality, proximal and distal readings are compared.

Normal SO manometry

In healthy subjects the baseline pressure is around 5-15 mmHg, phasic wave amplitude 100-140 mmHg, wave duration 4-6 s, and frequency 3-6 waves per minute. Most contractions are coordinated, and the direction of contractions is mostly antegrade, with only 5%-20% being retrograde[32]. After cholecystectomy no significant alterations are seen in patients who no longer have symptoms[33,34].

Abnormal SO manometry

SO manometric abnormalities comprise elevated baseline pressure, increased phasic wave amplitude, frequency, and disordered propagation mode (Figure 6, Figure 7). It has been suggested to define SO abnormality as a baseline

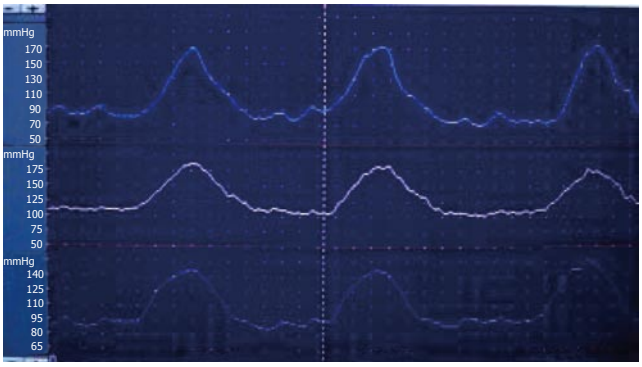

Figure 6 Endoscopic sphincter of Oddi manometry in a patient with elevated baseline pressure.

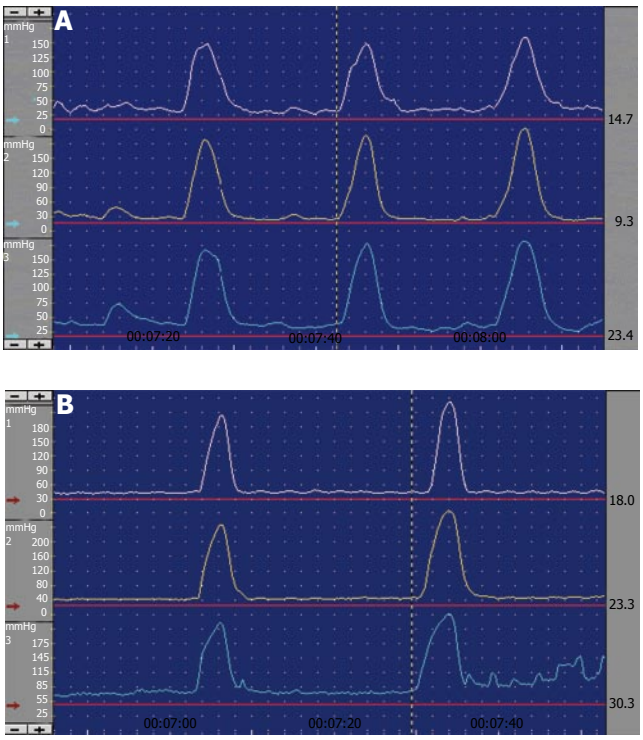

Figure 7 Endoscopic sphincter of Oddi manometry. **A**: Normal antegrade contractions; **B**: Abnormal retrograde waves.

pressure of more than 40 mmHg, phasic amplitude above 350 mmHg, frequency of more than 7 waves per minute; and a pattern of more than 50% retrograde waves[8]. The clinical importance of these abnormalities is not clear, except for elevated baseline pressure, where it was shown in a randomised study that patients with this abnormality improved clinically after endoscopic sphincterotomy[17].

Pain studies

The fact that there are still "holes" in our understanding of patients with functional biliary pain has led investigators to focus on sensory mechanisms. Clinically, it has been observed that some patients develop pain upon manipulation with the papilla (tender papilla), or during intraductal contrast injection. A further step forward was taken with the demonstration of duodenal-specific visceral hyperalgesia in post-cholecystectomy patients with persistent abdominal pain[35]. Stawowy *et al*[36-38] has investigated the referred pain area in patients with uncomplicated gallstones and acute cholecystitis before and after cholecystectomy. Although hypersensitivity was found in both groups of patients, the hypothesized prolonged neuroplastic changes, as a possible explanation of post-cholecystectomy syndrome could not be proven. However, in the future it will be of importance to conduct studies in patients with post-cholecystectomy syndrome and also in patients with suspected gallbladder dysfunction.

Abstract

Gastrointestinal (GI) sensory-motor abnormalities are common in patients with diabetes mellitus and may involve any part of the GI tract. Abnormalities are frequently sub-clinical, and fortunately only rarely do severe and life-threatening problems occur. The pathogenesis of abnormal upper GI sensory-motor function in diabetes is incompletely understood and is most likely multi-factorial of origin. Diabetic autonomic neuropathy as well as acute suboptimal control of diabetes has been shown to impair GI motor and sensory function. Morphological and biomechanical remodeling of the GI wall develops during the duration of diabetes, and may contribute to motor and sensory dysfunction. In this review sensory and motility disorders of the upper GI tract in diabetes is discussed; and the morphological changes and biomechanical remodeling related to the sensory-motor dysfunction is also addressed.

INTRODUCTION

Diabetes mellitus (DM) is a chronic disease requiring lifelong medical attention in order to limit the development of potentially devastating late complications and to manage them if they occur. In the USA, the per capita cost of healthcare in 2002 was $13 243 for patients with diabetes and $2560 for patients without diabetes[1]. Gastrointestinal (GI) disorders are common in diabetic patients[2,3]. As many as 75% of patients attending DM clinics report significant GI symptoms[2]. The entire GI tract from the esophagus to the anorectal region may be affected. Common complaints include dysphasia, early satiety, reflux, constipation, abdominal pain, nausea, vomiting and diarrhea. The symptoms may be severe and substantially decrease quality of life. The pathogenesis of the GI abnormalities is complex of nature, multi-factorial (motor dysfunction, autonomic neuropathy, glycemic control, psychological factors, *etc.*) and is not well understood[4]. A number of abnormal conditions have been described in different segments of the GI tract in patients with diabetic autonomic neuropathy (DAN): esophagus (dysmotility), stomach (dysmotility, delayed emptying) and small and large bowel (dysmotility, delayed transit, bacterial overgrowth and diarrhea)[4]. Only a few studies have addressed the visceral sensory function in DM[5-7] and have demonstrated abnormalities in perception thresholds, vagal tonus and evoked brain potentials in patients with DAN. This indicates that DM related neuronal changes may be located both in the peripheral and in the central nervous system (CNS). As mentioned the entire GI tract may be involved in DM, but our review describes the upper GI tract only.

Many studies have demonstrated prominent morphological changes of the small intestine and esophagus in DM[8-11]. Lately, several studies have described biomechanical remodeling as well as morphological remodeling in experimental diabetic rats[12-18]. Recently, Frøkjær *et al*[19] have shown that both the neuronal function of the contractile system as well as the structural apparatus of the GI tract may be affected in patients with longstanding DM and DAN. Therefore we suggest that

along with DAN and glycemic control, the structural and biomechanical changes may play important roles in the symptomatology of GI abnormalities in long-standing DM. The future management of diabetic patients with GI symptoms may develop accordingly.

SYMPTOMS FROM THE UPPER GI TRACT IN DIABETES MELLITUS

Motor and sensory abnormalities in DM may affect the entire GI tract or part hereof, and the perceived symptoms may originate from one or several parts of the gut, such as the esophagus, stomach and small intestine[20,21]. The prevalence of upper GI symptoms is high in both insulin dependent DM (IDDM) and non-insulin dependent DM (NIDDM)[22-28]. The symptoms relating to the esophagus, stomach and small intestine are as follows: (1) Esophagus: Heartburn, dysphagia and chest pain[37]; (2) Stomach: weight loss and abdominal pain[38]; (3) Small intestine: Diarrhea, discomfort, pain and pseudo-obstruction. Most symptoms are non-specific of nature and may relate to other GI disorders not necessarily related to DM. Therefore, when dealing with GI symptoms, some specific issues need to be addressed. Chest pain may relate to reflux or esophageal motor disorders, but ischemic heart disease and other causes of non-cardiac chest pain are also possible causes and must be excluded. Dysphagia, the most characteristic symptom of impaired esophageal transit, may be caused by motility disorders of the esophagus. It is very important, however, to emphasize that dysphagia is more often caused by mechanical obstruction such as tumors and peptic stenosis than by motility disorders. A number of other incidental conditions must be excluded when diabetic gastroparesis is suspected: gastric outlet obstruction caused by tumors and ulcer disease; metabolic abnormalities such as diabetic ketoacidosis or uremia and side effects of pharmacotherapy. A gastroscopy and biochemical screening followed by physical examination are obligatory requisites to reach the correct diagnosis. The symptoms of diabetic gastroparesis tend to increase in intensity and frequency over the duration of diabetes in patients affected. Most often symptoms are vague and nonspecific such as early satiety, slight abdominal discomfort and perhaps bloating, and fortunately more rarely do nausea and vomiting develop. When nausea and vomiting becomes continuous hospitalization is needed to control glucose homeostasis, electrolytes and fluid substitution is needed. This is a potential life threatening situation. In the long run diabetic gastroparesis may be accompanied by poor diabetic control, weight loss and diminished quality of life partly due to frequent hospital contacts. The symptoms may last for days to months, and do often occur in cycles with symptom free intervals[29,30]. Diabetic patients frequently report abdominal pain and this may be the only symptom of diabetic gastroparesis; however, abdominal pain can also be seen in diabetic ketoacidosis and severe metabolic acidosis[31]. These conditions are followed by other symptoms as well and therefore distinguishable from gastroparesis. Diabetic patients with thoracic polyradiculopathy, a rare condition, may also suffer from abdominal pain[32]. Diarrhea in DM patients may be induced by a number of factors. These may include food composition, abnormal intestinal motility, small intestinal bacterial overgrowth, excessive loss of bile acids, pancreatic insufficiency and more[33]. Abnormal small intestinal motility (rapid or delayed transit) is a frequent condition in the diabetic patients as described below. Rapid transit may induce an increase in intra-luminal contents that reach the caecum, whereas delayed transit may cause bacterial overgrowth, both potentially resulting in diabetic diarrhea. Bacterial overgrowth has been reported in up to 40% of diabetic patients with diarrhea[34,35]. Celiac disease is overrepresented in IDDM and a cause of severe diarrhea to be excluded when dealing with diabetic diarrhea[36]. In its most fulminate form, diabetic diarrhea is a devastating and horrible condition for the person affected, sometimes resulting in catastrophical nightly soiling in bed and an uncontrollable condition during daytime. Most often, fortunately, this condition is self limiting and symptoms are more manageable.

SENSORY DYSFUNCTION

Although both the afferent and efferent nerves are affected in DM, the data related to the sensory dysfunction of the GI tract are sparse compared with those relating to the motor dysfunction of the upper GI tract. Elevation of perception thresholds to esophageal electrical stimulation has been observed in patients with DAN and different severity of GI symptoms[7]. Increased vagal tonus and abnormal evoked brain potentials to mechanical and electrical stimulation of the esophagus has also been shown[5,6]. Rayner *et al* performed isovolumetric and isobaric distensions of the proximal stomach in ten randomly selected patients with IDDM[39]. They demonstrated that the perception of gastric distension during euglycemia was increased compared with healthy controls. To study mechanisms behind postprandial symptoms in patients with diabetes, the gastric accommodation of the meal was assessed by abdominal ultrasound[40]. In DM patients, a large proximal stomach was associated with perception of fullness and a large antrum was associated with perception of pain after a meal. More recently, Frøkjær *et al*[41] used a multimodal stimulation device (Figure 1) to investigate the visceral sensitivity to mechanical, thermal and electrical stimulation in the esophagus and duodenum in IDDM patients with DAN and GI symptoms. This study demonstrated that the patients had decreased sensitivity to the stimulations of the esophagus and duodenum. This indicates that the affection of the sensory nerves is widespread in the GI tract. As the multimodal approach is thought to stimulate the mucosa, submucosa and muscle layers differentially, the disease seems to be generalized to nerves in all layers of the gut.

MOTILITY DISORDERS

Long ago, it was known that abnormal motility of the GI tract occurred during the development of DM[42]. So far many studies have demonstrated that DM patients have slow transit and abnormal motility. The most frequent

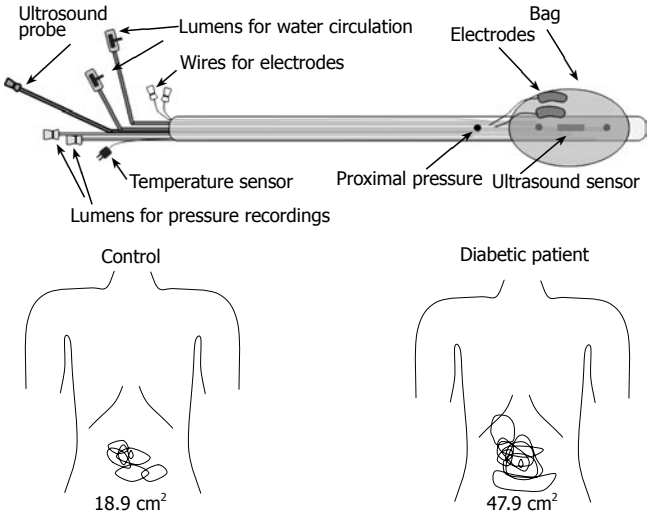

Figure 1 Top: The probe design allowing mechanical, heat and electrical stimulation of both the oesophagus and duodenum. The centre of the bag contains the sensor of the ultrasound probe imaging the oesophagus and duodenum during mechanical distension. The thermal stimuli were given by a pump system, which re-circulates water at 60 ℃ through two channels in the probe. The electrodes allowed electrical stimulation delivered directly to the mucosal surface. Bottom: The somatic referred pain areas to mechanical distension of the duodenum for the controls (left) and diabetic patients (right). The areas were larger for the diabetic patients.

motility disorders of upper GI tract are shown in Table 1.

Upper GI transit disorders in DM

Esophagus: Impaired esophageal transit has been reported both in IDDM and NIDDM patients[43-47]. The esophageal transit appears to be delayed in about 50% of patients with long-standing DM[48]. The retarded esophageal transit in the DM usually reflects either peristaltic failure or focal low-amplitude pressure waves[49].

Stomach: Several animal studies reported a slowing gastric emptying in IDDM and NIDDM rats[50-55], whereas other studies on IDDM and NIDDM animals demonstrated that gastric emptying increased[56-59]. Using radionuclide measuring techniques it has been demonstrated that gastric empting of solid, or liquid meals was abnormally slow in 30%-50% of patients with long-standing IDDM and NIDDM[60,61]. The gastroparesis in DM has been known clinically for more than 50 years[29]. It is not surprising that the gastric emptying delay in DM is related to both slow transit with increased retention of food in the proximal and distal stomach[62,63], and abnormal motility of the gastric wall[64].

Small intestine: Delayed and rapid transit in the small intestine was observed in animal diabetic models[65,66,67,68]. El-Salhy reported that the GI transit was rapid in non-obese diabetic mice[67] and was slower in obese diabetic mice[68]. Anjaneyulu and Ramarao[69] reported an increase in intestinal transit and a decrease in intestinal tone due to increased cholinergic and decreased beta-adrenergic receptor activities in DM rats. Slow small intestinal transit in DM patients have been documented using breath hydrogen appearance time after the ingestion of lactulose[70,71], by using radiopaque markers[72,73] and by use of metal-detector test[74]. On the other hand, Keshavarzian and Iber[75] investigated intestinal transit in IDDM patients after the ingestion of both liquid and solid meals and showed abnormal fast intestinal transit in their sample of diabetic patients. Nguyen *et al*[76] used intraluminal multiple impedance measurements to identify the postprandial duodenal chyme transport in patients with long standing IDDM. They demonstrated that the patients had disturbed propulsive chyme transport through the duodenum and the duodenal chyme clearance activity was decreased.

Table 1 Motility disorders of upper GI tract in DM

Organ	Motility disorder
Esophagus	Amplitude[88,89] and number[46,90] of peristaltic contractions↑
	Number of spontaneous and non-propagated contractions↑[45]
	Amplitude of lower esophageal sphincter pressure↓[88]
	Multi-peaked contractions[78,79]
Stomach	Antral IMMC↓[87]
	Post-prandial antral activity and the number of antral contractions↓[91]
	Pyloric dysmotility[92]
Small intestine	Frequency and amplitude of the antropyloroduodenal contractions↑↓[93]
	Duration of MMC cycle↑[85]
	Early recurrence of the MMC and clusters of contractile activity[94]

The transit disorders can occur in any region of the gut and in every stage of diabetes[74], and can affect each other. Since transit of food through the esophagus is relative fast, the gastric emptying rate is the major determinant of the food delivery to the small intestine. The relationship between esophageal transit and the rate of gastric empting appears to be poor[43] and the gastroparesis is often associated with the intestinal transit delay in DM[74,77].

Abnormal patterns of upper GI motility in DM

Esophagus: Esophageal manometric abnormalities occur in over 50% of patients with DM (see Table 1)[37]. The reduced amplitude of lower esophageal sphincter pressure is in accordance with the increased prevalence of gastro-esophageal reflux disease in DM. More recently the evoked esophageal contractile activity to standardized bag distension was assessed using a specialized ultrasound-based probe by Frøkjær *et al*[19]. A balloon-like bag was positioned 10 cm above the lower esophageal sphincter and inflated. It was demonstrated, both at the bag and 6 cm proximally, that the distension induced hyperreactivity and impaired the coordination of the contractions in the diabetic patients.

Stomach: Motility disorders of the fundus and pylorus have been demonstrated in the diabetic animals[80-83]. In the human studies, it is recognized that disordered gastric contractile activity as assessed by manometry and gastric emptying occurs frequently in DM[84,85]. The motility disorders may include three aspects: Inter-digestive migrating motor complex (IMMC), amplitude and frequency of contractions, and pyloric dysfunction (Table 1).

Small intestine: Camilleri and Malagelada reported that

small intestinal motility was abnormal in about 80% patients of long-standing DM with delayed gastric emptying[86]. Both postprandial and fasting small intestinal dysmotility in the DM was reported (Table 1). Dooley *et al*[87] studied fasting GI motility by manometry for a mean of 210 min in a group of 12 NIDDM patients with diarrhea and DAN. The patients showed grossly disordered motility. The migrating motor complex (MMC) disorders reflect the prolongation of phase II without change in the duration of phase I and III. The results of studies on postprandial motility at the level of the small intestine are inconsistent. However, abnormal motility patterns were observed in the diabetic subjects[85].

Table 2 Acute hyperglycemia and upper GI disorders

Motility disorder	Sensory disorder
Peristaltic wave duration[98]↑	Amplitude of the cortical evoked brain potentials to moderate esophageal distension↑[98]
Peristaltic velocity in the distal part of the esophagus↓[103]	Perception during proximal gastric distension in healthy subjects both in the fasted state and during intra-duodenal lipid infusion↑[95]
Pressure of the low esophageal sphincter↓[103]	Influencing the postprandial fullness in IDDM patients↑[105]
Gastric emptying of both solids and nutrient liquids↓[104]	
Motility index and propagation of duodenal and jejunal waves↓[84]	
Cycle length of inter-digestive motor activity in the fasted state↓[56]	
Small intestinal transit↓[71]	
Proximal duodenal pressure waves↓[104]	

PATHOPHYSIOLOGY OF GI MOTILITY AND SENSORY DYSFUNCTION IN DM

Hyperglycemia

Disordered GI function in DM has been attributed to irreversible DAN but it is now clear that acute high blood glucose concentration *per se* have a major reversible influence on upper-GI tract motility and sensory function. An animal study demonstrated that the correction of hyperglycemia to euglycemic levels restores the delayed transit[65]. Several studies in both healthy subjects and DM patients have shown that the GI motor function is impaired during acute hyperglycemia (Table 2)[84,95-97]. Marked acute hyperglycemia affects the motility in every region of the GI tract[98]. This may indicate that cholinergic activity is affected during hyperglycemia. Hyperglycemia may also affect the perception of sensations arising from the GI tract (Table 2). However, much of the data have been observational, and there is relatively little information relating to potential mechanisms by which these effects are mediated. Because both stimulatory and inhibitory effects occur during the hyperglycemia, the effects of glucose are likely to be mediated by neural or humoral mechanisms, rather than a direct effect on the smooth muscle of the GI tract. The secretion of pancreatic polypeptide, which is under vagal cholinergic control, is diminished during acute hyperglycemia in healthy control subjects[99]. In healthy volunteers, plasma concentrations of motilin are less during hyperglycemia when compared with euglycemia[100]. Considering the effects of systemic changes in blood glucose concentrations, animal studies have revealed the presence of glucose-responsive neurons in the central nervous system, which may modify vagal efferent activity[101]. Neurons responsive to glucose have recently been identified in the rat small intestine[102], but their response to systemic rather than luminal glucose is unclear. Much work is required to elucidate the neural, humoral, and cellular mechanisms by which systemic glucose levels affects GI motility and sensation.

Peripheral and central neuronal changes

DAN is seen as a major factor in the pathogenesis of disordered GI motor and sensory functions in DM[106,107]. Although GI manifestations related to DAN are diverse, many GI complications of DM seem to be related to DAN[19,48,72,108-110].

Histological findings: The best-characterized signs of damage to the autonomic nervous system during DM are morphological animal studies[111-117]. The number of myelinated axons in the vagosympathetic trunk is decreased in diabetic rats[118]. In the GI tract, many changes of nerves and ganglia were observed i.e. (1) dystrophic axonopathy[119]; (2) degeneration of mesenteric nerves and ganglia[111]; (3) number of vasoactive intestinal peptide (VIP)-IR neurons in myenteric ganglia[112]; (4) relative volume density in myenteric plexus[120]; (5) number of adrenergic and serotonergic neurons[111]. In addition, the surrounding tissue is also often disturbed. There is a thickening of the endothelium[121,122], which may sensitize axons to damage from increased pressure or decreased oxygen and glucose availability. It is thus possible that axonal damage may be secondary to disorders in tissue surrounding the neurons. Nitric oxide (NO) is a key neurotransmitter in the regulation of GI motor function[123,124]. In rodents with streptozotocin (STZ)-induced diabetes, NO synthase expression in the gastric myenteric neurons is diminished[125] and associated with delayed gastric emptying. The results of morphologic studies of the vagal nerves in diabetic patients are less consistent. One study demonstrated a decrease in unmyelinated axons in the abdominal vagus, another study found no abnormalities[126,127].

Clinical findings: One study has shown that abnormal esophageal motility is more frequent in the diabetic patients with evidence of DAN than in those without[37]. The presence of abnormal gastroesophageal reflux in diabetic patients has also been associated with the existence of DAN[128]. Increased cholinergic tone may relate to multipeaked waves in the diabetic esophagus in these patients[78]. Gastric emptying largely depends on vagus nerve function, which can be severely disrupted in DM[60]. Studies using cardiac autonomic nerve function tests to assess the involvement of the autonomic nerve system in diabetic patients have indicated that the prevalence and severity of dysmotility of the small intestine is substantially greater in DM patients with DAN compared to patients with normal autonomic function[129]. Diarrhea is evident in 20% of diabetic patients, particularly those with known DAN[130,131]. Altogether, abnormal upper GI motility in DM has been associated to DAN. However, the question arises as to whether neuropathic changes in the intramural GI plex-

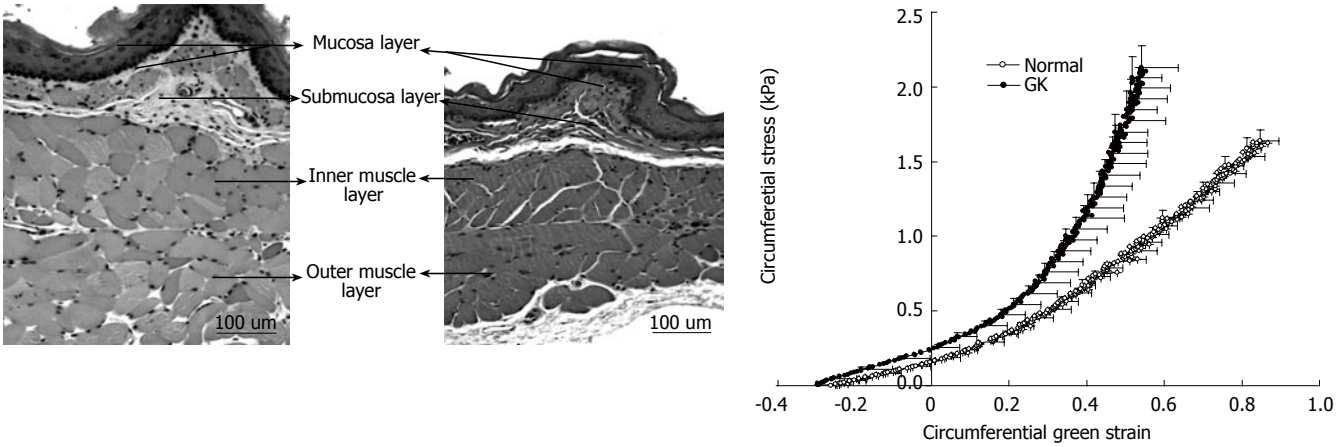

Figure 2 Microphotos of esophageal layer thickness in GK rats (left) and normal rats (middle). The muscle layer was biggest in the GK esophagus. Correspondingly the circumferential stress-strain curves of diabetic and non-diabetic esophageal wall showed in the right. The curve in the GK rats was shifted to the left, indicating that the esophageal wall stiffness increased.

uses, the extrinsic neuronal pathways or in the central nervous system are primary or secondary. In a recent study, Frøkjær *et al* found hyperreactivity and impaired coordination to bag distension of the esophagus in IDDM patients, which indicates that a neuronal dysfunction is responsible for the hyperreactivity[19]. This dysfunction can theoretically be addressed to the mechano-sensitive afferent fibers, inter-neurons or efferent fibers located in the esophageal wall. However, impaired extra-intestinal pathways can potentially also affect the motor response. In another study, Frøkjær *et al* demonstrated that IDDM patients had decreased sensitivity to the stimulations of the esophagus and duodenum[41]. This was accompanied by an increase in somatic referred pain areas to the gut stimulation (Figure 1). As the referred pain is a result of convergence between visceral and somatic afferents on central neurons, the findings are indirect evidence for central hyperexcitability and neuroplastic changes. Altogether, this indicate that the neuronal changes can be located both peripherally (receptors, nerve fibers, ganglions) and in the CNS. Sensory nerve dysfunction in the gut may explain why diabetic patients with severe GI motility disorders often do not suffer from the GI symptoms expected from the abnormal motility and motor function. On the another hand a large subgroup of patients with longstanding DM suffers from severe GI symptoms[2,26,27]. This overall hyperalgesia/hypersensitivity is in contrast to the peripheral autonomic afferent neuropathy that most likely impairs the perception from the GI tract. The mismatch between hypo-and hypersensitivity can likely be explained by an impaired balance between peripheral and central neuronal changes. Hence, the impaired function of the peripheral afferent nerves is likely counterbalanced (or even overruled) by increased central (spinal and/or brain) neuronal excitability and this balance may determine the symptoms in individual patients.

It is likely that different pathophysiological mechanisms contribute to the peripheral and central neuronal changes in DM, including metabolic alterations, microvascular changes, and inflammatory changes[132]. Hypoxia, hyperglycemia, and increased oxidative stress in DM contribute directly and indirectly to Schwann cell dysfunction[133]. This will result in impaired paranodal barrier function, damaged myelin, reduced antioxidative capacity, and decreased neurotrophic support for axons. Furthermore, the direct effects of prolonged hyperglycemia through the glycation on nervous tissue are also important in the development of DAN[134-136].

Morphological and biomechanical remodeling

Although the hyperglycemia and neuropathy seem to be the main mechanisms to the motor-sensory dysfunction in the upper GI tract in DM, the question remains whether the disordered motor and sensory functions of the GI tract are only due to the neuronal changes and dysfunction or if primary diabetes-induced structural and biomechanical changes in the GI tract also play a role? Data on the biomechanical properties are crucial for the understanding of the motor function of the GI tract because, (1) peristaltic motion that propels the food through the GI tract is a result of interaction of the passive and active tissue forces and the hydrodynamic forces in the food bolus and (2) remodeling of the mechanical properties reflects the changes in the tissue structure that determine a specific motor dysfunction. Therefore, the morphological and biomechanical remodeling of the GI wall may also be an important factor in the pathogenesis to the GI motor-sensory dysfunction in the diabetic patients.

Esophageal remodeling: Many studies have shown that DM causes morphological changes and biomechanical remodeling in the esophagus. Yang *et al*[13] in the *in vitro* study on the STZ-induced diabetic rat esophagus found that the wall thickness and cross-sectional wall area increased after the induction of diabetes. Twenty-eight days after the diabetic esophagus became stiffer both in shear and in the longitudinal direction. The esophageal remodeling was also found in NIDDM rat esophagus[18]. In the diabetic rats the opening angle and residual strain distribution in the outer surface of the wall decreased, the collagen fraction in the mucosa-submucosa layer and the passive circumferential stiffness of the esophageal wall increased (Figure 2). Furthermore, the esophageal weight per length, wall thickness and cross-sectional wall area increased in the NIDDM rats.

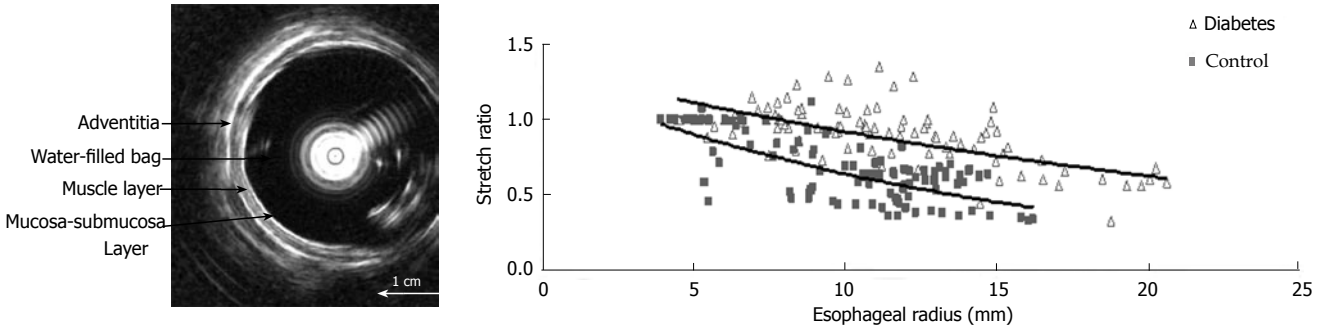

Figure 3 Left: Cross-sectional ultrasound image of the distended distal esophagus allows identification of the esophageal layers, i.e. mucosa-submucosa, muscle and adventitia layers. The white round shadow in the center is caused by the intraluminal ultrasound probe. Right: The distension-induced change in longitudinal stretch ratio is illustrated as function of the esophageal radius. The curves were obtained during smooth muscle relaxation with butylscopolamine. Exponential trend lines of the patients and controls are shown. The shortening during distension was clearly reduced in the diabetic patients.

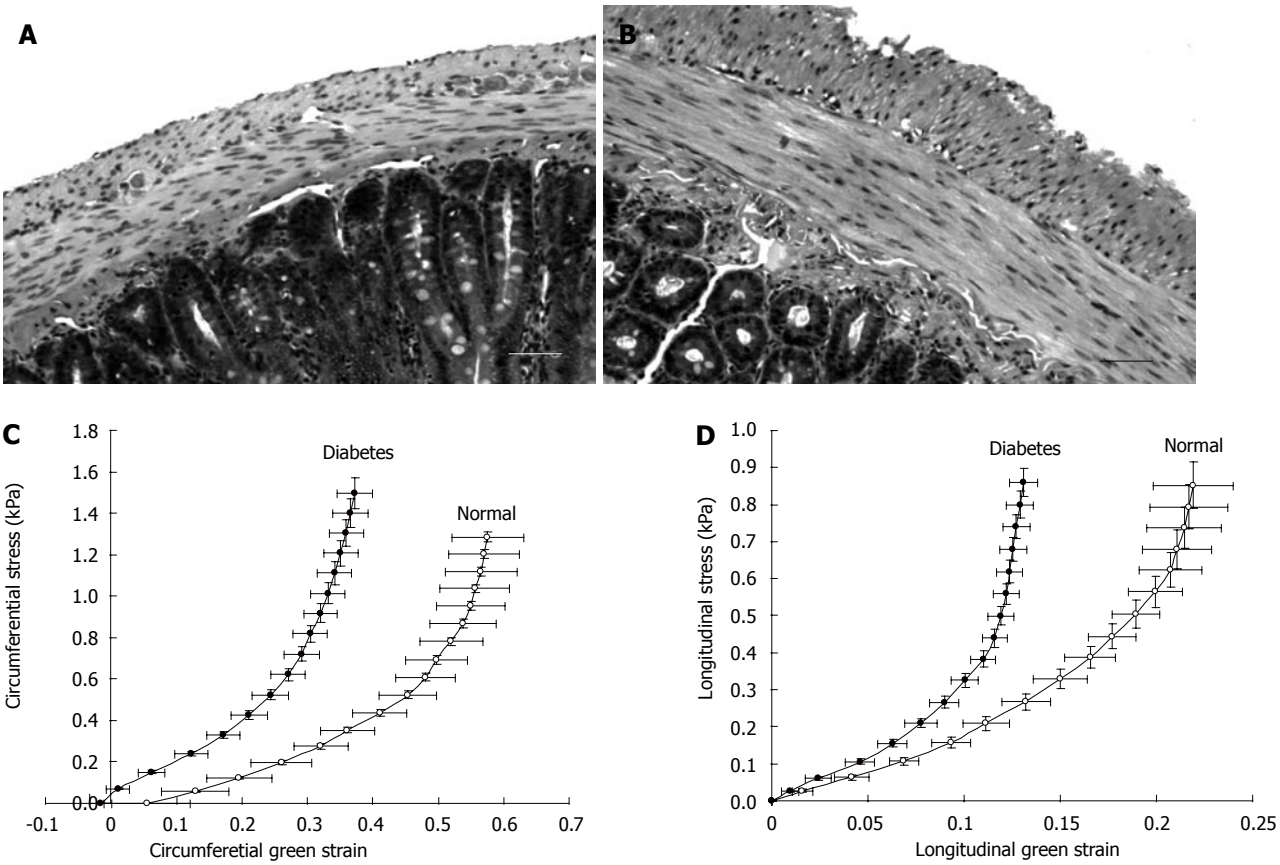

Figure 4 The micro-photographs show the normal (**A**) and 4 wk STZ-induced diabetic (**B**) duodenal histological sections. It clearly demonstrates that the muscle and submucosa layers in the diabetic duodenum became much thicker than in the normal duodenum. The bar is 100 μm. Correspondingly, the circumferential (**C**) and longitudinal (**D**) stress-strain relation curves of the duodenum in the STZ-induced diabetic rats shifted to the left indicating the wall became stiffer.

One previous human study reported that among six cases of diffuse muscular hypertrophy of the esophagus, four cases were associated with DM[137]. Recently, Frøkjær *et al*[19] in an human study found an increase in esophageal wall thickness and altered deformation to the distension with reduced longitudinal shortening and the radial stretch in IDDM patients (Figure 3).

Stomach remodeling: A morphological study in DM rats demonstrated that the gastric mucosa thickness increased in DM rats compared with controls[138]. Remodeling of the interstitial cells network of Cajal in the stomach were found both in animals and humans with DM[139-141]. A histopathological study of the human stomach in DM patients with severe gastroparesis showed prominent collagenization and smooth muscle atrophy of the muscle layer[142]. Regarding the biomechanical remodeling of the stomach only one report by Liao *et al* is available[17]. The rat stomach was distended *in vitro*. Gastric compliance, the surface tension, and circumferential and longitudinal deformation-pressure curves were calculated based on three-dimensional ultrasound reconstructions of non-diabetic and diabetic stomach models. In experimental DM, gastric compliance was lowered both in the non-glandular stomach (proximal part) and the whole stomach (Figure 4). Fur-

Table 3 Morphological and biomechanical changes of small intestine in DM

Morphological change	Biomechanical change
Intestinal weight, length, and weight per unit length↑	Opening angle and residual strain in duodenum↓
Surface area of mucosa↑	Opening angle and residual strain in jejunum and ileum↑
Number of goblet cells per villus↑	Circumferential stiffness of the intestinal wall↑
Smooth muscle mass↑	Longitudinal stiffness of the intestinal wall↑
Different layer thickness↑	Stress relaxation of small intestine↓
Proliferating cell nuclear antigen (PCNA) ↑	
interstitial cells of Cajal volume↓	

thermore, the circumferential stiffness in the non-glandular part increased. The structural changes of the stomach due to DM may together with the sensory and motor nerve dysfunction contribute to the delayed gastric emptying and the symptoms in diabetic patients.

Small intestinal remodeling: Many human[2,11,143,144] and animal [2,3,10,145-148] studies have shown that DM causes morphological alterations in the small intestine (Table 3). However, only few data exist relating to biomechanical remodeling of the small intestine in DM[12]. Recently we did a series of studies on the morphological and biomechanical remodeling of small intestine in the STZ-induced diabetic rats[14-16]. The major findings in our studies are summarized in Table 3 and briefly showed that the stiffness of the diabetic intestinal wall increased in a time-dependent manner (Figure 5). The viscoelastic behavior of intestinal wall also changed during the development of diabetes (Table 3). The stress-strain distribution and viscoelastic behavior mainly reflects the elastic properties of intestine. The changes in elastic properties reflect the structural remodeling of the intestinal wall during the diabetic development.

Advanced glycation end products (AGEs) produced during the development of DM likely relate to the morphological changes and biomechanical remodeling of the GI tract in DM. AGEs are generated by the sequential non-enzymatic glycation of protein amino groups and by oxidation reaction[149]. The accumulation of AGEs in tissues will alter the structure and function of matrix proteins[150]. Studies on DM and ageing show that AGEs are causing cross-linking of collagen molecules responsible for basement membrane thickening and loss of matrix elasticity[151-153]. AGEs may contribute to the diabetic GI morphological and biomechanical remodeling by at least two major mechanisms. The first is receptor-independent alteration of the extracellular matrix architecture by non-enzymatic glycation and the formation of protein cross-links. The second mechanism is receptor-dependent and consists of modulation of cellular functions through ligation of specific cell surface receptors[154-156]. Sanchez SS and coworkers have demonstrated that the expression of small intestinal extracellular matrix proteins have changed in STZ-induced diabetic rats[152]. Therefore, the nonenzymatic glycation of the GI tissue induced by long-term hyperglycemia seems to be an important mechanism behind the GI wall remodeling in DM.

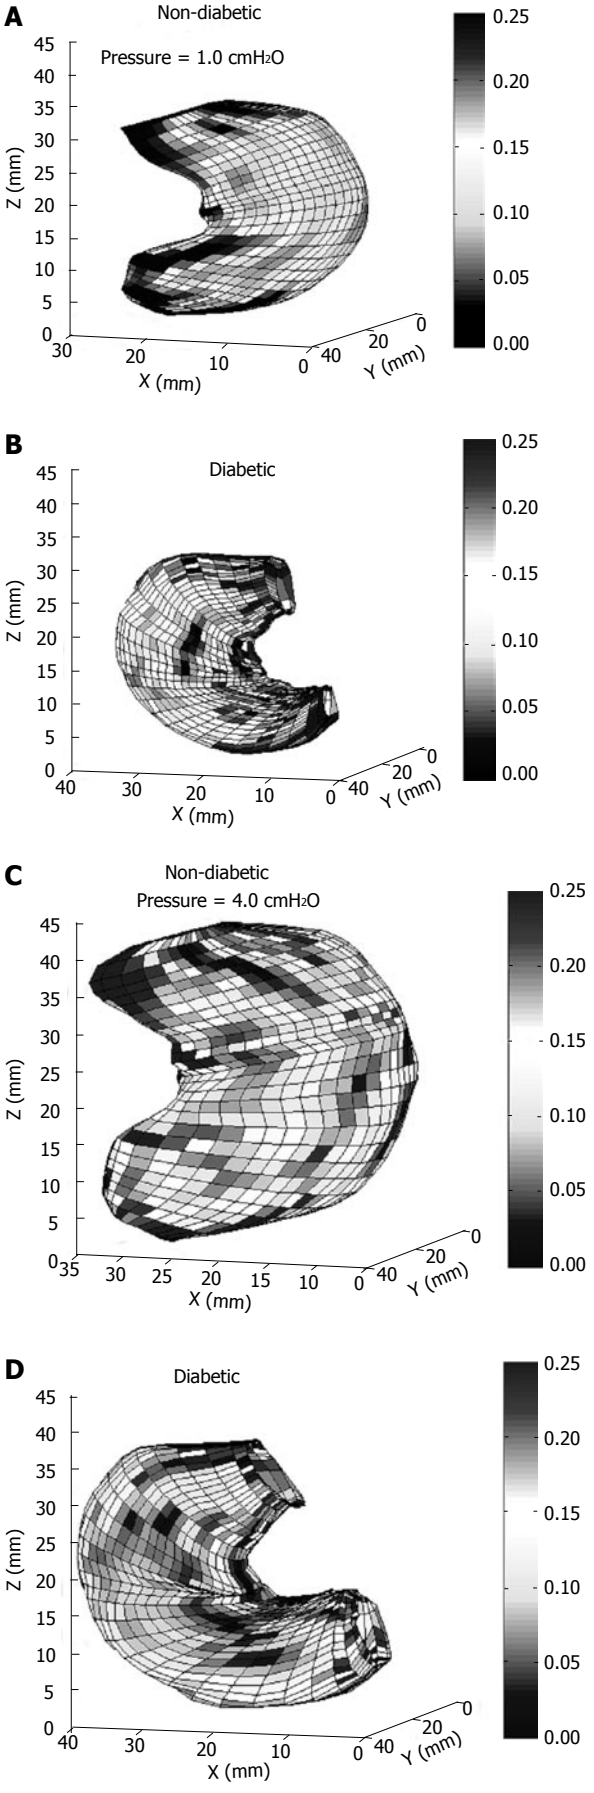

Figure 5 The circumferential curvature at the distension pressure of 1.0 (**A**,**B**) and 4.0 (**C**,**D**) cmH2O in the non-diabetic (**A**,**C**) and the diabetic stomach (**B**,**D**). The circumferential deformation of the stomach in the non-diabetic rats was significantly bigger than that in the diabetic Goto-Kakizaki (GK) rats, indicating the stiffness of the diabetic gastric wall increased in the diabetic GK rats.

Implication of GI remodeling on mechanosensory assessments: Mechanosensation is of fundamental importance for the GI function. The mechanosensitive nerve endings exist extensively in the GI tract where they serve a critical role in homeostasis. Several mechanoreceptor-like structures have been identified such as intraganglionic laminar nerve endings (IGLE) and intramuscular arrays (IMA) in the GI tract[157-164]. The mechanosensitive afferents in the intrinsic and extrinsic pathways were described as low-, wide-dynamic- or high-threshold tension-receptors[165]. Therefore, the GI tract structure as well as the tension, stress and strain distribution in the wall is important for the GI sensory and motor function. The GI wall structure or deformation changes in the DM will alter the relative positions of the mechanosensitive afferents (zero setting of the mechanosensitive afferents)[166]. The biomechanical remodeling in the DM such as alterations of residual strain and stress distribution and increase the wall stiffness will alter the tension and stress distribution of the mechanosensitive afferents. As results, the perception and motility of the GI tract will change as well. Hence, the morphological changes and biomechanical remodeling of GI tract in the DM is likely to affect the function of mechanosensitive afferents in the GI wall and further affect the motor and sensory function. However, so far the data are sparse about the association between the morphological and biomechanical remodeling of GI tract and the motor-sensory dysfunction in the DM[19,41]. The multimodal stimulations have proven accurate and reliable in the assessment of visceral sensation in several studies[167-169]. The geometry data of GI tract can be obtained by impedance and cross-sectional imaging such as ultrasound[170-172]. Combined with pressure recordings, biomechanical parameters such as tension, stress and strain can be obtained and correlated to the symptoms and mechanosensory data in the DM subjects[41]. Therefore, combined studies the GI motor-sensory dysfunction and morphological and biomechanical remodeling in the diabetic GI tract will improve our understanding about the pathophysiology of GI disorders in the DM patients. In the future, animal studies are needed to investigate the passive and active biomechanical and mechanosensory properties of the GI tract related to DM. The experiments should simulate the physiological conditions both *in vivo* and *in vitro* in normal and diabetic animals. The identification of mechanosensitive afferents and enteric nerve responses to the different stimuli will obviously be beneficial to understand the mechanisms of GI motor-sensory dysfunction in the DM.

In conclusion, GI symptoms are frequent in the diabetic patients and are associated with sensory-motor abnormalities, such as impaired perception and motility of the GI tract. The pathogenesis of abnormal GI sensory-motor function in DM is clearly multi-factorial. DAN seems to be the major factor in the pathogenesis of disordered GI motor and sensory functions in DM. Hyperglycemia has also been shown to impair GI motor and sensory function. Furthermore, the morphological changes and biomechanical remodeling of the GI wall may compromise the GI motor function and affect the function of the mechanosensitive afferents in the GI wall. Studies of the relation between the GI motor-sensory dysfunction, morphological changes and biomechanical remodeling in the diabetic GI tract may shed of more light to understand the mechanism of GI motor-sensory dysfunction in the diabetic patients. This knowledge may prove to be valuable in the development of new treatment strategies, which can also be evaluated with the developed methods. New treatments that may be based on the present knowledge and methods are: (1) neurostimulation of afferent visceral nerves, i.e. gastric electric stimulation, (2) agents which can break down already formed glycation end product protein-protein cross-links, and (3) modulation of the central nervous system excitability by drugs.

Abstract

Endosonography is a useful tool for studying the morphology and motor function of the gastrointestinal tract. Intraluminal ultrasonography is the common denomination of ultrasound examinations using intracorporal transducers which are inserted into the GI tract. Thus, the visceral wall and adjacent structures can be imaged in detail. This review describes the usefulness of endosonography in gastroenterology, in particular with respect to studies of the biomechanical and motor function of the gastrointestinal tract. New techniques such as 3-D EUS, elastography and strain rate imaging are discussed.

INTRODUCTION

Disorders of the gastrointestinal (GI) tract may be examined using endoscopy, X-ray, radionuclide studies, electromyography, magnetic resonance imaging (MRI) and manometry. Specific analysis of structural changes occurring within the GI wall is, however, difficult to study by these techniques. Intraluminal ultrasonography (endosonography (ES), endoscopic ultrasonography (EUS) is the common denomination of ultrasound examinations using intracorporal transducers which are inserted into the GI tract. Thus, the visceral wall and adjacent structures can be imaged in detail[1-3]. Acoustic coupling is usually achieved by filling water into the lumen or into a balloon around the ultrasound transducer. Alternatively, the ultrasound probe can be applied directly on the endoluminal surface.

Endosonography is currently mostly performed in the upper GI tract and rectum. However, endosonographic imaging of the colon and distal ileum as well as intraductal ultrasonography (IDUS) of biliary and pancreatic ducts are frequently performed with miniprobes. Dedicated echocolonoscopes are also available, but these have so far gained limited clinical application.

ENDOSONOGRAPHIC INSTRUMENTS

Echoendoscopes combine endoscopy with integrated ultrasound transducers. These instruments can be classified both according to the type of endoscope and the US system. Echoendoscopes may have radial or curvilinear array US transducers using frequencies between 7.5 and 30 MHz. These systems are being continuously improved. The possibility to combine echoendoscopes with conventional ultrasound machines has allowed the use of different ultrasound modalities like B-mode, M-mode and Doppler technology. Ultrasound elastography is a new method with the potential of separating normal from pathological tissue. Recently, elastography and contrast enhanced ultrasound have been applied also in endosonographic imaging[4]. US miniprobes have a diameter which allows the probe to be inserted through the biopsy channel of a conventional endoscope or a suitable catheter (Figure 1). Currently, available US miniprobes comprise mechanical sector, electronic phased arrays, or single crystal linear compound systems operating with frequencies between 12 and 30 MHz. Systems that combine linear compound scanning with mechanical sector scanning or M-mode registration are also available making it possible to switch between these modalities.

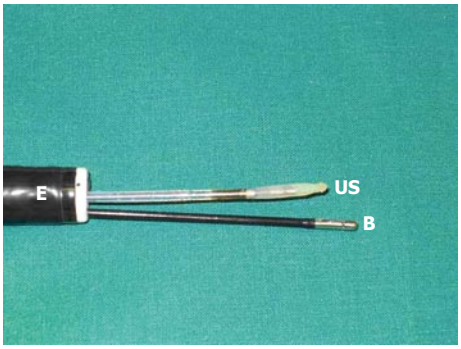

Figure 1 An endoscope with two channels. A miniature ultrasound transducer (US) and a biopsy forceps (B) are inserted through the channels.

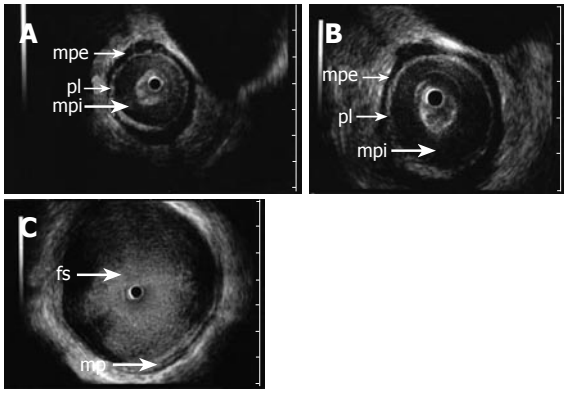

Figure 2 ES images (**A** and **B**) obtained with a 15 MHz miniprobe in a patient with achalasia showing the longitudinal, outer layer of the proper muscle (mpe) separated from a thickened circular, inner layer (mpi) by an echogenic layer corresponding to the localization of the plexus myentericus (pl). **C**: shows a dilated esophageal lumen with food content (fs). A normal aspect of the proper muscle is seen.

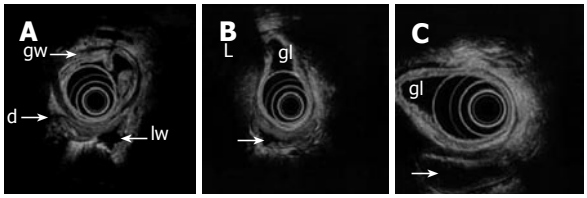

Figure 3 Endosonography with an echoendoscope (12 MHz frequency is used) placed in the gastric lumen (gl) showing the layers of the gastric wall (gw) and GI loops outside the stomach. Lumen is partly collapsed (d), partly waterfilled (arrows). Motility and contractions of native GI loops may be studied. High frequency miniprobes are less suitable for this purpose due to higher frequencies and small transducer diameter.

The small size and high frequencies of miniature probes reduce the size of the US image and the penetration depth of the US beam into the tissue as compared to echoendoscopes. However, small diameter probes can be passed into stenotic areas not traversable with conventional echoendoscopes. Doppler sonography may provide important information about vascular flow and separate vessels from other echo-poor structures. Some echoendoscopes have integrated Doppler technology and Doppler miniprobes for transendoscopic use have also been developed[5]. Other ultrasound systems designed for use within the GI tract do not have an optical system. Transrectal probes have been used for imaging the prostate, bladder, uterus, and rectum. These probes are either linear array or mechanical sector.

ENDOSONOGRAPHIC ASSESSMENT OF GI MOTILITY AND BIOMECHANICS

In recent years ultrasound has been applied in studies of the biomechanical function of the GI tract. In this sense biomechanics should be understood in a much broader sense than the term motility. Motility considers active properties such as peristaltic contractions whereas biomechanics deals with active and passive forces and deformation of the tissue. Biomechanical alterations and abnormal motility in the GI tract is found in several diseases which may be localized in the organ itself or related to the nearest surroundings or to systemic diseases. Luminal manometry has so far been the most widely used method to study GI tract physiology. However, despite the development of high-resolution manometry systems there are still problems in the investigation of GI motor function. The strength of a contraction may vary considerably, thus giving more or less reliable manometric registrations. Furthermore, respiration, aortic pulsation and cardiac contractions may affect the recordings.

The presence of probes in the GI lumen has an influence on physiology and biomechanical studies should therefore ideally be examined without intraluminal devices. ES miniprobes combine the advantages of high ultrasound frequencies with small transducers, allowing detailed images of GI wall layers to be obtained with less influence on the GI lumen than the larger echoendoscopes. Hence, these probes have been regarded suitable for motility studies of the GI tract, especially when applied in lumina with small diameter, like the esophagus (Figure 2). However, echoendoscopes can also be used for examination of motility if positioned in wider lumina like the stomach. Since echoendoscopes generally utilize lower ultrasound frequencies and larger ultrasound probes they can also be used to study motility of neighbouring GI structures (Figure 3). Endosonographic real time B-mode imaging alone or in combination with other methods, as manometry and electromyography, have been used for studying correlation between the pressure and electric potential changes and structural changes in the GI wall. Correct interpretation of ultrasound images of the GI wall is crucial when applying this technique for detailed examination of physiological characteristics. The GI wall consists of mucosa, submucosa, muscularis propria and adventitia/serosa. Muscularis propria has an inner circular and an outer longitudinal layer that is separated by the myenteric plexus.

The normal GI wall is imaged by ultrasonography as a layered structure consisting of 3-9 layers depending on the thickness and structure of different layers, ultrasound frequency, and applied pressure on the wall[6,7]. In most cases, a five-layer structure of the wall can be demonstrated, as determined by the histological layers and the appearance of interface echoes (Figure 2, Figure 4). When the visceral wall is imaged with an endoluminal transducer, the interface between the luminal contents and

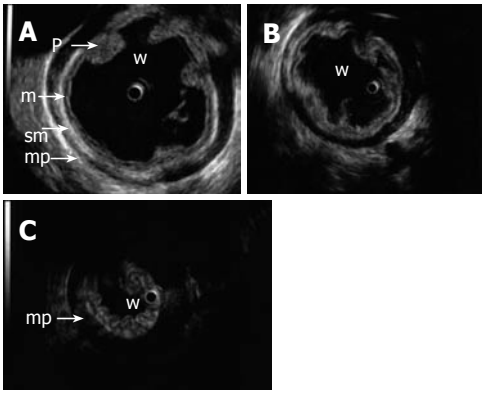

Figure 4 Contraction sequence (**A**, **B**, **C**) demonstrated with a 15 MHz miniprobe in a water-filled (w) stomach. Gastric fold (p), mucosa (m), submucosa (sm), proper muscle (mp).

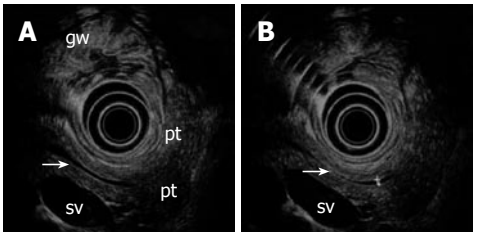

Figure 5 A normal pancreas imaged from the stomach with a 6 MHz echoendoscope. The compressed posterior gastric wall is closely related to the surface of the pancreas. The pancreatic duct is seen (arrow) with minor (**A**) and slightly increased transducer pressure (**B**). The non-compressed gastric wall with folds (gw) is seen on the opposite side of the transducer. Pancreatic tail (pt), splenic vein (sv).

the mucosa accounts for the first, echo-rich layer. The rest of mucosa appears as a second, echo-poor layer. The third, echo-rich layer usually includes the interface between the lamina propria and muscularis mucosae, the submucosa, and the interface at the border of the muscularis propria. In a five-layer structure, the rest of muscularis propria is imaged as an echo-poor fourth layer. The fifth, echogenic layer represents the outer wall delineation and is an interface echo at the serosa or adventitia level.

Sometimes, the use of high-frequency ultrasound produces an interface echo between the different aspects of the muscularis propria, probably reflecting the connective tissue embedding the myenteric plexus. A thick muscularis mucosa may also be identified as an echo-poor layer dividing the third, echogenic layer. Hence, the ultrasonographic wall structure may consist of seven or even nine different layers[6,8].

CLINICAL APPLICATIONS OF ENDOSONOGRAPHY IN BIOMECHANICS AND MOTILITY

Esophagus is often associated with motility disorders which can be studied with different techniques. Endosonography has been regarded as a suitable tool for examination of esophagus because this organ is a straight tube with a small diameter. McCray *et al*[9] studied the high pressure zone between the esophagus and stomach (lower esophageal sphincter and extrinsic crural diaphragm) in normal subjects with a dual high resolution endosonography-manometry catheter. This catheter recorded simultaneously manometric pressures and corresponding ultrasound images while being pulled through the distal esophagus. They found that simultaneous high-resolution endoluminal sonography and pressure manometry separate the two components of the high-pressure zone in the distal esophagus.

Endoscopic ultrasound findings have also suggested that an association exists between sustained longitudinal layer contraction in the esophageal body and chest pain of unknown origin[10]. Furthermore, Nicosia *et al*[11] combined manometry and ultrasound and used conservation of mass principles to quantify local axial shortening of the esophagus. A relationship between contractions in the circular and longitudinal muscle layers during swallowing was established. They also made 3D (space-time) reconstructions of the inner wall of the circular muscle layer for representative swallows. Takeda *et al*[12] used combined ultrasound and manometry to determine circumferential stress-strain properties in the esophagus. In a study by Taniguchi *et al*[13] the sheep esophagus was investigated with M-mode echoesophagram recording and manometry with the goal to measure simultaneously changes in the thickness of the individual esophageal wall layers and the corresponding changes in intraluminal pressure. The maximum manometric pressure, the esophageal wall layer thickness, and the duration of contraction were measured. Swallowing events up to one hour were recorded and in one trial both dry and wet swallows were compared. All swallowing events produced simultaneous increase in intraluminal pressure and esophageal wall thickness. The thickness of the inner (circular) muscle layer increased in dry as well as wet swallows.

The combination of manometry with a 20 MHz ultrasound transducer has also been used to correlate wall thickness, luminal diameter and contractive activity in healthy volunteers[14]. The increase in muscle width by ultrasonography was found to correlate with the increase in luminal pressure by manometry. Recently, Hoff *et al*[15] described a multimodal device inserted into esophagus combining bag distension, manometry, high frequency intraluminal ultrasound, laser Doppler flowmetry and symptom registration. Preliminary experience indicates that these modalities can be used in combination without significant technical influence on each other. Thus, this method can provide a basis for further studies, probably within both the upper and lower GI tract.

Achalasia

Achalasia is a disorder in esophageal motility and is defined by its typical pattern at manometry. The diagnosis can be supported by findings at barium radiography that may show delayed passage through the lower esophageal sphincter and dilatation of the body of the esophagus. At manometry, achalasia is characterized primarily by aperistalsis of the esophageal body and incomplete relaxation of the lower esophageal sphincter. In autopsy

studies of patients with achalasia, the thickness of the lower esophageal sphincter is increased. Using high frequency US probes, it has been shown that the thickening of muscularis propria mainly appear in the inner circular portion (Figure 2). Thickening of the circular layer of the muscularis propria at the cardia may support the diagnosis of evolving achalasia[16-23].

A study of the esophageal wall in patients with newly diagnosed achalasia has also been performed using a sector scanning echoendoscope with 12 MHz transducer frequency. The endosonographic findings were correlated with manometric features and clinical symptoms. In these patients, an increase in total wall thickness and thickness of the muscularis propria was found at the level of the lower esophageal sphincter and the proximal 5 cm of the sphincter[16]. Miller *et al*[21] used a 20 MHz radial ultrasound transducer to examine the width of the total muscularis propria, and the circular and longitudinal smooth muscles at the lower esophageal sphincter in 29 patients with achalasia, comparing them with 19 normal subjects. They found that the mean width of these muscles was increased in patients with achalasia. However, because of overlap in muscle width thicknesses between these groups it was concluded that a thickened muscularis propria cannot be used to differentiate clinically between patients with achalasia and normal controls. Nevertheless, they found that the mean diameter of both the longitudinal and the circular smooth muscle layers at the lower esophageal sphincter were wider in patients with achalasia than in normal subjects. Trowers *et al*[22] used a single crystal transendoscopic probe providing linear images. Six achalasia patients were examined, demonstrating the thickness of the muscularis propria to be increased four-fold, and all patients were abnormal compared to controls.

Scleroderma

Patients suffering from systemic sclerosis have frequently clinical gastrointestinal manifestations, especially excessive deposition of collagen in the esophagus which may cause swallowing problems. Endoluminal US seems capable of defining morphologic as well as physiologic abnormalities of the esophagus in patients with scleroderma of the esophagus. Lieu *et al*[24] examined four patients and found that US images correlated with established pathologic descriptions like smooth muscle atrophy, variable fibrosis, and collagen deposition. Increased echogenicity and thinning of the muscularis propria, consistent with fibrosis and atrophy of the smooth muscle were observed. Miller *et al*[25] used a 20 MHz ultrasound transducer in examining 13 patients suffering from systemic sclerosis and 13 healthy subjects. Also postmortem autopsy study was performed to compare histopathological abnormalities with sonographic findings in the esophagus. In the postmortem ultrasound study of two cases, hyperechoic echoes were seen in the normally hypoechoic muscularis propria. These findings corresponded to fibrosis found in histological examinations. Hyperechoic abnormalities were ultrasonographically seen in the muscularis propria in patients but not in normal controls. A strong positive correlation between esophageal hyperechoic and manometric abnormalities was also found.

Nutcracker esophagus

Patients with nutcracker esophagus (NE) suffer dysphagia and/or chest pain due to strong peristaltic contractions. High-pressure amplitudes are found at manometry. Melzer *et al*[26,27] used an echoendoscope to examine the thickness of the muscularis propria at the gastroesophageal junction and in the lower, middle, and upper esophagus in patients with nutcracker esophagus. The muscularis propria was thickened in one-third of the patients. This thickening, however, did not correspond to the location and magnitude of the manometric abnormality and did not correlate with the clinical presentation. They also reported a patient with NE and esophageal pressures exceeding 800 mmHg in whom endoscopic ultrasonography demonstrated a markedly thickened esophageal muscularis propria. The hypertrophy of the muscularis propria extended from the gastroesophageal junction upwards to the middle esophagus.

Reflux esophagitis

Esophageal dysfunction can be seen in patients with reflux esophagitis. Important pathophysiological factors are impaired esophageal acid clearance and a hypotonic lower esophageal sphincter. The intraluminal esophageal pressure is related to the contraction of the inner circular smooth muscle. Dysfunction of the lower esophageal sphincter area may cause esophageal reflux disease. Contraction of the longitudinal smooth muscle during swallowing causes axial shortening of the esophagus. This muscle may also stiffen the esophagus and thus generate intraluminal pressure during peristalsis. In patients with reflux esophagitis, inflammatory changes are present, affecting all or individual wall layers in the distal part of the esophagus. Periesophageal inflammation may also be present and, depending on the degree of total inflammation, it may affect the esophageal motility and thus also acid clearance. These changes can usually be imaged by ultrasound miniprobes, which thus may provide insights into the pathophysiology of reflux esophagitis.

GASTRODUODENAL MOTILITY

Endosonography of the stomach and duodenum is in essence performed in the same way as in the esophagus. However, endosonography can be technically more challenging in wide and curved organs. Transabdominal ultrasound is applied in studying gastroduodenal motility, also in combination with intraluminal pressure devices. Recently, mechanosensory properties in the human gastric antrum were evaluated using transabdominal ultrasound scanning during volume-controlled antral distension[28,29]. Furthermore, a device which combines endosonographic real - time imaging with intraluminal volume-controlled bag distensions has been developed also for use in large lumina. Thus, detailed images of GI wall layers corresponding to the area of bag pressure can be obtained. Arslan *et al*[30] investigated duodenum with high-frequency ultrasound to study wall layers and motility during allergenic

provocation. A 20 MHz miniature ultrasound probe was inserted through a nasoduodenal tube and ultrasound examination was performed before and after provocation. Clinical symptoms were recorded and the thickness of mucosa, submucosa and muscularis propria was measured directly on ultrasonographic images. Endosonographic changes (i.e. any resolvable wall thickening, contraction or new echogenic layer) were observed in 15 of the 20 patients. Mucosal thickening, changes in the number of wall layers and sustained contractions of duodenum were observed in some patients after provocation. The mucosal thickening could represent mucosal edema in response to provocation. A new echorich layer was observed in two patients, probably caused by an additional interface at the border of a thicker muscularis mucosa due to the allergic reaction.

Rectum, large and small intestine

These organs may be examined in the same way as described for esophagus, stomach and duodenum using dedicated echoendoscopes and rectal probes. However, ES miniprobes, which can easily be inserted through the biopsy channel of standard endoscopes, seem to be a practical method for imaging the colon as well as the rectum. The interpretation of wall layers, organ contractions and other motility aspects is similar to that of the upper GI tract. Endoscopy of the small intestine is now possible in some GI laboratories. New enteroscopes may in the future be integrated with ultrasound transducers making ES/EUS of the small intestine possible. Capsule endoscopy which also is a relatively new method, allows endoscopic imaging of the entire small intestine. If a miniature ultrasound device is integrated in this capsule, EUS of the small intestine may possibly be performed.

NEW TECHNIQUES

Three-dimensional EUS

3D- images are assumed to be easier to understand and communicate than the mental reconstruction of several 2D-images. 3D-techniques are currently under development for most imaging modalities and 3D-EUS may be applied for improved recognition of the GI anatomy and pathological lesions. 3D-EUS images can be obtained using images acquired by echoendoscopes or miniprobes. Mostly, a pullback device has been used to obtain parallel 2D images which are reconstructed to a 3D-image. Acquired ultrasound images can be stored and digitized using frame grabbing but direct digitizing of ultrasound raw data is being increasingly used in new scanners. Advanced software programs containing different rendering or other reconstruction algorithms are used for postprocessing and display of 3D ultrasound data, which can be studied using anyplane slicing, segmentation and volume calculation[31,32].

Elastography

The stiffness of normal and pathological tissue is usually different and may be evaluated by ultrasound which is based on B-mode scanning during compressions (elastography) (Figure 5). Elastography has been applied on the GI tract, kidney, muscle, breast and the heart. The underlying principle is that the deformation of tissue by a mechanical excitation is a function of its mechanical properties. For gastrointestinal purposes, the intraluminal pressure may be used as the excitation force[33,34].

Imaging of ultrasound tissue elasticity has gained considerable interest as a method to differentiate normal from abnormal tissue, particularly malignant from non-malignant disease. However, normal structures also have variable internal sonoelastic properties. When compressed by an ultrasound transducer, the ultrasound image of normal as well as pathological tissue is changed. It has been demonstrated that increased pressure on the GI wall changes the thickness, layers and echogenicity of the wall as imaged by B-mode ultrasonography[7].

Strain rate imaging

Strain rate imaging is a recently introduced technique to measure deformation of biological tissue. The technique is based on tissue velocity imaging, which is an ultrasound technique that provides quantitative information on velocities within a tissue. By color-coded tissue velocity imaging, velocity data from the whole field of view are available simultaneously[35]. This allows extraction of other parameters through spatial and temporal processing of the velocity data. Strain rate and strain are examples of such parameters. The methods have primarily been used in echocardiography, but other uses have also been reported, including measurements of gastric motor function[36].

Further development of specialized EUS instruments can allow the investigators to choose the most appropriate instruments for the separate tasks. Miniature probes, which are less costly and easier to operate, will most likely be available in a majority of endoscopy units within a few years. Different modalities can probably be merged into new multimodal devices making it possible to obtain multiple motility parameters in one procedure. A successful development of such devices can hopefully be achieved on the basis of fruitful collaboration between medicine, technology and soft-ware producers.

Abstract

The motor function of the gastrointestinal tract has primarily been studied using manometry and radiography, though more indirect tests have also been applied. Manometry and radiography do not provide detailed information about the muscle properties as can be assessed from studies of muscle properties in muscle strips in vitro. In recent years a technique based on impedance planimetric measurement of pressure-cross-sectional area relations in a distending bag has proven to provide more detailed information about the muscle function in vivo. This review shows examples of new muscle function analysis such as length-tension diagrams, force-velocity curves and preload-afterload diagrams.

INTRODUCTION

The gastrointestinal (GI) tract is a continuous channel through the body with oral and anal orifices for intake and output. It consists of a series of organs with the biliary tract as a major side-branch. These organs resemble one another in constitution, the elements being variously arranged in such a way as to produce cylinders, spheroids, or intermediate forms[1]. The wall of the GI tract is a laminated composite structure. The general structure is an outer muscle coat consisting of a longitudinal muscle layer and a circular muscle layer. The collagen-rich submucosa layer and a mucosa layers are found inside the outer muscle coat. A third layer of muscle, the muscularis mucosae, exists throughout almost the entire tract. A network of nerves, the myenteric plexus, is embedded in the loose collagen matrix of the intermuscular plane. This set of nerves is essential in the regulation of the contractions of the adjacent musculature, the two layers of the muscularis propria. The motions of the GI tract must, at all times, keep the contents of the tract in their intended place, i.e. to bring them to the site of absorption. This means not only that they accomplish net antegrade flow but also that they mix the contents and move it across the surface where absorption occurs. The contractile patterns and transit varies greatly from one part of the tract to another. The muscle layers provide the forces that distort the cylindrical conduit in the form of contractions. The connective tissue layers provide a framework, or stroma, that determines the passive physical properties of the gut wall.

As stated above, the gross mechanical function of the GI tract depends on the coordinated muscle function and neuromuscular circuits. In bioengineering terms the mechanical properties of the GI tract has mainly been studied in vitro under standardized isometric and isotonic conditions and length-tension and force-velocity characteristics have been described[2]. The muscle function is altered in a number of organic and functional GI diseases, as well as it can be modified by drugs. Despite the importance of the muscle function, only few methods exist to evaluate the mechanics of GI muscle function in vivo. Manometry has become a standard method for clinical motility testing but it merely provides a proxy of the force developed by the muscles and is in many diseases poorly related to the organ dysfunction and symptoms[3].

Heart muscle function has attracted more attention that GI muscle function in the past and pressure-volume loops and ventricular function curves can be generated from measurements obtained *in vivo*[4,5]. Inspired by the cardiovascular research similar "muscle function" curves can now be obtained in the GI tract from impedance planimetric studies and such analyses provide new insight into the behavior and function of the GI tract. The review provides the background for advanced muscle analysis in vivo and takes the readers through some examples.

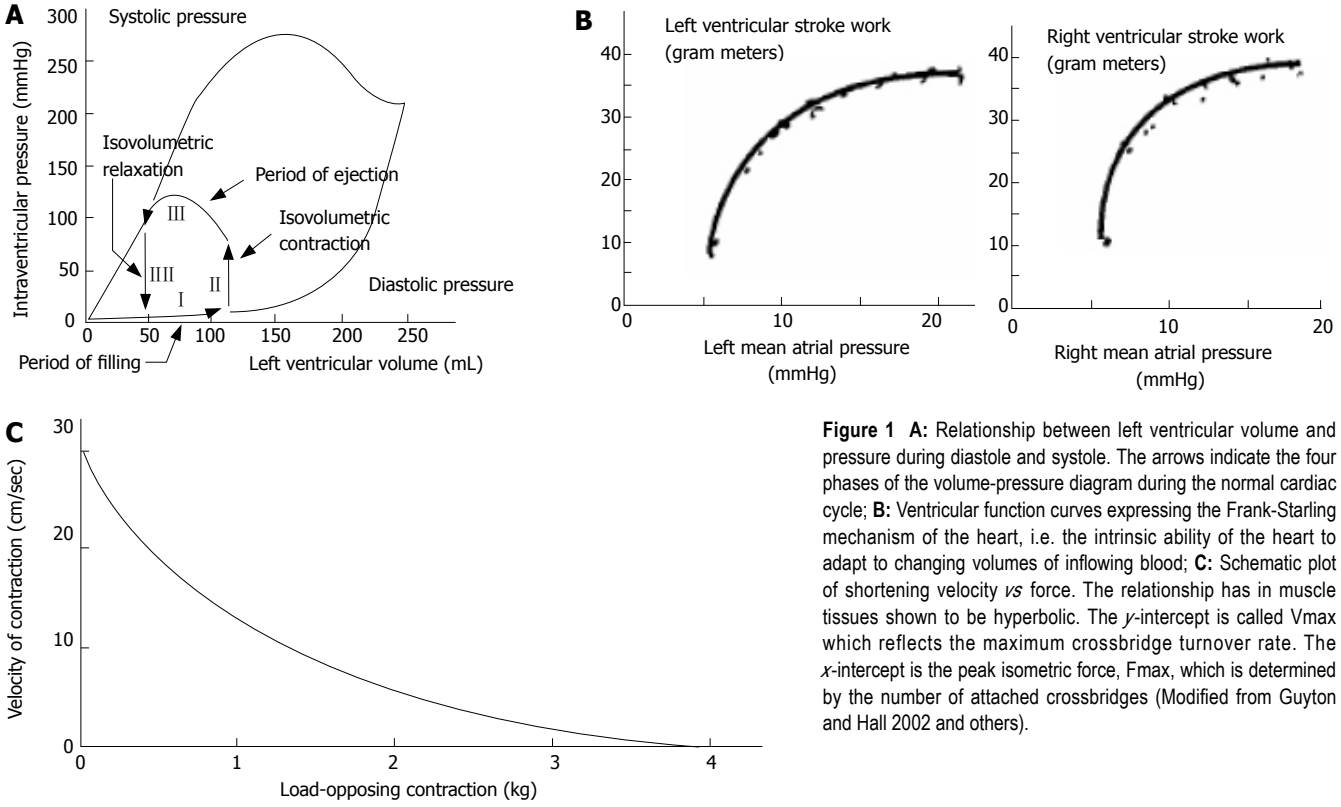

Figure 1 **A:** Relationship between left ventricular volume and pressure during diastole and systole. The arrows indicate the four phases of the volume-pressure diagram during the normal cardiac cycle; **B:** Ventricular function curves expressing the Frank-Starling mechanism of the heart, i.e. the intrinsic ability of the heart to adapt to changing volumes of inflowing blood; **C:** Schematic plot of shortening velocity *vs* force. The relationship has in muscle tissues shown to be hyperbolic. The *y*-intercept is called Vmax which reflects the maximum crossbridge turnover rate. The *x*-intercept is the peak isometric force, Fmax, which is determined by the number of attached crossbridges (Modified from Guyton and Hall 2002 and others).

CURRENT METHODS FOR EVALUATING MUSCLE FUNCTION

The cardiac cycle and cardiac mechanics-function relationship have been studied in much more detail than contractile properties of GI smooth muscle in vivo. Curves are often derived from pressure-volume data where four phases during the cardiac cycle can be identified (Figure 1A), and from stroke work output as function of atrial pressures (Figure 1B). Such data are clinically useful for explaining the pumping mechanics of the left ventricle. One of the best known relationships concerning muscle action is the hyperbolic force-velocity relation[4,6] (Figure 1C). Although this relationship originally was derived for isolated muscle, it has been confirmed for whole striated muscle movements[7]. The curve implies that velocity of muscle contraction is inversely proportional to the load, that a large force cannot be exerted in very rapid movements, that the greatest velocities are attained under conditions of low loading, and that the intermediate values of force and velocity depend on the maximal isometric force.

Most mechanical studies in vitro on GI smooth muscle is isometric length-tension experiments conducted at resting conditions in small organ baths and during stimulation or inhibition with pharmacological substances[2]. Such studies have given valuable information about the regulation of contractions and passive tissue properties.

Only few methods are established for evaluation of GI motor and biomechanical function in vivo. Luminal pressure recordings are the key measurement technique for determining the contractile pattern in many parts of the GI tract. Manometry has been used for more than 50 years to monitor motility in the gastrointestinal tract. These systems often use reliable perfused hydraulic-capillary systems where pressure at a sensor outside the body can be used to accurately measure pressure at a point along a catheter *via* a low flow rate perfused channel. This system has been used extensively to measure force via a pressure measurement in lumens and in liquid filled balloons. Other tests may give a more indirect measure of the motor function. These include transit time studies, pH-metry in the esophagus, radiography, *etc*. The measurement of luminal pressure, however, is not a direct measure of muscle tone and tension. It is a proxy of changes in force generated by the surrounding tissues[8,9].

During recent years, bag distension has become popular as a research tool for GI studies, primarily because mechanical data may be obtained. Furthermore, distension provokes pain and therefore can be used to study the sensory function in patients with functional chest pain[10]. Only few distension studies using inhibitory drugs focused on separating phasic and tonic contractions[11,12]. Recently, tools were developed for studying both the active (phasic and tonic contractions) and passive behavior using impedance planimetric distension before and during administration of inhibitory drugs[9,13,14]. Tension, stress and strain are of principal interest because these parameters give information about the esophageal elastic properties and mechanoreceptors respond more directly to these parameters than to pressure and volume[9]. Furthermore, the muscle function is better evaluated when the forces and tensions can be measured rather than the pressure generated by contractions[1,15]. The most used bag distension technique is the barostat but other techniques such as impedance planimetry and distensions combined

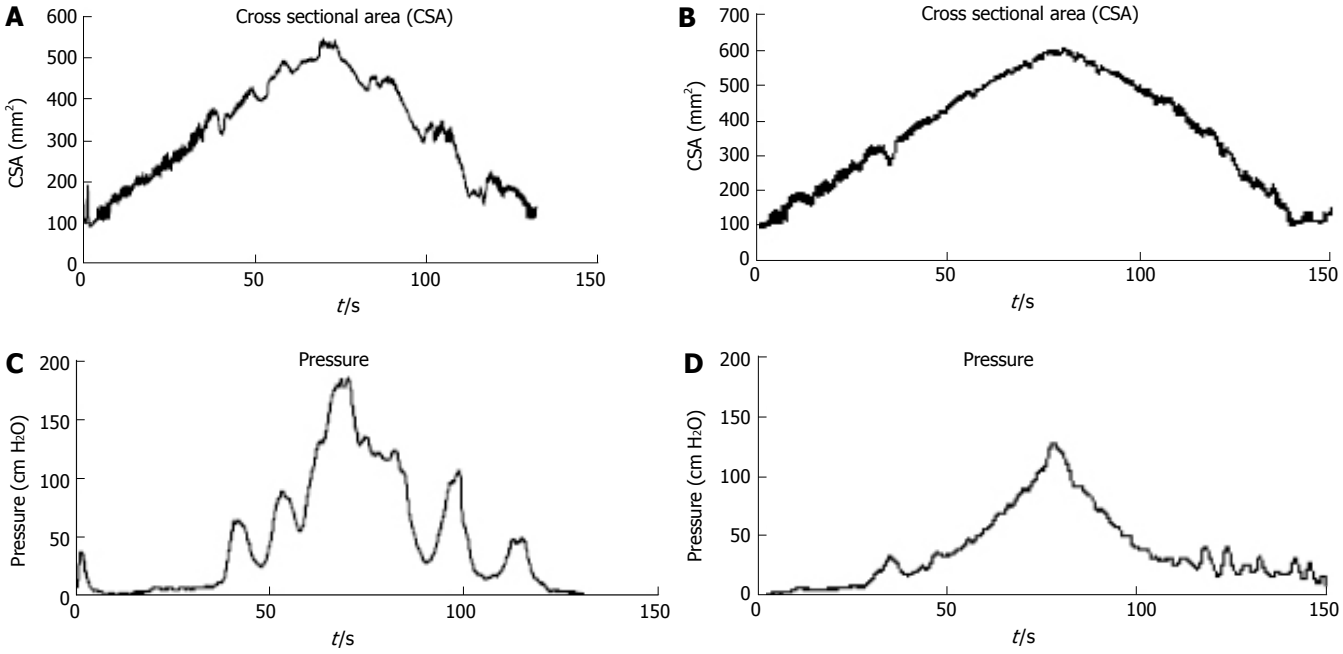

Figure 2 Cross-sectional area (CSA), and pressure as function of time during the distension of esophagus without (**A, C**) and during (**B, D**) the administration of butylscopolamine. Modified from previous publications by Gregersen and coworkers.

with imaging techniques give more detailed geometric information. Rather than analyzing pressure-volume relationships based on the barostat, impedance planimetry enables data on the CSA of the bag during distension to be gathered. CSA shows a better relationship to the diametrical changes in the alimentary lumen than volume[1].

THE IMPEDANCE PLANIMETRIC PRINCIPLE

Impedance planimetry is a technique for performing bag distensions in hollow visceral organs. It has been used to measure CSA together with bag pressure in animal and human studies and the wall tension and strain in the organ can be estimated[1,16]. From Ohm´s law we know that

$$V = IZ$$

where V, I and Z denote the potential difference, the current and the electrical impedance. In the case of a fluid filled bag on a probe with an alternating constant current set up between two excitation electrodes (E), Ohms law will apply for the field between two inner sensing electrodes (S). The impedance depends on the distance (D) between the S electrodes, the conductivity (ς) of the liquid in the bag and the CSA of the bag between the S electrodes. Since

$$Z = \frac{D}{\varsigma CSA}$$

the potential difference can be written as

$$V = \frac{DI}{\varsigma CSA}.$$

If the conductivity of the solution remains constant (the temperature must be constant), the distance between the S electrodes is fixed, and the current source exciting the E electrodes is kept constant, then

$$V = \alpha \frac{1}{CSA},$$

where α is a calibration constant. Thus, the voltage crossing the S electrodes is proportional to the inverse of the CSA. Direct proportionality can be obtained by reciprocation. Data are conditioned and stored on a PC for further analysis.

EXAMPLES OF MUSCLE ANALYSIS

The new analysis consist of *in vivo* (1) phasic and tonic length-tension diagrams; (2) preload-afterload analysis (3) pressure-CSA and tension-radius plots (4) force-velocity and force-power plots.

Basic distention studies

The studies have been done using different step or volume-controlled ramp protocols. An example of CSA and pressure recordings is shown in Figure 2 where a volume-controlled ramp distension was done using an infusion rate of 25 mL/min. The data provide information on the contractile pattern and can be used for computation of elasticity.

Assessment of phasic, tonic and passive length-tension relationship in vivo

Length-tension diagrams can be obtained in vivo in the GI tract using impedance planimetry. Passive curves obtained during administration of butylscopolamine and active curves in terms of both phasic and tonic curves can be generated by analyzing data in accordance with the tracings in Figure 3. For simplicity in the first approach, the circumferential wall tension (T) is calculated according to the law of Laplace for cylindrical structures.

$$T = \Delta P r$$

where T is the circumferential wall tension and r is the bag radius and ΔP is the transmural pressure. The radius is calculated assuming a cylindrical shape of the bag during

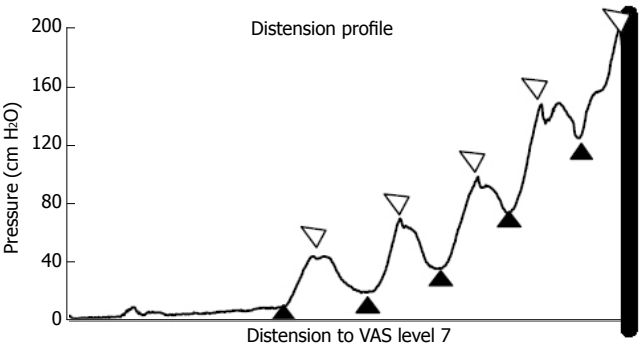

Figure 3 Illustration of a ramp distension curve in the human esophagus. The thick line at the end of the curve is the reverse point. The open symbols above the curve mark the phasic part and the afterload pressure. The closed symbols under the curve mark the tonic part of the distension curve and the preload pressure. The passive pressure is measured from the tonic part of the curve during administration of butylscopolamine. At the symbols pressure and CSA was measured and radius and tension was computed from these values. Modified from previous publications by Gregersen and coworkers.

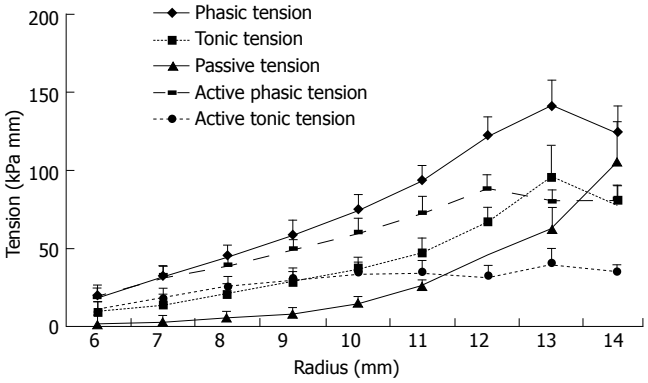

Figure 4 The active and passive tension-radius curves for a subject where the maximum active tension is reached before the moderate pain level (top). The bottom graph shows the averaged data from all volunteers. Mean and SEM values are shown. Modified from previous publications by Gregersen and coworkers.

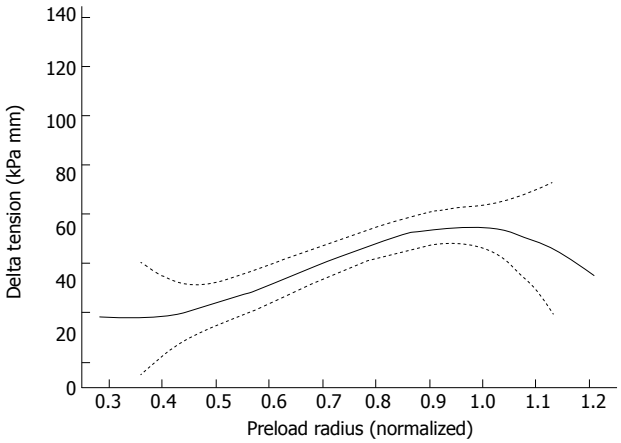

Figure 5 Representation of the change in muscle tension during distension-induced contractions as function of the radius immediately before the contraction (preload-afterload properties) of the esophageal muscles. The solid line is the polynomial fit and the dotted lines represent 95% confidence intervals. Modified from previous publications by Gregersen and coworkers.

distension and by knowing the CSA. The circumferential stretch ratio can be computed as the fractional change in radius (r/r_0) where r is the radius at any distension state and r_0 is the reference radius.

The distentions induce contractile activity. For each contraction, tonic tension (tension computed from pressure and CSA between phasic contractions) and phasic tension (tension during maximum contraction) can be identified from the tension-time curve. Since both active and passive tissue properties contribute to the total tension developed in the small intestine during distension, both the tonic and the phasic tensions must be separated into active and passive components. The passive tension can be derived from the distensions during butylscopolamine infusion and the total tension. Thus, the active tensions can be computed as:

$T_{tonic\text{-}total} = T_{tonic\text{-}active} + T_{passive}$ and $T_{phasic\text{-}total} = T_{phasic\text{-}active} + T_{passive}$

where $T_{\text{tonic-total}}$ $T_{\text{tonic-active}}$, $T_{\text{phasic-total}}$ $T_{\text{phasic-active}}$ and T_{passive} are the total tonic tension, the active tonic tension, the total phasic tension, the active phasic tension, and passive tension, respectively.

The graph in Figure 4 shows averaged data from the normal human esophagus. The passive tension increased exponentially as function of the radius, whereas the tonic and combined phasic-tonic tension increased until a maximum at a radius of 13 mm. This corresponded with the pain threshold. The active tension decreased at higher radii. The major finding was that both active curves exhibited a maximum tension. The active tensions were most important at low distending loads whereas the passive tension was predominant at higher loads. Thus, the esophagus can contribute its largest active force to transport the bolus within the physiological range. The maximum active tension appears close to the pain threshold and before overstretching the esophageal wall. Thus, the esophagus has its physiological function in the ascending leg of the length-tension curve. Exceeding this level it becomes inefficient, like the heart that also functions at the ascending leg of the curve. The maximum active tension is presumably reached at a level of optimum overlap between the sliding filaments in the intestinal muscle cells. When the esophageal wall was stretched to a degree where pain appeared, the passive tension predominated. The passive curves were exponential-like in accordance with findings in other soft tissues. The exponential behavior protects the tissue against overdistension and damage at high luminal pressure loads, while distending easily and facilitating flow in the physiological pressure range.

Preload-afterload diagrams

A way to express the Frank-Starling mechanism in the heart is preload-afterload curve (Figure 1B). In Figure 5 this concept was borrowed from cardiac physiology and it is shown that GI muscle behaves in a similar fashion. The change in tension during individual distension-induced contractions (afterload) was analyzed as function of the radius immediately before the contractions (preload radius). In a similar way the change in radius during distension-induced contractions was plotted as function of the preload radius. These diagrams correspond to heart function curves in terms of the ventricular stroke work as function

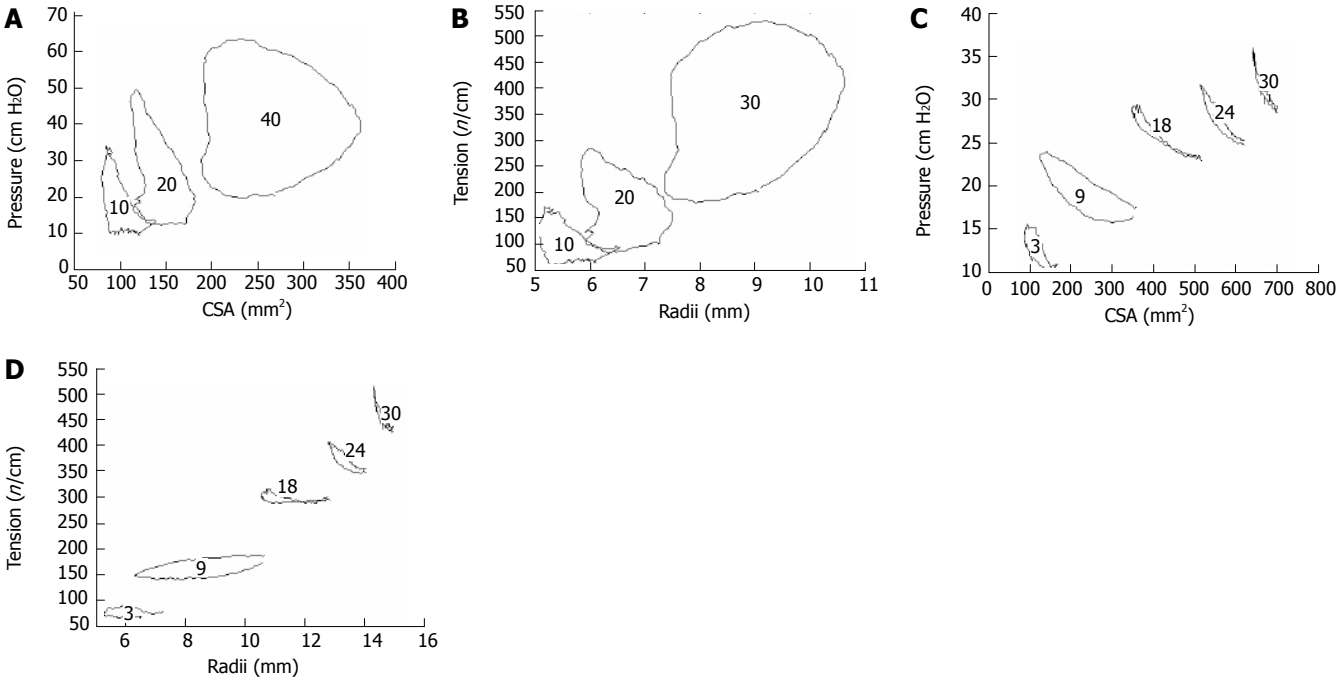

Figure 6 Pressure-CSA and tension-radius relations during esophagus contractions (**A, B**) and during duodenum contractions (**C, D**). The numbers in the figures indicate the volume in ml.

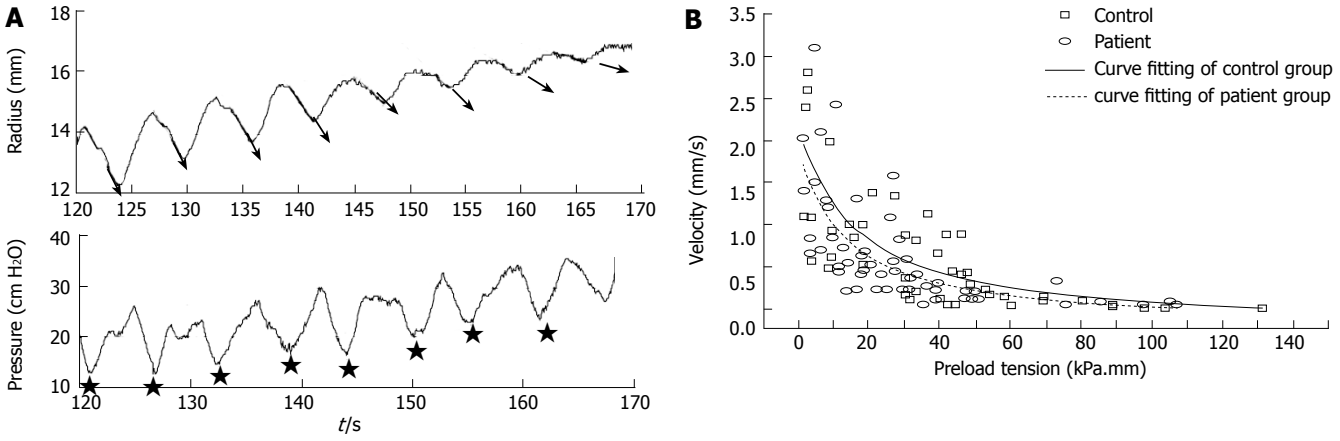

Figure 7 **A:** Arrows indicate that the slope (velocity decreases at high loads. The stars indicate the preload tension; **B:** Force-velocity curves represented as circumferential preload tension-radius shortening velocity and preload tension-circumferential preload tension*CSA rate in SS patients (symbol O and dashed line) and controls (and solid line). The tension-velocity data were curve fitted using Hill's equation. Modified from previous publications by Gregersen and coworkers.

of the mean atrial pressure. Such curves demonstrate the Frank-Starling mechanism of the heart[4,5]. The change in tension during bag-distension-induced contractions increased at normalized radii (radius divided by the radius at the pump reverse point) up to 0.95 (corresponding to radii of 5-12 mm) (Figure 5). This may be called the ascending leg of the curve. At higher radii the change in tension decreased again (the descending leg).

The preload is considered to be the initial muscle length (radius) preceding the contraction during the distension, whereas the afterload is evaluated as the active tension during the contraction. In cardiac physiology the preload is usually considered to be the end-diastolic pressure or radius and the afterload is considered to be the arterial pressure during the systole. The explanation of the Frank-Starling mechanism is that when an extra amount of blood flows into the ventricles, the cardiac muscle itself is stretched to greater length. This causes the muscle to contract with increased force because the actin and myosin filaments are brought to a more nearly optimal degree of interdigitation for force generation. In cardiac physiology the importance of the concept of preload and afterload is that in many abnormal functional states of the heart and circulation, the pressure during filling of the ventricle or the arterial pressure against which the ventricle must contract, or both, are severely altered from the normal. Transferring this concept to GI physiology, the development may have interest for evaluation of normal GI physiology, aging and in the pathophysiology of gastro-esophageal reflux disease, systemic sclerosis, obstruction, achalasia, functional chest

pain, spasms and other esophageal disorders.

P-CSA and tension-radius plots

These curves correspond to the well known pressure-volume curves obtained in the heart (as shown in Figure 1A. The data below was generated from analyzing pressure and CSA data during contractile events at various levels of bag distension in the esophagus and duodenum (Figure 6). It is clearly shown that loops consisting of different "phases" can be determined. However, definition of contraction and relaxation phases seems not as clear cut as in the heart. It is evident that duodenum and esophagus muscle behaves in a very different way. Especially the esophagus curves show a large degree of hysteresis. The area enclosed by the tracing is a measure of the work done during the contraction.

Force-velocity analysis

Figure 1C shows a schematic of the well known force-velocity relationship for muscle tissue and Figure 7 shows data obtained in the GI tract. The tension and shortening velocity were quantified from the contraction waves in the tension-time and radius-time curves simultaneously. For each contraction the preload tension was defined as the tension preceding the contraction. The shortening velocity was defined as the radius shortening rate which is the slope of the radius-time curve for each contraction (arrows in Figure 7A). Since it turned out that the tension-shortening velocity relationship was a hyperbola similar to that described for skeletal muscle, Hill's equation can be used to characterize this relationship[5].

$(T + a)(V + b) = (T\max + a)b$

where T represents tension, V the velocity of shortening, Tmax the maximum tension at which the muscle is first unable to move, a and b are constants with dimensions of force and velocity, respectively. Figure 7A shows the bag radius (derived from the CSA) and the pressure during ramp distension of the duodenum. The slope of the contraction curve (arrows representing the contraction velocity) decrease as a function of the degree of distension. Force-velocity curves expressed as circumferential preload tension-radius shortening velocity diagrams are shown in Figure 7B for the duodenum in controls and systemic sclerosis patients. The velocity of shortening decreased with increasing preload tension. *T*max and the muscle power were lowest in the patients and association was found between the duration of the disease and the maximum stretch ratio. Decreased muscle function may explain the GI symptoms reported in this patient group and should be considered as an important factor in the diagnosis and treatment.

In conclusion, current understanding of the "mechanical" physiology of the GI tract is based on measurement techniques such as manometry. The development of new analysis of bag distention data will contribute significantly to the understanding of digestion in health and disease in the future. The impact of the proposed analysis is to better understand the muscle properties and how they relate to mechanism involved in symptom generation in organic and functional diseases in visceral hollow organs. Examples of frequent diseases of great interest are GERD, non-cardiac chest pain and functional dyspepsia. The perspective is that future treatment of GI disorders with affection of neuromuscular pathways can be mechanism- and evidence based with respect to such function curves.

Abstract

The biomechanical changes during functional loading and unloading of the human gastrointestinal (GI) tract are not fully understood. GI function is usually studied by introducing probes in the GI lumen. Computer modeling offers a promising alternative approach in this regard, with the additional ability to predict regional stresses and strains in inaccessible locations. The tension and stress distributions in the GI tract are related to distensibility (tension-strain relationship) and smooth muscle tone. More knowledge on the tension and stress on the GI tract are needed to improve diagnosis of patients with gastrointestinal disorders. A modeling framework that can be used to integrate the physiological, anatomical and medical knowledge of the GI system has recently been developed. The 3-D anatomical model was constructed from digital images using ultrasonography, computer tomography (CT) or magnetic resonance imaging (MRI). Different mathematical algorithms were developed for surface analysis based on thin-walled structure and the finite element method was applied for the mucosa-folded three layered esophageal model analysis. The tools may be useful for studying the geometry and biomechanical properties of these organs in health and disease. These studies will serve to test the structure-function hypothesis of geometrically complex organs.

INTRODUCTION

Biomechanical changes due to functional loading and unloading of the human gastrointestinal (GI) tract are not fully understood. The GI function is usually studied by introducing probes in the GI lumen, e.g. for pressure recordings. Computer modeling based on medical imaging offers a promising alternative approach in this regard, with the additional ability to predict regional stresses and strains in inaccessible locations. Thus, the three-dimensional (3-D) geometry of visceral organs is of considerable interesting since the morphology and geometry are changed in various diseases[1,2]. The tension and stress distributions in the GI tract are related to distensibility (tension-strain relationship) and smooth muscle tone. The most widely used method for biomechanical stimulation of the gastrointestinal tract is bag distension[3,4]. Distension data are traditionally based on pressure-volume measurements[5-9]. Several studies suggest that the mechanoreceptors located in the gastrointestinal wall are tension receptors[10,11]. Distension technology has been refined by the introduction of the impedance planimetry technique and the endoscopic ultrasound probe[12-23]. These are now well-established methods for assessing circumferential strain, tension, stress and stiffness (slope of stress-strain relation). Previous GI studies have provided data on wall tension and stress in visceral organs. These studies, however, were based on two-dimensional models; i.e., the circumferential tension and stress have been determined at one specified position along the long axis of the organ. However, the tension distribution is related to the geometry (radii of curvature) and the distension pressure according to Laplace's law. Complex geometries will result in heterogeneous tension distributions. Therefore, three-dimensional geometry based on medical images is necessary for computing the tension and stress in the GI tract at various physiological and pathophysiological states.

Recently, 3-D surface model of the gall bladder, stomach, rectum and sigmoid colon have been developed by simultaneous cross-sectional imaging using ultrasonography, computer tomography (CT) or magnetic resonance

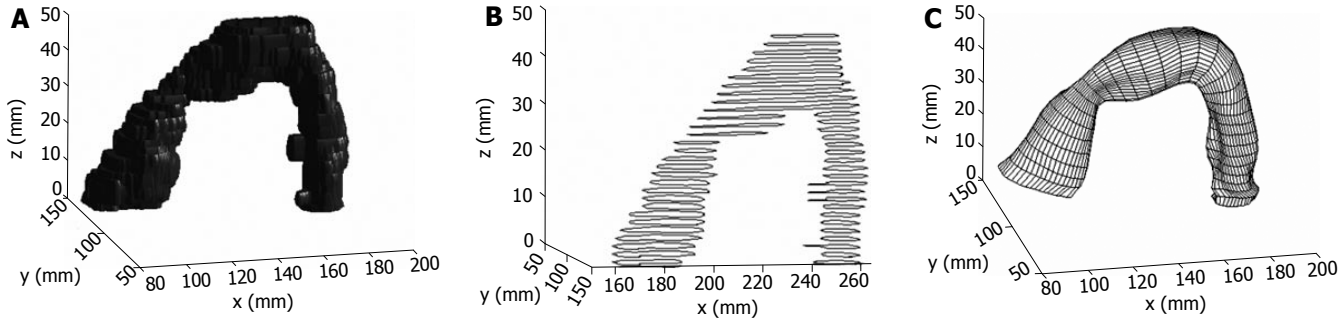

Figure 1 A 3-D sigmoid colon solid model (**A**), the surface model based on the cross sectional images (**B**)and the 3-D surface model with slices along the centre axis (**C**).

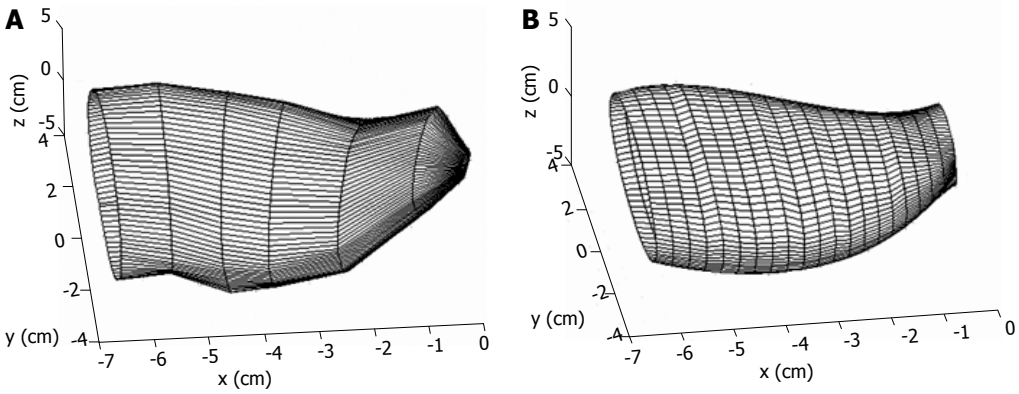

Figure 2 A 3-D reconstructed stomach antrum wall surface before (**A**) and after (**B**) surface smoothing by using the Fourier transform method.

imaging (MRI)) and pressure measurement during distension[24-27]. Using this method it is possible to model the 3-D geometry and mechanical properties of the gastrointestinal tract, including the spatial distribution of the 3-D principal curvatures, radii of curvature, wall thickness, tension and stress.

Examples of 3-D surface models of the GI organs, including stomach, rectum, sigmoid colon and gall bladder and the mucosal folded three layered esophageal finite element model are presented. Two different mathematic algorithms used for surface analysis were introduced. The human stomach[24] and gall bladder[25] models were generated based on the cross sectional images and the surfaces were analyzed theoretically by using a Fourier transform method. The human rectum[26], human sigmoid colon and rat stomach[27] were established from re-sliced images. The surfaces were analyzed locally by using a numerical method.

GEOMETRIC MODELS

Image acquisition and model reconstruction

The anatomical data used for the construction of the initial GI 3D models were obtained from ultrasonography, computed tomography (CT) or magnetic resonance imaging (MRI). The image processing method was used to identify the inner and outer wall boundaries and then a data cloud of a 3-D model was obtained. A 3-D sigmoid colon model built from cross sectional images is illustrated in Figure 1.

For GI organs such as the stomach[24], rectum[26] or sigmoid colon (Figure 1), the centre axis are curved. The distended organs are deformed along the curved axis. Alignment of data points along this curved centre axis was necessary to describe the GI model deformation. Based on a 3-D solid model generated from the cross sectional images, it can be re-sliced along the curved centre axis and the surface model based on the re-sliced images can be obtained. Figure 1 show a sigmoid colon solid model and a surface model generated from the re-sliced images.

Surface smoothing

The reconstructed surfaces have some irregularities due to the discretization of the images. The irregularities were removed using two different smoothing methods in our studies, one method was based on the Fourier transform algorithm and another one is a modified non-shrinking Gaussian smoothing method[28]. The two smoothing algorithms used in the surface analysis are illustrated in Appendix A and B. By using the algorithm described in appendix A, a complex surface can thus be described and smoothed by the surface function of Eq. A3. A smoothed stomach antrum model is illustrated in Figure 2. Figure 3 shows a sigmoid colon model that was smoothed based on the Gaussian smoothing method. With the continuous and smoothed surface, thus the surface can be approximated locally by a biquadric surface patch. The parametric surface used in our studies is a tensor product B-spline surface which gives the necessary continuity properties and with good surface approximation[29].

GEOMETRIC ANALYSIS

Curvature calculation

With the surface function Eq. (A3) or Eq.(B1) at the local co-ordinate system, the principle curvatures of

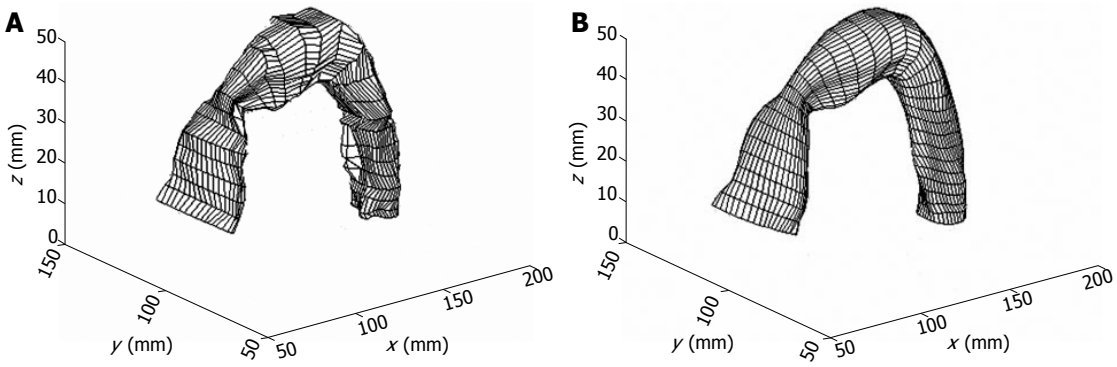

Figure 3 A 3-D sigmoid colon segment surface before (**A**) and after (**B**) surface smoothing by using the non-shrinking Gaussian method.

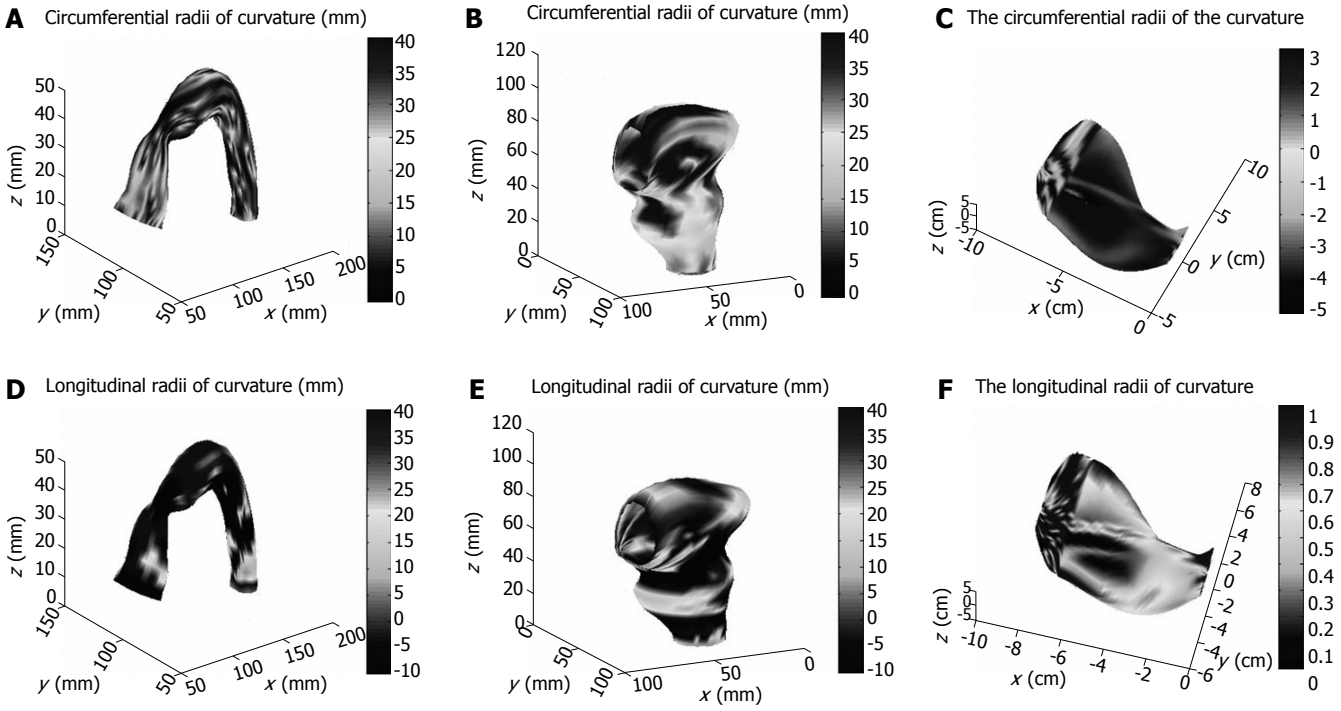

Figure 4 Circumferential (**A, B, C**) and longitudinal (**D, E, F**) radii of curvatures distributions in sigmoid colon (**A, D**), rectum (**B, E**) and human stomach (**C, F**).

the surface were generated from the coefficient of the first fundamental form (E,F and G) and the second fundamental form (L, M and N) of the surface function. The principal curvatures κ_1 and κ_2 can be combined from the *Gaussian* curvature (K_G) and the *Mean* curvature (K_M):

$$K_G = \kappa_1\kappa_2 = \frac{LN - M^2}{G - F^2} \quad (1)$$

$$K_M = \frac{1}{2}(\kappa_1 + \kappa_2) = \frac{1}{2}\frac{NE - 2MF + LG}{EG - F^2} \quad (2)$$

K_G is a particularly useful curvature parameter that indicates an elliptical surface ($K_G > 0$), a parabolic surface ($K_G = 0$) or a hyperbolic surface ($K_G < 0$).

Circumferential and longitudinal curvatures distribution on human sigmoid colon, human rectum and human stomach models are illustrated in Figure 4.

Tension and stress calculation

If we assume that the GI organs are thin-walled and its material properties are isotropic, the surface tension at a surface point is related to the transmural pressure by Laplace's equation as follows:

$$P = T[\kappa_1 + \kappa_2] \quad (3)$$

where κ_1 and κ_2 are the principal surface curvatures at a surface point. This equation is valid as long as the membrane is so thin that bending rigidity can be neglected and the curvature changes are not sudden. Accordingly, only the spatial points with positive Gaussian curvature were used for tension (and stress) calculations in this study. Stress is defined as the force acting on a unit area. The stress distribution on the surface can be calculated from wall tension and normal wall thickness as:

$$\sigma = T/h \quad (4)$$

T is the surface tension and h is the normal wall thickness. An example of tension and stress distribution on the rectum model are illustrated in Figure 5.

FINITE ELEMENT ANALYSIS FOR MUCOSAL FOLDED LAYRED ESOPHAGUS

The major shortcoming of the above surface analysis is the thin wall assumption. Thus only surfaces with positive principal curvatures in both directions could use Laplace's

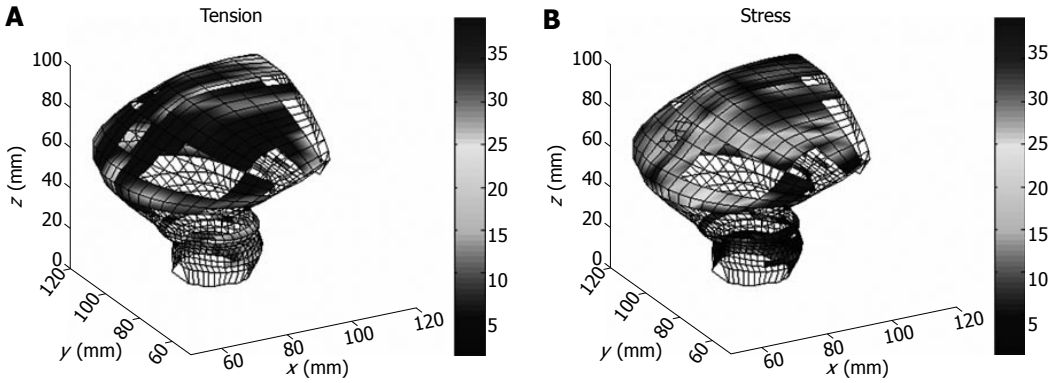

Figure 5 Tension (**A**) and stress (**B**) distribution on a distended rectum model.

equation for tension and stress calculation (Figure 5). To overcome this limitation, numerical methods such as finite element analysis must be adopted. The finite element method has been used for modeling GI tract bioelectric activity[30,31] and the layered esophagus distension simulation[32,33]. Figure 6 is a mucosal folded three layered esophageal finite element model. It is indicated that the stress distribution throughout the esophageal wall was not uniform and the stress was discontinuous between the muscle and mucosal-submucosal layer (Figure 6). Thus the Laplace's law is no longer valid in such layered and thick wall models.

PERSPECTIVES

Mechanosensitive receptors are important for GI tract function and sensation. The intraganglionic laminar nerve ending (IGLE) is believed to be a mechanosensitive receptor and is located within the smooth muscle-lined regions of the GI tract[34,35]. It is generally believed that they are tension receptors. The neurons respond in an intensity-dependent manner to the gastric distension[35,36]. Hence, determination of the stress or tension locally is important for understanding the mechanical environment at receptor sites. Methods based on pressure-volume measurements obtained during bag distension (such as the barostat) do not directly measure variables used in plane stress and strain analysis[5,8,12,22]. Because the bag can elongate, cross-sectional area cannot be derived from bag volume. Moreover, the main assumption for the computation of tension using the barostat and Laplace's law is that the geometry is spherical, although it seems obvious from medical imaging modalities such as ultrasound and magnetic resonance (MR)-scanning of the complex GI organs such as stomach or rectum that the assumption is not valid. Impedance planimetry measures luminal pressure and cross-sectional area in a short segment of hollow viscera during bag distension[14-18,22,37]. Based on these measures the circumferential strain, tension (applying Laplace law) and stiffness (slope of tension-strain relation) of a specific cross-sectional segment can be computed. This approach has limitations in irregular organs like the stomach, rectum or sigmoid colon because the calculated tension is based on the assumption of circularity, is only valid for thin walled structures, and only accounts for circumferential tension.

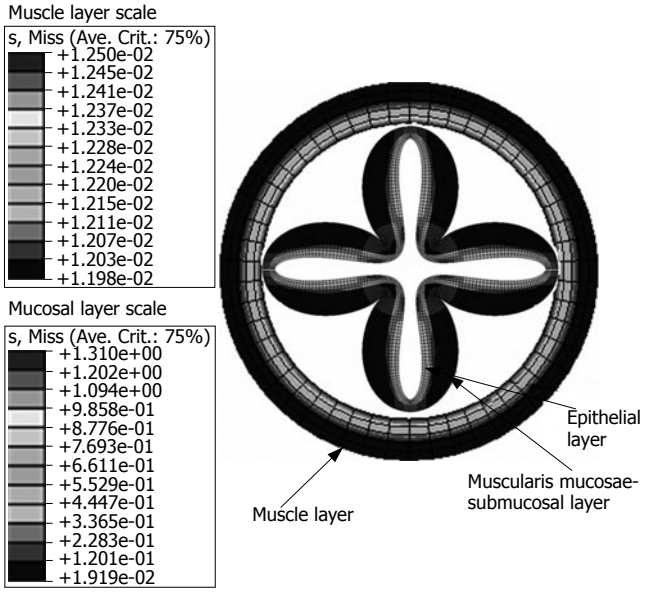

Figure 6 Mises stress (left) distribution in the mucosal folded three-layered esophagus at the bonded state.

In our 3D surface analysis, we generated the organ geometry based on 3-D ultrasound or MR images measurements. It is clear that GI organs such as the stomach, rectum, sigmoid colon and gall bladder have heterogeneous curvature distributions. Consequently, the geometry cannot be assumed spherical or cylindrical and that tension estimations based on Laplace's law are dubious because the geometry of the surface is complex. Two different methods were used for building 3D model and the surface approximation. By using the Fourier transform method the whole surface was reconstructed and smoothed simultaneously, i.e. the surface can be described theoretically and then the curvatures can be computed with good accuracy. However, it is difficult to describe all geometry characters in such complex GI organs by using only one function. Furthermore, the Fourier transform method can only be used on the surface generated from the horizontal cross sectional images. The analysis employed in these surface models produces large errors at both polar ends, especially to models with a curved center axis, such as the stomach, rectum or sigmoid colon. Since 3D solid model can be re-sliced in any direction, a new method for re-generating the 3-D surface

from the solid model was developed. By using the new method, all geometric characters can thus be kept in the surface model.

The major limitation of the surface analysis is the thin wall assumption. Thus only surfaces with positive principal curvatures in both directions could use Laplace's equation for tension and stress calculation. The finite element analysis or the finite difference method should be developed for further GI modeling analysis in the future. 3-D modeling based on cross-sectional imaging (CT, MRI and ultrasonography) has been used to characterize biomechanics and geometry in for instance the stomach[24,27], the rectum[26] cardiovascular system[38], and in computer-aided orthopedic surgery. The present analytical tool can be used to analyze complex structures for understanding biomechanical properties and visceral perception in other hollow visceral organs. The geometry and sensory aspects of diseases in the sigmoid colon (diverticular disease, irritable bowel syndrome, *etc.*), small bowel (motility disorders), stomach (motility disorders, non-ulcer dyspepsia, *etc.*) and esophagus (esophagitis, gastro-esophageal reflux disease, non-cardiac chest pain, *etc.*) can be obtained by applying a modified version of this method.

APPENDIX A

Surface smoothing based on the Fourier transform method

Arbitrary point in a given cross section of the surface can be expressed in a polar co-ordinate system as (r, θ, z), where r, θ and z are the polar radius, angle and section height with respect to the origin. Each point can be fitted using a Fourier series as

Math1

$$r(\theta) = a_0 + \sum_{n=1}^{n=d} a_n \cos(n\theta) + \sum_{n=1}^{n=d} b_n \sin(n\theta) \qquad \text{(A1)}$$

where d denotes the degree of the Fourier series.

To approximate the Fourier coefficient as a function of the section height z, orthogonal polynomial were used as

$$a_i(z) = c_{0i} + c_{0i} z + c_{2i} z^2 + \cdots + c_{pi} z^p \qquad \text{(A2)}$$

where p is the degree of the polynomial and i is the index of the Fourier coefficient. The (r, θ, z) coordinates were described using vector rotation as

$$X(\theta, z) = (r(\theta, z)\cos(\theta), r(\theta, z)\sin(\theta), z) \qquad \text{(A3)}$$

where

Math2

$$r(\theta, z) = \begin{bmatrix} 1 \\ \cos\theta \\ .... \\ \sin d\theta \end{bmatrix}^T \begin{bmatrix} c_{00} & \cdots & c_{p0} \\ c_{01} & \cdots & c_{p1} \\ .... & ... & .... \\ c_{0(2d+1)} & \cdots & c_{p(2d+1)} \end{bmatrix} \begin{bmatrix} 1 \\ z \\ .... \\ z^p \end{bmatrix} \qquad \text{(A4)}$$

Hence, all the information of the surface is contained in the coefficient matrix, i.e., the surface was now transformed from a three-dimensional Cartesian coordinates (x, y, z) to a two-dimensional local tangent plane coordinates system (θ, z), where the θ is the tangent direction corresponding to the circumferential muscle direction and z to the longitudinal muscle direction, respectively.

APPENDIX B

Surface smoothing based on modified non-shrinking Gaussian method

This smoothing algorithm consists of two consecutive Gaussian smoothing steps with a positive scale factor λ applied to all the vertices of the shape, a second Gaussian smoothing step applied to all the vertices but with a negative scale factor μ, greater in magnitude than the first scale factor ($0 < \lambda < -\mu$). To produce a significant smoothing effect, these two steps must be repeated, alternating the positive and negative scale factors, a number of times. The relation between the position of the vertices of the surface before and after N iteration can be expressed as

$$X^N = ((I - \mu K)(I - \lambda K))^N X \qquad \text{(B1)}$$

where N was the number of iterations, λ and μ are two scale factors, I is the $n_V \times n_V$ identity matrix, $K = I - W$, W is the weight matrix and n_V is the number of the neighborhood of a vertex. In fact this method produces a low pass filter effect. The two scale factors determine the pass band and the stop band.

Abstract

Hepatitis B virus (HBV) infection is a global public health problem. Of the approximately 2 billion people who have been infected worldwide, more than 400 million are chronic carriers of HBV. Considerable numbers of chronic HBV carriers suffer from progressive liver diseases. In addition, all HBV carriers are permanent source of this virus. There is no curative therapy for chronic HBV carriers. Antiviral drugs are recommended for about 10% patients, however, these drugs are costly, have limited efficacy, and possess considerable side effects.

Recent studies have shown that immune responses of the host to the HBV are critically involved at every stage of chronic HBV infection: (1) These influence acquisition of chronic HBV carrier state, (2) They are important in the context of liver damages, (3) Recovery from chronic HBV-related liver diseases is dependent on nature and extent of HBV-specific immune responses. However, induction of adequate levels of HBV-specific immune responses in chronic HBV carriers is difficult. During the last one decade, hepatitis B vaccine has been administered to chronic HBV carriers as a therapeutic approach (vaccine therapy). The present regimen of vaccine therapy is safe and cheap, but not so effective. A dendritic cell-based therapeutic vaccine has recently been developed for treating chronic HBV infection. In this review, we will discuss about the concept, scientific logics, strategies and techniques of development of HBV-specific immune therapies including vaccine therapy and dendritic cell-based vaccine therapy for treating chronic HBV infection.

INTRODUCTION

Hepatitis B Virus (HBV) is a hepatotropic, noncytopathic, DNA virus which can cause acute as well as chronic infection. Chronic HBV infection remains a significant public health problem world-wide. It is estimated that there are at least 400 million HBV carriers in the world and that up to one million die annually due to HBV-associated liver diseases. Although the majority of the chronic HBV carriers may remain in an inactive phase associated with low viral replication and histological remission, a significant proportion will develop chronic hepatitis B (CHB), which is characterized by the presence of high viral replication, and chronic necroinflammation of the liver. Patients with CHB develop serious complications like liver cirrhosis (LC) and hepatocellular carcinoma (HCC). Indeed, all chronic HBV carriers are at higher risk for HCC when compared with general population; the risk becomes much higher when LC develops. In addition, all chronic HBV carriers (inactive HBV carrier, patients with CHB [both treated and untreated], patients with LC and HCC) are permanent and living sources of HBV. Presence of million of chronic HBV carrier is practically responsible for the incidence of acute and fulminant hepatitis due to HBV[1].

No specific treatment is provided to 90% of chronic HBV carrier ('do nothing strategy'). Antiviral drugs are recommended only for patients with high HBV replication and necroinflammatory liver diseases. These drugs include type-1 interferons (IFN) and nucleosides analogues such as lamivudine and adefovir. It is difficult to assess the real therapeutic impact of antiviral drugs in chronic HBV carriers. On one hand, these drugs are recommended in some selected patients with CHB. On the other hand, the response varies considerably depending on virological and immunological statuses of the patients. Finally, many terms such as complete responder, biological responder, virological responder, transient responder, and sustained responder are used to assess responses to antiviral drugs. In general, antiviral drugs exhibit some beneficial effects in about 20%-30% of treated patients. However, IFNs

are costly and a significant proportion of patients with CHB are not eligible for treatment due to various reasons. On the other hand, lamivudine may need life-long usage. Treatment with lamivudine gives rise to emergence of mutant HBV and breakthrough hepatitis in considerable numbers of patients with CHB[2,3]. These problems related to currently available anti-viral therapies necessitate the development of alternative therapeutic approaches for chronic HBV carriers.

HBV is a non cytopathic virus and the immune responses of the hosts to HBV are important in different aspects of HBV infection. Although the cellular and molecular mechanisms underlying host/HBV interactions are not completely understood, various evidences suggest that host immune responses may have dual role in chronic HBV carriers. In one hand, liver damages in chronic HBV carriers are initiated and maintained by host immune responses. On the other hand, recovery from chronic HBV carrier state is dependent on the intensity and nature of host immune responses[4,5]. Accordingly, induction or suppression of generalized or polyclonal immune responses in HBV carriers is not likely to have therapeutic potentials. In line of this, it has been shown that although chronic HBV carriers exhibit impaired T helper 1 (Th1) responses, Th1-inducing cytokines (interleukin (IL)-12 and IFN-gamma) possess no notable therapeutic effects in these patients[6].

Only recently, some investigators have shown functional differences of HBV-specific immune responses and non HBV-specific immune responses in chronic HBV infection. It appears that products of non HBV-specific immune responses are responsible for liver damages. On the other hand, HBV-specific immune responses possess antiviral potentials without inducing liver damage in chronic HBV carriers[7,8].

Although this indicates that induction of HBV-specific immune responses in chronic HBV carriers may have therapeutic effect, it is extremely difficult to achieve this *in vivo*. Indeed, this is a confusing task. All chronic HBV carriers harbor HBV DNA and all HBV-related antigens. However, they do not exhibit adequate levels of HBV-specific immune responses. Initially, it has been assumed that chronic HBV carriers may be tolerant to some HBV-related antigens such as hepatitis B surface antigen (HBsAg). However, recent studies have revealed that HBsAg-specific immune responses are present in chronic HBV carriers, although the magnitude of immune responses may not adequate to clear or suppress the virus in chronic HBV carriers[9,10]

ROLE OF IMMUNE RESPONSES DURING ACQUISITION AND PROGRESSION OF CHRONIC HBV INFECTION AND ALSO DURING RECOVERY

Two billion people of the world exhibit either present or past infection with HBV and about 400 million of them are chronically infected with HBV. This indicates that less than 20% HBV-infected persons become chronic HBV carriers. It is natural to ask why some persons become chronic HBV carriers, whereas, others control the virus after an acute infection. Again, it is not clear why some chronic HBV carriers do not show any evidence of liver diseases, whereas, others suffer from progressive liver diseases like CH, LC and HCC. Finally, it is elusive why some chronic HBV carriers recover spontaneously. Although the exact cellular and molecular mechanisms underlying these are not completely clear, experimental evidences indicate that viral factor alone do not influence the courses of HBV diseases. Acquisition of HBV carrier state, degrees of liver damages in chronic HBV carriers and recovery from HBV carrier state are not dependent on any particular viral factor such as the amounts of the HBV, genotypes of the HBV, mutations at certain region of the HBV or expression of certain proteins of the HBV[1,2]. Recent investigations have revealed that immune responses of the hosts to HBV may be important in this context (Table 1). Vertical transmission of HBV from HBV-infected mothers (especially hepatitis B e antigen-positive) to neonates usually results in chronic HBV carrier state. This may be related to the concept of 'Neonatal Tolerance' as described by Burnett *et al*[11]. On the other hand, this may be due to impaired functional capacities of neonatal antigen-presenting cells[12].

Table 1 Role of immune responses in chronic HBV carrier

	HBV carriers	Possible causes
A: Acquisition of chronic State	A: Neonates of HBV-carrier mothers B: Immune suppressed Individuals	Inability to induce HBV-specific immunity
B: Induction and Progression of Hepatitis	Chronic hepatitis B	Accumulation of non-specific lymphocytes

	B: Acute hepatitis C: By antiviral drugs	HBV-related immune responses B: Antiviral therapy effective in immune modulatory phase

Some chronic HBV carriers never show any feature of liver diseases during their life time, although they harbor the HBV from their birth day. On the other hand, considerable numbers of chronic HBV carriers exhibit features of necroinflammatory liver diseases. Many of them also suffer from progressive liver diseases such as LC and HCC. HBV is a non-cytopathic virus and it is assumed that HBV-specific HLA-class restricted cytotoxic T lymphocytes (CTLs) act as the principle event determining the intensity of liver damages[13]. However, recent studies indicate that direct destruction of hepatocytes by the CTLs may not the only or principle mechanism of liver damages in patients with CHB. A series of investigations have shown that most of the liver-infiltrating lymphocytes are not HBV-specific. Liver injury could occur as a consequence of large infiltrate of antigen non-specific mononuclear cells. Different types of proinflammatory

cytokines such as IFN-gamma and tumor necrosis factoralpha may be responsible for induction of liver damages because neutralization of these cytokines prevent liver damages in various experimental models of hepatitis[14].

Host immune responses are also important during recovery from chronic HBV carrier state. The HBV-specific immune responses are strong and multispecific in patients with acute hepatitis B who control the virus replication after an acute infection. On the other hand, these are narrowly focused, weak and mono-specific in chronic HBV carriers who are unable to control the virus[13]. This indicates that if proper immune responses against the HBV are initiated after HBV infection, the patients are likely to recover. This is also manifested by the fact that antiviral drugs are mostly effective in immunodulatory phase, but not in immunetolerant phase, of chronic HBV carriers[15].

DEVELOPMENT OF EVIDENCE-BASED IMMUNE THERAPY FOR CHRONIC HBV INFECTION

As described above, immune responses of the hosts to HBV play important roles during acquisition of chronic HBV infection, during progression of liver damages in chronic HBV carriers and also for recovery from chronic HBV carrier state. In this context, it is natural ask what is meant by 'immune response of the host' in chronic HBV infection. This is a very complex issue and this review is not primarily intended to give a detail account of cellular and molecular events related to this. Here, we will focus on HBV-related 'immune responses' those are relevant for developing immune therapy for chronic HBV carriers.

All chronic HBV carriers studied to date, even the immune competent adults who acquire HBV infection, display infrequent, narrowly-focused, and weak HBV-specific immune responses[13]. The purpose of immune therapy in patients with chronic HBV infection is aimed at induction of strong HBV-specific immune responses *in vivo*.

It has been assumed that HBV-specific CTLs are primarily responsible for clearance of HBV-infected hepatocytes in chronic HBV carriers. CTLs are thought to destroy HBV-infected hepatocytes by cytolytic mechanisms. However, the overall concept regarding CTL and their role in destroying virus-infected cells has been changed not only in the context of HBV infection but also in other viral infections. First, CTL is not the only effector cells capable of destroying HBV-infected hepatocytes. Rather, other cells of both innate and adaptive immune system such as HBV-specific CD4 T cells, natural killer cells, macrophages, and neutrophils may also regulate replication of HBV and destruction of hepatocytes[14]. The next, CTLs are not only committed to destroy HBV-infected cells by directly interacting with hepatocytes. Rather, one of the major functions of CTL is to produce various types of cytokines. Series of experiments by different investigators have sown that cytokines are able to induce destruction of HBV or reduced replication of HBV by a non cytopathic mechanism[5,14,16].

Moreover, both HBV-specific and non HBV-specific immune responses are seen in patients with CHB. Several investigators have shown that HBV-specific immune responses are needed for control of HBV replication. On the other hand, non HBV-specific immune responses may induce destruction of hepatocytes. Patients with CHB express high levels of proinflammatory cytokines and accumulation of mononuclear cells in the liver. Recently, it has been shown that most of these mononuclear cells are non HBV-specific[17,18].

Taken together, these features indicate that induction of immune responses is not the main target of immune therapy for chronic HBV carriers. Rather, induction and maintenance of HBV-specific immune responses may have therapeutic implications. The challenging issue is to accomplish this in patients with chronic HBV infection.

VACCINE THERAPY: INDUCTION OF HBV-SPECIFIC IMMUNE RESPONSES

As an approach to induce HBV-specific immune responses in chronic HBV carriers, vaccines containing HBsAg and/or other HBV-related antigens have been administered in patients with CHB. Dienstag *et al* have used hepatitis B vaccine in patients with CHB in early 1980s, however, that study has not been regarded as vaccine therapy because the purpose of that investigation was to evaluate induction of anti-HBs in chronic HBV carriers[19]. The first clinical trial of vaccine therapy was done by Pol *et al* in 1994[20]. Subsequently, clinical trials of vaccine therapy have been performed during last one decade (Table 2)[21-27]. Most of these studies were pilot studies. The present regimen of vaccine therapy has been well tolerated in patients with CHB. It has caused reduced HBV replication, seroconversion to anti-HBe and normalization of serum transaminases in some patients with CHB. However, there is no standard protocol of vaccine therapy. Vaccine therapy has mainly been conducted as pilot studies. All investigators have used their own protocol to perform vaccine therapy. Variable doses of HBsAg (10-20 micrograms) have been used. In some clinical trials, only HBsAg-containing vaccines were used, whereas, in others vaccines containing HBsAg plus preS1 and preS2 proteins were used. The numbers of immunization also varied among studies (3-12 times). Most importantly, there are no standard criteria to assess the response of vaccine therapy.

CAN VACCINE THERAPY STAND THE TASTE OF TIME?

The present regimen of vaccine therapy is unlikely to be an independent therapeutic approach for patients with CHB. A lot of works must be done regarding vaccine therapy. There should be randomized controlled trials of vaccine therapy in different countries. More studies are needed regarding optimum doses of vaccine, compositions of vaccine and numbers of immunization. This therapy is safe for human usage. No side effects of this therapy have yet been published. Vaccines are commercially available and comparatively cheaper. At present, therapeutic efficacy of vaccine therapy is not so satisfactory. But, that is not so important if we consider its future potentials. The concept

of vaccine therapy is unique. Treatment of chronic infection by inducing antigen-specific immune responses deserves attention. There are ample opportunities to improve the present regimen of vaccine therapy.

At present, it appears that the present regimen of vaccine therapy can be used in some specific patients with CHB such as in patients with anti-HBe positive CHB and patients with low levels of HBV replication. The next, vaccine therapy can be used in combination with other antiviral agents. Vaccine therapy can be started after using antiviral drugs for some times in patients with CHB. This may allow better action of this therapy due to decrease of HBV load by antiviral drugs. Again, vaccine therapy can be used first and then antiviral agents can be applied after induction of host immune responses by vaccine therapy. This may be manifested in better therapeutic potential of antiviral agents in CHB patients. We have recently reported a combination therapy of lamivudine and vaccine therapy in patients with CHB. All patients receiving combination therapy became negative for HBV DNA in the sera, whereas, only 56% patients with lamivudine monotherapy lost HBV DNA in the sera within 12 mo. Also, patients with combination therapy did not develop HBV DNA mutation or breakthrough hepatitis[28].

Table 2 Vaccine therapy in patients with chronic hepatitis B. The criteria of response to this therapy have been determined by individual investigators

Protocol	Response	Reference
HBsAg/pre S2, 3 times	Responders: 12 of 32 (38%)	Pol *et al*[20]
HBsAg/anti-HBs vaccine; 3 times	Responders: 9 of 15 (60%)	Wen *et al*[21]
PreS2/S, 3 times (controlled trial)	Responders: 18.8%	Pol *et al*[22]
HBsAg; 12 times	Responders (1 yr: 55%, 2 yr: 77%)	Horiike *et al*[23]
PreS2 vaccine; 3 times	Responders: 60%	Senturk *et al*[24]
S/pre S2; 6 times	Decreased HBV DNA	Ren *et al*[25]
HBsAg/preS2; 3 times	Immune tolerant phage: no significant change	Dikici *et al*[26]
PreS2; 3 times	anti-HBs; 3 of 31 cases	Yalcin *et al*[27]
Combination of lamivudine and HB vaccine	HBV DNA negativation in all 15 cases at 1 yr	Horiike *et al*[28]

DEVELOPMENT OF NEXT GENERATION VACCINE FOR TREATMENT OF CHRONIC HBV INFECTION

Vaccine therapy in patients with CHB was started without adequate discussions regarding its scientific validity and utility. Vaccine therapy was done without paying full attention to common consensuses of immunology and virology. It was surprising to most clinicians why administration of vaccine containing HBsAg in CHB patients will have therapeutic effect because all CHB patients have abundant amounts of HBsAg in the sera and the liver. Moreover, it has been assumed that HBsAg is a tolerogenic antigen in CHB patients. Also the mechanism of action of vaccine therapy in patients with CHB has not been properly analyzed. In general, new therapeutic approaches are usually tested in animal models of human diseases and then these are applied in patients. Vaccine therapy is an exceptional type of therapy. It was first done in patients with CHB without performing preclinical trials in animal models of chronic HBV infection.

In fact, there has been no good animal model of chronic HBV infection. Natural infection of the HBV is limited to some animals only. Lack of an animal model was a major limitation to study immune pathogenesis of chronic HBV infection. During 1980s, HBV transgenic mice (HBV-TM) were produced by microinjecting HBV genome into fertilized eggs of mice[29]. Naturally, there are many differences between HBV-TM and patients with CHB, but HBV-TM represent a suitable immunological animal model of HBV infection. We and others used HBV-TM to develop insights about HBV immunopathogenesis to study various cellular events those can not be investigated directly in human[29,30].

We used a line of HBV-TM that expressed HBsAg and HBV DNA in the sera. This HBV-TM also expressed HBV-related mRNAs in the liver[31]. HBV-TM did not express antibody to HBsAg (anti-HBs) and HBsAg-specific lymphocytes were not detected in HBV-TM. We showed that HBV-TM were unresponsiveness to HBsAg due to impaired function of antigen-presenting dendritic cells (DCs)[32]. Moreover, the immune response defects of HBV-TM were over come by activating endogenous DCs of HBV-TM[33,34]. Next, four controlled trials of vaccine therapy were conducted in HBV-TM. HBV-TM were immunized with vaccine containing HBsAg once in a month for 12 times. It was possible to induce both HBsAg-specific humoral and cellular immune responses in HBV-TM by administration of vaccine containing HBsAg[35-38]. Study on the mechanism of action of vaccine therapy revealed that vaccine therapy induced HBsAg-specific immune responses by activating autologous DCs[37]. Also, the functions of DCs prior to start of therapy had prognostic value during vaccine therapy[38].

DEVELOPMENT OF HBSAG-PULSED DC

DCs are essential for induction and maintenance of antigen-specific specific immune responses. DCs recognize antigens at the site of their localization. They internalize antigens and process them at their endosomal compartments. This leads to expression of antigenic peptides at the surface of DCs. These DCs migrate to lymphoid tissues and activate lymphocytes to become either CTL or CD4+ T cells or antibody-producing B cells[39,40].

During vaccine therapy in HBV-TM, vaccine containing HBsAg was administered to HBV carriers to induce HBsAg-specific immune responses. This was done with the assumption that DCs of HBV-TM will recognize injected HBsAg. Subsequently, HBsAg would be captured, internalized, and processed by DCs of HBV-TM. It was assumed that DCs would activate lymphocytes to induce HBsAg-specific immune responses (Figure 1). But, DCs of HBV-TM had impaired functional capacities and thus endogenous DCs of HBV-TM are not potent inducer of HBsAg-specific immune responses.

We postulated that a powerful regimen of vaccine therapy can be developed by loading DCs with HBsAg in vitro (HBsAg-pulsed DCs). If HBsAg-pulsed DCs exhibit markers of activation and maturation, HBsAg-pulsed DCs will be able to directly induce HBsAg-specific immune responses without any influence of endogenous DCs of chronic HBV carriers. Accordingly, we cultured murine spleen DCs and HBsAg together to produce HBsAg-pulsed DCs. HBsAg-pulsed DCs were more immunogenic than unpulsed DCs. Only two injections of HBsAg-pulsed DCs caused negativity of HBsAg from HBV-TM (Figure 2). HBV-TM injected with HBsAg-pulsed DCs also developed anti-HBs in the sera[41]. Administration of HBsAg-pulsed DCs also induced anti-HBs in immunosuppressed HBV-TM [42, 43].

TRANSLATION OF IMMUNOLOGICAL KNOWLEDGE FROM THE BENCHES TO PATIENT'S BEDSIDES

Wang *et al*. have first reported about functional impairment of DCs in patients with CHB[44]. Subsequently, we localized HBV DNA and HBV RNA in human blood DCs and also showed low IL-12 production capacity of DCs from CHB patients[45]. Similar data regarding functional defects of DCs of chronic HBV carriers have been reported by other investigators during the last 3 year[46,47]. These studies provided the scientific basis for developing DC-based therapy for patients with CHB.

We followed a very careful protocol to produce HBsAg-pulsed blood DCs for human usage[48]. DCs were enriched from human peripheral blood and cultured with HBsAg to prepare HBsAg-pulsed DCs. We used commercial vaccine as a source of HBsAg. The functional capacities of HBsAg-pulsed DCs were assessed *in vitro*. Next, HBsAg-pulsed DCs were administered to human volunteers. There was no features of inflammation, abnormal liver and kidney functions in any volunteers. No volunteer showed any features of autoantibody or autoimmune diseases. Administration of HBsAg-pulsed DCs induced anti-HBs antibody in all volunteers, although the levels of antibody varied among volunteers.

Then, a study was conducted to assess the safety of HBsAg-pulsed DCs in patients with CHB. We prepared DCs from peripheral blood of patients with CHB. Human blood DCs were cultured with HBsAg in commercial vaccine to prepare HBsAg-pulsed DCs. HBsAg-pulsed DCs were administered to patients with CHB. No adverse effects were detected in these patients. Recently, a group of researcher from China has used HBsAg-pulsed DCs for treating patients with CHB[49]. The data of their study is highly encouraging because HBsAg-pulsed DCs exhibited both antiviral and immune modulatory capacities in some patients with CHB. Moreover, they have reported that patients of CHB with normal transaminase levels may also be benefited from this therapy. Although the data of this study is highly stimulating, more information is necessary about the source of HBsAg and characterization of HBsAg-pulsed DCs. Also, detailed data about study protocol will allow undertaking more clinical trials of these therapeutic approaches.

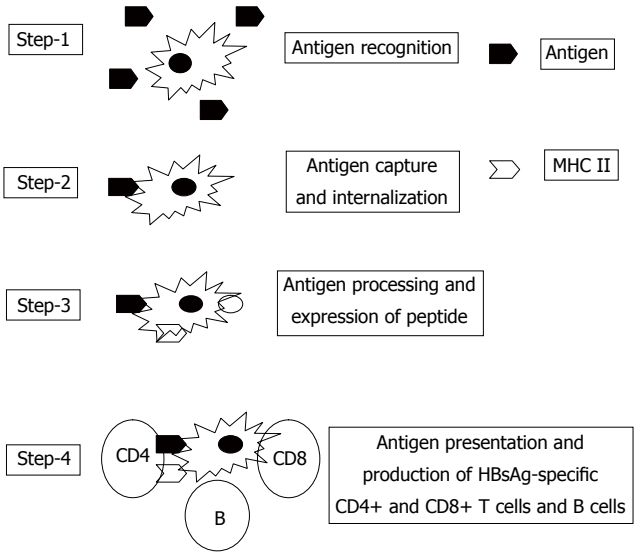

Figure 1 DC/antigen interactions have been shown in 4 steps. Three of these steps are accomplished *in vitro* (step 1-3) when HBsAg-pulsed DCs are prepared.

PRESENT AND FUTURE OF IMMUNE THERAPY AGAINST CHRONIC HBV INFECTION WITH AN EMPHASIS OF IT'S UTILITY IN DEVELOPING NATIONS

The life cycle of HBV, presence of cccDNA of HBV at hepatocytes, and existence of HBV at different extrahepatic sites are major obstacles for eliminating this virus from chronic HBV carriers. It is now apparent that complete eradication of the HBV from chronic HBV carriers may be an unachievable goal[2].

It is also evident that there should be different strategies of HBV control program in developed and developing nations of the world. Less than 10% of total HBV carriers live in developed countries. Moreover, both vertical and horizontal transmissions of HBV have effectively been controlled in most of these countries.

On the other hand, the health care delivery system and economic conditions of developing nations are completely different from those of developed nations, where more than 90% chronic HBV carriers reside. The public health measures are not well developed in most developing nations. Contaminated needles and syringes are used in many facilities, especially in rural areas. There are many chronic HBV carriers among professional blood donors. The numbers of drug abusers are increasing in many of these courtiers. Thus, the numbers of HBV carriers will remain unchanged or increase in most developing nations. China alone harbors about 130 million HBV carriers. Also, there are several million HBV carriers in India.

Regarding treatment, the medical infrastructures of most developed nations allow usage of costly antiviral drugs, regular follow up of treated patients, proper handling of complications and adequate approaches to fight against the mutant HBV. Newer nucleoside analogues are coming to the market. In future, combination therapy with different nucleoside analogues will mainly be used

in patients with CHB in most developed countries. In developed countries, national liver and gastroenterology associations update therapeutic regimens for chronic HBV infection from time to time.

However, usage of antiviral drugs in patients with chronic HBV infection and proper follow up of these patients are difficult in developing nations. IFNs can be afforded by a very small percentage of patients with CHB in these countries. Most of them are not aware of limitation of antiviral drugs in chronic HBV infection. It is generally told that antiviral drugs are effective in about 30% patients with CHB. However, antiviral drugs are recommended for only 10% patients with chronic HBV infection. These drugs are not recommended for majority of chronic HBV carriers. In most developing nations, there is no appropriate system to follow emergence of mutant HBV following lamivudine therapy.

Vaccine therapy in patients with CHB was first conducted in 1994. However, few randomized controlled trials of vaccine therapy have been conducted till now. This situation is different regarding clinical trials of antiviral drugs in developed countries. Antiviral drugs are developed by multinational companies. In contrary, vaccine therapy for chronic HBV carriers has been developed by scientists. This is a cheap therapeutic option for patients with CHB. It is also safe. Vaccine therapy may be popularized if data of controlled trials show their real potentialities. There should be randomized controlled trials of vaccine therapy in patients with CHB in developing countries.

One of the main purposes of immune therapy is to achieve what antiviral drugs could not accomplish in most chronic HBV carriers. The potentiality of vaccine therapy for treating chronic HBV carriers lies in its concept, not in its present ways of application. Truly speaking, this therapy is still in its infancy. Several clinical and experimental studies should be done to optimize protocols of vaccine therapy. At present, commercial vaccines contain HBsAg and/or other components of surface antigens such as preS and preS2 antigens are used in vaccine therapy against chronic HBV carriers. Vaccines containing hepatitis B core antigen or polymerase antigen can also be used in future for treating patients with CHB. However, the main problem is to get safe and human consumable forms of these antigens.

Till now, antigen-pulsed DCs have been used almost exclusively in patients with cancers. Although there are ample opportunities of using antigen-pulsed DCs in chronic infection, allergy and autoimmunity, very few investigators have tried to materialize this in nonmalignant patients. However, we have learnt many important lesions from DC-based therapy in patients with cancers. In the context of DC-based therapy, there is a need to get proper antigens. The next is about the method of preparation of immunogenic antigen-pulsed DCs. Culture of DCs and antigens may lead to production of immunogenic as well as tolerogenic DCs. Accordingly, it is needed to check the nature of antigen-pulsed DCs before administration those to patients. Again, safety is a major concern when antigen-pulsed DCs are administered to patients

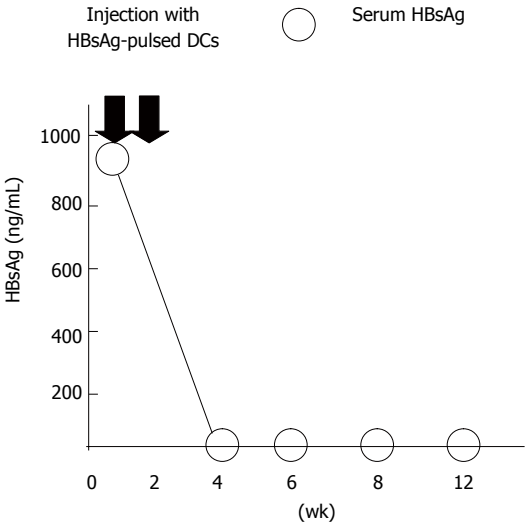

Figure 2 Potent immune modulatory capacity of HBsAg-pulsed DCs in HBV transgenic mice. HBV transgenic mice expressed HBsAg in the sera but not anti-HBs. After two injections of HBsAg-pulsed DCs, these mice became negative for HBsAg in the sera.

with chronic HBV infection. In contrast to patients with cancers, patients with chronic HBV infection are immune competent. Administration of antigen-pulsed DCs may induce autoimmunity in these patients.

At present, clinical trials have been conducting with HBsAg-pulsed DCs. In future, hepatitis B core antigen-pulsed DCs may be used in patients with CHB. The major limitation is to get human grade HBV-related antigens. We used commercial vaccine containing HBsAg to pulse DCs with HBsAg. Chen *et al*[49] have used HBsAg-pulsed DCs in patients with CHB, but they have not mention about the source of HBsAg. The availability of GMP standard HBsAg and other HBV-related antigens will contribute significantly for conducting more clinical trials with antigen-pulsed DCs in patients with CHB. A major challenge will be to achieve GMP standard in developing nations for conducting cell-based therapies including DC-based therapy. This issue can be solved by establishing scientific collaboration among developing countries, developed countries and international agency like World Health Organization.

Abstract

Non-steroidal anti-inflammatory drugs (NSAIDs) including cyclooxygenase 2 (COX-2) selective inhibitors, are potential agents for the chemoprevention of gastric cancer. Epidemiological and experimental studies have shown that NSAID use is associated with a reduced risk of gastric cancer although many questions remain unanswered such as the optimal dose and duration of treatment. The possible mechanisms for the suppressor effect of NSAIDs on carcinogenesis are the ability to induce apoptosis in epithelial cells and regulation of angiogenesis. Both COX-dependent and COX-independent pathways have a role in the biological activity of NSAIDs. Knowledge of how NSAIDs prevent neoplastic growth will greatly aid the design of better chemopreventive drugs and novel treatments for gastric cancer.

INTRODUCTION

Gastric cancer is a major cause of death in the world. However, the etiology of gastric cancer is not fully understood. Although early diagnosis and treatment of gastric cancer significantly improve prognosis[1,2], the 5-year survival rate is only 10%-15% in those with advanced disease[3]. Therefore, the primary prevention of gastric cancer is of particular importance. Several studies have shown that human gastric carcinoma expresses significantly higher levels of cyclooxygenase (COX)-2 than non-cancerous adjacent mucosa[4], suggesting that COX-2 plays a possible role in gastric carcinogenesis. Numerous observations and clinical studies have suggested that the use of NSAIDs is associated with reduced incidence of gastric cancer[5-8]. NSAIDs, particularly the highly selective COX-2 inhibitors, are promising chemopreventive agents[9-12].

Although the effects of NSAIDs on gastric cancer remain unclear, both COX-dependent and independent mechanisms may have roles in the biological activity of NSAIDs. In this review, we concentrate on the use of NSAIDs for gastric cancer prevention and the underlying mechanisms. Furthermore, we also suggest research opportunities on clinical application of NSAIDs for gastric cancer prevention.

NSAIDS AND GASTRIC CANCER

Epidemiological evidence

There are indications, although still limited and preliminary, of a protective effect of NSAIDs on gastric cancers. The risk of gastric cancer is reduced, though not significantly, in the Swedish[13] cohorts of patients with rheumatoid arthritis, with the relative risk (RR) of 0.63 (95%CI = 0.5 to 0.9) for NSAID users. In the American Cancer Society cohort, there is a significant reduction in the risk of death for gastric cancer in aspirin users (RR = 0.64, 95%CI = 0.51 to 0.80). In addition, a dose-dependent trend in risk reduction has been observed, with the RR of 0.73 (95%CI = 0.56 to 0.96) for occasional use (1-15times per month) and 0.49 (95%CI = 0.33 to 0.74) for use 16 or more times per month[5]. With regard to case-control studies, in an American study of cancers of the esophagus and stomach, based on 261 adenocarcinomas of the cardia, 368 noncardia and 695 population controls, current aspirin users have a lower risk for noncardia cancer (RR = 0.46, 95%CI = 0.31 to 0.68), but not for cardia cancer (RR = 0.80, 95%CI = 0.54 to 1.19) when compared to never users. However, there is no significant trend for the risk reduction of gastric cancer with the frequency and the duration of aspirin use[6]. A case-control study from Russia was conducted on 448 gastric cancer cases and 610 hospital controls. The use of aspirin is significantly associated with a risk reduction for the development of gastric cancer (RR = 0.49, 95%CI = 0.31 to 0.77), although the favorable effect seems to be limited for patients with noncardia cancer and *Helicobacter pylori* (*H pylori*) infection[7]. Another case-control study from Sweden, conducted on 567 cases

and 1165 hospital controls, reported that users of aspirin have a moderately reduced risk of gastric cancer compared to never users (RR = 0.7, 95% CI: 0.6 to 1.0), and gastric cancer risk falls with the increasing frequency of aspirin use. Moreover, the risk reduction is statistically significant not only for cardia but also for noncardia cancer, and is slightly more marked in patients with *H pylori* infection[8].

However, there are several limitations for the above observational studies. First, the small number of cases may result in inadequate statistical power[7,8,15]. Second, the choice of control subjects in case-control studies may distort the results because hospital-based controls can not represent population-based controls[16]. Third, different definition of drug exposure and different doses of drugs have been evaluated in these studies. Therefore, the optimal duration and dose of treatment could not be recommended from these studies.

A recent systematic review with meta-analysis of nine observational studies evaluating the association between NSAID use and the risk of gastric cancer suggested that long-term use of aspirin or other NSAIDs is associated with a statistically significant, dose-dependent reduction in the risk of gastric cancer (OR = 0.78, 95%CI = 0.69 to 0.87). When the analysis is stratified by the site of gastric cancer, use of NSAIDs is associated with a statistically significant lower risk for noncardia gastric cancer (OR = 0.72, 95%CI = 0.58 to 0.89), but not for gastric cancer at the cardia. However, whether the minimum effective duration of NSAID use can reduce gastric cancer risk remains undetermined because of the relatively small number of studies, the use of different cut-off time points of treatment duration, and varying definitions of drug exposure[14]. More prospective studies are needed to clarify whether a duration effect exists in the relationship between NSAID use and gastric cancer risk.

Animal models and in vitro studies

The results obtained from animal models evaluating the effect of NSAIDs on gastric cancer have been conflicting. Two studies on animal models of carcinogens suggested that NSAIDs (aspirin and flurbiprofen) could enhance chemical-induced gastric carcinogenesis in rats[17,18], indicating that prostglandins (PGs) produced by the gastric mucosa protect against the action of carcinogens in this rodent model. In contrast, broad anticarcinogenic effects of NSAIDs have been demonstrated both *in vivo* using laboratory animals and *in vitro* using cancer cell lines. Chemically-induced gastric tumors can be reduced by aspirin[19], indomethacin[20], sulindac and ibuprofen[21] in mice. Sawaoka *et al*[22] have investigated the effects of NS-398, a selective COX-2 inhibitor, or indomethacin, a non-selective COX-2 inhibitor, on the growth of gastric cancer xenografts *in vivo*. Both drugs could reduce the tumor volume significantly in a dose-dependent manner. Fu *et al*[23] also found that sulindac and celecoxib obviously decrease the blood vessel quantity and tumor size of SGC7901 cancer xenografts. In a recent study Hu *et al*[24] showed that treatment with celecoxib could suppress MNNG-induced gastric cancer in rats. Indomethacin, sulindac and NS-398 significantly inhibit the proliferation and growth of human gastric cancer cell line MKN28 *in vitro*[25,26].

POSSIBLE MECHANISMS OF CANCER PREVENTION

The results described above provide convincing evidence that non-selective NSAIDs and selective COX-2 inhibitors can inhibit gastric cancer cell formation and growth. However, the molecular basis for the striking chemo-preventive effects has not been fully clarified. Several studies indicate that COX-2 expression is a relatively early event during carcinogenesis in the stomach[27-30]. The best known target of NSAIDs is COX, the rate limiting enzyme in the conversion of arachidonic acid to prostanoids. Thus, the chemo-preventive effects of NSAIDs on gastric cancer may be attributed to inhibition of COX and the resulting decrease in production of PGs[31-33]. However, there are several studies that conflict with this observation. For example, NSAID derivates that lack the ability to inhibit COX (sulindac sulfone) have been shown to inhibit gastrointestinal tumor growth *in vivo* and *in vitro*[34-37]. COX-1 and COX-2 null mouse embryofibroblast cells remain sensitive to the anti-proliferative and anti-neoplastic effects of NSAIDs[38]. Furthermore, the concentration of NSAIDs that inhibits the growth of cancer cells *in vitro* is 10-100 times higher than that required to inhibit COX activity, suggesting the existence of additional cellular targets.

Induction of apoptosis

A substantial body of evidence now supports the idea that the induction of programmed cell death (apoptosis) is one of the main ways by which NSAIDs prevent cancer in a COX-2 dependent manner or a COX-2 independent manner.

COX 2-dependent mechanisms

One of the primary pharmacological properties of the NSAIDs is their ability to inhibit the COX. Analysis of COX expression has shown that COX-2 is increased in gastric cancer, but not in normal mucosa[4,39-42]. These findings support the idea that COX-2 over-expression is important during gastric carcinogenesis. In addition, over-expression of COX-2 can increase production of PGE2, adhesion to the extra-cellular matrix, concentrations of BCL2, and reduce TGF-2 receptor expression and E-cadherin protein. All these changes, which suggest an increased tumorigenic potential, support the notion that COX-2 overexpression alters the biology of cells and plays a part in the transformation process[43,44]. The question of how COX-2 inhibition induces apoptosis has been hotly debated. Several studies have suggested that decreased COX-2 activity can reduce eicosanoids such as the PGs, and in turn affect cell proliferation and apoptosis[45]. So far, there is no definitive evidence that supports the existence of a signaling pathway through which PGs can directly affect apoptosis. However, specific observations provide some clues and warrant mention here. The peroxisome proliferator-activated receptors (PPARs), a family of ligand-activated transcription factors comprising a subset within the steroid receptor family of intracellular receptors, have been shown to modulate the apoptotic response of various cell types[46,47]. It is conceivable that certain COX-2

products may be physiological ligands for the PPARs. Thus, it is hypothesized that PPARs are downstream of COX-2 in gastric carcinogenesis and may play a part in NSAIDs-mediated antineoplastic effects[48-50].

Arachidonic acid may also provide a mechanism underlying COX-2-dependent NSAIDs-induced apoptosis. Arachidonic acid is produced by hydrolysis of phospholipids and triglycerides. The phospholipase A2 cleaves phospholipids and releases arachidonic acid into the cytosol. Once released, it serves as a precursor for PGs production and is a signaling molecule in its own right. Treatment with various NSAIDs results in inhibition of COX-2 and a dramatic increase in the concentration of arachidonic acid, the main substrate for COX-2[45,51]. This buildup of arachidonic acid stimulates the sphingomyelinase to convert sphingomyelin to ceramide, a potent inducer of apoptosis[52-55]. Other studies have shown that the cellular concentration of arachidonic acid is a general mechanism by which apoptosis is regulated[56-59]. It seems that arachidonic acid can alter mitochondrial permeability and cause cytochrome C release, leading to apoptosis[58,60].

COX 2-independent mechanisms

Several recent observations cast doubt on the idea that COX is the sole target of NSAID action. The finding that some NSAIDs can inhibit proliferation and induce cell death in cells that do not express COX, suggests that other targets may play a part in NSAIDs-mediated apoptosis[61].

One potential mechanism involves the transcription factor NF-κB, which promotes cell survival and enhances proliferation. Several investigators have suggested that NSAIDs could promote apoptosis by inhibiting NF-κB signaling pathway[62-64]. The effect that seems to be due to its ability to inhibit the activity of IκB kinase β (IKKβ), an enzyme that activates the NF-κB pathway by phosphorylating the inhibitory subunit of NF-κB (IκB-α) and targeting it for destruction. Subsequently, genes required for cancer cell growth and survival may not be transcribed[65]. Furthermore, Yasui *et al*[66] reported that sulindac inhibits TNF-α-mediated NF-κB activation and greatly sensitizes human gastric cancer cell line MKN45 to TNF-α. The study data strongly suggest that combination therapy of TNF-alpha with sulindac may sensitize tumor cells to TNF-α and augment its proapoptotic potential. Moreover, Wong *et al*[67] showed that SC236, a selective COX-2 inhibitor, could inhibit NF-κB mediated gene transcription and binding activity in gastric cancer. This effect occurs through a mechanism independent of COX activity and PG synthesis. Furthermore, unlike aspirin, SC236 affects neither the phosphorylation, degradation, nor the expression of IκB-α, suggesting that the effects of SC236 are independent of IKK activity and IκB-α gene transcription. Instead, SC236 works directly through suppressing the nuclear translocation of RelA/p65. It is possible that SC236 directly targets proteins that facilitate the nuclear translocation of NF-κB[67].

The role of protein kinase C (PKC) and apoptosis-related oncogenes has also attracted more attention. Zhu *et al*[68] showed that both aspirin and indomethacin induce apoptosis in gastric cancer cells which may be mediated by up-regulation of *c-myc* proto-oncogene. PKC activation can abrogate the effects of NSAIDs by decreasing *c-myc* expression. Jiang *et al*[69] also showed that SC-236 induces apoptosis in AGS cells. SC-236 down-regulates the protein expression and kinase activity of PKC-β(1) in AGS cells, which provides an explanation for COX-independent apoptotic effects of selective COX-2 inhibitors in cultured gastric cancer cells. They also suggested that PKC-β(1) acts as a survival mediator in gastric cancer. Down-regulation of PKC-β(1) by SC-236 may provide new targets for future treatment of gastric cancer[69].

Furthermore, it was reported that the pro-apoptotic proteins Bax and Bak play a role in NSAIDs-induced gastric cancer cell apoptosis[70], suggesting that one of the major pathways mediating the anti-tumor response of aspirin and indomethacin in gastric cancer cells is through the up-regulation of Bax and Bak and activation of caspase-3.

Besides, Wu *et al*[71] demonstrated that SC-236 induces apoptosis in gastric cancer cells via the up-regulation of 15-lipoxygenase-1 (15-LOX-1), and increases endogenous 13-S-hydroxyoctadecadienoic acid (13-S-HODE), a novel target for chemoprevention effect of NSAIDs.

Regulation of angiogenesis

It is now clear that angiogenesis is critical for the progression of most human cancers[72]. Angiogenesis is a complex process controlled by a balance of angiogenic and angiostatic factors involved in multiple pathways that result in endothelial cell proliferation, differentiation, and organization into a functional network of vascular channels. Among the reported angiogenic factors, vascular endothelial growth factor (VEGF) is the most powerful endothelial cell specific mitogen that plays a key role in the complicated process of angiogenesis.

COX-2 has been shown to directly promote angiogenesis in several different experimental systems[73,74]. Masferrer *et al*[80] have examined more than 150 samples of different types of human cancers and found that COX-2 is present in the angiogenic vasculature in most of the tumors analyzed. Therefore, COX-2-derived PGs contribute to tumor growth by inducing newly formed blood vessels that sustain tumor cell viability and growth. Furthermore, xenografts of COX-2 over-expressing gastric cancer, when implanted into nude mice, express angiogenic factors in a COX-2-dependent manner, and both angiogenesis and tumor growth can be inhibited in these mice by administration of NSAIDs[23,78].

COX-2 expression has been shown to correlate with microvessel density (MVD), an accepted histologic marker of tumor angiogenesis in several different human malignancies, including gastric cancer[30]. Recent years, the relationships between COX-2 expression, VEGF expression, tumor angiogenesis, and outcome parameters in gastric cancer patients have been reported[75-77]: COX-2 expression significantly correlates with VEGF, and the colocalization of these proteins is most frequent at the advancing edge of cancer cells[75]. MVD is higher in COX-2 and VEGF positive cases than in COX-2 and VEGF negative cases[76]. Co-expression of COX-2 and VEGF, age, lymph node status, and serosal invasion are

independent prognostic factors for overall survival in gastric cancer patients[77].

Interestingly, COX-1, the other isozyme expressed in tumor vascular endothelia, participates in tumor angiogenesis, because an anti-sense oligonucleotide of COX-1 suppresses *in vitro* angiogenesis induced by COX-2-overexpressing cells. Non-specific COX inhibitors reduce the growth and angiogenesis in cancer xenografts by inhibiting COX-1 in vascular endothelial cells, even when the tumor does not express COX-2. These results demonstrate that COX inhibitors suppress angiogenesis and tumor growth by inhibiting expression of angiogenic factors and vascular endothelial cell migration[79].

COX-2 expression and H pylori infection

H pylori infection is also a strong risk factor for the development of gastric cancer via the pathway of atrophy, intestinal metaplasia and dysplasia in chronic infection. Infection with *H pylori* up-regulates mediators of the inflammatory response, leading to the production of inflammatory cytokines and PGs which themselves may suppress cell-mediated immune responses and promote angiogenesis. These factors may also have effects on cell growth and survival signaling pathways, resulting in induction of cell proliferation and inhibition of apoptosis[81].

H pylori up-regulates COX-2 mRNA expression and PGE_2 synthesis in gastric cancer cells[82], and both pre-malignant and malignant gastric lesions demonstrate high COX-2 expression levels[83]. Therefore, *H pylori*-induced gastric carcinogenesis may be associated with the elevated expression of COX-2 in gastric epithelium. It is possible that NSAIDs may inhibit the replication and proliferation of *H pylori*[84,85], neutralize the increased COX-2 expression and PG synthesis and reverse the increased apoptosis and proliferation of epithelial cells associated with *H pylori* infection[86,89], thereby reducing the risk of gastric cancer[90,91]. Experimental models of cell proliferation have also shown that, in hyperplastic gastritis in the murine model infected with *H pylori*, treatment with etodolac could significantly decrease PGE_2 production and the thickness of gastric pits in the infected groups[87].

Whether eradication of *H pylori* can prevent gastric cancer remains contradictory. COX-2 expression remains in gastric epithelium even after successful eradication of *H pylori*[88]. This may suggest that combined treatment of COX-2 inhibitors and *H pylori* infection may be more useful in eliminating *H pylori*-induced COX-2 expression than either anti-*H pylori* antibiotics or COX-2 inhibitors alone. This issue deserves further study.

CONCLUSIONS AND FUTURE DIRECTIONS

Combining the evidence from humans, animal models and cell culture systems can establish the targeted inhibition of COX-2 was a viable approach to gastric cancer prevention and/or treatment. However, despite these successes, many questions remain unanswered such as the optimal dose and duration of treatment. Selective COX-2 inhibitors, which have an advantage of minimizing the gastrointestinal side-effects, have received wide attention. An exciting area for future investigation is to investigate whether COX-2 inhibitors can be used in the treatment of patients who have preneoplastic gastric lesions or suffer from gastric cancer, and whether combination therapy with COX-2 inhibitors and the drugs targeting other oncogenic pathways can lead to improved clinical outcomes.

Abstract

AIM: To study the antitumor effect of Chinese compound Jinlongshe (JLS) granules on sarcoma 180 and MKN-45 human gastric cancer cell lines *in vivo* and its mechanism.

METHODS: After establishment of S180 sarcoma (S180) and MKN-45 gastric cancer model of nude mice, the tumor-bearing mice were divided into 5 groups at random. Three experimental groups were respectively given the aqueous extract of JLS granules at doses of 120 g, 60 g and 20 g /(kg per 6/wk, *i.g*) for 3 wk in S180 and 6 wk in nude mice model. Positive control was given cyclophosphamide (Cy) at a dose of 50 mg/(kg per 3 /wk, *i.g*) for 3 wk in S180 models and 5- Fluorouracil (5-FU) 20 mg/(kg per 3 /wk, *i.g*) for 3 wk in nude mice model. Negative control was given normal saline (NS) at a dose of 0.18 g/(kg per 6/wk, *i.g*) respectively. After 3 wk in mice bearing S180 tumor and 6 wk in nude mice model, the experimental animals were sacrificed and the masses of tumor were weighed, and the rates of tumor inhibition of each treated group were calculated respectively. To determine the antitumor mechanisms, the morphological changes, cell cycle and apoptosis were observed in MKN-45 nude mice model. Annexin V-FITC/PI double staining FCM assay was used to further determine the live cells, apoptotic cells, necrotic cells and debris.

RESULTS: The inhibitory rates of JLS granules at the doses of 20 g/kg, 60 g/kg and 120 g/kg were 50.31%, 55.94% and 68.13% ($P < 0.01$) in nude mice models and 40.90%, 50.32% and 58.46% ($P < 0.01$) in S180 model. The inhibitory rate of Cy was 85.22% in S180 models and the inhibitory rate of 5-FU was 53.43% in nude mice model ($P < 0.01$). Nuclear chromatin and margination were observed under a transmission electron microscope (TEM). The G0/G1 phase was arrested, typical apoptotic peak appeared, the apoptotic rate was 22.81%-38.54% in three JLS granule-treated groups. Annexin V-FITC/PI double staining FCM assay showed that the apoptotic cells were 4.36%, 3.08%and 7.08% in three dosages, most cells were localized in the low right quadrant.

CONCLUSION: Jinlongshe granules possess anti-tumor effects on experimental tumor models *in vivo*, and apoptosis induction is one of its anti-tumor mechanisms.

INTRODUCTION

Gastric cancer is one of the most leading causes of cancer-related deaths worldwide[1]. Despite its decreasing trend in the Western world during the recent two decades, gastric cancer still accounts for about 23.2% of all cancer deaths in China[2-4]. Although surgery, chemotherapy, and irradiation are the mainstream therapeutic methods for gastric cancer, undesirable chemotherapy reaction and poor prognosis in the advanced gastric cancer patients are still the major problem for gastric cancer treatment[5]. Consequently, combination of multi-therapeutic methods may effectively improve gastric cancer patient's symptoms and prolong their survival time[6-7].

Jinlongshe (JLS) granules are an oral Chinese medicine compound, consisting of Chinese herbs (*Rhizome Arisaemat, Rhizoma Pinelliae, corium stomachium galli, Radix*

Glycyrrhizae preparata, etc.), developed by our department based on TCM theories of "phlegm" as the key factor in preventing and treating gastric cancer[8]. However, the exact antitumor mechanism of JLS granules is unclear. This study was to observe the anti-tumor effect of JLS granules and to determine its mechanism using sarcoma 180 and human gastric cancer cell line MKN-45 *in vivo*.

MATERIALS AND METHODS

Experimental animals

BALB/C nude mice (19-22 g) and Kunming mice (20-22 g) were provided by Experimental Animal Center of Chinese Academy of Sciences, Shanghai, China. All experimental animals were housed in specific-pathogen free (SPF) condition for 1 wk to adapt the surroundings before initiation of the experiment and had free access to food and water throughout the study.

Cancer cell lines

S180 cell line and MKN-45 human gastric denocarcinoma cell line were provided by Institute of Pharmaceutical Research, Shanghai, Chinese Academy of Sciences.

Drug samples and reagents

Crude JLS granules were purchased from Leiyunshang Company, Shanghai, China. An aqueous extract of JLS granules at a concentration of 6 g/mL of raw materials was provided by Shanghai Changzheng Hospital. The aqueous extract was diluted with purified water before use. Cyclophosphamide injection (Cy, Lot No. 040909) was produced in Hualian Pharmaceutical Co., Ltd, Shanghai, China. OB Biogel (Lot No.040514) was produced in Baiyun Medical Biogel Co., Ltd, Guangzhou, China. Ketamine hydrochloride injection (Lot No.02072332) was produced in Hengrui Pharmaceutical Co., Ltd, Jiangsu, China.

Establishment of in situ-transplanted human MKN-45 gastric carcinoma nude mouse model

The procedure of *in situ*-transplanted gastric cancer nude mouse model was referred to Xu and Chen Ling *et al*[9-10]. In brief, before transplantation, nude mice bearing gastric denocarcinoma MKN-45 cell lines were killed. Then the tumor was dissected and put into aseptical saline. Pieces of intact, fish meat-like tumor tissue of 1 mm × 1 mm × 1 mm in diameter from margin were prepared after removal of tumor capsule. Mice anesthetized with ketamine (50 mg/kg, ip) were sterilized with caseoiodine and a transverse incision was made on the left upper quadrant. After exposure of the greater curvature of stomach, serosa and muscular layer were incised with needle. Then tumor tissues were transplanted under serosa of stomach and one drop of OB biogel was applied to the tumor tissue. After 40 s, stomach was brought into abdominal cavity and abdominal wall was finally closed. The whole operation procedure was completed following the doctrine of aseptic manipulation.

Establishment of S180 model

This model was by subcutaneous injection as previously described[11]. Briefly, the S180 mouse sarcoma cells with ascites were harvested, diluted with sterilized saline at a ratio of 1:8 (cell concentration was adjusted to 1.0×10^6/mL), and inoculated subcutaneously into the right armpit region of Kunming mice.

Inhibitory effect of JLS granules on S180 and MKN-45 in vivo

Forty-eight hours after establishment of the MKN-45 gastric cancer model and 24 h after establishment of S180 model, the transplanted mice were divided into 5 groups according to the method described in "National Requirements for *in vivo* Screening of Anti-neoplastic Drugs"[12]. The dose of JLS granules was decided according to the clinical dose used in humans. The mice bearing S180 were killed by dislocation of cervical vertebra 3 wk after treatment. The nude mice bearing *in situ*-transplanted MKN-45 gastric cancer cell line were sacrificed 6 wk after treatment. The tumor weights were measured and the inhibitory rates were calculated according to the following equation: rate of inhibition (%) = (mean tumor wt of negative control -mean wt of treated group)/mean tumor wt of negative control ×100.

Morphologic assessment of apoptosis in MKN-45 nude mice

We selected NS group, 5-FU group and 60 g/kg JLS granules group for morphologic assessment of apoptosis in MKN-45 nude mice. Tumor tissue was cut into small pieces, homogenized into 1 mm × 2 mm, prefixed with 4% paraformaldehyde for 4 h and washed with PBS (0.1 mmol/L), post-fixed with 1% osmic acid, dehydrated in graded ethanol-acetonum, embedded in an Epon 812 mixture, and cut into sections on a ultramicrotome. After stained with uranyl acetate and lead citrate, the sections were examined under a Hitachi-800 transmission electron microscope.

Cell cycle and apoptosis in MKN-45 nude mice

Fresh tumor tissue separated from nude mice was chopped with mechanical method. Single cell-suspended solution was obtained with 200 filter screens. The suspensions were divided into two parts. One part was fixed with 70% ice-cold ethanol for at least 12 h at 4 ℃ and then washed with PBS again before examination. The fixed cells were treated with RNase A and stained with PI at 37 ℃ for 30 min. Analysis was performed with a Coulter FCM (EPICS-XL) and data were analyzed with Multicycle DNA content and cell analysis software.

Annexin V-FITC/PI double staining for FCM-assessed apoptosis

The Annexin V FITC kit (Jingmei Company, Lot No. 20050910) was used for detecting apoptosis according to manufacturer's instructions. The suspensions were washed twice and adjusted to a concentration of 1×10^6 cells/mL with ice cold 4 ℃ PBS. The Falcon tubes (12 mm × 75 mm, polystyrene round-bottom) were used in experiment, 100 μL of suspensions was added to each labeled tube, 10 μL of Annexin V-FITC and 10 μL 20 μg/mL PI were added into the labeled tube, incubated for at least 20 min at room temperature in the dark, then 400 μL of PBS

Table 1 Anti-tumor effect of JLS granules on mice bearing S180

Group	*n*	Tumor weight (g)	Inhibition rate (%)
Control	10	4.67 ± 3.27	-
120 g/kg	10	1.94 ± 2.03[ab]	58.46
60 g/kg	10	2.32 ± 2.83[ab]	50.32
20 g/kg	10	2.76 ± 2.32[ab]	40.90
Cy	10	0.69 ± 0.33[b]	85.22

[a]$P < 0.05$ *vs* Cy; [b]$P < 0.01$ *vs* control.

Table 2 Anti-tumor effect of JLS granules on MKN-45 cells in nude mice

Group	*n*	Tumor weight (g)	Inhibition rate (%)
Control	10	3.20 ± 0.96	-
120 g/kg	10	1.02 ± 0.57[b]	68.13
60 g/kg	10	1.41 ± 1.39[b]	55.94
20 g/kg	10	1.59 ± 1.12[b]	50.31
5-FU	8	1.49 ± 1.37[b]	53.43

[b]$P < 0.01$ *vs* control.

binding buffer was added to each tube without washing and analyzed by FCM as soon as possible (within 1 h).

Statistical analysis

Data were presented as mean ± SD and analyzed with SPSS 11.0 software. The analysis of variance (ANOVA) was used and least significant difference *t* test (LSD-*t*) was used for group comparison. $P < 0.05$ was considered statistically significant.

RESULTS

Anti-tumor effect of JLS granules on S180

JLS granule at the doses of 20 g/kg, 60 g/kg and 120 g/kg significantly inhibited the growth of S180 subcutaneous tumor($P < 0.01$) in a dose-dependent manner, but lower than the inhibitory rates of Cy ($P < 0.05$) (Table 1).

Anti-tumor effect of JLS granules on in situ-transplanted gastric cancer MKN-45 cell lines

JLS granule at the doses of 20 g/kg, 60 g/kg and 120 g/kg significantly inhibited the growth of orthotopic-transplanted MKN-45 gastric cancer($P < 0.01$) in a dose-dependent manner, but no difference statistically compared with 5-FU ($P > 0.05$) (Table 2).

Morphology changes

Condensation of chromatin at margins of nuclei, disintegration of nucleolus, vacuoles in cytoplasm were observed in 60 g/kg group and 5-FU also had the same apoptotic appearance under TEM (Figure 1).

Assessment of cell cycle and apoptosis of MKN-45 cells in nude mice

The percentage of G0/G1 cells in JLS granules group was higher than that in NS group and 5-FU group in a dose-dependent manner ($P > 0.05$). The cell percentage of S phase in of JLS group and 5-FU group was lower than that in control group ($P < 0.05$), the apoptotic rate in 120 g/kg JLS group was higher than that in control group, 20 g/kg JLS group and 5-FU group ($P < 0.05$). The typical apoptotic peak was observed (Table 3, Figure 2).

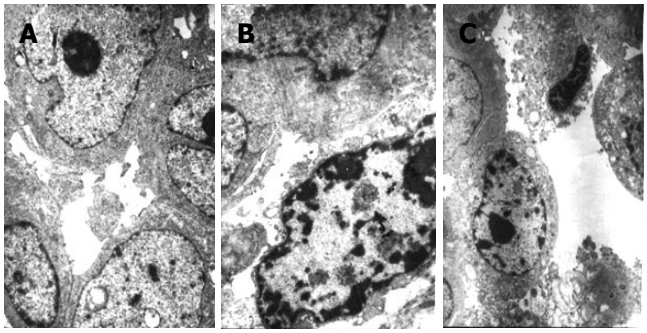

Figure 1 Ultra-structure observed under transmission electron microscopy in control group × 4 000 (**A**), 60 g/kg JLS group × 6 000 (**B**), 5-FU group × 3 000 (**C**).

Table 3 Effect of different treatments on cell cycle and apoptosis of MKN-45 cells (mean ± SD)

Group	*n*	G_0/G_1	G_2/M	S	Apoptotic rate
Control	10	42.40 ± 11.28	21.28 ± 11.43	36.92 ± 12.21	19.88 ± 14.83[c]
120 g/kg	10	50.58 ± 8.78	26.45 ± 12.53	14.56 ± 9.35[a]	38.54 ± 12.65[a]

Assessment of apoptosis in MKN-45 nude mice

Results by Annexin V-FITC/PI double staining for FCM assay showed that the early apoptotic cells were 4.36%, 3.08% and 7.08% in the three JLS granules groups (Figure 3), and most of cell populations in 5-FU treated group were located in the up right quadrant and the cells on the lower right quadrant were not many as compared with JLS granules groups.

DISCUSSION

Tumorigenesis, in a sense, is due to the deregulation in cell proliferation and apoptosis[13-14], accordingly tumor treatment not only inhibits cell proliferation, but also induces apoptosis. More and more attention is paid to apoptosis in treatment of tumors and the effectiveness of anti-tumor agents is often evaluated[15,16]. Investigators have confirmed that many Chinese herbs have antitumor property and induction of apoptosis is one of the mechanisms[17-20]. But most of these studies aimed directly at single herbs, bioactive constituents or leading compounds extracted from herbs, and could not educe the multi-target action of Chinese compounds and traditional Chinese medicine (TCM) theories in disease therapy[21].

In TCM theories, "phlegm" is not only a pathologic metabolite, but also a causative agent. The metabolites such as ectopic hormone, growth factor and tumor

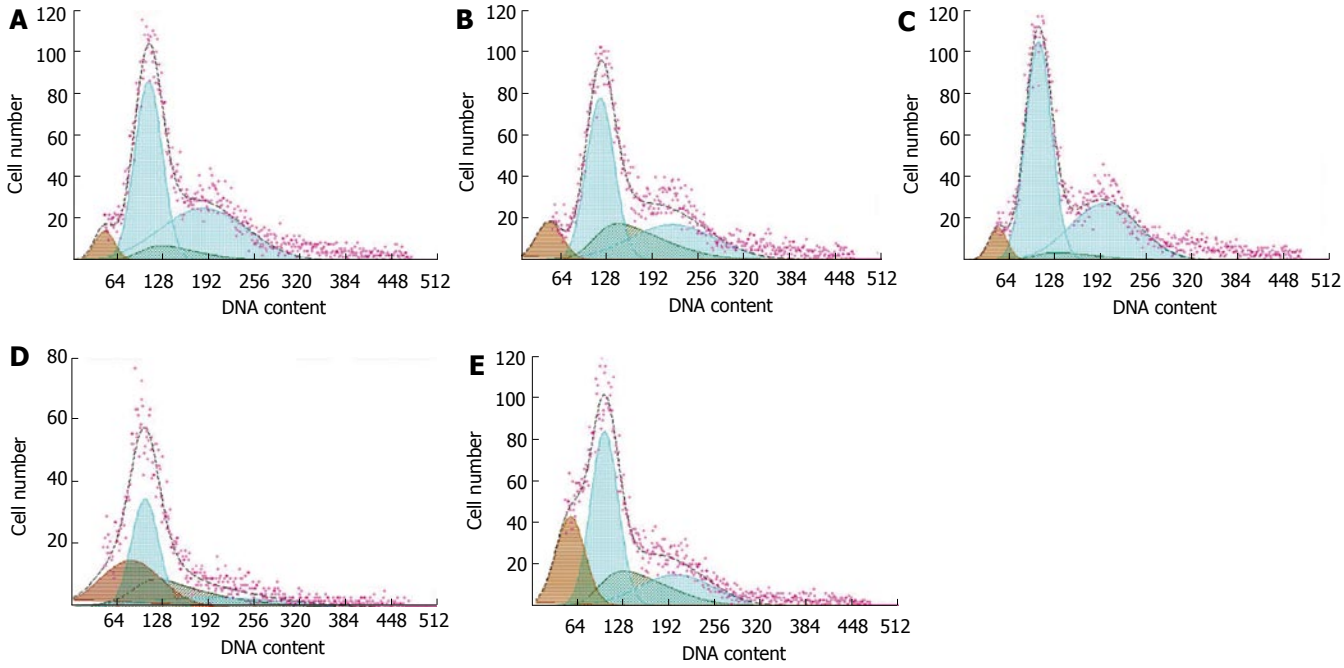

Figure 2 Histogram observed under FCM in 120 g/kg JLS group (**A**), 60 g/kg JLS group (**B**), 20 g/kg JLS group (**C**), control group (**D**), and 5-FU group (**E**).

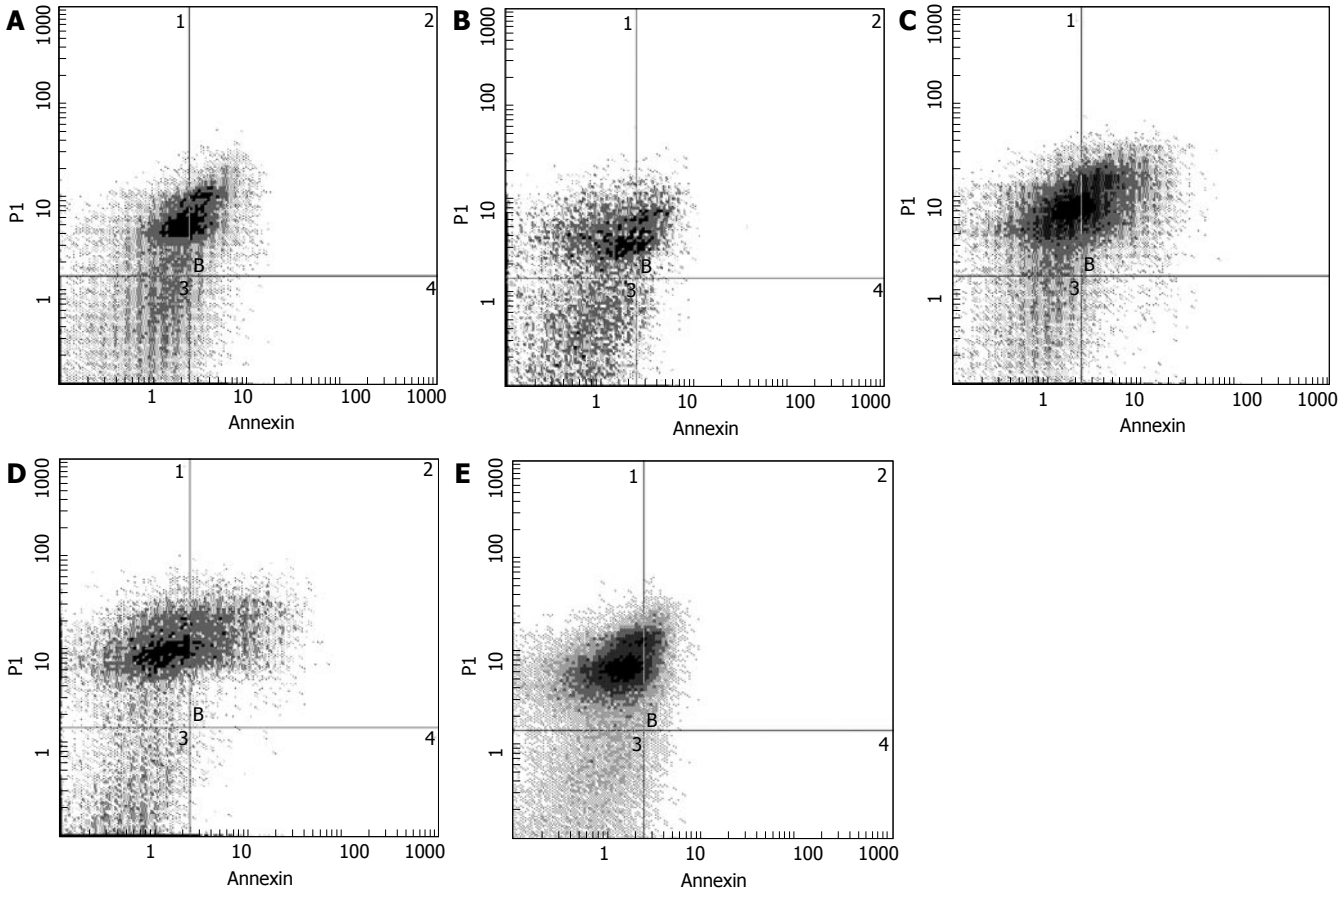

Figure 3 Cytogram observed by Annexin V-FITC/PI double staining assay in 120 g/kg JLS group (**A**), 60 g/kg JLS group (**B**), 20 g/kg JLS group (**C**), control group (**D**), and 5-FU group (**E**).

markers produced by tumor cells all belong to "phlegm", which can devitalize physiologic functions and stimulate tumor invasion and metastasis in turn. Therefore, "dispersing phlegm and eliminating stagnation" (cleaning metabolites produced by tumor) is one of the regimens for tumor treatment in TCM. JLS granules are an anti-

tumor compound prescription developed according to the methods of "dispersing phlegm and eliminating stagnation". Our previous experiments have shown that "dispersing phlegm and eliminating stagnation" inhibit could VEGF, Ras mRNA and protein expression[22-24] and have good antitumor and anti-metastasis potency *in vivo*. However whether it induces apoptosis is unclear. Our studies showed that JLS granules had anti-tumor effects on S180 and MKN-45 human gastric cancer. The ultra-structure of MKN-45 gastric cancer tissue treated with JLS granules showed that there were apoptosis changes. Cell cycle and apoptosis analysis also demonstrated that JLS granules could arrest MKN-45 cells at G0/G1 phase, decrease S phase cell populations. The typical apoptosis peak further confirmed its apoptosis-inducing effect.

In addition, changes in the plasma membrane are one of the earliest morphological features of apoptosis. At this time, the membrane phospholipid phosphatidylserine (PS) is translocated from the inner to the outer leaflet of the plasma membrane, thereby exposing PS to the external cellular environment. Annexin V is a 35-36kD Ca^{2+}-dependent phospholipid binding protein that has a high affinity for PS, thus Annexin V staining serves as a sensitive probe for flow cytometric analysis of cells undergoing apoptosis[25-26]. Therefore, staining with Annexin V in conjunction with vital dyes such as propidiumiodide (PI) can identify early apoptotic cells (Annexin V positive, PI negative). In our study, cells treated with JLS granules were located in the low right quadrant and cells in 5-FU-treated group were located in the upper left quadrant, suggesting that the earlier apoptotic cells in JLS granules-treated groups are higher than those in 5-FU-treated group and that JLS granules induce apoptosis in human gastric cancer MKN-45 cells.

In conclusion, JLS granules have the inhibiting effects on human gastric carcinoma and induction of apoptosis may be one of its mechanisms.

Abstract

AIM: To investigate the role of Beclin 1 on the susceptibility of HepG2 cells to undergo apoptosis after anti-Fas antibody or doxorubicin treatment.

METHODS: Beclin 1 silencing was achieved using RNA interference. DNA ploidy, the percentage of apoptotic cells and the mitochondrial membrane potential were assessed by flow cytometry. Levels of Beclin 1, Bcl-X_L and cytochrome *c*, and the cleavage of poly (ADP-ribose) polymerase (PARP) were assayed by using Western blots.

RESULTS: Beclin 1 expression decreased by 75% 72 h after Beclin 1 siRNA transfection. Partial Beclin 1 silencing significantly increased the percentage of subG1 cells 24 and 40 h after treatment with doxorubicin or anti-Fas antibody, respectively, and this potentiation was abrogated by treatment with a pan-caspase inhibitor. Partial Beclin 1 silencing also increased PARP cleavage, mitochondrial membrane depolarization and cytosolic cytochrome *c*. The pro-apoptotic consequences of partial Beclin 1 silencing were not associated with a decline in Bcl-X_L expression.

CONCLUSION: Partial Beclin 1 silencing aggravates mitochondrial permeabilization and apoptosis in HepG2 cells treated with an anti-Fas antibody or with doxorubicin.

INTRODUCTION

Beclin 1, a recently discovered tumor suppressor gene located on human chromosome 17q21, is mono-allelically deleted in 40%-70% of sporadic mammary, ovarian and prostate tumors[1]. Heterozygous beclin $1^{+/-}$ transgenic mice display a high incidence of spontaneous malignancies, including hepatocellular carcinoma (HCC), although the remaining beclin 1 allele is neither lost, mutated or silenced in these tumors[2,3]. These data have led to the conclusion that beclin 1 is a haploinsufficient tumor suppressor. One mechanism whereby beclin 1 haploinsufficiency can promote cancer is impaired autophagy, and increased cell proliferation[4]. However, it is not yet clear how Beclin 1 modulates cell death in cancer cells.

Several studies have reported a role of Beclin 1 in autophagic cell death. When embryonic fibroblasts from Bax/Bak double knockout mice were treated with etoposide, cells underwent a non-apoptotic cell death characterized by the presence of a number of autophagosomes/autolysosomes and the accumulation of both Beclin 1 and the APG5-APG12 complex[5]. Cell death was largely prevented by autophagy inhibitors as well as by silencing of Beclin 1 or APG5. In another study, treatment of mouse L929 fibroblastic cells or human U937 monocytoid cells with a pan-caspase inhibitor induced autophagic cell death[6]. Silencing of Beclin 1 or ATG7, another protein required for the formation of autophagic vacuoles, reduced z-VAD-induced cell death. Beclin 1 physically interacts with the anti-apoptotic proteins, Bcl-2 and Bcl-X_L[7], but the functional significance of this interaction on apoptosis is yet unclear. Thus, although beclin $1^{-/-}$ mouse embryos exhibited widespread cell death and died *in utero*, the *in vitro* apoptotic rate of beclin $1^{-/-}$ embryonic stem cells after UV irradiation or serum withdrawal was not significantly increased compared to wild-type cells[3]. By contrast, mice infected with a recombinant chimera of the neurotropic Sindbis virus combined with full-length human Beclin 1 exhibited

increased survival, fewer apoptotic brain cells and lower brain viral titers than mice infected with chimeras encoding a Beclin 1 protein lacking the Bcl-2 binding domain or with a premature stop codon[7]. However, these results did not provide information on whether the protective effects of Beclin 1 were a consequence of anti-apoptotic effects, anti-viral effects, or a combination of both mechanisms. Lastly, a recent study reported that the over-expression of Beclin 1 in MKN28 human gastric cancer cells stimulated *cis*-diamminedichloroplatinum (CDD)- or doxorubicin-induced cell death, while a Beclin 1 siRNA protected the cells from apoptosis in the same experimental conditions[8].

We have previously observed a significant correlation between Beclin 1 and Bcl-X_L mRNA expression in human hepatocarcinoma (unpublished results), suggesting that Beclin 1 over-expression may prevent hepatocyte apoptosis. In order to test this assumption, we investigated the effect of Beclin 1 silencing on the response of HepG2 cells to apoptotic stimuli. In the present study, we showed that partial Beclin 1 silencing aggravates the mitochondrial permeabilization and the apoptotic response induced by an agonistic anti-Fas antibody or by doxorubicin in a human HCC cell line.

MATERIALS AND METHODS

Materials

HepG2 cells were grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with 100 mL/L fetal calf serum and 1% penicillin/streptomycin sulfate (Gibco, Invitrogen).

Small interfering RNA (siRNA) duplexes were purchased from Dharmacon (Lafayette, CO). We used the beclin 1 siRNA: 5'-CAGUUACAGAUGGAGCUAA tt-3' (nt 655-673), which is located downstream from the initiation codon of the human beclin coding region, and a luciferase siRNA as a control siRNA: 5'-CUUACGCU GAGUACUUCGAtt3'. HepG2 cells (15-25 × 10^6 cells) were collected by trypsinization. The pellet was washed with serum-free OptiMEM (Gibco, Invitrogen) without antibiotics, and cells were resuspended in 500-600 μL of the same medium containing 12 μmol/L siRNA. After 10 min on ice, cells were electroporated at 230 V, 960 μF. Cells were resuspended in DMEM containing 100 mL/L fetal calf serum without antibiotics, and were plated in 60 mm Petri dishes (approximately 10^6 cells per dish). Antibiotics were added 3 h later.

In a first treatment protocol, 5 μg/mL of an agonistic anti-Fas antibody (7C11, Immunotech, Beckman Coulter, Miami, FL) was added 24 h after siRNA transfection, with or without 10 μmol/L benzyloxycarbonyl-valyl-alanyl-aspartic acid (o-methyl)-fluoro-methylketone (z-VAD-fmk) (Alexis, Coger, Paris, France), a pan-caspase inhibitor, and apoptosis was detected 40 h later, except for the assessment of cytochrome *c* release, which was detected at 24 h.

In a second treatment protocol, 6 μmol/L doxorubicin (Sigma, Saint-Louis, MO) was added 48 h after siRNA transfection, with or without 100 μmol/L z-VAD-fmk, and apoptosis was detected 24 h later except for the assessment of cytochrome c release, which was detected at 20 h.

Measurement of Beclin 1 mRNA expression by ribonuclease protection assay (RPA)

Attached HepG2 cells were washed twice with PBS and lysed in 5 mol/L guanidine thiocyanate and 0.1 mol/L EDTA (pH 7.4). RPA was carried out on cell lysates without previous RNA extraction[9]. The following DNA fragments were used to prepare riboprobes: a 200-bp fragment (nt 554-753, accession no. AF139131) from human beclin 1, and a 131-bp fragment (nt 553-683, accession no. NM00101) from human S6 used to normalize mRNA levels. The RPA and the separation of the protected mRNA fragments by polyacrylamide gel electrophoresis were performed as previously described[9]. Gel radioactivity was assessed with an Instant Imager (PerkinElmer, Courtaboeuf, France), and the ratio of the studied mRNA to the S6 mRNA was computed.

Western blot analysis of Beclin 1 and Bcl-X_L

Attached HepG2 cells were washed twice with PBS, harvested in PBS, and pelleted by centrifugation. The pellet was weighed and suspended in 2 × Laemmli buffer. Proteins were separated on SDS-polyacrylamide gels (70 g/L polyacrylamide for Beclin 1 and 120 g/L for Bcl-X_L) and transferred onto nitrocellulose membranes. After blocking, membranes were incubated for 1 h with either the anti-Beclin 1 antibody supplied by Dr Yoshimori[10], or an anti-Bcl-$X_{S/L}$ antibody (S-18) (Santa Cruz Biotechnology, Santa Cruz, CA), followed by a horseradish peroxidase-conjugated anti-rabbit IgG antibody (Immunotech, Beckman Coulter). Specific bands were detected by an enhanced chemiluminescence system (Pierce, Rockford, IL). Membranes were subsequently probed with a monoclonal anti-β-actin antibody (Sigma), and the β-actin signal was used to normalize protein loading.

Poly(ADP-ribose) polymerase (PARP) cleavage

Attached and floating HepG2 cells were harvested in culture medium and pelleted by centrifugation. Nuclear proteins were extracted according to Sadowski and Gilman[11]. After protein measurement (Biorad Reagent, Pierce), nuclear extracts underwent SDS-7% polyacrylamide gel electrophoresis and blotting as described above, and were revealed with a monoclonal anti-human PARP antibody (clone C2-10, BD Pharmingen, San Diego, CA).

Assessment of cell DNA content by flow cytometry

Pooled, free and adherent HepG2 cells were centrifuged, washed with PBS and fixed with 700 mL/L cold ethanol. The pellet was resuspended in 100 μL RNAse A (180 μg/mL) and incubated at room temperature for 30 min. Propidium iodide (Merck, Darmstadt, Germany; final concentration, 50 μg/mL) was added, and cells were incubated at room temperature in the dark for 15 min. The percentage of cells with a low DNA content (subG1 cells) was quantified by flow cytometry using an Epics Elite ESP coulter cytometer (Beckman coulter, Fullerton, CA). Propidium iodide was excited at 488 nm and fluorescence was analyzed at 630 nm.

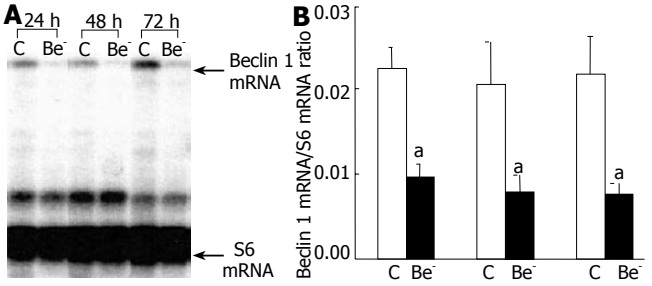

Figure 1 Beclin 1 mRNA expression after transfection of HepG2 cells with a Beclin 1 siRNA or a control siRNA. **A:** Representative RPA gel; **B:** Quantification of the Beclin1/S6 mRNA ratio. Results are means ± SE for 4 experiments ($^aP < 0.05$ *vs* C).

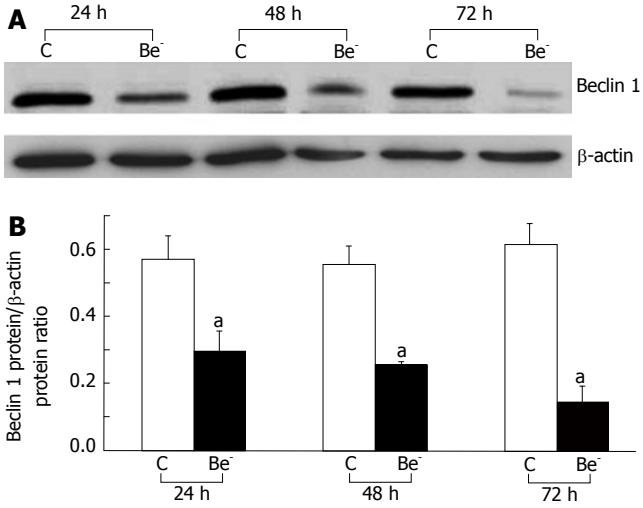

Figure 2 Beclin 1 protein expression after transfection of HepG2 cells with a Beclin 1 siRNA or a control siRNA. **A:** Representative Western blot of Beclin 1 and β-actin; **B:** Quantification of the Beclin 1 protein normalized to β-actin. Data are means ± SE for three experiments ($^aP < 0.05$ *vs* C).

Assessment of the mitochondrial membrane potential by flow cytometry

To determine the mitochondrial membrane potential, we used DIOC6(3) (Molecular Probes, Eugene, OR), a lipophilic cationic dye, which accumulates into polarized mitochondria. Free and adherent HepG2 cells were collected, rinsed with PBS, and suspended in the culture medium. DIOC6(3) was added at a final concentration of 100 nmol/L, and cell suspensions were incubated at 37 ℃ in the dark for 30 min. Propidium iodide (1.5 μmol/L) was added before flow cytometry to exclude dead cells and to only take into account the fluorescence DIOC6(3) in living cells. DIOC6(3) fluorescence was measured by flow cytometry. DIOC6(3) was excited at 488 nm and detected at 510 nm.

Measurement of cytochrome c release

Mitochondrial and cytosolic extracts were prepared using the ApoAlert® cell fractionation kit (BD Biosciences Clontech, Mountain View, CA, USA). Equal levels of protein were separated on SDS-12.5% polyacrylamide gel electrophoresis, transferred and immunoblotted with an anti-cytochrome *c* antibody supplied with the kit.

Statistical analysis

Data were expressed as means ± SE. An unpaired Student's *t* test was used to assess statistical differences between HepG2 cells transfected with the control siRNA or the Beclin 1 siRNA. A paired Student's *t* test was used to assess differences resulting from treatments in control siRNA- or in Beclin 1 siRNA-transfected HepG2 cells.

RESULTS

Effects of partial Beclin 1 silencing on Fas- and doxorubicin-mediated apoptosis

We used RNA interference to partially silence the Beclin 1 gene in HepG2 cells. The Beclin 1 mRNA was decreased by 57%, 61% and 65%, 24, 48 and 72 h after transfection of the Beclin 1 siRNA, respectively (Figure 1), and the Beclin 1 protein was decreased by 48%, 54% and 76%, respectively (Figure 2).

We then measured the percentage of cells with a decreased DNA content (subG1 cells) as a consequence of DNA fragmentation after treatment of transfected cells with doxorubicin or with an agonistic anti-Fas antibody, which both trigger apoptotic cell death in HepG2 cells[12,13]. We compared the percentage of cells with a subG1 DNA content in HepG2 cells transfected with the control siRNA (control cells) or the Beclin 1 siRNA (Be⁻ cells) (Figure 3). The percentage of subG1 cells was not significantly increased in the untreated Be⁻ cells compared to the untreated control cells (Figure 3B). However, after exposure to the anti-Fas antibody or doxorubicin, the increase in subG1 cells was much higher in the Be⁻ cells compared to the control cells (Figure 3B). In both control cells and Be⁻ cells, the pan-caspase inhibitor z-VAD-fmk markedly decreased subG1 cells after treatment with the anti-Fas antibody or doxorubicin (Figure 3C).

We also studied the apoptotic response of HepG2 cells by assessing PARP cleavage (Figure 4). The cleaved p85 fragment of PARP was not detected in the untreated control cells or untreated Be⁻ cells. After treatment with the anti-Fas antibody, the cleaved p85 fragment was still absent in the treated control cells, but present in the treated Be⁻ cells. After treatment with doxorubicin, the p85 fragment was more abundant, and the uncleaved p116 fragment less abundant, in the Be⁻ cells compared to the control cells (Figure 4).

Since the apoptotic effects of Fas or doxorubicin are amplified by mitochondria[14-16], we determined whether Beclin 1 depletion increases the mitochondrial pathway of apoptosis by first assessing changes in the mitochondrial membrane potential (Figure 5). The percentage of living cells with a low mitochondrial membrane potential was not significantly increased in the untreated Be⁻ cells compared to the untreated control cells. After treatment with the anti-Fas antibody or doxorubicin, the percentage of living cells with a low mitochondrial membrane potential was significantly higher in the Be⁻ cells than that in the control cells (Figure 5). We next investigated whether Beclin 1 silencing increases the release of mitochondrial cytochrome *c* into the cytosol after treatment with the anti-Fas antibody or doxorubicin[14,16]. We firstly checked that the cytosolic fraction was not contaminated by

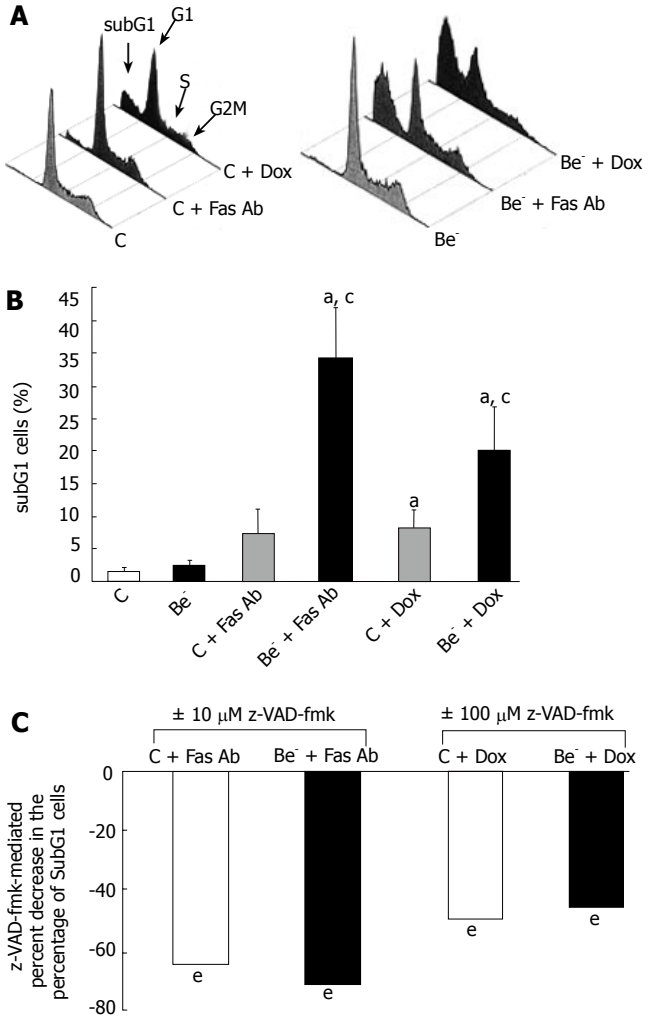

Figure 3 Percentage of subG1 cells after treatment of siRNA-transfected HepG2 cells with an agonistic anti-Fas antibody or doxorubicin. **A:** Representative flow cytometry analysis of the cell cycle; **B:** Quantification of the subG1 peak. Results are means ± SE for 5 to 8 experiments ($^{a}P < 0.05$ *vs* untreated cells; $^{c}P < 0.05$ *vs* cells transfected with the control siRNA); **C:** Effects of z-VAD-fmk. The figure shows the mean percent decrease in subG1 cells for 3 to 5 experiments ($^{e}P < 0.05$ between cells incubated with and without z-VAD-fmk).

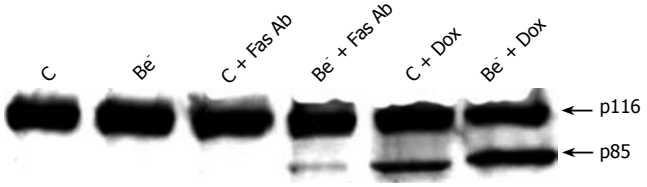

Figure 4 Western blot analysis of PARP cleavage after treatment of siRNA-transfected HepG2 cells with an agonistic anti-Fas antibody or doxorubicin.

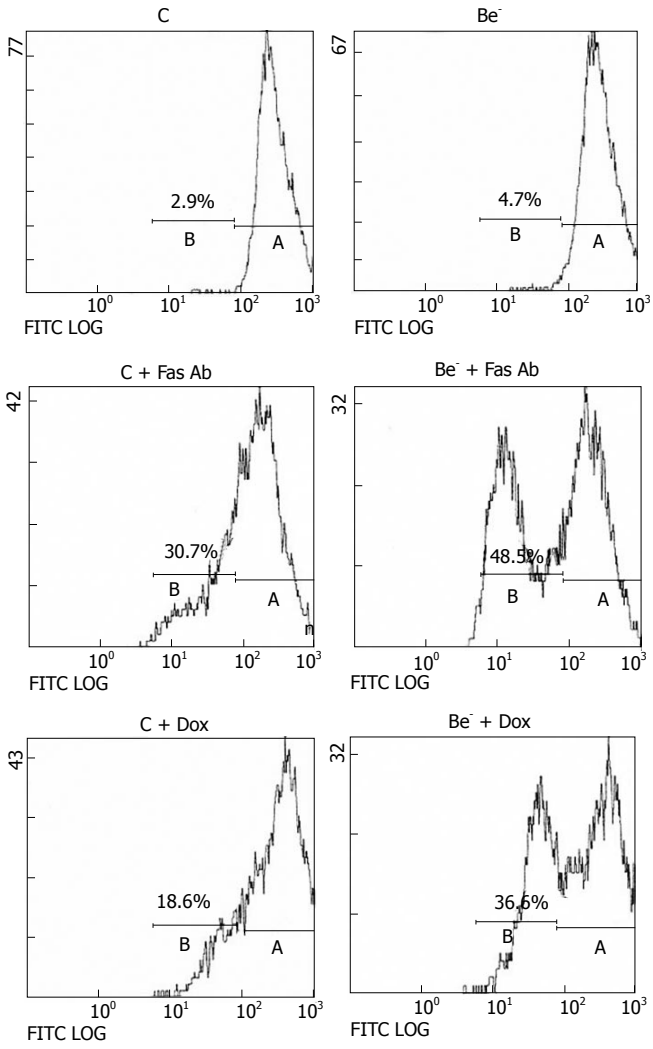

Figure 5 Assessment of the mitochondrial membrane potential in HepG2 living cells after siRNA transfection and treatment with an agonistic anti-Fas antibody or doxorubicin (Dox). In four to five different experiments, the percentage (mean ± SE) of cells with a low mitochondrial membrane potential was 4.5 ± 1.3% in C cells, 7.7 ± 2.9% in the Be- cells, 29.1 ± 4.9% in C cells treated with the Fas Ab, 52.5 ± 7.1% in Be- cells treated with the Fas Ab ($P < 0.05$ *vs* treated C cells), 23.6 ± 3% in C cells treated with Dox, and 38.8 ± 3.8% in Be- cells treated with Dox ($P < 0.05$ *vs* treated C cells).

mitochondria by assessing COX4 (data not shown). Cytosolic cytochrome *c* was increased by the anti-Fas antibody or the doxorubicin treatment in the control cells, and this increase was further enhanced in the Be- cells compared to the control cells, particularly after treatment with the anti-Fas antibody (Figure 6).

To test whether this effect could be mediated by decreased Bcl-X_L expression, we assessed this protein in the untreated and treated cells (Figure 7). Bcl-X_L was not significantly decreased 24, 48 or 72 h post-transfection in the cells transfected with Beclin 1 siRNA compared to the cells transfected with the control siRNA (Figures 7A-B). Treatment with the anti-Fas antibody caused no further changes (Figures 7C-D). Although treatment with doxorubicin tended to decrease Bcl-X_L expression in the control cells, and even more in the Be- cells, the doxorubicin-mediated decline in Bcl-X_L did not differ significantly between the control cells and Be- cells (Figures 7C -D).

DISCUSSION

Although beclin 1 haploinsufficiency is involved in several extrahepatic human cancers[1,4], and increases the frequency of various tumors, including HCC in transgenic mice[2,3], its role in human HCC is still not clear[17], and its potential involvement in liver apoptosis has not been investigated

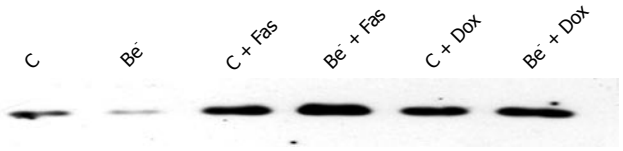

Figure 6 Assessment of cytochrome c release in HepG2 cells after siRNA transfection and treatment with an agonistic anti-Fas antibody or doxorubicin.

yet. The aim of the present study was to assess the effects of partial Beclin 1 silencing on the susceptibility of HepG2 human hepatoma cells to undergo apoptosis.

In the cells transfected with a Beclin 1 siRNA (Be- cells), the Beclin 1 protein was decreased by 50% at 24 h and by 75% at 72 h compared to the cells transfected with a control siRNA (control cells). Although the spontaneous apoptotic rate of the Be- cells was not significantly increased over that of the control cells, their apoptotic response to doxorubicin or an agonistic anti-Fas antibody was markedly aggravated (Figure 3). The percentage of subG1 cells was much higher in the treated Be- cells compared to the treated control cells (Figures 3A-B) and dropped significantly when cells were pre-treated with the pan-caspase inhibitor, z-VAD-fmk (Figure 3C). In addition, PARP cleavage was more extensive in the treated Be- cells than that in the treated control cells, especially after doxorubicin poisoning (Figure 4).

Two reasons prompted us to investigate the potential effect of Beclin 1 depletion on the mitochondrial pathway. Firstly, Beclin 1 physically interacts with Bcl-2 or Bcl-XL[7,8], two anti-apoptotic proteins predominantly localized to the mitochondrial membrane that prevent loss of mitochondrial membrane potential and cytochrome *c* release[18-20]. Secondly, the apoptotic effects of Fas or doxorubicin are amplified by mitochondria, in particular in hepatocytes and hepatoma cell lines[14-16]. The dissipation of mitochondrial membrane potential after anti-Fas antibody or doxorubicin treatments was more severe, and the cytochrome *c* release was more abundant in the Be- cells than that in the control cells (Figures 5 and 6), suggesting that Beclin 1 depletion activates the mitochondrial pathway of apoptosis. In a previous study, the over-expression of full-length human Beclin 1 was associated with decreased neuronal apoptosis in mice infected with the neurotropic Sinbis virus, whereas a deleted Beclin 1 construct lacking the region interacting with Bcl-2 or Bcl-XL was not protective[7]. This previous observation may suggest that the interaction of Beclin 1 with either Bcl-2 or Bcl-XL is essential for the anti-apoptotic effects of Beclin 1[7]. Since several studies have reported that Bcl-2 is not constitutively expressed in HepG2 cells[21-23] and Bcl-2 over-expression does not protect these cells from Fas or doxorubicin treatment[22-24], Bcl-XL seems to be the major anti-apoptotic protein in the HepG2 cell line. In the present study, partial Beclin 1 silencing increased apoptosis without significantly decreasing the Bcl-XL protein (Figure 7), suggesting that normal Beclin 1 levels are required to protect HepG2 cells from apoptotic stimuli, possibly by maintaining the expression of the Bcl-XL-Beclin 1 complex. How does the interaction between Beclin 1 and Bcl-XL or other proteins act to modulate mitochondrial permeabilization and apoptosis remains to be determined.

In contrast to our results, Furuya *et al*[8] instead observed that Beclin 1 over-expression aggravated CDD- or doxorubicin-induced apoptosis in a gastric cancer cell line, while Beclin 1 silencing had the opposite effects[8]. However, Beclin 1 silencing did not protect another gastric cancer cell line (with lower Bcl-2 and Bcl-XL expression) against CDD-mediated apoptosis. It thus appears that Beclin 1 differently modulates apoptosis in different cell lines. Although reasons for these differences are unknown, changes in the molecular environment of Beclin 1 from one cancer cell line to another might be involved, including different expression of Bcl-2 and Bcl-XL[8], and other pro-apoptotic proteins of the Bcl-2 family interacting with these proteins, but not with Beclin 1[7,8,24,25]

In conclusion, our data demonstrate that partial Beclin 1 silencing augments the mitochondrial permeabilization and the apoptosis induced by Fas stimulation or doxorubicin treatment in hepatoma-derived HepG2 cells. As Takehara *et al*[21] reported that down-expression of Bcl-XL by antisense oligonucleotide aggravates apoptosis induced by staurosporine or serum deprivation in HepG2 cells, the use of both Beclin 1 and Bcl-XL antisense oligonucleotides in combination with chemotherapeutic drugs might efficiently trigger apoptosis in human hepatocarcinoma. The different effects of Beclin 1 on apoptosis in different cell lines[3,7,8] show that Beclin 1, unlike Bcl-2 or Bcl-XL, can be pro-apoptotic, anti-apoptotic or non-effective, depending on the cellular context.

Abstract

AIM: To investigate the inhibitory effect of small interfering RNA (siRNA) on the expression of survivin in pancreatic cancer cell line PC-2 and the role of siRNA in inducing PC-2 cell apoptosis and enhancing its radiosensitivity.

METHODS: A siRNA plasmid expression vector against survivin was constructed and transfected into PC-2 cells with Lipofectamine™ 2000. The down regulation of survivin expression was detected by semi-quantitive RT-PCR and immunohistochemical SP method and the role of siRNA in inducing PC-2 cell apoptosis and enhancing its radiosensitivity was detected by flow cytometry.

RESULTS: The sequence-specific siRNA efficiently and specifically down-regulated the expression of survivin at both mRNA and protein levels. The expression inhibition ratio was 81.25% at mRNA level detected by semi-quantitive RT-PCR and 74.24% at protein level detected by immunohistochemical method. Forty-eight hours after transfection,apoptosis was induced in 7.03% cells by siRNA and in 14.58% cells by siRNA combined with radiation.

CONCLUSION: The siRNA plasmid expression vector against survivin can inhibit the expression of survivin in PC-2 cells efficiently and specifically. Inhibiting the expression of survivin can induce apoptosis of PC-2 cells and enhance its radiosensitivity significantly. RNAi against survivin is of potential value in gene therapy of pancreatic cancer.

INTRODUCTION

Survivin, a structurally unique member of the inhibitors of apoptosis protein (IAP)family, is involved in the control of cell division and inhibition of apoptosis. Survivin inhibits apoptosis via its baculovirus inhibitor of apoptosis repeat (BIR) protein domain by either directly or indirectly interfering with the function of caspases. Survivin is also a chromosomal passenger protein that is required for cell division. Survivin is expressed in embryonic tissues as well as in the majority of human cancers, but not in most normal adult tissues. The cancer-specific expression of survivin, coupled with its importance in inhibiting cell apoptosis and regulating cell division, makes it a useful diagnostic marker and a potential target for cancer treatment[1].

RNA interference (RNAi) is a process of post transcriptional gene silencing (PTGS) in which double-stranded RNA (dsRNA) inhibits gene expression in a sequence-dependent manner *via* degradation of the corresponding mRNA [2-5]. RNAi is initiated by an event while dsRNAs are recognized by Dicer, a member of the RNase III protein family[6]. The Dicer enzyme cleaves dsRNAs into 21 to 23 nucleotide short siRNAs. These siRNA duplexes are incorporated into a protein complex called the RNA-induced silencing complex, which recognizes and cleaves the cognate mRNA[7, 8]. Recently, Elbashir and his colleagues reported that introduction of synthetic 21nt siRNA into

mammalian cells could suppress gene expression in a sequence-specific manner[9]. By using dsRNAs of such a small size, the activation of dsRNA-dependent protein kinase and 2', 5'- oligoadenylate synthetase, which occurs as an interferon response to long dsRNA (i.e. longer than 30nt), leading to a global decrease in protein synthesis, is avoided [10,11]. Thus, siRNA has now become a powerful tool for studies on gene function, cancer and viral disease therapy. In this study, a siRNA against survivin plasmid expression vector was constructed and transfected into PC-2 cells. The changes of survivin expression following RNAi and the role of siRNA in inducing PC-2 cell apoptosis and enhancing its radiosensitivity were investigated, which may lay a foundation for further studies on the functions of survivin and genetic therapy involved in human pancreatic cancer.

MATERIALS AND METHODS

Cell line and culture

Human pancreatic cancer cell line PC-2 was purchased from the Medical Experimental Animal Center of the Fourth Military Medical University. The cells were cultured in RPMI 1640 medium supplemented with 100 mL/L fetal bovine serum (FBS), 1×10^5 U/L penicillin and 0.1 g/L streptomycin in a humidified incubator containing 50 mL/L CO_2 at 37 ℃.

Construction of siRNA plasmid expression vector against survivin

Plasmid vector Pgenesil-1 was purchased from Wuhan Genesil Biotechnology Co, Ltd. Aiming at the sequence of survivin[12] (5'-GGA CCA CCG CAT CTC TAC A-3'), two DNA chains were synthesized as following: 5'-GATCC GGA CCA CCG CAT CTC TAC A TTCAAGACG TGT AGA GAT GCG GTG GTC C TTTTTT GAATTC A-3' and 3'-G CCT GGT GGC GTA GAG ATG T AAGTTCTGC ACA TCT CTA CGC CAC CAG G AAAAAA CTTAAG TTCGA-5'. The structure of the DNA chains is *Bam*HI + sense chain + loop + antisense chain + termination signal + *Eco*RI + *Hin*dIII. Equal amount of the two DNA chains was annealed and phosphorylated, then the double-stranded DNA was ligated with the linearized plasmid vector Pgenesil-1 completely digested with *Bam*HI and *Hin*dIII. The ligated plasmid DNA was transfected into competent cells $DH5\alpha$ which were then seeded on solid LB medium containing 0.05 g/L kanamycin and cultured at 37 ℃ overnight. Three monoclonal colonies were picked out and seeded in 3 mL LB culture fluid containing 0.05 g/L kanamycin and cultured at 37 ℃ overnight in a rocking bed. The plasmid was extracted and verificated by digesting with restriction endonucleases and sequencing. The new plasmid was named Pgenesil-sur(+). The negative control plasmid Pgenesil-sur(-) was constructed as the same process. The target sequence is 5'-GAC TTC ATA AGG CGC ATG C-3' and does not have any homology with human beings or mice. The sequences of the two DNA chains are 5'-GATCC GAC TTC ATA AGG CGC ATG C TTCAAGACG GCA TGC GCC TTA TGA AGT C TTTTTT GTCGAC A-3' and 3'-G CTG AAG TAT TCC GCG TAC G AAGTTCTGC CGT ACG CGG AAT ACT TCA G AAAAAA CAGCTG TTCGA -5'. Their structure is *Bam*HI + sense chain + loop + antisense chain + termination signal + *Sal*I + *Hin*d III.

Extraction of plasmids

The plasmid extraction kit without endotoxin was purchased from Beijing Tianwei Corporation. The plasmids were extracted following the manufacturer's instructions. The concentration and purity of the plasmids were detected with an ultraviolet spectrophotometer. The plasmids were stored at -20 ℃ for following experiments.

Transfection of plasmids

Transfection reagent Lipofectamine™2000 was purchased from Invitrogen Corporation. Transfection was performed following the manufacturer's instructions. The ratio of plasmids: Lipofectamine™2000 was 1:3. Twenty-four hours before the transfection, the common complete medium was replaced by the antibiotics- free medium containing serum. Six hours after the transfection, the medium was replaced by the common complete medium again. Twelve hours after the transfection, expression of EGFP in PC-2 cell was observed under an inverse fluorescence microscope.

Expression of survivin mRNA detected by semi-quantitive RT-PCR

PC-2 cells were seeded in 6cm culture capsules and divided into blank control group, negative control group and positive experiment group. Each group contained 3 culture capsules. Only Lipofectamine™2000 was used for the transfection in the blank control group, plasmid Pgenesil-sur(-) was used for the transfection in the negative control group and plasmid Pgenesil-sur(+) was used for the transfection in the positive experiment group. Twenty-four hours after the transfection, 1×10^6 cells were collected and total RNA was extracted using the Trizol reagent following the manufacturer's instructions. The concentration and purity of the total RNA were detected with ultraviolet spectrophotometer. RT-PCR was performed by two-step method. Synthesis of cDNA was performed using the RevertAid™ first chain cDNA synthesis kit following the manufacturer's instructions. PCR was performed using the one tube convenient PCR kit purchased from Beijing Tianwei Corporation. Amplification of human GAPDH served as an internal standard. The primers used are 5'-CGA AGT CAA CGG ATT TGG TCG TAT-3' (forward primer) and 5'-AGC CTT CTC GGT GGT GAA GAC-3' (reverse primer). The amplification product was 306bp.The primers of survivin are 5'-GCA TGG GTG CCC CGA CGT TG-3' (forward primer) and 5'-GCT CCG GCC AGA GGC CTC AA -3' (reverse primer). The amplification product was 447bp. The PCR products were separated in 1.5% agarose gels, visualized by staining with ethidium bromide. Semi-quantitative analysis was performed with the Dolphin 1D software. The expression intensity of survivin was denoted with the ratio of the photodensity of the RT-PCR products of survivin and GAPDH. The inhibition ratio of survivin expression was calculated with the following formula: inhibition ratio of survivin expres-

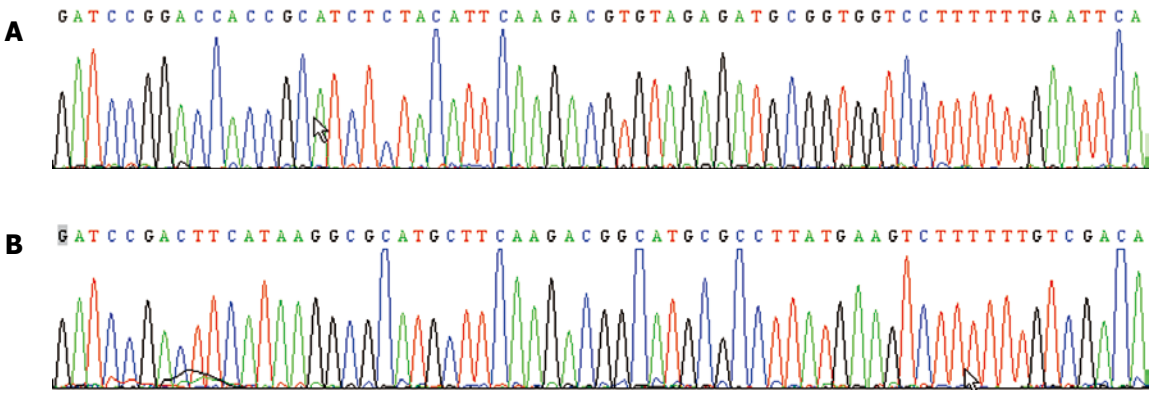

Figure 1 Reports of the sequencing of plasmid Pgenesil-sur(+) (**A**) and plasmid Pgenesil-sur (-) (**B**).

sion = (1-the expression intensity of survivin in the observation group/ the expression intensity of survivin in the blank control group)×100%.

Expression of survivin protein detected by immunohistochemical method

PC-2 cells were seeded in 24-well plates with a small square cover slip in each well. Grouping and transfection were performed the same as above. Each group contained 8 wells. Twenty-four hours after the transfection, the cells were fixed with cold 65% liquor pyroaceticus. The expression of survivin protein was detected by immunohistochemical SP method. The anti-survivin antibody was a rabbit anti-human monoclonal antibody purchased from Beijing Zhongshan Corporation. The working concentration was 1:50. A petroline section of breast cancer expressing survivn positively was used as a positive control, PBS was used to replace the anti-survivn antibody to make a negative control. Cells with brown-yellow granulations in endochylema or nuclei were considered as positive cells. According to the coloration, the cells were scored as following: 0, no staining; 1, faint-yellow; 2, brown-yellow; 3, dark-brown. Five fields of vision of each cover slip were observed under high power lens randomly. The cells were calculated and scored. The sum of the scores was divided by the number of cells, the result was considered as the expression intensity of survivin. The inhibition ratio of survivin expression was calculated with the following formula: inhibition ratio of survivin expression = (1-the expression intensity of survivin in the observation group/ the expression intensity of survivin in the blank control group)× 100%.

Radiation and apoptosis of PC-2 cells detected by flow cytometry

Cells were seeded in 25 cm^2 culture flasks and divided into blank control group, negative control group, positive experiment group, blank control + radiation group, negative control + radiation group, and positive experiment + radiation group. Each group contained 5 culture flasks. Transfection was performed the same as above. Twenty-four hours after the transfection, cells of groups 4, 5, 6 were radiated with 15 Gy of X-ray(6MV) at room temperature using a Varian 2300 C/D linear accelerator. The radiation conditions were ounce-skin distance = 100 cm, radiation dose rate=2 Gy/min. After radiation, the cells were continuously cultured for another 24 h, digested, collected and washed twice with PBS. Then the cells were fixed with cold 75% ethanol at 4 ℃ overnight. The cells were centrifuged at 1000 r/ min for 5 min, the supernate was poured out, the cells were washed twice with PBS. The cells were resuspended with PBS containing 0.05 g/L RNase and incubated for 30 min at room temperature avoiding light to eliminate the intracellular RNA. The cells were centrifuged at 1000 r/min for 5 min, the supernate was poured out. The cells were resuspended with PBS containing 0.06 g/L propidium iodode again and incubated for 30 min at room temperature avoiding light, then cell apoptosis was detected by flow cytometry. The management was the same in cells of groups 1-3 except for no radiation.

Statistical analysis

Data were expressed as mean ± SD. All statistical analyses were performed using SPSS 10.0 software(one-way ANOVA). $P < 0.05$ was considered statistically significant.

RESULTS

Verification of plasmids

The multiclone sites of plasmid Pgenesil-1 were as following: *Hin*dIII-*Xba*I-*Sal*I -*Pst*I-*Bam*HI-U6 Promotor-*Eco*RI-*Sal*I-*Xba*I-*Dra*III. An *Eco*RI site for plasmid Pgenesil-sur(+) and a *Sal*I site for plasmid Pgenesil-sur(-) were designed in the inserted fragments between the sites of *Bam*HI and *Hin*dIII. If the insertion was correct, a band about 400 bp should be cut off by *Eco*RI or *Sal*I. The results of digestion with restriction endonucleases and sequencing showed correct plasmids(Figure 1).

Results of transfection

Twelve hours after plasmid Pgenesil-sur(+) or plasmid Pgenesil-sur(-) was transfected into PC-2 cells using Lipofectamine^{TM}2000, expression of EGFP could be observed under an inverse fluorescence microscope. Twenty-four hours after the transfection, the expression of EGFP was the strongest. Seventy-two hours after the transfection, the expression of EGFP was attenuated gradually(Figure 2).

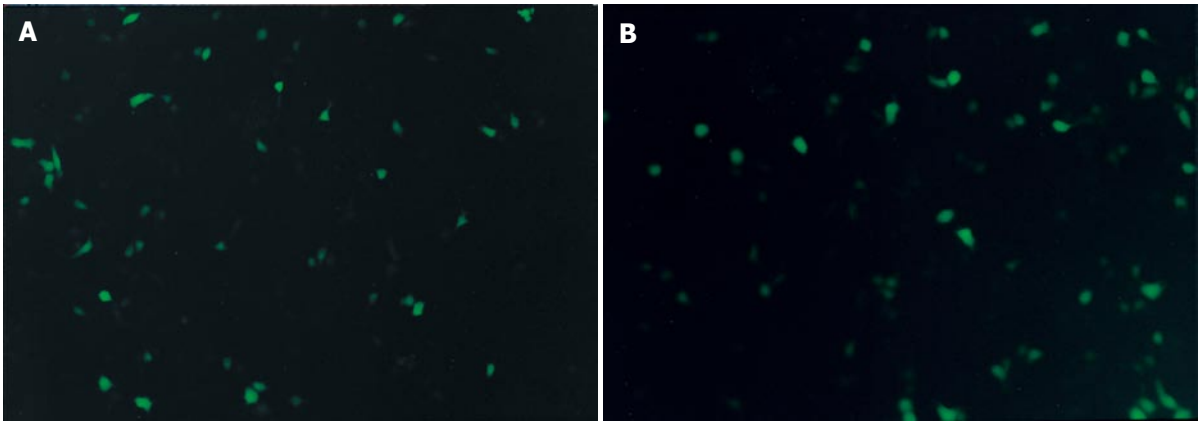

Figure 2 Expression of EGFP in PC-2 cells 24 h after trancfection of plasmid Pgenesil-sur(+) (**A**) and plasmid Pgenesil-sur(-) (**B**) (original magnification×200).

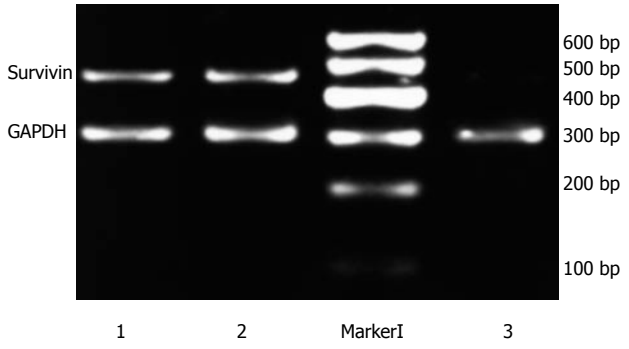

Figure 3 Down-regulation of survivin mRNA expression detected by semi-quantitive RT-PCR. 1: The blank control group; 2: The negative control group; M: Marker I; 3: The positive experiment group.

Significant down regulation of survivin mRNA expression by siRNA

Twenty-four hours after the transfection, the expression intensities of survivin mRNA in blank control, negative control and positive experiment groups were 0.96±0.02, 0.98 ± 0.03 and 0.18 ± 0.03, respectively. The statistical analysis showed that the expression of survivin mRNA in PC-2 cells was down regulated significantly after transfection with plasmid Pgenesil-sur(+) ($P < 0.05$), the inhibition ratio was 81.25%. Then expression of PC-2 cells transfected with plasmid Pgenesil-sur(-) had no effect on the expression of survivin mRNA ($P > 0.05$)(Figure 3).

Significant down regulation of Survivin protein expression by siRNA

Twenty-four hours after the transfection, the expression intensities of survivin protein in blank control, negative control and positive experiment groups were 2.29 ± 0.23, 2.34 ± 0.15 and 0.59 ± 0.16, respectively. The statistical analysis showed that the expression of survivin protein in PC-2 cells was down- regulated significantly after transfected with plasmid Pgenesil-sur(+) ($P < 0.05$), the inhibition ratio was 74.24%. The expression of PC-2 cells transfected with plasmid Pgenesil-sur(-) had no effect on the expression of survivin protein ($P > 0.05$) (Figure 4).

Role of siRNA in inducing PC-2 cell apoptosis and enhancing its radiosensitivity detected by flow cytometry

Forty-eight hours after transfection, no cell apoptosis was detected in blank control and negative control groups, but in (7.03 ± 1.12)% cells in the positive experiment group. The apoptosis rate in blank control + radiation group, negative control + radiation group and positive experiment + radiation group was (1.77 ± 0.30)%, (1.66 ± 0.46)% and (14.58 ± 2.72)%, respectively. The statistical analysis showed that transfection with plasmid Pgenesil-sur(+) could induce spontaneous apoptosis of PC-2 cells in a certain degree and the effect was better than that of 15 Gy of X-ray radiation. Inhibiting the expression of survivin could enhance the radiosensitivity of PC-2 cells significantly. siRNA against survivin combined with radiation could induce significant apoptosis of PC-2 cells (Figure 5).

DISCUSSION

Pancreatic cancer is one of the most malignant tumors with a very poor prognosis. The 5-year survival rate of pancreatic cancer patients receiving surgery and chemotherapy ranges 1%-2%. One of the reasons for this low survival rate is the insensitivity of pancreatic cancer to most oncologic therapies such as chemotherapy, radiotherapy and immunotherapy. Tumor development and progression as well as resistance to most oncologic therapies result mainly from lacking response to apoptotic stimuli[13].

Survivin, a member of the IAP family, is a bifunctional protein that suppresses apoptosis and regulates cell division. Recent studies showed that there is a close relationship between survivin and malignant tumors. The expression of survivin is highly cancer-specific, and is one of the top four transcripts uniformly up-regulated in human cancers, but not in normal tissues[14]. The overexpression of survivin appears to correlate with aggressive tumor behavior and poor prognosis in colorectal cancer[15-17], neuroblastomas[18], melanomas[19], non small cell lung cancers[20], breast carcinomas[21], esophageal squamous cell carcinomas[22] and soft-tissue

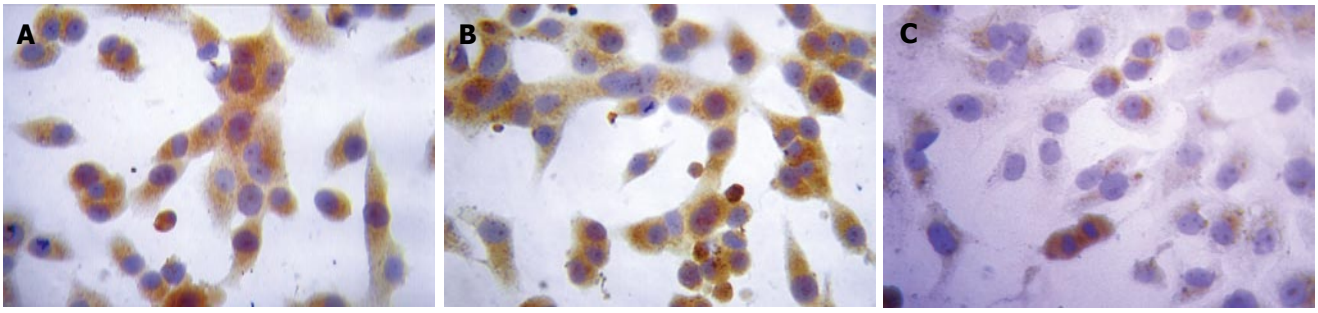

Figure 4 Down-regulation of survivin expression detected by immunohisto- chemical SP method in the blank control group (**A**), negative control group (**B**), and positive experiment group (**C**) (coloration with DAB, original magnification × 400)

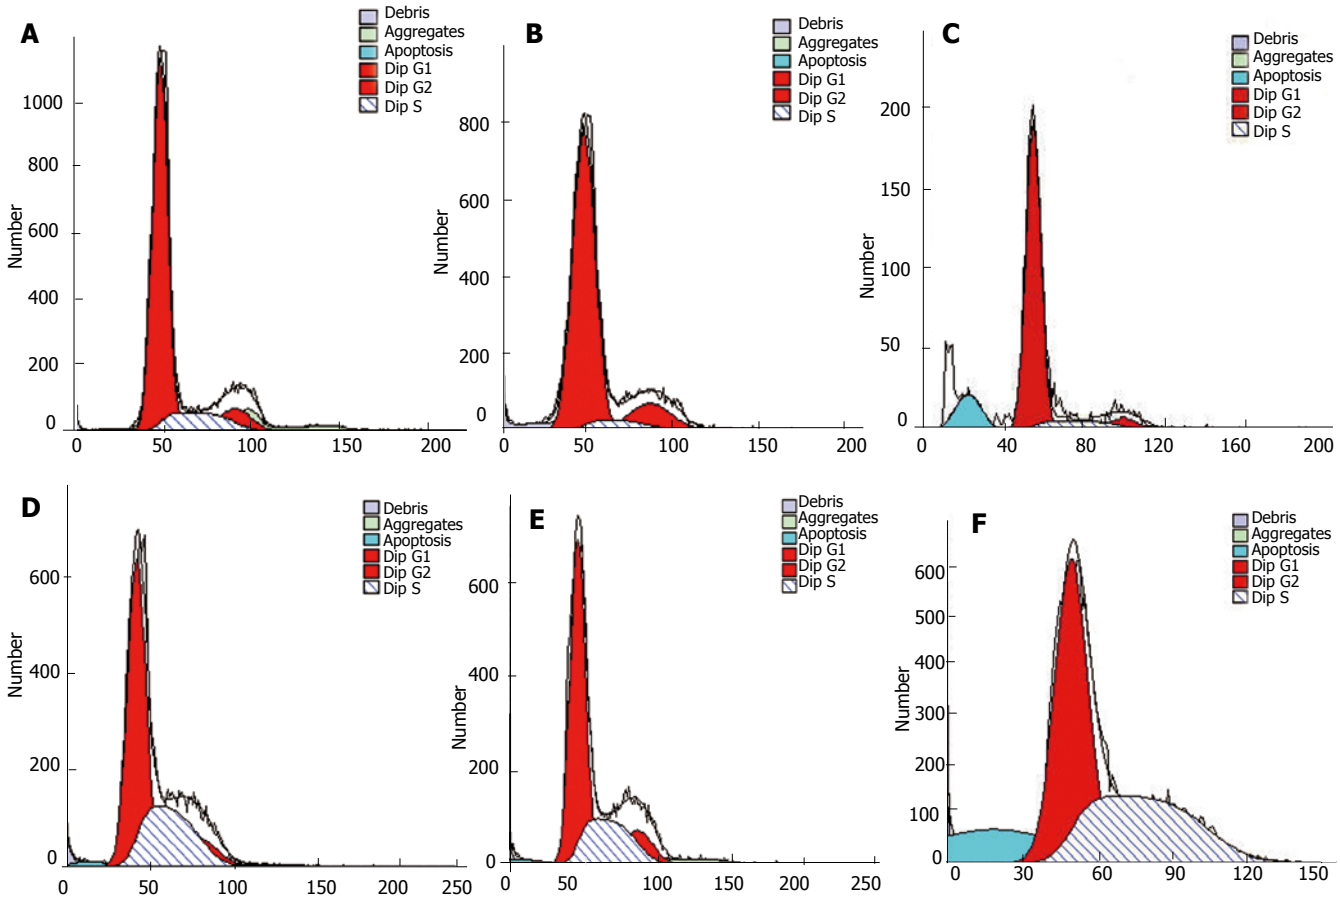

Figure 5 Apoptosis of PC-2 cells detected in 6 groups by flow cytometry (stained with PI)

sarcoma[23]. Additionally, survivin overexpression is also correlated with insensitivity to chemotherapy and radiotherapy in cancers[24,25]. Inhibiting the expression of survivin can induce tumor cell apoptosis, sensitize tumor cells to chemotherapy, radiotherapy and inhibit tumor-angiogenesis[26-29]. Survivin has become an ideal target for the diagnosis and treatment of cancer.

Studies on the relationship between the expression of survivin and pancreatic cancer showed that survivin is also overexpressed in pancreatic cancer, and participates in the development and progress of pancreatic cancer by inhibiting apoptosis. Its overexpression is associated with the insensitivity of pancreatic cancer to chemotherapy and radiotherapy, and is a poor prognosis marker[30-33]. All these studies suggest that survivin is of great potential value in the treatment of pancreatic cancer.

The mechanisms by which survivin inhibits cell apoptosis and cell division are still highly controversial. Survivin may regulate apoptosis by directly or indirectly inhibiting the activity of caspases (caspase-3, -7, -6, -8, -9, -10), or by interacting with cdk4 which releases P_{21} from its complex with cdk4 making it possible for P_{21} to complex with caspase-3, the initial step in inactivating caspase-3 in mitochondria. Survivin may possibly function to inhibit the activity of caspases indirectly *via* binding to and sequestering Smac/DIABLO, thus preventing Smac/DIABLO binding to other IAPs. Survivin might be an additional chromosomal passenger protein just like inner

centromere protein (INCENP), TD-60 and Aurora-B, and is important for cytokinesis and chromosome movement during cell division. Overexpression of survivin may overcome the G2/M phase checkpoint to enforce progression of cells through mitosis[1].

RNAi is characterized by high efficiency, high specificity and low toxicity. siRNA has become a powerful tool for studies on gene function, cancer and viral disease therapy. In this study, we designed and constructed the siRNA plasmid expression vector. Its transcript can form a short hairpin RNA(shRNA) with inverted repeat sequence separated by a short loop sequence, then the shRNA is processed into functional siRNA to degradate target mRNA and silences its expression. The siRNA plasmid expression vector constructed in this study contains the EGFP gene that makes it convenient to observe the result of transfection. By aiming at different sequence of the target gene, the effect of RNAi may be greatly different [34, 35] suggesting that it is very important to find the proper sequence. The sequence of Kappler consulted in this study has been confirmed effective in multiple tumor cell lines[12,36]. The results of our studies also demonstrated that it was effective both in pancreatic cancer cell line PC-2 and in breast cancer cell line MCF-7 (data not shown), suggesting that this sequence may be of universality in malignant tumors and should be a preferential sequence when study on the RNAi against surviving is carried out.

In this study, we investigated whether the sensitivity to X-irradiation could be affected by inhibiting survivin expression with siRNA. The results showed that the siRNA against survivin plasmid expression vector constructed in this study had highly specificity, and could suppress the expression of survivin in PC-2 cells efficiently suggesting that inhibiting the expression of survivin can induce spontaneous apoptosis of pancreatic cancer cells in a certain degree and enhance its radiosensitivity significantly. siRNA against survivin is of potential value in the treatment of pancreatic cancer.

Abstract

AIM: To investigate the effects of hyperlipidemia on acute pancreatitis (AP) and the possible mechanisms.

METHODS: Rat models of hyperlipidemia and AP were established by Triton WR1339 and cerulein respectively. Human albumin was used to treat AP complicated by hyperlipidemia. In each group, we compared the histological score, volume of ascites, ratio of pancreatic wet/dry weight, serum amylase (AMY) and pancreatic acinar cell apoptosis. The level of protein kinase C (PKC) membrane translocation in pancreatic tissue was detected by Western blot.

RESULTS: In the hyperlipidemia model established by Triton WR1339, triglyceride (TG) increased remarkably and reached its peak 6 h after injection, and most rats developed mild acute pancreatitis. Histological score, volume of ascites, ratio of wet/dry weight and serum AMY in AP animals with hyperlipidemia were obviously higher than those in AP animals ($P < 0.05$) and decreased after albumin therapy but not significantly ($P > 0.05$). Apoptotic cells detected by terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL) increased in AP animals with hyperlipidemia and did not change distinctly after albumin therapy. PKC membrane translocation level increased in AP animals with hyperlipidemia and decreased remarkably after albumin therapy ($P < 0.05$).

CONCLUSION: Hyperlipidemia may induce AP or intensify pancreatic injury. Albumin therapy can not alleviate pancreatic lesion effectively. PKC activation may be one mechanism by which AP is intensified by hyperlipidemia.

INTRODUCTION

Acute pancreatitis (AP) is a common disease that normally runs a benign course in the majority of patients. However in up to 20% of individuals the disease is severe and may be associated with a mortality of about 20%[1,2]. Since Speck in 1865[3] noted the association between hyperlipidemia and AP, their relationship has been studied by many scholars. Currently, hyperlipidemia is another main cause of AP besides cholelithiasis and alcohol abuse[4]. Serum triglyceride (TG) levels higher than 1000 mg/dl seem to be a serious factor for developing AP, particularly in patients suffering from familial hyperlipidemia (types 1, 4 or 5 according to Fredrickson's classification). AP occurs with an incidence of up to 21%[5,6]. Hydrolysis of TG by pancreatic lipase with the local release of large quantities of free fatty acids (FFAs) has been proposed as the pathogenic mechanisms. Hyperlipidemia is a common cause of AP. Moreover, lipid levels increase above normal in up to 50% of patients with AP of any cause[7].

Several studies in humans and animals have been performed to evaluate hyperlipidemia as a risk factor for developing AP. However, there is no ideal animal model of hyperlipidemic AP. Information about the influence of hyperlipidemia on the course of AP is relatively rare. The majority of investigators considered that hyperlipidemia can intensify the pancreatic lesion and systemic inflammatory response. Saharia *et al*[8] perfused the pancreas preparations with TG and FFAs (oleic acid) and found that they can lead to edema of the isolated pancreas, weight gain, and elevation of serum AMY. The injury caused by FFAs is similar to that seen with TG infusion, but it occurs more rapidly. These studies add support to the concept that hypertriglyceridemia can initiate pancreatic injury and the release of FFAs may be the mechanism. Kimuru *et al*[9] initiated an AP model with cerulein, retrograde duct injection of sodium taurocholate,

bile/pancreatic duct respectively and found that the isolate pancreatic damage is increased by TG perfusion. However, some reports suggest that hyperlipidemia could not aggravate the course of AP. Paye *et al*[10] prepared an AP model with cerulein and injected TG simultaneously, and found that histological alterations, pancreatic enzyme level and ascites in these models do not differ from those in AP patients without TG injection. To approve this result further, the authors collected very low density lipoprotein (VLDL) from AP patients and found that the VLDL intravenous infusion for hypertriglyceridemia does not alter the course of AP[11]. Therefore the role of hyperlipidemia in acute pancreatitis seems questionable.

The mechanism by which hyperlipidemia leads to AP is still unclear. A well-accepted mechanism proposed by Havel *et al*[12] is that unbound FFAs are toxic and could produce acinar cells or capillary injury. Increased concentration of chylomicrons in pancreatic capillaries causes capillary plugging and leads to ischemia and acidosis. FFAs can induce activation of trypsinogen and initiate AP. Recently, it was reported that FFAs are toxic to pancreatic β-cells leading to diabetes and insulin resistance syndrome. The toxicity is associated with abnormalities in the insulin signaling cascade and may be mediated by FFA activation of protein kinase C (PKC)[13]. Also, there is abundant PKC in pancreatic acinar cells[14]. Other similar mechanisms of FFAs may damage acinar cells.

The aim of the present work was to determine whether endogenous hyperlipidemia aggravates *in vivo* cerulein-induced edematous AP and activates PKC in pancreas of rats.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats, weighing 250-270 g were used. Experiments were performed in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals. The rats were maintained at 23 ℃ in a 12 h light dark cycle, with free access to water and standard rat chow. The rats were fasted for 12 h prior to the experiment, but with free access to water. They were anesthetized with chloral hydrate (300 mg/kg intraperitoneal injection). Body temperature was monitored and maintained at 37.5 ± 1 ℃ using a heating device.

Models of hyperlipidemia, AP, and AP with hyperlipidemia

Hyperlipidemia was induced by intravenous injection of 10% Triton WR1339 solution (TyloxAPol, Sigma, USA) through the left external iliac vein. Triton WR1339, a non-ionic surface active detergent leads to an increase of endogenous TG and total cholesterol (TCH) blood concentrations[15, 16]. We determined the required amounts of Triton WR1339 with two doses of 100 mg/kg and 400 mg/kg body weight respectively. A volume of 400 mg/kg Triton WR1339 solution could induce maximal hyperlipidemia. The non-hyperlipidemic animals received an injection of physiological saline solution intravenously instead of Triton WR1339.

AP was induced by 4 h abdominal subcutaneous injection of cerulein (Sigma, American, 20 μg/kg in 0.5 mL of saline vehicle) as previously described[17].

To explore the influence of hyperlipidemia on acute experimental pancreatitis, we used five different groups of animals with 12 rats in each group. The animals of the first group [$C_{(sal)}$] received 1.0 mL saline (sal) solution, and the second group [$C_{(tri)}$] received 1.0 mL of 10% Triton WR1339 (tri) intravenously. In these two groups [$C_{(sal)}$ and $C_{(tri)}$] no pancreatitis was induced. AP was induced in the third group (AP) and the fourth group (HAP) as described above. The animals of group HAP received an injection of 1.0 mL of Triton WR1339 intravenously 6 h before pancreatitis was induced with cerulein infusion. Since albumin could effectively combine FFAs in circulation to prevent cellular damage[18], in the fifth treatment group (THAP), the rats received an injection of 1.25 g/kg albumin intravenously after pancreatitis was induced.

Analysis of serum lipid, AMY activity and histology

Blood samples were taken from all animals before and 3, 6, 9 h after induction of hyperlipidemia or AP with hyperlipidemia. The samples were used to measure TG, TCH, AMY activity.

Three and six hours after induction of AP, the rats were sacrificed by aortic puncture and blood samples taken for plasma biochemical measurements. A complete macroscopic examination of the peritoneal cavity and ascites was immediately performed, and the pancreas was removed using a standardized monobloc surgical technique. The pancreas was divided into three parts. The pancreatic head was fixed in Bouin's solution, embedded in paraffin, sliced, and stained with hematoxylin and eosin. The pancreas body was put into liquid nitrogen for PKC analysis. To better estimate the amount of edema, the remaining pancreatic tissue was weighed and dessicated for 24 h at 173 ℃ to measure its dry weight. We used the wet to dry ratio to quantify edema formation.

To quantify the histological changes, two pathologists judged the tissue samples using a point score as previously described[19,20]. Plasma AMY concentrations were determined after plasma dilution (1/20) by the colorimetric assay AMYL (Boehringer Mannhein, Germany). Plasma TG was measured using the colorimetric assay TG GPOPAP (Boehringer).

Detection of apoptosis

Recent studies indicate that mild acute pancreatitis is related to the extent of acinar cell apoptosis[21-23]. A pancreatic tissue section was prepared and assayed with the *in situ* cell death detection kit, POD (Boehringer Mannheim, Germany) following the manufacturer's instructions. Slides were counterstained with hematoxylin and viewed under a light microscope.

Activation of protein kinase C

PKC activation was determined in both cytosolic and particulate fractions as previously described[24]. Frozen pancreatic tissue(50 mg) was rapidly thawed and homogenized at 4 ℃ in lysis buffer A (mM: Tris-HCl 50; pH 7.4; NaCl 150; EDTA 2; EGTA 2; DTT 2; Na py-

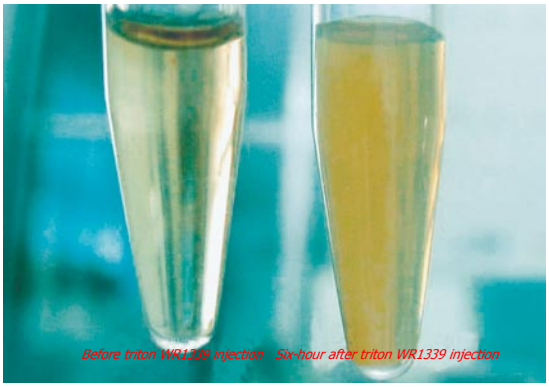

Figure 1 Development of chylomicronemia after Triton WR1339 injection.

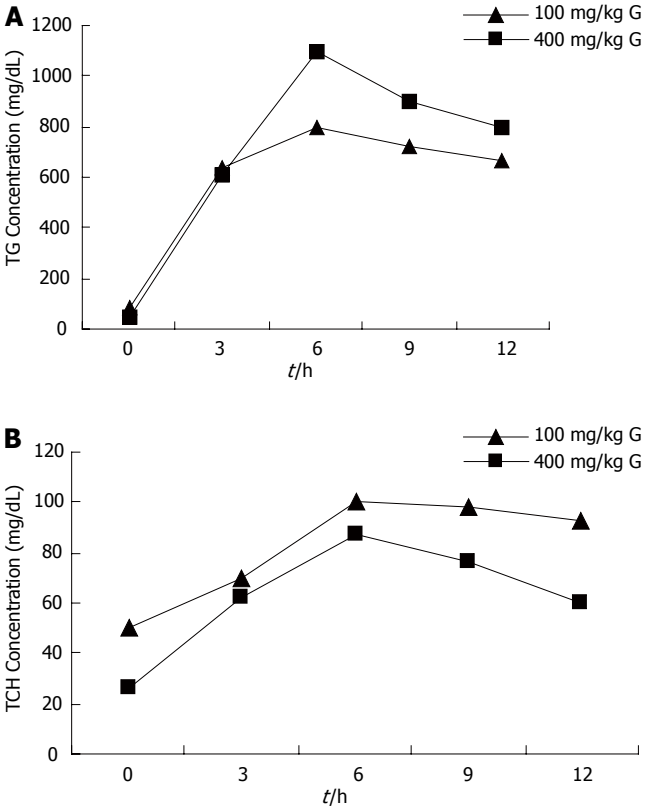

Figure 2 Curves of serum TG and TCH induced by Triton WR 1339 in rats.

rophosphate 5; KF 50; PMSF 1; 1μg/mL: Aprotinin, Leupeptin, Pepstatin A). Homogenates were centrifuged at 100 000 r/min for 30 min at 4 ℃ in an Optima TLX ultracentrifuge to yield cytosol. The pellet fractions were resuspended in 100 μL of buffer A containing 0.5% Nonidet *P*-40, sonicated and centrifuged again. The resulting supernatants taken as the particulate fractions with the cytosolic fractions were assayed for PKC immunoreactivities. Throughout the study, protein concentrations were determined by the Lowry's method with bovine serum albumin as standard. Aliquots of the cell lysates containing 100 g of total protein were resolved in 10% SDS-PAGE and transferred to PVDF membranes (Amersham Biosciences, Inc.). The membranes were blocked in TBS-Triton-X 100 (0.2% v/v, pH 7.4) containing 5% milk for 2 h at room

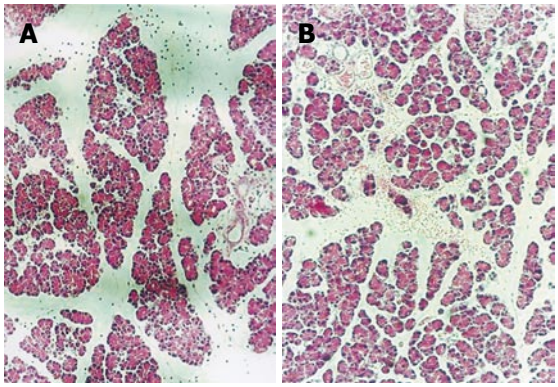

Figure 3 Microscopic pancreatic changes in rats with AP induced by cerulean (**A**) and hyperlipidemic AP induced by cerulein and Triton WR1339 (**B**) 6 h after injection (HE × 200).

temperature followed by incubation with PKC antibody at the dilution described by manufacturer's instructions at 4 ℃ overnight. The membranes were incubated with anti-goat horseradish peroxidase complex (diluted 1:2000) for 2 h at room temperature. The proteins on the membranes were exposed to X-ray films at multiple time points and visualized by ECL detection system (Amersham Biosciences, Inc.).

Statistical analysis

Data were expressed as mean ± SD and analyzed using Student's *t* test or Student's Newman Keuls-test by SPSS 11.0 software. Quantitative analysis for immunoblot was done by scanning the x-ray film and determined using the Fotodyne Gel-Pro analyzer program.

RESULTS

Changes of serum lipid, AMY and pathology of pancreas in $C_{(tri)}$ group

The animals receiving 100 mg/kg and 400 mg/kg Triton WR1339 had high TG and TCH. The serum TG increased most obviously and reached its peak 6 h after Triton WR1339 infusion with induction of chylomicronemia (Figure 1). The TG value increased 10-fold and 20-fold after 100 mg/kg and 400 mg/kg Triton WR 1339 infusion respectively, whereas the serum TCH increased only 2-fold and 3-fold (Figure 2). The serum AMY activities did not significantly increase after induction of hyperlipidemia ($P > 0.05$). The animals did not demonstrate ascites and pancreatic edema in macroscopy. Nine rats (9/12) showed mild pancreatic edema, whereas no histological changes occurred in the saline-treated animals (group $C_{(sal)}$).

Effects of hyperlipidemia on pancreatic histology in AP rats

The pancreatic changes included interstitial edema, increased interlobular interstice and infiltration of some inflammatory cells in the animals 3 h after cerulein infusion. The pancreas of AP animals 6 h after cerulein injection had serious edema with tensioned capsules and separated small lobuli. Wide lobular and acinar interstices, anamorphic acinar structure, intracytoplasmic vacuolization and

	6 h	1167.33 ± 228.28	211.00 ± 14.02	16524.39 ± 5273.52

[a]$P < 0.05$, [c]$P < 0.05$ *vs* triton group.

infiltrated inflammatory cells were observed (Figure 3). After 3 h, the pancreatic damage was intensified in the animals of group HAP, and some apoptotic bodies (inclusion) and more inflammatory cells appeared. There were scattered erythrocytes and inflammatory cells, distended small veins in the pancreas 6 h after HAP model was induced (Figure 3). There were no pathological changes after albumin therapy.

Pancreatic histological score, volume of ascites and pancreatic wet/dry ratio in rats

The animals receiving cerulein (group $C_{(tri)}$) had significantly ($P < 0.05$) higher pancreatic histological score, volume of ascites and pancreatic wet/dry ratio than the control group. The pancreatic histological score, volume of ascites and pancreatic wet/dry ratio were significantly higher ($P < 0.05$) in the AP animals with hyperlipidemia (group HAP) than in the animals receiving only cerulein infusion (group $C_{(tri)}$). After albumin treatment (group THAP) these parameters decreased slightly but were higher in the 6 h group than in the 3 h group ($P > 0.05$). These results suggested that hyperlipidemia could aggravate pancreatic edema of the AP animals and albumin therapy was not obviously effective (Table 1).

Serum TG, TCH and AMY in rats

The serum TG and TCH concentration increased 1-2 folds in the cerulein-induced AP animals. There were no statistical differences between group AP and group $C_{(sal)}$ ($P > 0.05$). The hyperlipidemic AP animals had significantly higher serum TG and TCH values than the rats receiving Triton WR1339 (group $C_{(tri)}$) injection. The serum TG and TCH concentration in the animals with albumin therapy (group THAP) decreased slightly. The AMY activities in the hyperlipidemic group $C_{(tri)}$ remained unchanged throughout the investigation, and increased obviously ($P < 0.05$) in the AP group. In comparison with the AP group, the AMY values of group HAP and THAP were significantly higher ($P < 0.05$). This result demonstrated that AP could induce mild hyperlipidemia. Albumin could not decrease the circulating lipid and AMY concentration (Table 2).

Apoptosis of pancreatic cell in rats

It was reported that the extent of acinar cell apoptosis is related to the severity of mild AP[22]. Careful biochemical and morphological examination of experimental models of AP has shown that severe AP is associated with necrosis, whereas mild acute pancreatitis is associated with apoptotic cell death[20,21]. In our study, the TUNEL methods was used for *in situ* apoptotic acinar cell identification. The apoptotic cells were not visible in the pancreas of control group, but a few apoptotic cells (brown) were visible in cerulein-induced AP animals. A subpopulation of apoptotic cells scattered throughout the tissue section was stained brown Figure 4, but the apoptotic cells did not markedly decrease after albumin therapy.

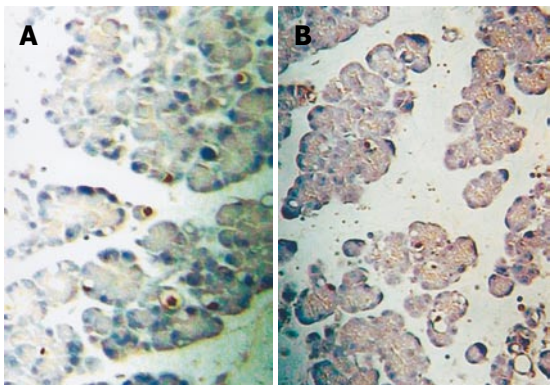

Figure 4 Detection of apoptotic cells by TUNEL in rats with AP induced by cerulein (**A**) and hyperlipidemic AP induced by cerulean and Triton WR1339 (**B**) counterstained with hematoxylin (H × 200).

Translocation of PKC in pancreatic tissue

To confirm the activation of PKC, we examined the translocation of the enzyme from the cytosol to the particulate membrane by Western blot. The cytosolic PKC gradually decreased in the control group $C_{(sal)}$, hyperlipidemic group $C_{(tri)}$, cerulein-induced AP group and HAP group. After albumin treatment the cytosolic PKC increased remarkably in group THAP. However, the particulate PKC gradually increased in the above four groups and decreased after albumin therapy (Figure 5). The degree of PKC translocation was evaluated by the proportion of particulate PKC in the total PKC as previously described[25]. The translocation rate of PKC was significantly higher ($P < 0.05$) in hyper-

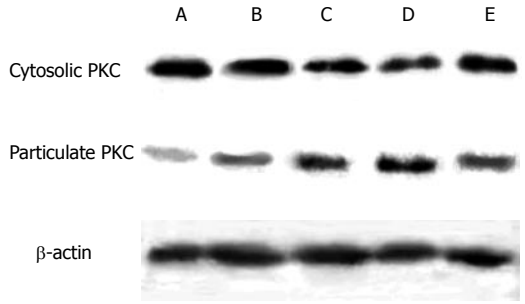

Figure 5 Effects of hyperlipidemia, AP, AP accompanying hyperlipidemia and albumin therapy on PKC membrane translocation detected by Western blot in rats of control group (A), Triton group (B), caerulein group (C), Triton+caerulein group (D), Triton+caerulein+albumin group (E).

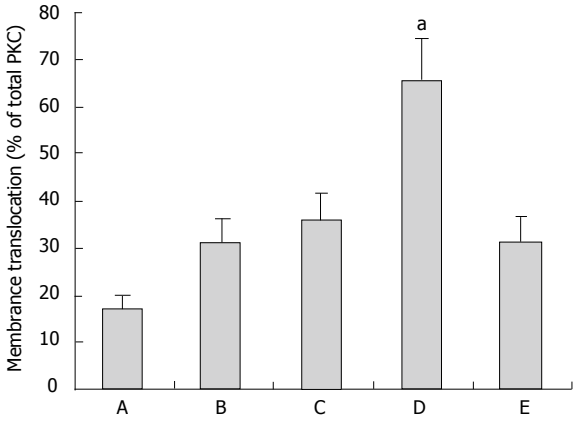

Figure 6 Effects of Triton hyperlipidemia, caerulein pancreatitis, AP with hyperlipidemia and albumin therapy on PKC membrane translocation in rats. Quantitative analysis of PKC membrane translocation level was detected by Western blot. $^{a}P < 0.05$ Triton+caerulein group *vs* caerulein and Triton+caerulein+albumin group ($n = 6$).

lipidemic AP animals (group HAP) than in non-hyperlipidemic AP rats (group AP)(Figure 6). In the hyperlipidemic AP group, the translocation rate of PKC was significantly decreased ($P < 0.01$) after albumin treatment. This result implied that hyperlipidemia could induce pancreatic PKC activation in normal and AP rats, which was consistent with the pancreatic injury. Albumin could reduce hyperlipidemia-induced PKC activation.

DISCUSSION

Hypertriglyceridemia is an etiological factor in patients with AP while TG level exceeding 1000 mg/dL or lactescent serum is a necessary condition for hyperlipidemic AP diagnosis[26]. Triton WR1339 could increase serum TG and is an ideal drug to establish hyperlipidemic animal model with TG elevation.

The rats without pancreatitis showed no clinical differences after Triton WR1339 infusion compared with saline infusion. Macroscopically, the pancreas of the hyperlipidemic and normal animals showed no difference. Microscopically, the animals treated with Triton WR1339 showed smooth edema, whereas no changes occurred in the non-hyperlipidemic animals, suggesting that severe hyperlipidemia may cause mild AP. The serum AMY activities were also slightly increased after hyperlipidemia induction, but there was no significant difference ($P > 0.05$). To investigate the effect of hyperlipidemia on AP, we established the AP model when the endogenous hyperlipidemia induced by Triton WR1339 reached its maximal value. Theoretically, significant influence of hyperlipidemia on AP would appear. We produced the hyperlipidemic AP animal model by injecting cerulein 6 h after Triton WR1339 infusion. It was reported that albumin could effectively alleviate the toxicity of TG to pancreatic cells[18]. A medium dose of albumin was injected through external iliac vein in the hyperlipidemia AP animals to observe the changes of pancreatic damage. As a result, hyperlipidemia aggravated pancreatic edema, volume of ascites and pancreatic cell apoptosis. The serum lipid in the hyperlipidemic AP animals increased compared with that in the hyperlipidemic animals, suggesting that hyperlipidemia may aggravate the course of AP while AP may exacerbate hyperlipidemia. There is a vicious circle between hyperlipidemia and AP. Accordingly, it is very important to decrease circulating lipid in clinical patients with AP. In our studies, the pancreatic damage aggravated by hyperlipidemia was not prevented by simultaneous perfusion of albumin, which might be due to the fact that the concentration of albumin in the inflamed pancreas may be too low or there may be other mechanisms of pancreatic injury. It was reported that FFAs could inhibit division and proliferation of pancreatic endocrine cells by activating PKC and induce apoptosis of pancreatic β-cells. As a result insulin secretion is decreased and diabetes occurs[27]. There is abundant PKC in pancreatic acinar cells[14]. Our study showed that FFAs could cause injury of pancreatic exocrine cells. PKC activity of pancreas increased in the hyperlipidemia and AP animals. The PKC activity changes were consistent with the degree of pancreatic injury, suggesting that PKC may participate in the course of hyperlipidemia inducing or aggravating pancreatic injury of AP. The PKC activity in hyperlipidemic AP animals was decreased significantly ($P < 0.01$) after albumin therapy, which implies that albumin may reduce the PKC activation through binding to FFAs. Although PKC activation decreased obviously ($P < 0.01$) after albumin therapy, the pancreatic injury was slightly relieved ($P > 0.05$), suggesting that PKC activation may be an important aspect of hyperlipidemia aggravating AP, and there may be other mechanisms of hyperlipidemia-induced AP.

Abstract

AIM: Microcirculatory dysfunction and free oxygen radicals are important factors in the pathogenesis of severe acute pancreatitis. Additional oxygen delivery might enhance lipid peroxidation but may also improve pancreatic microcirculation. This study assesses the effect of free cellular bovine hemoglobin on the formation of oxygen radicals and microcirculation in a rodent model of severe acute pancreatitis.

METHODS: Fifteen minutes after induction of acute pancreatitis Wistar rats received either 0.8 mL bovine hemoglobin (HBOC-200), hydroxyethyl starch (HES) or 2.4 mL of normal saline to ensure normovolemic substitution. After 6 h of examination the pancreas was excised and rapidly processed for indirect measurement of lipid peroxidation products malondialdehyde (MDA) and reduced glutathione (GSH) in pancreatic tissue.

RESULTS: The single application of HBOC-200 improved pancreatic microcirculation and reduced histopathological tissue damage significantly. Tissue concentration of MDA did not differ between the groups. Also no differences in GSH levels were detected.

CONCLUSION: Though the single application of HBOC-200 and HES improve pancreatic microcirculation, no differences in lipid peroxidation products were detected. The beneficial effect of additional oxygen supply (HBOC-200) does not lead to enhanced lipid peroxidation.

INTRODUCTION

Microcirculatory dysfunction and free oxygen radicals are important factors in the pathogenesis of acute experimental pancreatitis[1-3]. Oxygen free radicals are formed during aerobic cellular metabolism. Under physiological conditions they are eliminated by a system of enzymatic and non-enzymatic antioxidants. Under conditions of imbalance like in acute pancreatitis between antioxidants and oxidants as in hyperoxygenation, ischemia and reperfusion and tissue inflammation "oxidative stress" occurs[4-8].

Oxygen species initiate a pronounced peroxidation of membrane lipids, detectable after 30 min by a significant rise in the lipid peroxidation marker malondialdehyde (MDA), persisting up to 16 h[8,9]. At the same time a significant decrease in glutathione thiols (GSH, potent antioxidant in the pancreas) occurs[10,11]. In the human, acute pancreatitis increases the amount of lipid peroxidation products and decreases antioxidants[12-14].

It has been shown that pancreatic microcirculatory deficits can be treated with bovine haemoglobin, which improves fluidity due to its colloid effects and delivers cell free oxygen to oxygen deprived tissue[15]. However, additional application of cell free oxygen might potentially enhance detrimental O_2 radical products[16], which could limit the positive value of bovine haemoglobin in the treatment of severe acute pancreatitis.

This study assesses the relationship between free oxygen radicals and pancreatic microcirculation in a rodent model of severe acute pancreatitis after therapeutic application of a hemoglobin based oxygen carrier (HBOC).

MATERIALS AND METHODS

The experimental protocol was approved by the Ethical

Committee of the Hamburg Federal Board of Veterinary Medicine and Animal Care. After overnight fasting with free access to water containing 20% glucose, thirty female Wistar rats (230-250 g) were randomly assigned to three groups (n = 10). Anesthesia was induced by intraperitoneal pentobarbital (40 mg/kg BW) and ketamine (10 mg/kg BW) allowing spontaneous breathing by tracheostomy. Ringer lactate was infused for fluid resuscitation keeping the central venous pressure between 4 and 6 mmHg and heart rate as well as mean arterial pressure within 10% of baseline frequency throughout the experiment (Datex AS/3 monitoring system; Hoyer, Bremen, Germany).

Acute pancreatitis was induced according to a standardised regimen[17] using a combination of intravenous cerulein infusion (5 mg/kg per hour; Takus, Pharmacia, Erlangen, Germany) at a rate of 1 mL/h over 6 h and intraductal infusion of glycodeoxycholic acid (GDOC: 10 mmol/L; 1 mL/kg for 300 s; infusion pressure 25 to 30 mmHg).

Fifteen minutes after induction the animals received either 0.8 mL bovine hemoglobin (HBOC-group) (HBOC-200, Biopure MD, USA), 0.8 mL hydroxyethyl starch (HES-group 3) or 2.4 mL of normal saline (NaCl-group) to ensure normovolemic substitution. *In vivo* fluorescence microscopy was performed with an epi-illumination unit (Zeiss, Germany). Microcirculation was observed for 6 h, measurements were performed in the head of the pancreas: 0 min was defined as the intraductal infusion of GDOC. Leucocyte adherence (area of adherent leucocytes in a percentage of the vein cross section) and functional capillary density (number of perfused capillaries to the total number of capillaries) were studied. After 6 h of examination the animals were sacrificed by an intravenous injection of pentobarbital. Pancreatic tissue samples were excised for determination of tissue damage and malondialdehyde (Lipid Peroxidation Assay Kit, Calbiochem, San Diego, USA) and GSH concentrations (Glutathion Assay Kit, Calbiochem, San Diego, USA) specified in μmol/L/g protein. The samples were immediately processed and stored at -80 ℃. The Glutathione Assay Kit takes advantage of a 2-step reaction. The first step involves the formation of thioethers when a patented reagent reacts with all mercaptans (including glutathione) in the sample. The second step is an elimination reaction that takes place in alkaline conditions. This second reaction is mediated by 30% NaOH which specifically transforms the substitution product obtained with GSH into a chromophoric thione with a maximal absorbance at 400 nm. The main advantage of the method is that it does not require any enzyme as a reagent.

The Lipid Peroxidation Assay Kit takes advantage of a chromogenic reagent (10.3 mmol/L N-methyl-2-phenylindole, in acetonitrile) which reacts with MDA and 4-hydroxyalkenals at 45 ℃. Condensation of one molecule of either MDA or 4-hydroxyalkenal with 2 molecules of 10.3 mmol/L N-methyl-2-phenylindole yields a stable chromophore with maximal absorbance at 586 nm.

Tissue protein concentration was detected by using the BCA Protein Assay Reagent Kit (Pierce, Rockford, IL, USA). The BCA Protein Assay is a detergent-compatible formulation based on bicinchoninic acid (BCA) for the colometric detection and quantitation of total protein. This method combines the reduction of Cu^{+2} to Cu^{+1} by protein in an alkaline medium (the biuret reaction) with the colometric detection of the cuprous cation (Cu^{+1}) using a unique reagent containing bicinchonic acid[18].

The histopathological scoring was analyzed by light microscopy using a validated score quantifying acinar necrosis, fat necrosis and hemorrhage, leucocyte infiltration and edema[19].

Statistical analysis

Statistical analysis of the changes from baseline values in each group of animals utilized the paired Student's t-test. Significances between the groups were assessed by the unpaired t-test. $P < 0.05$ was considered significant. All data are presented as mean ± SD.

RESULTS

Results of pancreatic microcirculation and tissue damage have been reported elsewhere[15].

Microcirculation[15]

In essence pancreatic microcirculation improved in the HBOC-200-group when compared to NaCl-group [functional capillary density (fcd): 0.7 (SD 0.3) *vs* 0.33 (0.12); $P < 0.05$]; leucocyte adherence (la): 0.27 (0.14) *vs* 0.54 (0.19); $P < 0.05$). HES also improved pancreatic microcirculation when compared to NaCl-group (fcd: 0.49 (0.15) *vs* 0.33 (0.12); $P < 0.05$ and la: 0.39 (0.11) *vs* 0.54 (0.19); $P < 0.05$).

Tissue damage[15] (Figures 1-4)

The histological score showed significantly less tissue damage in HBOC-group (Figure 1) versus NaCl-group (6.25 *vs* 9.25) (range 3-8.5 *vs* 8-10.75); $P < 0.001$. The overall score is reflected within all subgroups. Comparing HES and HBOC-therapy significantly less tissue damage was found (6.25 *vs* 8) (range 3-8.5 *vs* 6.5-10.25); $P = 0.006$ in the HBOC group. When comparing HES (Figure 2) and NaCl (Figure 3) less necrosis and hemorrhaging (1.75 *vs* 2.75) (range 1.5-2.75 *vs* 2.25-3.5) was found in the HES therapy group(Figure 4).

Oxygen radicals

Tissue concentration of MDA did not differ between the groups (HBOC-200-group: 4.37 ± 1.11 μmol/L per g protein; HES-group: 3.77 ± 1.45 μmol/L per g protein; NaCl-group: 4.31 ± 1.19 μmol/L per g protein. MDA-tissue levels (n = 10) of sham operated rats were 5.41 ± 2.12 μmol/L per g protein.

Also no differences in GSH levels were detected HBOC-group: 2.93 ± 1.72 μmol/L per g; HES-group: 4.46 ± 3.55 μmol/L per g; NaCl-group: 3.7 ± 3.5 μmol/L per g. Control GSH-tissue levels (n = 10) of sham operated rats were 12.19 ± 7.04 μmol/L per g protein (Figure 5).

DISCUSSION

Clinical investigations with free hemoglobin solutions have

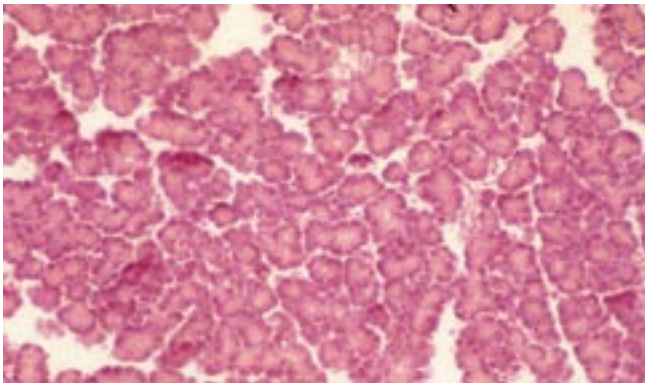

Figure 1 Light microscopy (display alternation = 200) of pacreatic tissue 6 h after induction of acute pancreatitis and traement with HBOC (score: 6 points out of 16).

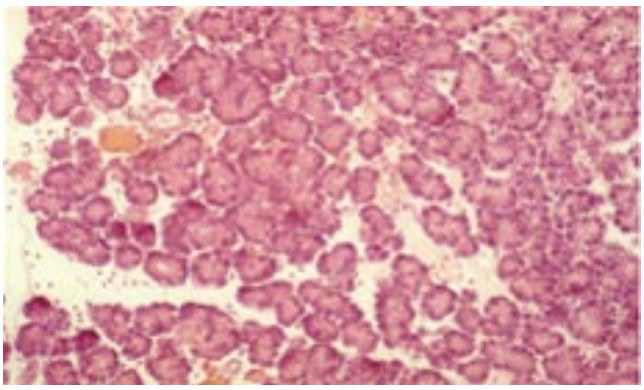

Figure 2 Light microscopy (display alternation = 200) of pacreatic tissue 6 h after induction of acute pancreatitis and traement with HES (score: 8.5 points out of 16).

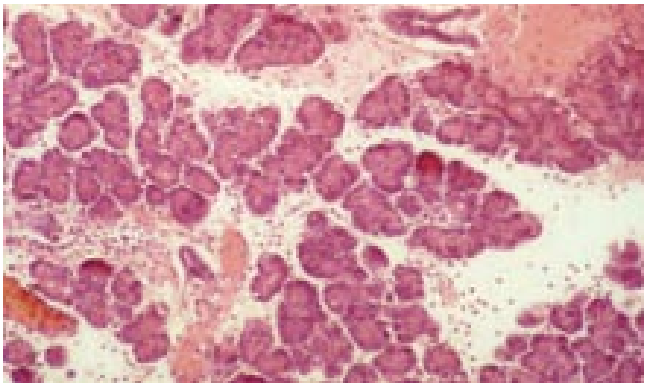

Figure 3 Light microscopy (display alternation = 200) of pacreatic tissue 6 h after induction of acute pancreatitis and treatment with NaCl (score: 10 points out of 16).

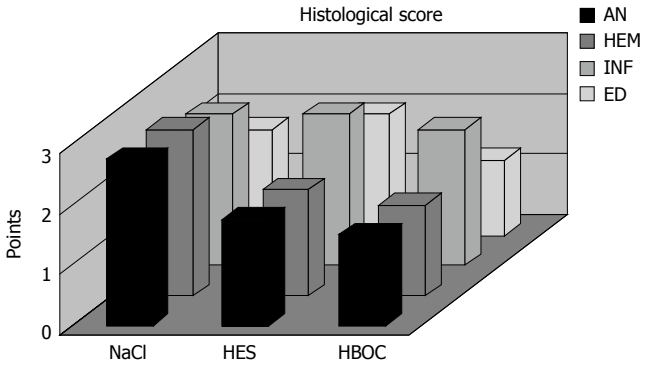

Figure 4 Histological scoring of pancreatic tissue 6 h after induction of acute pancreatitis. Values are mean ± range. (AN = acinar necrosis, HEM = hemorrhage, INF = leucocyte infiltration, ED = edema).

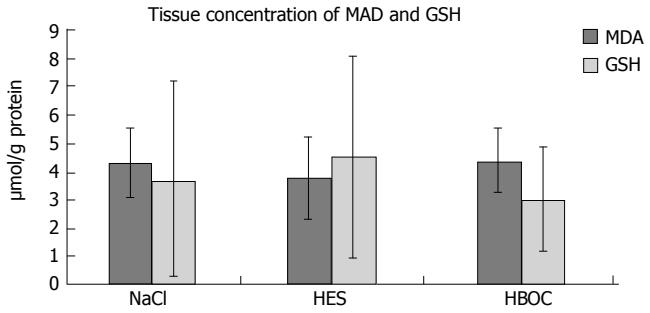

Figure 5 Tissue concentration of MDA and GSH in pancreatic tissue 6 h after induction of acute pancreatitis. Values are mean ± SD.

been performed since the late 1800 s. Over the years complications like renal toxic effects and short circulation time have been reduced. The new blood substitutes are able to replace blood, colloid and crystalloid solutions act as oxygen transporter in many experimental settings. The ability of potent oxygen transport to oxygen deprived tissue has been shown in different animal models[15,20].

Vincent *et al* investigated the influence of heme-binding proteins in heme-catalyzed oxidations. They confirmed previous studies that heme acts as a catalyst of H_2O_2-dependent lipid peroxidation[21]. It has been shown that diene conjugation caused by oxygen radicals gives an adequate assessment of lipid peroxidation in tissue extracts. Several studies emphasize the role of oxygen free radicals in the pathogenesis of experimental acute pancreatitis[1,3,22-26]. Oxygen radicals are generated by different biological systems. Sources are reperfusion injury as well as the respiratory burst of PMN-leucocytes[27-30]. Local tissue damage has successfully been treated by the use of radical scavengers[31,32]. However increased heme and oxygen availability like in HBOC-therapy might lead to higher generation of oxygen radicals and tissue damage caused by lipid peroxidation.

A single application of a hemoglobin based oxygen carrier in this model of severe acute pancreatitis reduces the tissue damage and ensures a stable microcirculation. Colloids like HES and Dextrane have also been proven to be an effective therapy for microcirculatory dysfunctions[33-36]. The superiority of HBOC[34,36,37] might be explained by the combining effect of a colloid and noncorpuscular oxygen carrier. HBOC releases oxygen in areas of poor perfundation and ensure tissue oxygenation.

However, the hypothesis that hyperoxygenation and additional oxygen supply might lead to an increased production of oxygen free radicals was not supported by this data. This study could not confirm former publications suggesting that increased heme availability promotes the enhencement of lipid peroxidation. Dunne *et al* demonstrated the reactivity of various modified hemoglobins to hydrogen peroxide in terms of free radical formation. They compared PHP hemoglobin (crosslinked between the β-subunits

and conjugated with polyoxyethylene) with DBBF hemoglobin (crosslinked between the β-subunits using dibromosalicylfumerate, and control HbA_0. All the blood substitutes generated free radicals. MDA- levels were equal in nearly all groups. When compared to sham operated animals MDA-levels in the HBOC groups reached the same levels. One explanation of this finding could be that the level of MDA and GSH might have reached their peak within the first hours of pancreatitis and decreased to normal levels after 6 h. This theory is underlined by former studies[23,32,38-39] Schoenberg *et al* determined the peroxidation products, conjugated dienes and MDA in hemorrhagic pancreatitis induced by retrograde injection of sodium-taurocholate . The tissue levels of MDA increased, reaching their highest level after 1 h. Two hours later the lipid peroxides had returned to control levels.

GSH-tissue levels also showed no statistically relevant differences in the groups. Compared to GSH-levels of sham operated rats a decrease was found which might be an indication for oxidative stress in all groups. Dabrowski *et al* were able to show a decrease in pancreatic GSH at an early stage of cerulein-induced pancreatitis in rats[40,41].

Other researchers were able to prevent local tissue damage in experimental pancreatitis by the use of radical scavenging therapy[26,31-32]. Since we could not detect differences in oxidative stress markers we would explain the reduced histopathological damage by an improved pancreatic microcirculation. An excess formation of free oxygen radicals in the setting of additional oxygen supply was not detected.

Abstract

AIM: To evaluate magnetic resonance cholangiopancreatography (MRCP) findings in conjunction with magnetic resonance (MR) images in autoimmune pancreatitis (AIP) patients.

METHODS: Nine patients with AIP underwent MRI, MRCP, endoscopic retrograde cholangiopancreatography (ERCP), computed tomography, and ultrasonography. The MRCP and MR images taken before and after steroid therapy were reviewed and compared with other imaging modalities. The MRCP findings of the AIP cases were compared to those of 10 cases with carcinoma of the head of the pancreas.

RESULTS: On MRCP, the narrowed portion of the main pancreatic duct noted on ERCP was not visualized, while the non-involved segments of the main pancreatic duct were visualized. The degree of upstream dilatation of the proximal main pancreatic duct was milder than that seen in cases of pancreatic carcinoma. Stenosis or obstruction of the lower bile duct was detected in 8 patients. MR images showed enlargement of the pancreas with decreased signal intensity on T1-weighted MR images, increased signal intensity on T2-weighted MR images, and, in 3 patients, a hypointense capsule-like rim. After steroid therapy, the previously not visualized portion of the main pancreatic duct was seen, along with improvement of the bile duct stenosis. Pancreatic enlargement decreased, and the abnormal signal intensity on both T1- and T2-weighted MR images became isointense.

CONCLUSION: MRCP cannot differentiate irregular narrowing of the main pancreatic duct seen with AIP from stenosis of the main pancreatic duct seen with pancreatic carcinoma. However, MRCP findings in conjunction with MR imaging of pancreatic enlargement that shows abnormal signal intensity on T1- and T2-weighted MR images are useful in supporting a diagnosis of AIP.

INTRODUCTION

Autoimmune pancreatitis (AIP) has recently been described as a peculiar type of chronic pancreatitis with underlying autoimmunity[1-5]. Patients with AIP almost always have enlargement of the pancreas[1-5], and their major presenting symptom (65%[6]-68%[7]) is obstructive jaundice due to obstruction of the bile duct. Since, pancreatic or bile duct carcinoma is suspected, pancreaticobiliary duct system is examined by endoscopic retrograde cholangiopancreatography (ERCP). The hallmark finding of AIP on direct pancreatogram is irregular narrowing of the main pancreatic duct; stenosis of the intra- or extrahepatic bile duct is frequently detected on cholangiography[1,2,5-7].

Magnetic resonance cholangiopancreatography (MRCP) has become popular as a non-invasive method for obtaining high quality images of the pancreaticobiliary tree[8]. Although the features of AIP on computed tomography (CT) and ERCP have been reported, the MRCP features of AIP have not been clarified. The aim of this study was to describe the MRCP findings in AIP patients before and after steroid therapy and to review the utility of MRCP for the diagnosis for AIP.

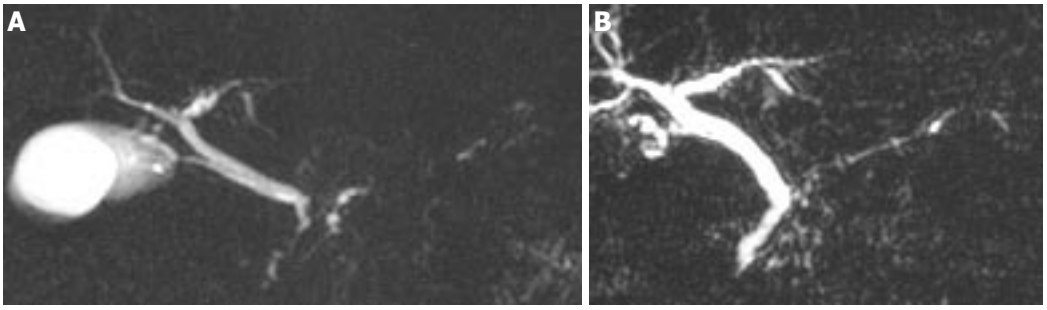

Figure 1 A: On MRCP of a patient with autoimmune pancreatitis, 2 segmentally skipped lesions of the main pancreatic duct in the head and body of the pancreas were not visualized; **B:** After steroid therapy, the entire MPD was seen on MRCP.

Table 1 ERCP and MRCP findings of patients with autoimmune pancreatitis

ERCP	MRCP
Diffuse narrowing of MPD in entire pancreas (n = 1)	Non-visualized MPD in entire pancreas (n = 1)
Segmental narrowing of MPD in the head of pancreas (n = 3)	Non-visualized MPD in the head of pancreas (n = 3)
Two skipped narrowing of MPD in the head and body of pancreas (n = 3)	Two skipped non-visualized MPD lesions in the head and body of pancreas (n = 3)
Segmental narrowing of MPD in the tail of pancreas (n = 2)	Non-visualized MPD in the tail of pancreas (n = 2)

MPD: main pancreatic duct.

MATERIALS AND METHODS

Subjects

Nine patients (6 males and 3 females, average age 60.3 years) with AIP who had MRCP in the time period from 1997 to 2005 were enrolled in this study. All patients had ERCP, ultrasonography (US), and CT. ERCP showed irregular narrowing of the main pancreatic duct in all patients [diffuse (n = 1), segmental-head (n = 3), segmentally skipped-head and body (n = 3), segmental-tail (n = 2)]. CT and US showed enlargement of the pancreas in 8 patients [diffuse (n = 3), segmental-head (n = 3), segmental-tail (n = 2)]. Six patients had elevations of serum IgG, 7 patients had elevations of serum IgG4, and 3 patients had antinuclear autoantibody. Six patients presented with obstructive jaundice. On cholangiography, stenosis of the bile duct was detected in 8 patients [lower common bile duct (n = 5) and intrahepatic and lower common bile duct (n = 3)]. All patients were given steroid treatment and responded both morphologically and serologically. From the radiological and serological findings, in addition to effectiveness of steroid treatment, all 9 patients were diagnosed as having AIP.

Methods

MRCP was done using a 1.5 T magnetic resonance imaging (MRI) machine (INTERA, PHILIPS Co Ltd, Netherlands) by coronal heavily T2-weighted single-shot rapid acquisition with relaxation enhancement. The MRCP and MR images taken before and after steroid therapy were reviewed and compared with other imaging modalities. The MRCP findings of the AIP cases were compared to those of 10 cases with carcinoma of the head of the pancreas.

RESULTS

The narrowed portion of the main pancreatic duct seen on ERCP was not visualized on MRCP, while the non-involved segments of the main pancreatic duct were seen on MRCP. On MRCP, the entire main pancreatic duct was not seen in 1 patient in whom the main pancreatic duct showed diffuse narrowing on ERCP. In 3 patients in whom the main pancreatic duct was segmentally narrowed in the head region on ERCP, the MRCP visualized the main pancreatic duct only in the body and tail of the pancreas, but not in the head region. In 2 patients, MRCP showed the main pancreatic duct only in the head and body of the pancreas, but not in the tail region. On MRCP, 2 segmentally skipped lesions of the main pancreatic duct in the head and body of the pancreas were not visualized in 3 patients (Figure 1A and Table 1). Although upstream dilatation of the proximal main pancreatic duct was detected in 6 patients, the degree of dilatation was milder than that in cases of pancreatic carcinoma. Stenosis or obstruction of the lower bile duct was detected in 8 patients, of whom 3 patients also showed stenosis of the intrahepatic bile duct accompanied by dilatation of the proximal bile duct, similar to the findings on ERCP.

All patients showed enlargement of the pancreas with abnormal signal intensity on T1- and T2-weighted images, though the degree of abnormal intensity was different among the cases. On T1-weighted MR images, the signal intensity of the affected pancreatic lesion was decreased compared to the signal intensity in the liver (Figure 2A). T2-weighted MR images showed increased signal intensity in the pancreatic parenchyma compared to that of the liver (Figure 2B). A capsule-like rim, which was hypointense on both T1- and T2-weighted images, was detected in 3 patients.

After steroid therapy, the portion of the main pancreatic duct that was previously not visualized on MRCP was seen (Figure 1B), and an improvement of the upstream dilatation of the proximal main pancreatic duct was evident. Stenosis or obstruction of the lower or hilar bile duct was found to be improved. The enlarged pancreas became normal in size (n = 6) or atrophic (n =

Figure 2 **A:** On T1-weighted MR images of a patient with autoimmune pancreatitis, the signal intensity of the affected pancreatic lesion was slightly decreased compared to the signal intensity in the liver; **B:** T2-weighted MR images showed increased signal intensity in the pancreatic parenchyma than that of the liver with a capsule-like rim which was hypointense; **C:** After steroid therapy, the enlarged pancreas became atrophic on T1-weighted MR images.

3) after steroid therapy. In all patients on both T1- and T2-weighted MR images, the abnormal signal intensity improved to being isointense with that of the liver, and the capsule-like rim disappeared (Figure 2C).

DISCUSSION

Since Yoshida *et al*[9] first proposed the existence of AIP in 1995, many cases of AIP have been reported. This unique form of chronic pancreatitis appears to be a distinct disease entity. AIP occurs predominantly in elderly males and frequently presents as obstructive jaundice[1,2,5-7]. This presentation is also typical of pancreatic carcinoma. As most patients with AIP respond to oral steroid therapy, an accurate diagnosis of AIP is necessary to avoid unnecessary laparotomy or pancreatic resection. Recently, MRCP has become a viable alternative to diagnostic ERCP as a non-invasive method for obtaining high quality images of the pancreaticobiliary tree[8]. We compared MRCP findings and MR images before and after steroid therapy in AIP patients.

The characteristic radiological images of AIP include irregular narrowing of the main pancreatic duct on ERCP and enlargement of the pancreas on CT and US[1-3,5-7]. The irregular narrowing of the main pancreatic duct on direct pancreatography, which is usually longer than the stenosis of the main pancreatic duct detected in patients with pancreatic carcinoma, is one of the useful findings that differentiate AIP from pancreatic carcinoma[1,3,10]. In the present study, the narrowing of the main pancreatic duct on ERCP was not visualized on MRCP, while the other region of the main pancreatic duct was visualized. After steroid therapy, the previously unvisualized lesions of the main pancreatic duct were seen. Thus, non-visualization of the main pancreatic duct might suggest narrowing of the main pancreatic duct. MRCP cannot differentiate irregular narrowing of the main pancreatic duct from stenosis of the main pancreatic duct in pancreatic carcinoma; thus, ERCP is necessary to diagnose AIP. However, MRCP findings of skipped, non-visualized main pancreatic duct lesions, accompanied by a lesser degree of upstream main pancreatic duct dilatation than that seen in pancreatic carcinoma, might suggest the presence of AIP. The MRCP of AIP patients frequently showed stenosis of the intra- or extrahepatic bile duct. T1-weighted MR images of AIP patients showed enlargement of the pancreas with decreased signal intensity, while T2-weighted MR images showed increased signal intensity, sometimes associated with a hypointense capsule-like rim in the involved segments. In previous reports, a decreased signal intensity on T1-weighted MR images, reflecting fibrosis in the pancreatic parenchyma, has been reported. Irie *et al*.[11] noted the hypointense capsule-like rim in the involved segment on T2-weighted MR images; this appears to be a characteristic finding of AIP, and is thought to be related to an inflammatory process involving peripancreatic tissue.

There have been no previous reports dealing with the change in the intensity in the pancreas of patients with AIP after steroid therapy. In the present study, on both T1- and T2-weighted MR images, abnormal signal intensity of the pancreas improved to isointensity with that of the liver. The enlargement of the pancreas and the capsule-like rim disappeared. Thus, MRCP and MR images are useful for evaluating the effectiveness of steroid therapy.

In conclusion, MRCP cannot differentiate the irregular narrowing of the main pancreatic duct seen with AIP from the stenosis of the main pancreatic duct seen with pancreatic carcinoma. However, the MRCP findings of skipped, non-visualized main pancreatic duct lesions, accompanied by a lesser degree of upstream dilatation of the main pancreatic duct, might suggest the presence of AIP. These MRCP findings, in conjunction with MR images of pancreatic enlargement showing abnormal signal intensity on T1- and T2-weighted MR images, are useful in supporting a diagnosis of AIP.

Abstract

AIM: The use of low-dose aspirin to prevent cardiovascular disease events is well established. However, the incidence and predictors of upper gastrointestinal bleeding (UGIB) with its use are unknown. We studied prospectively the incidence and outcome of peptic ulceration in low-dose aspirin users.

METHODS: A total of 991 patients with coronary artery disease (CAD) on low-dose aspirin were prospectively followed-up for two years for the occurrence and clinical features of first hospitalized episode of UGIB.

RESULTS: UGIB had a bimodal presentation with 45% occurring within four months of aspirin initiation and had an overall prevalence of 1.5% per year. There was no UGIB-related death. Hypertension (*OR* = 4.6, 95%CI 1.5 - 14.7, *P* = 0.009), history of peptic ulceration (*OR* = 3.1, 95%CI 1.1 - 9.0, *P* = 0.039), tertiary education (*OR* = 3.08, 95%CI 1.1 - 9.0, *P* = 0.039) and higher lean body mass (*P* = 0.016) were independent factors associated with UGIB. Use of nitrate did not reduce UGIB.

CONCLUSION: The incidence of UGIB in patients with CAD on long-term low-dose aspirin is low, but is accompanied with significant morbidity. With prolonged use of aspirin, UGIB continues to be a problem for those with risk factors and especially in patients with a history of peptic ulcers, in which UGIB tends to occur early after aspirin therapy.

INTRODUCTION

Anti-platelet therapy with low-dose aspirin (75-325 mg) reduces the risk of vascular events in patients with established coronary artery disease (CAD)[1-3]. However, the use of aspirin, even at a low dose for secondary prevention of cardiovascular events, is associated with a small but significant increase in the risk of upper gastrointestinal bleeding (UGIB). In addition, previous studies have also reported several risk factors, such as the use of non-steroidal anti-inflammatory drugs (NSAIDs) and old age, implicated in the development of UGIB in patients taking aspirin[4-8]. However, the incidence of aspirin-related UGIB in patients with CAD for the secondary prevention of cardiovascular events and the time frame of UGIB occurrence are uncertain. In addition, effects of several emerging therapies, such as the use of dual antiplatelet agents, nitrate or ulcer-protecting drugs for the development of UGIB, have not been systematically evaluated.

In a cohort of patients with established CAD recruited into a Cardiac Rehabilitation Programme, we prospectively monitored the time of occurrence of UGIB in patients taking low-dose aspirin for the secondary prevention of

cardiovascular events over two years. We also sought to determine the possible predictive factors associated with UGIB.

MATERIALS AND METHODS

Study population

In this prospective study, we recruited all patients with established ischemic heart disease (myocardial infarction, angina pectoris, angiographic-proven coronary artery disease) referred to a Cardiac Rehabilitation Programme in Tung Wah Hospital (an University-affiliated hospital) between September 1997 and April 2002. All the patients were started on low-dose aspirin (75-300 mg) according to referring physicians' discretion. Apart from collecting data on demographics, other parameters related to cardiac rehabilitation like education level, functional class, left ventricular function, exercise capacity, body mass index, body fat content, body lean mass content, medications used were also recorded. A database was specially designed to collect the required information prospectively. Patients were followed-up once every 3-4 mo and the occurrence of UGIB was noted. Detailed information about each UGIB event was obtained from interpretation and review of hospital records.

Upper gastrointestinal bleeding

The occurrence of UGIB was defined as the clinical presentation of hematemesis or passage of melena or unexplained drop in hemoglobin of $\geqslant$ 20 g/L. Upper gastrointestinal endoscopy with therapeutic intervention(s) to obtain haemostasis (using epinephrine injection or heater probe application, when needed) was performed in all these patients presented with UGIB. *Helicobacter pylori* (*H pylori*) status was determined using a 24-h rapid urease test on antral biopsy specimens and histological detection of *Helicobacter*-like organisms using the haematoxylin and eosin stain, and Giemsa stain on biopsies taken from the gastric antrum and/or body. The rapid urease test at 24 h has been validated in our hospital with a sensitivity and specificity of 99% and 100%, respectively[9]. In addition, the use of histological examination of these biopsy specimens, the *H pylori* status was correctly evaluated even in patients with active UGIB, with the understanding that rapid urease test would be rendered inaccurate at those situations.

Statistical analysis

Univariate analyses were performed, using Student's *t* test and Mann-Whitney *U* test for continuous variables and Chi-square test or Fisher's exact test for categorical variables to assess the risk factors associated with UGIB. A multiple logistic regression model was designed to determine the factors (age, gender, educational level, occupation, hypertension, diabetes mellitus, renal impairment, history of peptic ulcer diseases, lean body mass, body fat, obesity, New York Heart Association (NYHA) functional class, left ventricular function, use of dual anti-platelet agents/NSAID/ulcer protective drug) associated with UGIB. To find the best model, a backward elimination stepwise procedure was carried out such that the factor would be eliminated from the analysis if the corresponding *P* value was greater than 0.15. A two-tailed *P* value of 0.05 or less was considered statistically significant.

Table 1 Baseline characteristics of 991 patients with coronary artery disease started on low-dose aspirin (mean ± SD, *n*, %)

	No UGIB (*n* = 962)	UGIB (*n* = 29)	*P* values

RESULTS

Characteristics of patients and incidence of upper gastrointestinal bleeding (Table 1)

Between September 1997 and April 2002, a total of 991 patients with established ischemic heart disease were enrolled into the study and followed-up prospectively for two years. Of these, 716 (72.3%) were male (mean age, 64.8 ± 11 years); 552 (55.7%) had history of myocardial infarction (MI); 541 (54.8%) were hypertensive; 352 (35.5%) had diabetic mellitus; and 546 (54.7%) patients were smokers. Nitrate use was found in 561 (57.1%) patients. One hundred and twelve patients (11.3%) had received tertiary education. Twenty-nine patients developed UGIB over a follow-up period of two years, giving the incidence of 1.5% per year. For those who had a bleeding event, 72% did not have new-onset ulcer pain; 52% required blood transfusion (mean, 3.3 units; range, 1-8 units); 62% with a drop in hemoglobin of greater than 3 g/dL; 24% of these patients required more than one therapeutic upper gastrointestinal endoscopies for haemostasis. Peptic ulceration was the main cause of UGIB in our series (gastric ulcer, 38%; duodenum ulcer, 52%); aspirin-related hemorrhagic gastritis did not occur in our cohort. *H pylori* positivity status was present in 50% of patients presented with UGIB.

Of those who had UGIB, 21% of all the events occurred in the first month and 45% occurred in the first 4 mo after initiation of low-dose aspirin (early bleeders) (Figure 1). The 'late bleeders' (55%) developed UGIB at a mean of 20.8 ± 5.3 mo after initiation of therapy, with 88% (14/16) of them bled at least once after one year of aspirin therapy. In addition, about a third of those

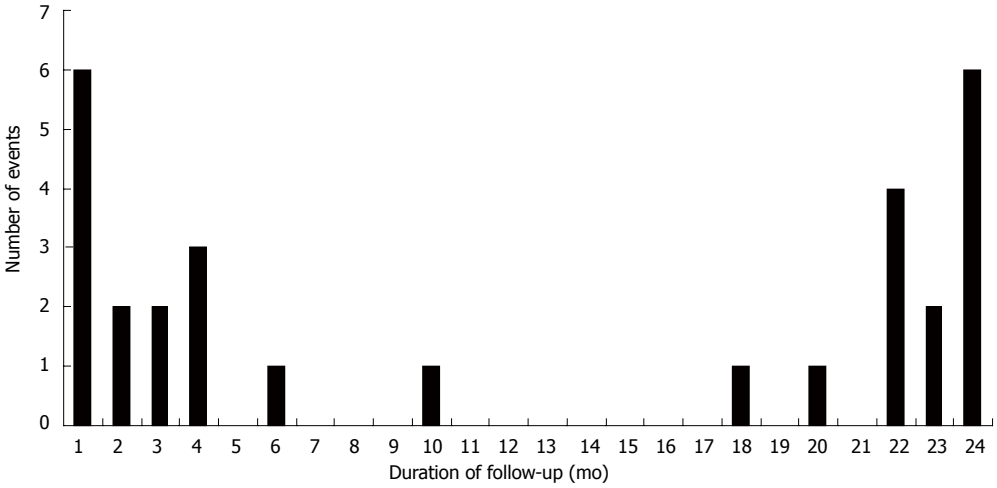

Figure 1 Bimodal presentation of upper gastrointestinal bleeding events in a two-year follow-up period.

who presented with UGIB (9/29) had a history of peptic ulcer/GIB/gastrectomy, in which 56% (5/9) of them were early bleeders. This indicates a 1:8 chance of having UGIB in patients with history of peptic ulceration while started on low-dose aspirin, which have a tendency to have early bleeding event; 97% of patients with UGIB required hospitalization. Death or myocardial infarction did not occur during the UGIB episodes and no patient required surgery for treatment of the UGIB. Nitrate use was recorded in 62% of the bleeders; 21% of those who had an UGIB were on ulcer-protecting drugs during presentation, but only 10% of them reported concurrent use of NSAID.

Predictors of UGIB

Univariate analyses showed that the presence of hypertension (*OR* = 3.1, 95%*CI* 1.3 - 7.7, *P* = 0.008), renal impairment (*OR* = 4.8, 95%*CI* 1.7 - 13.1, *P* = 0.001), history of peptic ulcer (*OR* = 4.6, 95%*CI* 2.0 - 10.7, *P* = 0.002), patients with impaired left ventricle function (EF < 40%) (*P* = 0.034) or NYHA functional class III-IV (*OR* = 3.0, 95%*CI* 1.2 - 7.6, *P* = 0.048), patients with high lean body mass (70% ± 7% *vs* 66% ± 8%, *P* = 0.049) or low body fat content (30% ± 7% *vs* 34% ± 7%, *P* = 0.036) and patients with tertiary education (*OR* = 3.1, 95%*CI* 1.1 - 9.0, *P* = 0.05) were predictors of the development of UGIB. Use of anti-ulcer therapy (in small number of patients) was not associated in prevention of UGIB. The use of nitrate did not reduce the risk of UGIB (*P* = 0.09). However, multivariate analyses using a logistic regression model demonstrated that only patients with hypertension (*OR* = 4.63, 95%*CI* 1.5 - 14.7, *P* = 0.009), history of peptic ulcer (*OR* = 3.1, 95%*CI* 1.1 - 9.0, *P* = 0.039), tertiary education (*OR* = 3.1, 95%CI 1.1 - 9.0, *P* = 0.039) or with high lean body mass (707% ± 7% *vs* 667% ± 8%, *P* = 0.0157) had a higher probability of UGIB while taking low-dose aspirin for secondary prevention of cardiovascular events (Table 2).

Table 2 Multivariate analysis of predictors of upper gastrointestinal bleeding in patients with coronary artery disease on low-dose aspirin (mean ± SD)

	95%*CI*	Odds ratio	*P* values
Education level (tertiary)	1.05 - 8.98	3.08	0.039
Hypertension	1.46 - 14.74	4.63	0.009
History of peptic ulcer	1.05 - 9.00	3.08	0.039
% Lean body mass (body fat content)			0.0157

DISCUSSION

To the best of our knowledge, this is the first prospective study for the first UGIB in patients started with low-dose aspirin for secondary prevention of cardiovascular events. UGIB occurred at a rate of 1.5% per year, and was due to peptic ulceration that required hospitalization and blood transfusion. Twenty-four percent of those with UGIB required more than one therapeutic endoscopy to secure haemostasis. On the other hand, new-onset ulcer syndrome was not present in majority of those patients that developed an UGIB. These data also showed that when patients started with low-dose aspirin and bled subsequently, 21% of them had the event in the first month of treatment, 45% of all bleeding events occurred in the first 4 mo of starting low-dose aspirin; whereas most of the other bleeding events took place after at least one year of therapy. This observation implies that not only the risk of UGIB associated with low-dose aspirin use does not decrease with time, rather, there exists a bimodal presentation of the event in our series with one peak occurring in the early phase of starting treatment and the second occurred beyond the first year. This is in contrary to previous studies, in which the rate of UGIB occurred in a constant fashion throughout the entire period of study[4,8]. There are several possible explanations for the difference. Unlike other studies, we prospectively recorded first episode of UGIB after aspirin initiation instead of recruiting those presenting with the event[5]. In addition, others reported the use of a higher-dose of aspirin for the prevention of cardiovascular events[6]. Furthermore, some animal studies reported the possibility of adaptation of the gastric mucosa to aspirin therapy with time, and this might explain why patients begin to have less bleeding after receiving several mo of aspirin therapy[14].

We demonstrated the predictors of UGIB events for patients taking low-dose aspirin. Better-educated people

were more likely to experience UGIB (*OR* = 3.1, the odds of UGIB was about 3 times more among people who received tertiary education than those who received secondary education or less). One explanation is that better educated people might be more compliant to prescribed medications, and they generally have much higher pressure/stress at work, and hence have a higher incidence of UGIB[10-11]. Consistent to previous reports, patients with a past history of peptic ulcer problems or UGIB were still at high risk of developing UGIB despite the use of low-dose aspirin[4]. Furthermore, we showed that most of them bled early on initiation of aspirin and thus deserve treatment for ulcer prophylaxis. In our study, patients with hypertension had the highest odds ratio for developing UGIB, concur with the traditional association between hypertension and the development of peptic ulcer[15]. Another interesting finding was that patients with a higher lean body mass had a higher probability for having an UGIB. A recent report suggested that obese patients are more prone to the development of aspirin resistance[12], so whether non-obese patients with slender-build (and hence a higher lean body mass content) are more susceptible to aspirin effect, including its toxicity on the stomach, will need further evaluation. Unlike a previous report[4], the use of nitrate was not linked to a reduction of UGIB in our study (P = 0.09). This may be due to a purely statistical problem as a large majority (57.1%) of the CAD patients in our cohort were on nitrate, which might mask the protective effect, if any of the latter; alternatively, other confounding factors, such as hypertension, leaner subjects in our series, might negate the effect of nitrate. The presence of renal impairment or heart failure/left ventricular dysfunction was believed to be predictors of UGIB as reported in our series using an univariate analysis, but these factors dropped out after multivariate adjustment. This might be due to the small number of events recorded in the present cohort. Our patients were younger (mean, 65 years; range, 35-87 years) compared to those in the previous study. With this age range, age appears not to be a predictive factor for UGIB.

The incidence of UGIB event in patients with CAD started on low-dose aspirin was low, and if occurred, was associated with good clinical outcome though most patients required hospitalisation. Nevertheless, with better understanding of the pathogenesis of the former and, in particular, its relation to *H pylori* status, our group has reported a possible method for the prevention of recurrence of peptic ulcer complication from long-term low-dose aspirin use[12]. On the other hand, our study showed that certain high-risk group of patients, especially those with history of peptic ulceration who tend to have early UGIB, should be target for primary prevention of peptic ulceration development and continued surveillance needed as well for these patients while on low-dose aspirin.

The small number of patients in our cohort that were on regular NSAID (1.1%) might not be able to show its deleterious effect on patients taking low-dose aspirin. Likewise, there was insufficient number of patients taking ulcer-protecting agents 21% to show a statistically significant benefit for patients taking these medications for ulcer prevention. However, the low usage of NSAID and ulcer-protecting drugs allowed us to determine the natural history of UGIB secondary to low-dose aspirin in this patient cohort, in which future therapeutic strategy can be planned. Finally, we failed to obtain the *H pylori* status for all patients, Regardless of whether they had or had not had an event, from which the value of that might be much more elicited. In addition, serological assay for *H pylori* infection was not universally available at time of our study. Nevertheless, local study reported that 55% of the population was infected with *H pylori* though symptoms and clinical disease developed in only a minority of infected individuals during their lifetime[13].

In summary, the incidence of UGIB in patients with CAD on low-dose aspirin remains low at 1.5% per year. Patients with hypertension, history of peptic ulcer problem, low body fat content (high lean body mass) and those that had received tertiary education were at risk of having an UGIB event. There exists bimodal presentation of the UGIB event with the early bleeders presenting in the first few months of starting treatment and the late bleeders after at least one year of therapy. Patients who had an event were likely to be hospitalized and required blood transfusion.

Abstract

AIM: To explore the susceptibility of children to intrauterine HBV infection by studying the relationship between IFN-γ gene polymorphism, including IFN-γ+874A/T single nucleotide polymorphism(SNP) and CA repeat microsatellite polymorphism and intrauterine HBV infection.

METHODS: A TaqMan fluorescence polymerase chain reaction in the IFN-γ+874A/T single nucleotide polymorphism was tested in the intrauterine HBV infection group(group I) and the normal immune children group(group II). Capillary electrophoresis was performed in the above two groups to assay the IFN-γ CA repeat microsatellite polymorphism.

RESULTS: Frequencies of AA, AT and TT genotypes were 67.4%, 19.6% and 13.0% in the intrauterine HBV infection group, and 45.2%, 30.1% and 24.7% in the normal immune children group, respectively. A significant difference was found in the frequency distribution of IFN-γ+874 genotype between the two groups (χ^2 = 5.102, P = 0.02389). In the intrauterine HBV infection group the AA genotype was more common than in the normal immune group. Frequency of IFN-γ+874A allele was 77.17% in the intrauterine HBV infection group, and 60.27% in the normal immune children group. In the intrauterine HBV infection group the IFN-γ+874A allele was more common than in normal immune group. A significant difference was found in the frequency distribution between the two groups (χ^2 = 7.238, P = 0.02389, OR = 2.228, 95% CI = 1.244-3.992). $(CA_{12})^+/(CA_{12})^+$ of IFN-γ CA microsatellite polymorphism was 11.90% in the intrauterine HBV infection group and 26.47% in the normal immune children group. A significant difference was found in the frequency distribution between the two groups (χ^2 = 5.64, P = 0.0176). Frequency of IFN-γ CA repeat was 25% in the intrauterine HBV infection group and 43.38% in the normal immune children group. The frequency of IFN-γ CA repeat was less in the intrauterine HBV infection group than in normal immune group. A significant difference was found in the frequency distribution between the two groups (χ^2 = 7.548, P = 0.0060).

CONCLUSION: There is a relationship between IFN-γ+874A/T SNP and intrauterine HBV infection as well as between IFN-γ CA microsatellite polymorphism and intrauterine HBV infection. IFN-γ gene polymorphism might be important in determining individual's susceptibility to intrauterine HBV infection.

INTRODUCTION

IFN-γ+874A/T SNP within the first intron can increase or decrease the binding of a particular transcription factor and ultimately the export of cytokine product[1-2]. The registered DNA sequences of the human IFN-γ gene deposited in Genbank show the presence of a CA repeat element in the first intron, 875 bp downstream from the start of the first exon. There are seven CA repeats of variable lengths In a consecutive study, 12 CA repeats are confirmed its role as a marker of high IFN-γ production[2]. We have reported in a previous study that higher IFN-γ secretion than spontaneous secretion could be found in the intrauterine HBV infection group and the normal immune children group with HBsAg stimulation, but the increase in the intrauterine HBV infection group is strikingly lower than that in the normal immune children group[3]. IFN-γ production is positively associated with IFN-γmRNA expression[3]. In the present study, we studied the IFN-γ+874 SNP and CA repeat microsatellite polymorphism in the intrauterine HBV infection group and the normal immune children group in order to explore the association between IFN-γ gene polymorphisms and susceptibility to intrauterine HBV infection.

MATERIALS AND METHODS

Subjects

The subjects were selected from outpatients who were in our hepatitis B (HB) vaccine follow up clinics. These subjects whose mothers were HBV carriers were inoculated with HB vaccine or HB vaccine plus hepatitis B immunoglobulin (HBIg) and followed up for serum alanine transaminase (ALT) and HBV marker. Intrauterine HBV-infected children were defined based on their positive HBsAg and/or HBV-DNA at birth and lasting for six months (group I). Normal immune children were defined based on their negative HBV marker after birth and high HBsAb titers (group II). ALT of all subjects was normal.

TaqMan fluorescence polymerase chain reaction

Genomic DNA was extracted from peripheral blood using the kits supplied by Sangon Bioengineering Company (Shanghai, China). Polymorphisms at +874 were identified using the ABI Prism 7700 fluorescent automatic sequencer. PCR products were obtained after amplification in a 10 μL volume containing 1×Taqman buffer A, 200 μmmol/L(each) dATP, dCTP, dGTP, 400 μmmol/LdUTP, 3.5 mmol/L $MgCl_2$, 300 μmmol/Lβ-actin forward primer, 300 μmmol/L β-actin reverse primer, 200 μmmol/Lβ-actin probe, AmpliTaq Gold, 0.025 U/μL DNA polymerase, 0.01 U/μL AmpErase UNG, 900 nmmol/L(each) forward & reverse primers, 250 nmol/L TaqMan MGB probe, 20ng DNA template. The forward primer sequence is 5'-ACA TTC CAC AAT TGA TTT TAT TCT TAC AAC A-3'. The reverse primer sequence is 5'-ACG AGC TTT AAA AGA TAG TTC CAA ACA-3'. The TaqMan MGB probe sequences are as follows: Fam: AAA TCA AAT CtC ACA CAC ACA C; Vic: AAA TCA AAT CaC ACA CAC ACA C. Forty-five cycles of PCR amplification were performed at 50 ℃ for 2 min, at 95 ℃ for 10 min, at 95 ℃ for 30 s and at 60 ℃ for 30 s.

Capillary electrophoresis

DNA was amplified in a 7.5 μL reaction volume containing 0.75 μL of 10 × buffer, 0.75 μL 25 mmol/L $MgCl_2$, 0.75 μL 2.5 μmmol/LdNTP, 2.5 U/μL Taq Gold, 0.06 μL DNA polymerase, 1 μL (each) forward & reverse primers, 2 μL DNA template, 1.19 μL ddH_2O. The forward primer sequence is CTT CGT TGC TCA CTG GGA TT-6-FAM. The reverse primer sequence is GCA AAG CCA CCC CAC TAT AA. The microsatellite region in the first intron of the IFN-γ gene was amplified on a PTC-100 thermal cycler. Following an initial denaturation (12 min at 95 ℃), samples were subjected to 10 cycles of PCR amplification, for each cycle, the sample was amplified at 94 ℃ for 30 s, at 53 ℃ for 30 s, at 75 ℃ for 45 s, followed by 30 cycles at 89 ℃ for 30 s, at 53 ℃ for 30 s, at 75 ℃ for 45 s, and a final extension at 4 ℃. The IFN-γ CA repeat microsatellite polymorphisms were monitored by ABI PRISM 3700 capillary electrophoresis automatic analysis.

Statistical analysis

IFN-γ+874A/T allele frequencies and IFN-γ CA microsatellite frequencies were evaluated by gene count. Allelic frequency was calculated with the following equation: allelic frequency = $n/2N$ (n represents the number of alleles, and N represents the total number of subjects). Allelic frequencies were compared using the chi-square test. A P value less than 0.05 was considered statistically significant. The strength of an association was expressed as odds ratio (OR) with 95% confidence interval. STATA 6.0 software was used to determine the statistical significance.

Table 1 Clinical characteristics of patients and controls

RESULTS

General clinical characteristics

No significant difference was found in sex, HBeAg positivity of mother and HBIg injection to pregnant women between the two groups (Table 1).

IFN-γ+874A/T SNP

The distribution of IFN-γ+874A/T allele frequencies in two groups was in accordance with Hardy-Weinberg hereditary equilibrium law. Frequencies of AA, AT and TT genotypes were 67.4%, 19.6% and 13.0% in the intrauterine HBV infection group and 45.2%, 30.1% and 24.7% in the normal immune children group, respectively. A significant difference was found in the frequency distribution of IFN-γ+874 genotype between the two groups ($\chi^2 = 5.102$, $P = 0.02389$). In the intrauterine HBV infection group, the AA genotype was more common than in normal immune group (Table 2). Frequency of IFN-γ+874A allele was 77.17% in the intrauterine HBV infection group and 60.27% in the normal immune children group. In the intrauterine HBV infection group, the IFN-γ+874A allele was more common than in normal immune group. A significant difference was found in the frequency distribution between the two groups ($\chi^2 = 7.238$, $P = 0.02389$, OR = 2.228, 95%CI1.244-3.992)(Table 3).

Table 3 +874T and +874A IFN-γ allele frequencies in patients and controls

DISCUSSION

The clinical features of HBV infection depend on the activities of the host immune response and the virus. The cell-mediated immune response to HBV-encoded antigen is responsible both for viral clearance and for disease pathogenesis during this infection. T-helper lymphocyte response mediated through secretion of IFN-γ plays an important role in inducing viral clearance[4]. During the early aspecific phase of host defence, production of IFN-γ by natural killer(NK) cells plays an important role in bringing about acute inflammation. In the subsequent antigen-specific phase of the immune response, IFN-γ acts as a regulator of antigen presentation and proliferation as well as differentiation of lymphocytes. High-level production of IFN-γ during this phase plays an important role in viral clearance[5-6].

Cytokine production is genetically controlled. The cytokine genes SNPs in cis-acting regions can alter transcriptional activity and are associated with the production of cytokine[7]. Genetic susceptibility to diseases is likely influenced by common DNA variants in the form of SNPs[8-9]. Pravica *et al*[2] described a variable length CA repeat sequence in the first intron of the human IFN-γ gene and showed that 12 CA repeat is associated with high *in vitro* IFN-γ production. In a further study, a SNP T to A at the end of the CA repeat region in the first intron of the human IFN-γ gene(+874A/T) was described, showing an absolute correlation between the T allele and the high IFN-γ microsatellite polymorphism. The +874T allele is associated with the high production of genotype and the +874A allele is associated with the low production of genotype[10]. *In vitro* production of IFN-γ has a significant correlation with the CA microsatellite polymorphism. Twelve CA repeats have been shown to have a higher expression of IFN-γ[11-12]. Japanese researchers[13] have reported the frequencies of 13 CA repeats are significantly greater in patients with IgA nephropathy than in the healthy control group (43% versus 23%, $P<0.05$). High production of genotype (12 CA repeats) for IFN-γ may have an influence on acute rejection of kidney transplants[14]. The frequency of the IFN-γ12 CA repeats is significantly greater in WHO class V lupus nephritis patients than in WHO class IV patients[15]. Susceptibility to and severity of rheumatoid arthritis are related to a microsatellite polymorphism

within the first intron of the IFN-γ gene[16]. There is a highly significant increase in the low-production of IFN-γ genotype(13 CA repeats) in patients with type 1 diabetes compared with normal healthy controls[17]. This result suggests that polymorphisms of the IFN-γ gene may modify the function of this proinflammatory mediator and the response to pancreatic islet βcells. This +874A/T polymorphism coincides with a putative NF-Kappa B binding site, which might have functional consequences for transcription of human IFN-γ gene. Therefore, the T to A polymorphism might directly influence the level of IFN-γ production associated with the CA microsatellite polymorphism[18]. Patients with tuberculosis have a lower frequency of +874TT genotype than the controls, suggesting that genetically determined variability in IFN-γ and expression might be important for the development of tuberculosis[19]. A significant correlation has been detected between the presence of high-expression polymorphisms of the IFN-γ genes and bronchiolitis obliteration syndrome(BOS) after lung transplantation($P = 0.039$). +874TT of the IFN-γ gene significantly increases the risk of BOS after lung transplantation[20]. There is no report on the relationship between IFN-γ gene polymorphism and susceptibility to intrauterine HBV infection.

In this study, the frequency of the +874AA genotype of the IFN-γ was greater in the intrauterine HBV infection group than in normal immune group, the $(CA_{12})^+/(CA_{12})^+$ of IFN-γ CA microsatellite polymorphism was 11.90% in the intrauterine HBV infection group and 26.47% in the normal immune children group. A significant difference was found in the frequency distribution between the two groups($\chi^2 = 5.640$, $P = 0.0176$). The frequency of IFN-γ CA repeat was less in the intrauterine HBV infection group than in the normal immune group. A significant difference was found in the frequency distribution between the two groups($\chi^2 = 7.548$, $P = 0.0060$). The findings suggest that the presence of low-expression polymorphism at +874 of the IFN-γ gene significantly increases susceptibility to intrauterine HBV infection. IFN-γ gene polymorphism might be important in determining an individual's susceptibility to intrauterine HBV infection and might result in viral persistence.

Abstract

AIM: To prospectively study the incidence and the natural history of acute diverticulitis in young patients.

METHODS: A total of 207 patients hospitalized at our hospital between January 2000 to February 2005 with the diagnosis of acute diverticulitis were included. Their demographic characteristics, medical history, physical, radiographic and endoscopic findings as well as therapy were recorded. Patients were followed every 6 mo for the first year and later annually.

RESULTS: The mean patients' age was 61 (range 27-92) years. Twenty- five patients (12%) were younger than 45 years. Acute diverticulitis was significantly more prevalent among male in the young age group as compared to the older age group (19/25, 76% *vs* 61/182, 33%, respectively, $P = 0.0001$). Complications occurred more often in the young age group; 32% *vs* 13%, ($P = 0.002$). During follow-up, 6 patients (28%) remained asymptomatic in the young age group as compared to 87 patients (55%) in the older age group ($P = 0.024$). As a result, sigmoidectomies were performed twice as often in the young age group (38% *vs* 13%, $P = 0.002$).

CONCLUSION: Diverticulitis in young patients has a male predominance, a more aggressive course with a higher rate of complications and a higher recurrence rate. An earlier surgical approach might be considered in young patients with acute diverticulitis.

INTRODUCTION

Diverticular disease of the colon is a common disease in Western countries. The development of colonic diverticula is associated with a low fiber diet, which is common in the developed countries[1,2]. The incidence of diverticular disease rises with age, and by the age of 85 about 65% of the population would have diverticuli[3,4]. It is much less frequent in the younger age group and less than 10% of the population under the age of 40 years would have diverticuli[5] . Most of the patients will remain asymptomatic, and only 10%-25% will become inflamed and evolve into diverticulitis[4,6-9]. The clinical presentation of acute diverticulitis varies widely from mild inflammation to full-blown perforation and peritonitis. In most patients however, the disease is mild and responds to antibiotic therapy[10] .

In recent years, there has been conflicting information regarding the incidence and natural history of diverticulitis in young patients. While earlier studies found the incidence to range between 2%-7%[11-15] , more recent studies reported a higher incidence ranging between 18%-34%[16,17]. The natural course and outcome of diverticulitis in the young patient has also been a matter of debate. While earlier studies reported a more severe course with a higher rate of complications in young patients with diverticulitis[1,2,11-14,18], recent reports suggested a milder course, not different from that in the general population[10,16]. All those studies, however, were retrospective. We performed a prospective study in which all patients with acute diverticulitis were enrolled and followed for a period of up to 5 years. We compared the natural history and the course of acute diverticulitis in the young age group to that of the older population.

MATERIALS AND METHODS

Patients

All patients with acute diverticulitis who were hospitalized at the Chaim Sheba Medical Center between January 2000 and February 2005 were enrolled. In fact, our patients' population included all patients who were diagnosed with acute diverticulitis in the emergency room, since the general policy of our institution is to hospitalize these patients regardless the severity of the disease.

Methods

The diagnosis of acute diverticulitis was based on lower

abdominal pain (usually on the left side), fever and leukocytosis. All patients underwent abdominal CT and only those with characteristic findings on CT were included. CT criteria for acute diverticulitis included the presence of colonic diverticuli with thickening of the colonic wall at the site of the diverticuli and peri-colonic fat infiltration. In some of the patients extra colonic air or fluid was seen as well. Patients with a lesion suspicious of colonic cancer on CT scan were excluded. Demographic characteristics of all patients and their medical history, concomitant use of medications, physical, laboratory, radiographic and endoscopic findings and their therapy were recorded.

Patients were followed up during their hospitalization and later by regular phone calls every 6 mo for the first year and then annually. Follow-up was conducted by a specialized study coordinator who was unaware of the patients' course of disease. At their follow-up visits or phone calls, patients were asked about the occurrence of attacks of lower abdominal pain with or without fever, hospitalizations and operations. Based on their reports, patients were classified into 4 major categories: patients who had undergone sigmoidectomy following their discharge, patients who had another episode of acute diverticulitis which required hospitalization and antibiotic therapy, patients who had LLQ abdominal pain for more than twice a week and for at least one hour's duration and patients who had not experienced symptoms suggestive of diverticulitis.

Data was analyzed for the whole group of patients and then for the two subgroups based on their age (older than and younger than 45 years). The age of 45 years was chosen as the average between the different ages used in the literature to define the young age group with acute diverticulitis (40 *vs* 50 years).

Statistical analysis

Patients' demography and other characteristics were analyzed by the Student's *t*-test for continuous variables and χ^2- test (with Yates correction) or Fisher's exact test for categorical variables. Statistical analyses were conducted by using Statsoft software (Tulsa, OK, USA).

RESULTS

Two-hundred and seven patients with acute diverticulitis were hospitalized between January 2000 and February 2005. Eighty were males and 127 were females. Their age ranged between 27-92 (mean 62 ± 12) years. Twenty-five patients (12%) were younger than 45 years. Their demography and co-morbidities are shown in Table 1. There was a striking male predominance in the young age group with a male: female ratio of 3:1. The older age group showed a female predominance with a female: male ratio of 2:1. As expected, the associated co-morbidities were far more common in the older age group, though only hypertension and ischemic heart disease reached statistical significance. The younger age group had almost no co-morbidities. However, twice as many abdominal operations had been performed in the young age group; 16% appendectomy and 12% inguinal hernioplasty as compared to 8.8% and 6%, respectively.

Table 1 Demographic data and co-morbidities of study subjects

Age (yr)	< 45 *n* = 25 (%)	>45 *n* = 182 (%)	*P* value
Gender (M/F)	19/6	61/121	0.0001
Co-morbidities			
Hypertension	1(4)	57 (31)	0.004
Hypothyroidism	0(0)	19 (10)	0.185
COPD	0(0)	10 (5.5)	0.481
Diabetes mellitus	0(0)	19 (10)	0185

Malignancy	0(0)	7 (3)	0.684
Crohn's disease	1(4)	1 (0.5)	0.100
Chronic renal failure	0(0)	4 (2.2)	0.979

COPD: chronic obstructive pulmonary disease.

Table 2 Patients' complications during hospitalization

Age (yr)	< 45 *n* = 25 (%)	>45 *n* = 182 (%)	*P* value
Peri-diverticular air on CT	5 (20)	15 (8)	0.063
Abdominal abscess	2 (8)	4 (2)	0.150
Free perforation	1 (4)	5 (3)	0.540
Death	0 (0)	2 (1)	0.598
Total complication rate	8 (32)	24 (13)	0.030

Clinical course during hospitalization

All patients were followed during hospitalization and their clinical outcome was recorded. One-hundred and seventy-five patients (85%) had a mild course with no complications. The other 32 patients had a more severe and complicated course (Table 2). The most common complication was peri-diverticular air on CT which resolved in all patients by keeping patients fasting and on IV fluids and antibiotics. Six patients (2.8%) developed an abdominal abscess and 3 required CT guided percutaneous drainage. The abscesses resolved in all patients with no need for further intervention. There were 6 patients (2.8%) who developed free perforation and all were operated on. Two patients (0.1%) died during hospitalization, one from sepsis and another from multi-organ failure. Both were older than 80 years and had several co-morbidities. Their deaths were related to the diverticulitis.

The majority of the complications were more common in the young age group (Table 2). Abdominal abscess (8% in the young group *vs* 2% in the old group, $P = 0.155$) and peri-diverticular air on CT (20% in the young *vs* 8% in the old, $P = 0.063$) were the most common. The presence

Tables 3 Patients' follow-up after discharge

Age (yr)	<45 *n* = 21(%)	>45 *n* = 159 (%)	*P* value
Operations following discharge	8 (38)	20 (13)	0.002
Recurrent diverticulitis (not operated)	2 (10)	20 (13)	0.688
Abdominal pain[1]	5 (24)	27 (17)	0.442
No further symptoms	6 (28)	87 (55)	0.024

[1]Abdominal pain- pain more than 2 times per week that lasts for at least one hour.

of free perforation, however, was almost equal in both groups; 4% in the young and 3% in the old age group. The overall complication rate was higher in the young age group ($P = 0.03$).

Follow-up

Patients were contacted by telephone every 6 mo for the first year and yearly thereafter. The range of follow up was between 6 and 60 mo, mean: 30 ± 14 mo. Four patients in the young age group (16%) and 23 patients in the old age group (13%) were lost to follow up. Three of the patients in the old age group (2%) died during the follow-up period, all of whom were older than 75 years and their deaths were not related to the diverticular disease.

Data on patients in whom complete follow up was achieved is shown in Table 3. Sigmoidectomy was significantly more often performed in the young age group (38% *vs* 13%, $P = 0.002$). Most of the patients in the older age group, unlike the younger one, were asymptomatic during their follow up (55% *vs* 28%, respectively, $P = 0.024$).

DISCUSSION

Our prospective study showed that patients younger than 45 years comprised 12% of all patients who presented to our hospital with acute diverticulitis. The younger age group was male predominant and tended to have a more severe course with a higher complication rate, mainly peri-diverticular air and intra-abdominal abscess. Their recurrence rate during follow-up was higher and as a result their rate of sigmoidectomy was higher also. In 1986, Freischlag *et al*[13] found that in young patients, the first onset of diverticulitis was often severe and required urgent operation. Other retrospective studies supported this impression[1,2,18] and described a high recurrence rate and a high complication rate in their young patients with diverticulitis[19,20]. It was therefore recommended that an elective operation should be performed following the first episode of diverticulitis[17,19,21]. This policy was even further supported by Chautems *et al* who followed patients with acute diverticulitis under the age of 50 years for nearly 10 years. They found that in the young age group patients experienced a more aggressive disease[22]. However, other studies published in the last decade, failed to support this finding[10,16,23-26]. These studies reported a course of disease in young patients not different from the older age group and with a similar rate of complications. The conclusion of those recent studies was that elective surgery after one episode of acute diverticulitis in young patients is not advocated and such patients should be managed in a similar way to the older ones[25,26]. The explanation for the difference between studies that either support or reject a severe course in young patients is not clear. A possible explanation might be the difference in the study populations. Studies that found a similar course in both age groups had in their young age group a high proportion of Latino originated patients[10,16,23]. Young Latinos were reported to have an increased tendency to develop acute diverticulitis[27]. On the other hand, studies that described a severe course in young patients with acute diverticulitis did not include the Latino originated population. In fact, some of the studies were performed in Europe where Latino origin is quite rare[19,20,22]. Our study population also did not have patients of Latino origin. Thus, we speculate that young Latino patients with acute diverticulitis have a more benign course similar to that of older patients. The reason for this is not clear.

As a group, our young patients were more prone to recurrent symptoms. Our data is consistent with earlier studies that reported a higher recurrence rate of diverticulitis among young patients[2,20].The total complication rate was significantly higher in the young age group. None of the specific complications (free perforation, abdominal abscess or peri-diverticular air) reached statistical significance, probably because of the relative small number of patients in the young age group. Death occurred only in the older age group probably as a result of their higher co-morbidity rates.

In our study, the young patients with acute diverticulitis underwent significantly more sigmoidectomies as compared to our older patients. All those who underwent a sigmoidectomy had recurrent episodes of diverticulitis. The high rate of sigmoidectomies in the young age group was, therefore, the result of a more severe course of the disease in patients who were otherwise in good general condition.

Of interest is that the young age group underwent twice as many appendectomies and inguinal hernioplasties as compared to the older age group. Acute appendicitis in the young age group was even more prevalent than the life time risk for acute appendicitis in the general population (estimated 8.6% in men and 6.7% in women)[28]. The significance, if at all, of this observation is unclear. Misdiagnosis of previous attacks of acute diverticulitis is a possible explanation.

In conclusion, our prospective, long-term follow-up study shows that acute diverticulitis in general is a mild disease with a low complication rate. In young patients there is male predominance and the disease tends to be more aggressive with a high recurrence rate. An earlier surgical approach might be considered in young patients with acute diverticulitis.

Abstract

AIM: To observe the effect of ischemic preconditioning on cyclinD$_1$ expression in rat liver cells during early ischemic reperfusion.

METHODS: Fifty-four SD rats were randomly divided into ischemic preconditioning group (IP), ischemia/reperfusion group (IR) and sham operation group (SO). The IP and IR groups were further divided into four sub-groups (n = 6). Sham operation group (SO) served as the control group (n = 6). A model of partial liver ischemia/reperfusion was used, in which rats were subjected to liver ischemia for 60 min prior to reperfusion. The animals in the IP group underwent ischemic preconditioning twice for 5 min each time prior to the ischemia/reperfusion challenge. After 0, 1, 2, and 4 h of reperfusion, serum and liver tissue in each group were collected to detect the level of serum ALT, liver histopathology and expression of cyclinD$_1$ mRNA and protein. Flow cytometry was used to detect cell cycle as the quantity indicator of cell regeneration.

RESULTS: Compared with IR group, IP group showed a significantly lower ALT level in 1 h to 4 h sub-groups (P < 0.05). Proliferation index(PI) indicated by the S-phase and G$_2$/M-phase ratio [(S+G$_2$/M)/(G$_0$/G$_1$+S+G$_2$/M)] was significantly increased in IP group at 0 and 1 h (26.44 ± 7.60% *vs* 18.56 ± 6.40%,41.87 ± 7.27% *vs* 20.25 ± 6.70%, P < 0.05). Meanwhile, cyclinD$_1$ protein expression could be detected in IP group. But in IR group, cyclinD$_1$ protein expression occurred 2 h after reperfusion. The expression of cyclinD$_1$ mRNA increased significantly in IP group at 0 and 1 h (0.568 ± 0.112 *vs* 0.274 ± 0.069, 0.762 ± 0.164 *vs* 0.348 ± 0.093, P < 0.05).

CONCLUSION: Ischemic preconditioning can protect liver cells against ischemia/reperfusion injury, which may be related to cell proliferation and expression of cyclinD$_1$ during early ischemic reperfusion.

INTRODUCTION

Hepatic ischemia/reperfusion (IR) injury is an important clinical problem occurring in hepatic resection or liver transplantation. Ischemic preconditioning (IP) has been proven to be an effective method protecting the liver against ischemia/reperfusion injury[1-3]. Many mechanisms are associated with this phenomenon[4-8], but some are still unclear. Previous studies showed that the analogous conditioning phenomenon induced by carbon tetrachloride (CCl_4) is related to hepatocellular proliferation[9]. Whether IP promotes hepatocellular regeneration remains unknown. Changes in cell proliferation can be determined by cell cycle analysis. S-phase and G$_2$/M-phase ratio is an indication the proliferation index (PI). Furthermore, cyclin and cyclin-dependent kinases (CDKs) are related to cell cycle regulation[10]. CyclinD$_1$ is an important cyclin, which controls liver cell proliferation[11]. This study was to assess the effects of IP on cell regeneration and expression of cyclinD$_1$ and to explore the possible mechanisms of IP protection.

MATERIALS AND METHODS

Experimental animals and grouping

Fifty-four male SD rats weighing 200-250 g, were randomly divided into ischemia group (IR group), ischemia preconditioning group (IP group) and sham operation group (SO). In IP group, each rat was subjected to 5 min

ischemia, followed by 5 min reperfusion, twice, prior to 1 h hepatic ischemia. Specimens were taken after 0, 1, 2, and 4 h of reperfusion, respectively (n = 6). Before the experiment, all rats were fasted for 12 h and housed in a 12 h dark/12 h light cycle.

Experimental animal model

A 70% partial liver ischemia/reperfusion model was established according to the method reported by Ohmori *et al*[12]. After anesthesia with ketamine (40 mg/kg), the belly of each rat was cut open from the center. The portal vein and hepatic artery supplying the left and median lateral hepatic lobes were dissected and clamped with a small artery clamp. After 1 h ischemia, blood flow was restored by unclamping the vessels. After 0, 1, 2, and 4 h of reperfusion, serum and liver tissue of each group were collected to assess the level of serum ALT, liver histopathology, expression of cyclinD$_1$ mRNA and protein. Liver tissue samples were homogenized and washed with PBS. The solution was filtered and centrifuged at 1000 r/min for 5 min. The cell pellet was resuspended in ice-cold ethanol to a final concentration of 80%. Flow cytometer was used to detect liver cell S-phase and G$_2$/M-phase ratio as the quantity indicator of cell regeneration. In IP group, each rat was subjected to 5 min ischemia followed by 5 min reperfusion, twice, prior to 1 h hepatic ischemia. The other procedure was the same as in IR group. In SO group, each rat was only cut open from the center without any other procedure.

Histological examination of liver

Liver tissue specimens were procured from the left lateral hepatic lobe, fixed with 10% neutral formaldehyde solution and embedded with paraffin. Sections were made and stained with H&E and observed under microscope.

Measurement of blood concentrations of ALT

Three mL of blood was withdrawn from the vena cava at certain time points, coagulated at room temperature, then centrifuged at 3000 r/min for 5 min for detecting the levels of alanine transaminase (ALT) with an automatic biochemistry analyzer (AU800, Olympus, Japan).

Detection of cell cycle

Single cell suspensions of hepatocytes were washed three times in PBS. RNase (1% w/v) was then added for 30 min at 37 ℃ and 50 mg/L PI (Sigma Company, Danmark) for 20 min. Samples were detected with a FACSORT flow cytometer (Becton Dickinson Company, USA), 10 000 cells were obtained by Cell Quest software and cell cycle was analyzed by Modfit software.

CyclinD$_1$ mRNA detection by reverse transcription-polymerase chain reaction (RT-PCR)

Primers synthesized according to the GenBank of Bioya Biotechnology Limited Company(Shanghai, China) included cyclinD1 sense primer (5'-TGGAGCCCCTGA AGAAGAG) cyclinD1 anti-sense primer (5'- AAGTGCGTTGTGCGGTAGC -3') amplified products (424bp), GAPDH sense primer (5'-GGCTGAGAATGGGAAGCTG-GTCAT-3') and GAPDH anti-sense primer (5'-CAGCCTTCTCCATGGTGGTGAA- GA-3) amplified products (152bp).

Total RNA was extracted from the frozen liver specimens with Trizol (GibcoBrl Company, USA). Reverse transcription synthesis of cDNA was carried out according to the instructions of SuperScript One-Step RT-PCR with Platinum Taq kit (Invitrogen Company, USA). PCR was performed with a Gene Amp PCR System 2400 (PE Company, USA). The reaction system was composed of a cDNA template (1.0 μL), 2×buffer (12.5 μL), 5 mmol/L $MgCl_2$(2.5 μL), cyclin D1, GAPDH sense and anti-sense primer (0.5 μL respectively), SSRT polymerase (0.5 μL) and deionized water (6.5 μL). The reaction system was put into a PCR machine for amplification. Cyclin D1 and GAPDH were amplified for 35 cycles of PCR. The amplification conditions were at 55 ℃ for 30 min, at 94 ℃ for 2 min, at 94 ℃ for 30s, at 55 ℃ for 30 s, at 72 ℃ for 45 s, a final extension at 72 ℃ for 7min. The amplified products were preserved at 4 ℃. Ten μL of PCR products was electrophoresed on 1.5% agarose gel containing 5 μg/mL ethidium bromide (Sigma Company, USA). Marker was DL-2000 DNA marker. The results were detected by GeneSnap (SynGene, England) and analyzed by GeneTools (SynGene, England).

CyclinD$_1$ protein detection

Liver tissues were homogenized in 10 volumes of ice-cold buffer containing 50 mmol/L Tris–HCl (pH7.5), 150mmol/L NaCl, 1%Triton-X 100, 1 mmol/L EDTA,1mmol/L DTT,10μg/mL pepstatin,10μg/mL leupeptin, 10 μg/mL aprotinin, 1mM PMSF. The homogenates were centrifuged at 12 000 r/min for 15 min at 4 ℃. The supernatant was frozen and stored at -80 ℃ for further analysis. After measurement of the supernatant sample concentration, the sample was mixed with an equal volume buffer containing 0.1mol/LTris (pH 6.8), 100 mmol/L DTT, 2% SDS, 10% glycerin, 0.01% bromophenol blue and put in water bath to boil for 3-5 min. Fifty micrograms of protein was separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The stacking and resolving gels were composed of 4% and 10% polyacrylamide, respectively. After SDS-PAGE, the gels were electroblotted onto nitro-cellulose (NC) membranes at 100 mA for 2 h. The membranes were blocked for 1 h in blocking solution at room temperature, which contained 1 mL/L Tween 20 (PBS-T) and 50 g/L non-fat dry milk. Then they were immunolabeled with the primary antibody (1:500 rabbit anti-rat Santa Cruz Company, USA) in blocking solution for 1 h at room temperature and was washed three times with TBST for 15 min. The NC membranes were incubated with a horseradish peroxidase-conjugated secondary antibody (1:1000 goat anti-rabbit Santa Cruz Company, USA) for 1 h at room temperature and washed three times with TBST for 15 min again. Color solution of diaminobenzidine (DAB) was prepared according to the manufacturer's directions (Maxim Company, China). After incubation with this color solution, the protein bands were visible on the NC membranes.

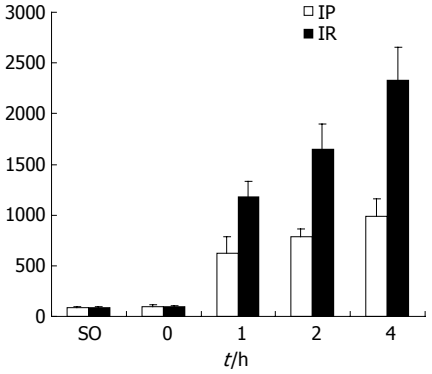

Figure 1 Serum ALT levels SO, IP and IR groups.

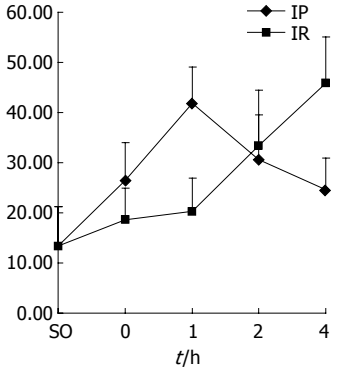

Figure 2 PI in SO, IP and IR groups.

Table 1 CyclinD1 mRNA relative activity in different groups (mean ± SD)

Group	IR	IP
SO	0.256 ± 0.042	0.256 ± 0.042
0 h	0.274 ± 0.069	0.568 ± 0.112[a,b]
1 h	0.348 ± 0.093	0.762 ± 0.164[a,b]
2 h	0.521 ± 0.157[b]	0.574 ± 0.172[b]
4 h	0.709 ± 0.178[b]	0.474 ± 0.144[a,b]

[a]$P < 0.05$ *vs* IR, [b]$P < 0.05$ *vs* SO.

Statistical analysis

The results were presented as mean ± SD. Multivariate analysis of variance and *t* test were performed by SPSS11.5 for window. $P < 0.05$ was considered statistically significant.

RESULTS

Morphology

Swelling of hepatocytes and structural derangement were observed in IR group during the early period of reperfusion. Spot necrosis, hemorrhage and inflammatory cell infiltration could be seen in hepatic lobes or around central veins, with extended reperfusion time. Compared with IR group, IP group showed moderate hepatocyte swelling and less necrotic area.

ALT

The levels of serum ALT increased gradually as reperfusion time was extended in both groups. Compared with IR group, the level of serum ALT in IP group was significantly lower at all time points after reperfusion ($P < 0.05$) (Figure 1).

Hepatocellular proliferation

PI increased significantly at 0 and 1 h of reperfusion in IP group compared with IR group. There was a statistically significant difference ($P < 0.05$) (Figure 2).

Expression of cyclinD1 mRNA and protein

The RT-PCR results showed that cyclinD1 mRNA was expressed in SO, IR and IP groups. The expression of cyclinD1 mRNA in IP group increased at 0-1 h after reperfusion. Compared with IP group, the expression of cyclinD1 mRNA in IR group was significantly lower at 0-1 h after reperfusion ($P < 0.05$). No significant difference in the expression of cyclinD1 mRNA was found between SO and IR groups at 0-1 h after reperfusion ($P > 0.05$, Table 1, Figure 3A).

CyclinD1 protein was not detectable until 2 h after reperfusion in IR and SO groups. Whereas cyclinD1 protein was expressed in IP group soon after the reperfusion was begun (Figure 3B).

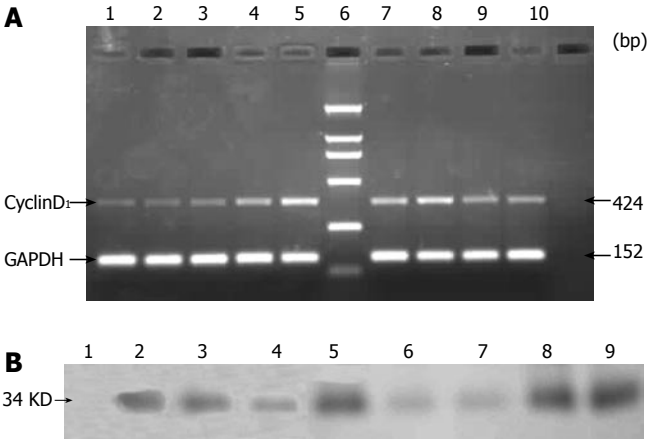

Figure 3 Expression of cyclin D1 mRNA (**A**) and cyclin D1 protein (**B**) at different time points in SO, IP and IR groups.

DISCUSSION

It is widely accepted that IP protects organs against IR injury. It has been reported that IR injury is related with many mechanisms, such as suppression of inflammatory reaction[13], improvement of local microcirculation[14], diminution of cell apoptosis and decreased production of local active oxygen-derived free radicals[15,16]. But some of the mechanisms remain uncertain. To probe into the mechanisms of IP protection may help to find an effective method against IR injury. In this study, we adopted the rat model of ischemic preconditioning against subsequent hepatic IR injury and confirmed that it could reduce the levels of serum ALT and the extent of liver necrosis.

Application of flow cytometry to cell cycle analysis makes it possible to analyze cell proliferation. Cell cycle can discriminate cells at the G_0/G_1-phase, S-phase and G_2/M-phase. It is considered that cells at the S-phase and G_2/M-phase can proliferate. S-phase and G_2/M-phase ratio could indicate the proliferation index (PI).The finding of the present work is that IP could promote liver cell proliferation during early ischemic reperfusion, which is possibly related to IP protection. Zhang *et al*[17] showed that proliferating liver cells can resist IR injury. The mechanisms of cellular proliferation involved in IP are still obscure, but

may be related to reactive oxygen species (ROS) and tumor necrosis facter-α (TNF-α).The liver underlying IP could generate ROS and TNF-α during early reperfusion[18,19]. ROS could stimulate cell mitosis and proliferation[20]. TNF-alpha is a known mitogen for hepatocytes and an important factor for liver cell proliferation. In the presence of anti-TGF-alpha neutralizing Abs, the mitogenic activity of TNF-alpha is abrogated[21].

Breakthrough in cell cycle regulation is the understanding of cyclin and cyclin-dependent kinase, which regulates cell cycle progression. Mitotic cellular division requires cells to leave the resting state (G_0/G_1) and proceed through the phase of DNA synthesis (S) and mitosis (G_2/M). There is a check point between G_0/G_1-phase and S-phase. CyclinD$_1$ is an important cyclin which can make cells pass through the check point and enter S-phase and G_2/M-phase. Higher expression of cyclinD$_1$ could promote cell proliferation in rat liver[11]. Our data showed that IP could stimulate cyclinD$_1$ mRNA and protein expression during the early reperfusion in IP group and not in IR group. The mechanisms may be related to the fact that IP activates the p38MAPK pathway[22], leading to activation of regulatory proteins and production of DNA synthetic proteins, such as cyclinD$_1$ and interleukin-6(IL-6)[23]. The p38MAPK pathway is an important signaling pathway involved in IP. Blockade of the p38MAPK pathway can lead to loss of protection of IP[24]. When the p38MAPK pathway is activated, the p38kinase transfers to cell nuclei and induces the production of cyclinD$_1$[25]. In our study, the cyclinD$_1$ protein was expressed in IR group 2 h after reperfusion, although cyclinD$_1$ mRNA was expressed during the early reperfusion. In SO group, cyclinD$_1$ mRNA was expressed but cyclinD$_1$ protein was not expressed. These data suggest that cyclinD$_1$ expression is posttranscriptionally regulated. Awad and Gruppuso[26] showed that a posttranscriptional mechanism regulating cyclin D1 content is involved in temporary hepatocyte growth arrest. They speculated that this posttranscriptional regulation may be downstream from the p38 mitogen-activated protein kinase pathway. The posttranscriptional regulation could keep adult hepatocytes in a quiescent state, but the mechanism is not completely clear.

In conclusion, IP could promote cyclinD$_1$ expression and lead to hepatocellular proliferation during early ischemic reperfusion, which is possibly one of the protective mechanisms against IR injury. However their underlying regulatory pathway and biological role remain unclear.

Abstract

AIM: To examine matrix metalloproteinase-2 (MMP-2) expression in gastric cancer tissues and to evaluate its relationship with lymph node micrometastasis.

METHODS: The authors studied 850 lymph nodes resected from 30 patients with gastric carcinoma who underwent gastrectomy with lymphadenectomy using reverse transcription polymerase chain reaction (RT-PCR) assay in addition to H-E staining. MMP-2 expression of the tumor tissues was detected by immunohistochemical technique (EliVision™ plus).

RESULTS: MMP-2 expression was positive in 21 (70%) cases and negative in 9 (30%) cases. No significant correlations were found between MMP-2 expression and other variables such as age, gender, tumor location, tumor diameter, Lauren classification and lymphatic invasion. In contrast, MMP-2 expression correlated significantly with depth of tumor infiltration (P = 0.022), lymph node metastasis (P = 0.030) and tumor differentiation (P = 0.043). Lymph node micrometastases were detected in 77 (12.5%) lymph nodes of 14 (46.7%) gastric carcinoma patients. MMP-2 expression was positive in 12 (85.7%) of the 14 patients with lymph node micrometastasis, and in 9 (56.3%) of the 16 patients without lymph node micrometastasis (P = 0.118).

CONCOUSION: Our results demonstrate that MMP-2 expression has significant correlation with tumor invasion, tumor differentiation and lymph node metastases. MMP-2 expression may be an important biological characteristics and significant prognostic parameter of gastric carcinoma. We also conclude that MMP-2 may participate in the development of lymph node micrometastasis of gastric carcinoma. Further investigations are needed to draw a conclusion.

INTRODUCTION

Lymph node metastasis is the most important prognostic factor of gastric carcinoma. Many clinical studies demonstrate that the existence of lymph node micrometastasis is often overlooked by conventional histopathological examination (H-E staining)[1-10]. However, the mechanisms of lymph node micrometastasis remain unclear heretofore. MMP-2 has been reported to be associated with tumor invasion and lymph node metastasis of gastric carcinoma by mediating the degradation of extracellular matrix components[11-14]. However, the relationships between MMP-2 expression in cancer tissues and lymph node micrometastasis have not yet been explored. Therefore, the aim of this study was to investigate correlations between MMP-2 expression and clinicopathologic characteristics of gastric carcinoma and possible relationships between lymph node micrometastasis and MMP-2 expression.

MATERIALS AND METHODS

Patients and specimens

A total of 850 lymph nodes resected from 30 patients with gastric carcinoma who underwent gastrectomy at the Department of Gastrointestinal and Pancreatic Surgery at Sun Yat-sen University of Medical Sciences were studied. There were 17 men and 13 women, ranging in age from 26 to 82 years, with a mean age of 56.8 years. None of these patients had received preoperative chemotherapy or radiotherapy. Total gastrectomy was performed in

16 patients, distal subtotal gastrectomy in 13 patients, and proximal subtotal gastrectomy in 1 patient. One patient underwent D1 lymphadenectomy, 22 patients underwent D2 lymphadenectomy, 4 patients underwent D3 lymphadenectomy, and 3 patients underwent palliative resection. According to the Lauren' criteria, 19 tumors were classified as diffusive type carcinomas, and 11 tumors were intestinal type carcinomas. Depth of tumor invasion and extent of lymph node metastasis were classified according to UICC TNM classification.

Half of each resected lymph node was fixed in 10% formalin and embedded in paraffin for routine histopathological examination. The other half was stored in 1ml RNA later (Sigma, USA) at 4 ℃ overnight, then transferred to a clean freezing tube and stored at -70 ℃ for RNA extraction. The resected primary tumors were also fixed in 10% formaldehyde and embedded in paraffin. Consecutive 4 μm sections were cut and stained with hematoxylin and eosin (H-E) staining and immunohistochenistry with anti-MMP-2 antibody.

RNA extraction

Lymph node samples were homogenized in 1 mL of Trizol Reagent (Invitrogen) per 50-100 mg of tissue using a power homogenizer. RNA extraction was carried out according to the protocol recommended by the manufacturer. Total RNA was dissolved in diethylpyrocarbonate-treated water and the volume and quality of the RNA then assessed by the ultraviolet spectrophotometer.

RT-PCR

Complementary DNA (cDNA) was synthesized and amplified from total RNA using the Access RT-PCR system (Promega). The primer sequences used for CK-20 detection were 5'-ggtcgcgactacagtgcatattaca-3' (sense) and 5' -cctcagcagccagtttagcattatc-3' (anti-sense)[15]. cDNA synthesis was monitored by beta-actin RT-PCR using the following primers: 5'- caaatgcttctaggcggact -3' (sense) and 5' - atgctatcacctcccctgtg -3' (anti-sense). The RT-PCR was performed in a 25 μL reaction mixture containing 11 μL nuclease-free water, 5 μL 5 × Reacton Buffer, 0.5 μL dNTP (10 mmol/L), 0.5 μL each of beta-actin primers (20 μmol/L), 1.25 μL each of CK-20 primers (10 μmol/L), 1 μL MgSO4 (25 mmol/L), 0.5 μL AMV reverse transcriptase (5 u/μL), 0.5 μL Tfl DNA polymerase (5 u/μL), and 3 μL RNA sample. The Access RT-PCR condition was set up as follows: 1 cycle at 48 ℃ for 45 min (reverse transcription), 1 cycle at 94 ℃ for 2 min (AMV RT inactivation), followed by 40 cycles at 94 ℃ for 30 s (denaturation) and at 62 ℃ for 1 min (annealing) and at 68 ℃ for 1.5 min (extension), followed by a final extension at 68 ℃ for 7 min. The resultant cDNA products of CK-20 and beta-actin were 121 base pairs and 381 base pairs, respectively. The RT-PCR products were analyzed by electrophoresis on 2% agarose gels stained with ethidium bromide.

In this report, "micrometastasis" in the regional lymph nodes was defined as metastasis that was detected only by the RT-PCR assay but not by routine H-E staining (Figure 1).

Immunohistochemistry

MMP-2 immunohistochemical staining was performed using EliVision™ plus IHC Kit (Maixin Biological, Fuzhou, China). After the sections were deparaffinized with xylene and dehydrated with ethanol, they were placed in 10 mmol/L citrate buffer and heated in a microwave at 700 W for 5 min for the retrieval of antigens in the specimens. Endogenous peroxidase activity was blocked by incubation of the slides in 3% hydrogen peroxide in absolute methanol at room temperature for 10 min. The sections were then incubated sequentially with 50 μL of mouse monoclonal antibody against MMP-2 (Maixin Biological, Fuzhou, China) overnight at 4 ℃, with 50 μL of polymer enhancer for 20 min, and 50 μL of polymerized HRP-anti mouse IgG for 30 min. The reaction products were visualized with diaminobenzidine (DAB Kit, Maixin Biological, Fuzhou, China), and sections were counterstained with hematoxylin, dehydrated, and evaluated under light microscope. Tris-buffered saline (TBS) solution was used instead of the primary antibody for negative controls.

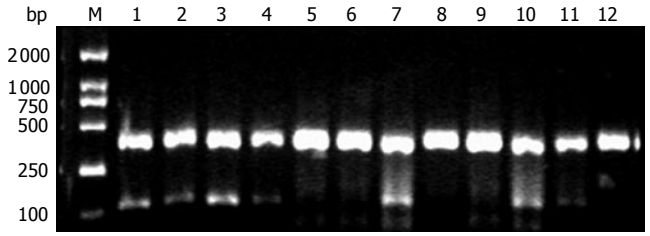

Figure1 Comparison of the results of RT-PCR and H-E staining. M: DL 2000 Marker; Lanes1-12: dissected lymph nodes. Lymph nodes of Lane 7, Lane 10, and Lane 11 were diagnosed lymph node micrometastasis.

For the purpose of data analysis, MMP-2 expression was graded according to the proportion of positive tumor cells. If more than 25% of the tumor cells were positively stained for MMP-2, the tumor was classified as positive MMP-2 expression. In contrast, if 25% or less of the tumor cells were positively stained, the tumor was classified as negative MMP-2 expression (Figure 2). The stained sections were observed independently by two pathologists who had no knowledge of the clinicopathological data.

Statistical analysis

Statistical analysis was performed by the Fisher's exact test to examine the association of MMP-2 expression of tumor tissues with the clinicopathologic characteristics of gastric carcinoma, and the relationship between MMP-2 expression of tumor tissues and lymph node micrometastasis was evaluated. Statistical significance was defined as $P < 0.05$.

RESULTS

Correlations between MMP-2 expression and clinicopathologic characteristics of gastric carcinoma

MMP-2 expression was positive in 21 (70%) cases and negative in 9 (30%) cases. No significant correlations were found between MMP-2 expression and other variables such as age, gender, tumor location, tumor diameter, Lauren classification and lymphatic invasion. In contrast, MMP-2 expression correlated significantly with depth of tumor infiltration ($P = 0.022$), lymph node metastasis ($P = 0.03$) and tumor differentiation ($P = 0.043$) (Table 1).

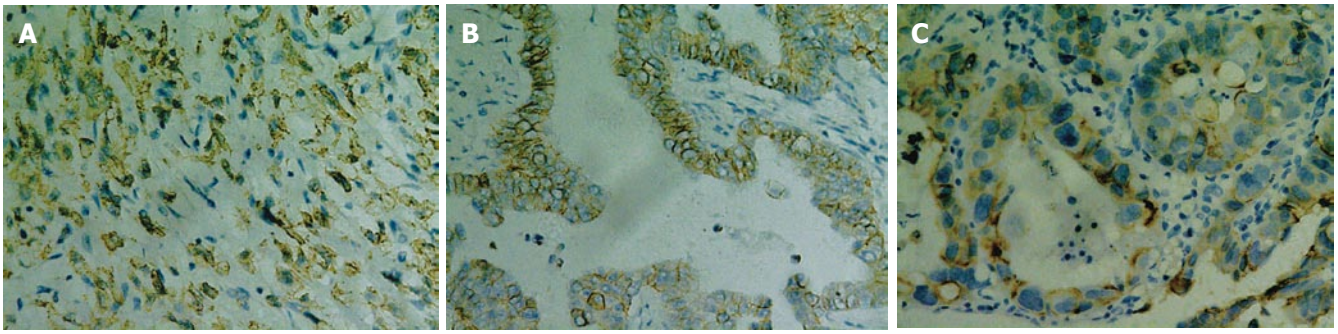

Figure 2 Expression of MMP-2 in gastric carcinoma. **A:** poorly-differentiated gastric carcinoma (× 400); **B:** moderately -differentiated gastric carcinoma (× 400); **C:** well-differentiated gastric carcinoma (× 400).

Table1 Correlation between MMP-2 expression and clinicopathologic characteristics of gastric carcinoma

Variable	Patients (*n*)	MMP-2 expression		
		Negative (%)	Positive (%)	*P* value
Gender				
Male	17	6 (35.3)	11 (64.7)	
Female	13	3 (23.1)	10 (76.9)	*P* = 0.691
Age				
< 50 yr	10	1 (10)	9 (90)	
⩾ 50 yr	20	8 (40)	12 (60)	*P* = 0.204
Superficial diameter				
< 5 cm	17	7 (41.2)	10 (58.8)	
⩽ 5 cm	13	7 (15.4)	6 (84.6)	*P* = 0.229
Tumor location				
Upper/Middle third	17	5 (29.4)	12 (70.6)	
Lower third	13	4 (30.8)	9 (69.2)	*P* = 1.000
Histologic type				
Intestinal	11	5 (45.5)	6 (54.5)	
Diffuse	19	4 (21.1)	15 (78.9)	*P* = 0.225
Depth of invasion				
T1	5	4 (80)	1 (20)	
T2	16	4 (25)	12 (75)	
T3/T4	9	1 (11.1)	8 (88.9)	*P* = 0.022
Histologic differentiation				
Well	7	4 (57.1)	3 (42.9)	
Moderate	6	3 (50)	3 (50)	
Poorly	17	2 (11.8)	15 (88.2)	*P* = 0.043
Lymph node metastasis				
Positive	20	3 (15)	17 (85)

Lymphatic invasion				
Positive	18	3 (16.7)	15 (83.3)	
Negative	12	6 (50)	6 (50)	*P* = 0.102

Table 2 Correlation between MMP-2 expression of tumor tissues and lymph node micrometastasis

Micrometastasis	Patients (*n*)	MMP-2 expression		
		Negative (%)	Positive (%)	*P* value
Positive	4	2 (14.3)	12 (85.7)	
Negative	16	7 (43.7)	9 (56.3)	*P* = 0.118

Relationships between lymph node micrometastasis and MMP-2 expression

Lymph node micrometastases were detected in 77 (12.5%) lymph nodes of 14 (46.7%) gastric carcinoma patients. MMP-2 expression was positive in 12 (85.7%) of the 14 patients with lymph node micrometastasis, and in 9 (56.3%) of the 16 patients without lymph node micrometastasis. However, the difference between these two groups was not statistically significant ($P = 0.118$) (Table 2).

DISCUSSION

The protein MMP-2 (type IV collagenase) belongs to the family of metalloproteinases. Its function is related to cellular matrix degradation including basement membrane type IV collagen. MMP-2 has been reported to play an important role in the metastatic process and tumor invasion of gastric carcinoma[16-19].

Monig *et al*[13] investigated correlations between MMP-2 immunoreactivity and currently used classification systems and possible relationships between lymph node metastasis and MMP-2 expression in a prospective study. MMP-2 expression correlated significantly with depth of tumor infiltration, lymph node metastasis, distant metastasis, and UICC stage. In contrast, no significant correlations were found between MMP-2 expression and other variables such as age, tumor differentiation, WHO, Lauren, Goseki, and Ming classifications. Sundblad *et al*[12] also reported that MMP-2 expression showed significant correlations with parietal depth of infiltration ($P = 0.03$) and with metastases in regional lymph nodes ($P = 0.05$). However, Ko *et al*[20] reported that MMP-2 expression was not correlated significantly with lymph node micrometastasis or depth of invasion ($P > 0.05$). They also reported that TIMP-2 expression (MMP-2 inhibitor) showed a strong relationship with lymph node micrometastasis and depth of tumor infiltration ($P < 0.05$).

In the present study, MMP-2 expression was observed in 70% (21 of 30 cases) of gastric carcinoma. MMP-2 expression increased in accordance with the depth of tumor invasion. MMP-2 expression was more frequent in T3/T4 tumors (8 of 9 cases, 88.9%) and T2 tumors (12 of16 cases, 75%), as compared with T1 tumors (1 of 5 cases, 20%). The difference was statistically significant ($P = 0.022$). In 20 gastric carcinomas with lymph node metastasis 17 (85%) showed positive MMP-2 expression, while in 10 gastric carcinomas without lymph node metastasis only 4 showed positive MMP-2 expression ($P = 0.030$). In addition, we also found that there was a significant correlation between MMP-2 expression and tumor differentiation. 88.2% (15 of 17 cases) poorly differentiated gastric carcinomas showed MMP-2 expression, while positive MMP-2 expres-

sion of moderately- and well-differentiated gastric carcinomas were only 50% (3 of 6 cases) and 42.9% (3 of 7 cases) respectively. The difference was also statistically significant ($P = 0.043$).

Our results demonstrate that MMP-2 expression has significant correlation with tumor invasion, tumor differentiation and lymph node metastasis. For gastric carcinoma, MMP-2 expression may be an important biological characteristic and a significant prognostic parameter.

Recent advances in immunohistochemistry and molecular biology techniques have made it possible to detect lymph node micrometastasis not evidenced by routine H-E staining. 28%-68.1% of patients with gastric carcinoma were reportedly identified micrometastases in regional lymph nodes[21-25]. However, the mechanism of lymph node micrometastasis is still not completely known now. Therefore, the main objective of this study was to examine MMP-2 expression in the tumor tissues and explore its relationship with lymph node micrometastasis. Totally, 77 (12.5%) lymph nodes of 14 (46.7%) patients with gastric carcinoma were detected lymph node micrometastases. In 14 gastric carcinoma patients with lymph node micrometastases 12 (85.7%) showed positive MMP-2 expression, while in 16 gastric carcinoma patients without lymph node micrometastases only 9 (56.3%) were examined MMP-2 expression. The results indicate that MMP-2 may participate in the development of lymph node micrometastasis of gastric carcinoma, however, the difference was not statistically significant ($P = 0.118$). This may be explained by the fact that the cases in our study were comparatively few. To draw a further conclusion, a large-scale investigation is needed.

Abstract

AIM: To discuss the clinical value of CT three-dimensional (3-D) imaging in diagnosing gastrointestinal tract diseases.

METHODS: Three-D imaging findings of 52 patients were retrospectively analyzed. Three-D imaging methods included shaded surface display (SSD), volume rendering (VR), virtual endoscopy (VE) and multiplanar reformatting (MPR). The diagnosis results of CT 3-D were evaluated by comparison with those of endoscopy and/or surgical finding.

RESULTS: Fifty-two patients with gastrointestinal tract diseases were diagnosed by CT 3-D imaging, of whom 50 cases were correctly diagnosed and 2 were misdiagnosed. There were 33 cases of gastric diseases (27 with carcinoma, 5 with peptic ulcer and 1 with leiomyoma) and 19 large intestinal diseases (10 with colon carcinoma, 2 with carcinoma of the rectum, 5 with colon polypus and 2 with tuberculosis of the ileocecal junction). Twenty-two cases with prominent lesions (9 with subsequent hollow lesions), 20 with stenosis of cavity (8 with concomitant prominent lesions) and 10 with hollow lesions (5 with concomitant prominent lesions) were shown in 3-D images. The minimal lesion shown was 1.0 cm × 0.8 cm × 0.5 cm.

CONCLUSION: CT 3-D imaging, a non-invasive examination without pain, can display clearly and directly the lesions of gastrointestinal tract with accurate location and high diagnosis accuracy. It is an important complementary technique to endoscopy.

INTRODUCTION

Barium studies and endoscopy are two conventional examinations of gastrointestinal tract diseases. In recent years, with the advancement of spiral CT (single-detector row spiral CT, SDCT) and multi-detector row spiral CT (MDCT) scanner, CT three-dimensional (3-D) imaging has gained wide application and high diagnosis accuracy in gastrointestinal tract diseases[1-4]. Here we report the results of CT 3-D imaging in diagnosing gastrointestinal tract diseases in our hospital, and evaluate its clinical application.

MATERIALS AND METHODS

General information

From Jan 2000 to Oct 2005, 52 patents with complete clinical data were examined by 3-D imaging (From Aug 2001 to Oct 2003, due to short supply of effervescent granules, no such examination was carried out), among whom 30 cases were males and 22 females. The average age of the patients was 57.3 years (range, 20-85 years). Thirty-three patients were examined in stomach and 19 in large intestine.

Examination instrument

SDCT scanner (Somatom plus/4, Siemens, Germany) and workstation with 3-D imaging software (SUN magicview 1000) were used in 28 cases (18 in stomach and 10 in large intestine). MDCT scanner (LightSpeed/16, GE, America) and workstation with 3-D imaging software (Advantage Workstation 4.2) were used in 24 cases (15 in stomach and 9 in large intestine).

Examination methods

All the patients were required to fast for 12 h. The patient examined in the stomach took one pack (3 g) of efferves-

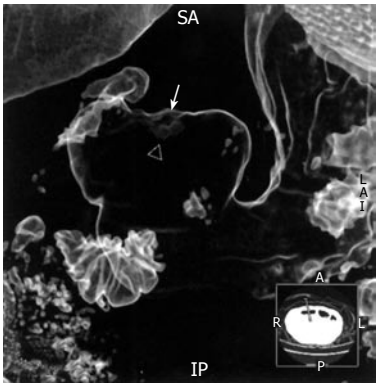

Figure 1 The ulcero carcinoma of stomach (on the anterosuperior wall of gastric antrum): the anterior-view of stomach on the VR image shows clearly the hollow lesion (↑) and the concomitant prominent lesion (△), with gas filling the stomach.

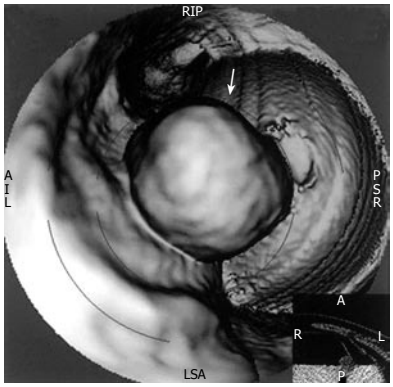

Figure 3 The leiomyoma of stomach (on the greater curvature of stomach): the axial-view of gastric cavity on VE image shows the prominent lesion (↑), with gas filling the stomach.

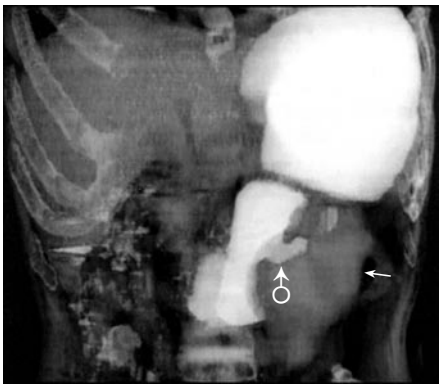

Figure 2 The ulcero carcinoma of stomach (on the greater curvature of stomach): the anterior-view of stomach on VR image shows the prominent lesion (↑) and the subsequent hollow lesion (♂), with 2% - 3% Omnipaque 300 filling the stomach.

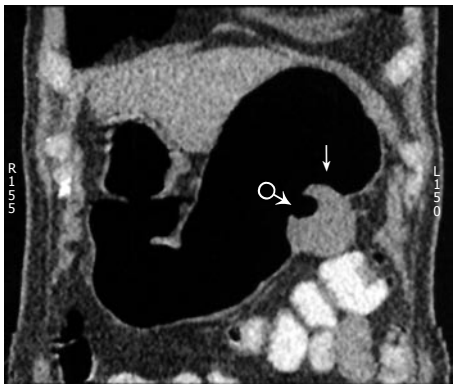

Figure 4 The same patient of **Figure 3**: the gastric coronal plane on MPR image shows the prominent lesion (↑) and the subsequent hollow lesion (♂).

cent granules (malu，Shanghai，China), lay in scanning bed and rolled to spread gas in stomach. A scout projection in supine position was made to confirm whether stomach was distended by gas. If distention was insufficient , another pack of effervescent granules (10 such cases in this study) or 500-1000 mL of 2%-3% Omnipaque 300 (Amersham, Shanghai，China) was added as an oral contrast agent to increase the contrasting effect and distending extent (8 such cases in this study). Another scout projection was scanned again. Holding breath for 10 s to 30 s, the patient was scanned with collimation of 5 mm (or 1.25 mm), pitch of 1.5 (or 1.375), increment of 2.4 mm (or 0.6 mm), scanning voltage of 120 kVp and a scanning current of 100-150 mA(the parameters in the brackets were used in scanning by MDCT). Another position of prone or lateral decubitus was often selected to better show some lesions (8 such cases in this study). The patients examined in the large intestines were asked to have a cleaning enema the night before and 30 min prior to the examination. A total of 600-1000 mL of air was infused through the anal canal as the contrasting agent. The following steps were the same as that used in stomach.

Image processing

Three-dimensional imaging methods included surface display (SSD), volume rendering (VR), virtual endoscopy (VE) and multiplanar reformatting (MPR). By selecting reconstruction thresholds of gastrointestinal walls from 15 Hu to 40 Hu and gastrointestinal cavities from -200 Hu to -1500 Hu, and necessary cutting technique, we obtained satisfactory 3-D images on the workstation. The exhibition of gastrointestinal tract lesions on the 3-D images was analyzed and measured, and the diagnosis results of CT 3-D imaging were evaluated by comparison with those of endoscopy and/or surgical finding.

RESULTS

Diseases diagnosed

Fifty-two patients with gastrointestinal tract diseases were histologically proven, of whom 33 cases had gastric diseases (27 with carcinoma, 5 with peptic ulcer and 1 with leiomyoma) and 19 had intestinal diseases (10 with colon carcinoma, 2 with carcinoma of rectum, 5 with colon polypus and 2 with tuberculosis of ileocecal junction). Fifty cases were correctly diagnosed (Figure 1, Figure 2, Figure 3, Figure 4, Figure 5, Figure 6) and 2 misdiagnosed (1 with leiomyoma in stomach and 1 with tuberculosis in ascending colon).

Lesions shown

Prominent lesions (Figures 2-5) were shown in 3-D images in 22 cases (9 with subsequent hollow lesions, with maximal size of 5.4 cm × 6.0 cm × 2.1 cm and minimal of 1.5 cm × 1.2 cm × 0.8 cm), stenosis lesions (Figure 6) in 20 (8 with concomitant prominent lesions) and hollow lesions (Figure 1) in 10 (5 with concomitant prominent lesions, maximal of 2.0 cm × 1.8 cm × 1.1 cm, minimal of 1.0 cm × 0.8 cm × 0.5 cm). The locations, sizes and shapes of lesions in the 3-D images were close to that seen under endoscopy and/or in surgery.

Characteristics of imaging methods

Three-D images with VR, VE, SSD and MPR could

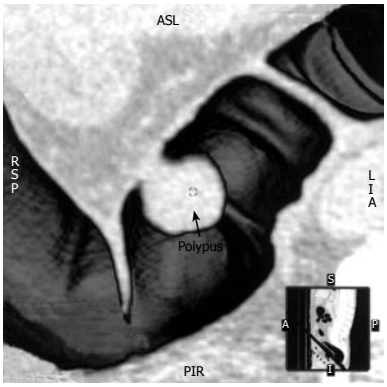

Figure 5 The polypus of colon: the anterior-view of colon on SSD image, by using the cutting technique, shows the prominent lesion (↑), with air filling the large intestine.

Figure 6 The carcinoma of descending colon: the anterior-view of large intestine on VR image shows the stenosis of intestinal cavity (↑), with air filling the large intestine.

show gastrointestinal tract lesions (Table 1), each with its own characteristics. SSD-imaging should be made with necessary cutting technique (Figure 5). VE-imaging could only show the extraluminal lesions. MPR-imaging had no perception of 3-D, but it could show clearly wall invasion (Figure 4). VR-imaging could show both extraluminal and intraluminal lesions (Figures 2, 6).

Table 1 Gastrointestinal tract lesions by3-D imaging with SSD, VR, VE and MPR

Methods	Prominence ($n=22$)			Hollow ($n=10$)			Stenosis ($n=20$)

DISCUSSION

Characteristics in showing lesions

Gastrointestinal tract lesions could be clearly shown by 3-D imaging, and the exact location and accurate size of a lesion could be obtained when it was more than 5 mm. In our study, the minimal lesion shown by 3-D image was 1.0 cm × 0.8 cm × 0.5 cm. This result is accordant with that reported by Zhang and Gluecker[3,5]. The main advantages of 3-D imaging over two-dimensional (2-D) multiplanar reformatting are added perspective and enhanced depth perception. The relationship between the lesion and adjacent structures can be better appreciated. It is often helpful to use the combinations of different 3-D imaging methods in different lesions, and to start with 2-D multiplanar reformatting and then to proceed to 3-D imaging[6]. Therefore in order to increase the diagnostic accuracy, we suggest several 3-D images be observed as well as the original axial images.

Influence of examination techniques on 3-D image

Theoretically, the quality of 3-D images is related to slice thickening, pitch and tube current[7]. Our study found that a satisfactory 3-D image of increased spatial resolution and decreased moving artificial shadows was obtained with thinner collimations and appropriate tube current and pitch. Interference of the contents in the gastrointestinal tract was avoided and adequate distention was obtained by using gas from effervescent granules of air as the contrasting agent of gastrointestinal tract, or by setting the patient in the prone, lateral decubitus and left posterior oblique position[8]. If gastrointestinal tract is not well distended or gastrointestinal wall has collapsed, some lesions may be overlooked and some similar disease may appear[9]. Traditionally, low or high attenuation contrasting agent can both be taken to enhance and distend the gastrointestinal tract. As to whether to take low or high attenuation contrasting agent, we think low-attenuation, e.g. gas, should be the first choice, as the agents are safer, well tolerated, and always result in good gastrointestinal tract distention. 2%-3% Omnipaque 300 may be optimal when stomach cannot be well distended. Horton *et al*[1,10] reported low-attenuation agents, e.g. oil-based oral contrast agents, whole milk and water, resulted in satisfactory evaluation of detection of subtle diseases of the gastric wall, and did not interfere with the manipulation of 3-D data sets. It is necessary to conduct further study on the clinical application of oral contrast agents.

Comparisons among 3-D imaging methods

All the 3-D imaging methods could show the lesions of gastrointestinal tracts, each with its own characteristics: MPR image could show the lesion in any section, e.g. sagittal or oblique. Though it could not get 3-D perception, it could remedy the defects of transverse-images, with the advantages of showing the gastrointestinal lesions of wall invasion. Images of VE and SSD with cutting techniques can show the size and shape of the lesions[6], especially intraluminal prominent lesions, and show the structure of gastrointestinal tracts, e.g. semilunar fold and ileocecal valve, from any directions without being influenced by a narrow cavity. They can better show the base and pedicel of lesions, but cannot discern surface coloration of lesion and extraluminal tumor invading [11]. VR images can be made translucent, similar to those of double contrast barium studies, and can demonstrate the overall contour changes of gastrointestinal tracts, but with poor mucosal information[12].

Clinical value of 3-D imaging

Accurate staging of gastrointestinal cancer is essential because surgical resection is the treatment only for local-

ized disease. Endoscopy and conventional barium study can only detect intraluminal lesions, but cannot evaluate extraluminal lesions. Traditional CT images can show anatomic structure and lesions of the gastrointestinal tract, but lack continuity and three dimensions. CT 3-D imaging has many advantages in the staging of primary tumor, assessing for local spread and detecting nodal involvement and distant metastases. It can provide valuable additional information and improve the detection and staging of both early and advanced gastric tumors and the detection of colorectal cancer and polypus[1,13,14]. CT 3-D imaging, with the same volume data obtained by spiral CT, especially by MDCT, can be repeatedly made with different reconstruction methods and avoid leakage of the section and moving artificial shadows. It has a high accuracy, sensitivity and specificity in showing prominent lesions and stenosis lesions, and in diagnosing gastric carcinoma and colon carcinoma[15]. 3-D imaging is a non-invasive examination without pain, and can easily be accepted by patients[14]. It may be used as an important complementary technique to endoscopy, particularly when the cavity is too narrow for endoscopy to go through. However, 3-D imaging examination has its limitations, e.g. it cannot show the color of lesions or make bioscopy[2].

Summary

CT 3-D imaging can clearly and directly show lesions of gastrointestinal tract. Diagnostic accuracy can be improved by observing different 3-D images together with original 2-D images. Three-D imaging is a non-invasive examination without pain, with characteristics of accurate localization of lesions and comprehensive observation of shapes. It is an important complementary technique to endoscopy.

Abstract

Simple liver cysts are congenital with a prevalence of 2.5%-4.25%. Imaging, whether by US, CT or MRI, is accurate in distinguishing simple cysts from other etiologies, including parasitic, neoplastic, duct-related, and traumatic cysts. Symptomatic simple liver cysts are rare, and the true frequency of symptoms is not known. Symptomatic simple liver cysts are predominantly large (> 4 cm), right-sided, and more common in women and older patients. The vast majority of simple hepatic cysts require no treatment or follow-up, though large cysts (> 4 cm) may be followed initially with serial imaging to ensure stability. Attribution of symptoms to a large simple cyst should be undertaken with caution, after alternative diagnoses have been excluded. Aspiration may be performed to test whether symptoms are due to the cyst; however, cyst recurrence should be expected. Limited experience with both laparoscopic deroofing and aspiration, followed by instillation of a sclerosing agent has demonstrated promising results for the treatment of symptomatic cysts. Here, we describe a patient with a large, symptomatic, simple liver cyst who experienced complete resolution of symptoms following cyst drainage and alcohol ablation, and we present a comprehensive review of the literature.

INTRODUCTION

Liver cysts are classified as true or false, depending on the presence of an epithelial lining[1]. True cysts include congenital cysts (simple cysts and polycystic liver disease), parasitic (hydatid) cysts caused by *Echinococcus granulosis* and *multilocularis* tapeworms, neoplastic cysts (including cystadenoma, cystadenocarcinoma, cystic sarcoma, squamous cell carcinoma, and metastatic ovarian, pancreatic, colon, renal and neuroendocrine cancers), and biliary duct-related cysts (Caroli's disease, bile duct duplication, and peribiliary cysts)[1]. False cysts may be caused by spontaneous intrahepatic hemorrhage, post-traumatic hematoma, or intrahepatic biloma[1].

The pathogenesis of liver cysts is not clear. Simple liver cysts are congenital[2]. They are lined by cuboidal epithelium and originate from the abnormal development of intrahepatic ducts *in utero*. They are generally stable in size over time, but may slowly enlarge and occasionally become symptomatic due to mass effect, rupture, hemorrhage, or infection[3]. However, an enlarging cyst should prompt consideration of diagnosis other than simple cysts. Although simple cysts are generally solitary, more than one cyst may be present ("several solitary"), even in the absence of polycystic liver disease, as is the case with the patient described below.

We report herein a case of a patient with a large, symptomatic, simple hepatic cyst with resolution of symptoms immediately after therapy. In addition, we present a comprehensive literature review of diagnosis and treatment options of symptomatic hepatic cysts.

CASE REPORT

A 59-year-old African-American woman was referred to the Division of Gastroenterology at the University of Pennsylvania for evaluation of abdominal pain for 2 years. The patient described frequent, intermittent epigastric pain and bloating not associated with meals or bowel movements. Typically, pain would last for one-half hour before spontaneously resolving. She had twice presented to the emergency room with abdominal pain

Figure 1 Enhanced abdominal CT scan showing large, simple hepatic cyst.

and was discharged without definitive diagnosis. She also complained of early satiety and occasional nausea without weight loss.

The patient was taking daily fiber supplements and had regular, daily bowel movements. Reflux symptoms were well controlled with esomeprazole. Hypertension was treated with metoprolol and amlodipine. Other chronic medications were progesterone and estrogen. She denied non-steroidal anti-inflammatory drug usage. Physical examination was unremarkable.

Laboratory evaluation showed normal liver-associated enzymes, metabolic panel, complete blood count, and urinalysis. Screening colonoscopy, performed two years prior to presentation, revealed internal hemorrhoids and melanosis. Upon presentation, she underwent double contrast upper gastrointestinal examination, which suggested antral gastritis and a hiatal hernia. On subsequent upper gastrointestinal endoscopy, the mucosa appeared normal, and a medium-sized hiatal hernia was present. Treatment with a proton pump inhibitor, fiber, and hyoscyamine failed to improve symptoms by six months.

The patient underwent abdominal CT scan with intravenous and oral contrast, which showed a large (7.7 cm) hepatic cyst in the lateral segment of the left lobe, as well as several other smaller cysts (Figure 1). Gallstones without gallbladder wall thickening or pericholecystic fluid were also visualized. On ultrasonography, tenderness was elicited specifically over the site of the cyst, which measured 10.3 cm in its longest dimension.

After several months of expectant management, the patient was referred to interventional radiology for drainage of the large hepatic cyst. Under ultrasonographic guidance, an 8-gauge French catheter was placed into the cyst, serous non-bilious fluid was aspirated, and the catheter was placed to gravity drainage. One week later, after drainage had ceased, the patient underwent ethanol sclerosis. At 4 mo follow-up, the patient was completely symptom-free. Follow-up ultrasound showed complete cyst resolution.

DISCUSSION

Previous studies, based on autopsy and surgical series, estimated a very low prevalence of simple non-parasitic hepatic cysts (0.14%-0.17%)[4]. More recently, among patients referred for abdominal ultrasonography, the prevalence of simple hepatic cysts has been reported 2.5%-4.65%[5,6]. Liver cysts have been recognized increasingly as the routine use of imaging studies becomes more widespread. Hepatic cysts may be more common in women[5] and in patients older than 40 years[6]. Symptoms, though quite rare, may be related to the space-occupying effect of large cysts[7] and may be more common in right-sided cysts[8]. Symptoms may include abdominal discomfort, chronic right upper quadrant or epigastric abdominal pain, early satiety, dyspnea, increasing abdominal girth, nausea, and vomiting[7,9]. Sanfelippo *et al*[4] reported that among 15 symptomatic patients with solitary non-parastic liver cysts, abdominal mass was present in 54%, hepatomegaly in 40%, abdominal pain in 33% and jaundice in 9% patients.

Table 1 Rare complications of simple liver cysts

Obstructive jaundice
Infection
Intracystic haemorrhage
Spontaneous rupture
Inferior vena cava obstruction
Neoplastic transformation
Primary squamous cell carcinoma
Cystadenocarcinoma
Adenosquamous carcinoma
Adenocarcinoma
Hepatocellular carinoma
Cholangiocarcinoma

Although the natural history of simple hepatic cysts is not well known, complications appear to be quite rare (Table 1). Obstructive jaundice caused by solitary non-parasitic liver cyst is rare[11-15], and such cysts are usually large and located centrally in the liver, causing compression of the hepatic hilum[13]. However, sometimes even small hepatic cysts (3 cm in diameter) may cause common bile duct stenosis and intrahepatic biliary dilatation[15].

Liver cysts may also cause obstruction of the inferior vena cava, which may lead to massive edema of the legs[16,17] and scrotum[16]. Infections of simple hepatic cysts with *Klebsiella pneumoniae*[18] and *Escherichia coli*[19], presenting with acute onset of right upper quadrant abdominal pain, diarrhea, and fever have also been reported. Other documented complications include intracystic haemorrhage[19-23] and spontaneous rupture[23]. Neoplasms arising from solitary non-parasitic liver cysts, including primary squamous cell carcinoma[24-26], cystadenocarcinoma, adenosquamous carcinoma, adenocarcinoma, hepatocellular carinoma, and cholangio carcinoma[27-29], have been reported, but appear to be very rare. A possible association with Peutz-Jeghers syndrome has also been suggested[30].

Imaging modalities (ultrasound, CT, and MRI) are highly accurate for diagnosing simple cysts (Table 2). Large differences in echogenicity between hepatic parenchyma and cyst fluid allow for easy recognition of simple cysts by ultrasound[31]. The ultrasonographic appearance of simple cyst is characterized by well-defined, echo-free lesions with

Table 2 Radiologic features of simple hepatic cysts

Features supporting diagnosis of a simple cyst	Features not supporting diagnosis of a simple cyst
Anechoic lesion	Echoic lesion
Thin wall	Thick wall
Absence of septations	Presence of septations
No peripheral enhancement on CT/MRI	Peripheral enhancement on CT/MRI
Homogeneous appearance	Heterogeneity within the cyst
	Hydatid sand
	Presence of daughter cysts
	Heavy wall calcifications

Table 3 Alternative explanations for symptoms in patients with simple hepatic cysts

Diagnosis
Biliary colic
Gastroesophageal reflux
Peptic ulcer
Non-ulcer dyspepsia
Irritable bowel syndrome
Chronic pancreatitis
Abdominal wall pain syndrome

good through transmission and an imperceptible wall[3,32]. The presence of acoustic enhancement results from relative lack of absorption and reflection of sound by cyst fluid, as compared with hepatic parenchyma[32]. On CT scan, simple cysts appear as well-demarcated, water-density sacs, which do not demonstrate peripheral enhancement after intravenous contrast [3]. The presence of septations suggests that a cyst is not simple. Occasionally, large simple cysts may have "septations" due to hemorrhage. MRI shows simple cysts as hypointense lesions on T1-weighted and hyperintense on T2-weighted images[32,33]. Simple cysts differ from cavernous hemangiomas in that they are more hypointense on T1-weighted and of equal hyperintensity on T2-weighted images[33]. Radiologic characteristics which would argue against a cyst being simple include a thick wall, peripheral enhancement on CT or MRI, heterogeneity within the cyst, and an increase in size over time. Hepatic cysts should be differentiated from hepatic abscesses, hematomas, necrotic metastases, an intrahepatic gallbladder, biliary cystadenoma, and echinococcal (hydatid) cysts[32].

Radiologic imaging can accurately identify hydatid cysts, with an accuracy of 96% in one series[34]. Presence of hydatid sand, internal sepatations, daughter cysts, and heavy wall calcifications argue for *Echinococcus granulosis* infection, instead of a simple cyst. Epidemiologic features and serology in combination with radiologic imaging generally lead to the correct diagnosis non-invasively.

Distinction between cystic and solid hepatic lesions can be made accurately by ultrasonography, though CT or MR imaging may be more sensitive for the detection of focal hepatic masses[35]. The presence of any peripheral enhancement or thick-walled component suggests the possibility of hepatic abscess or neoplasm[32]. Small hepatic lesions with diameter < 1 cm are difficult to classify[36]. Such lesions should be differentiated from benign cysts, hepatic metastases with central necrosis, and microabscesses[36]. In order to differentiate small cysts from small metastases, follow-up imaging may be considered in selected cases[36].

The vast majority of simple hepatic cysts require no treatment. Large cysts (diameter of 4 cm or more) can be followed for stability with repeated imaging[37]. If the cyst remains unchanged for 2 years, further monitoring may be discontinued[37]. Symptomatic or enlarging cysts require consideration of alternative diagnoses, including cystadenoma, cystadenocarcinoma, and hepatic metastases. It should be stressed that attribution of symptoms to simple cysts should be undertaken with caution after excluding alternative diagnoses. Epigastric or right upper quadrant abdominal pain provoked by eating may indicate biliary colic, if gallstones are present. A successful trial of acid suppression therapy points to gastroesophageal reflux disease. Selected patients may undergo upper gastrointestinal endoscopy to diagnose erosive esophagitis or peptic ulcer disease. Esophageal pH monitoring can confirm the diagnosis of gastroesophageal reflux. If symptoms fluctuate in concert with changes in stool frequency or form, a diagnosis of irritable bowel syndrome should be suspected. Finally, a diagnosis of non-ulcer dyspepsia may be entertained in patients with unremarkable upper gastrointestinal endoscopy who have continued prominent upper abdominal pain, possibly in association with nausea and vomiting (Table 3). If the preceding diagnoses can be confidently excluded, then treatment of a large, symptomatic hepatic cyst may be undertaken. Treatment options include needle aspiration with or without injection of sclerosing solution, internal drainage with cystojejunostomy, wide deroofing, and different degrees of liver resection[37].

Percutaneous US- or CT-guided needle aspiration of hepatic cysts is associated with high recurrence rates (78%-100%)[38,39]. Several small case series have demonstrated efficacy for the performance of US- or CT-guided needle aspiration of hepatic cysts combined with alcohol injection[40-44]. Because US-guided aspiration with ethanol sclerosis is generally safe, effective, and relatively non-invasive, it may be a first-line treatment for selected symptomatic congenital hepatic cysts, especially in patients with high surgical risk or polycystic liver disease[15]. The 95%, 96% and 99% alcohol solutions are equally safe and effective[15,42,45]. Enough alcohol should be instilled to replace 25% of the aspirated cyst fluid volume[46]. For larger cysts (> 400 mL), multiple alcohol injections in the same sitting have been proposed[46]. Alcohol fixes the cells lining the cyst cavity, disabling their ability to secrete fluid and promote cyst enlargement[46]. Recurrence may occur if alcohol does not come in contact with all cells lining the cyst cavity[46] and may be more common in uncooperative patients[47]. Combinations of percutaneous aspiration with other sclerosing substances, such as iophendylate (pantopaque)[48], tetracycline chloride[49-52], doxycycline[52], minocycline chloride[53-56], and hypertonic saline solution[8] have also achieved good outcomes.

Several recent series have demonstrated good results for laparoscopic deroofing procedures. Widest possible excision of the cystic wall and concomitant argon beam

Table 4 Comparison of treatment options for symptomatic simple liver cysts

Treatment options	Advantages	Disadvantages
Observation alone	- Because most cysts are asymptomatic, intervention is unlikely to be helpful and may be harmful	- Only effective cyst treatment can prove whether symptoms are related to the cyst
US-guided aspiration	- Simple procedure - May be used as a diagnostic test to assess whether symptoms are related to the cyst	- High recurrence rate
US-guided aspiration with sclerotherapy	- Relatively non-invasive - Complications are rare - Effective - Possible in poor surgical candidates	- Less effective for uncooperative patients - Can not be performed if cyst communicates with biliary tree
Laparoscopic unroofing	- Technically feasible and effective in > 80% cases - Improved results with extensive fenestration and argon beam coagulation or electrocoagulation - Low recurrence rate (0%-20%) - Visualization of cyst interior (exclude other diagnoses)	- More invasive - Morbidity in up to 25% - Less effective for cysts which are superior, posterior, or deep within hepatic parenchyma - Less effective if prior surgery has been attempted
Laparotomy (resection, fenestration, or excision)	- Effective - Allows treatment of laparoscopically inaccessible cysts - Useful for cysts with complications - May perform cystojejunostomy at time of laparotomy for cysts with biliary communication	- Most invasive - Larger scars - Longer hospital stays compare to laparoscopy - Significant post-surgical morbidity

coagulation or electrocoagulation may improve the durability of results[57-61]. Recurrence has ranged from 0% to 20% with morbidity in 0% to 25%[57-60,62]. In one series, laparoscopic fenestration of simple hepatic cysts was found to be technically feasible in 90% with symptomatic relief in 95% during 38.5 mo follow-up[61]. Careful selection of patients who have not previously undergone surgical treatment and have large, symptomatic, superficial, and anterior cysts may improve outcomes[63]. US- or CT-guided cyst aspiration can be performed prior to laparoscopic fenestration in selected cases to assess whether symptoms are truly referable to the cyst[63]. Reported complications associated with laparoscopic deroofing include wound infection, bile leak, chest infection, subphrenic hematoma, and prolonged post-procedure drainage[37]. In selected cases, an open surgical procedure (fenestration, excision, or resection) may be preferred, despite longer recovery times and larger surgical scar, because of cyst location, surgeon expertise, or the presence of complicating factors[8,39,61,63,64].

Laparoscopic deroofing and cyst aspiration, followed by sclerosis, are both reasonable approaches for the majority of symptomatic simple liver cysts (Table 4)[64]. Whereas sclerosis may be less invasive and associated with lower rates of complications, laparoscopy is effective and provides the opportunity to directly examine the cyst interior to rule out etiologies other than a simple hepatic cyst[64,65].

It is important to rule out biliary communication before sclerosing a cyst, as irreversible sclerosing cholangitis has been reported as a complication[7,16,46,52,66]. The presence of cystobiliary communication may be established by endoscopic retrograde cholangiography or aspiration of bile-stained cystic fluid and is often treated by open cystojejunostomy[39], although the cystobiliary communication may be closed laparoscopically[67].

In summary, we present the case of a large, symptomatic simple hepatic cyst. We established that the cyst was the cause of symptoms only after systematically excluding alternative diagnoses through testing and empiric therapy. The usual standard of care for patients with large, simple hepatic cysts is observation, but our case demonstrates that large cysts can occasionally be responsible for symptoms. In selected cases, symptoms may respond to cyst treatment. Our treatment approach was ultrasound-guided aspiration and ethanol sclerotherapy. We believe that aspiration alone is associated with unacceptably high rates of recurrence. In our patient, excellent symptomatic and radiologic responses were achieved. In the case of cyst recurrence laparoscopic deroofing may be considered, though complications may occur in up to 25% of cases.

Abstract

Retroperitoneal fibrosis is an uncommon disorder characterized by the formation of a dense plaque of fibrous tissue in the retroperitoneum, and its etiology remains unknown. Autoimmune pancreatitis is a rare type of chronic pancreatitis characterized by fibrosis with abundant infiltration of IgG4-positive plasma cells and lymphocytes and obliterative phlebitis in the pancreas. We present a case of autoimmune pancreatitis that developed 10 mo after the occurrence of retroperitoneal fibrosis. Histological findings of the resected retroperitoneal mass were marked periureteral fibrosis with abundant infiltration of IgG4-positive plasma cells and lymphocytes and obliterative phlebitis. These findings suggest a common pathophysiological mechanism for retroperitoneal fibrosis and autoimmune pancreatitis in this case. Some cases of retroperitoneal fibrosis might be a retroperitoneal lesion of IgG4-related sclerosing disease.

INTRODUCTION

Retroperitoneal fibrosis is an uncommon disorder characterized by the formation of a dense plaque of fibrous tissue in the retroperitoneum. Although retroperitoneal fibrosis leads to ureteral encasement and consequently hydronephrosis in most cases, it may also involve other structures in the retroperitoneum as well as in multiple unattached sites. Retroperitoneal fibrosis may be part of a systemic fibrosing disease[1,2]. Although the exact etiology of retroperitoneal fibrosis remains unknown, some cases respond well to steroid therapy[2,3].

Autoimmune pancreatitis is a recently noted clinical entity and a rare group of pancreatitis in which autoimmunity is suspected as a pathogenic mechanism. It is characterized by enlargement of the pancreas, irregular narrowing of the main pancreatic duct, elevated serum IgG4 concentrations, favorable response to steroid therapy and lymphoplasmacytic infiltration with fibrosis in the pancreas[4,5]. Recent studies have revealed occasional coexistence of autoimmune pancreatitis with other systemic exocrinopathy, such as sclerosing cholangitis[6] or sclerosing sialadenitis[7]. We have previously reported 2 other cases of autoimmune pancreatitis associated with retroperitoneal fibrosis[8]. Here, we report a case of autoimmune pancreatitis that occurred 10 mo after retroperitoneal fibrosis. We also focus on the common histopathological features with abundant IgG4-positive plasma cell infiltration in both the pancreas and retroperitoneal mass.

CASE REPORT

A 75-year-old male was admitted to another hospital with a complaint of back pain. Abdominal computed tomography (CT) showed left hydronephrosis (Figure 1A) caused by a retroperitoneal mass with encasement of the ureter (Figure 1B), which was highly suggestive of a ureteral tumor. Resection of the left lower ureter and ureterostomy were performed. Histological examination of the retroperitoneal mass revealed marked periureteral fibrosis with dense perivascular infiltration of lymphocytes and plasma cells (Figure 2A) and obliterative phlebitis (Figure 2B). These findings were compatible with retroperitoneal fibrosis. Ten months later, jaundice with abdominal pain appeared, and he was referred to our hospital for further examination.

Laboratory studies on admission were as follows: total serum bilirubin 10.4 mg/dL (normal range: 0.2-1.1 mg/dL), alkaline phosphatase 1418 IU/L (115-359 IU/L), γ-glutamyl trasnpeptidase 558 IU/L (9-70 IU/L), glutamic-

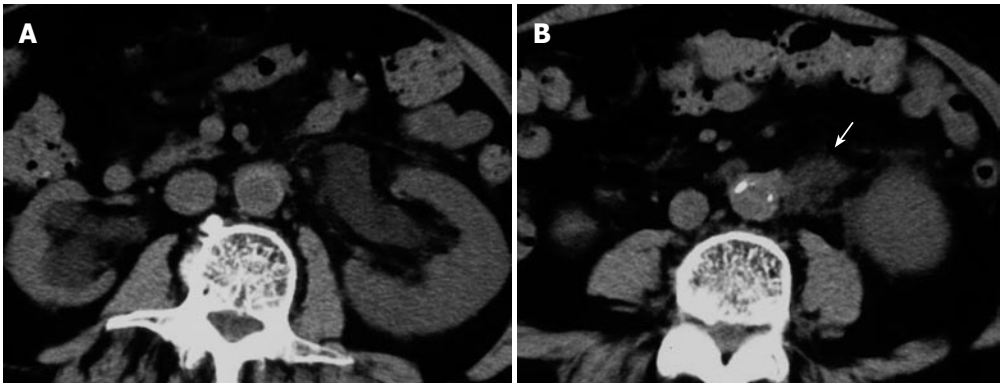

Figure 1 CT performed performed in another hospital showing left hydronephrosis (**A**) caused by a retroperitoneal mass (arrow) (**B**).

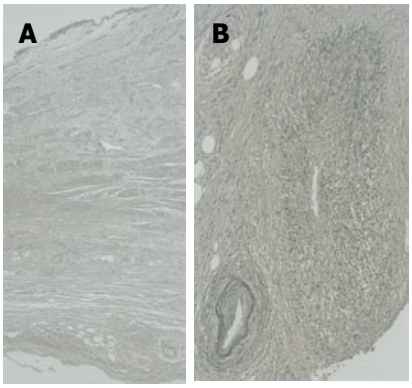

Figure 2 Histological findings of the retroperitoneal mass showing marked periureteral fibrosis with dense perivascular infiltration of lymphocytes and plasma cells (**A**, H&E) and obliterative phlebitis (**B**, Elastica Van Gienson stain).

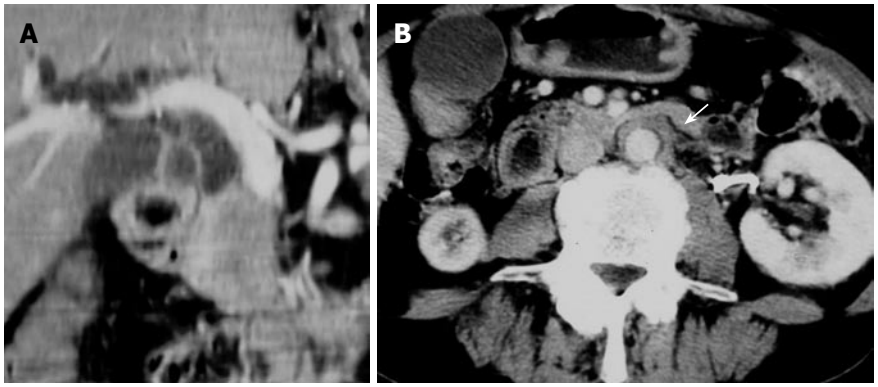

Figure 3 CT performed in our hospital showing the lower common bile duct obstructed with focally swollen pancreatic head (**A**) and soft tissue surrounding the aorta (arrow) (**B**).

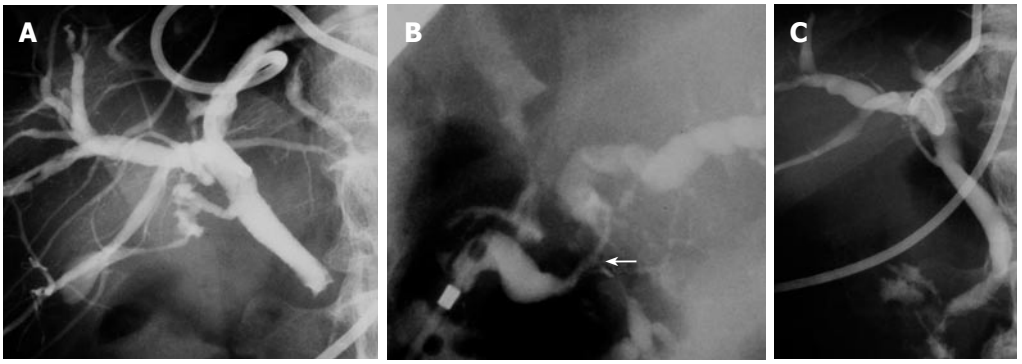

Figure 4 Percutaneous transhepatic cholangiography showing complete obstruction of the lower common bile duct (**A**) and resolution of the bile duct after steroid therapy (**C**). Endoscopic retrograde cholangiopancreatography demonstrating segmental narrowing of the main pancreatic duct in the pancreatic head (arrow) (**B**).

oxaloacetic transaminase 277 IU/L (12-32 IU/L), amylase 79 IU/L (45-155 IU/L), and elastase-1 1313 ng/mL (72-432 ng/mL). Tumor marker levels were within normal range. Although serum IgG level was 1380 mg/dL (870-1 700 mg/dL), serum IgG4 levels was elevated to 240 mg/dL (< 70 mg/dL). Antinuclear antibody and rheumatoid factor were negative. CT showed the lower common bile duct obstructed with focally swollen pancreatic head (Figure 3A) and soft tissue surrounding the aorta (Figure 3B). Magnetic resonance cholangiopancreatography (MRCP) showed the stricture of the lower common bile duct with dilatation of the upper common bile duct, but the pancreatic duct was not visualized. Percutaneous transhepatic biliary drainage was performed, and the common bile duct was completely obstructed in the lower portion (Figure 4A). Endoscopic retrograde cholangiopancreatography (ERCP) demonstrated segmental narrowing of the main pancreatic duct in the pancreatic head (Figure 4B). Biopsy specimen taken from the major duodenal papilla during duodenoscopy revealed severe lymphoplasmacytic infiltration. Immunohistochemical studies using anti-IgG4 antibody (Binding Site, Birmingham, UK) with avidin-biotin-peroxidase complex (ABC) revealed abundant infiltration of IgG4-positive plasma cells in tissue specimens of both resected retroperitoneal mass (Figure 5A) and biopsied major duodenal papilla (Figure 5B). We diagnosed autoimmune pancreatitis and treated him with 30 mg predonisolone daily for 2 wk. The dose was

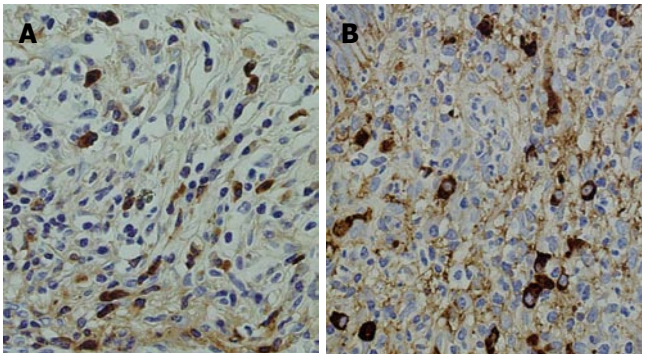

Figure 5 IgG4 immunostaining showing abundant infiltration of IgG4-positive plasma cells in tissue specimens of resected retroperitoneal mass (**A**) and biopsied major duodenal papilla (**B**).

tapered by 2.5-5 mg every 1-2 wk until a daily maintenance dose of 5 mg. After steroid therapy, findings on cholangiopancreatography and CT improved (Figure 4C), and the biliary drainage tube could be withdrawn. Serum IgG4 lowered to 83 mg/dL.

DISCUSSION

We have previously reported 2 other cases of autoimmune pancreatitis associated with retroperitoneal fibrosis[8]. A total of 9 cases including the present case have been reported[8-12]. All were middle-aged or elderly males. Autoimmune pancreatitis was synchronous to retroperitoneal fibrosis in 4 cases, and metachronous to retroperitoneal fibrosis in 3 cases. Retroperitoneal fibrosis was metachronous to autoimmune pancreatitis in 2 cases. Steroid therapy was effective for both pancreatic and retroperitoneal lesions.

Histological findings characteristic to autoimmune pancreatitis are dense lymphoplasmacytic infiltration with fibrosis and obliterative phlebitis in the pancreas[3,4]. We have reported that this lymphoplasmacytic infiltration with fibrosis is observed in the peripancreatic retroperitoneal tissue, biliary tract, and salivary glands, as well as in the pancreas of patients with autoimmune pancreatitis. Furthermore, an abundant infiltration of IgG4-positive plasma cells was observed in the various organs of patients with autoimmune pancreatitis, including the peripancreatic retroperitoneal tissue, biliary tract, salivary glands, gastric mucosa, lymph nodes, and pancreas, but an abundant infiltration of IgG4-positive plasma cells was not detected in the organs of patients with other diseases[13,14]. Major duodenal papilla also showed fibrosis with abundant infiltration of IgG4-positive plasma cells[15]. We proposed the existence of a novel clinicopathological entity, an IgG4-related systemic disease characterized by a preponderance for elderly male, and extensive IgG4-positive plasma cell and T lymphocyte infiltration of organs[14]. We also suggest that autoimmune pancreatitis is not simply a pancreatitis but that, in fact, it is a pancreatic lesion reflecting an IgG4-related systemic disease, and that in some cases only organs other than the pancreas might be clinically involved[14].

In the present case, the retroperitoneal mass, that occurred 10 mo prior to autoimmune pancreatitis, histologically showed marked periureteral fibrosis with abundant infiltration of IgG4-positive plasma cells and lymphocytes and obliterative phlebitis, which were similar findings to those in the pancreas and peripancreatic retroperitoneal tissues of patients with autoimmune pancreatitis. These findings suggest a common pathophysiological mechanism for retroperitoneal fibrosis and autoimmune pancreatitis in this case. Although the exact etiology of retroperitoneal fibrosis remains unknown, some cases might be a retroperitoneal lesion of IgG4-related sclerosing disease.

Abstract

Breast metastases from gastric cancer are extremely rare. A case report of a 37-year-old female with breast inflammatory invasion and ascites is described. Breast biopsy revealed carcinomatous invasion of the lymphatics from adenocarcinoma cells with signet-ring features. Estrogen (ER) and progesterone receptors (PR) and c-erb-B2 were negative. Upper gastrointestinal endoscopy revealed a prepyloric ulcerative mass. Histopathologic examination of the lesion showed infiltration from a high-grade adenocarcinoma, identical with that of the breast. Immunostaining was positive for cytokeratins CK-7 and CK-20 and CEA and negative for ER and PR. Ascitic fluid cytology was positive for adenocarcinoma cells. Mammography was not diagnostic. Abdominal CT scanning revealed large ovarian masses suggestive of metastases (Krukenberg's tumor). A cisplatin-based regimen was given but no objective response was observed. The patient died six months after initial diagnosis. A review of the literature is performed.

INTRODUCTION

Breast metastases from extra-mammary neoplasms are extremely rare. The incidence ranges between 1%-2% in clinical and 1.7%-6.6% in autopsy series[1-2]. Less than 500 cases of secondary breast tumors have been reported so far in the English speaking literature[3]. The most common primary malignancies metastasizing to the breast are malignant melanoma, lung cancer, carcinoid tumors, ovarian cancer, renal cancer, gastrointestinal carcinomas and a variety of other primaries[2-4]. Herein, a case of a woman with gastric signet-ring adenocarcinoma presenting with breast metastasis is described.

CASE REPORT

A 37-year-old female presented to our department in September 2003 with abdominal distention and painful and edematous left breast. Her medical history was unremarkable except for three attempts of *in vitro* fertilization during the last two years. Physical examination revealed ascites and marked left breast inflammation. Neither discrete tumor nodules in the breast nor any enlarged axillary nor supraclavicular lymph nodes were palpable. Mammography showed diffuse increased density and skin thickening, without evidence of mass or microcalcifications. Abdominal ultrasonography established the presence of bilateral cystic adnexal masses with thickened walls and ascitic fluid. Abdominal CT confirmed the presence of large ovarian masses suggestive of metastases (Krukenberg's tumor); however, there was no evidence of lung, liver or bone metastases. Serum tumor markers CEA, CA 15-3 and CA 19-9 were within normal limits and CA 125 was slightly elevated (63.6 U/L). Ascitic fluid cytology was found positive for adenocarcinoma. Core needle biopsy of the left breast revealed diffuse infiltration of the lymphatics in form of tumor emboli from neoplastic cells with signet-ring features (Figure 1). Immunohistochemical studies for estrogen receptor (ER) and progesterone receptor (PR) as well as for c-erb-B2 were negative. Upper gastrointestinal endoscopy demonstrated a large prepyloric ulcerative mass. Biopsy of the lesion revealed infiltration from a diffuse-type high-grade gastric adenocarcinoma with signet-ring features (Figure 2 and Figure 3). Malignant cells were positive for cytokeratins 7 and 20 (CK7, CK20) and CEA, and negative for ER and PR. Subsequent study of the breast biopsy revealed similar findings (positive staining for CK7, CK20 and CEA). The patient was treated with cisplatin-based chemotherapy; but she showed no objective response and died six months after the initial diagnosis.

DISCUSSION

Metastatic breast involvement from extra-mammary

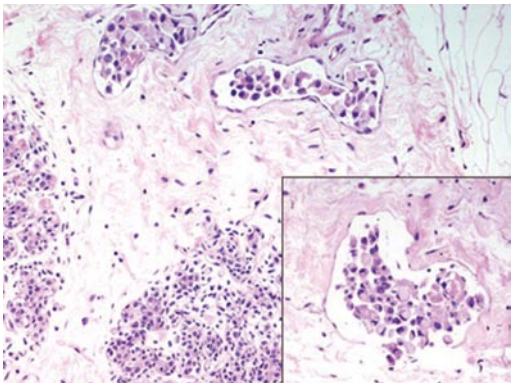

Figure 1 Breast biopsy showing breast lymphatic invasion from neoplastic cells with signet-ring features (Hematoxylin & eosin, 200 ×, 400 ×).

primaries is unusual. Most cases are related with extensive disease burden and carry an unfavorable prognosis[5]. Breast invasion is the initial manifestation of the disease in 25%-40% of the cases[2]. Mammographically, metastatic tumors in the breast present as well-circumscribed nodules without microcalcifications, mimicking benign breast lesions[5]. Calcifications may be seen in metastatic deposits from ovarian carcinoma with psammoma bodies[6]. The most common localization of metastatic lesions is the upper-outer quadrant of the left breast. Breast involvement is bilateral in 25% of the cases, and there is concomitant axillary lymph node enlargement in up to 15%[5]. The occurrence of multiple tumor nodules is unusual and diffuse involvement mimicking inflammatory breast carcinoma is rare[7,8]. The latter clinical manifestation, due to lymphatic invasion, is rapidly progressive, and may produce clinical signs of breast involvement before a firm metastatic nodule is formed, which is even more common in hematological malignancies (leukemias, lymphomas).

Breast metastases from gastric cancer are extremely rare. To date, only 25 cases have been reported in the English speaking literature and are mentioned in Table 1. Signet-ring features have been reported in 13 cases. From reports with available data, it seems that breast involvement usually follows the detection of gastric carcinoma. Breast metastasis as initial manifestation of a primary gastric tumor, as in our case, has been reported in 10 cases. In half of these cases breast involvement had the clinical appearance of inflammatory breast cancer.

Breast metastases from gastric carcinoma differ from primary breast cancer in their histopathologic characteristics. Immunostaining is usually negative for estrogen and progesterone receptors[9,10] as well as for c-erbB-2[3]. GCDFP-15 (gross cystic disease fluid protein-15) is also absent[10]. There is no evidence of an *in situ* component[3,5] and a lack of desmoplastic response[3]. On the contrary, lymphatic tumor emboli and epithelial markers like CK7, CK20 and CEA are usually present[3,5].

In our case, the presence of signet-ring cells within breast lymphatics, the absence of mass or microcalcifications in the mammography, the lack of an *in situ* component and hormone receptor negativity strongly suggested an extra-mammary primary. It is of noted interest that Steinbrecher and Silverberg in 1976[11] first described primary signet-ring carcinoma of the breast, as a subtype of lobular carcinoma, with aggressive biological behavior and an increased tendency to metastasize in the abdomen and in the gastrointestinal tract compared to other histological subtypes[9,10]. Signet-ring carcinoma of the breast metastatic to the stomach has also been reported[12,13].

The presence of cystic ovarian masses suggested metastatic ovarian involvement (Krukenberg's tumor). Unfortunately, the patient's unfavorable clinical condition did not allow histological confirmation. Metastatic involvement of the breast and the ovaries is extremely rare and has been reported in only 5 cases so far. Selective invasion of hormone-dependent organs seems quite intriguing, especially in pre-menopausal women. Increased blood supply of the breast has been proposed as the

[4] Breast metastasis was the initial manifestation of disease.
[5] No histological confirmation.

mechanism for the increased incidence of breast metastasis in pre-menopausal women[14-15]. On the other hand, gastric cancer seems to have a more aggressive biologic behavior in younger age groups, where hormonal factors are implicated[16]. The appearance of breast metastases in men with gynecomastia supports the latter hypothesis[17]. In our patient, hormonal therapy for the induction of ovulation may have influenced the natural history of the disease[1]. However, no conclusions about the pathogenesis of the phenomenon can be drawn.

Metastatic disease of the breast is rare, and usually has atypical clinical and mammographic presentation. In cases of breast inflammation or lumps, biopsy should be performed, even in the presence of an extra-mammary neoplasm. Likewise, peculiar histological features from malignant breast lesions should be co-estimated with other clinical parameters toward the diagnosis of metastatic disease. Thus, avoidance of unnecessary radical surgical procedures and an adequate treatment is more probable to be given in these patients.

Abstract

Multiple pyogenic liver abscesses have been rarely described. We report a fatal case of multiple pyogenic liver abscesses affecting a 38-year-old woman requiring surgical drainage. Evolution was marked by occurrence of a septic shock with multi-organ system failure. The patient died 48 h after surgery. Causes, therapeutics and outcome of the disease are discussed.

INTRODUCTION

The mortality rate of pyogenic liver abscess is 11%-31%[1]. The overall mortality is high in patients with multiple liver abscesses[2]. However, multiple pyogenic liver abscesses are not frequently reported in the literature. We report a fatal case of multiple and gigantic liver abscess affecting a 38-year-old woman.

CASE REPORT

A 38-year-old woman was admitted to our hospital for abdominal pain in the right upper quadrant, fever, vomiting and anorexia as well as chills and jaundice. On examination she had marked tenderness in the right upper quadrant. The temperature was 40.1 ℃, the pulse was 119, and the respiratory rate was 30/min. The blood pressure was 80/30 mmHg. The patient did not drink alcohol.

Laboratory tests performed on admission revealed 41.5% hematocrit, 26 300 white-cell count (per mm^3), 62 000 platelet count (per mm^3), 30% prothrombin time, 269 μmol/L total bilirubin, 170 μmol/L conjugated bilirubin, 11 mmol/L urea nitrogen, 42 μmol/L creatinine, 4.5 mmol/L glucose, 117 mmol/L sodium, 4 mmol/L potassium, 87mmol/L chloride, 16 mmol/L carbon dioxide, 51U/L aspartate aminotransferase, 21 U/L alanine aminotransferase and 208 U/L creatine kinase.

Ultrasonography of the abdomen revealed that the hepatic parenchyma appeared diffusely heterogeneous, with hypoechoic foci in the right lobe, suggesting the presence of abscess or multiple hydatid cysts.

CT scan of the abdomen (Figures 1A-B) before and after intravenous injection of contrast material confirmed the presence of multiple irregular abscesses varying in size, predominantly in the right lobe of the liver.

Microbiological culture was performed (hemoculture) and the patient received intravenously cefotaxime, gentamicin, metronidazole, omeprazole, fluid, and electrolytes. Surgical drainage was performed 48 h after hospital admission. *Escherichia coli, Bacteroides fragilis and prevotella oralis* were found in cultures of the pus.

Evolution was marked by occurrence of septic shock with multi-organ system failure. The patient died 48 h after surgery.

DISCUSSION

Pyogenic liver abscesses are found in 0.3%-1.4% of autopsies[3]. Patients with diabetes mellitus, immune deficiency, sickle cell anemia, malignancy, and liver transplants are at a greater risk for developing liver abscess[1]. The majority of pyogenic liver abscesses are caused by infection originating in the biliary or intestinal tracts[4]. About 10% of pyogenic liver abscesses develop as a result of bacteria entering the liver via the hepatic artery[5]. In the majority of cases, more than one organism has been isolated from their abscesses[6]. The most commonly infecting organisms are Gram-negative aerobes and *Escherichia coli* is the most frequently encountered[7]. In our case three organisms were identified, suggesting that pyogenic liver abscesses are caused by infection originating in the intestinal tract. Without appropriate diagnosis and treatment, pyogenic liver abscesses are almost uniformly fatal[2,4]. Early diagnosis as well as treatment with appropriate antibiotics and selective drainage can substantially reduce mortality. Our observation has confirmed this hypothesis.

Antibiotic therapy should include penicillin, which is

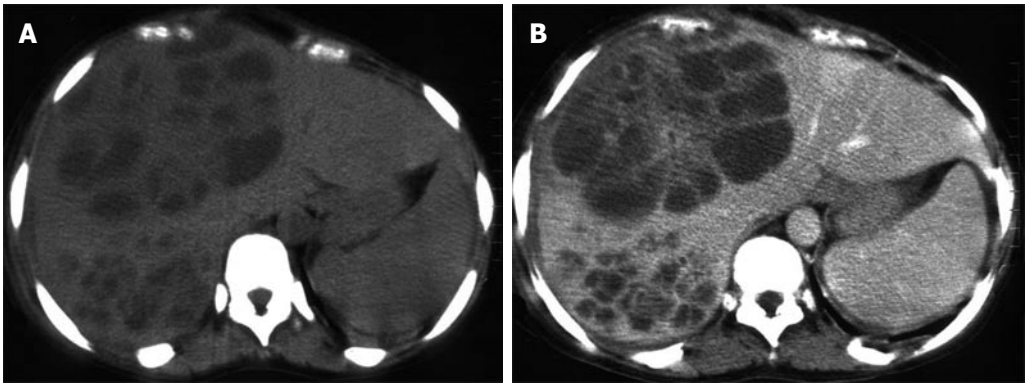

Figure 1 CT scan without (**A**) and with (**B**) contrast injection of the abdomen showing multiple irregular liver abscesses in the right hepatic lobe.

effective against *E coli, K pneumonia, bacteroides, enterococcus,* and *anaerobic streptococci*[1]. Antibiotics alone are effective for only a few patients and most patients require percutaneous aspiration or catheter drainage guided by ultrasonography or computed tomography[1]. In our case open surgery was performed because the patient suffered from multiple liver abscesses and septic shock.

The overall mortality may be as high as 30%-40% in patients with multiple liver abscesses, malignant biliary obstruction, inadequate drainage, and immunodeficiency[1,2]. In our case no pathological antecedent was found, however we cannot exclude immunodeficiency in this woman.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included.

Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

_____

Author Name in abbreviation (Family names are put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

Abstract

Hepatic encephalopathy (HE) is a common neuropsychiatric abnormality, which complicates the course of patients with liver disease and results from hepatocellular failure and/or portosystemic shunting. The manifestations of HE are widely variable and involve a spectrum from mild subclinical disturbance to deep coma. Research interest has focused on the role of circulating gut-derived toxins, particularly ammonia, the development of brain swelling and changes in cerebral neurotransmitter systems that lead to global CNS depression and disordered function. Until recently the direct investigation of cerebral function has been difficult in man. However, new magnetic resonance imaging (MRI) techniques provide a non-invasive means of assessment of changes in brain volume (coregistered MRI) and impaired brain function (fMRI), while proton magnetic resonance spectroscopy (^{1}H MRS) detects changes in brain biochemistry, including direct measurement of cerebral osmolytes, such as myoinositol, glutamate and glutamine which govern processes intrinsic to cellular homeostasis, including the accumulation of intracellular water. The concentrations of these intracellular osmolytes alter with hyperammonaemia. MRS-detected metabolite abnormalities correlate with the severity of neuropsychiatric impairment and since MR spectra return towards normal after treatment, the technique may be of use in objective patient monitoring and in assessing the effectiveness of various treatment regimens.

INTRODUCTION

Although the phenomenon of mental disturbance in patients with disordered liver function was probably first described over 2000 years ago by Hippocrates, the precise mechanisms associated with the development of hepatic encephalopathy (HE) remain unclear. The syndrome occurs in two distinct forms: in the context of acute liver failure, acute HE results in impaired consciousness which may progress to coma and death over a period of hours or days, whereas chronic HE describes the neuropsychiatric syndrome, most commonly associated with hepatic dysfunction and portosystemic shunting in cirrhosis. This may also exist in patients with surgical portosystemic shunts[1]. In most patients the condition is "minimal" and, on a functional basis, it is discernible in prolongation of reaction times in the activities of daily living, such as driving and operating machinery, but in about 30% of patients with chronic liver disease, the syndrome is more severe with alterations in behavior, mood, personality and disturbances in consciousness[1].

In routine clinical practice, brain imaging in the form of a CT scan has been commonly used to exclude other

diagnoses, such as subdural hematomata, which may also cause impaired consciousness in patients with chronic liver disease. Until recently, the use of other imaging modalities such as magnetic resonance imaging (MRI) has been a second-line investigation in many countries, whereas magnetic resonance spectroscopy (MRS) has been largely confined to research applications, where significant advances in the understanding of pathophysiological mechanisms have been made. While most clinical MRI systems have operated at magnetic field strengths of 0.5-1.5 Tesla (T), higher field strength whole body systems are now increasingly becoming available at 3T and above, providing increased resolution and sensitivity. This article will review the published MR studies in HE and with the advent of new MR imaging capabilities, we speculate on areas of new research for the future.

HEPATIC ENCEPHALOPATHY

"Minimal" HE is the term used to describe the presence of cognitive impairment on psychometric testing and/or slowing of electroencephalographic (EEG) mean cycle frequency in the absence of any clinically overt signs[1,2]. This form of HE is present in the majority of patients with cirrhosis, but where the condition is more profound, it is usually characterised by remissions and relapses, manifested by obvious mood disorders, personality changes and disturbances in consciousness[1]. However, in a small minority of patients the neuropsychiatric impairment may follow a more persistent course. Elevated circulating ammonia levels, which are present owing to impaired hepatic nitrogen excretion or because of portosystemic shunting, are thought to be key to the changes in neurotransmitter systems that underlie the disturbances in function observed clinically[3]. These include increased GABAergic tone, elevated glutamine levels and changes in several other neurotransmitter systems and their receptors, such as reduced glutamate excitatory transmission and increased serotonergic inhibition[4]. Other abnormalities include selective alterations of blood-brain barrier permeability and changes in cerebral energy metabolism[5]. However, the central question of how these relate to elevated ammonia concentrations is an unresolved issue.

MAGNETIC RESONANCE IMAGING

CT and MRI have long been used to detect obvious structural abnormalities in the brain such as cerebral atrophy, which occur in patients with chronic alcoholism, who do not necessarily have significant liver disease[6,7]. However, MR techniques may provide non-invasive insight into the pathogenesis of HE. Apart from structural changes associated with the direct effects of alcohol, a longstanding MR observation has been that patients with cirrhosis of any aetiology show hyperintensity in the basal ganglia on T_1-weighted MRI (Figure 1)[8-11]. Hypermanganesemia due to occupational exposure or total parenteral nutrition also results in similar appearances, which reverse after correction of the blood manganese levels[12,13]. In cirrhosis, a correlation between blood manganese levels and globus pallidus signal intensity has been reported[10,14,15] and elevated *post-mortem* globus pallidus manganese concentrations have been detected in patients who have died with terminal liver disease[10,16]. It was initially suggested that basal ganglia hyperintensity might be an important aetiological association of the form of HE that complicates chronic liver disease[8,11]. However, a number of studies found no correlation between basal ganglia T_1-weighted signal intensity and clinical encephalopathy or neuropsychological test performance[9,17,18], although the extrapyramidal symptoms seen in a minority of patients with HE may be related[14]. Instead, basal ganglia T_1-weighted signal intensity and manganese accumulation appears to be related to the underlying degree of hepatic dysfunction or more particularly to the severity of cholestasis and/or the presence of portosystemic shunting, rather than directly to neuropsychiatric impairment[19]. The relationship with cholestasis is important, since manganese itself is normally eliminated from the body via the biliary route[20].

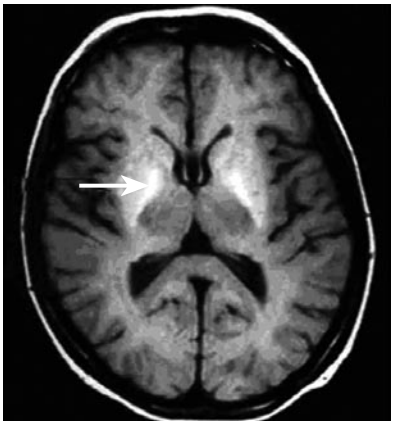

Figure 1 T1-weighted brain MR image through the basal ganglia acquired at 1.5T, showing bilateral globus pallidus (arrow) hyperintensity in a patient with cirrhosis of the liver.

It has recently been proposed by Häussinger and colleagues that a major contributory event in the development of HE in patients with chronic liver disease is an increase in astrocyte hydration, or in other words, a low-grade cerebral oedema without a clinically overt increase in intracranial pressure[5]. This may occur as a consequence of ammonia uptake by astrocytes and subsequent detoxification by the enzyme glutamine synthetase to form glutamine from glutamate[3]. This deamidation process is thought to result in the accumulation of glutamine within astrocytes, which acts as a cerebral osmolyte with resultant cell swelling. With conventional neuroimaging, brain oedema is not evident in the vast majority of patients with chronic liver disease who have HE, probably because if present, the brain swelling is minimal and is thus beyond the threshold for detection on standard MRI. This is unlike the encephalopathy associated with fulminant hepatic failure, which is obviously characterised by cerebral oedema [21]. However, a number of recent studies, which employed magnetization transfer imaging (MT), suggested that there may be an increase in total brain water in the HE of chronic liver disease[22-24].

MAGNETIZATION TRANSFER IMAGING

MT allows indirect measurement of bound and free

water compartments in the brain and may be affected by changes in membrane fluidity, heavy metal deposition and alterations in total water content[23,24]. The technique itself is a method for manipulating tissue contrast[25,26]. In addition to enabling the acquisition of enhanced contrast images, techniques employing MT also allow the measurement of MT ratios (MTR). The MTR is a quantitative tissue characteristic that reflects the behavior of normally MR-invisible protons bound to macromolecules. MTR measurement may detect brain parenchymal changes that may not be visible using standard MR techniques. In essence, protons in tissues can be described as existing in two pools. The free pool consists of mobile protons, such as those in body water, and has a narrow spectral line with relatively long T_1 and T_2 relaxation times (Figure 2). The bulk of the signal in conventional MR systems comes from this free pool, as the MR excitation frequency range is narrow and centered upon these freely mobile protons. A second pool of protons bound in proteins, other macromolecules and membranes, is conventionally said to be MR invisible, as it falls outside the typical excitation range. This pool has a broad spectral line and very short relaxation times (Figure 2). Magnetization can be transferred bi-directionally between pools by direct interaction between spins, the transfer of nuclei or by direct chemical means. Under normal circumstances, the transfer of magnetization is the same in both directions.

Techniques that employ MT do so by saturating the magnetization in the bound pool while leaving the free pool largely unaffected. This is possible because the bound pool has a broad spectral line and can be excited by the application of an "off-resonance" RF pulse (Figure 2). This saturation results in substantial attenuation of the magnetization in the bound pool. As a consequence, there is little transfer of magnetization to the free pool and both the effective longitudinal magnetization within it and its T_1 are reduced. Pulse sequences that incorporate the application of an "off-resonance" pulse can be designed to allow quantification of the effect of MT in different tissues, in health and disease[25]. Reduced MTRs may result from pathologies that alter the structural integrity and the relative macromolecular-water composition of brain parenchyma, such as in multiple sclerosis plaques or in end-stage cirrhosis[27-29]. These observations may also result from the deposition of paramagnetic substances in the brain. MR experiments with manganese chloride phantoms have demonstrated a strong inverse linear relationship between the manganese concentration and the MTR[29]. This property has been exploited for the use of paramagnetic contrast agents, such as gadolinium-based compounds. Furthermore, manganese is excreted via the biliary route and can thus accumulate in cholestatic conditions, including in the basal ganglia in patients with chronic liver disease[19]. It is of note, therefore, that our group has reported reduced MTRs in the basal ganglia of fatigued patients with primary biliary cirrhosis, which correlate strongly with ambient plasma manganese levels[30].

In the context of HE, the reported change in MTR in patients with cirrhosis could represent an alteration in the structure of cell membranes, leading to cell membrane fluidity. However, these observations may, perhaps, be accounted for by an increase in cerebral water content[22-24]. If the interpretation of the MT papers in HE is correct[22-24], an increase in brain hydration, as represented by altered MT ratios, will not be dramatic enough to cause an increase in intracranial pressure, but may reflect "lower-level" astrocyte swelling, which could be sufficient enough to trigger alterations in astrocyte function[22-24]. The possible functional effects of low grade astrocytic swelling are numerous and could possibly explain many of the features of HE complicating chronic liver disease, including alterations in blood brain barrier permeability, neurotransmitter processing and receptor density and upregulation of cerebral neurosteroid production[5]. At present, the MTR data remain an interesting observation and future studies incorporating newer MR imaging techniques are required to provide more definitive answers on pathogenesis.

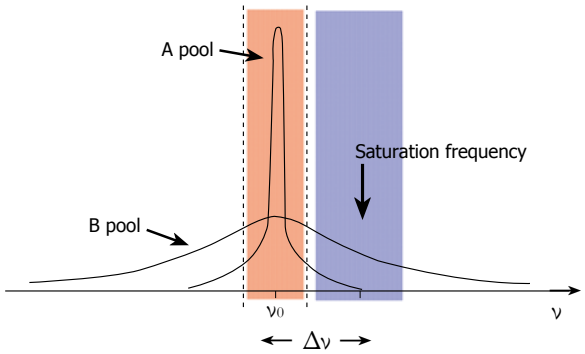

Figure 2 Model demonstrating the concepts underlying the phenomenon of magnetization transfer. The free pool of protons (**A**) resonates at the Larmor frequency (ν_0) and has a narrow spectral line. It is excited by an RF pulse which covers the frequencies shown in pink. The "bound" pool of protons (**B**) has a broad spectral line and can be excited and saturated by the application of RF irradiation at a frequency offset by $\Delta\nu$, shown in blue, without significantly affecting pool A.

DIFFUSION IMAGING

Diffusion-weighted imaging (DWI) is a method used to quantify the movement of water molecules. One of the first applications of this technique was the detection of acute cerebral ischemia in the early 1990s[31,32]. Further recognized indications include the investigation of multiple sclerosis[33] and brain tumors[34,35].

The diffusion of water molecules follows the principles of Brownian motion. Thus, when these molecules are unconstrained, their movement is random and therefore equal in all directions, being described as "isotropic". However, the motion of water molecules in structured environments is restricted, according to the physical surroundings. The motion of water molecules in the brain is restricted by the microstructure within grey and white matter. Water molecules on average tend to move parallel to, rather than perpendicular to the white matter tracts[36,37]. This motion is described as "anisotropic", as it is no longer equal in all directions. The motion of the molecules in the x, y and z directions and the correlation between

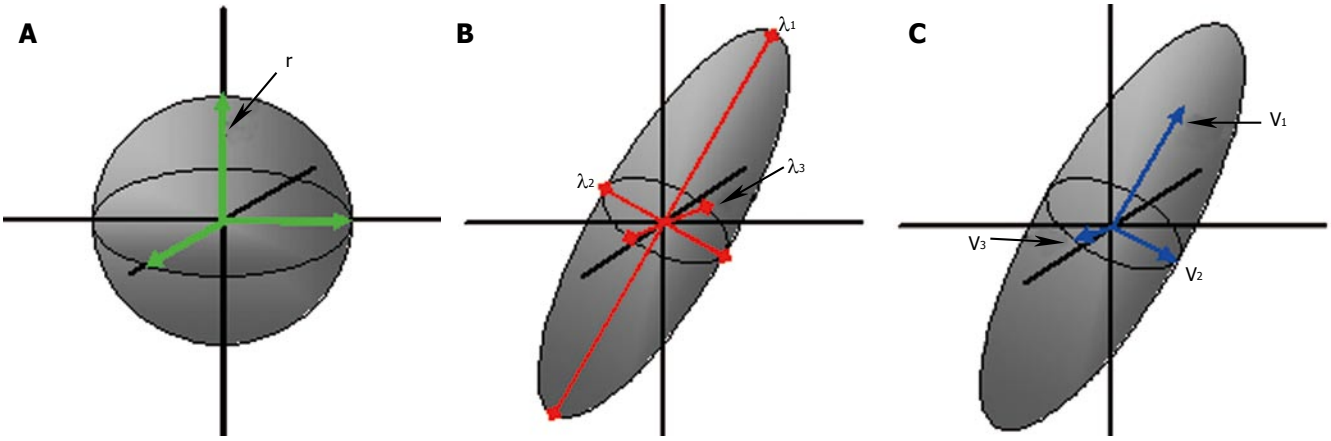

Figure 3 Principles of diffusion: A water molecule in an unconstrained environment would move randomly and equally in all directions; isotropic diffusion (**A**). The probability of motion can be defined by the radius '*r*', of the spherical range of motion. Diffusion in an ordered environment such as the white matter will assume an elliptical range of motion (**B** and **C**). Three eigenvalues, λ_1, λ_2 and λ_3 define the shape and three eigenvectors v_1, v_2 and v_3 define the orientation of the ellipsoid.

the directions is described with the diffusion tensor[38,39]. A tensor is a mathematical construct that defines the properties of a three-dimensional ellipsoid. To define the diffusion tensor requires acquisition of diffusion data in a minimum of six non-collinear directions, this is known as diffusion tensor imaging (DTI). The diffusion tensor is graphically represented by a three-dimensional ellipsoid, with the long axis representing the primary direction of motion (Figure 3). Eigenvalues and eigenvectors describe the magnitude and directions of the three principal axes of the diffusion ellipsoid[40]. The diffusion tensor is evaluated at each pixel location and so maps of the magnitude and dominant direction of diffusion can be produced. The dominant directions can be followed from one pixel to another, plotting lines along which diffusion is likely to occur. This practice is known as tractography, the name coming from the implication that these paths are believed to represent white matter tracts. Using a minimum of 2 differently weighted DWI images, a measure of diffusion can be calculated. These data can then be mapped to create an apparent diffusion coefficient (ADC) image[41]. The ADC is a measure of tissue water diffusivity and is dependent upon interactions between water molecules and their surrounding chemical and structural environment[42]. Diffusion data may be expressed in terms of the mean diffusivity, sometimes called the mean ADC or the trace ADC. This is the average of three ADC measurements in three orthogonal directions. DTI gives rise to detailed information on the microstructure within an imaging voxel, including mean diffusivity, the degree of anisotropy and the direction of diffusivities[43]. The mean diffusivity reflects the displacement of water molecules and the presence of obstacles at both the cellular and subcellular level. Fractional anisotropy (FA) and relative anisotropy (RA) are commonly used to express the degree of anisotropy. Anisotropy will be related to the characteristics of any physical barriers, such as the orientation, density, size and shape of nerve fibers within white matter tracts. However, interestingly, myelination has been demonstrated not to be a primary determinant of anisotropy, but may indeed have modulatory effects[44]. The directionality of

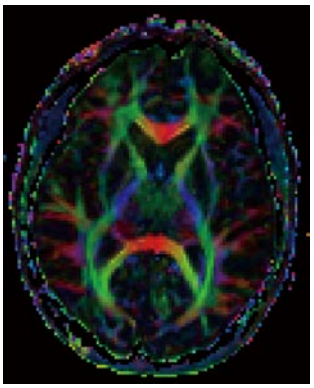

Figure 4 Color fractional anisotropy (FA) image from a 44 year-old healthy male volunteer. Diffusion tensor imaging (DTI) performed on a 3T Philips Intera™ using 32 different directions of diffusion sensitization. The different colors represent the principle diffusion directions and hence the direction of the white matter tracts: green represents anterior-posterior, blue represents caudo-cranial, red represents transverse. FA maps were generated using DTI studio version 2.1©, (Jiang and Mori, Johns Hopkins University, MD, USA).

fibers can be expressed on color-coded two-dimensional maps, or by three-dimensional tractography images. The orientation of the major axonal fiber bundles can be calculated using the eigenvectors and eigenvalues by various algorithms[40]. The expression of DTI data in the form of 3D images is one of the latest developments in this technique and may provide insight into defects in brain connectivity (Figure 4).

In the field of HE, one study has looked at regional brain ADC values in patients with cirrhosis, secondary to viral hepatitis[45]. Seven patients had no encephalopathy, six had grade I and one grade II hepatic encephalopathy, according to Parsons-Smith criteria[46]. The authors found that except in the thalamus, ADC values were significantly increased in all white matter and deep grey matter areas examined. Furthermore, except for the caudate nucleus, there was a positive correlation between ADC values in all areas of the brain and venous ammonia concentrations. They suggest that their findings are related to increased brain water content, which would support the brain swelling hypothesis.

FUNCTIONAL MRI

It is well recognized that HE encompasses a broad spectrum of neuropsychiatric and cognitive impairments. Investigators have used a variety of non-invasive

techniques, such as electroencephalography (EEG)[47] and magnetoencephalography (MEG) [48] to study the brains of patients with chronic liver disease, but these methodologies suffer from limited spatial resolution. Positron emission tomography (PET) has also been used to investigate both metabolic impairments and neurotransmitter deficits in patients with HE[49-52], but PET does not readily lend itself to serial studies, owing to the necessity for injection of radioactive tracers.

However, functional MRI (fMRI) provides the opportunity to study brain function in detail without the drawbacks of those other techniques, albeit with a reduced sensitivity resulting in long scan times. The most common method of assessing an alteration in cerebral activity in fMRI is by measuring the "blood oxygenation level dependent" (BOLD) signal, which represents local changes in hemoglobin oxygenation due to cerebral blood flow changes[53-55]. The signal arises because of the different magnetic properties of oxygenated hemoglobin, which is isomagnetic, and deoxyhemoglobin, which is paramagnetic relative to tissue[56]. PET studies have previously demonstrated that cerebral blood flow increases by up to 50% in response to functional activation, but the cerebral metabolic rate for oxygen increases only by 5%[57,58]. Thus, in fMRI there is a reduction in the proportion of deoxyhemoglobin, and hence in the magnetic properties of the activated brain region, which contributes to the BOLD signal. In the context of chronic liver disease, one study has used fMRI to investigate cognitive alterations in a cohort of 9 patients with minimal or "non-manifest" hepatic encephalopathy (nmHE)[59]. The patients were given a stimulus of a flickering light of decreasing frequency and were asked to indicate when the light appeared to change from a fused light to a flickering light; the "critical flicker frequency" threshold[60]. The BOLD signal was measured during this task, and the investigators observed a decrease in activation in the right inferior parietal cortex of the nmHE patients, compared to healthy age-matched volunteers. These data also suggested impaired neural connections between several cortical structures[59].

CEREBRAL BLOOD FLOW

It is well known that cerebral blood flow (CBF) changes in encephalopathic patients[49,61]. There are a variety of MRI techniques that can potentially be used to study this, including arterial spin-labeling (ASL) and contrast-enhanced perfusion MRI (CEMRI)[62-64]. Perfusion can be calculated by measuring the change in signal in the brain as a contrast agent (Gd-DTPA) flows into the brain. If an accurate measure of the arterial input function (AIF) can be extracted then quantitative measures of blood volume, flow and transit time can be calculated. Accurate measurement of the AIF is difficult and so absolute quantification is rare. In addition, the use of contrast agents is not desirable in patients with poor liver function. As always with contrast agents, longitudinal studies are also not recommended which explains the lack of such studies to date. An emerging methodology is arterial spin labeling where the blood is used as an endogenous contrast agent. The blood is tagged (usually in the carotid artery) using an RF pulse, similar to those used in standard MR imaging. The arrival of this "bolus" of tagged blood is then monitored in the brain by imaging. ASL is a very low sensitivity method compared to CEMRI and so requires significantly longer imaging times to acquire robust data (10-20 min compared to < 1 min for CEMRI). This means that ASL really only becomes feasible at higher field strengths (3T+), where imaging times become acceptable due to increased sensitivity. At the time of writing this methodology has yet to be applied to the study of HE, but the technology is now at a level of development that the known CBF changes associated with HE may be able to be quantified and response to treatment tracked using such methods.

VOLUMETRIC MRI

Until recently, MR measurement of brain and ventricular volumes was not sensitive enough for direct, serial measurement of small changes in brain size in patients with HE, who have structurally normal brains. However, the rapid development of MR analysis software now allows for precise measurements of whole or regional brain volumes and allows very small differences in brain size to be monitored that may not be visible to standard radiological inspection (coregistered MRI)[65,66]. These volume changes may be measured to allow inter- or intra-group comparisons and to follow up individuals or groups longitudinally. The techniques have been applied to a number of clinical conundra including pre-eclampsia[67-70] and given the recent interest in the possibility of low-grade oedema as a central factor in chronic HE[5], a useful application of MR is to investigate the brain volume changes that may occur in HE. One such study was performed by our group[71]. Six patients had minimal HE and three had overt HE. Seven patients were treated with lactulose for 6 weeks and three of them improved on serial psychometric testing with a consequent reduction in brain size on repeat MR imaging. Although measurable changes were found after treatment intervention, these were not correlated with the degree of encephalopathy. A recent study used voxel-based morphometric analysis of MR data to calculate brain volumes in patients with cirrhosis of varying etiologies[72]. It is not clear whether these patients were formally assessed for the presence of encephalopathy. However, the investigators found that patients with alcoholic cirrhosis had atrophy involving both grey and white matter structures[72], the latter finding in white matter is consistent with early neuropathological studies[73]. Interestingly these authors also found that patients with cirrhosis, caused by viral hepatitis also had similar, but quantitatively less atrophy[72].

LOCALIZED BRAIN WATER CONTENT

One imaging group has developed an MR technique to measure localized cerebral water content in a quantitative fashion[74,75]. This technique has been used to investigate

a cohort of patients with hepatic encephalopathy[76]. Results from this pilot study show a significant correlation between the severity of HE and white matter water content. This could be a technique of great interest, if it can be translated to other MR systems in other centers around the world.

MAGNETIC RESONANCE SPECTROSCOPY

Further evidence for changes in brain hydration and cerebral osmolytes in HE which complicates chronic liver disease comes from studies using MRS. *In vivo* MRS is a non-invasive technique which can be used to provide localized biochemical information on cerebral metabolic processes. The underlying principles of physics that govern MRS are essentially the same as for MRI. Nearly all elements possess at least one naturally occurring isotope amenable to MR study. The most commonly used isotopes have been hydrogen-1 (^{1}H), and phosphorus-31 (^{31}P). ^{1}H MRS can be utilized to provide information on brain metabolites such as choline, creatine, N-acetyl aspartate (NAA), glutamine and glutamate, as well as osmolytes such as myoinositol and taurine[77].

Several studies have reported characteristic spectral appearances in HE, typified by a reduction in the myoinositol and choline resonances and an increase in the glutamate/glutamine composite resonance, which correlate with neuropsychiatric impairment (Figure 5)[77-85]. Ammonia itself cannot be detected by ^{1}H MRS, but the increase in signal from the glutamine/glutamate is likely to reflect ammonia incorporation into glutamine. The astrocyte swelling hypothesis predicts that homeostatic mechanisms occur to limit the osmotic load in astrocytes, leading to the extracellular release of osmolytes, such as myoinositol[5]. This is supported by the observation of reduced intracellular myoinositol in ^{1}H MRS studies.

The choline resonance contains contributions from phosphocholine and glycerophosphorylcholine, which are cell membrane precursor and degradation products[86]. This observed reduction is likely to reflect alterations in phospholipid metabolism, membrane fluidity, or secondary changes in water content, because glycerophosphorylcholine is itself a cerebral osmolyte[87].

The typical cerebral ^{31}P MR spectrum contains at least seven resonances, which can be assigned to phosphomonoesters (PME), inorganic phosphate (Pi), phosphodiesters (PDE), phosphocreatine, γATP, αATP and βATP (Figure 6)[88]. ^{31}P MRS provides information on the status of energy phosphates and on phospholipid metabolism. Compared to ^{1}H MRS, there is less agreement in the published cerebral ^{31}P findings in patients with HE, due to the small populations studied and variation in the techniques that have been used. Early studies reported reductions in cerebral inorganic phosphate or phosphocreatine, which were interpreted as indicating defects in cerebral energy metabolism[89]. Our group has consistently found reductions in the PME/βATP and PDE/βATP ratios, which correlate with the reduction in choline using ^{1}H MRS[83,84,90,91]. A recent study which used proton-decoupled ^{31}P MRS, a technique which allows the components of the composite PDE peak to be resolved, showed a reduction in glycerophosphorylcholine, which is a major component of PDE and, as discussed above, may be reduced as a consequence of disturbances of cerebral osmoregulation[87].

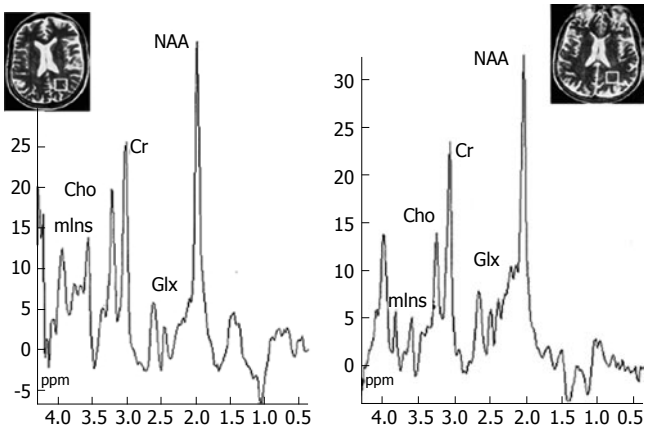

Figure 5 ^{1}H MR spectroscopy water-suppressed proton spectra of an 8 mL voxel located in the parietal region including predominantly normal appearing white matter (insert images show position of the voxel) in a healthy control subject (left) and in a cirrhotic patient (right), acquired using a STEAM pulse sequence [1600/20/30/256 (TR/TE/TM/acquisitions)]. The main resonances correspond to N-acetylaspartate (NAA, 2.0 ppm), glutamate/glutamine (Glx, 2.1-2.5 ppm), creatine/phosphocreatine (Cr, 3.02 ppm), choline-containing compounds (Cho, 3.2 ppm), and myo-Inositol (mIns, 3.55 ppm). Comparison of the spectra shows a decrease in Cho and mIns resonances with an increase in the glutamate/glutamine region in the cirrhotic patient. Reproduced with the permission of Springer Science and Business Media, from Cordoba *et al* 2002[28].

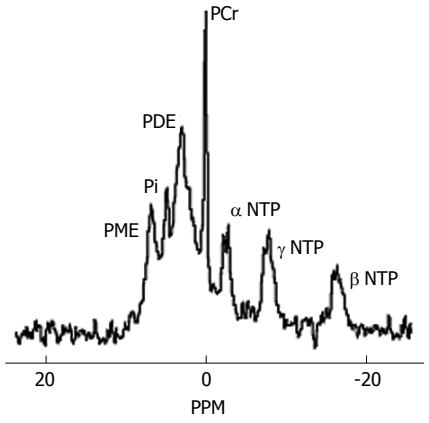

Figure 6 Normal brain phosphorus-31 MR spectrum acquired at 1.5T. PME = phosphomonoesters, Pi = inorganic phosphate, PDE = phosphodiesters, PCr = phosphocreatine, NTP = nucleotide triphosphate. The PME resonance provides information on cell membrane precursors and the PDE resonance on cell membrane degradation products.

FUTURE MRS DEVELOPMENTS

The current limitations of MRS include the limited resolution of metabolites which resonate within a narrow spectral range, such as glutamine and glutamate, and the inability to detect low concentration metabolites. Possible advances in the field include the use of two-dimensional spectroscopy, spectral editing and the use of higher magnetic field strength systems (for example at 3T).

Of these, two-dimensional spectroscopy has already been used to investigate HE. Investigators have reported enhanced spectral resolution with the additional finding of an increased taurine resonance, which was well resolved [92] (Figure 7). However, currently this technique suffers from

low signal-to-noise, and despite the use of a surface head coil, it is unable to probe the deeper grey matter structures, such as the basal ganglia.

Spectral editing involves only the acquisition of a desired spectrum of interest by suppressing the signal of other metabolites and then attempting to acquire only the signal of interest. This approach is of importance in HE in order to separate glutamate from glutamine, which overlap in conventional MR spectra. It should be noted that spectral editing is particularly sensitive to motion artefact and instrument instability. However, these methodologies have been used to highlight taurine, GABA and myo-inositol *in vivo* and suppress unwanted resonances[93-95]. Such sequence development promises much in the future for HE patients, but with respect to resolving glutamate from glutamine *in vivo*, another approach called averaged TE spectroscopy has been used to resolve glutamate from glutamine[96]. This has been used in multiple sclerosis at 3T, but not yet in HE patients[97].

With the advent of clinical magnet systems operating at higher magnetic fields, such as 3T, which is twice that used hitherto in published studies, the sensitivity of the technique may be enhanced further with improved signal-to-noise ratios. The possibility of performing multiple MR sequences in the same examination of the brain is now possible, because acquisition times are usually faster at these higher field strengths. It will thus be feasible to perform MRS studies on cerebral osmolyte levels in the same examination as acquiring data suitable for computer-enhanced visual detection of brain swelling and fMRI which should pinpoint cognitive and perceptive derangements. Since MR does not involve ionising radiation, serial studies will be possible to look at treatment effects in HE.

CONCLUSIONS

In vivo MRI and MRS provide a non-invasive way of studying brain chemistry and metabolism in patients with liver disease. These techniques have been central in the study of the underlying mechanisms of liver-related brain disease. MRS remains a research tool in the setting of liver disease. However, simple MRS sequences can be added to a standard MR examination to provide metabolic information that could help monitor response to therapy. MR studies in HE have provided important *in vivo* data, which have contributed to the current theories on astrocyte swelling[5]. This model accommodates many of the common precipitating factors for CHE, such as hyponatremia, benzodiazepine administration and infection (raised inflammatory cytokines), since these events also lead to astrocyte swelling *in vitro*[5]. Astrocyte swelling may therefore be a common pathway for multiple synergistic factors in the pathogenesis of HE complicating chronic liver disease. However, further MR studies are clearly required before these ascertations can be confirmed. A whole variety of new MR techniques now exist to study HE in more depth.

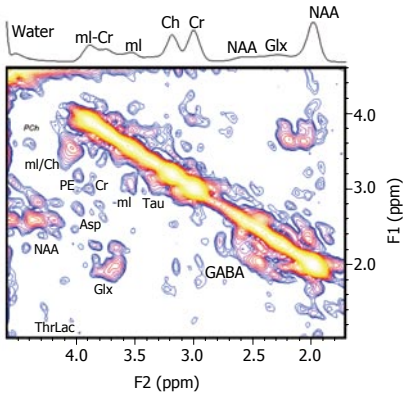

Figure 7 A localized two-dimensional correlated spectroscopy (two-dimensional L-COSY) spectrum of a 40-year-old patient. A projected one-dimensional spectrum is also shown on top of the figure. Peaks are presented in the magnitude mode. Reproduced with permission from John Wiley and Sons Inc, from Binesh N *et al* 2005[93].

ACKNOWLEDGEMENTS

Abstract

Gastric cancer remains a global killer with a shifting burden from the developed to the developing world. The cancer develops along a multistage process that is defined by distinct histological and pathophysiological phases. Several genetic and epigenetic alterations mediate the transition from one stage to another and these include mutations in oncogenes, tumour suppressor genes and cell cycle and mismatch repair genes. The most significant advance in the fight against gastric caner came with the recognition of the role of *Helicobacter pylori (H pylori)* as the most important acquired aetiological agent for this cancer. Recent work has focussed on elucidating the complex host/microbial interactions that underlie the neoplastic process. There is now considerable insight into the pathogenesis of this cancer and the prospect of preventing and eradicating the disease has become a reality. Perhaps more importantly, the study of *H pylori*-induced gastric carcinogenesis offers a paradigm for understanding more complex human cancers. In this review, we examine the molecular and cellular events that underlie *H pylori*-induced gastric cancer.

INTRODUCTION

Gastric cancer remains a major health problem being the fourth commonest cause of cancer death in Europe[1]. On a global scale, gastric cancer remains the world's second commonest malignancy, having only been overtaken by lung cancer in the late 1980's[2-4]. There is substantial international variation in gastric cancer incidence with the highest rates reported from Korea, Japan and eastern Asia. Other high incidence areas include Eastern Europe and parts of Latin America, while Western Europe and the US generally have low incidence rates. The global burden of gastric cancer is shifting rapidly from the developed world to the developing world. Despite the worldwide decline in incidence and the major improvements in diagnosis and treatment, less than 20% of patients survive to 5 years.

PATHOLOGY OF GASTRIC CANCER

The vast majority of gastric cancers are sporadic. However there is strong evidence that occasional cases have an inherited component. Over 95% of malignancies of the stomach are adenocarcinomas. Lymphoma, sarcomas and carcinoid tumours comprise the remaining less common neoplasm's. Adenocarcinoma of the stomach comprises a spectrum of different conditions classified according to the site of tumour origin and the pathological appearance of the lesion. Lauren composed a histological classification that is widely applied. According to this classification neoplasms are described as intestinal or diffuse types[5]. Intestinal tumours are comprised of malignant cells that are united to form structures resembling functional glands of the gastrointestinal tract. In contrast, the less common diffuse tumour type comprises cells that lack cohesion and are no longer capable of gastric function. The evolution of intestinal tumours has been characterised as progressing through a number of sequential steps. These steps begin with gastritis which progresses to mucosal atrophy (atrophic gastritis) followed by intestinal metaplasia, dysplasia and carcinoma with subsequent metastatic dissemination. No preceding steps have been identified in the pathogenesis of diffuse carcinoma other than the obvious chronic gastritis that is the hallmark of *Helicobacter pylori* (*H pylori*) pathogenesis. Diffuse adenocarcinoma has an increased propensity for intra and transmural spread and is therefore associated with a poorer prognosis. Unfortunately the histological classification of an individual gastric adenocarcinoma is not clear-cut with a tumour often comprising a mixture of intestinal and diffuse tissue types.

AETIOLOGY OF GASTRIC CANCER

The pathogenesis of gastric cancer represents a classic example of gene-environment interactions[6,7]. For many

decades it was well established that the cancer developed along well-defined histological and pathophysiological stages. Chronic inflammation with gastric atrophy was shown to be the most important pathological entity with hypochlorhydria being the most important physiological abnormality. Diets high in food preservatives such as salts and nitrates are thought to induce gastric malignancy whereas increased consumption of food containing natural antioxidants such as fresh fruit and vegetables may slow or prevent the disease. Alcohol and smoking are also thought to contribute to the aetiology. Achlorhydria, pernicious anaemia and blood group A are also associated with a higher risk of gastric malignancy.

Hereditary factors clearly increase the risk of gastric cancer and this malignancy is part of a number of familial cancer syndromes. The most celebrated familial case of gastric cancer is that of Napoleon Bonaparte. It is well documented at autopsy that the exiled Emperor had a malignant gastric ulcer complicated by a chronic perforation and haemorrhage. His father, Charles Bonaparte, died from scirrhous carcinoma of the pylorus at the age of 39, and his grandfather, Joseph Bonaparte, also died of "suspected" gastric cancer at the age of 40. At least one of his brothers and one of his sisters also died of the same malignancy[8]. Lending support to the genetic aetiological hypothesis is the recognition that patients with hereditary nonpolyposis colon cancer and Familial Adenomatous Polyposis are at an increased risk of developing malignancy in the stomach. Following the discovery of *H pylori* it is has become apparent that the preceding aetiological factors only account for a small proportion of the cases and this review will focus primarily on *H pylori*-induced sporadic gastric cancers.

H pylori infection

The discovery of *H pylori* infection in the early eighties proved a turning point in understanding the pathogenesis of gastric cancer[9]. While the link between *H pylori* and peptic ulcer disease was established soon after successful culture of the bacterium, the association with gastric cancer lagged almost a decade before credible evidence was presented. The major reason for this delay was inability to demonstrate the presence of active infection in gastric tissue of cancer patients. A major advance in this field came with the recognition that chronic *H pylori* infection induces physiological and morphological changes within the gastric milieu that increase the risk of neoplastic transformation. It is widely accepted that chronic *H pylori* infection induces hypochlorhydria and gastric atrophy, both of which are precursors of gastric cancer (Figure 1). Presence of the infection in the final stages of this cascade is therefore not necessary for cancer to develop as irreversible damage had already occurred.

Microbiology of H pylori

The *Helicobacter* genus consists of at least 24 species found in the GI tracts of animals and humans. One of these species is *H pylori* a Gram-negative, spiral shaped, microaerophilic bacilli known to chronically infect over half the world's population[10]. It is usually acquired in childhood, and if left untreated can persist for decades within the extreme environment of the human stomach[11]. The infection can be acquired via the faecal/oral or gastric/oral routes, and if not treated with antibiotics, can persist throughout life. The organism is non-invasive, nonspore-forming, measuring approximately 3.5 × 0.5 micrometers, with 4 to 6 unipolar flagellae[12]. These flagellae are protected from damage by the acidic environment of the stomach by a sheath. This allows the bacterium to move through the mucus layer within the stomach and to reside between this layer and the gastric epithelium[13]. Eighty percent of the bacilli are free-living, however the remainder adhere tightly to the underlying cells and induce ultra-structural changes in the gastric epithelial cell[10,14].

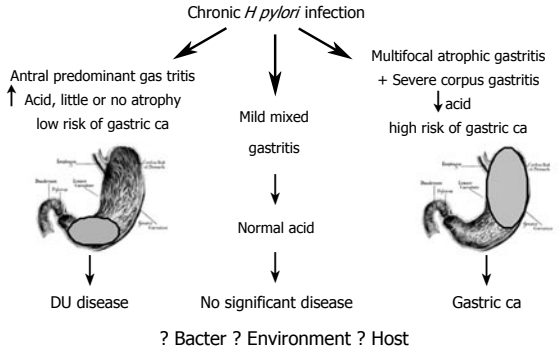

Figure 1 Divergent responses to *H pylori* infection.

Adaptation of H pylori to the gastric environment

While *H pylori* is well equipped to colonise the inhospitable acidic gastric environment, it is essentially a neutralophile that grows best at a pH of between 6.0 and 8.0[13]. In order to do this, *H pylori* is equipped with several factors that allow it to colonise and evade the host defences including the immune response. *H pylori* possesses a urease enzyme that allows it to hydrolyse gastric urea into ammonia and carbon dioxide. This permits *H pylori* to maintain a constant internal and periplasmic pH, even in the presence of a very high external H^+ concentration. In addition, *H pylori* expresses a urea transport protein (UreI) with unique acid-dependent properties that attenuates the rate of urea entry into the cytoplasm[15]. The combination of a neutral pH-optimum urease and an acid-regulated urea channel explains why *H pylori* is unique in its ability to inhabit the human stomach[16,17]. Indeed, isogenic urease-negative mutants of *H pylori* are incapable of colonising the gastric mucosa[18]. To conserve energy and resources, *H pylori* seeks out a niche that does not constantly challenge its acid-resisting and acid adaptation machinery. This explains why the initial colonisation is maximal in the antral part of the stomach, a region with a higher pH than the acid-producing corpus mucosa. This also explains why the distribution of infection changes when gastric acid secretion is inhibited by pharmacological means. In these circumstances, *H pylori* and its associated inflammation spread to involve the hitherto protected corpus mucosa.

H pylori's role in gastric disease

Since early in the 20th century, it has been known that different patterns of gastritis can occur following *H pylori* infection, which ultimately results in differing clinical outcomes. The majority of *H pylori* infected individuals develop mild pangastritis, a condition that does not adversely alter gastric physiology and is not associated with significant disease (Figure 1). Antral predominant gastritis is associated with hyperchlorhydria, which carries a low risk of developing gastric cancer, but a high risk of developing duodenal ulcer disease[19]. In contrast corpus predominant gastritis, which leads to hypochlorhydria and gastric atrophy, carries an increased risk of gastric cancer[20]. It is thought that following the development of the hypochlorhydric atrophic gastric environment, other bacteria, such as nitrogen-fixing bacteria are able to colonise. These bacteria produce carcinogenic N-nitroso compounds through the conversion of nitrates, and the increasing mutagenic and genotoxic pressure coupled with the lack of free radical scavengers is thought to drive gastric cancer progression.

The key question is how chronic *H pylori* infection can be associated with such divergent clinical outcomes? Much research has focussed on *H pylori* strain differences such as virulence factors as the source of the disease specificity. However, although these factors undoubtedly contribute to the severity of the disease, they do not define the clinical outcome[21]. This has prompted research in to other factors that could affect an individual's response to *H pylori* infection. These factors include environmental and host genetic factors.

Role of bacterial virulence factors

There is substantial evidence that genetic differences play a role in the clinical outcome of *H pylori* infection, particularly *H pylori*-virulence associated genes such as *cag*A, *vac*A, *ice*A and *bab*A.

The *cag* Island: The best characterised *H pylori* virulence factor is the *cag* pathogenicity island (*cag*-PAI), a 40 kb chromosomal DNA, which contains approximately 31 genes[22,23]. Several of the genes present on the *cag*-PAI encode components of a type IV secretion system, which allows CagA (cytotoxin-associated gene A), a 120-130 kDa protein product and other bacterial proteins encoded by the *cag*-PAI to be injected into the epithelial cell cytosol (Figure 2)[10,12]. After entering the cell, CagA is phosphorylated and binds to tyrosine phosphatase, which induces secretion of IL-8, a potent chemotactic and activating factor for neutrophils, by the activation of nuclear factor kappa B (NF-κB) complexes[10,24]. The *cag*-PAI also induces cell surface remodelling including the induction of pedestal formation, activation of the transcription factor AP-1 and expression of the proto-oncogenes c-*fos* and c-*jun* by activation of the ERK/MAP kinase cascade[25,26]. *H pylori* strains which do not contain the *cag*-PAI or possess mutated *cag* genes do not induce these changes or do so to a much lesser extent[24,26,27].

H pylori strains can be divided into 2 groups based on the presence/absence of the *cag*-PAI: - type 1 strains, which possess the *cag*-PAI, and type 2 which do not. Type 1 strains are associated with severe gastritis, peptic ulcer disease, gastric atrophy and non-cardia gastric cancer, thus linking the presence of PAI to increased virulence[28-30]. It should be noted however, that not all type 1 isolates contain the entire PAI. Infection with a cagA expressing strain is also associated with reduced apoptosis whereas infection with a cagA negative strain is associated with increased apoptosis. Therefore cagA may act to inhibit gastric epithelial-programmed cell death.

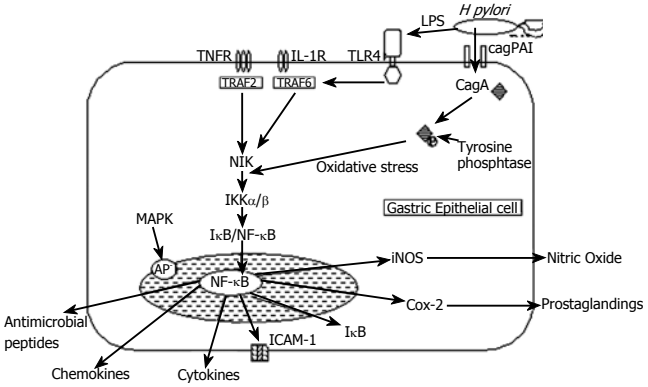

Figure 2 *H pylori* induced gastric epithelial inflammation.

***vac*A gene:** The *vac*A gene encodes the expression of a vacuolating cytotoxin VacA, which induces vacuole formation in eukaryotic cells and stimulates epithelial-cell apoptosis[31,32]. The toxin inserts itself into the epithelial-cell membrane forming a voltage dependent channel through which bicarbonate and organic anions can be released. Unlike the *cag*-PAI, all *H pylori* strains possess the *vac*A gene, although only approximately 50% of strains express the VacA protein. Differences in expression are due to gene sequence variation[33]. Humans infected with VacA expressing *H pylori* demonstrate a greater degree of gastritis than non-expressing strains. *H pylori* infection is invariably associated with elevated gastric epithelial cell proliferation, thought to be a consequence of the epithelial damage.

***bab*A gene:** The *bab*A gene encodes an outer-membrane protein BabA, which binds to fucosylated Lewis B blood group antigen on gastric cells[11,34]. BabA expressing strains adhere more tightly to gastric epithelial cells, and there is significant evidence accumulating that BabA expression may influence disease severity[11]. *H pylori* strains that possess *bab*A, *vac*A and *cag*A carry the highest risk of gastric cancer[11].

***ice*A gene:** A further putative virulence factor has described-*ice*A (induced by contact with epithelium) comprises two main variants *ice*A*1* and *ice*A*2*[35]. However, the function of *ice*A*2* is currently undefined[36]. Significant homology has been found between *ice*A*1* gene and *nla*III a type II restriction endonuclease of *Neisseria lactamica*. Expression of *ice*A*1* is up-regulated by contact of *H pylori* with human gastric epithelial cells and in some populations it is associated with peptic ulcer disease.

Host genetic factors and gastric cancer

It is now well recognised that the development of gastric

cancer and the precursory changes of gastric atrophy and hypochlorhydria are strongly influenced by host genetic factors. The importance of these factors was indicated by the association of Interleukin-1β gene polymorphisms and those affecting its receptor antagonist with an increased risk of developing hypochlorhydria and gastric atrophy in a Caucasian population of gastric cancer relatives, in the presence of *H pylori*[37]. The risk of gastric cancer is also exacerbated by carriage of these polymorphisms. The estimated odds ratio in a logistic regression model for *IL-1B*-511T +/-31C+ and *IL-1RN**2/*2 were 1.6 (95% CI, 1.2-2.2) and 2.9 (95% CI, 1.9-4.4) respectively, in a Caucasian population[38]. The influence of these proinflammatory IL-1β and IL-1 receptor antagonist gene polymorphisms on the development of gastric pre-malignant lesions and carcinoma has subsequently been verified by other investigators[39,40]. IL-1β is relevant to the pathogenesis of *H pylori*-induced inflammation and the subsequent neoplastic process as the expression is up-regulated by the infection, it has proinflammatory actions and it is a powerful inhibitor of acid secretion[41]. Emphasising the multi-factorial nature of *H pylori* related gastric carcinoma, when these polymorphisms are combined with bacterial virulence factors, such as CagA, vacA s1 and vacA m1 positivity, the risk of developing the disease is greatly enhanced[36].

Several other cytokines in addition to IL-1β are involved in the inflammatory response to *H pylori* and are potential host-genetic risk factors. TNF-α is also up-regulated at an early stage after infection and subsequently influences transcription of several mediators[42]. Conversely IL-10 is an anti-inflammatory cytokine that inhibits cell-mediated immune responses. Functional, pro-inflammatory polymorphisms affecting both the genes encoding TNF-α and IL-10 have been associated with an increased risk of non-cardia gastric cancer[43]. The combination of three or four pro-inflammatory cytokine polymorphisms affecting IL-1β (*IL-1B*-511T), IL-1 receptor antagonist (*IL-1RN**2), TNF-α (*TNF-A*-308A) and IL-10 *(IL-10* haplotype ATA) results in a highly significant increased risk of developing non-cardia gastric cancer (OR 27.3 95% CI 7.4-99.8)[43]. More recently a functional pro-inflammatory polymorphism affecting the *IL-8* gene (*IL-8*-251A) has been associated with increased gastric cancer[44-46].

Several other candidate genes have been studied in the attempt to discover associations with the development of gastric cancer. Cytochrome P450 is involved in the metabolism of dietary carcinogens such as *N*-nitrosamines and the *CYP2E1 (c1/c1)* genotype appears to be associated with an increased risk of cardia cancer, particularly in smokers[47]. HLA class II DR-DQ alleles also appear to influence gastric carcinoma development with DRB1*1601 being associated with an increased risk of gastric cancer, particularly in the absence of *H pylori*[48].

THE ROLE OF INFLAMMATION IN GASTRIC CANCER

H pylori-induced inflammation

It is known that *H pylori* is a potent activator of NF-κB in gastric epithelial cells[49-52] (Figure 2). *H pylori* infection causes activation of the NF-κB pathway by a variety of mechanisms which are discussed in more detail below. Activation of NF-κB by *H pylori* induces nuclear translocation, which causes an increase in IL-8 messenger RNA and protein levels[50,53]. This has important implications since other NF-κB responsive genes including pro-inflammatory cytokines have been found in elevated levels in *H pylori* infected gastric mucosa. NF-κB activation is known to regulate cellular growth responses, including apoptosis, and is required for the induction of inflammatory and tissue-repair genes, including macrophage inflammatory protein (MIP)-2, metalloproteinase 3 (MMP3) and vascular endothelial growth factor (VEGF). The NF-κB pathway is also responsible for the generation of several cell adhesion molecules including ICAM-1 whose expression is significantly correlated with an increase in *H pylori* induced gastritis[54].

Mechanism of H pylori-induced activation of NF-κB

Lipopolysaccharide (LPS), which is a component of the outer membrane of Gram-negative bacteria including *H pylori,* is a signalling molecule for the innate immune system and is the main source of inflammation in Gram-negative infections[55]. LPS targets the transmembranous pattern-recognition receptor called toll-like receptor 4 (TLR4), which is expressed on macrophages and monocytes[56]. LPS binding to TLR4 activates signal transduction through MyD88, interleukin-1 receptor associated kinase and TRAF6 to activate the NF-κB and mitogen-activated protein kinase pathways[57-59], which leads to the synthesis and release of inflammatory cytokines such as IL-1, IL-8 and TNF-α, various chemokines GROα, IP10, MIG and MIP -1α & β[60], iNOS[61,62] and antimicrobial peptides providing a critical link to the adaptive immune system[63,64].

Induction of inflammation is an important component in the defence against *H pylori*. The presence of *H pylori* leads to the release of mutagenic substances such as metabolites of inducible nitric oxide synthase (iNOS), which is known to promote oncogenesis[65]. Nitric oxide generated by iNOS is converted to reactive nitrogen species, which can exert oncogenic effects including direct DNA and protein damage, inhibition of apoptosis, mutation of DNA and cellular repair functions such as p53 and also promotion of angiogenesis[66]. *H pylori* infection is also known to induce the expression of pro-inflammatory Cyclooxygenase enzyme (COX-2)[67-71]. COX-2 expression is normally undetectable in most normal tissues, but is induced rapidly during an inflammatory reaction[72,73]. Cox-2 activity is induced by a variety of mediators including inflammatory cytokines such as TNF-α, interferon-γ and IL-1[74]. COX-2 facilitates tumour growth by inhibiting apoptosis, maintaining cell proliferation and stimulating angiogenesis within cancer cells[75-77].

Production of reactive oxygen species

A positive association between ROS production and *H pylori* infective load has been established[78]. It has also been suggested that the source of ROS production was most

probably host neutrophils, which had been activated by the presence of *H pylori*. It has also been shown that ROS production is enhanced by infection with *cag*A-positive *H pylori* strains[79].

MOLECULAR MECHANISMS OF GASTRIC CARCINOGENESIS

The bacterial, environmental and host genetic factors discussed above influence the development of gastric carcinoma. In the following section, we discuss the molecular mechanisms underlying the disease. These include abnormalities of oncogenes, tumour suppressor genes, cell adhesion molecules and cell cycle regulators. Additionally genetic instability and alterations in growth factors and cytokines contribute to the complex pathways involved in gastric carcinogenesis. Differences exist in the pathways leading to diffuse- and intestinal-type gastric carcinoma, and these are summarised in Figures 3 and 4.

Oncogenes

Many proto-oncogenes are activated in gastric carcinoma, with variations between the differing histological subtypes. The *c-met* gene, encoding a receptor for hepatocyte growth factor/scatter factor is amplified in 19% of intestinal-type and 39% of diffuse-type gastric cancers[80]. The majority of gastric carcinomas express two different c-met transcripts, of 7.0 kb and 6.0 kb. Expression of the 6.0kb transcript correlates well with prognostic factors such as tumour staging, depth of tumour invasion and lymph node metastasis[81]. The K-sam (KATO-III cell-derived stomach cancer amplified) oncogene is also frequently activated in gastric carcinomas, and has at least four transcriptional variants[82]. One of these, Type II, encodes a receptor for keratinocyte growth factor. K-sam is preferentially amplified in 33% of advanced diffuse or scirrhous -type gastric carcinomas but not in intestinal-type cancers[83]. Over-expression of this gene in gastric carcinoma is associated with a poorer prognosis.

Another proto-oncogene, *c-erb*B2, is preferentially amplified in 20% of intestinal-type gastric cancers but this is not a feature of the diffuse-type[84]. Over-expression of this gene is also correlated with poorer prognosis and liver metastases[85,86]. Mutations of K-ras are seen in intestinal-type gastric adenocarcinomas and the precursor lesions intestinal metaplasia and adenomas[87-89]. The incidence of this mutation is low and it is not a feature of diffuse-type carcinomas.

Tumour suppressor genes

The tumour suppressor gene p53 is frequently inactivated in gastric carcinoma by loss of heterozygosity (LOH), missense mutations and frame shift deletions. This occurs in over 60% of gastric cancers, regardless of the histological subtype, and is frequently observed in precursor lesions such as intestinal metaplasia, dysplasia and adenomas[88,90-94]. Mutations commonly occur at A:T sites in intestinal-type carcinomas, with GC-AT transitions being common in diffuse-type carcinomas[91]. These GC-AT transitions can be caused by carcinogenic

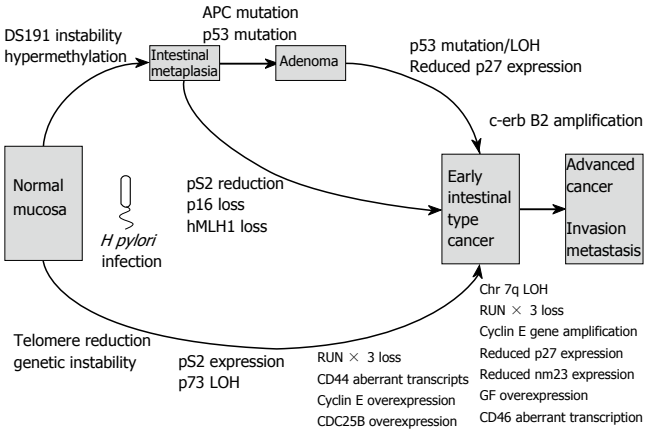

Figure 3 Intestinal type gastric cancer: Genetic and epigenetic alterations during carcinogenesis.

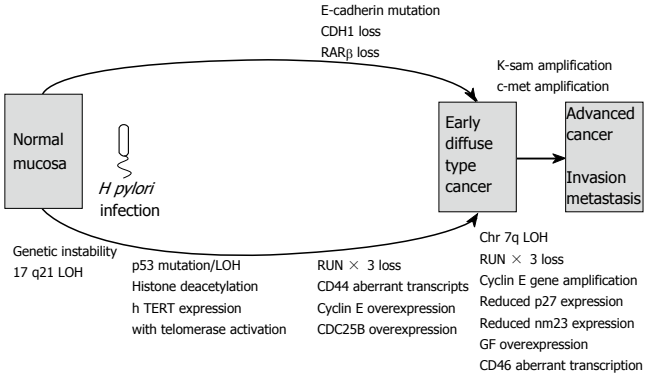

Figure 4 Diffuse type gastric cancer: Genetic and epigenetic alterations during carcinogenesis.

N-nitrosamines that are found in several foodstuffs and can be produced from dietary amines and nitrates in the acidic gastric environment[95,96]. Mutations in the codon 72 of exon 4 of the p53 gene have recently been associated with an increased risk of distal gastric cancer[97]. LOH of p73, a tumour suppressor gene related to p53 is detected in 38% of gastric cancers, and alterations of this gene are predominant features of foveolar-type gastric cancers with pS2 expression[98]. pS2 is a gastric-specific trefoil factor normally expressed in gastric foveolar epithelial cells. Inactivation of the pS2 gene results in dysplasia, adenoma and adenocarcinomas in mice[99,100]. Reduction or loss of the pS2 gene by DNA methylation in the promoter region occurs in intestinal metaplasia and gastric adenomas, suggesting this process may be important at an early stage in intestinal-type gastric carcinoma development[101].

Mutations of the tumour suppressor gene APC, involved in familial polyposis coli, are also observed in intestinal-type gastric carcinoma[102]. Although APC gene missense mutations are common in the intestinal subtype, occurring in over 50% of cases, they are not involved in diffuse-type cancers. Somatic mutations of the APC gene are observed in 20%-40% of gastric adenomas and 6% of intestinal metaplasias[103,104]. The expression of β-catenin, which acts as an oncogene, is enhanced by APC inactivation.

A further tumour suppressor is nuclear retinoic acid receptor β (RARβ). Hypermethylation of this gene with reduced expression is observed in 64% of intestinal gastric cancers but this is not observed in the diffuse subtype[105]. Additional tumour suppressor gene alterations include those affecting distinct chromosomal loci. LOH at 1q and 7q are frequently associated with intestinal-type cancers while 1p is commonly affected in advanced diffuse cancers[88]. LOH of the bcl-2 gene is also frequently observed in intestinal-type cancers[106].

The *RUNX* gene family is composed of three members, *RUNX1/AML1*, *RUNX2* and *RUNX3*[107]. It also encodes the DNA-binding α subunits of the Runt domain transcription factor polyomavirus enhancer-binding protein 2 (PEBP2)/core-binding factor (CBF), which is a heterodimeric transcription factor. Of the RUNX family, *RUNX3* is involved in gastric carcinogenesis, being necessary for the suppression of cell proliferation in the gastric epithelium. The gastric epithelium of *RUNX3* knockout mice exhibits hyperplasia, reduced rate of apoptosis and reduced sensitivity to TGFβ1, suggesting the tumour suppressor activity of *RUNX3* operates downstream of the TGFβ signalling pathways. In humans, loss of *RUNX3* by hypermethylation of the promoter CpG island is observed in several different cancers, including 64% of gastric carcinomas. *RUNX3* methylation is also a feature of 8% of chronic gastritis, 28% of intestinal metaplasia and 27% of gastric adenomas[108]. This suggests *RUNX3* is a target for epigenetic gene silencing in gastric carcinogenesis[109,110].

Other genes that appear to be affected in gastric carcinogenesis include the *FHIT* gene and loss of heterozygosity at the DCC locus, which is a feature of intestinal-type cancers[88,111]. Promoter hypomethylation of a novel cancer/testis antigen gene CAGE has recently been described in 35% of chronic gastritis and 78% of gastric cancer[112]. Histone H4 is progressively deacetylated during the development of gastric cancer, and this is a common event in both intestinal-type and diffuse type cancers[113].

Cell-adhesion molecules and metastasis-related genes

Cell adhesion molecules may act as tumour suppressors, with mutations in the E-cadherin gene occurring preferentially in 50% of diffuse type gastric carcinoma[114]. This homophilic cell adhesion molecule belongs to a family of cell-cell adhesion molecules with an important role in intercellular adhesion by establishing cell polarity, maintaining tissue morphology and cellular differentiation in normal cells[115,116]. E-cadherin binds to the actin cytoskeleton via a series of catenin proteins[117]. Therefore changes in E-cadherin expression have a direct effect on cell adhesion and therefore plays an important step in cancer development. E-cadherin mutations affecting exons 8 or 9 induce the scattered morphology, decreased cellular adhesion and increased cellular motility of diffuse gastric cancers[118]. Mutations in β-*catenin* and γ-*catenin* have also been observed in gastric cancer cell lines, and together with E-cadherin mutations appear to be involved in the development and progression of diffuse and schirrhous-type cancers[119-121].

Abnormal CD44 transcripts are frequently associated with gastric carcinomas and metastatic deposits, with the pattern of these abnormal transcripts varying between the intestinal and diffuse subtypes[122]. All gastric cancer cell lines and tissues exhibit abnormal CD44 transcripts containing the intron 9 sequence[123]. This feature is also observed in 60% of gastric intestinal metaplasias but is absent from normal mucosa[124]. Osteopontin (OPN), a protein ligand of CD44, is overexpressed in 73% of gastric carcinomas and when co-expressed with CD44v9 correlates lymphatic invasion and metastasis[125,126]. Reduced expression of nm23, involved in c-myc transcriptional activation, and galectin-3, a galactoside-binding protein, are also implicated in metastatic gastric carcinoma[127,128].

Cell-cycle regulators

The cell-cycle regulator, cyclin E, is amplified in 15%-20% of gastric carcinomas that are associated with its overexpression. Gene amplification or overexpression of cyclin E are associated with aggressiveness and lymph node metastasis[129]. The expression of the CDK inhibitor p27 that binds to a wide variety of cyclin/CDK complexes and inhibits kinase activity is frequently reduced in advanced gastric carcinoma while being preserved the majority of gastric adenomas and early cancers[130]. Reduced p27 expression correlates with tumour invasion and nodal metastasis. This reduction in p27 occurs at a post-translational level, and results not from genetic abnormalities but rather from ubiquitin-mediated proteosomal degradation[131]. A family of E2F transcription factors is an important target of cyclin/CDKs at the G1/s transition. Overexpression of E2F is observed in 40% of primary gastric cancers, and this tends to be co-expressed with cyclin E[132]. Gene amplification and abnormal expression of the E2F gene may permit the development of gastric cancer.

Micosatellite and chromosomal instability

Microsatellite instability (MSI) is a hallmark of the DNA mismatch repair deficiency that is one of the pathways of gastric carcinogenesis. Microsatellites are short DNA sequence repeats that are scattered throughout the human genome and occur in nearly every case of gastric cancer associated with germline mutations of the mismatch repair (MMR) genes *hMSH2, hMLH1, hPMS1*, *hPMS2*, and *MSH6/GTBP*[133,134]. Errors that occur in DNA mismatch repair mechanisms in tumour cells can cause expansion and contraction of these repeats. MSI due to epigenetic inactivation of *hMLH1* is found in 15%-39% of sporadic intestinal-type cancer, 70% of which are associated with loss of hMLH1 by hypermethylation of the promoter[135,136]. Such intestinal type cancers with MSI often occur in older patients and arise in the antrum. They are associated with lymphocyte infiltration, multiple tumours and a potentially favourable prognosis. Meanwhile MSI of the D1S191 locus is found in 26% of intestinal metaplasia and 46% of intestinal type gastric cancer. An identical pattern of this MSI of D1S191 is observed in adjacent intestinal metaplasia and intestinal type cancer

that suggests the sequential development from the former to the latter[137]. Diffuse type cancers with MSI are more commonly observed in younger patients and have no germline mutations of *hMLH1* and *hMSH2*, with no alteration in BAT-RII[138]. However, these cancers are frequently associated with LOH on chromosome 17q21 including the BRCA1 gene.

Human telomerase reverse transcriptase (hTERT) is an important determinant of telomerase activity, the enzyme that catalyses the telomere DNA synthesis. The majority of intestinal carcinomas have shortened telomere length, high levels of telomerase activity and a significant expression of hTERT[139]. Over 50% of intestinal metaplasias express low levels of telomerase activity, equivalent to 10% of the activity in gastric carcinoma[140]. hTERT is unregulated at an early stage in gastric carcinogenesis and H pylori may act as a trigger factor for hyperplasia in hTERT positive "stem cells" in intestinal metaplasia[139].

Growth factors and cytokines

Gastric cancer cells express a wide array of growth factors and cytokines that act via autocrine, paracrine and juxtacrine mechanisms. Again the expression of these mediators varies depending on the histological subtype. These interactions are summarised in Figure 5. The EGF family, which includes EGF, TGFα, IGF II and bFGF, are commonly overexpressed in intestinal-type carcinoma. Meanwhile TGFβ, IGF II and bFGF are predominantly overexpressed in the diffuse subtype[101]. Co-expression of EGF/TGFα, EGFR and cripto correlates well with the biological malignancy, as these factors induce metalloproteinases[141,142]. Overexpression of cripto is frequently associated with intestinal metaplasia and gastric adenoma[143]. Gastric cancer cells express neutrophilin-1 (NRP-1), a co-receptor for VEGF receptor 2 endothelial cells[144]. EGF induces both NRP-1 and VEGF expression, suggesting that regulation of NRP-1 expression in gastric cancer is intimately associated with the EGF/EGFR system.

Interleukin-1α is produced by inflammatory cells and also gastric cancer cells. It acts as an autocrine growth factor for gastric carcinoma cells and is important in EGF and EGF receptor expression[145]. The interplay between IL-1α and the EGF/receptor system acts to stimulate gastric cancer growth. IL-6 also acts in an autocrine fashion to stimulate gastric cancer cells. Il-1α and IL-6 both stimulate the expression of each other by tumour cells{167}. IL-8, a member of the CXC family of chemokines has numerous roles in gastric carcinogenesis with over 80% of gastric tumours expressing both this cytokine and its receptor[146,147]. IL-8 enhances expression of EGF receptor, type IV collagenase (metalloproteinase (MMP)-9), VEGF and IL-8 mRNA itself by gastric cancer cells, while reducing E-cadherin mRNA expression.

The negative growth factor TGFβ is frequently overexpressed in gastric carcinoma, particularly diffuse type carcinomas with diffusely productive fibrosis[148]. Angiogenic factors such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF) and IL-8 are produced by tumour cells and result in neovascularisation within gastric carcinoma tissue. VEGF promotes angiogenesis and progression of gastric carcinomas, particularly those of the intestinal subtype, while bFGF is has a stronger association for diffuse gastric carcinoma[149,150]. HGF/SF (hepatocyte growth factor/scatter factor) is produced by stimulated stromal cells such as fibroblasts, and functions in a paracrine manner as a morphogen or motogen[101].

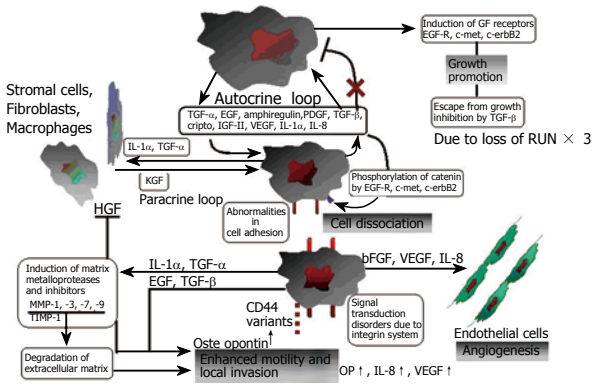

Figure 5 Cancer-stromal interaction in gastric cancer through growth factors and cytokines.

It can be seen that several of the molecular mechanisms are distinct for intestinal- and diffuse-type gastric carcinoma development, while some are common to both. Regarding intestinal-type carcinogenesis, there are three possible routes leading to carcinoma development. Firstly, progression through the pre-cancerous lesions of intestinal metaplasia to adenoma and finally carcinoma. Secondly, intestinal metaplasia may proceed directly to carcinoma. The third route involves the development of de novo gastric carcinoma with no preceding stage.

Summary of Molecular Mechanisms involved in gastric carcinogenesis

The first two pathways are summarised in Figure 3 and Figure 4. Genetic instability and hyperplasia of hTERT positive stem cells precede replication error at the DS191 locus, DNA hypermethylation at the D17S5 locus, pS2 loss, RARβ loss, RUNX3 loss, CD44 abnormal transcripts and p53 mutation, all of which accumulate in 30% of incomplete intestinal metaplasia. All of these epigenetic and genetic changes are common events in intestinal-type cancers.

An adenoma to carcinoma sequence is observed in around 20% of gastric adenomas with APC mutations. Molecular events associated with this sequence are loss of heterozygosity and mutation of p53, reduced p27 expression, loss of RUNX3, over-expression of cyclin E and abnormal c-met transcription. The resulting advanced intestinal-type gastric carcinomas frequently exhibit DCC loss, APC mutations, 1qLOH, loss of p27, reduced TGFβ receptor expression, reduced nm23 and c-erbB2 gene amplification. The "de novo" pathway of gastric carcinoma development involves LOH and abnormal expression of p73 exhibited in the development of foveolar-type gastric cancers. Meanwhile, diffuse-type gastric carcinogenesis

involves LOH at chromosome 17p, MOH or mutation of p53, RUNX3 loss and mutation or loss of E-cadherin. Several of the above molecular events may be present in mixed gastric cancers that have both intestinal and diffuse components.

CONCLUSION

It is evident that gastric carcinoma results from a complex interaction between bacterial, environmental, host-genetic and molecular mechanisms. The importance of *H pylori* and the mechanisms by which the host recognises and responds to the bacterium are crucial in determining the resulting phenotype. Several common events are shared between the differing histological subtypes while distinct differences also highlight the fascinating divergence in histogenesis. The aetiology of these differences remains to be elucidated. Better understanding of these events will no doubt contribute significantly to our fight against this killer cancer. More importantly, the improved understanding of the pathogenesis of gastric cancer will serve as a paradigm for understanding other human cancers.

REVIEW

Helicobacter pylori infection causes gastric cancer? A review of the epidemiological, meta-analytic, and experimental evidence

Abstract

Since the discovery of *Campylobacter*-like organisms *Helicobacter pylori* (*H pylori*) more than two decades ago the possibility of a relationship with gastric cancer has been postulated, tested and supposedly proven. There have been numerous human studies of various designs from many countries around the world. Several meta-analyses have been published and more recently a small number of experimental animal studies were reported looking at the association between *H pylori* infection and gastric cancer. Over the years, the human epidemiological studies have produced conflicting results; the meta-analyses have as one would expect produced similar pooled estimates; while the early experimental animal studies require replication. The exact mechanisms by which *H pylori* might cause gastric cancer are still under investigation and remain to be elucidated.

INTRODUCTION

"They (Helicobacter pylori) may have a part to play in other poorly understood gastritis associated diseases (ie, peptic ulcer and gastric cancer)." [1]

The suggestion of a link between *Helicobacter pylori (H pylori)* infection and gastric cancer was first proposed by co-discoverer Marshall in 1983[1]. It is of interest that at that time the majority of physicians and scientists around the world did not even believe that there was a link between *H pylori* and gastritis[2,3]. Just over a decade later in 1994, the International Agency for Research on Cancer (IARC) classified *H pylori* as a definite class 1 carcinogen[4], despite some conflicting results[5,6]. No experimental studies had been conducted at that time and the epidemiological studies that had been done produced mixed results. Almost all of the studies did not take into consideration other important potential confounders or sources of interaction (e.g., salt intake, diet, alcohol consumption, and smoking). A number of additional studies have also failed to detect an association even in high risk populations[7,8], which has led some to question whether there is a causal link[9]. However, these epidemiological observations appear to be directly supported by early data from animal models on cancer development following *H pylori* infection[10].

This review addresses some of the controversies in the expanding literature supporting a positive association for *H pylori* infection leading to gastric cancer. This review will not address the relationship between *H pylori* and mucosa-associated lymphoid tissue (MALT) lymphoma. An excellent review on this topic has recently been published[11]. Specifically, this review aims to assess the epidemiological evidence based on Bradford Hill's criteria of causality[12], experimental data using Henle-Koch's[13] postulates (Evan's postulates will not be reviewed)[14] and summarize the meta-analytic evidence for the association between *H pylori* and gastric cancer.

MATERIALS AND METHODS

The search strategy involved the major computer databases, including Medline, PubMed, EMBASE and Current Contents (January 1983 to February 2006). The search methodology involved using combinations of the following keywords: *H pylori*, *Camplyobacter pylori*, *Campylobacter pylordis*, gastric cancer, gastric carcinoma, stomach cancer, meta-analysis, systematic review, gastric adenocarcinoma, experimental, animal studies, systematic review. Additional manual searches were made using the reference lists from the selected articles to retrieve other papers relevant to the topic. No language restriction was placed on any of the literature searches.

RESULTS

The IARC-WHO report

In 1994, The International Agency for Research on Cancer (IARC) published a report based on a meeting of experts between 7-14 June of that year in Lyon, France[4]. In terms of a link between *H pylori* and gastric cancer, the conclusions reached in this report stated that there was sufficient evidence for carcinogenicity among humans and inadequate evidence for carcinogenicity in animals, with an overall evaluation classifying *H pylori* as a group 1 definite carcinogen. Sufficient evidence relating carcinogenicity in humans as stated in the report is: "Sufficient evidence of carcinogenicity: The Working Group considers that a causal relationship has been established between exposure to the agent, mixture or exposure circumstance and human cancer. That is, a positive relationship has been observed between the exposure and cancer in studies in which chance, bias and confounding could be ruled out with reasonable confidence." Inadequate evidence relating carcinogenicity in animals as stated in the report is: "Inadequate evidence of carcinogenicity: The studies cannot be interpreted as showing either the presence or absence of a carcinogenic effect because of major qualitative or quantitative limitations, or no data on cancer in experimental animals are available."

In the overall evaluation a Group 1 carcinogen as stated in the report is: "Group 1 - The agent (mixture) is carcinogenic to humans: The exposure circumstance entails exposures that are carcinogenic to humans: This category is used when there is sufficient evidence of carcinogenicity in humans. Exceptionally, an agent (mixture) may be placed in this category when evidence in humans is less than sufficient but there is sufficient evidence of carcinogenicity in experimental animals and strong evidence in exposed humans that the agent (mixture) acts through a relevant mechanism of carcinogenicity." The findings of the IRAC were four years before the published experimental animal data or meta-analysis of the human epidemiological studies[10,15]. So why was *H pylori* given such a classification? Would another classification have been more appropriate and if so, which one?

The overall IARC evaluation options (Group 1, Group 2A, Group 2B, Group 3, Group 4) appear to assume that there are usually experimental animal data but may not be sufficient human data to support that an agent is carcinogenic to humans. However, in the case of *H pylori* and gastric cancer the opposite is actually true. There were human studies, but at that point in time (1994) there were no actual animal or experimental data. From a cause and effect point of view, one would think that animal data would be essential to link an agent with causing carcinogenic effects, but this does not occur with *H pylori*. Of all the agents assessed in the IARC monograph, only *H pylori* with inadequate animal evidence but 'sufficient human evidence' was classified as a class 1 definite carcinogen (Table 1). All the other agents except for *H pylori* and *Opisthorchis felineus* had at least a limited amount of animal data on which an overall evaluation regarding their carcinogenicity to humans was based. Therefore, based on the data available in 1994 regarding *H pylori* and gastric cancer, it might appear that the IARC prematurely classified *H pylori* as a definite class 1 carcinogen.

Table 1 IARC evaluation of schistosomes, liver flukes and *H pylori*

Agent (infection with)	Degree of evidence of carcinogenicity		Overall evaluation
	Human	Animal	
Schistosoma haematobium	Sufficient	Limited	Definite carcinogen
Schistosoma japonicum	Limited	Limited	Possible carcinogen
Schistosoma mansoni	Inadequate	Limited	Not classifiable
Opisthorchis viverrini	Sufficient	Limited	Definite carcinogen
Opisthorchis felineus	Inadequate	Inadequate[1]	Not classifiable
Clonorchis sinensis	Limited	Limited	Probable carcinogen[2]
Helicobacter pylori	Sufficient	Inadequate[1]	Definite carcinogen

[1] No data available. [2] Other relevant data taken into account in making overall evaluation.

This is because the available epidemiological evidence was insufficient in quality (confounders not adequately assessed) and quantity to establish causal link and there were no experimental animal studies at that time.

Epidemiological data

In 1965, Bradford Hill (1897-1991) published his seminal paper titled "The Environment and Disease: Association or Causation?"[12] This paper was initially written to assess causal links between sickness and injury related to work. Bradford Hill's criteria will be used to assess the possibility of a causal association between *H pylori* and gastric cancer[16].

Consistency: The association is consistent when results are replicated in studies in different settings using different methods. The human epidemiological studies have produced mixed results with approximately 50% finding a positive association between *H pylori* infection and gastric cancer and 50% reporting a negative relationship[15,17,18]. This variation also exists within countries and between countries[15,17,18]. The majority of studies reported were case-control in design with a smaller number of cohort (usually nested case-control) studies which also provided mixed results[15,17,18].

Strength: This is defined by the size of the risk as measured by appropriate statistical tests. The strength of the relationship between *H pylori* and gastric cancer varies quite considerably. Negative studies have produced results as low as (OR: 0.54, 95% CI: 0.24-1.19)[6], and positive studies as high as (OR: 13.3, 95% CI: 5.30-35.60)[19]. The average strength of the relationship as determined by meta-analysis produces an effect size (odds ratio) of approximately 2.00[15,17,18].

Specificity: This is established when a single putative cause produces a specific effect. *H pylori* is predominantly found in the stomach and is associated with gastritis, peptic ulcer disease, and gastric cancer; however, it is linked with

numerous extra-gastric conditions including foetal intra-uterine growth restrictions[20], glaucoma[21], Raynaud's phenomenon[22], gallstones[23], primary headache[24], diabetes[25], ischemic heart disease[26], Sjögren's syndrome[27], Schönlein-Henoch purpura[28], autoimmune thyroiditis[29], chronic bronchitis[30], Parkinson's disease[31], non-arterial anterior optic ischemic neuropathy[32], chronic idiopathic urticaria[33], rosacea[34], alopecia areata[35], sideropenic anemia[36], growth retardation[37,38], late menarche[39], hepatic encephalopathy[40], and stroke[41]. Thus, currently *H pylori* is not associated with a single specific condition or disease within or outside the human stomach[42-46]. It must be remembered that none of these conditions are causally linked with *H pylori*.

Dose-response relationship: An increasing level of exposure (in amount and/or time) increases the risk. It is well known that infection with *H pylori* involves an inflammatory process occurring over many years[47-51], thus, the risk of gastric cancer may correlate with the duration of infection with *H pylori*. Therefore, those individuals who are infected during childhood have a longer time to develop mutations compared to those who acquire infection during adulthood. It has been suggested that a child's stomach might be physiologically different from an adult's stomach, because children have less acute inflammation and an increased number of lymphoid follicles than adults[52]. However, the amount of organisms living in a human's stomach has never been correlated with pathology.

Temporal relationship: Exposure always precedes the outcome. This is the only absolutely essential criterion. Current epidemiological evidence suggests that infection is usually acquired during childhood and is attributed to a cohort effect[53-57]. A recent study showed that age of acquisition after one year of age is not the most important factor related to the differences in incident rates of gastric cancer in adulthood[58]. However, studies have also shown that re-infection with *H pylori* is also possible, even though it may occur infrequently[59, 60].

Biological plausibility: The association agrees with currently accepted understanding of pathobiological processes. This criterion should be applied with caution. The prospect that cancer might be spread via an infectious mechanism has been considered for centuries[61,62]. Moreover, over the last decade there has been an exponential increase in the scientific knowledge related to infectious agents associated with cancer[63-65]. There are a large number of infectious agents associated with cancers including Epstein-Barr virus (EBV), human papillomaviruses (HPVs), hepatitis B or C virus, human herpesvirus type 8 (HHV-8), *Salmonella typhi/paratyphi*, *Schistosoma hematobium*, polyoma viruses[66-72]. Over the last decade there has certainly been an enormous increase in the amount of data on association between *H pylori* and gastric cancer, with numerous studies and hypothetical mechanisms explored[73-77]. However, while it is definitely plausible that *H pylori* could cause gastric cancer, at present the exact mechanism remains unknown.

Coherence: The association should be compatible with existing theory and knowledge. Epidemiologically, at times, there are clear signs of a relationship between *H pylori* and gastric cancer, for example, studies that reported a high prevalence of *H pylori* among a population with a high rate of gastric cancer (e.g., Japan)[9,78,79]. Conversely, there are times when a high prevalence of *H pylori* correlated with the low rate of gastric cancer (e.g., Africa)[9,79,80]. However, one African study reported that there was no difference in prevalence of *H pylori* infection among gastric cancer cases and non-ulcer dyspepsia controls[81]. The fact that only approximately 1% of those infected with *H pylori* actually go on to develop gastric cancer suggests a lack of coherence. Of course there are exceptions; in Changle, China, up to 20% of *H pylori* infected individuals developed gastric cancer. Should not all those infected with *H pylori* eventually develop gastric cancer? Indeed, if 50% of the world is infected then this equates to 30 million cases of gastric cancer, which is a gigantic number of potentially preventable malignancies. The latest epidemiological data from GLOBOCAN 2002 (data reported 2-5 years earlier) reported that there were 933 937 incident cases and 700 349 deaths due to gastric cancer in that year (Table 2)[79]. Histopathologically, there is a paradox where *H pylori* organisms are not found in the stomachs of gastric cancer cases, which may explain the lower antibody response among these patients[82-84]. These are arguments against coherence for the causal relationship between *H pylori* and gastric cancer.

Experiment: The condition can be altered by an appropriate experimental regimen. This is possibly the most important support for a causal relationship. Thus,

the strongest proof for a link between *H pylori* and gastric cancer would be established only if controlled trials demonstrate that elimination or prevention of *H pylori* infection prevents malignancy. An animal study has documented that among Mongolian gerbils treated with *N*-methyl-*N*-nitrosourea (MNU) and infected with *H pylori* where 2 of the 6 groups underwent eradication of *H pylori* infection at 21 weeks, after 50 weeks they showed a decrease in the number of gastric cancers developed[85].

Recently, a human prospective randomized, placebo-controlled prevention trial compared patients who received eradication therapy for *H pylori* (n = 817) and those taking placebo (n = 813) and at follow-up (7.5 years) determined the incidence of gastric cancer between the groups[86]. However, there was no significant difference in gastric cancer incidence between those who received eradication therapy and placebo (P = 0.33). This study was criticised for being stopped early, as it was believed that if the study had continued for a few more years it might have yielded more conclusive results[87]. Kamada *et al*[88] conducted a prospective non-randomized follow-up study of 1787 patients who underwent *H pylori* eradication therapy and were followed up after 9 years. Gastric cancer occurred in 20 patients (1.1%), while early gastric cancer consisted of 5.7% (6/105) after endoscopic resection. This study concluded that even after successful eradication therapy for *H pylori* endoscopic assessment should be undertaken for occult early gastric cancer or severe mucosal atrophy. Moreover, studies trying to determine if gastric atrophy is a reversible process have produced conflicting results[89]. Thus, endoscopic screening in high risk populations still remains appropriate[90,91]. It should be remembered that epidemiological evidence by itself is insufficient to establish causality, but it does provide strong circumstantial evidence.

Meta-analysis

At present, five meta-analyses have been published assessing the relationship between *H pylori* and gastric cancer[15,17,18,92,93], and one that focuses specifically on the CagA cytotoxin, will be discussed separately[94]. An additional earlier combined-analysis[95] which contained only three early (all published in 1991) prospective studies produced a pooled odds ratio of 3.80 (95% CI: 2.30-6.20). This paper will not be discussed in this review due to the lack of information regarding this particular combined-analysis. These meta-analyses vary in several different ways: (1) the number of studies included in the analysis; (2) the types of studies included; (3) whether the studies were peer-reviewed or in abstract form; (4) published language of the studies; (5) databases used; (6) the search terms used; (7) method of *H pylori* diagnosis; (8) statistical analyses used; (9) statistical heterogeneity; (10) if quality assessment was undertaken; (11) determination of publication bias; (12) how to deal with duplicate studies; and (13) the number of reviewers involved in data extraction. Of the five meta-analyses that assessed the association between *H pylori* and gastric cancer the number of studies included in each of the meta-analyses varies mostly due to study design. The number of studies included ranged between 11-44. Moreover, the number of studies used in the statistical analysis is exactly the same as the number of studies included except for one meta-analysis where the analysis was undertaken based on 10 out of the 44 studies (Table 3)[18]. Three of the meta-analyses combined both case-control and cohort studies[15,17,18], whereas, two meta-analyses contained only case-control studies[15, 17].

Two meta-analyses placed no language restrictions on the publications included[17,18], one incorporated only English language publications[15] while another only used those published in Chinese[92]. The types and number of databases used differed with the majority using only one database[15,18,92,93], and one meta-analysis using five databases[17]. Only three meta-analyses incorporated manual searches of reference lists[15,17,18], one searched conference proceedings[15], and two contacted investigators[17,93]. The meta-analyses also used assorted search terms varying in number between 3-5. Three meta-analyses only used studies that determined *H pylori* status by serology[15,18,93] while one used a combination of serology and histology[17] and one did not state the method of *H pylori* determination[92]. Statistical methods also differed with four of the meta-analyses using a combination of a fixed and random-effects procedure. The pooled estimates from these five meta-analyses ranged between 1.92-2.56 (mean 2.28) with confidence intervals ranging between 1.35-3.55. Quality assessment was only undertaken in two of the meta-analyses[15,17], with only one using quality scores[17]. In addition, publication bias was only determined in one of the meta-analyses[17]. Duplicate studies were removed in two of the meta-analyses[15,17], and not stated in the other meta-analyses. The number of assessors also differed between the meta-analyses ranging between one and three and two studies having an unknown number of assessors.

The additional meta-analysis, focused on the relationship between cagA seropositivity and gastric cancer[94]. Previous studies have reported a higher prevalence of cagA-positive strains among populations with a high incidence of gastric cancer[94]. This meta-analysis included 16 case-control studies, and there were no language restrictions used on the literature search which included the databases of Medline and PubMed that only assessed publications between the years 1990-2003. The study produced a pooled odds ratio of 2.28 with a confidence interval ranging between 1.71-3.05. However, there was significant heterogeneity among the studies included in this analysis. A quality assessment was undertaken but did not involve producing a score for each particular study included in the meta-analysis. The authors did assess publication bias, while duplicate studies were removed and three authors conducted the literature searches. One meta-analysis[17] found that younger subjects were at lower risk (OR 0.77, 95% CI: 0.68-0.89) of developing gastric carcinoma if infected with *H pylori*, which is supported by the epidemiological data. However, another meta-analysis[15] showed that the odds ratios decreased significantly with increasing age (9.29, 3.43-34.04 aged 20-29 years; 1.05, 0.73-1.52 aged $\geqslant$ 70 years). The reason for this difference may be due to the staging of

gastric cancer and the difficulty in diagnosing *H pylori* infection in the advanced stages where the normal gastric mucosa has been destroyed.

All these meta-analyses showed that *H pylori* infection is associated with approximately a two-fold increased risk of developing gastric cancer (Figure 1). The strength and consistency of these meta-analyses in terms of a lack of heterogeneity (as only one meta-analysis reported heterogeneity) suggests that these observations are reliable. One of the possible reasons for this heterogeneity might be the variation in study design as both case-control and cohort studies were included.

Animal experimental data

In order to assess a causal relationship experimentally between *H pylori* and the formation of gastric cancer a systematic approach similar to that applied in epidemiological studies is essential. Historically, Henle-Koch postulates (1877 and 1882)[13] have been used to determine causal relationships, however, these postulates were revised in 1976 by Evans (Evans 1976)[14]. This review will only use Henle-Koch postulates to assess this relationship. These were developed in 1877 by Jacob Henle and subsequently revised in 1882 by Robert Koch. The postulates from Last[16] are: The agent must be shown to be present in every case of the disease by isolation in pure culture. As mentioned previously, not all animals or humans infected with *H pylori* go on to develop gastric cancer[10]. At present 50% of the animal studies have used carcinogens in combination with *H pylori* infection[96-98] and the remainder have only used the organism in an attempt to induce gastric cancer[10,99,100].

The agent must not be found in cases of other disease. *H pylori* is associated with other gastrointestinal diseases (chronic gastritis, gastric ulcer, duodenal ulcer, and gastric MALToma) and also a large number of extra-gastric diseases[20-46]. Thus, currently *H pylori* is not associated with a single specific condition or disease within or outside

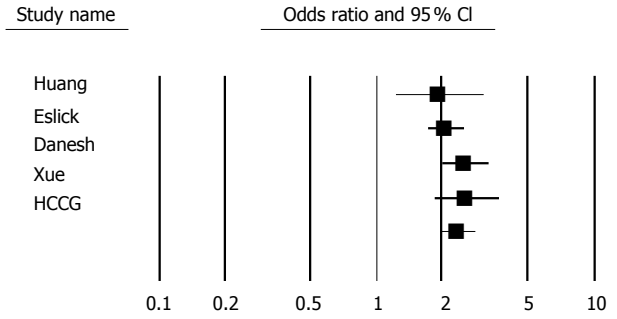

Figure 1 Odds ratios and 95% confidence intervals for individual meta-analyses.

the human stomach. However, it must be highlighted that none of these disease conditions have as yet been definitively/causally linked with *H pylori* infection.

Once isolated, the agent must be capable of reproducing the disease in experimental animals. Marshall's classic back-to-back publications which were published in 1985 in the *Medical Journal of Australia* where the authors aimed to fulfill Koch's postulates[101,102]. These publications described the now famous experiment where Dr Marshall ingested a 10 mL suspension of approximately 10^9 colony forming units of *H pylori* which had been isolated from a patient with gastritis (then referred to as *pyloric Campylobacter*). Over the course of the next ten days, the subject developed symptoms (increased abdominal peristalsis, epigastric fullness, vomiting, headache, soft faeces, and halitosis). A gastroscopy was performed and biopsies taken for both light and electron microscopy, which revealed gastritis and spiral organisms (*pyloric Campylobacter*). These organisms were cultured and freeze-dried. The authors were able to fulfil Koch's postulates in humans for gastritis[101,102]. However, it is not possible to complete Koch's postulates for gastric cancer in humans. It was not until 1998 when the first report by Watanabe *et al*[10] of *H pylori* leading to gastric carcinogenesis that animal models could be assessed in terms of Koch's postulates. It has been suggested that these postulates have been fulfilled for *H pylori* and gastric cancer[103], however, no studies to date have specifically undertaken or successfully proven Koch's postulates using animal models. It appears that these statements are not based on the strict adherence to these postulates of causation, but rather that 'sometimes' *H pylori* is associated with gastric cancer.

The agent must be recovered from the experimental disease produced. It is not always possible to isolate *H pylori* organisms from gastric cancer tissue whether this be from humans or animals[104]. This is due to the histopathological changes that occur which decrease the ability of *H pylori* to adhere to the stomach and thus over time leads to a decreased antibody response[93,105,106].

CONCLUSION

Currently, the epidemiological data are conflicting on the relationship between *H pylori* and gastric cancer. The independent meta-analyses provide an overall consensus that *H pylori* infection is associated with an increased risk (approximately a two-fold increased risk) of developing gastric cancer even though 50% of the studies have produced negative findings. However, there is still a lack of 'cause and effect' evidence concerning this relationship, which requires further animal and epidemiological studies to determine the possible carcinogenic mechanisms by which *H pylori* might cause gastric cancer. One of the major problems in determining a true causal association with *H pylori* and a disease is related to its high world-wide prevalence making associations with many conditions possible. Only strict adherence to Bradford Hill's criteria, Henle-Koch's and/or Evan's postulates ensures that cause-and-effect relationships are correctly identified. Prevention studies in the form of *H pylori* eradication randomised placebo controlled trials among gastric cancer patients are currently being conducted.

DEDICATION

I would like to dedicate this manuscript to Professor Barry Marshall and Emeritus Professor Robin Warren who were awarded the 2005 Nobel Prize for Medicine or Physiology for their discovery of *H pylori*. This finding changed many of our lives and made the practice of clinical gastroenterology more challenging and gastrointestinal research more extraordinary, with advances in numerous areas of medicine (*New Engl J Med* 2005; 353: 2421-2423).

ACKNOWLEDGEMENTS

The author thanks Dr J. Danesh and Dr Jia-Qing Huang for providing information regarding their meta-analysis papers.
