Abstract

AIM: To investigate whether activin regulates the cell proliferation of human gastric cancer cell line SNU-16 through the mRNA changes in activin receptors, Smads and p21$^{CIP1/WAF1}$.

METHODS: The human gastric cancer cell lines were cultured, RNAs were purified, and RT-PCRs were carried out with specifically designed primer for each gene. Among them, the two cell lines SNU-5 and SNU-16 were cultured with activin A for 24, 48 and 72 h. The cell proliferation was measured by MTT assay. For SNU-16, changes in ActRIA, ActRIB, ActRIIA, ActRIIB, Smad2, Smad4, Smad7, and p21$^{CIP1/WAF1}$ mRNAs were detected with RT-PCR after the cells were cultured with activin A for 24, 48 and 72 h.

RESULTS: The proliferation of SNU-16 cells was down regulated by activin A whereas other cells showed no change. Basal level of inhibin/activin subunits, activin receptors, Smads, and p21$^{CIP1/WAF1}$ except for activin βB mRNAs was observed to have differential expression patterns in the human gastric cancer cell lines, AGS, KATO III, SNU-1, SNU-5, SNU-16, SNU-484, SNU-601, SNU-638, SNU-668, and SNU-719. Interestingly, significantly higher expressions of ActR IIA and IIB mRNAs were observed in SNU-16 cells when compared to other cells. After activin treatment, ActR IA, IB, and IIA mRNA levels were decreased whereas ActR IIB mRNA level increased in SNU-16 cells. Smad4 mRNA increased for up to 48 h whereas Smad7 mRNA increased sharply at 24 h and returned to the initial level at 48 h in SNU-16 cells. In addition, expression of the p21$^{CIP1/WAF1}$, the mitotic inhibitor, peaked at 72 h after activin treatment in SNU-16 cells.

CONCLUSION: Our results suggest that inhibition of cell growth by activin is regulated by the negative feedback effect of Smad7 on the activin signaling pathway, and is mediated through p21$^{CIP1/WAF1}$ activation in SNU-16 cells.

INTRODUCTION

Inhibins and activins, members of the transforming growth factor-β (TGF-β) superfamily, are polypeptides that were originally isolated from ovarian fluid, based on their effect on pituitary follicle-stimulating hormone (FSH) production. Inhibins are heterodimers that are composed of a common α subunit and one of the two homologous β subunits (βA and βB). Activins are either heterodimers or homodimers of inhibin β subunits (βAβA, βBβB, and βAβB)[1-3].

Activin plays an important role in the proliferation, differentiation, and apoptosis of target cells. The biological activity of activin is mediated by receptor complexes consisting of two different types of receptors, the type I (ActR I) and type II (ActR II) activin serine/threoine kinase receptors[4]. ActR II binds to activin independently of ActR I, but is unable to signal without ActR I. The formation of heteromeric complexes of ActR I and ActR II is required for the mediation of the cellular signal[5]. ActR I and ActR II mRNAs have been widely detected in several human tissues, including prostate cancer, breast cancer, and epithelial ovarian cancer[6-8].

Smad proteins have been known as intracellular signaling mediators of the activin[9, 10]. Smad1, Smad2, Smad3, and Smad5 proteins are phosphorylated by activated specific type I serine/threonine kinase receptors, and thus act in a pathway-restricted fashion. Smad4 protein forms hetero-oligomeric complexes with pathway-restricted Smad proteins, which translocate into the nuclei and activate transcriptional responses. Smad6 and Smad7 function as inhibitors of TGF-β family signaling, including activin[11-13]. Smad7 selectively interferes with different

activin signaling pathways and inhibits erythroid leukemia cells and liver Hep3B cells by blocking intracellular activin signaling[14, 15]. In addition, the mitotic inhibitor $p21^{CIP1/WAF1}$ thas suppresses the growth of malignant cells *in vitro* and *in vivo* can be up-regulated by activin[16-18].

This study was to investigate whether activin can affect cell proliferation in human gastric cancer cell line SNU-16 through the changes in activin receptors, Smads and $p21^{CIP1/WAF1}$ mRNA levels.

MATERIALS AND METHODS

Cell culture and reagents

Human gastric cancer cell lines AGS and KATO III were purchased from the American Tissue Culture Collection (ATCC, Rockville, MD). SNU-1, SNU-5, SNU-16, SNU-484, SNU-601, SNU-638, SNU-668, and SNU-719 cells were supplied from the Korean Cell Line Bank. Cells were cultured in RPMI 1640 medium (GIBCO, Grand Island, NY) containing 10% fetal bovine serum (FBS, GIBCO), 100 U/mL penicillin and 100 μg/mL streptomycin at 37 ℃ in a humidified 50 mL/L CO_2 and 95% air. The appropriate amount of recombinant human activin A (activin A, R & D systems, Minneapolis, MN) was added to the culture media.

MTT assay

Cell proliferation was measured with CellTiter 96 Aqueous One Solution (Promega, Madison, WI). Cells were seeded at 5×10^3 cells/well in 6-well plates and incubated with different concentrations of activin A (0, 10, 50, and 100 ng/mL) at 37 ℃ for 24, 48, and 72 h respectively. Cell viability was determined by a colorimetric assay with PMS/MTS (20 μL/well). The absorbance was determined at 492 nm with background subtraction at 650 nm.

Cell number assay

For the cell viability assay, cells were seeded at 5×10^4 cells/mL in 6-well plates. The cells were cultured with 100 ng/mL of activin A for 24, 48, and 72 h respectively. Then cells were washed with phosphate buffered saline (PBS) and resuspended in PBS. Viable cells were counted by the trypan blue exclusion method at each time using a hemocytometer.

RNA extraction and RT-PCR procedures

Total RNA was extracted from cultured cells using the RNAzol B solution kit following the manufacturer's protocol (Tel-test, Friendswood, Texas). First-strand cDNA synthesis was performed using a cDNA synthesis kit (Roche, Mannheim, Germany). cDNA synthesis was performed by reverse transcription in a total volume of 20 μL reaction mixture containing 1 μg RNA, 1× reaction buffer, 1 mmol/L dNTP, 5 μmol/L oligodT, 20 units of RNase inhibitor, and 20 units of AMV reverse transcriptase. The reaction mixture was incubated at 42 ℃ for 1 h, terminated by heating at 95 ℃ for 5 min. Polymerase chain reaction (PCR) was performed with 5 μL (α, βA, βB subunits, and $p21^{CIP1/WAF1}$) or 1 μL (activin receptors, Smads and β-actin) cDNA in a 50 μL reaction mixture of 1× PCR buffer, 0.2 mmol/L of each dNTP, 20 pmoL primer, and 1 unit of Taq DNA polymerase (Roche). Primer sequences are shown in Table 1. The conditions for amplification were as follows: first denaturation at 95 ℃ for 4 min, then denaturation at 95 ℃ for 30 s, annealing at 50 ℃ to 62 ℃ for 30 s, and extension at 72 ℃ for 1 min for 30 cycles (25 cycles for β-actin) and a final extension at 72 ℃ for 7 min. Ten μL of PCR products was separated by electrophoresis on a 2% agarose gel containing ethidium bromide and visualized by image analysis (Gel Doc 1000 gel document system, Bio-Rad, Hercules, CA). The intensities of PCR bands were measured by densitometry (Model GS-700, Bio-Rad) and expressed relative to β-actin.

Statistical analysis

Values were expressed as mean ± SD. Student's *t* test was used to evaluate differences between control and activin A-treated samples. $^aP < 0.05$ and $^bP < 0.01$ were considered statistically significant.

RESULTS

Effects of activin A on cell proliferation

Ten human gastric cancer cell lines were treated with various concentrations of activin A (10-100 ng/mL) for 24,

Table 2 Effects of activin A on cell proliferation in human gastric cancer cell lines (mean ± SD, ng/mL)

Values are the percentage for three individual experiments, each with triplicate samples. [a]$P < 0.05$ and [b]$P < 0.01$ *vs* the control values.

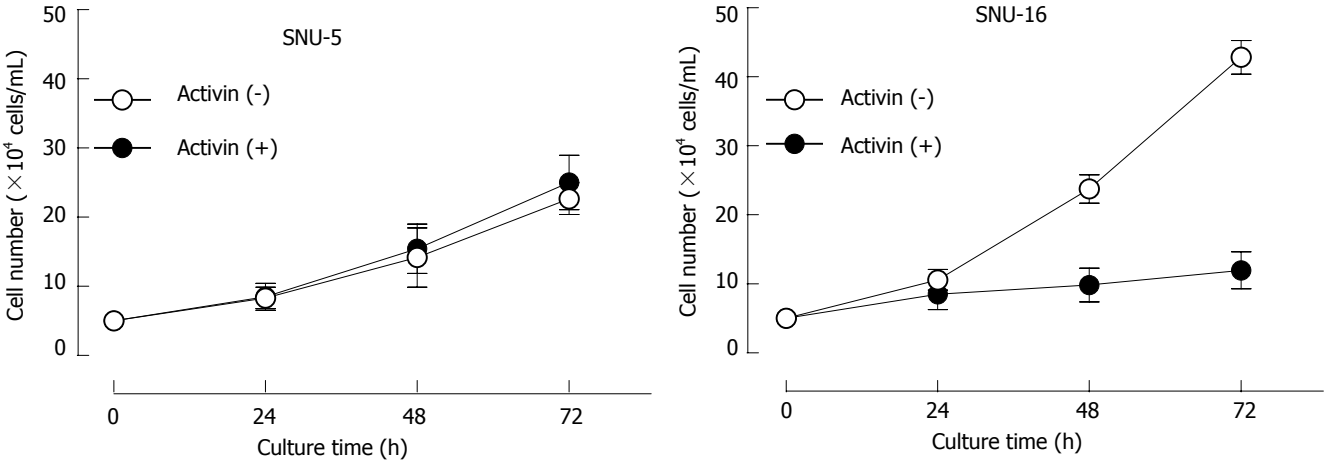

Figure 1 Effects of activin A on cell viability in SNU-5 and SNU-16 cells. Cells (5 × 10^4 cells/mL) were cultured with activin A (100 ng/mL) in a time-dependent manner and viable cells were counted with a hemocytometer. Values are the mean ± SD of three individual experiments. [b]$P < 0.01$ *vs* the control values.

48, and 72 h respectively. The effect of activin on cell proliferation was assessed by MTT assay (Table 2). Activin induced a significant decrease in SNU-16 cell proliferation in a dose- and time-dependent manner, whereas other cells showed no detectable response. To evaluate the growth inhibition of activin in SNU-5 and SNU-16 cells, the cells were cultured with 100 ng/mL of activin A for 24, 48, and 72 h respectively. The cell number was counted by a hemocytometer. Activin A treatment resulted in a significant decrease in the number of SNU-16 cells in a time-dependent manner, whereas no effect was observed in the number of SNU-5 cells (Figure 1).

Expression of inhibin/activin subunit, activin receptor, Smads, and p21$^{CIP1/WAF1}$ mRNAs

Basal expressions of inhibin/activin subunits, activin receptors, Smads, and p21$^{CIP1/WAF1}$ mRNA in human gastric cancer cell lines were investigated by RT-PCR (Figure 2). The expression of inhibin α mRNA was detectable only in SNU-638 cells whereas the activin βA mRNA was expressed in the majority of cells tested, but not in SNU-5 or SNU-719 cells. The activin βB was not detected in all cells. The activin receptor IA and IB mRNAs were expressed in all the cell lines tested. The primers for ActR IIA and IIB amplification were designed to locate within intracellular kinase domains of ActR IIA and IIB. The ActR IIA and IIB mRNAs were expressed in all the cell lines tested. Interestingly, significantly higher expressions of ActR IIA and IIB mRNAs were observed in SNU-16 cells when compared to other cells. The Smad2, 4, and 7 mRNAs were expressed in all cells and p21$^{CIP1/WAF1}$ mRNAs were not expressed in SNU-1, SNU-484, and SNU-668 cells.

Effects of activin A on expression of activin receptors, Smad and p21$^{CIP1/WAF1}$ genes

To detect the effects of activin on ActR I and ActR II mRNA expression in SNU-16 cells, RT-PCR analysis was performed using the cells treated with 100 ng/mL of activin A for various durations (Figure 3A). Expression of

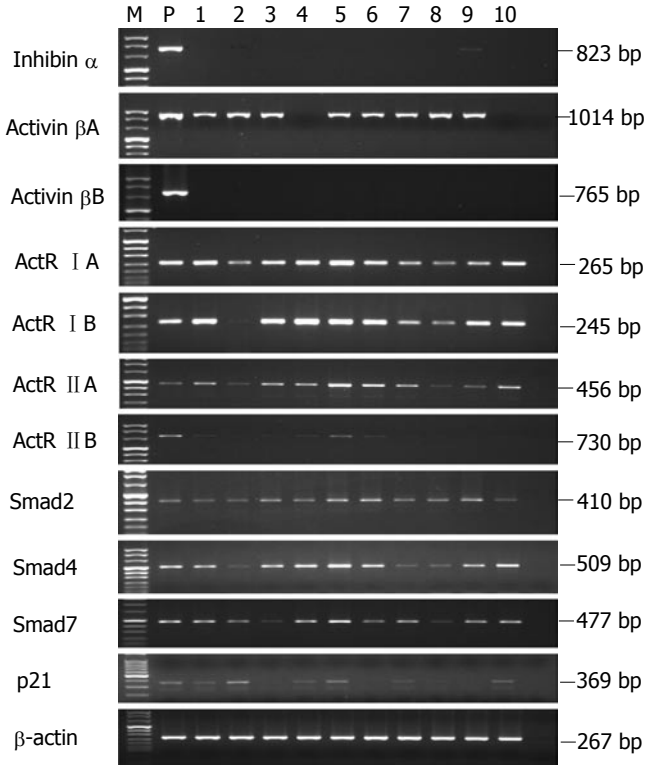

Figure 2 mRNA expressions of inhibin/activin subunits, activin receptors, Smads, and $p21^{CIP1/WAF1}$ in human gastric cancer cell lines. The mRNA levels were analyzed by RT-PCR. M: DNA size marker; P: positive control; lane **1**: AGS; lane **2**: KATO III; lane **3**: SNU-1; lane **4**: SNU-5; lane **5**: SNU-16; lane **6**: SNU-484; lane **7**: SNU-601; lane **8**: SNU-638; lane **9**: SNU-668; lane **10**: SNU-719. Positive control was used for inhibin/activin subunits (mouse ovary), activin receptor (K562), Smad and $p21^{CIP1/WAF1}$ (human keratinocytes) respectively.

ActR IA, IB, and IIA mRNA was decreased after activin A treatment, whereas ActR IIB mRNA level was increased significantly for up to 48 h in SNU-16 cells. To detect the effects of activin-signaling on Smad mRNA expression in SNU-16 cells, RT-PCR analysis was investigated using the cells treated with 100 ng/mL of activin A for various durations (Figure 3B). Although no detectable change was observed in Smad2 mRNA of SNU-16 cells, the expression of Smad4 mRNA was increased at 48 h after activin A treatment. Expression of Smad7 mRNA was increased vigorously at 24 h after activin A treatment in SNU-16 cells and decreased significantly to below initial basal level at 48 h when compared to control cells. In addition, to determine the regulation of $p21^{CIP1/WAF1}$ mRNA expression by activin in SNU-16 cells, the cells were treated with 100 ng/mL of activin A for various durations and investigated by RT-PCR (Figure 3C). Expression of $p21^{CIP1/WAF1}$ mRNA was highly increased at 72 h after activin A stimulation in SNU-16 cells.

DISCUSSION

Activin has several biological functions, including regulation of cell proliferation and inhibition of tumor cells. Activin inhibits cell growth in human prostate cancer LNCaP cells[6], human HepG2 hepatoma cells [19], and mouse B-cell hybridoma cells[20]. In this study, treatment with activin A (10-100 ng/mL) induced a significant decrease in the proliferation of SNU-16 cells in a dose-and time-dependent manner. In contrast, some human gastric cancer cell lines were relatively resistant to the growth inhibition induced by exogenous activin treatment. Interestingly, activin A (100 ng/mL) decreased the number of SNU-16 cells in a time-dependent manner. The mechanism of growth inhibition by activin in SNU-16 cells remains uncertain, but activin may act as a growth inhibitor in SNU-16 cells, and the subsequent loss of this autocrine growth inhibitory pathway may lead to the development of cancer.

Basal expressions of inhibin/activin subunits, activin receptors, Smads, and $p21^{CIP1/WAF1}$ mRNAs in the human gastric cancer cell lines were demonstrated to have differential expression patterns for inhibin α, activin βA subunits, activin receptors, and Smads, as well as the presence of $p21^{CIP1/WAF1}$ and the absence of activin βB subunits. Interestingly, significantly higher expressions of ActR IIA and IIB mRNAs were observed in SNU-16 cells when compared to other cells.

To determine the time-course of activin's effects on mRNA levels of ActRs, Smads, and $p21^{CIP1/WAF1}$, RT-PCR was performed using SNU-16 cells treated with activin A (100 ng/mL) for different time durations. Activin A decreased ActR IA, IB, and IIA mRNA levels whereas increased ActR IIB mRNA level in SNU-16 cells. Treatment with activin A (10-100 ng/mL) could not affect ActR IIA and IIB mRNA expression for 24 h in OVCAR-3 cells[21]. Activins act primarily through Smad2, possibly in partnership with Smad4, which forms heteromeric complexes with ligand-specific Smads after activation. In OVCAR-3 cells, no detectable change has been induced in Smad4 mRNA expression within 72 h of activin treatment, but the Smad2 mRNA level gradually increases and is significantly higher than that in the control at 72 h[22]. Activin–induced HepG2 liver cell apoptosis involves ActRs and Smad proteins. Overexpression of ActR IB and IIB or Smad2 and Smad4 stimulates apoptosis, whereas the dominant negative mutant forms of ActR IIB or Smad2 block activin-stimulated apoptosis. Signal transduction from the cell surface to the nuclei through Smad proteins is required for activin-induced cell death in liver cells[23]. In SNU-16 cells, no difference was observed in Smad2 mRNA levels but the Smad4 mRNA level increased for up to 48 h after activin treatment. Taken together, these results suggest that enhanced levels of ActR IIB and Smad4 mRNAs likely contribute to activin signal transduction. A novel activity of Smad7 is the inhibition of erythroid differentiation by blocking the intracellular activin signaling[14]. Smad7 expression can be induced by activin, and the overexpression of Smad7 suppresses activin-induced apoptosis in mouse B hybridomas[24]. In the present study, expression of Smad7 mRNA increased vigorously after 24 h of activin stimulation in SNU-16 cells, and then decreased at 48 h to a level significantly below the initial basal level. These results indicate that Smad7 acts as a selective blocker of activin and provides feedback regulation in the activin- signaling pathway. In human pituitary tumors with activin-inhibited proliferation, $p21^{CIP1/WAF1}$ gene expression is up-regulated in a dose-

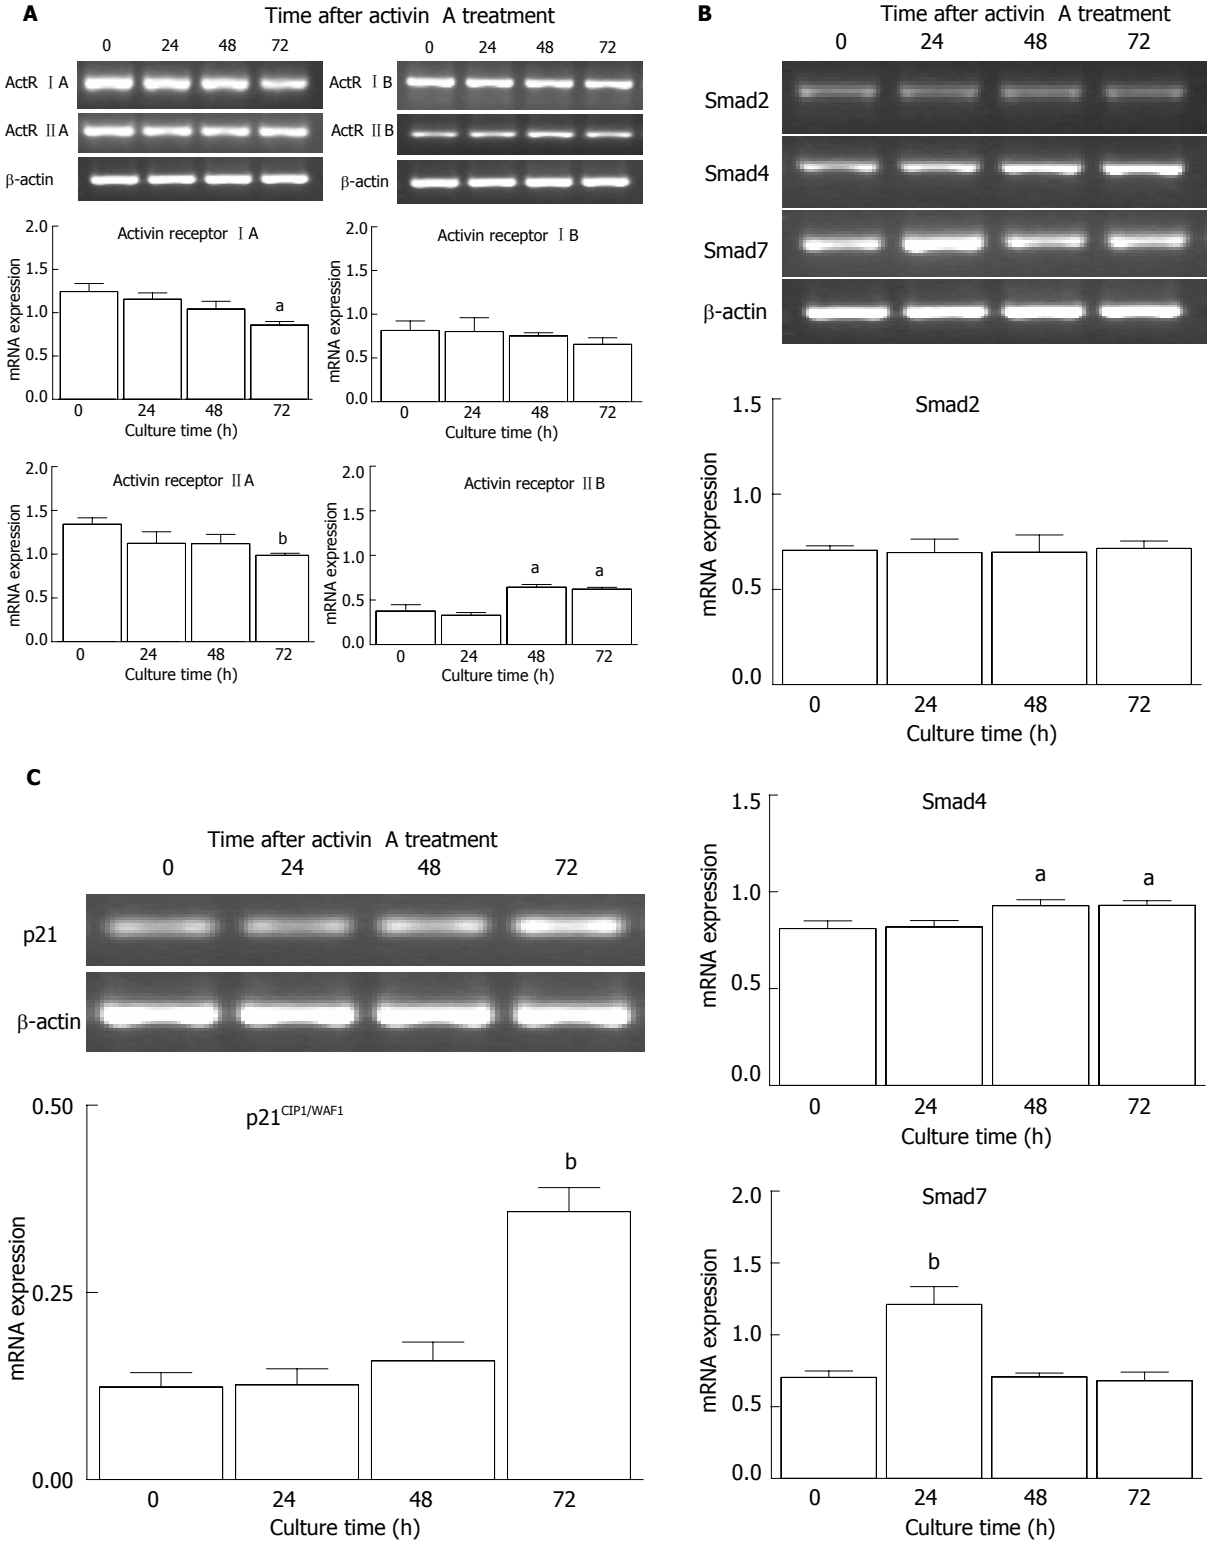

Figure 3 Effects of activin A on activin receptor mRNA expression (**A**), smad mRNA expression (**B**), and $p21^{CIP1/WAF1}$ mRNA expression (**C**) in SNU-16 cells. Cells (5×10^4 cells/mL) were cultured with activin A (100 ng/mL) in a time-dependent manner and mRNA levels were measured by RT-PCR. Values are mean ± SD of three individual experiments and reported as the ratio of activin receptors to β-actin signals, the ratio of Smad to β-actin signals, and the ratio of $p21^{CIP1/WAF1}$ to β-actin signals, respectively. $^aP < 0.05$ and $^bP < 0.01$ *vs* the control values.

dependent manner after 4 h[25]. The ectopic expression of mouse Smad7 in HS-72 cells suppresses the activin A-induced cell cycle arrest in G1 phase by abolishing the activin A-induced expression of $p21^{CIP1/WAF1}$ and the hypophosphorylation of retinoblastoma protein[25]. Compared with control cells, expression of $p21^{CIP1/WAF1}$ mRNA at 72 h after activin stimulation was higher in SNU-16 cells in this study, suggesting that the activin-induced inhibition of cell growth in SNU-16 cells is mediated through $p21^{CIP1/WAF1}$ activation.

In conclusion, inhibin/activin subunits, activin receptors, Smads, and $p21^{CIP1/WAF1}$ are expressed in human

gastric cancer cell lines. Moreover, the inhibition of cell growth by activin is regulated by the negative feedback effect of Smad7 on the activin signaling pathway, and is mediated through $p21^{CIP1/WAF1}$ activation in SNU-16 cells. Further investigation is needed to determine the molecular mechanisms of activin's inhibitory effects on cell growth, apoptosis, and cancer progression.

Abstract

AIM: To evaluate the *in vitro* anti-HBV activity of recombinant human IFN-γ, alone and in combination with lamivudine.

METHODS: A recombinant baculovirus-HBV/HepG2 culture system was developed which could support productive HBV infection *in vitro*. Expression of HBsAg and HBeAg in infected HepG2 culture medium was detected by commercial enzyme immunoassays. HBV DNA replication intermediates were detected in infected cells by Southern hybridization and viral DNA load was determined by dot hybridization.

RESULTS: IFN-γ at 0.1 to 5 μg/L efficiently down regulated HBsAg expression in transduced HepG2 cells. At 5 μg/L, IFN-γ also suppressed HBV DNA replication in these cells. While treatment with a combination of lamivudine and IFN-γ showed no additive effect, sequential treatment first with lamivudine and then IFN-γ was found to be promising. In this culture system the best HBV suppression was observed with a pulse of 2 μmol/L lamivudine for two days, followed by 1 μg/L IFN-γ for another four days. Compared to treatment with lamivudine alone, the sequential use of 0.2 μmol/L lamivudine for two days, followed by 5 μg/L IFN-γ for six days showed a 72% reduction in HBV cccDNA pool.

CONCLUSION: This *in vitro* study warrants further evaluation of a combination of IFN-γ and lamivudine, especially in IFN-α non-responder chronic hepatitis B patients. A reduced duration of lamivudine treatment would also restrict the emergence of drug-resistant HBV mutants.

INTRODUCTION

Hepatitis B virus (HBV) infection is widespread in humans, with an estimated 400 million persons infected globally and an annual death rate of 1.2 million[1]. HBV is a small DNA virus with a 3.2 kb genome and belongs to the family *Hepadnaviridae* which also includes related hepatotrophic viruses from other animal species[2]. This partially double stranded genome contains four overlapping open reading frames (ORFs) that encode the surface (S, including the pre-S regions), core (C, including the pre-core region), polymerase (P), and X proteins. The HBV DNA genome replicates by a unique mechanism that involves an RNA intermediate, called the pregenomic RNA (pgRNA). The viral relaxed circular (rc) DNA genome is released in the host cytosol, migrates to the nucleus, and is converted into a covalently closed circular DNA (cccDNA) form that serves as the template for all viral transcripts. One of the major transcripts, the pgRNA is reverse transcribed into a single-stranded DNA (ssDNA) form that is the hallmark of viral replication. This first (+) strand serves as template for the viral polymerase to further synthesize the second, comparatively short (-) strand to become a partial double stranded circle (rcDNA), a minor population of which remains as a double stranded linear DNA (dslDNA) in special cases[3].

One major hurdle in the study of HBV molecular biology, its pathogenesis and the development of new antiviral agents, is the lack of suitable *in vitro* or small animal models of chronic HBV (CHB) infection in

humans. Although the use of nucleos(t)ide analogs could potentially change the course of HBV infection due to the emergence of drug-resistant mutants, novel nucleos(t)ide analog-based drugs have opened up new frontiers and challenges in the treatment of CHB. Currently, combination chemotherapy with more than one nucleo(t)side analogs are being evaluated as a new approach towards management of CHB[4]. For many years, recombinant interferon-alpha (IFN-α) has been the only effective therapeutic agent able to provide long-term disease remission for some CHB patients. However, IFN-α treatment produces significant side effects such as fatigue, fever, muscular aches, bone marrow suppression, psychosis and autoimmune conditions[5]. Although many studies have examined a combination of IFN-α and lamivudine for HBeAg-positive CHB, published trials of combination therapy provide little support for IFN-α/lamivudine combination therapy over monotherapy[6-8].

The class II interferon, IFN-γ has been used to treat hepadnaviral infections including HBV, either alone or in combination with other IFNs[9-12]. *In vitro* studies using Hep-HB107 cell lines, have shown IFN-γ to inhibit HBV replication[13]. In pilot studies, IFN-γ was shown to be effective in suppressing HBV replication in a proportion of Caucasian patients with chronic HBV infection[14-16]. Very recently, IFN-γ associated antiviral effects have been shown in woodchuck HBV (WHBV) infected woodchuck primary hepatocytes, *in vitro* as well as *in vivo* in neonates[17]. Studies have shown that analogous to other interferons, IFN-γ alone has minimal inhibitory effects on serum HBV levels[12,15]. The emergence of HBV mutants resistant to lamivudine[18] and other novel nucleoside analogs such as adefovir dilivoxil[19], famcyclovir[20] and entecavir[21] , as well as reports of non-response to IFN-α therapy[22] further limits the use of these agents.

Therefore, in this study we evaluated the antiviral potential of IFN-γ on the kinetics of HBV genome replication, as well as its efficacy in combination with lamivudine. For this, we used a recombinant baculovirus-HBV (Bac-HBV)/HepG2 culture system, similar to that developed earlier by Delaney *et al*[23]. Our results showed that sequential treatment with lamivudine and IFN-γ leads to effective suppression of HBV gene expression and genome replication.

MATERIALS AND METHODS

Cell lines and antiviral agents

HepG2 cells were obtained from ATCC and were maintained in complete DMEM supplemented with 100 mL/L FCS, 10g/L DMSO and 5 mg/L insulin (Sigma, St. Louis, MO, USA) at 37 ℃ in a humidified incubator supplied with 50 mL/L CO_2. Infected cells were maintained in DMEM supplemented with 100 mL/L FCS, 10g/L DMSO and 50 μmol/L hydroxycortisone hemisuccinate (Sigma, St. Louis, MO, USA). Recombinant human IFN-γ expressed in *E. coli*, purified and optimized for bioactivity was kindly provided by Dr. Navin Khanna (ICGEB, New Delhi). The specific activity was 3×10^{10} U/g protein and the preparation was kept in 10 mmol/L PBS, 50 mmol/L NaCl, pH 6.0 at -20 ℃. Lamivudine (3TC) was provided by Dabur Research Laboratories, Sahibabad (U.P.), India, and was kept as a 1 mmol/L stock in DMSO at -20 ℃.

Construction of recombinant HBV-baculoviruses

A 1.6-times unit-length HBV genome (5.0 kb), constructed from the parent HBV subtype-ayw infectious clone pTKHH2 (a kind gift from Dr. Angeline Barthelomeuz, Victorian Infectious Diseases Reference Laboratory, Melbourne, Australia) was cloned into the baculovirus transfer vector, pBacPAK9 (Clontech, CA, USA) between *Xho*I and *Bgl*II sites, opposite to the polyhedrin promoter (p*Pol*) (Figure 1). The resulting pBacHep1.6 plasmid was cotransfected with Bsu36I-digested *Autographa californica* major nuclear polyhedrosis virus (AcMNPV) DNA into the cultured Sf21 insect cell line. The transfection and recombinant baculovirus selection procedures were followed as per the manufacturer's instruction. Viral plaques in the primary screen were selected by slot blot DNA hybridization with a ^{32}P-labeled HBV DNA probe. In the secondary screening, baculoviral DNA was subjected to PCR with HBV S-ORF primers. Finally, the selected recombinant Bac-HBV plaques were screened by PCR for all the HBV open reading frames. The HBV ORF-specific PCR primer sets used are as follows: C-ORF: sense, GCGGGATCCACTGTTCAAGCCTCCAAGCT; antisense, CGGAG GCGAGGGAGTTCTTCTTCT; S-ORF: sense, GCGGGATCCGGACTGGGGACC ATGTGACGAAC; antisense, GCGAAGCTTGTTAGG GTTTAAATGTATACCC; P-ORF: sense, GAAGATCTC AATCTCGGGAATCTC; antisense, GTTCGTCACAGG GTCCCCCAGTCC; X-ORF: sense, TGCCAACTGGAT CCTTCGCGGGACGTCCT; antisense, GCGAAGCTTA AGGAAAGAAGTCAGAAGG.

A high-titre stock of selected recombinant HBV-baculoviruses was prepared from 0.5 to 1.0 litre of infected Sf21 culture supernatant. The culture supernatant was cleared at 6000 r/min for 10 min and further centrifuged in a Ti45 rotor (Beckman) at 25 000 r/min for 45 min at room temperature. A bluish-white pellet seen at the bottom of the tubes was resuspended in 3 mL PBS. This was then gently overlaid on top of a 5% (3 mL) and 40% (30 mL) sucrose cushion prepared in PBS, followed by centrifugation in an SW28 rotor (Beckman) at 18000 r/min for 30 min. A band of virus particles from the 5%-40% sucrose interface was harvested and washed with 30 mL of sterile PBS by ultracentrifugation. Finally, the virus pellet was resuspended in 1 ml of sterile PBS and stored as 200 μL aliquots at -20 ℃. A working aliquot of the virus was kept at 4 ℃. The titer of the virus so prepared was determined by plaque assay on Sf21 cells to be in the range of 10^{10} pfu/mL.

Viral transduction and drug treatment of cultured cells

HepG2 cells were seeded in 12-well plates (0.5×10^6 cells/well) or 60 mm dishes (1.5×10^6 cells/dish) one day before transduction. On the day of transduction, the medium was discarded and the cells were washed twice with PBS and once with serum-free medium. Stock recombinant Bac-HBV was diluted in serum-free medium to a final multiplicity of infection (m.o.i.) of 100 in either 150 μL

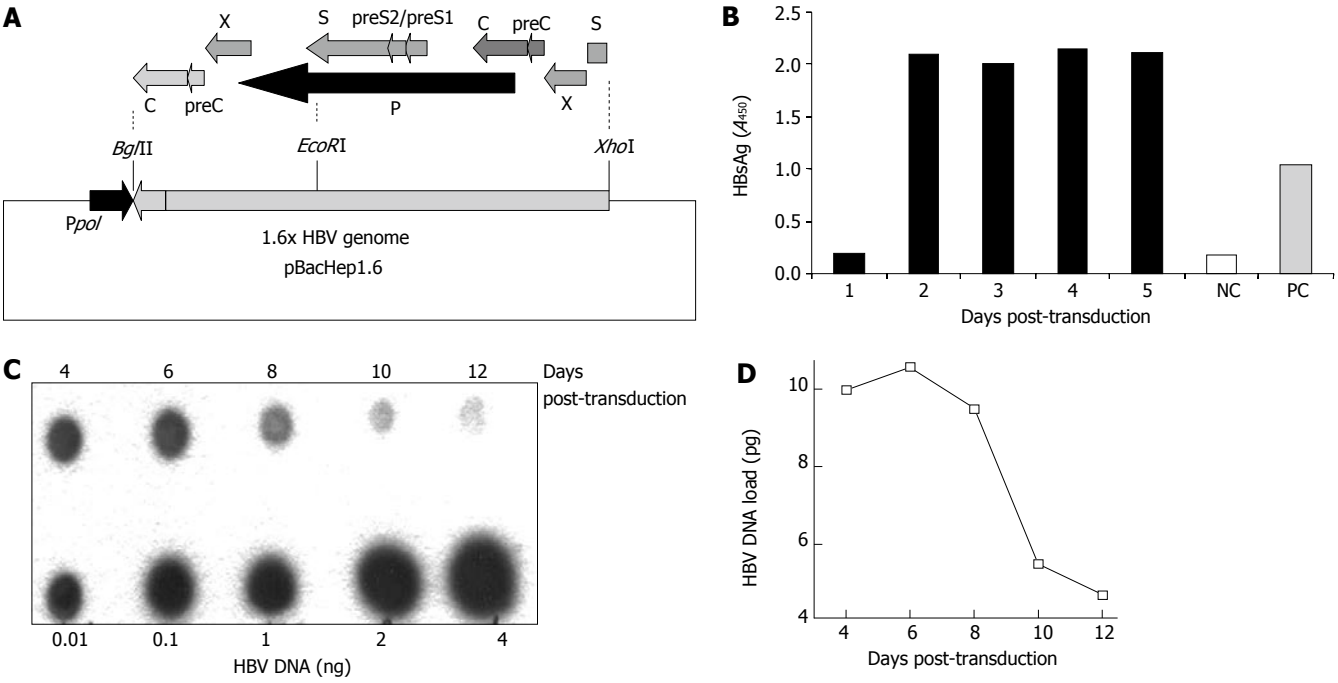

Figure 1 Construction of the recombinant Baculo-HBV virus (Bac-HBV). **A:** The recombinant transfer vector, pBacHep1.6 (10.5 kb) together with the 1.6 × genome length HBV cloned in an orientation opposite to the polyhedrin promotor (pPol) in vector pBacPAK9. The construct contains HBV-ORFs: PreS/S (1x), X (2x), P (1x), PreC/C (2x) and Enh I (2x), Enh II (2x) elements; **B:** HBsAg expression in culture medium upon transduction with 100 moi of Bac-HBV; **C:** Dot blot analysis of total HBV DNA in HepG2 cells transduced with 100 moi of Bac-HBV. (for each well of 12-well plate) or in 300 μL (for each 60 mm dish), overlaid on the cells and incubated at 37 ℃ in a CO_2 incubator for 1-1.5 h with gentle rocking every 15 min. The infectious medium was then replaced with fresh medium and the cells incubated for the desired period with media changes every alternate day. Antiviral drugs, either alone or in combination were added on d 2 post-transduction, or as indicated for different experiments, after analysis of the baseline HBsAg expression in the culture supernatants for productive HBV infection. The drug-containing medium was replaced every alternate day throughout the study period. The doses of antiviral agents were first tested in the HepG2.2.15 cell line, prior to their use in Bac-HBV transduced HepG2 cells. Every condition was set up in at least duplicate (sometimes triplicate) wells or plates.

Analysis of HBsAg and HBeAg expressions

The secreted HBsAg and HBeAg in the culture supernatants were analyzed by the use of commercial enzyme immunoassays: HBsAg microelisa (Organon Teknika, The Netherlands) and HBeAg EIA (DiSiron SPA, Italy).

Isolation of HBV DNA from infected cells

Total and cccDNA forms of HBV DNA were isolated essentially as described elsewhere[24]. For total DNA isolation, cells were washed twice with cold PBS and lysed in 1 ml of cold lysis buffer (50 mmol/L Tris-HCl, pH 8.0, 10 mmol/L EDTA, 150 mmol/L NaCl, 10 g/L SDS) on ice for 10 min. The lysate was collected in an eppendorf tube, and 100 μL of proteinase K (10 g/L) was added, mixed well and incubated at 37 ℃ for 4 h. Following phenol-chloroform-isoamyl alcohol extraction, the DNA was precipitated with chilled ethanol in the presence of sodium acetate (pH 5.2) and yeast tRNA. The DNA pellet was washed with 700 mL/L ethanol, air-dried, dissolved in 30 μL of TE (pH 8.0) and stored at 4 ℃ for further use. For isolation of cccDNA, the cells were washed and lysed as above. The lysate was collected in an eppendorf tube and 250 μL of 2.5 mol/L KCl was added and mixed properly. Following incubation on ice for 30 min, the mixture was centrifuged at 13000 r/min for 30 min in a microfuge. The supernatant containing viral cccDNA was separated and subjected to phenol-chloroform-isoamyl alcohol extraction and ethanol precipitation, as above. The cccDNA pellet was dried, dissolved in 30 μL of TE and stored at 4 ℃ for further use.

Analysis of HBV DNA

HBV DNA isolated from Bac-HBV transduced cells, either untreated or treated with antiviral drugs, was analyzed by dot blot hybridization for total viral DNA or by Southern blotting for replicative intermediates according to standard protocols. An HBV full length (3.2 kb) linear DNA was radiolabeled with 32P dCTP, using a nick-translation kit (Invitrogen, Carlsbad, CA, USA) as per manufacturer's instructions, purified through a Sephadex G50 column and used as a probe. The signals on dot blots and Southern blots were scanned, and the bands were quantitated by densitometry using the Kodak 1D image analysis software (Kodak Digital Science, Wauwatosa, WI, USA). The signal intensities were expressed as relative pixel values for each blot.

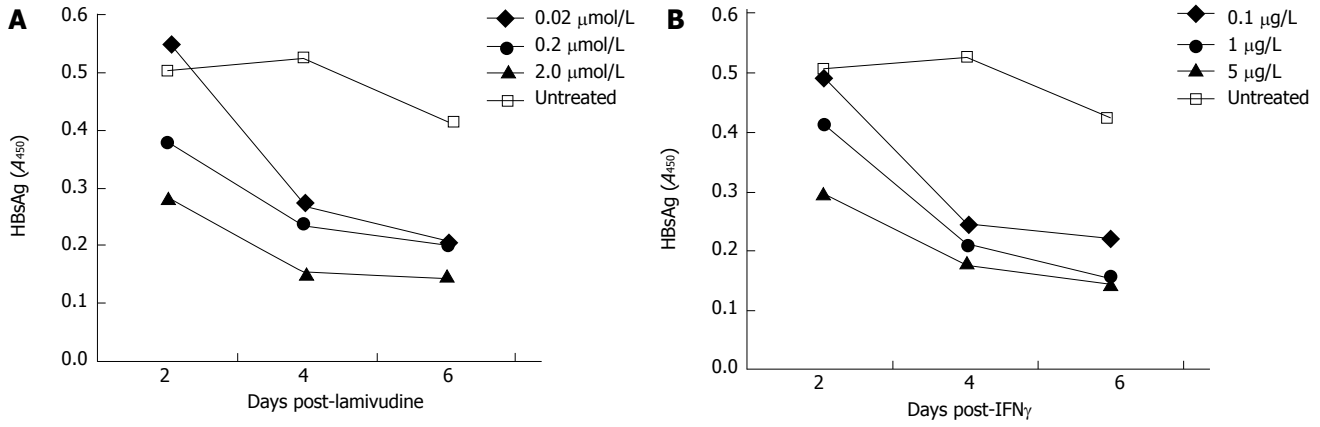

Figure 2 A time course HBsAg profile (ELISA) of transduced HepG2 cells, treated with variable doses of lamivudine and IFN-γ. **A:** Effect of lamivudine used at concentrations of 0.02, 0.2, and 2.0 μmol/L; **B:** Effect of IFN-γ used at concentrations of 0.1, 1.0 and 5.0 μg/L.

RESULTS

Generation and characterization of Bac-HBV

The subtype ayw infectious HBV clone pTKHH2 was used to isolate a 1.6 times genome-length HBV fragment as an *Xho*I-*Bgl*II fragment. This fragment included one complete copy each of the HBV P and S (including the pre-S regions) ORFs and two copies each of the C (including pre-C) and X ORFs (Figure 1A). The *Xho*I-*Bgl*II fragment was cloned into the baculovirus AcMNPV transfer vector pBacPak9 and a recombinant virus selected as described in Materials and Methods. Multiple recombinant baculoviruses were analyzed in three rounds of plaque purification. Since the HBV genome is placed in the transfer vector in an orientation opposite that of the baculovirus polyhedrin promoter, no HBV gene expression is expected in insect Sf21 cells used for recombinant baculovirus selection. However, in HepG2 cells the HBV transcription regulatory elements would be active and expression would be controlled by endogenous HBV promoters/enhancers. The Bac-HBV isolate A3-20 was finally selected for further experiments. The efficiency of transduction of HepG2 cells by Bac-HBV was estimated by HBsAg expression and total HBV DNA synthesis in transduced cells. Following transduction, we observed HBsAg synthesis (Figure 1B) and HBV DNA accumulation (Figure 1C) in HepG2 cells. High levels of HBsAg were observed in the culture medium starting at d 2 post-transduction and these levels remained constant till d 5 (Figure 1B). While it was not possible to carry on this HBsAg accumulation experiment beyond 5 d post-transduction, other experiments wherein the culture medium was changed every alternate day showed HBsAg expression to be uniformly high for up to 10 d post-transduction (data not shown). Total HBV DNA also accumulated in transduced HepG2 cells with a peak on d 6 followed by a rapid decline by d 10 (Figure 1C). The results showed that the Bac-HBV constructed here was functional and transduction of HepG2 cells led to the expression of HBV markers.

Effect of lamivudine and IFN-γ on HBV expression and replication

Since lamivudine is already established as a drug with anti-HBV properties, we tested its inhibition of the Bac-HBV system. In the range of 0.02 to 2 μmol/L lamivudine effectively reduced HBsAg levels in the culture medium of treated cells, compared to untreated cells (Figure 2A). A reproducible dose response was observed wherein with increasing drug concentration lower levels of HBsAg were observed at each of the three sampling points, d 2, 4 and 6 post-treatment. In the same experiment we also evaluated the anti-HBV effect of IFN-γ. At concentrations of 0.1 to 5 μg/L that corresponded to 3000 to 150 000 IU/L, IFN-γ also showed a marked reduction in HBsAg levels compared to untreated cells (Figure 2B). There was a rapid decline in HBsAg levels in the d 2 to d 4 period following IFN-γ treatment. We also tested whether cells pre-treated with IFN-γ and then transduced with Bac-HBV showed a similar response. HepG2 cells were either treated with IFN-γ for 24 h prior to transduction (pre-treatment group) or were first transduced and IFN-γ treatment was then initiated 24 h later (post-treatment group). In both cases, HBsAg levels in culture media were estimated 4 d after IFN-γ treatment. Pre-treatment with IFN-γ (0.01 to 10 μg/L) was found to have no significant effect on HBsAg expression, while treatment with IFN-γ after transduction was found to inhibit HBsAg expression, as observed earlier (data not shown).

To evaluate the effect of IFN-γ on HBV replication, we transduced HepG2 cells with Bac-HBV followed by treatment with 5 μg/L IFN-γ as earlier, and extracted total DNA from untreated control and treated cells at regular intervals up to ten days following IFN-γ treatment. The replicative forms of HBV were separated, identified by Southern blotting and the signals quantitated by densitometry. The results are presented in Figure 3. While no significant effect of IFN-γ was observed on the relaxed circle (RC) and double-stranded linear (DSL) forms of HBV DNA, IFN-γ treatment led to significant reduction in the covalently closed circular (CCC) and single-stranded (SS) forms of HBV DNA. The latter forms appear late in infection and are indicative of viral DNA replication as seen from their appearance around d 6 post-treatment (or d 7 of Bac-HBV transduction). While the cccDNA remains high once replication has taken place, the ssDNA form is the replicative intermediate that increases transiently and disappears at late time points. Both these

forms were suppressed around 75%-80% by IFN-γ. Overall, the kinetic study of HBV replication in transduced HepG2 cells demonstrated a time dependent, sequential synthesis of the different replicative intermediates and their inhibition by IFN-γ.

Effect of combination of lamivudine and IFN-γ on HBV expression and replication

Our *in vitro* data on lamivudine and IFN-γ monotherapy showed the effective doses of the two agents to be 2.0 μmol/L and 5 μg/L, respectively scheduled for six days (Figure 2). Comparable antiviral effects were observed at these doses. We hypothesized that a combination of lower doses of these two agents would efficiently downregulate HBV gene expression and DNA replication. If this were the case, it would be significant in a clinical setting in reducing the time of lamivudine treatment and the possibility of developing drug resistance. To test this hypothesis, we designed an *in vitro* treatment schedule of Bac-HBV transduced HepG2 cells with mixed doses of lamivudine and IFN-γ for a period of six days.

We tested two groups, one with IFN-γ at 1 μg/L and 0.02 μmol/L, 0.2 μmol/L or 2 μmol/L lamivudine, and the other group with lamivudine at 0.2 μmol/L and 0.1 μg/L, 1 μg/L or 5 μg/L of IFN-γ. Following treatment of transduced cells with these combinations, HBsAg expression levels and HBV DNA load were estimated at d 2, 4 and 6 post-treatment. As a control in the same experiment, monotherapy with same concentrations of either lamivudine or IFN-γ was also evaluated. We observed no significant reduction in either HBsAg levels or HBV load for the combinations compared to the single drugs (data not shown).

In view of these results, we further tested viral gene expression and DNA load using a sequential approach that included treatment with lamivudine alone for two days (pulse) followed by IFN-γ alone for the next four days (chase). We designed a "low" and "high" combination of the sequential treatment schedule for a period of 6 days (Figure 4A). No significant effect on either HBsAg expression (Figure 4B) or HBV DNA load (Figure 4C) was observed in the low dose sequential treatment group, when compared to either lamivudine or IFN-γ alone. However, in the high dose group, treatment first with 2 μmol/L lamivudine for 2 d followed by 1 μg/L IFN-γ for 4 d showed a significant and reproducible reduction in HBsAg expression and HBV DNA load compared to treatment with either agent alone. Since HBeAg expression and secretion in culture medium has been correlated with viral replication, we also tested its levels following lamivudine and IFN-γ treatment. Pulsing with 0.2 μmol/L lamivudine and chasing with 5 μg/L IFN-γ led to a significant reduction in HBeAg levels, compared to either agent alone (Figure 5).

With this information, we extended our studies to evaluate the inhibitory effects of a 2 d pulse of 0.2 μmol/L lamivudine, followed by a 6 d chase with 5 μg/L IFN-γ on the cccDNA pool. Southern hybridization analysis of the HBV cccDNA, isolated from the nuclei of treated or untreated Bac-HBV transduced HepG2 cells showed about 60% suppression of cccDNA by this sequential dosing, compared to lamivudine alone (Figure 6). Compared to the untreated control, this sequential dose reduced cccDNA levels by about 72%; under similar conditions, lamivudine alone reduced cccDNA forms by about 30%. Based on our *in vitro* studies, a sequential therapy with lamivudine given as a pulse of 0.2 μmol/L for the first two days and chased with 5 μg/L IFN-γ for another six days was found to efficiently suppress HBV infection.

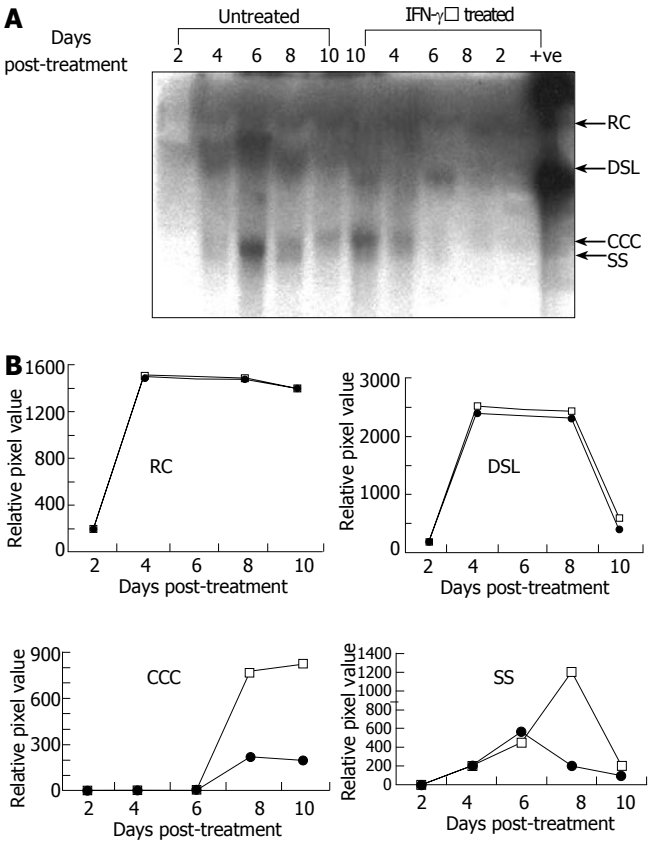

Figure 3 Representative Southern blot (**A**) and quantitative (densitometry) analysis (**B**) of effect of IFN-γ (5.0 μg/L) treatment on HBV DNA replication in transduced HepG2 cells. Synthesis of viral replicative intermediates: relaxed coil (RC), double stranded linear (DSL), covalently closed circular (CCC), and single stranded (SS) DNA forms in treated (•) and untreated (□) cells.

DISCUSSION

A major hurdle in the development of new anti-HBV agents is the lack of suitable *in vitro* as well as *in vivo* systems, which could accurately or closely model chronic HBV infection in humans. Since HBV does not directly infect cells in culture, several physicochemical and virus vector-based methods have been used to deliver HBV genome to establish productive infection *in vitro*[25,26]. A recombinant baculovirus-based system has been used to transfer HBV genome into cultured liver cell lines[23] and to test the efficacy of antiviral agents[27]. There are multiple features that make this recombinant baculo-HBV/HepG2 culture system a useful tool over stable HBV-expressing cell lines such as HepG2.2.15[23]. It is a transient system that does not require integration of the HBV genome into the cellular DNA and thus more accurately mimics CHB in humans[23]. The HBV-baculovirus infection, even at high

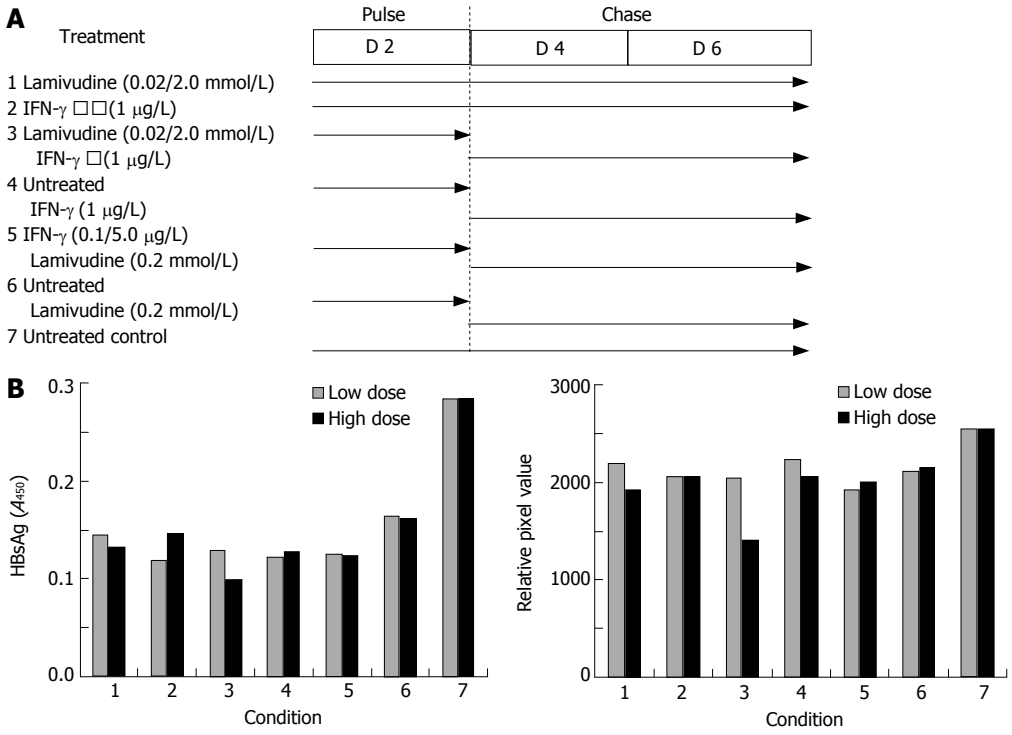

Figure 4 Effects of sequential treatment with "low/high-dose" of lamivudine and IFN-γ on HBV gene expression and total DNA load in transduced HepG2 cells. **A:** HBsAg profile; **B:** total HBV DNA upon sequential treatment of transduced cells. 1: Lamivudine (0.02 or 2.0 μmol/L) 6 d; 2: IFN-γ (1.0 μg/L) 6 d; 3: Lamivudine (0.02 or 2.0 μmol/L) 2 d + IFN-γ (1 μg/L) 4 d; 4: Untreated 2 d + IFN-γ (1.0 μg/L) 4 d; 5: IFN-γ (0.1 or 5 μg/L) 2 d + lamivudine (0.2 μmol/L) 4 d; 6: Untreated 2 d + lamivudine (0.2 μmol/L) 4 d; 7: Untreated control.

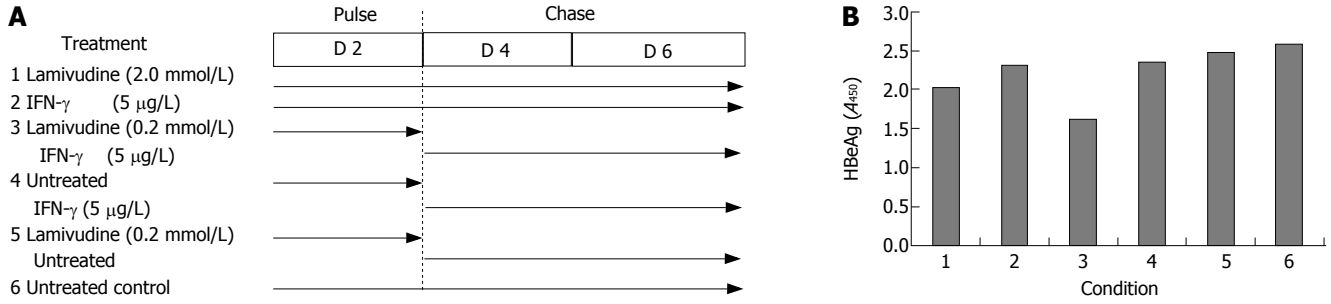

Figure 5 Effects of sequential treatment with "high-dose" of lamivudine and IFN-γ (**A**) on HBeAg expression in transduced HepG2 cells (**B**). 1: Lamivudine (2.0 μmol/L) 6 d; 2: IFN-γ (5.0 μg/L) 6 d; 3: Lamivudine (0.2 μmol/L) 2 d + IFN-γ (5 μg/L) 4 d; 4: Untreated 2 d + IFN-γ (5 μg/L) 4 d; 5: Lamivudine (0.2 μmol/L) 2 d and untreated 4 d; 6: Untreated control.

multiplicity of infection is not toxic to HepG2 cells, and HBsAg as well as HBV virions can be readily detected in the culture medium as early as 2-4 d post-infection. Many aspects of HBV biology, its pathogenicity and efficacies of antiviral drug have been studied in related hepadnaviruses like WHBV[28] and duck hepatitis B virus (DHBV)[29] that are useful models, but still different in the details of viral biology compared to HBV.

We developed our own Bac-HBV system based on published guidelines[23] and characterized it for HBsAg expression and the kinetics of HBV DNA accumulation. The analysis of HBV replicative intermediates in transduced HepG2 cells demonstrated a time-dependent, sequential synthesis of different viral DNA replicative intermediate species. The presence of high levels of dslDNA on the fourth day could be related to the onset of viral DNA replication, which coincided with the appearance of ssDNA (a hallmark of HBV replication) and kept increasing on the following days. A sudden appearance of high levels of cccDNA forms on the sixth day is likely to result from its accumulating pool

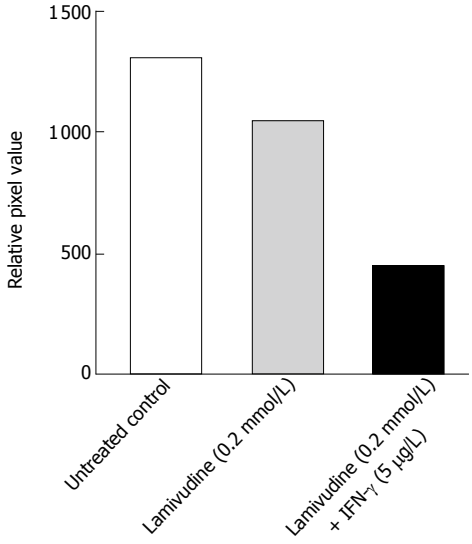

Figure 6 Effect of sequential treatment with "high-dose" of Lamivudine and IFN-γon HBV cccDNA pool in transduced HepG2 cells. The figure shows densitometric analysis of the 2 kb cccDNA form. 1: Untreated control; 2: Lamivudine (0.2 μmol/L) 8 d; 3: Lamivudine (0.2 μmol/L) 2 d + IFN-γ (5.0 μg/L) 6 d.

in the nuclei of HepG2 cells. The cccDNA is the only transcription template for all HBV RNA species, and is maintained as minichromosomes complexed with nuclear histone proteins[24,30]. This further stabilizes this minichromosomal DNA, which in turn becomes resistant to nucleases[30,31]. The cccDNA also gets recycled from the cytoplasmic-nascent rcDNAs[24]. That is probably why we observed a high cccDNA pool throughout, once it reached its equilibrium on the eighth day. The ssDNA seen at its maximum on d 8, indicated that viral genome replication was at its peak at that time. A sudden drop in its level by d 10 showed cessation of replication. Here, it is important to note that like ssDNA, the dslDNA also dropped on d 10 from its d 8 peak levels. The dslDNA is a byproduct of a minor HBV DNA replication strategy called illegitimate replication, already shown in DHBV models[31]. In this pathway, dslDNA is produced as a result of the failure to prime plus-strand DNA synthesis at the correct location, and is efficiently converted to cccDNA by non-homologous recombination near the two ends of the linear DNA. It is speculated that the low levels of virus expression in cells carrying out illegitimate replication might provide such cells a survival advantage during an antigen-specific cellular immune response[32].

Compared to IFN-α, IFN-γ is a potent immunostimulatory agent and is the major cytokine responsible for regulating the expression of both class I and class II antigens[33]. The classical concept that viral clearance is mediated by CTLs, which may destroy the infected hepatocytes has been challenged by recent studies that virus specific CTLs can abolish HBV gene expression, transcription and replication without killing the infected hepatocytes[34]. However, the distinction between the antiviral and cytotoxic effects of IFN-γ on HBV infected hepatocytes is not well characterized. In our *in vitro* study, IFN-γ was found to be effective in down regulating HBsAg levels at concentrations of 1.0 and 5.0 μg/L. The higher dose of IFN-γ was effective in suppressing viral replication by altering the kinetics of replicative DNA intermediates. It was effective on ssDNA only after the sixth day of treatment and the levels were reduced to 50% on the following days, clearly indicating cessation of replication. Interestingly, the cccDNA pool that was not effectively eliminated by lamivudine, was suppressed by 75%-80% by IFN-γ on the very day it appeared. This might be due to destabilization and degradation of cccDNA under high dose IFN-γ pressure. However, IFN-γ failed to suppress the rcDNA and dslDNA forms, despite continued therapy.

The three aims of any therapeutic strategy for CHB are (1) to decrease viral load to undetectable levels, (2) to decrease the rate of disease progression and, (3) to decrease the rate of emergence of drug-resistant HBV. Combination therapy has emerged as a new approach to treat CHB wherein the objective is to first bring down the viral load to the lowest possible levels with a potent nucleoside drug. This is then followed by a continued chemotherapy with another nucleoside analog or IFN-α in order to maintain or eliminate the remaining viral load[35-37]. Continuation with another nucleoside may again give rise to emergence of novel drug-resistance. Following the same strategy, we also evaluated combinations of lamivudine and IFN-γ in our *in vitro* system. This novel approach effectively reduced the cccDNA pool from the nuclei of transduced HepG2 cells.

Only about a third of individuals exposed to HBV are clinically diagnosed with symptomatic acute hepatitis[38]. This infection is identified only sporadically, usually post-factum, by accidental detection of circulating viral markers and serum HBV DNA. However, it has been shown that clinical recovery with biochemical normalization of liver function, the clearance of serum HBsAg and HBV DNA and the appearance of anti-HBs do not reflect virus eradication after an episode of hepatitis B[38-40]. HBV genomes persist in serum and liver despite the clearance of serum HBsAg and anti-HBs seroconversion during antiviral therapy for CHB[41,42]. Consistent molecular evidence of WHV replication not only in the livers but also in peripheral blood mononuclear cell (PBMC), bone marrow, spleen, lymph nodes, and, occasionally, in the thymus also supports the findings in the HBV-human situation. Overall, the results from recent studies unequivocally demonstrate that low-rate hepadnavirus replication in serologically undetectable infection progresses in lymphoid cells[43,44]. The lymphoid cells are believed to be an incessant, non-hepatocyte reservoir of the viral cccDNA pool as a result of "occult" infection. It is likely that this silent cccDNA may reactivate synthesis of viral transcripts and proteins and therefore a rebound of active viral replication. Therefore, elimination of cccDNA pool from infected cells still remains a challenge in HBV therapy. To the best of our knowledge, no drug or combinations of drugs to date, has been shown to effectively eliminate cccDNA.

In this study, using a combination of lamivudine and IFN-γ, we were able to successfully eliminate about three-fourths of the HBV cccDNA pool from transduced HepG2 cells. In our dot-blot analysis of the total HBV DNA levels, there was a little reduction in treated cells compared to untreated controls. This can be explained by the kinetics of HBV DNA replicative intermediates, discussed above. IFN-γ was only found to be capable of inhibiting ssDNA and cccDNA molecules. The ssDNA levels peaked on the eighth day and effects of IFN-γ were seen afterwards. The accumulation of cccDNA also started after the sixth day. Therefore at day 6 post-transduction, we cannot expect cccDNA in the total HBV DNA pool. On the other hand, IFN-γ had no effect on the other two forms, rcDNA and dslDNA. So, it is only the ssDNA, which could be suppressed on the sixth day of treatment. This is why the levels of total HBV DNA were found to be slightly down regulated, compared to the untreated controls. Overall, our *in vitro* observations of inhibitory effects of IFN-γ on HBV gene expression and DNA replication are in agreement with the published data from other groups[13,15,16]. The differences between such studies however, could be related to different dose designs, duration of chemotherapy and method of preparation of the IFN-γ used.

In conclusion, we have used the HBV-baculovirus/ HepG2 system to show that sequential treatment with lamivudine and IFN-γ efficiently suppressed HBV infection by down regulating viral replicative intermediates,

particularly the cccDNA pool. These *in vitro* results support further clinical evaluation and inclusion of IFN-γ with lamivudine as an effective combination therapy for chronic HBV infection. Such an approach may benefit those patients who do not respond to IFN-α. Further, a shortened time-course of lamivudine treatment could also help minimize emergence of drug-resistant mutants of HBV in clinical situations.

ACKNOWLEDGMENTS

We thank Dr. Angeline Bartholomeuz (VIDRL,Melbourne, Australia) for the HBV infectious clone pTKHH2 and Dr. Navin Khanna (ICGEB, New Delhi, India) for bioactive recombinant IFN-γ.

Abstract

AIM: To explore the relationship among interferon-γ (IFN-γ) activity, fibrogenesis, T cell immune responses and hepatic inflammatory activity.

METHODS: Peripheral blood samples from a total of 43 hepatitis B cirrhotic patients (LC) and 19 healthy controls (NC) were collected to measure their serum levels of IFN-γ, interleukin-2 (IL-2), soluble interleukin-2 receptor (sIL-2R), interleukin-10 (IL-10) and three serological markers of fibrosis including hyaluronic acid (HA), procollagen type III peptide (PIIIP), and type IV collagen were measured using a double antibody sandwich ELISA. Also, serum total bilirubin (TB) and alanine aminotransferase (ALT) were measured by routine measures.

RESULTS: The concentrations of serological markers of fibrosis in patients with active cirrhosis (ALC) were significantly higher than those in stationary liver cirrhosis (SLC) or NC groups. The levels of serological markers in HBeAg-positive patients were significantly higher than those in HBeAg-negative patients. In SLC and ALC patients, a negative linear correlation was found between IFN-γ levels and the serological markers of fibrosis. IFN-γ and IL-2 levels in the ALC group were significantly higher than those in the SLC and NC groups, but the statistical difference was not significant between the latter two. In contrast, IL-10 levels in the SLC group were significantly higher than that in the NC group, but no significant difference was found between SLC and ALC groups. The sIL-2R level was elevated gradually in all these groups, and the differences were significant. Positive linear correlations were seen between IFN-γ activity and ALT levels (r = 0.339, P < 0.05), and IL-2 activity and TB levels (r = 0.517, P < 0.05). sIL-2R expression was positively correlated with both ALT and TB levels (r = 0.324, 0.455, P < 0.05), whereas there was no statistically significant correlation between IL-10 expression and serum ALT and TB levels (r = -0.102, -0.093, P > 0.05). Finally, there was a positive correlation between IFN-γ and IL-2 levels.

CONCLUSION: T cell immune responses are correlated with fibrosis and hepatic inflammatory activity and may play an important role in liver cirrhosis.

INTRODUCTION

In Chinese population, infection with the hepatitis B virus is the major cause of liver injury. Inflammation stimulates hepatic stellate cells, which have been shown to be involved in fibrogenesis. Liver fibrosis is primarily due to an imbalance of proliferation and degradation of the extracellular matrix (ECM) triggered by hepatocytic necrosis and inflammation. Liver fibrosis is characterized by a frequent release of cytokines, such as transforming growth factor β1 (TGF-β1), platelets-derived growth factor (PDGF), tumor necrosis factor α (TNF-α), IL-6, interferon-γ (IFN-γ), hepatocyte growth factor (HGF), insulin-like growth factor (IGF) and IL-10[1]. Currently, the serum markers of fibrosis are hyaluronic acid (HA), procollagen type III peptide (PIIIP), and type IV collagen. These markers are used to reflect the activity of hepatic fibrotic process[2].

The relationship among immune response, viral clearance, inflammatory process, and liver fibrosis is very complicated. IFN-γ is not only an anti-fibrotic agent, but also a Th1-type cytokine, which participates in the immune response involved in fibrogenesis, as well as the inflammatory process. Thus, the role of T cell immune response in hepatic fibrosis is not clear.

The goal of this study was to characterize the relationship among T cell immune responses, inflammatory

activity and liver fibrosis. Thus, we assayed serum levels of IFN-γ and other T cell-type cytokines and serological markers of fibrosis in patients with varying degrees of liver inflammation stemming from hepatitis B cirrhotics.

MATERIALS AND METHODS

Patients

Forty-three patients with LC (18 females and 25 males with a mean age of 58.4 years) and 19 normal healthy adults (NC) (9 females and 10 males with a mean age of 51.4 years) were enrolled in this study. The patients with LC were all diagnosed by the same pathologist and classified according to WHO's histological classification of LC. Among them, six patients were HBeAg-positive. The patients were confirmed to have moderate hepatic fibrosis pathology, according to the Scheuer and Chevallier scoring system[3,4], stemming from chronic hepatitis B for 6 months to 30 years and none had received any form of antiviral therapy. Twenty-three of the cases were placed in the stationary LC (SLC) group and twenty cases in the active LC (ALC) group. Group designations were made according to the "2000 National Prevention and Treatment Plan of Viral Hepatitis", in which inflammation grades (G) were classified as G0, G1-2, G3 and G4 for no inflammation, mild, moderate and severe inflammation, respectively. SLC was defined as LC patients with normal level of aminotransferase, no obvious jaundice and no or mild inflammation according to pathologic inflammation grade. ALC was defined as LC patients with elevated aminotransferase and bilirubin, and moderate or severe inflammation according to pathologic inflammation grade. The clinical pathological features of each patient were reviewed and are shown in Table 1. Written informed consent was obtained from all subjects before study entry.

Peripheral whole blood samples were collected from patients and normal controls and serum was frozen at -70 ℃ until used.

Enzyme-linked immunosorbent assay (ELISA)

We measured the serum levels of IFN-γ, IL-2, sIL-2R and IL-10 as well as HA, PIIIP, IV-C by the double antibody sandwich ELISA. The IFN-γ assay kit was provided by the American R&D Corporation, IL-2 detecting reagents were purchased from the French Diaclone Corporation, and the kits for sIL-2R and IL-10 were obtained from Beijing Jinmei Biotech, Beijing. HA, PIIIP and collagen IV were determined using kits from Shanghai Maoyuan Biotech, Shanghai. Assays were performed following the manufacturer's instructions. Optical density of each well was determined within 30 min, using a microplate reader set at 450 nm.

Serum total bilirubin (TB) and alanine aminotransferase (ALT) were measured by routine methods.

Statistical analysis

All biochemical data were expressed as mean ± SD. SPSS PC+ software package was used to analyzed differences between groups for statistical significance using *t* tests. Differences were considered significant when *P* values were < 0.05. Additionally, Pearson's correlation coefficients were calculated.

Table 1 Grouping of patients with LC

According to state of illness		According to virus replication	
Group	*n*	Group	*n*
SLC	23	HBeAg (+)	6
ALC	20	HBeAg (-)	37

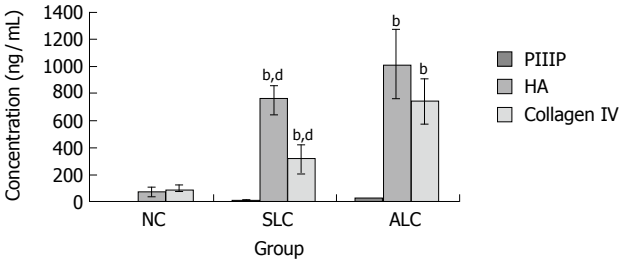

Figure 1 PIIIP, HA and type IV collagen levels in the three groups. There was a statistically significant difference between ALC and NC ($^bP < 0.01$, ALC *vs* NC) and ALC and SLC ($^dP < 0.01$, ALC *vs* SLC).

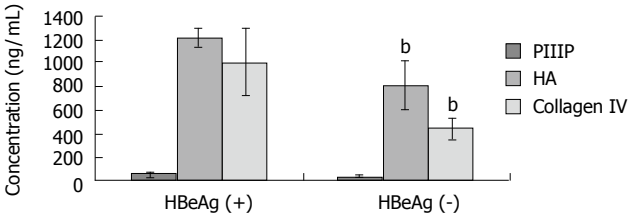

Figure 2 Relationship between serologic markers of fibrosis and HBeAg. There were statistically significant differences in levels of serologic markers of fibrosis between HbeAg (+) and HbeAg (-) groups ($^bP < 0.01$).

RESULTS

Serological markers of fibrosis and HBeAg

Figure 1 shows the concentrations of serological markers of fibrosis in NC, SLC and ALC patients [PIIIP: 2.322 ± 2.209, 16.730 ± 11.142 and 41.315 ± 20.635 ng/mL; HA: 79.247 ± 28.531, 752.870 ± 114.838 and 1 013.300 ± 252.988 ng/mL; type IV collagen: 101.974 ± 27.855, 323.661 ± 104.021 and 747.950 ± 160.929 ng/mL ($^bP < 0.01$ for all)]. The concentrations of serological markers of fibrosis in the ALC group patients were significantly higher than those in the SLC or NC groups. In addition, levels of serologic markers of fibrosis were significantly higher in HbeAg-positive patients as compared with the HBeAg-negative patients [PIIIP: 49.774 ± 21.831 *vs.* 24.665 ± 17.996 ng/mL; HA: 1 207.650 ± 79.832 *vs.* 819.866 ± 203.495 ng/mL; type IV collagen: 1 007.614 ± 286.012 *vs.* 442.105 ± 84.827 ng/mL ($^bP < 0.01$ for all, Figure 2)].

Association of IFN-γ with fibrosis

A negative linear correlation was observed between serum IFN-γ levels and serological markers of fibrosis HA, PIIIP and type IV collagen in patients with LC. The correlation

Table 2 Correlations between serum IFN-γ level and serological markers of fibrosis

	SLC			ALC		
	PIIIP	HA	Collagen IV	PIIIP	HA	Collagen IV
Correlation coefficient (*r*) with IFN-γ	-0.531[b]	-0.523[a]	-0.599[b]	-0.482[a]	-0.499[a]	-0.578[b]

[a]$P < 0.05$, [b]$P < 0.01$.

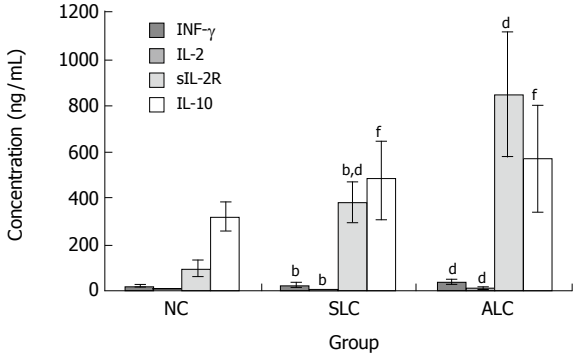

Figure 3 Serum IFN-γ, IL-2, sIL-2R and IL-10 levels in the three groups. IFN-γ and IL-2 levels were significantly higher in the ALC group compared to the SLC and NC groups ([b]$P < 0.01$, ALC *vs* SLC; [d]$P < 0.01$, ALC *vs* NC), but no obvious difference was found between the SLC and NC groups ($P > 0.05$, NC *vs* SLC). IL-10 levels were significantly higher in the SLC group compared to the NC and ALC groups ([f]$P < 0.01$, SLC *vs* NC; $P < 0.05$, SLC *vs* ALC). sIL-2R levels elevated gradually in all three groups ([b]$P < 0.01$, ALC *vs* SLC; [d]$P < 0.01$, ALC *vs* NC; [d]$P < 0.01$, NC *vs* SLC).

coefficients (*r*) of HA, PIIIP and type IV collagen with IFN-γ are listed in Table 2.

Association of T cell immune responses with inflammatory activity

Figure 3 shows IFN-γ, IL-2, sIL-2R and IL-10 levels in NC, SLC and ALC groups (IFN-γ: 21.213 ± 5.876, 23.619 ± 8.183 and 35.881 ± 9.032 pg/mL; IL-2: 5.404 ± 2.161, 6.003 ± 2.174 and 11.989 ± 7.232 pg/mL; IL-10: 320.684 ± 59.864, 480.455 ± 169.554 and 570.500 ± 230.451 pg/mL; sIL-2R: 94.917 ± 33.672, 380.571 ± 92 and 848.656 ± 268.105 pg/mL). IFN-γ and IL-2 levels in the ALC group were significantly higher than those in the SLC and NC groups ($P < 0.01$), but no significant difference between the SLC and NC groups was observed. IL-10 levels in the SLC group were significantly higher than that in the NC group ($P < 0.01$), likewise, there was no significant difference between the SLC and ALC groups. sIL-2R levels elevated gradually in all three groups, and the differences were significant ($P < 0.01$).

Positive linear correlations were found between IFN-γ activity and ALT levels ($r = 0.339$, $P < 0.05$) and IL-2 activity and TB levels ($r = 0.517$, $P < 0.05$; Table 3). sIL-2R expression was significantly positively correlated with both ALT and TB levels ($r = 0.324$, 0.455, $P < 0.05$). But the correlation between IL-10 expression and ALT and TB levels was not significant ($r = -0.102$, -0.093, $P > 0.05$). Furthermore, a positive correlation between IFN-γ and IL-2 levels ($r = 0.324$, $P < 0.05$) was observed.

Table 3 Correlations between serum IFN-γ, IL-2, sIL-2R, IL-1 levels and ALT, TB levels in LC patients

	IFN-γ	IL-2	sIL-2R	IL-10
ALT	$r = 0.339$[a]	$r = 0.119$	$r = 0.324$[a]	$r = -0.102$
TB	$r = 0.287$	$r = 0.517$[a]	$r = 0.455$[a]	$r = -0.093$
IFN-γ		$r = 0.324$[a]	$r = 0.110$	$r = 0.183$
IL-2			$r = 0.220$	$r = 0.018$
sIL-2R				$r = 0.086$

[a]$P < 0.05$.

DISCUSSION

Liver fibrosis is a common feature in chronic liver disease, which is relevant to inflammation, viral replication and T cell immune responses. T helper (Th) cells are important in T cell immune responses and are divided into Th1, Th2 and Th0 cells characterized by different cytokines they secrete. Th1 cells are characterized by IFN-γ, IL-2 and TNF-β production, whereas Th2 cells are characterized by IL-10, IL-4, IL-5 and IL-6 production. The cytokines produced by Th1 and Th2 cells can influence and restrain each other.

The present study showed that IFN-γ levels were remarkably high in the ALC group and positively correlated with ALT levels. In fact, several studies have shown that IFN-γ is associated with elevation of ALT levels in chronic hepatitis B patients[5,6]. This might be due to different immune responses in chronic *versus* acute infections.

Using IFN-γ and IL-2 levels to report the functional state of Th1 cells and IL-10 levels to report the functional state of Th2 cells in patients with LC, we found that Th1 cells predominated in the ALC group, while Th2 cells predominated in the SLC group. Recently, an imbalance of Th1/Th2 cells was found in HBV-infected chronic patients, and T cells were activated in the patients with chronic hepatitis B[7]. The majority of peripheral blood mononuclear cells shown in hepatitis B patients were Th0 cells, but the proportion of Th1 cells increased remarkably along with the hepatic inflammatory activity[8]. Th1-type cytokines levels were higher in patients with serious inflammation than those with milder inflammation. Our results also showed that there was no significant difference in IFN-γ or IL-2 levels between SLC and NC groups, thereby suggesting that Th1-type cytokines decrease with alleviation of inflammation.

An imbalance of Th1 and Th2 cells exists in patients with LC. Our results indicated a predominance of IFN-γ, IL-2 and sIL-2R in LC patients with active inflammation and a predominance of Th2-type cytokine IL-10 in ALC patients. Detection of serum levels of these cytokines might provide insight into the occurrence of liver inflammation, immune response and outcome of the patients.

IFN-γ plays a crucial role in modulating immune responses for HBV-induced cirrhosis[9-12]. Our study showed that serum IFN-γ levels were negatively correlated with serologic markers of fibrosis in ALC and SLC

patients, suggesting that IFN-γ may play a role in the fibrogenesis process in patients with LC. Many scholars hypothesize that there are two mechanisms involved in the anti-fibrotic role of IFN-γ. One role is to lower the mRNA expression level of precollagen I, III in fibroblasts. Sakaida *et al*[10] found a decrease in precollagen I, III levels and myofibroblasts in a rat liver fibrosis model, after giving the rats IFN-γ (50 000 U) daily. A second role is to inhibit activation and proliferation of hepatic stellate cells. In IFN-γ-treated animals, activation of hepatic stellate cells induced by liver injury was reduced, as shown by the decrease of proliferating hepatic stellate cells and the reduction of parenchymal area occupied by smooth muscle-specific alpha-actin (α-SMA)-positive cells. In addition, there may be some other explanations. For example, IFN-γ can cause changes in the expression of Bcl-2 and Bax genes in liver fibrosis in rats. Additionally, IFN-γ may promote myofibroblasts apoptosis and inhibit ECM synthesis[13]. Results from this study showed that levels of serologic markers of fibrosis were much higher in ALC than in SLC patients. Additionally, our results showed significantly higher levels of serologic markers of fibrosis in HBeAg-positive as compared with HBeAg-negative patients. Taken together, the data suggest that inflammation and viral replication promote the process of fibrosis.

HBV activates T cells, B cells and macrophages to express IL-2R with high competency. It has been proposed that sIL-2R as well as IL-2 might cause hepatic injury in chronic active hepatitis C[14]. sIL-2R levels decreased substantially after IFN treatment in patients with chronic hepatitis C. Consistent with our results, Sawayama *et al*[15] reported an increase of sIL-2R levels in LC patients and a positive correlation between IL-2 and ALT levels. The reason for the sIL-2R increase is still unknown, but it may be due to changes in cytokine clearance in the liver. On the other hand, activated T cells can promote the production of sIL-2R and may therefore augment serum sIL-2R levels.

A low IL-10 level could lead to an increase in pro-inflammatory cytokines and a worse prognosis. But in this study, we found non- significant correlation between IL-10 expression and ALT and TB levels (r = -0.102, -0.093, P > 0.05). In fact, an imbalance of IL-10 and IFN-γ may play an important role in promoting inflammatory reactions leading to massive liver damage[16,17], since excessive IL-10 secretion would restrain the immune response against the virus. This imbalance may thus lead to a sustained hepatitis B viral infection[5,18-20].

Because of the existence of interactions between IFN-γ and IL-2 in the immune response, we examined IL-2 levels in the LC patients. Our results showed that IL-2 levels in the ALC group were significantly higher than those in the SLC or NC groups, but IL-2 levels in the SLC and NC groups did not differ significantly. A positive correlation was found between IFN-γ and IL-2 levels as well as between IL-2 and TB levels.

In conclusion, IFN-γ ameliorates liver fibrogenesis and also participates in the cellular immune response as an important Th1-type cell, which enhances the action

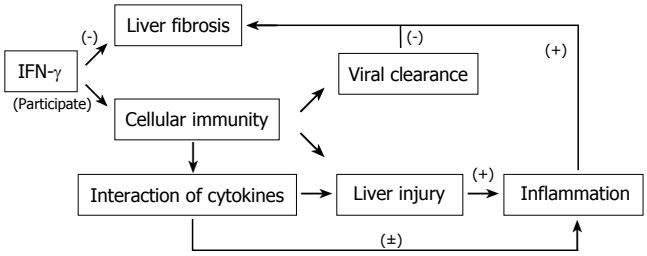

Figure 4 Simplified schemes showing the effects of IFN-γ on fibrosis. (+): upregulate; (-): downregulate.

of cytolytic T cell (CTL) to clear HBV and slows the progression of fibrosis (Figure 4). However, Th1-type cellular immunoresponses can cause liver injury during viral clearance. Inflammatory cells are recruited to the sites where hepatocytic necrosis has occurred and initiates and augments liver fibrosis. Thus, when IFN-γ is given as a treatment for LC patients during an active stage, the pro-inflammatory role of IFN-γ must be considered. At the Annual meeting of the Americans for the Study of Liver Disease (AASLD), IFN-γ has been formally recommended to be the preferred anti-fibrotic drug. Our results indicate that there still remain many problems to be solved in the course of treatment, such as IFN-γ dosage, and how to assess the efficacy of the treatment, as linked to the stage of fibrosis, inflammatory processes and serum concentration levels of IFN-γ in those patients. However, our results are important for evaluation and discussion of the feasibility of IFN-γ use in treating patients with liver cirrhosis.

Abstract

AIM: To determine DNA aneuploidy in mucosal biopsies of achalasia patients for subsequent rapid diagnosis.

METHODS: Biopsies from the middle third of the esophagus were obtained in 15 patients with achalasia. Immunohistochemical staining was carried out with monoclonal antibodies MIB-1 for Ki67 and PAb 1801 for p53, in addition to the conventional histologic examination for dysplasia. Nuclei of fresh biopsy material were enzymatically and mechanically isolated, and the DNA content was determined with image cytometry after Feulgen staining. DNA grading of malignancy was assessed according to Boecking to determine the variability of DNA values noted around the normal diploid peak. Further indices measured included the aneuploid rate, and the 5c-, 7c- and 9c-exceeding rate.

RESULTS: The histological examination did not demonstrate dysplasia; while MIB-1 (basal) showed a positive reaction in 8/15 achalasia specimens, p53 was negative in all specimens. Image cytometric DNA analysis detected aneuploidy in 4/15 (26.7%) specimens. Samples from 15 patients with squamous cell carcinoma as well as specimens obtained exclusively 2 cm proximal to the tumor served as reference tests. All carcinomas (15/15) as well as 9 of the peritumoral samples (9/15) were aneuploid. The comparison of biopsies from achalasia patients with peritumoral and carcinoma specimens revealed statistically significant differences regarding the aneuploid rate (diploid: $P < 0.0001$; tetraploid: $P = 0.001$), grading of malignancy according to Boecking ($P < 0.0001$) and the 5c- ($P < 0.0001$), 7c- ($P < 0.0001$), and 9c- ($P = 0.0001$) exceeding rate with progredient DNA alterations in the respective order.

CONCLUSION: The finding that DNA aneuploidy was identified by image cytometry in esophageal specimens of patients with achalasia, which may be due to specific chromosomal alterations presenting as precancerous lesions in 27% of patients, leads us to conclude that image cytometry represents a valuable screening tool.

INTRODUCTION

Achalasia is a rare motility disorder of the esophagus characterized functionally and manometrically by failed relaxation of a hypertensive lower esophageal sphincter and the absence of progressive peristalsis of the esophageal body[1]. The predominant morphologic alteration is a reduction in or complete absence of ganglia cells in the myenteric plexus in combination with an inflammatory infiltrate[2-5]. Patients with achalasia are at an increased risk of developing squamous cell carcinoma of the esophagus. The incidence of carcinoma reported in the literature ranges from 0%-29%, and has led various authors to describe achalasia as a precancerous stage[6-12]. In achalasia, the carcinoma is frequently, presumably due to the presence of dysphagia, diagnosed only at an advanced stage, with a corresponding poor prognosis[8,13,14]. The detection of precancerous alterations thus remains a diagnostic challenge. In addition to the currently available optical techniques, static DNA image cytometry offers the possibility of identifying cytogenetic alterations at an early stage. In the present study, we therefore aimed to determine and investigate DNA aneuploidy in biopsy specimens from patients with primary achalasia, using a rapid diagnostic test.

MATERIALS AND METHODS

Patients

From November 1, 2003 to October 7, 2004, specimens were collected (forceps biopsies) from the middle third of the esophagus in 15 patients with achalasia in the course of screening endoscopy. The study was performed with approval of the Local Ethics Committee [number 837.347.03 (4009), 2003]. The diagnosis was confirmed in all patients enrolled in the study by esophageal manometry, as well as endoscopic and radiological examination, which enabled exclusion of the presence of secondary achalasia. Enrolled in the study were 9 male and 6 female patients with a median age of 49 (28-75) years at the time of biopsy. The median interval from the time of the initial diagnosis was 54 (1-647) mo.

Squamous cell carcinoma of the esophagus

In 15 patients with squamous cell carcinoma of the esophagus, reference specimens were obtained from the center of the carcinoma, as well as from peritumoral tissue 2 cm proximal to the tumor margin (surplus material from the surgical specimen resected in the course of esophagectomy with informed patient consent). Included in this group of patients were 1 female and 14 male patients with a median age of 64 (40-79) years.

Clinical symptoms

Clinical symptoms were assessed with the Eckardt symptom score[15] . The possible score for each symptom ranged from 0-3, depending upon the presence of dysphagia, regurgitation, and retrosternal pain occurring occasionally, daily, several times a day, or at each mealtime. An additional score was recorded for weight loss (no weight loss, < 5 kg, 5-10 kg, and >10 kg). The total possible score therefore ranged from a minimum of 0 to a maximum of 12 points.

Esophageal manometry

The investigations were carried out using a capillary perfusion system as previously described[15] . Recorded in addition to the resting tonus and relaxation of the lower esophageal sphincter were the contraction amplitudes at 5 and 10 cm above the lower esophageal sphincter after 10 barium swallows. The manometric criteria for the diagnosis of achalasia included the absence of peristalsis in the esophageal body, as well as a non-relaxing lower esophageal sphincter. Due to the fact that in one patient passage of the manometry probe into the lower esophageal sphincter was not possible, and another patient had previously undergone distal esophagus and fundus resection at an outside institution, the documentation in these patients refers to the motility of the esophageal body only.

Radiological examination

Barium swallow was performed in the patient in the supine, semisupine, and upright positions. Measurements were made of the maximum diameter of the esophageal body, as well as of the narrowest point of the gastroesophageal junction.

Therapy

Pneumatic dilatations were carried out in a total number of 10 patients (3 patients had a second, and 1 patient a third dilatation in the course of therapy). Five patients had a prior Heller myotomy in combination with anterior partial fundoplication according to Dor *et al*[16]. Nine additional patients were scheduled to undergo myotomy (in 1 of these patients re-myotomy was performed for recurrent disease).

Histology

The paraffin-embedded specimens were cut into 3-4-μm thick sections and stained with hematoxylin and eosin (H&E). The non-malignant tissue was classified as normal, inflammatorily altered, or dysplastic. The definition of invasive carcinoma was based on the detection of infiltrative growth patterns for individual malignant cells or glands.

Immunohistochemistry

Consecutive sections for immunohistochemical evaluation were cut after deparaffinization and rehydration, and 30 mL/L hydrogen peroxide was used to block endogenous peroxidase. The slides were incubated with the monoclonal antibodies MIB-1 (mAb) (1:200, Dako, Denmark) for Ki67 antigen and PAb 1801 (1:100, Becton Dickinson) for p53. After microwave pretreatment, specimens were incubated with MIB-1 and PAb for 1 h at room temperature, followed by sequential 20-min incubations with biotinylated anti-mouse IgG and peroxidase-labeled streptavidin. The staining procedure was described as positive if more than 20% of cells reacted for p53-mAb.

Image cytometric DNA analysis

A computerized image analysis system was used for DNA measurements (AutoCyte QUIC-DNA Workstation; AutoCyte, Elon College, NC, USA). The measurements were analyzed with AutoCyte QUIC-DNA software. The homogenized tissue was dissolved in 2 mL 0.01 g/L pronase solution (Pronase (lyophilyzed) Dako, Denmark) and incubated in PBS (pH 7.4). The prepared tissue was then filtered through a 50-μL pore size nylon mesh. This method enables specific staining of DNA *in situ*[17] . The possibility of DNA quantification according to the Feulgen reaction is due to the fact that the staining intensity during this reaction is in direct proportion to the DNA concentration[18] .

Approximately 250-300 test cells were measured for interactive image cytometry. The cells were selected on the screen on the basis of nuclear morphology. The DNA content of >30 reference nuclei was measured in each case to obtain accurate values at the different staining intensities for the individual slides. A reference extinction was assigned to the normal 2c-value of the reference cells. Gray levels in the microscopic image were transformed into digitalized signals and evaluated, with the System 256 allowing differentiation between gray level intervals. Measurements were made with 566-nm monochromic light. Light absorption is proportional to the DNA

content of the cell. DNA aneuploidy is assumed when cells with a DNA content of 2xG1 of the reference cell fraction are detected. In tissues without polyploidization, a threshold value of the 5c-results (5c-exceeding events) is sufficient for classification. The demonstration of 1% of cell nuclei with a DNA content of > 5c serves as proof of malignancy[19]. The following indices were calculated based on the DNA measurements: Aneuploidy (measured values outside the interval of +/- 12.5% of the value of the simple powers of 2c); aneuploid rate (percentage of aneuploid cells out of the total number of test cells); grading of malignancy according to Boecking (logarithmic transformation of the variance of DNA values on a scale from 0-3); and the 5c-, 7c- and 9c-exceeding rate (percentage of cells with ploidy values higher than 5c, 7c and 9c in relation to the total number of test cells).

Statistical analysis

The SPSS 11.0 software package (SPSS, Chicago, IL, USA: 2001) was used for data analysis. Data were expressed as median values with ranges (minimum-maximum) and as percentages. In the comparative analysis of the patient groups, the χ^2 test with Pearson's correction, as well as Fisher's exact test were employed. The Kruskal-Wallis test was used for the comparison of DNA alterations in achalasia, peritumoral, and carcinoma biopsies. Spearman' s linear regression model served to calculate potential correlations between mucosal DNA alterations or proliferation markers and clinical findings. P <0.05 was considered statistically significant.

RESULTS

The median symptom score according to Eckardt was 3 (range 1-10) points at the time of the investigation. Roentgenographic findings showed a mean maximum esophageal body diameter of 30 (20-60) mm, and a mean lumen diameter of 7 (1-10) mm at the narrowest point of the esophagogastric junction. Esophageal manometry measured a median lower esophageal sphincter resting tonus of 17.7 (5.9-28.5) mmHg (n =13). Sphincter relaxation in swallowing was absent in all patients. The contraction amplitude in the distal esophagus (mean value for 10 barium swallows) was 35.3 (6.0-65.3) mmHg at 5 cm above the lower esophageal sphincter, and 32.5 (10.0-122.8) mmHg at 10 cm.

The conventional histopathologic examination of the 15 biopsies from patients with achalasia did not demonstrate the presence of dysplasia. The immunohistochemical evaluation showed a median staining intensity with MIB-1 (basal) of 25% (0%-40%) (Figure 1), and was thus > 20% in 8 achalasia patients. Conversely, a positive reaction was noted in all patients with squamous cell carcinoma, at a median value of 70% (60%-80%). While all achalasia biopsies showed a negative reaction for p53, a positive reaction was observed for 60% of the carcinomas.

Image cytometric DNA analysis detected aneuploidy in 4 of 15 (26.7%) patients. In 9 of 15 (60%) of the peritumoral samples, aneuploidy was identified at 2 cm proximal to the tumor margin, and was present in all tumor specimens. The aneuploidy rate in achalasia was 0.9% (0%-9.4%) diploid and 0 (0%-2.4%) tetraploid. In the peritumoral tissue, the rate was 2.6% (0%-15.0%) diploid and 0 (0%-4.5%) tetraploid, compared to 12.5% (1.2%-48.0%) diploid and 1.4% (0%-15.0%) tetraploid at the center of the carcinoma. Grading of malignancy according to Boecking (scale of 0-3) was 0.2 (range 0.1-0.8) in patients with achalasia, 0.4 (range 0.1-1.5) in peritumoral tissue, and 1.3 (range 0.6-1.9) in the tumor center. The 5c-exceeding rate was 0.3% (0%-5%) in the achalasia specimens, 1.3% (0%-9.6%) in the peritumoral samples, and 10.5% (3.1%-32.6%) in the tumor center. Corresponding to the smaller sample numbers due to overlapping, the 7c- and 9c-exceeding rates were lower than the 5c-rate; there was a similar increase from achalasia to peritumoral samples and to carcinoma for these rates as that observed for the above factors.

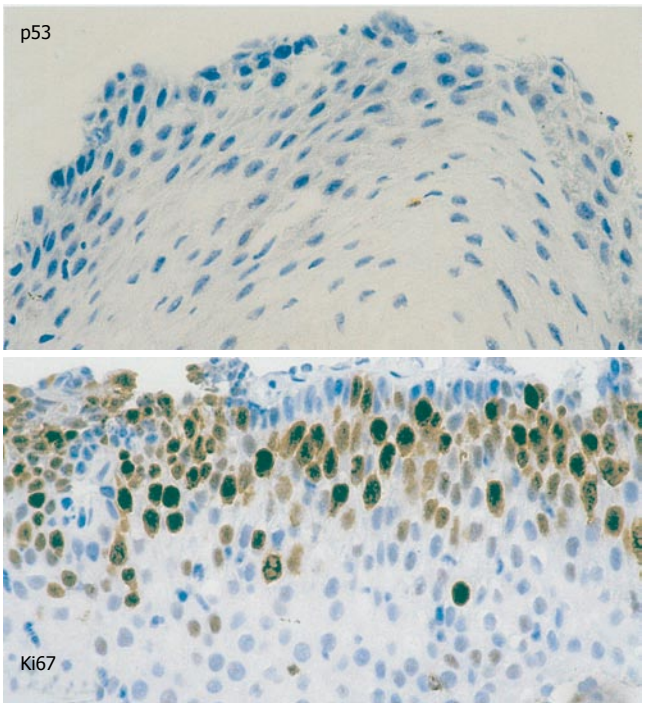

Figure 1 Immunohistochemical evaluation, staining with PAb 1801 for p53 and MIB-1 (basal) for Ki67 antigen in a patient with achalasia.

Figure 2 shows the progression of DNA aneuploidy on the basis of nuclear morphology with the respective histogram for achalasia samples (A), in peritumoral tissue 2 cm proximal to the tumor border (B), and in the tumor center of the squamous cell carcinoma (C). The comparison of biopsies from patients with achalasia, and the peritumoral as well as the carcinoma specimens employing the Kruskal-Wallis test demonstrated statistically significant differences for the aneuploidy rate (diploid: P < 0.0001; tetraploid: P = 0.001), grading of malignancy according to Boecking (P < 0.0001), as well as the 5c- (P < 0.0001), 7c- (P < 0.0001), and 9c- (P < 0.0001) exceeding rates.

There was no correlation in patients with achalasia between mucosal DNA alterations or proliferation markers

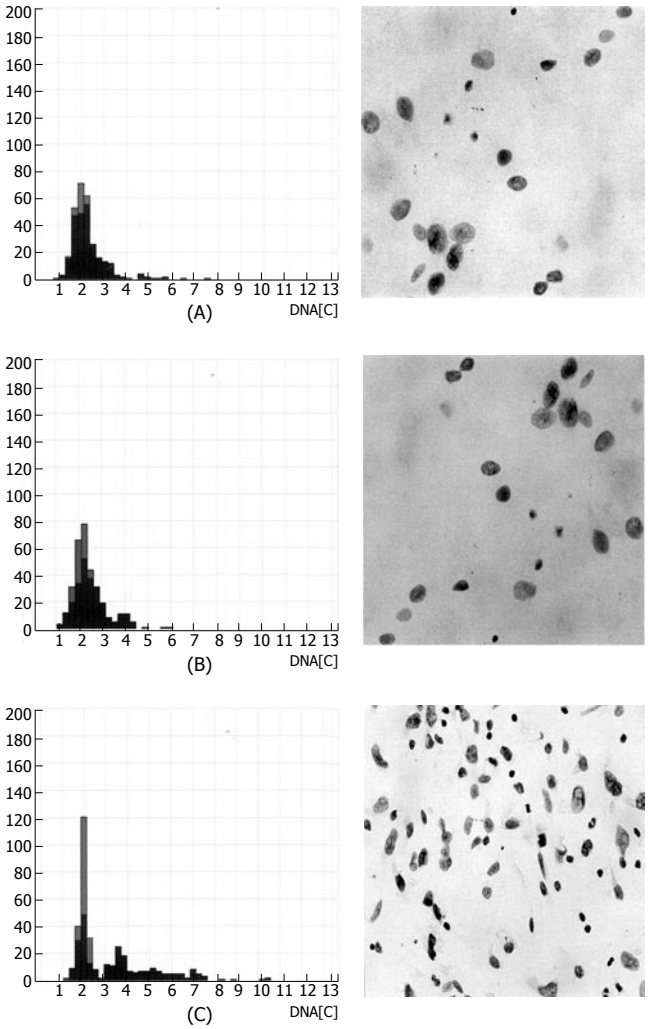

Figure 2 Image cytometric DNA analysis: histogram and nuclear morphology. (**A**) achalasia; (**B**) peritumoral tissue (esophageal carcinoma); (**C**) tumor center (esophageal carcinoma).

and the presence of clinical symptoms, the Eckardt-Score, the maximum diameter of the esophageal body, or the resting pressure of the lower esophageal sphincter ($P > 0.05$). Following allocation of the patients with achalasia to 2 groups (patients with aneuploidy: $n = 4$ and without aneuploidy: $n = 11$), a difference in the diameter of the esophageal body becomes apparent, which is relevantly larger (42.5 *vs* 30 mm) in the patients with aneuploidy; however, no differences were observed with regard to persistence of symptoms, the Eckardt-Score, and resting pressure.

DISCUSSION

DNA aneuploidy and increased cell proliferation have an important role in the pathogenesis of esophageal carcinoma. The prognostic significance of aneuploidy has been described for squamous cell carcinoma and adenocarcinoma of the esophagus[20-22]. Even in the absence of positive findings on conventional histopathology, Image cytometry offers the detection of early mucosal DNA alterations and therefore serves as a useful tool in the selection of a defined group of patients at risk for malignancy. One of the advantages of image-directed cytometry over flow cytometry is that it enables measurement of the integrated optical staining density per specimen in a digitalized image, allowing the visual assessment of the individual measured objects with the exclusion of artifacts. The presence of aneuploidy in 27% of our patients with achalasia is in accordance with the increased malignancy rate known for this disorder, and provides the possibility of early tumor detection. In addition, the method used in this study, which is based on the modification of enzymatic nuclear isolation with pronase, represents a useful rapid diagnostic test for the identification of DNA alterations.

Conventional methods of nuclear isolation for Feulgen staining and subsequent image cytometric DNA diagnosis have primarily been performed in paraffin-embedded samples and were characterized by both a minimal yield of nuclei and low staining intensity for the small number of available nuclei[23,24]. The disadvantage of paraffin-embedded or formalin-fixed samples is that unavoidable artifacts and alterations in the cell structure occurring during nuclear isolation lead to falsification of the results[25,26]. The described modification of the pronase method for nuclear isolation from non-formalin-fixed native specimens used in this study was shown to be readily reproducible. This was due to the high number of cell nuclei, which were markedly in excess of the required number of 250 study and 30 reference nuclei, as well as to negligible clumping and clearly identifiable nuclear structures in the absence of artifacts. The evaluation of the samples prepared according to the described method in combination with additionally performed grading of malignancy proved to be highly reliable.

It has been speculated that precancerous alterations in achalasia develop as sequelae of a chronic inflammatory reaction of the esophageal squamous epithelium due to the retention and stasis of food and secretions. Conventional histomorphology has identified various mucosal alterations, including diffuse squamous epithelial hyperplasia, lymphocytic esophagitis, lymphocytic inflammatory alterations of the lamina propria mucosa, and the submucosa with prominent germinal centers, as well as periductal or glandular inflammatory reactions with complete loss of submucosal glandular structures[27,28]. The development of a multistep process from squamous epithelial hyperplasia to dysplasia, culminating in the manifestation of carcinoma may be hypothesized.

DNA aneuploidy in achalasia has previously been investigated only by one study, which observed a markedly lower number of chromosomal alterations (10%) than that found in the current investigation. As reported by Bektas *et al*[29], there were no pathologic findings in the control group of his study (0/18 controls). However, the method used by Bektas *et al*[29] was flow cytometry, whose limitations have been described elsewhere in this paper. The role of aneuploidy with regard to the neoplastic progression in achalasia-associated esophageal squamous cell carcinoma has been described in a case study carried out by Porschen *et al*[30]. In their patient, aneuploidy was also found in the mucosa adjacent to the

carcinoma, a phenomenon which was likewise observed in the reference specimens from the carcinoma patients of our study. This finding may correspond to the model of epithelial lateral spread in squamous cell carcinoma leading to the development of multiple adjacent carcinomas of monoclonal origin described by Brieger *et al*[31]. Nevertheless, the time of occurrence, cellular interactions and induction by endogenous and exogenous noxae, and the distribution pattern of precancerous alterations in achalasia are currently not known.

Although dysplasia was not identified in the achalasia patients of this study - in correlation with DNA alterations - a positive reaction for Ki67 as a marker of increased proliferation was nevertheless found. Fujii *et al*[32] noted an increased number of Ki67-positive cells in the non-malignant epithelium of 4 patients with achalasia and esophageal carcinoma. While mutations of the p53 tumor suppressor gene are known to be of crucial importance for the pathogenesis of esophageal squamous cell carcinoma, the role of this gene in the development of achalasia-associated carcinoma is still under discussion. Conversely, immunohistochemical studies with p21, p16 and EGF (epidermal growth factor) have shown that dysplastic epithelium found in esophageal carcinoma represents a borderline alteration between hyperplasia and the carcinoma *in situ* in achalasia[33].

DNA aneuploidy in patients with achalasia can be identified in 27% of cases in the absence of histomorphologically proven dysplasia using image cytometry. Marked overlapping of chromosomal alterations between achalasia biopsies with peritumoral tissue and the tumor center was found in individual patients with esophageal squamous cell carcinoma. The identification of DNA aneuploidy may thus be of major importance in the early diagnosis of carcinoma in achalasia. Further long-term studies in patients with aneuploidy are needed to answer the question as to the cost-benefit effectiveness of this procedure. Should the decision favor of the use of image cytometry as an early diagnostic tool be made at this early stage, the described method could serve as clinically relevant rapid diagnostic test.

Abstract

AIM: To investigate the role of endogenous γ-amino-butyric acid (GABA) in pancreatic exocrine secretion.

METHODS: The isolated, vascularly perfused rat pancreas was employed in this study to eliminate the possible influences of extrinsic nerves and hormones. Cholecystokinin (CCK; 10 pmol/L) was intra-arterially given to stimulate exocrine secretion of the pancreas.

RESULTS: Glutamine, a major precursor of GABA, which was given intra-arterially at concentrations of 1, 4 and 10 mmol/L, dose-dependently elevated the CCK-stimulated secretions of fluid and amylase in the normal pancreas. Bicuculline (10 μmol/L), a $GABA_A$ receptor antagonist, blocked the enhancing effect of glutamine (4 mmol/L) on the CCK-stimulated exocrine secretions. Glutamine, at concentrations of 1, 4 and 10 mmol/L, dose-dependently increased the GABA concentration in portal effluent of the normal pancreas. The effects of glutamine on the CCK-stimulated exocrine secretion as well as the GABA secretion were markedly reduced in the streptozotocin-treated pancreas.

CONCLUSION: GABA could be secreted from β-cells into the islet-acinar portal system after administration of glutainine, and could enhance the CCK-stimulated exocrine secretion through $GABA_A$ receptors. Thus, GABA in islet β-cells is a hormone modulating pancreatic exocrine secretion.

INTRODUCTION

γ-aminobutyric acid (GABA), a well-known inhibitory neurotransmitter, is also present in islet β-cells of the pancreas at a very high concentration comparable to that in the brain[1,2]. Glutamic acid decarboxylase (GAD) and GABA transaminase also co-exist in islet β-cells[3-5]. GABA has been known as a modulator of the endocrine pancreas. It has been reported that GABA and its agonist inhibit release of somatostatin[6] and glucagon[7] whereas it stimulates release of insulin[8]. The GABA concentration and the GAD activity are very high in insulinoma tissue[1] while the GAD level is very low in the pancreatic tissue with insulin-dependent diabetes mellitus[9].

In the pancreas, a substance secreted from islet cells reaches acinar cells at a very high concentration through the intra-pancreatic circulation, the islet-acinar portal system, and then gives a vast influence on exocrine function[10,11]. Thus, we hypothesized that GABA might also play a role in pancreatic exocrine function if it would be secreted from islet β-cells into the portal system. There are some reports suggesting that islet β-cells may secrete GABA and that GABA may affect pancreatic exocrine function. The pancreatic β-TC6 cells, a murine β-cell line developed from insulinoma, secrete GABA in response to glucose[12]. Cultured rat β-cells also secrete GABA into the medium in response to glutamine[13]. High affinity binding sites of GABA have been determined in pancreatic exocrine cells[14]. We have previously reported that exogenous GABA enhances CCK-stimulated exocrine secretion while it has not any influence on spontaneous or secretin-stimulated exocrine secretion of the isolated rat pancreas[15].

Thus, this study was aimed to investigate whether GABA in islet β-cells acts as a hormone to modify pancreatic exocrine secretion. Secretion of GABA from islet β-cells and effects of endogenous GABA on pancreatic exocrine secretion were determined in this

study. Bicuculline was used to interfere with the GABA action by blocking $GABA_A$ receptors. Streptozotocin was employed to destroy islet β-cells containing GABA. The totally isolated, vascularly perfused pancreas model was used in this study to eliminate the possible influences of extrinsic nerves and hormones on exocrine secretion.

MATERIALS AND METHODS

Preparation of totally isolated and vascularly perfused pancreas

Male Sprague-Dawley rats, weighing 250-300 g, were anaesthetized with an intra-peritoneal injection of 25 g/L urethan (Sigma, St. Louis, MO) at a dose of 7 mL/kg of body mass after 24 h fasting with free access to water. Rats were sacrificed by an intravenous overdose of urethan after isolation of the pancreas. The isolated, vascularly perfused rat pancreas was prepared according to a method described previously[16,17]. In brief, the abdominal aorta was carefully dissected and cannulated with PE-50 tubing (Clay Adams, Parsippany, NJ) just above the celiac artery, and then tightly ligated below the superior mesenteric artery. The pancreatic duct was cannulated at the duodenal end with PE-10 tubing (Clay Adams). The portal vein was also cannulated with Tygon microbore tubing (Fisher Scientific, Pittsburgh, PA) to drain perfusate. The isolated pancreas was perfused with modified Krebs-Henseleit solution (pH 7.4, 305 mosmol/kg water) through the celiac and superior mesenteric arteries at a flow rate of 1.2 mL/min by using a multistaltic pump (Buchler, Kansas, MO). The perfusate contained 1 g/L bovine serum albumin (Sigma), 3 g/L Dextran T-70 (Sigma) and 18 mmol/L glucose (Sigma), and was continuously oxygenated with 95 mL/L O_2 containing 5 mL/L CO_2. The pancreas was isolated with the duodenum, but separated from other neighboring organs and tissues, and then placed in a temperature-controlled experimental chamber at 37 ℃. The chamber was also continuously supplied with Krebs-Henseleit solution at a flow rate of 0.35 mL/min and also oxygenated. After an equilibration period of 30 min, pancreatic juice secreted in 15 min was collected throughout the whole period of the experiment. Portal effluent drained in 15 min was also collected in ice-chilled tubes, and then kept at -70 ℃ for GABA assay.

Effects of glutamine and GABA on CCK-induced exocrine secretion

Exocrine secretion of the isolated rat pancreas was stimulated by intra-arterial infusion of synthetic CCK-8 (Squibb Institute, Princeton, NJ) at a concentration of 10 pmol/L for 90 min. Glutamine (Sigma), a major precursor of GABA[14,18], was added to perfusate at a concentration of 1, 4, or 10 mmol/L from 30 min prior to the infusion of CCK until the end of the experiment. For mimicking the effects of glutamine, GABA (Sigma) at a concentration of 30 μmol/L was intra-arterially infused to the pancreas from 30 min before the CCK infusion until the end of the experiment. Bicuculline (Tocris, Baldwin, MO), a $GABA_A$ receptor antagonist[15,19], was intra-arterially infused at a concentration of 10 μmol/L from 30 min before the infusion of CCK until the end of the experiment. Effects of glutamine (4 mmol/L) on the CCK-stimulated pancreatic exocrine secretion were also observed after destruction of islet β-cells by streptozotocin (Sigma). Streptozotocin was intra-peritoneally injected at a single dose of 75 mg/kg 3 d before the experiment.

Effects of glutamine on GABA secretion

Glutamine (Sigma) was intra-arterially infused to the isolated pancreas at a concentration of 1, 4, or 10 mmol/L from 30 min prior to the infusion of CCK until the end of the experiment. The GABA concentration in portal effluent drained in 15 min was determined by an enzymatic recycling for NADPH as reported previously[1,14]. Briefly, 500 μL portal effluent of the isolated perfused rat pancreas was lyophilized. The lyophilized samples were dissolved in 80 μL GABA assay reagent (0.3 mol/L Tris-HCl buffer-pH 8.9, 10002 nkat/L GABAse, 5 mmol/L α-ketoglutarate, 0.1 g/L mercaptoethanol, 0.5 mmol/L $NADP^+$) and incubated for 30 min at 37 ℃. At the end of the reaction, 20 μL of 1.5 mol/L NaOH was added and the incubation was continued for 20 min at 60 ℃. A 20 μL aliquot was mixed with 250 μL enzyme recycling reagent (0.2 mol/L Tris-HCl buffer-pH 8.0, 5 mmol/L ketoglutarate, 1 mmol/L glucose-6-phosphate, 25 mmol/L ammonium acetate, 1 mmol/L ADP, 0.2 g/L BSA, 55,011 nkat/L glutamate dehydrogenase, 2.5 mmol/L glucose-6-phosphate dehydrogenase). The reaction was carried out at 37 ℃ for 1 h and stopped by heating at 100 ℃ for 7 min. A 90 μL aliquot was mixed with 250 μL assay reagent (0.1 mmol/L Tris-HCl buffer-pH 8.0, 1 mmol/L $NADP^+$, 0.4 mmol/L EDTA, 366.7 nkat/L 6-phosphogluconate dehydrogenase) and incubated for 30 min at 25 ℃. The final absorbance was recorded at 340 nmol/L. All chemicals were purchased from Sigma.

Pancreatic secretions of fluid and amylase

The volume flow of pancreatic juice was determined by measuring the length of pancreatic juice collected in microtube with a capacity of 3.8 μL/cm. α-amylase activity in pancreatic juice was determined by a method reported previously [20, 21].

Statistical analysis

All results were illustrated as mean ± SE. The data were analyzed using the Student's *t* test. The difference was considered significant when $P < 0.05$.

RESULTS

Effects of glutamine on CCK-stimulated exocrine secretion

The isolated, perfused rat pancreas spontaneously secreted a minute amount of juice (34.8 ± 5.8 nL/min) and amylase activity (5.80 ± 1.86 nkat/min). CCK-8, given intra-arterially at a concentration of 10 pmol/L, significantly increased ($P < 0.01$) the basal pancreatic secretions of fluid and amylase to 304.7 ± 23.5 nL/min and 82.83 ± 7.11 nkat/min, respectively. Figure 1 illustrates the effects of glutamine on the CCK-stimulated exocrine secretions of the isolated rat pancreas. Glutamine, added in the perfusate at concentrations of 1, 4 and 10 mmol/L, dose-dependently elevated the CCK-stimulated pancreatic

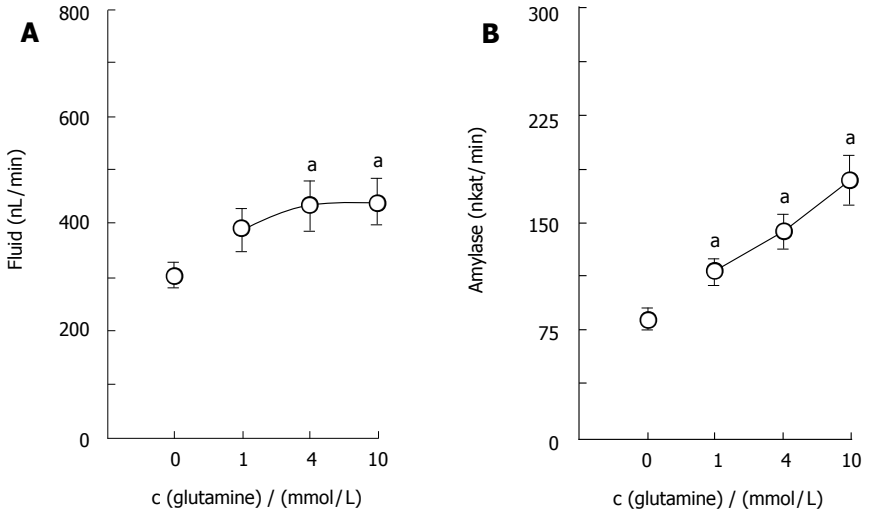

Figure 1 Dose-dependent effects of glutamine on CCK-stimulated secretions of fluid (**A**) and amylase (**B**) in the isolated, perfused rat pancreas (mean ± SE, $n = 7$). $^aP < 0.05$ *vs* without glutamine.

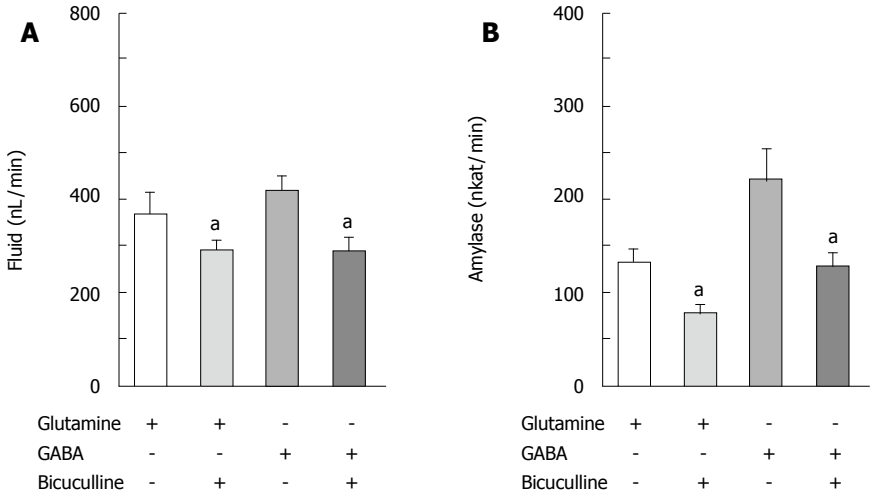

Figure 2 Effects of bicuculline on glutamine- or GABA-enhanced, CCK-stimulated secretions of fluid (**A**) and amylase (**B**) in the isolated, perfused rat pancreas (mean ± SE, $n = 7$). $^aP < 0.05$ *vs* without bicuculline.

secretions of fluid and amylase to 387.3 ± 39.0 nL/min and 115.71 ± 9.50 nkat/min, 432.3 ± 48.3 nL/min and 144.02 ± 11.88 nkat/min, 439.0 ± 45.3 nL/min and 179.18 ± 17.48 nkat/min, respectively. Figure 2 illustrates the effects of bicuculline, a $GABA_A$ receptor antagonist, on actions of glutamine and GABA in pancreatic exocrine secretions. Synthetic GABA, given intra-arterially at a concentration of 30 μmol/L, also increased ($P < 0.001$) the CCK-stimulated pancreatic secretions of fluid and amylase to 418.7 ± 31.8 nL/min and 221.82 ± 32.11 nkat/min, respectively. Bicuculline at a concentration of 10 μmol/L significantly reduced ($P < 0.001$) the glutamine (4 mmol/L)- or GABA (30 μmol/L)-enhanced, CCK-stimulated pancreatic secretions of fluid and amylase to 289.3 ± 22.0 nL/min and 78.72 ± 7.00 nkat/min or 290.2 ± 27.7 nL/min and 130.00 ± 13.41 nkat/min, respectively. The enhancing effects of glutamine (4 mmol/L) on the CCK-stimulated secretions of fluid and amylase were greatly diminished in the pancreas isolated from the streptozotocin-treated rats (Figure 3).

Effects of glutamine on GABA secretion

The mean basal concentration of GABA in portal effluent of the normal pancreas was 0.72 ± 0.08 μmol/L. Figure 4 demonstrates the dose-dependent effects of glutamine on GABA secretion in the isolated rat pancreas. When glutamine, at concentrations of 1, 4 and 10 mmol/L, was added to the perfusate containing 10 pmol/L CCK, the GABA concentrations in portal effluent increased from the basal level to the peak level of 4.72 ± 1.01 μmol/L, 8.94 ± 0.81 μmol/L and 12.11 ± 0.75 μmol/L, respectively. Figure 5 illustrates the effects of glutamine on GABA secretion in the pancreas isolated from streptozotocin-treated rats. The streptozotocin-treated pancreas spontaneously secreted GABA at a rate of 0.55 ± 0.04 μmol/L, which was significantly lower ($P < 0.05$) than that obtained in the normal pancreas. When glutamine, at 4 mmol/L, was added to the perfusate containing 10 pmol/L CCK, the GABA concentration was increased from the basal level to the peak level of 2.08 ± 0.28 μmol/L, which was also significantly lower ($P < 0.001$) than that observed in the normal pancreas.

DISCUSSION

The results of the present investigation clearly demonstrate that glutamine has an influence on exocrine secretion in the isolated, perfused rat pancreas. When glutamine was intra-arterially given at a concentration of 1, 4 or 10 mmol/L to the isolated pancreas, the CCK-

stimulated pancreatic secretions of fluid and amylase were further elevated in a dose-dependent manner. Synthetic GABA, administered intra-arterially at a concentration of 30 μmol/L, also further increased the CCK-stimulated pancreatic secretions of fluid and amylase, as demonstrated previously[15]. Bicuculline, a $GABA_A$ receptor antagonist[19], effectively blocked the enhancing effects of glutamine or GABA on the CCK-stimulated pancreatic secretions. Because glutamine is a major precursor of GABA[18], the results strongly suggest that glutamine may enhance the CCK-stimulated pancreatic exocrine secretion by inducing secretion of GABA. So far, there is no direct evidence that GABA is secreted from the islet β-cells into the intra-pancreatic circulation although cultured β-cells secrete GABA into medium[14]. Thus, we examined whether GABA is secreted from the β-cells into the portal circulation of the pancreas in this study. When glutamine was added in the perfusate at concentrations of 1, 4 and 10 mmol/L, the GABA concentration in portal effluent was elevated dose-dependently. The effect of glutamine on the CCK-stimulated exocrine secretion was reduced in the pancreas isolated from rats treated with streptozotocin, a well-known β-cell toxin. Furthermore, not only at the basal state but also at the glutamine-infused state, the GABA concentration in portal effluent was much lower in the streptozotocin-treated pancreas than in the normal pancreas. The results firstly show that GABA is secreted by a secretagogue from islet β-cells into the intra-pancreatic circulation, which enhances the CCK-stimulated pancreatic exocrine secretion. There is good evidence that β-cells may secrete GABA. It has been reported that β-cells contain not only GABA but also GAD, a GABA synthesizing enzyme at high concentration[1,2,22]. β-cells include synaptic-like microvesicles that may be concerned with GABA secretion[22]. The pancreatic β-TC6 cells[13] or cultured rat β-cells[14] secrete GABA into the medium in response to glucose or glutamine. GABA may be also secreted from the GABAergic neurons in the pancreas because GABA-containing neuronal cell bodies locate at the periphery of islets, and numerous GABA-containing processes of the neurons extend into the exocrine pancreas[23]. Secretion of GABA from the GABA-containing neurons should be elucidated in future studies.

Endogenous GABA appears to exert the enhancing effects on the CCK-stimulated pancreatic exocrine secretion via $GABA_A$ receptors. In this study, the enhancing effects of glutamine on the CCK-stimulated pancreatic secretion were effectively blocked by bicuculline, a $GABA_A$ receptor antagonist[15,19]. Existence of $GABA_A$ receptors has been reported in pancreatic exocrine cells of neonatal rats[12] and in AR42J cells, a pancreatic cancer cell line[24]. Endogenous GABA may elevate the CCK-stimulated pancreatic exocrine secretion indirectly by modulating release of islet hormones. It has been reported that GABA or its agonist inhibits release of somatostatin[6,25], which inhibits CCK-stimulated pancreatic exocrine secretion[26,27]. We have already reported that a somatostatin antagonist further elevates the enhancing effects of GABA on CCK-stimulated pancreatic exocrine secretion[15]. It has been also documented that GABA stimulates release of insulin[8], which increases CCK-stimulated pancreatic exocrine secretion[28,29]. In addition, the GAD activity in the pancreatic islet is very low in mice suffering from insulin-dependent diabetes mellitus[9], in which pancreatic exocrine secretion is reduced[30]. Endogenous GABA may also enhance the intrinsic neuronal action on pancreatic exocrine secretion. Our previous studies showed that exogenous GABA further elevates pancreatic exocrine secretion evoked by electrical field stimulation as well as neurotransmitters such as gastrin-releasing peptide[27] and acetylcholine[32] in rat pancreas. Recently, GABA-sensitive neurons have been electrophysiologically observed in cat pancreas[33]. Although GABA could depolarize all ganglial

cells recorded in the study through $GABA_A$ receptor, only approximately 10% of neurons among them could generate action potential. Thus, it is unclear at present whether the GABA-induced neuronal activation results in modification of pancreatic exocrine secretion.

In summary, glutamine could further elevate CCK-stimulated pancreatic exocrine secretion of the isolated rat pancreas dose-dependently, which could be blocked by bicuculline. Glutamine could increase the GABA concentration in portal effluent of the isolated rat pancreas dose-dependently. The effects of glutamine on the CCK-stimulated pancreatic exocrine secretion as well as the GABA secretion were markedly reduced in the pancreas isolated from the streptozotocin-treated rat. Therefore, it is concluded that GABA can be secreted from islet β-cells into the islet-acinar portal system after administration of glutamine, which could enhance CCK-stimulated pancreatic exocrine secretion via $GABA_A$ receptors. The results strongly indicate that GABA in islet β-cells may be an islet hormone affecting exocrine secretion of the pancreas in rats.

Abstract

AIM: Lafutidine, a histamine H_2 receptor antagonist, exhibits gastro-protective action mediated by capsaicin-sensitive afferent neurons (CSN). We compared the effect between lafutidine and capsaicin, with respect to the interaction with endogenous prostaglandins (PG), nitric oxide (NO) and the afferent neurons, including transient receptor potential vanilloid subtype 1 (TRPV1).

METHODS: Male SD rats and C57BL/6 mice, both wild-type and prostacyclin IP receptor knockout animals, were used after 18 h of fasting. Gastric lesions were induced by the po administration of HCl/ethanol (60% in 150 mmol/L HCl) in a volume of 1 mL for rats or 0.3 mL for mice.

RESULTS: Both lafutidine and capsaicin (1-10 mg/kg, po) afforded dose-dependent protection against HCl/ethanol in rats and mice. The effects were attenuated by both the ablation of CSN and pretreatment with N^G-nitro-L-arginine methyl ester, yet only the effect of capsaicin was mitigated by prior administration of capsazepine, the TRPV1 antagonist, as well as indomethacin. Lafutidine protected the stomach against HCl/ethanol in IP receptor knockout mice, similar to wild-type animals, while capsaicin failed to afford protection in the animals lacking IP receptors. Neither of these agents affected the mucosal PGE_2 or 6-keto $PGF_{1\alpha}$ contents in rat stomachs. Capsaicin evoked an increase in $[Ca^{2+}]i$ in rat TRPV1-transfected HEK293 cells while lafutidine did not.

CONCLUSION: These results suggest that although both lafutidine and capsaicin exhibit gastro-protective action mediated by CSN, the mode of their effects differs regarding the dependency on endogenous PGs/IP receptors and TRPV1. It is assumed that lafutidine interacts with CSN at yet unidentified sites other than TRPV1.

INTRODUCTION

The mucosal integrity of the stomach is maintained by multiple factors, both paracrine and neuronal systems[1-4]. Prostaglandins (PGs)[1] and nitric oxide (NO)[4] are part of the paracrine system while capsaicin-sensitive afferent neurons play a central role in the neuronal protection of the stomach[2,3]. Studies have demonstrated that capsaicin, a selective stimulator of these afferent neurons, protects the gastric mucosa against various ulcerogenic stimuli such as necrotizing agents[2]. The protective action of capsaicin is mediated by these afferent neurons, because it is totally attenuated by chemical ablation of the neurons following pretreatment with a large dose of capsaicin[2,5]. Recently, the binding site of capsaicin has been identified and named transient receptor potential vaniloid subtype 1 (TRPV1)[6-8]. It is thought that capsaicin stimulates these afferent neurons through the activation of TRPV1, resulting in the release of the neurotransmitter calcitonin gene-related peptide (CGRP) and gastric protection[3].

Previous studies suggest that endogenous PGs sensitize sensory neurons to nociceptive stimulation[9,10]. Boku *et al*[11] recently reported a lack of release of CGRP in response to mild injury in the stomach of IP-receptor knockout mice. Ohishi *et al*[9] demonstrated using IP-receptor knockout mice that PGI_2 is a major nociceptive mediator in the acetic acid-induced writhing reaction. Since

capsaicin-induced gastric cytoprotection was attenuated by indomethacin and disappeared in IP-receptor knockout mice, it is assumed that endogenous prostacyclin (PGI_2) plays a supportive role in the mechanism of capsaicin-induced gastric cytoprotection, probably by sensitizing the sensory neurons through IP receptors[12].

Lafutidine, a histamine H_2-receptor antagonist [(±)-2-(furfurylsulfinyl)-N-[4-[4-(piperidinomethyl)-2-pyridyl]oxy-(Z)-2-butenyl]acetamide], is known to exhibit potent protective activity in the gastrointestinal mucosa, in addition to gastric anti-secretory action[13-15]. The protective action of lafutidine is independent of the anti-secretory effect and mediated by capsaicin-sensitive sensory neurons[14,15]. Indeed, the protective action of lafutidine is also abrogated by pretreatment with the CGRP antagonist $CGRP_{8-37}$ and the inhibitor of NO production N^G-nitro-L-arginine methyl ester (L-NAME), in addition to chemical ablation of capsaicin-sensitive afferent neurons[16]. However, it remains unknown whether this action of lafutidine results from interaction with TRPV1 or whether endogenous PGs are essential to the gastro-protective effect.

In the present study, we investigated the protective action of lafutidine with respect to the dependence on endogenous PGs and the interaction with TRPV1, and compared the results with those for capsaicin. In addition, we also examined the effect of lafutidine on HCl/ethanol-induced gastric lesions in mice lacking IP receptors, in an attempt to confirm the distinctive mechanism underlying the gastro-protection provided by lafutidine and capsaicin.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats (200-220 g; Nippon Charles River, Shizuoka, Japan) and C57BL/6 mice (25-30 g) were used. Mice lacking prostacyclin (PGI_2) IP-receptors were generated as described previously[11]. In brief, each gene encoding the IP receptors was individually disrupted, and chimeric mice were generated. These animals were then back crossed with C57BL/6 mice, and the resulting heterozygous litter mates [IP (+/-),] were bred to produce homozygous IP (-/-) mice. Homozygous mice were born at the predicted Mendelian frequency, grew normally, lived longer than 1 year and were fertile. The distribution of the IP receptor genes was verified by northern blot hybridization, which failed to detect messenger RNA encoding the respective receptors in IP (-/-) mice. The animals were deprived of food but allowed free access to tap water for 18 hr before the experiments. All studies were performed using 4-6 animals per group under unanesthetized conditions. The experimental procedures described here were approved by the Experimental Animal Research Committee of Kyoto Pharmaceutical University.

Induction of Gastric Lesions

The rats were given 1 mL of HCl/ethanol (60% in 150 mmo/L HCl) po through esophageal catheter, and killed 1 h later under deep ether anesthesia. The stomach was removed, inflated by injecting 10 mL of 1% formalin for 10 min to fix the inner wall, and opened along the greater curvature. The area (mm^2) of hemorrhagic lesions developed in the stomach was measured under a dissecting microscope with a square grid (×10). Lafutidine (1-10 mg/kg) or capsaicin (1-10 mg/kg) was given po 30 min before the administration of HCl/ethanol. In some cases, indomethacin (5 mg/kg, sc), L-NAME (20 mg/kg, sc) or capsazepine (TRPV1 antagonist: 12.5 mg/kg, po) was given 1 h or 30 min, respectively, before the administration of lafutidine or capsaicin. In addition, the protective effect of lafutidine and capsaicin against HCl/ethanol was also examined in rats with ablation of capsaicin-sensitive sensory neurons (chemical deafferentation). Chemical deafferentation was induced by s.c. injections of capsaicin once daily for three consecutive days (total dose: 100 mg/kg) 2 wk before the experiment[2, 5]. All capsaicin injections were performed under ether anesthesia, and the rats were pretreated with terbutaline (0.1 mg/kg, im) and aminophylline (10 mg/kg, im) to counteract the respiratory impairment associated with capsaicin injection. The effectiveness of the treatment was tested by examining the protective wiping movements of the eye.

In another experiment, wild-type mice and IP-receptor knockout mice were given HCl/ethanol po in a volume of 0.3 mL, and killed 1 hr later[17]. Then, the stomach was removed and treated with formalin, and the mucosa was examined for hemorrhagic lesions under a dissecting microscope, as described previously. In half the animals of each group, lafutidine (10 and 30 mg/kg) or capsaicin (10 mg/kg) was given po 30 min before the administration of HCl/ethanol.

Measurement of Mucosal PGE_2 and 6-keto $PGF_{1\alpha}$ Levels

Levels of PGE_2 in the rat gastric mucosa and those of 6-keto $PGF_{1\alpha}$ in the mouse stomach were measured 30 min after the po administration of lafutidine (10 mg) or capsaicin (10 mg/kg). In some cases, indomethacin (5 mg/kg) was given s.c. 1 h before the capsaicin. Under ether anesthesia, the stomachs were quickly removed, opened along the greater curvature, and rinsed with ice-cold saline. To separate the mucosal layer, the corpus mucosa was placed between two glass slides squeezed with a rubber band, and placed in hexane-frozen Dry Ice and acetone. These glasses were separated, and the mucosa was collected, weighed, and put in a tube containing 100% ethanol plus 0.1 mol/L indomethacin[18,19]. Then, the samples were homogenized, and centrifuged for 10 min at 12000 g at 4 ℃. The supernatant of each sample was used for the determination of PGE_2 and 6-keto $PGF_{1\alpha}$ levels by EIA with a PGE_2- and 6-keto $PGF_{1\alpha}$-kit, respectively (Cayman Chemical Co., Ann Arbor, MI).

Determination of the Ca^{2+} Response in VR1-Transfected HEK239 Cells

Human embryonic kidney 293 (HEK293) cells were maintained in Dulbecco's modified Eagle's medium (DMEM, Gibco BRL) supplemented with 15% fetal bovine serum (FBS, JRH Biosciences, KS) and 100 IU/mL of penicillin plus 100 μg/mL of streptomycin (Gibco BRL, MD) in an atmosphere of 5% CO_2 and 95% air at 37 ℃. HEK293 cells were seeded on glass cover slips coated with poly-L-lysine (Sigma Chem, MO) in 35 mm dishes. The cells grown to 70%-80% confluence were transfected with 3

μg of VR1-pCR3.1-Uni plasmid using LipofectA-MINE Reagent (Gibco BRL, MD) and were cultured in DMEM for 48 hr[20]. After the medium was changed once with calcium imaging buffer (CIB) consisting of 115 mmol/L NaCl, 5.4 mmol/L KCl, 0.8 mmol/L $MgCl_2$, 1.8 mmol/L $CaCl_2$, 13.8 mmol/L D-glucose, and 20 mmol/L HEPES (adjusted to pH 7.4 with NaOH), cells were incubated with CIB containing 5 μmol/L Fura-2-AM (Dojin, Kumamoto, Japan) at room temperature for 45 min. Then, cells were washed twice with CIB. The mobilization of Ca^{2+} was monitored with an ARGUS-100/CA system (Hamamatsu Photonics, Hamamatsu, Japan). Dual images (340 and 380 nm excitation, 510 nm emission) were collected for 180 s. The $[Ca^{2+}]i$ was calculated from Fura-2 ratios by the equation described in a previous paper[20,21], and the maximal responses were determined. Capsaicin (10^{-8}-10^{-6} mol/L) or lafutidine (10^{-4} mol/L) was added to the medium.

Preparation of Drugs

Drugs used were lafutidine (UCB Japan, Tokyo, Japan), capsaicin (Nakarai Tesque, Kyoto, Japan), indomethacin, capsazepine, N^G-nitro-L-arginine methyl ester (L-NAME)(Sigma Chemicals, St. Louis, MO), terbutaline (Bricanyl^R, Fujisawa, Osaka, Japan) and aminophylline (Neophyllin^R, Eisai, Tokyo, Japan). Lafutidine was suspended with 0.5% carboxymethylcellulose solution (CMC: Nacalai Tesque). Capsaicin was dissolved in a Tween 80-ethanol solution (10% ethanol, 10% Tween and 80% saline, w/w: Wako, Osaka, Japan) for sc injection while it was suspended in a 0.5% CMC for topical application. Indomethacin was suspended in saline with a drop of Tween 80 (Wako, Osaka, Japan). Other agents were dissolved in saline. Each agent was prepared immediately before use and given in a volume of 0.5 mL per 100 g body weight (rat) for po or sc administration or 0.1 mL per 10 g body weight (mouse) for po administration. Control animals received saline instead of the active agent.

Statistical analysis

Data are presented as the mean ± SE for 4-6 animals per group. Statistical analyses were performed using a two-tailed Dunnett's multiple comparison test, and values of $P < 0.05$ were regarded as significant.

RESULTS

Effect of Lafutidine and Capsaicin on HCl/Ethanol-Induced Gastric Lesions in Rats

Oral administration of HCl/ethanol (60% in 150 mmol/L HCl) produced multiple lesions in the glandular mucosa, along the long axis of the rat stomach. These lesions were dose-dependently prevented by prior administration of lafutidine (1-10 mg/kg, po). A significant effect was observed even at 1 mg/kg and the inhibition was 36.8% (Figure 1A). Likewise, pretreatment of the animals with capsaicin (1-10 mg/kg, po) also provided dose-dependent protection against HCl/ethanol-induced gastric lesions and a significant effect was observed at 3 mg/kg or greater (Figure 1B). The ED_{50} of lafutidine and capsaicin was 1.4 mg/kg and 3.1 mg/kg, respectively. The protective effects of both lafutidine (10 mg/kg) and capsaicin (10 mg/kg)

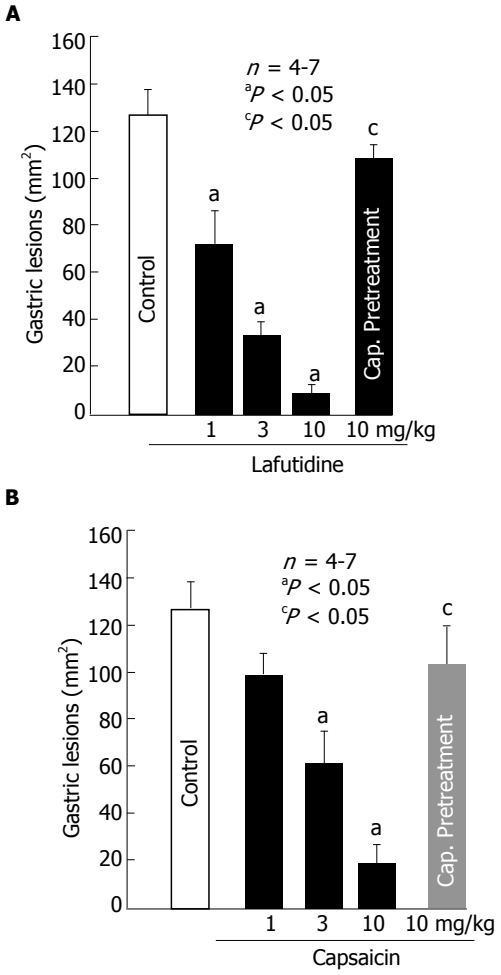

Figure 1 Effects of lafutidine (**A**) and capsaicin (**B**) on HCl/ethanol-induced gastric lesions in rats. The animals were given 1 mL of HCl/ethanol (60% ethanol in 150 mmol/L HCl) po and killed 1 h later. Lafutidine (1-10 mg/kg) and capsaicin (1-10 mg/kg) were administered po 30 min before HCl/ethanol. Ablation of capsaicin-sensitive afferent neurons was achieved by consecutive s.c. injections of capsaicin (total dose of 100 mg/kg) once daily for 3 d 2 wk before the experiment. Data are presented as the mean ± SE from 4-7 rats. $^aP < 0.05$, $^cP < 0.05$ *vs* control.

were almost totally reversed by chemical ablation of capsaicin-sensitive afferent neurons following capsaicin pretreatment (Figures 1 A and 1B). Sensory deafferentation by itself did not significantly affect the development of gastric lesions in response to HCl/ethanol (data not shown).

Effect of Capsazepine, L-NAME and Indomethacin on the Gastroprotection Afforded by Lafutidine and Capsaicin

Oral administration of lafutidine or capsaicin at 10 mg/kg provided a marked protection against HCl/ethanol-induced gastric lesions in rats. The protective effect of capsaicin was significantly negated by pretreatment with capsazepine (12.5 mg/kg, po), and the degree of protection afforded by capsaicin was 19.7%, which is significantly less than that (85.4%) observed in the vehicle-treated normal rats (Figure 2). Likewise, pretreatment of the animals with indomethacin (5 mg/kg, sc) also significantly abrogated the protective action of capsaicin (Figure 3). Although capsaicin afforded significant protection against HCl/ethanol-induced gastric lesions, even in the presence

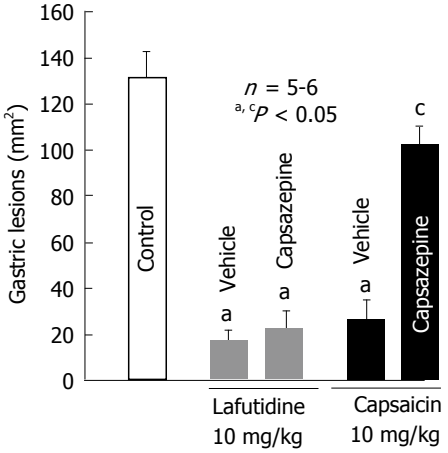

Figure 2 Effect of capsazepine on the protective action of lafutidine or capsaicin against HCl/ethanol-induced gastric lesions in rats. The animals were given 1 mL of HCl/ethanol (60% ethanol in 150 mmol/L HCl) po and killed 1 h later. Lafutidine or capsaicin was given po 30 min before HCl/ethanol. Capsazepine (12.5 mg/kg) was administered po 30 min before lafutidine or capsaicin. Data are presented as the mean ± SE from 4-7 rats. $^aP < 0.05$ *vs* control, $^cP < 0.05$ *vs* vehicle.

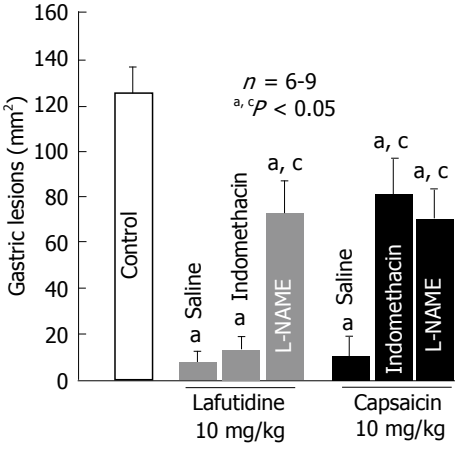

Figure 3 Effects of indomethacin and L-NAME on the protective action of lafutidine or capsaicin against HCl/ethanol-induced gastric lesions in rats. The animals were given 1 mL of HCl/ ethanol (60% ethanol in 150 mmol/L HCl) po and killed 1 h later. Lafutidine (10 mg/kg) or capsaicin (10 mg/kg) was given po 30 min before HCl/ethanol. Indomethacin (5 mg/kg) or L-NAME (20 mg/kg) was administered sc 1 h before HCl/ethanol. Data are presented as the mean ± SE from 6-9 rats. $^aP < 0.05$ *vs* control, $^cP < 0.05$ *vs* saline.

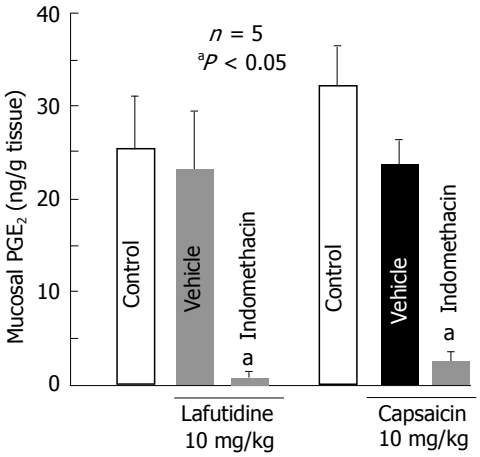

Figure 4 Effects of lafutidine and capsaicin on mucosal PGE_2 contents in rat stomachs. The animals were given lafutidine (10 mg/kg) or capsaicin (10 mg/kg) po and killed 1 h later. Indomethacin (5 mg/kg) was administered sc 30 min before capsaicin or lafutidine. Gastric mucosal PGE_2 content was determined by EIA. Data are presented as the mean ± SE from 5 rats. $^aP < 0.05$ *vs* control.

of indomethacin, the degree of protection was decreased to 31.9%, which is much less than that (89.7%) observed in the saline control group. By contrast, neither capsazepine nor indomethacin significantly affected the protective action of lafutidine against HCl/ethanol-induced gastric lesions (Figures 2 and 3). Lafutidine had a potent protective effect in the absence or presence of indomethacin and the degree of protection was 91.6% or 85.7%, respectively. On the other hand, the protective action of capsaicin as well as lafutidine was curtailed by prior administration of L-NAME (20 mg/kg, sc), the inhibitor of NO production. The degree of protection was 41.7% and 38.7%, respectively, and both values were significantly less than those observed in the absence of L-NAME.

Effect of Lafutidine and Capsaicin on PGE_2 Content in Rat Stomachs

Oral administration of capsaicin (10 mg/kg) did not significantly affect the mucosal PGE_2 content determined at 0.5 h after the administration (Figure 4). Likewise, the mucosal PGE_2 content was not significantly altered by the po administration of lafutidine at 10 mg/kg. Prior administration of indomethacin (5 mg/kg, sc) markedly reduced the PGE_2 content in the presence of capsaicin or lafutidine and the inhibition was 84.7% or 94.2%, respectively.

Effect of Lafutidine and Capsaicin on HCl/Ethanol-Induced Gastric Lesions in Mice

It was found that lafutidine, unlike capsaicin, provided gastric protection against HCl/ethanol-induced damage in rats, even in the presence of indomethacin. In addition, we previously found that endogenous PGs modulate the protective action of capsaicin through the activation of IP receptors[12]. To further investigate the involvement of IP receptors in the gastro-protection afforded by lafutidine, we examined the effect of this agent on ethanol-induced gastric lesions in both wild-type and IP receptor knockout mice, in comparison with that of capsaicin.

Intragastric administration of HCl/ethanol (0.3 mL) caused hemorrhagic lesions in the stomach of wild-type mice and the lesion area was 34.1 ± 4.9 mm² (Figure 5). HCl/ethanol produced gastric lesions in IP-receptor knockout animals, similar to wild-type mice, and the severity of these lesions did not differ between two groups. Similar to the findings in rats, the severity of these lesions in wild-type mice was significantly reduced by prior administration of capsaicin (10 mg/kg, po) and the inhibition was 82.3%. Likewise, intragastric lafutidine (3 and 10 mg/kg) significantly reduced the severity of these lesions in wild-type animals in a dose-dependent manner and the degree of protection was 68.2% and 79.8%, respectively.

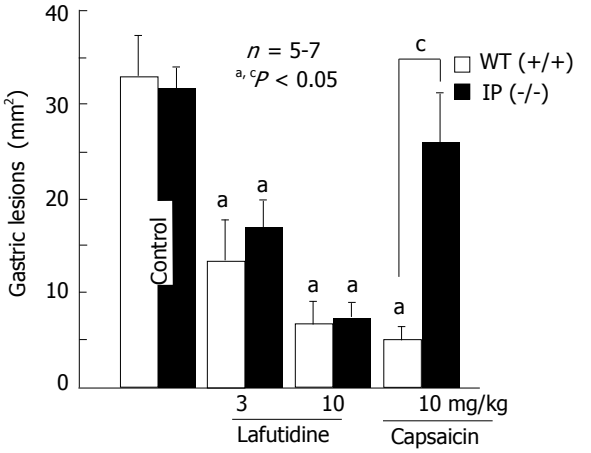

Figure 5 Effects of lafutidine and capsaicin on HCl/ethanol-induced gastric lesions in wild-type and IP-receptor knockout mice. The animals were given 1 mL of HCl/ethanol (60% ethanol in 150 mmol/L HCl) po and killed 1 h later. Lafutidine (10-30 mg/kg) or capsaicin (10 mg/kg) was given po 30 min before HCl/ethanol. Data are presented as the mean ± SE from 5-7 rats. $^aP < 0.05$ *vs* control.

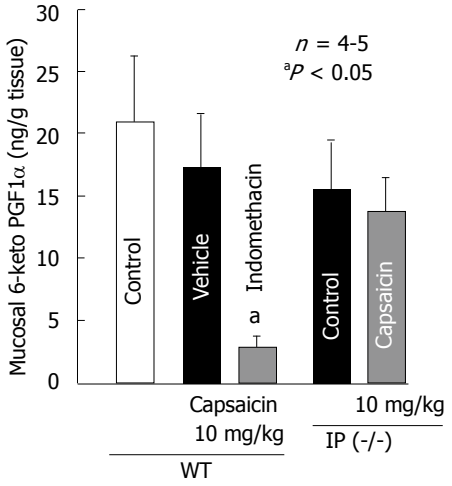

Figure 6 Effects of lafutidine and capsaicin on gastric mucosal 6-keto-$PGF_{1\alpha}$ levels in mice. The animals were given capsaicin (10 mg/kg) po and killed 1 h later. Indomethacin (5 mg/kg) was administered sc 30 min before capsaicin. Gastric mucosal 6-keto-$PGF_{1\alpha}$ levels were determined by EIA. Data are presented as the mean ± SE from 4-5 rats. $^aP < 0.05$ *vs* control.

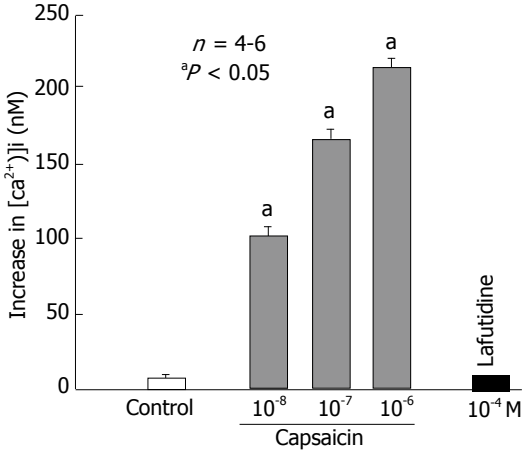

Figure 7 Changes in the intracellular concentration of Ca^{2+} in response to capsaicin and lafutidine in HEK293 cells transfected with VR1. Rat VR1 was introduced into HEK293 cells. Capsaicin (10^{-8}-10^{-6} mol/L) or lafutidine (10^{-4} mol/L) was added to the medium. Data are presented as the mean ± SE from 3 experiments. $^aP < 0.05$ *vs* control.

This agent protected the stomach of IP receptor knockout mice against HCl/ethanol as effective as observed in wild-type animals. However, the capsaicin did not afford significant protection in the animals lacking IP receptors and the degree of protection was 21.4%, which is significantly less than that (82.3%) observed in wild-type mice.

Effect of Capsaicin on 6-keto $PGF_{1\alpha}$ Content in Mouse Stomach

Since the protective action of capsaicin was not observed in IP-receptor knockout mice, we measured the effect of capsaicin on gastric 6-keto $PGF_{1\alpha}$ production in both wild-type and IP-knockout mice. Oral administration of capsaicin (10 mg/kg) did not significantly affect 6-keto $PGF_{1\alpha}$ content, same as the effect on PGE_2 content in rat stomachs (Figure 6). Indomethacin (5 mg/kg, sc) markedly decreased 6-keto $PGF_{1\alpha}$ content in the presence of capsaicin and the reduction was 84.1%. Similarly, capsaicin had no effect on 6-keto $PGF_{1\alpha}$ production in IP-receptor knockout mice.

Effect of Lafutidine and Capsaicin on the Ca^{2+} Concentration in Rat VR1-Transfected HEK239 Cells

To investigate the interaction of lafutidine with VR1 receptors, we examined the effect of lafutidine on the concentration of Ca^{2+} in rat VR1-transfected HEK239 cells. Addition of capsaicin (10^{-8}-10^{-6} mol/L) evoked a dose-dependent and significant increase in $[Ca^{2+}]i$ in the HEK239 cells (Figure 7). By contrast, lafutidine even at 10^{-4} mol/L did not effect the $[Ca^{2+}]i$.

DISCUSSION

Lafutidine, a histamine H_2 receptor antagonist, has been shown to afford protection in the gastrointestinal tract, partly through capsaicin-sensitive afferent neurons[16]. However, the precise mechanism of this action, including the dependence on endogenous PGs and the interaction with TRPV1, remains unknown. The present study confirmed that lafutidine protected the stomach from HCl/ethanol-induced injury through the activation of capsaicin-sensitive afferent neurons, similar to capsaicin. furthermore, we demonstrated that the action mode of these two agents differs in terms of dependency on PGs and interaction with TRPV1. It is assumed that lafutidine interacts with capsaicin-sensitive afferent neurons at yet unidentified sites other than TRPV1.

Lafutidine, an antiulcer drug developed in Japan[13], has been shown to have a potent antisecretory effect due to a blockage of histamine H_2 receptors and mucosal protective action in the gastrointestinal tract including the esophagus, stomach, small intestine and large intestine[14-16,22,23]. The latter effect is independent of the antisecretory action and mediated by capsaicin-sensitive afferent neurons[14,15,22,23], because the effect was not mimicked by cimetidine, another H_2-receptor antagonist, and was significantly abro-

gated by chemical ablation of the afferent neurons. In the present study, we also confirmed that the development of gastric lesions in response to HCl/ethanol was dose-dependently prevented by prior administration of lafutidine, and this effect was totally attenuated by sensory defunctionalization following pretreatment with a large dose of capsaicin. It is known that stimulation of capsaicin-sensitive afferent neurons releases calcitonin gene-related peptide (CGRP), and the action of CGRP is in part mediated by endogenous nitric oxide (NO)[3]. Indeed, several studies showed that the gastro-protective action of capsaicin, a selective stimulant of these afferent neurons, is attenuated by the NO synthase inhibitor L-NAME as well as the CGRP antagonist $CGRP_{8-37}$[16,24]. Onodera *et al*[16] reported that the protective effect of lafutidine on ethanol-induced gastric lesions was also significantly mitigated by prior administration of CGRP or L-NAME, suggesting the involvement of both CGRP and NO in the protective action. We previously reported that the protective effect of lafutidine on indomethacin-induced small intestinal lesions was abrogated by pretreatment with L-NAME as well as sensory deafferentation[15,25]. The present study also showed that pretreatment of the animals with L-NAME significantly attenuated the protective action of both capsaicin and lafutidine against HCl/ethanol-induced gastric lesions.

Interestingly, the presence of endogenous PGs is required for the expression of various capsaicin-induced actions in the stomach, including the mucosal protection, the increase in mucosal blood flow, and the stimulation of bicarbonate secretion[5,26,27]. Indeed, the gastro-protective effect of capsaicin was curtailed when animals were pretreated with indomethacin to inhibit PG production[5,28]. We confirmed in this study that the protective effect of capsaicin on HCl/ethanol-induced gastric lesions was significantly mitigated in the presence of indomethacin, confirming the involvement of endogenous PGs in this action. Consistent with our previous study[12], we observed that capsaicin failed to exhibit gastro-protective action in prostacyclin IP receptor knockout mice, suggesting a modulator role for IP receptors in the facilitation by endogenous PGs of gastric protection mediated by capsaicin-sensitive afferent neurons. Recently, it has been shown that endogenous phosphatidylinositol-4, 5-bisphosphate ($PtdIns(4,5)P_2$) inhibits TRPV1, and the repression can be alleviated by agents that activate phospholipase C (PLC)[29,30]. Bradykinin potentiates the activation of TRPV1 by capsaicin through the hydrolysis of $PtdIns(4,5)P_2$ in a PLC-dependent manner[30]. Thus, PGs might sensitize the afferent neurons to capsaicin through IP receptors, by somehow releasing TRPV1 from $PtdIns(4,5)P_2$-mediated inhibition. However, as shown in the present study, lafutidine exhibited a gastro-protective action against HCl/ethanol-induced damage in indomethacin-pretreated rats as well as in IP receptor knockout mice, as effective as in the respective control animals, strongly suggesting that the effect is independent of endogenous PGs. It is known that mucosal acidification increases HCO_3^- secretion in the stomach, and this response was attenuated by indomethacin [31]. We previously reported that lafutidine restored the response to capsaicin even in the presence of indomethacin [21]. It is thus assumed that lafutidine somehow plays a supportive role in the mechanism of action mediated by capsaicin-sensitive afferent neurons, similar to endogenous PGs.

The peptidergic afferent innervation of the stomach has been demonstrated in various species of animals including the rat [32]. Many studies including ours have shown that lafutidine affords gastric protection through capsaicin-sensitive sensory neurons, similar to capsaicin. However, it remains unknown how lafutidine interacts with these neurons. It is known that capsaicin stimulates the afferent neurons through the activation of TRPV1, resulting in the liberation of CGRP, the predominant neurotransmitter of spinal afferents in the rat stomach, and by so doing exerts a gastro-protective action [33]. This idea was supported by the present finding that the protective effect of capsaicin was totally inhibited by capsazepine, an antagonist of TRPV1. It is possible that lafutidine also interacts with TRPV1 to facilitate the activity of afferent neurons, similar to capsaicin. Nishihara *et al*[34], however, reported that lafutidine alone did not cause a release of CGRP from the stomach but enhanced the release induced by a submaximal dose of capsaicin. They also showed that lafutidine had no effect on the specific binding of [^{3}H]-resiniferatoxin to TRPV1[34]. These results suggest that although lafutidine modulates the activity of capsaicin-sensitive afferent nerves, this effect is not brought about through interaction with TRPV1. We also observed that lafutidine had no effect by itself on $[Ca^{2+}]i$ in rat VR1-transfected HEK 239 cells, although capsaicin produced a dose-dependent increase in $[Ca^{2+}]i$ in these cells. Thus, it is unlikely that lafutidine modulates the activity of capsaicin-sensitive afferent neurons through interaction with TRPV1. As observed in the present study, the TRPV1 antagonist capsazepine did not significantly influence the protective effect of lafutidine, confirming that this agent does not interact with TRPV1.

As mentioned above, it was concluded that although lafutidine exhibits gastroprotective action mediated by capsaicin-sensitive neurons, similar to capsaicin, the mode of its effect differs regarding the dependency on PGs/IP receptors or TRPV1. It is assumed that lafutidine interacts with capsaicin-sensitive afferent neurons at unidentified sites other than TRPV1 and mimics the effect of endogenous PGs to modulate the activity of the afferent neurons. The exact mechanism by which lafutidine interacts with capsaicin-sensitive afferent neurons awaits further study.

ACKNOWLEDGEMENTS

We thank Professor Shu Narumiya, Kyoto University Faculty of medicine for kindly supplying IP receptor-knockout mice.

Abstract

AIM: To determine whether gastric and enteric *Helicobacter* species are associated with pancreatic cancer.

METHODS: Patients with exocrine pancreatic cancer (n = 40), neuroendocrine cancer (n = 14), multiple endocrine neoplasia type 1 (n = 8), and chronic pancreatitis (n = 5) were studied. Other benign pancreatic diseases (n = 10) and specimens of normal pancreas (n = 7) were included as controls. Pancreatic tissue specimens were analyzed by *Helicobacter*-specific PCR-assay and products were characterized by denaturing gradient electrophoresis and DNA-sequencing. From a subset of the pancreatic cancer patients, gastric and/or duodenal tissue as well as gallbladder and ductus choledochus tissue were analyzed. Gallbladder and choledochus samples were included as controls. Stomach and duodenum samples were investigated to analyze whether a gastric *helicobacter* might disseminate to the pancreas in pancreatic cancer patients. Pancreatic specimens were analyzed by *Bacteroides*-specific PCR for detecting the translocation of indigenous gut microbes to the diseased pancreas.

RESULTS: *Helicobacter* DNA was detected in pancreas (tumor and/or surrounding tissue) of 75% of patients with exocrine cancer, 57% of patients with neuroendocrine cancer, 38% of patients with multiple endocrine neoplasia, and 60% of patients with chronic pancreatitis. All samples from other benign pancreatic diseases and normal pancreas were negative. Thirty-three percent of the patients were *helicobacter*-positive in gastroduodenal specimens. Surprisingly, *H. bilis* was identified in 60% of the positive gastroduodenal samples. All gallbladder and ductus choledochus specimens were negative for *helicobacter*. *Bacteroides* PCR-assay was negative for all pancreatic samples.

CONCLUSION: *Helicobacter* DNA commonly detected in pancreatic cancer suggests a possible role of the emerging pathogens in the development of chronic pancreatitis and pancreatic cancer.

INTRODUCTION

Pancreatic carcinoma, an extremely aggressive cancer with very poor prognosis, is one of the leading causes of cancer-related death in the Western world[1]. Consistently reported risk factors are age and cigarette smoking[1], whereas approximately 5% of pancreatic cancers seem to be primarily related to genetic traits[2]. Some early case control and data register studies suggested that chronic pancreatitis is a risk factor for pancreatic cancer[3, 4], which has been confirmed recently in prospective studies of chronic pancreatitis[5, 6]. *Helicobacter pylori (H pylori)*, the prototype species of the genus *Helicobacter*, which colonizes the stomach mucosa and causes acute and chronic gastritis as well as peptic ulcer disease, is a major predisposing factor for gastric cancer in human beings[7]. Other *Helicobacter* and *Campylobacter* species, including bile tolerant enteric *Helicobacter* species, colonize the intestine and hepatobiliary tract of many mammals and birds. *Helicobacter hepaticus* is the type organism of the enteric *Helicobacter* species and induces chronic active hepatitis, liver fibrosis, hepatocellular carcinoma, as well as inflammatory bowel disease in susceptible inbred strains of mice[8, 9]. Enteric *Helicobacter* species such as *H. pullorum*, *H. canis* and *H. cinaedi*, are associated with hepatitis in poultry, dogs, and macaques,

respectively, as well as gastroenteritis and bacteremia in human beings[9]. *H pylori* and the enteric species *H. bilis*, as well as *H pylori*-like *H.* species 'liver', are associated with biliary tract cancer, some chronic liver diseases as well as hepatocellular carcinoma in humans[10-14]. Two serology-based case-control studies have shown an association between *H pylori* and pancreatic cancer[15, 16], suggesting a possible relationship between *helicobacter* infections and pancreatic cancer development, which is supported by a recent study of *Helicobacter* species in a small number of patients with pancreatic exocrine cancer[17].

The purpose of the present investigation was to analyze the prevalence of gastric and enteric *Helicobacter* species DNA in samples from pancreatic cancer and chronic pancreatitis. Specimens from some benign pancreatic diseases (cysts or adenoma) as well as normal pancreatic tissue from patients with colon or choledochus cancer were included as controls. Translocation of some enteric bacteria to a diseased pancreas was analyzed by *Bacteroides* genus-specific PCR assay on pancreatic tissue.

MATERIALS AND METHODS

Patients

All patients were operated on at the Department of Surgery, Lund University Hospital. Formalin-fixed paraffin-embedded pancreatic tissue samples from 84 patients were obtained from the Department of Pathology at the same hospital. Prior to deembedding, one pathologist (U.S) reviewed all samples and approximately 100 mg of each tissue type was taken from the paraffin blocks with the tip of a scalpel. By carefully comparing the blocks with the slides, it was ascertained that a pure tissue type, i.e. tumor or normal etc, was obtained.

The tissue samples were from consecutive patients with primary exocrine cancer, predominantly of ductal type (PC) (n = 40, 20 females, mean age 59 years, range 44-77 years), neuroendocrine cancer (NE) (n = 14, 6 females, mean age 58 years, range 15-84 years), and multiple endocrine neoplasia type 1 (MEN) (n = 8, 1 female, mean age 52 years, range 42-69 years). In addition to a tumor specimen available from all 62 PC-, NE- and MEN patients, a sample of adjacent normal tissue was obtained from 41 patients (66%). Atrophic pancreatic tissue was available from 13 of the PC patients. Thus, 116 pancreatic tissue samples (1.9 samples per patient in average) were analyzed. Samples from patients with chronic pancreatitis (CP) of alcoholic, idiopathic, and epithelioid cell granulomatosis etiology (n = 5, 1 female, mean age 52 years, range 42-79 years), were also examined.

Pancreatic tissue specimens from patients with benign (other than pancreatitis) pancreatic diseases (n = *10*, 8 females, mean age 55 years, range 24-71 years) such as mucinous cystadenoma (n = 5), serous cystadenoma (n = 3), pancreatic cysts (n = 2), as well as histologically normal pancreatic tissue samples from patients with cancer of ductus choledochus (n = 4, 1 female, mean age 65 years, range 55-75 years), colon (male, mean age 60 years), duodenum (male, mean age 64 years), and retroperitoneal fibrosis (male, mean age 57 years), were included as controls (collectively denoted C). Gastric tissue samples of the antrum and/or fundus, as well as duodenal samples, were obtained from 23 PC patients and four NE- and MEN patients. An average of 2.5 stomach and/or duodenum specimens was tested per patient. Specimens of the gallbladder (n = 18) and ductus choledochus (n = 8) were also obtained from PC-, NE- and MEN patients. This study was approved by the Research Ethics Committee at Lund University (LU 726-02).

Bacterial strains

Bacterial strains were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA) and the Culture Collection of the University of Gothenburg (CCUG, Gothenburg, Sweden). Genomic DNA of *Bacteroides fragilis* (ATCC 25285), *H pylori* (CCUG 17874), *H. bilis* (CCUG 38995), *H. pullorum* (CCUG 33840), *H.* sp. flexispira (CCUG 23435), *H. hepaticus* (CCUG 33637), *Escherichia coli* (ATCC 25922), *Campylobacter jejuni* (ATCC 33560), *Clostridium difficile* (ATCC 9689), *Proteus mirabilis* (ATCC 43071), *Klebsiella pneumoniae* (ATCC 10031), *Enterococcus faecalis* (ATCC 29212) and *Enterobacter cloacae* (CCUG 6323) was extracted from 10^7 bacterial cells by the QIAamp® DNA Mini Kit (Qiagen) as described below.

Preparation of DNA

Paraffin-embedded tissue samples were heated at 60 ℃ for 10 min to melt excess paraffin, aseptically transferred to new micro-centrifuge tubes, washed in xylene for 2 × 5 min, rehydrated through graded ethanol (990 mL/L and 950 mL/L for 2 × 5 min and 700 mL/L for 5 min), and finally washed for 5 min in double-distilled water. Subsequently, the samples were homogenized in 170 mmol/L phosphate-buffered saline pH 7.2 by using a plastic micro-centrifuge tube-adapted pestle. Pancreatic tissue samples were homogenized at 10 g/L and other gastrointestinal specimens at 40-50 g/L. DNA was extracted from 100 μL of each homogenate by the QIAamp® DNA Mini Kit Tissue protocol (Qiagen, Hilden, Germany) according to the manufacturer's instructions. All DNA samples were stored at -20 ℃.

Helicobacter genus-specific PCR

DNA-extracts were amplified in a GeneAmp 2700 Thermocycler (Applied Biosystems, Foster City, CA, US) by semi-nested PCR-assay for *Helicobacter* species as previously described[18] with primers constructed by Goto *et al*[19]. The forward primer 1F (5´-CTATGACGGGTATCCGGC-3´) and reverse primer 1R (5´-CTCACGACACGAGCTGAC-3´) were used in the first step. In the second step, primer 1F and reverse primer 2R (5´-TCGCCTTCGCAATGAGTATT-3´) were used. Precautions were taken to minimize the risk of PCR cross contamination as described recently[20]. Detection of PCR-products was done in agarose gels as described previously[18].

Bacteroides genus-specific PCR

To rule out the non-specific translocation of a common gut microbe to the pancreas among the studied patients, a pancreatic tissue sample (n = 84) from each patient was amplified

by nested PCR with primers for the glutamine synthase gene of *Bacteroides* species. Primers BFR-1 (5´-ACTCTTTGTATC CCGACGATT-3´) and BFR-2 (5´-GAGGTTGATGCCT-GTATCGGT-3´), described by Kane *et al*[21], were used. For the second step, internal primers (forward primer BFR-3: 5´-GACAAAAACATCACCCGGGT-3´ and reverse primer BFR-4: 5´-GCCCAGCTTGTGACACTCTATT-3´), based on the sequence of the BFR1-BFR2 PCR-product, were constructed using the Vector NTI® Suite version 8.0 (Informax, Frederick, MD, US). The specificity of the *Bacteroides* species PCR-assay was evaluated using strains from the ATCC and CCUG. PCR-mixtures were prepared as described previously[18]. Amplification conditions for the first step were at 94 ℃ for 4 min; 30 cycles at 94 ℃ for 30 s, at 60 ℃ for 30 s, at 72 ℃ for 45 s and finally at 72 ℃ for 5 min. Conditions for the second step were at 94 ℃ for 10 min; 35 cycles at 94 ℃ for 30 s, at 60 ℃ for 30 s, at 72 ℃ for 30 s and finally at 72 ℃ for 5 min. Genomic DNA (0.1 ng) of *B fragilis* was used as a positive control.

Denaturing gradient gel electrophoresis

Denaturing gradient gel electrophoresis (DGGE) analysis of the V6-7 region of *Helicobacter* species 16S rDNA was performed as described previously[18]. Diluted (10×) first step PCR-products were amplified in the second step using forward primer GC-1F (5´-GCGGCCGCCCGTCCC-GCCGCCCCCGCCCCGCCGCGGCCGCCTAT-GACGGGTATCCGGC-3´) and 2R as described above. Electrophoresis was carried out using a *DCode*™ electrophoresis unit (BioRad, Hercules, CA, US). A mixture of amplicons of type strain DNA of *H pylori* (CCUG 17874), *H. bilis* (CCUG 38995), *H. pullorum* (CCUG 33840), *H.* sp. flexispira (CCUG 23435), and *H. hepaticus* (CCUG 33637) was used as gel migration markers.

DNA-sequence analysis

Nucleic acid products of the *Helicobacter* genus-specific PCR-assay were purified from agarose gels using the Montage DNA Gel Extraction Kit (Millipore, Bedford, MA, US), or from DGGE-gels as described previously[18]. DNA-sequence reactions were performed using the ABI PRISM™ dRhodamine Terminator Cycle Sequencing Ready Reaction Kit version 3.0 (Applied Biosystems) with modifications. One microliter of a BigDye™ mix and 1.5 μL of sequencing buffer (10 μL of 10× PCR-buffer II, 6 μL 25 mmol/L $MgCl_2$, 4 μL double-distilled water) were prepared in a total volume of 10 μL with primers (1F or 2R) and template according to the manufacturer's instructions. Products of the sequence reaction were aligned and the closest homologous DNA was identified by BLASTn-analysis as described elsewhere[17].

RESULTS

Helicobacter PCR of pancreas

As a rule, two pancreatic specimens were obtained from each patient in the PC-, NE- and MEN-groups. If at least one specimen was positive, the patient was considered *Helicobacter*-positive. Hence, 75% (tumor and/or surrounding tissue) of the PC-, 57% of the NE-, and 38% of the MEN patients were positive for the genus *Helicobacter* (Table 1). Three (one alcoholic, one idiopathic and one with epithelioid cell granulomatosis) of five patients with chronic pancreatitis were *Helicobacter*-positive. All benign tissue samples from cystadenoma- and pancreas cyst patients, as well as pancreatic tissue from the remaining C-patients, were negative for the genus *Helicobacter* (Table 1).

Table 1 ***Helicobacter*** **genus-specific 16S ribosomal DNA PCR-assay (positive/total)**

Patient group	*n*	Pancreas	Stomach/ duodenum	Gallbladder	Ductus choledochus
PC	40	30/40	7/23	0/12	0/6
NE	14	8/14	1/2	0/4	0/1
MEN	8	3/8	1/2	0/2	0/1
CP	5	3/5	_	–	–
C	17	0/17	–	–	–

PC: pancreatic exocrine cancer; NE: neuroendocrine cancer; MEN: multiple endocrine neoplasia type 1; CP: chronic pancreatitis; C: cysts, cystadenoma and remaining controls.

Table 2 ***Helicobacter*** **genus-specific PCR in tumors and surrounding tissue**

Patient group	Tumor (*n* = 62)	Atrophic (*n* = 13)		Normal (*n* = 41)	
		+	–	+	–
PC	+ (*n* = 19)	4	3	1	10
	– (*n* = 21)	5	1	7	4
NE	+ (*n* = 8)	–	–	1	5
	– (*n* = 6)	–	–	0	5
MEN	+ (*n* = 3)	–	–	0	3
	– (*n* = 5)	–	–	0	5

PC: pancreatic exocrine cancer; NE: neuroendocrine cancer; MEN: multiple endocrine neoplasia type 1.

Helicobacter DNA was detected in 48% of tumors of PC patients (11 PC patients were PCR-negative in the tumor but positive in surrounding normal or atrophic tissue, hence, a higher number of PC patients [75%] compared with that of PC tumor patients [48%] were *Helicobacter*-positive), 57% of neuroendocrine tumors, and 38% of MEN tumors (Table 2). Atrophic and normal pancreatic tissues of the PC patients were positive in 69% and 36% of the samples, respectively, whereas only 5% of normal pancreatic tissues surrounding NE and MEN tumors were *helicobacter*-positive (Table 2). Commonly, if a PC patient was positive for *Helicobacter* species in a tumor sample, normal tissue was often negative and vice versa. Positive atrophic tissue was common in both tumor-negative and positive samples (Table 2).

Helicobacter PCR in the stomach, duodenum, gallbladder and ductus choledochus

Stomach and/or duodenum samples demonstrated a *Helicobacter*-positive result in 33% of the patients (Table 1). Of the 40 PC patients, stomach and/or duodenum was obtained from 23. Among these 23 patients, 30% were positive in the stomach and/or duodenum whereas 74% were positive in the pancreas. Four PC patients and one

Helicobacter species	Pancreatic tissue				Gastric or duodenal samples
	Normal[1]	Atrophic[2]	Tumor[3]	CP[4]	
H pylori	7	6	12	2	2
H bilis					6
H hepaticus				2	
H sp. flexispira			7		
H cineadi			2		

[1] Tissue adjacent to tumor; [2] Atrophic tissue (PC only); or [3] Tumor from PC-, NE- and MEN patients; [4]Chronic pancreatitis.

NE patient were simultaneously positive both in the pancreas and in a gastric and/or duodenal specimen (Figure 1). All gallbladder as well as ductus choledochus tissue samples were negative in the *Helicobacter* genus-specific PCR (Table 1).

Bacteroides genus-specific PCR

The expected 600-bp product was amplified with genomic DNA of *B. fragilis* as a template in the first step of the assay. However, after nested analysis, the expected fragment of 228-bp was also produced with *E. cloacae* DNA. Extracted genomic DNA of the other tested reference strains was negative. A pancreatic sample from each patient (n = 84), including tumor-, benign-, and normal tissue, was analyzed. None of the samples showed positive amplification for the genus *Bacteroides* in the nested PCR-assay.

DGGE- and DNA sequence analysis

Forty-six *Helicobacter* 16S ribosomal DNA PCR-products were identified by DGGE, and 20 of those were subjected to DNA-sequence analysis. DGGE revealed four migration profiles, similar to the reference strains of *H pylori*, *H.* sp. flexispira, *H. bilis* and *H. hepaticus* (Figure 1). The two methods were in concordance except for two PCR-products migrating with *H.* sp. flexispira in DGGE analysis but with the highest similarity to *H. cinaedi* after sequence- and BLASTn analysis. Twenty-seven (of 29) identified *H pylori*-sequences were amplified from pancreatic tissue samples. Sequences of *H.* sp. flexispira (n = 7) and *H. cinaedi* (n = 2) were only detectable in pancreatic tumor specimens (Table 3). Seven (of 23) PC patients were *helicobacter*-positive in gastric and/or duodenal samples, but only one of them was identified as *H pylori*. Eight PCR-products related to enteric *Helicobacter* spp. (*H. bilis*, n = 6; *H. hepaticus*, n = 2) were identified in gastric and duodenal specimens from 7 pancreatic cancer patients (*H. bilis* was detected in the stomach as well as duodenum in one PC patient) (Table 3). Five patients (four with PC and one with NE) were simultaneously *Helicobacter* DNA-positive in the pancreas and the stomach and/or duodenum. Four patients had different species in the different tissues, whereas one duodenal sample of a MEN-patient with *H pylori* DNA in the pancreas demonstrated both *H. pylori* and *H. hepaticus* in the DGGE analysis (Figure 1, patient no. 7). Agarose- and DGGE gel images as well as the result of DNA-sequencing of pancreatic as well as gastric and/or duodenal samples of 7 patients are shown in Figure 1.

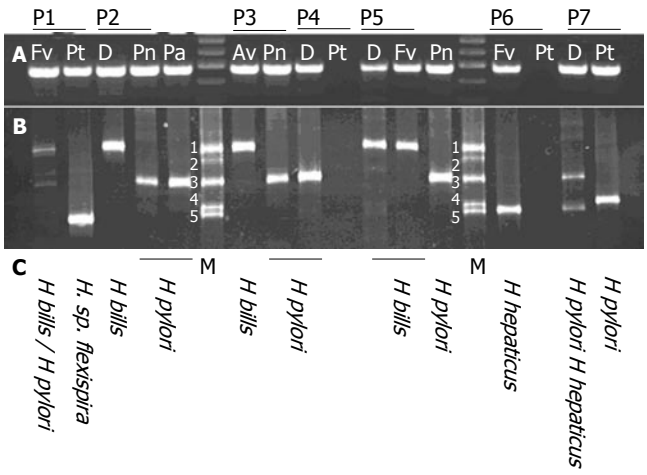

Figure 1 Agarose gel electrophoresis (**A**), DGGE (**B**), and the outcome of a public database comparison of *Helicobacter* 16S ribosomal DNA PCR-product sequences (**C**). From 7 pancreatic cancer patients (P), amplicons from the duodenum (D), fundus ventriculi (Fv), and antrum ventriculi (Av) were compared to amplicons from normal (Pn), atrophic (Pa) and pancreatic tumor (Pt) tissues. Migration markers (M) were (from top to bottom) amplified from DNA of H. bilis (1), *H. pullorum* (2), *H pylori* (3), *H. sp. flexispira* (4) and *H. hepaticus* (5).

DISCUSSION

We analyzed the prevalence of *Helicobacter* species ribosomal DNA by PCR in paraffin-embedded pancreatic and gastroduodenal samples from patients with pancreatic cancer and tissues of benign pancreatic diseases as well as controls of normal pancreas (from choledochus and colon cancer patients). *Helicobacter* species DNA was identified in the pancreas of 75% of the PC patients, 57% of the NE patients, 38% of the MEN patients, and 60% of the patients with chronic pancreatitis. Other benign pancreatic diseases and the normal pancreas controls were all *helicobacter*-negative (Table 1). Detection of *Helicobacter* species in pancreas is thus related to patients suffering from pancreatic cancer and chronic pancreatitis. Serological studies have previously demonstrated an association between serum antibodies to *H pylori* and pancreatic cancer[15, 16]. Moreover, *H pylori* increases the severity of tissue inflammation and production of proinflammatory cytokines in a rat model of ischemia/reperfusion-induced pancreatitis[22].

The distribution of *Helicobacter* ribosomal DNA in tumor and normal tissue of pancreatic cancer patients was also studied. *Helicobacter* species was commonly detected in tumors (48% of PC, 57% of NE, and 38% of MEN). The prevalence of *helicobacter* was much lower in the normal pancreas surrounding NE and MEN (5%) than surrounding PC (36%) (Table 2). There are at least two possible explanations. One is that *helicobacter* bacteria and/or *helicobacter* DNA may be taken up and retained by the diseased tissues such as tumors, the other is that *helicobacter* cells and/or cell debris in pancreas may be implicated in the genesis of PC and are therefore also found in the non-tumor pancreas, while in NE and MEN *helicobacters* may be an epiphenomenon and are thus uncommon in the non-tumor pancreas. Similar to the findings in normal tissues surrounding tumors in PC patients compared with NE and MEN, we have previously detected *Helicobacter* species in liver tissue

surrounding primary liver carcinoma but not colorectal liver metastases[23]. Hence, a possible participation of *Helicobacter* species in the genesis of exocrine pancreatic and liver carcinoma has to be further explored. Moreover, PCR detection of *H pylori* in the liver is associated with cirrhosis in hepatitis C patients with or without hepatocellular carcinoma[24], in analogy to *H pylori*-associated tissue inflammation in chronic atrophic gastritis progressing to gastric cancer[7, 25].

A majority of the PCR-products from pancreatic cancer samples are related to 16S ribosomal DNA sequences of *H pylori* previously identified in gallbladder tissue samples[26], and to *H.* sp. ´liver´, a putative subspecies of *H pylori* with liver tropism, detected in hepatocellular carcinoma[10], supporting the hypothesis of a *H pylori* subpopulation with hepatobiliary tropism[27]. We also identified *H. cinaedi* and *H.* sp. flexispira taxon 8 in some exocrine pancreatic cancer samples (Table 3). These species with a broad mammal host-range have been isolated from patients with bacteremia and gastroenteritis[28].

A low prevalence of *H pylori* DNA was found in gastric and duodenal samples from the patients in this study (Table 3). At least half of the adult human population is infected with *H pylori*[7], but only 14% of the PCR-products from the stomach of patients with exocrine pancreatic cancer could be identified as *H pylori*. However, *H. bilis* has been identified in 60% of *helicobacter*-positive gastroduodenal specimens. *H. bilis* is associated with chronic hepatitis and chronic enteric inflammation in susceptible laboratory mouse strains[28] and has been recently identified in both diseased human gallbladder and bile by PCR-based methods[12]. To our knowledge, *H. bilis* has not previously been detected in tissue samples of the human stomach and small intestine. The reason why the detection rate of *H pylori* is low in the stomach and duodenum of PC patients remains obscure. This may partly be explained by the fact that most or all patients were given metronidazole preoperatively.

We analyzed stomach and duodenum tissue specimens from pancreatic cancer patients to detect whether gastric *Helicobacter* species, such as *H pylori*, may disseminate to the pancreas in pancreatic cancer patients. However, DNA of different *Helicobacter* species in the pancreas compared with gastroduodenal tissue was identified in patients who were *Helicobacter*-positive both in the stomach and pancreas (Figure 1). Moreover, many pancreas-positive PC patients were negative in stomach samples and vice versa, not supporting migration of *helicobacter* microorganisms colonizing the stomach to the pancreas in the studied PC patients.

B. fragilis constitutes a part of the indigenous microflora of the human gut, predominantly of the colon. A nested PCR-assay for the genus *Bacteroides* was designed to study whether a major constituent of the normal microflora of the lower bowel could translocate to a diseased pancreas. None of the pancreatic tissue specimens was positive for *Bacteroides* spp., suggesting that bacterial translocation from the bowel to pancreas does not frequently occur in patients with cancer or a benign pancreas disease. However, the indigenous microflora may more easily be washed off tissues during sample preparations such as paraffin deembedding. Putative pathogens, such as some *Helicobacter* species, might be more closely associated with the gut mucosa.

Chronic inflammation is a characteristic feature of gastric-, colon- and hepatobiliary tract cancers[29]. Bacterial cell-wall peptidoglycan and lipopolysaccharide can stimulate the human innate immunity and induce inflammation. Bacterial DNA, so called CpG motifs, has been shown to activate macrophages, neutrophils as well as cell migration and to induce B cell activation and hyper-IgM production in patients with primary biliary cirrhosis[30, 31]. Proinflammatory cytokines, reactive oxygen species and other inflammatory mediators are associated with a chronic *Helicobacter*-induced tissue inflammation[25]. Such factors probably increase genomic DNA damage and cell proliferation as well as inactivate tumor-suppressor genes, events also associated with malignant transformation of pancreatic cells[1, 6, 32]. Tumor-associated chronic inflammation[29] may be induced and maintained by bacteria or bacterial cell debris, originating from *helicobacter* and/or other microbial species.

In conclusion, 16S ribosomal DNA of gastric *H pylori* and some enteric *Helicobacter* species is commonly detectable in tissue samples from patients with pancreatic cancer but not from controls. To further explore a possible role of gastric and enterohepatic *Helicobacter* species in pancreatic malignancy, more studies of pancreatic cancer and the emerging *Helicobacter* genus and related organisms are needed.

Abstract

AIM: To evaluate serum TIMP-1 level and the correlation between TIMP-1 expression and liver fibrosis in immune-induced and CCL_4-induced liver fibrosis models in rats.

METHODS: Immune-induced and CCL_4-induced liver fibrosis models were established by dexamethasone (0.01 mg) and CCL_4 respectively. Serum TIMP-1 level was detected with ELISA, while histopathological grade of liver biopsy was evaluated. Spearman rank-correlation test was used to analyse the difference of the correlation between the TIMP-1 expression and hepatic fibrosis in the two fibrosis models. Furthermore, *in situ* hybridization was used to determine the expression difference of TIMP-1 mRNA in the two models.

RESULTS: Positive correlation existed between serum TIMP-1 level of immune induced group and the histopathological stages of fibrosis liver of corresponding rats (Spearman rank-correlation test, $r_s = 0.812$, $P < 0.05$), and the positive *in situ* hybridization signal of TIMP-1 mRNA was strong. In CCL_4-induced liver fibrosis model, the correlation between the serum TIMP-1 level and the severity of hepatic fibrosis was not statistically significant(Spearman rank-correlation test, $r_s = 0.229$, $P > 0.05$). And compared with immune-induced model, the positive *in situ* hybridization signal of TIMP-1 mRNA was weaker, while the expression variation was higher in hepatic fibrosis of the same severity.

CONCLUSION: The correlations between TIMP-1 expression and liver fibrosis in two rat liver fibrosis models are different. In immune-induced model, serum TIMP-1 level could reflect the severity of liver fibrosis, while in CCL_4-induced model, the correlation between the serum TIMP-1 level and the severity of hepatic fibrosis was not statistically significant.

INTRODUCTION

Hepatic fibrosis is a pathological process with the net deposition of extracellular matrix (ECM) proteins. The change of ECM is mainly regulated by matrix metalloproteinases (MMPs), which are a family of proteolytic enzymes that are capable of degrading the ECM[1-3]. The activity of MMPs is tightly regulated by the amount of active protein and the concentration of specific inhibitors, called tissue inhibitors of metalloproteinases (TIMPs)[4,5]. Extensive studies have identified that TIMPs play a key role in the progression of fibrosis. TIMP-1 is the first discovered tissue inhibitor of TIMPs in liver which can inhibit most interstitial collagenases and MMP-9. Murawaki *et al* revealed that serum level of TIMP-1 could reflect the change of liver TIMP-1 in patients with chronic liver disease and liver TIMP-1 concentration increases with progression of the liver disease[6-9]. So, TIMP-1 has been considered as a useful diagnostic index of hepatic fibrosis[10-12]. Our previous studies[13-15] also concentrated on the establishment of the new hepatic fibrosis diagnostic index. Interestingly, in animal experiments we found the expression of TIMP-1 in liver tissue has remarkable difference in different rat liver fibrosis models[13,14]. In the present experiment, the serum TIMP-1 level of experimental rats of liver fibrosis model was detected with ELISA and association with histopathological grading of fibrosis liver was analyzed. Furthermore, *in situ* hybridization was used to analyze the expression difference of TIMP-1 mRNA between the two models.

MATERIALS AND METHODS

Animals

One hundred and twenty adult female Wistar rats (provided by Experimental Animal Center of Fourth Military Medical University, Xi'an, China) weighing 150-180 g, fed with common stuff and water, were employed in the study (Approval for this project was obtained from the Institutional Review Board at Fourth Military Medical University). Immune-induced rat liver fibrosis model was established according to the method of Wang *et al*[16]. Dexamethasone (0.01 mg) was injected into the rats through coccygeal vein in one hour after the first and second injection of human serum albumin (HAS). For CCL_4 group, 55 rats were injected with 400 mL/L CCL_4 in peanut oil subcutaneously at a dose of 3 mL/kg twice (Monday and Thursday) weekly, totally 10 wk[17]. Ten normal rats were served as control group.

Specimen preparation

From the first Sunday in the process of model induction (for immune induced group, from the first coccygeal vein injection of HSA), 5 rats from each group were selected randomly on Sunday, until all rats were involved. Rats taken out from immune induced group on the first Sunday were numbered IW1A to IW1E (Immune-induced rat liver fibrosis model wk 1st A-E), while the rats from CCL_4 induced group were numbered CW1A to CW1E (CCL_4-induced rat liver fibrosis model wk 1st A-E). All rats were immediately sacrificed under narcosis after taken out. Following decapitation 2 mL blood was collected from each rat. Liver was quickly excised, and rinsed in ice-cold saline. Ten rats in control group were treated in the same way after 10 wks' feeding. Blood specimen was centrifuged, and the serum was obtained, and stored at -70℃. Livers were cut into 1 mm × 1 mm × 1 mm blocks. Part of it was fixed in 40 g/L formaldehyde, and part was fixed in 25 g/L glutaraldehyde. All liver specimens were stored at -70℃. Specimens were treated all together after collected.

Pathologic observation and histopathological grading of fibrotic liver tissue

Liver sections were processed together for routine hematoxylin-eosin (HE) stain. Pathological diagnosis of each liver specimen was assessed and graded from 0 to VI by three pathologists in a blinded manner (fibrotic stage was determined when more than two pathologists reached the same diagnosis; if inconsistent results were reached among the three pathologists, the fourth determined the final diagnosis) according to the criteria described by Wang *et al*[18] (Table 1).

ELISA detection of serum TIMP-1

Enzyme-linked immunosorbent assay (ELISA) was used to evaluate the serum TIMP-2 level[19,20]. Mouse TIMP-2 monoclonal antibody was purchased from American Maxim Company (MAB-0283) and test was performed according to the protocol described previously[21]. The absorbance of serum TIMP-2 was determined at 450 nm with an ELISA reader (EL × 800, Bio-Tek Instruments. Inc, USA).

Table 1 Scoring system assessing the degree of fibrosis

Degree of fibrosis	Score
No fibrosis	0
Slight fibrosis expanding to some portal areas and central veins	I
Marked fibrosis expansion, but without portal to portal bridging	II
Fibrosis expanding to most portal areas with occasional portal to portal bridging	III
Pseudolobules formed and partly replacing the normal architecture of the liver lobules	IV
Occasional pseudolobules formed (incomplete cirrhosis)	V
Congested with pseudolobules, and between pseudolobules wide hyperplastic collagen fiber existed (complete cirrhosis)	VI

In situ hybridization of TIMP-1 mRNA in tissue of fibrosis liver

Paraffin sections were hybridized with digoxingenin-labelled cRNA probes as described by Wang *et al*[22]. The cRNA probe for TIMP-1 and the *in situ* hybridization kit were purchased from Boshide Biological Technology Limited Company, Wuhan, China (No MK1549). Expression of TIMP-2 mRNA was assessed quantitatively by image pattern analysis with gray scale scanning. Control was performed with normal liver tissue.

Specimen preparation for transmission electron microscopy

Specimens were routinely prepared for transmission electron microscopy (TEM) observation and examined under a JEOL JEM-100CXII electron microscope.

Statistical analysis

Spearman rank-correlation test, LSD-*t* and Student's *t* test were used to analyze the results. $P < 0.05$ was taken as significant.

RESULTS

Comparison of histopathology between immune induced and CCL_4 induced liver fibrosis groups

Distinct difference of histopathological changes presented between the liver fibrosis of immune group and CCL_4 group. The liver fibrosis in immune group rat was characterized by portal fibrosis with marked ductular proliferation extending to fibrous septa (Figure 1A, specimen from IW10E). Pseudolobules formed and partly replaced the normal architecture of the liver lobules, but the fibrotic septum was small and sparse. In CCL_4 group, prominent fatty degeneration and necrosis were found and the normal architecture of the liver lobules was markedly destroyed, most of which were replaced by pseudolobules (Figure 1B, specimen from CW10A). Compared with immune induced group, fibrotic septum in CCL_4 group was wide and compact.

Histopathological grading

All rats in immune induced group survived the experiment. In tissue specimens of IW1A-E, only slight hepatocyte swelling could be observed, whereas no obvious damage

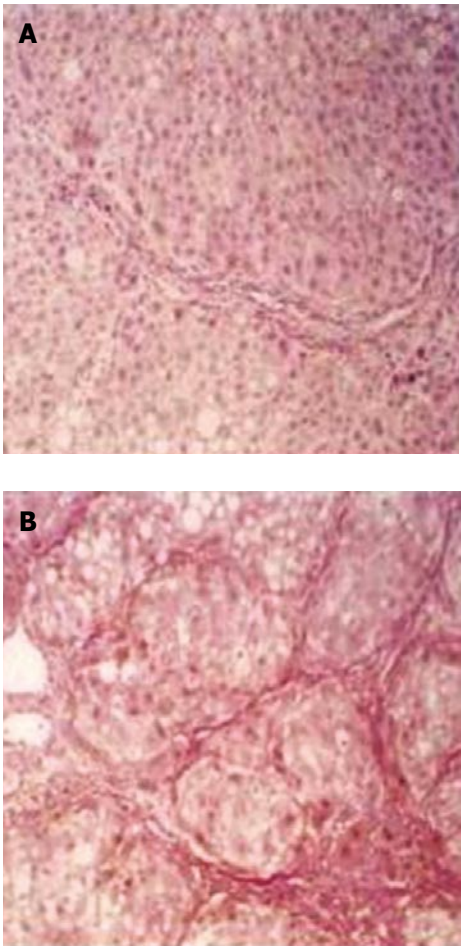

Figure 1 Light microscope observation of rat liver fibrosis (HE ×100). **A**: immune-induced liver fibrosis; **B**: CCl_4-induced liver fibrosis.

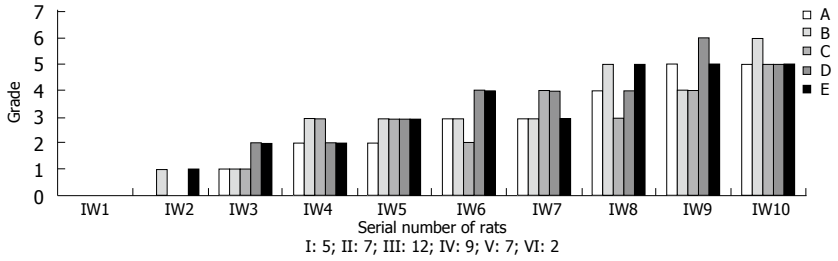

Figure 2 Histopathological grade of fibrosis of immune induced group.

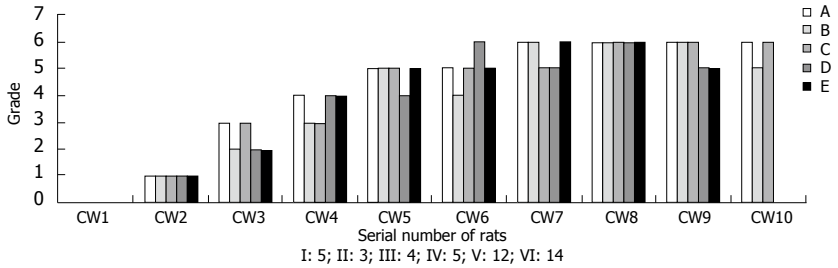

Figure 3 Histopathological grade of fibrosis of CCL_4 induced group.

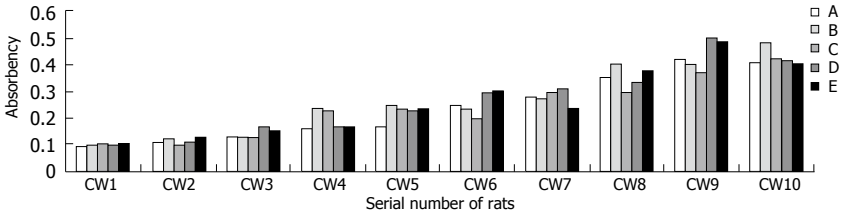

Figure 4 ELISA results of serum TIMP-1 of immune induced group.

presented. Histopathological stages of the five specimens were all determined to be stage 0. Among the specimens of IW2-5, obvious hyperplasia of connective tissues could be detected, but most of the histopathological stages were not above III. Among rats of immune induced group taken out after fifth week, with induction time extending, more livers were determined to be stage IV and V fibrosis. However, specimens determined to be stage VI were few (Only two fibrosis liver specimens of rats taken out at tenth week were determined to be stage VI) (Figure 2). Seven rats in CCL_4 induced group died in the process of experiment (5 rats died before wk 5 and 2 died at wk 7), which livers were immediately excised and frozen at -70℃. Histopathological observation of the died rats showed severe liver damages existed in the liver such as inflammation, necrosis, excessive collagen deposition and inflammatory cells infiltration, *etc*. Obvious damage already existed in the liver tissue of the five rats of CW1, but no fiber hyperplasia presented. Histopathological stages were stage 0 according to the criteria described above. Specimens of CW2 presented obvious hepatocyte degeneration and necrosis, and vacuole degeneration and inflammatory cell infiltration also could be observed, but fiber hyperplasia was not predominant. The histopathological stages were determined to be stage I. From wk 3, normal architecture of the liver was rather lost, replaced with volumes of connective tissue. Hereafter, with the passage of time, fibrotic separations increased between the portal areas or between the portal area and the central vein, leading to the increasing formation of pseudolobules, and histopathologically stage IV or V was determined. In most of the rats taken out after wk 7, liver tissues were congested with pseudolobules and between the pseudolobules large numbers of collagens deposited, which were classified as classic stage VI (Figure 3).

ELISA reading of serum TIMP-1

In theory, reading (absorbency) of ELISA reader correlates with serum TIMP-1 level, which could properly reflect the quantity of serum TIMP-1[23,24].

Results of serum TIMP-1 level of immune induced group and CCL_4 induced group are presented in Figures 4 and 5 respectively. Data of control group accorded with normal distribution (mean = 0.105, 95% percentile = 0.137).

Positive correlation existed between serum TIMP-1 level of immune induced group and the histopathological stages of fibrosis liver of corresponding rats (Spearman rank-correlation test, $r_s = 0.812$, $P < 0.05$), indicating serum TIMP-1 level could be considered as an index reflecting the degree of liver fibrosis.

No clear correlation between the serum TIMP-1 level

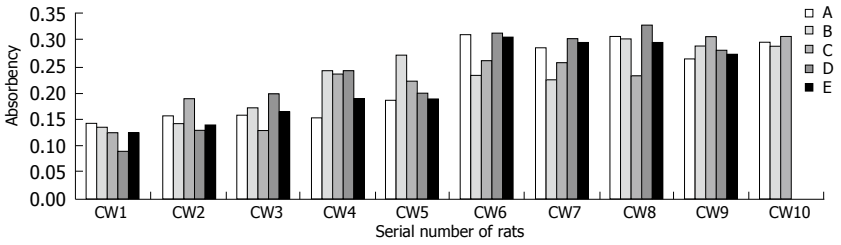

Figure 5 ELISA results of serum TIMP-1 of CCl_4 group.

Table 2 Results of image pattern analysis of expression of TIMP-1 mRNA

Group	*n*	TIMP-1 mRNA
Immune group[a]	7	421.90 ± 19.00
CCL_4 group[c]	7	188.80 ± 62.80
Control group	10	52.75 ± 4.25

[a]$P < 0.05$ compared with CCL_4 group, $t = 9.398$; [c]$P < 0.05$ compared with control group, $t = 3.414$.

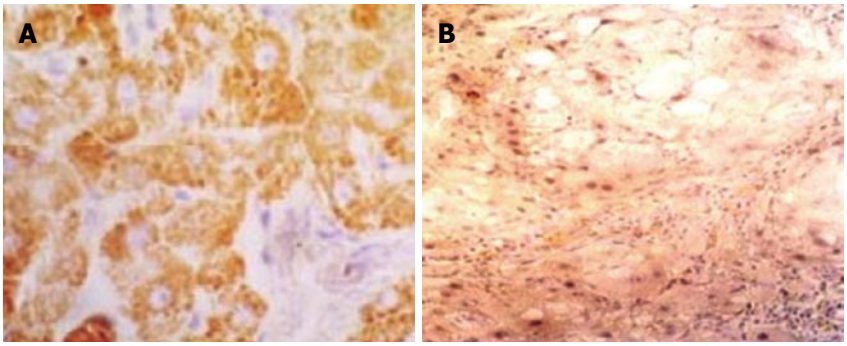

Figure 6 Expression of TIMP-1 mRNA in tissue of rat fibrosis liver. **A**: Immune-induced liver fibrosis (× 400); **B**: CCL_4-induced liver fibrosis (× 200).

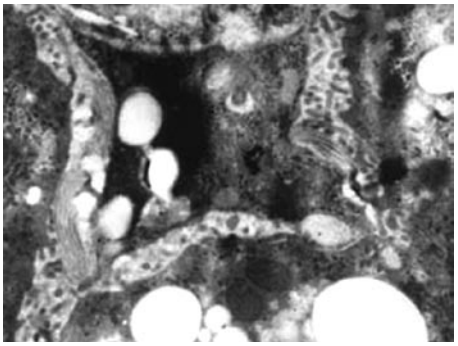

Figure 7 Activated HSC in immune induced rat liver fibrosis (× 10000).

of CCL_4 induced group and the histopathological stages of corresponding rats (Spearman rank-correlation test, $r_s = 0.229$, $P > 0.05$), indicating serum TIMP-1 level of CCL_4 group could not reflect the degree of liver fibrosis. Even so, the serum TIMP-1 level of CCL_4 group was obviously higher than that of control group (LSD-*t*, $P < 0.001$).

Expression of TIMP-1 mRNA in tissue of fibrosis liver

Seven specimens from immune group and CCL_4 group respectively, which were all determined as stage V histopathologically (for CCL_4 group, the seven specimens were randomly selected from the 12 stage V specimens), were used to compare the difference of TIMP-1 mRNA expression. Ten specimens of control group were detected at the same time. In the fibrosis liver of immune group, expression of TIMP-1 mRNA was detected in myofibroblasts, fibroblasts and vascular endothelial cells, especially predominant in the portal areas and fibrotic septum. The positive signals of TIMP-1 mRNA located in cytoplasm as brown particles, but not found in nucleus (Figure 6A). For CCL_4 group, myofibroblasts, fibroblasts in the portal area and vascular endothelial cells expressed TIMP-1 mRNA. However, compared with immune group, the signals were weaker (Figure 6B).

Image pattern analysis of *in situ* hybridization revealed that among immune, CCL_4 and control groups, expression of TIMP-1 mRNA of immune group was highest ($t = 9.398$, $P < 0.05$); while between CCL_4 group and control group, expression of TIMP-1 mRNA of CCL_4 group was obviously higher ($t = 3.414$, $P < 0.05$) (Table 2). The standard deviation of data of CCL_4 group was distinctly higher than immune group (62.80 > 19.00), indicating greater variation existed in the specimens of CCL_4 group even with the same histopathological stage.

Transmission electron microscope examinations

In liver fibrosis of immune group, large quantities of activated hepatic stellate cells (HSC) were detected. In the cytoplasm of activated HSCs, there were abundant rough endoplasmic reticulum, but fatty droplets were obviously decreased (Figure 7). Around the activated HSCs, in Disse space, between hepatocytes, and surrounding areas of bile duct, dense deposition of collagens could be found. Portal areas extended, where great number of myofibroblasts existed. In denatured hepatocytes, many swelling mitochondria and areas of fatty drops existed. For CCL_4 group, severe collagen deposition could be observed, but with fewer activated HSCs.

DISCUSSION

Hepatic fibrosis is a consequence of different chronic liver diseases caused by hepatitis viruses, drugs, alcohol, parasite, and autoimmune mechanism. Nowadays there are several kinds of animal model of liver fibrosis for the study of the mechanisms of liver fibrosis, among which CCL_4-induced rat liver fibrosis model and immune-induced rat liver fibrosis model were extensively investigated and applied[25]. Fibrosis caused by different pathogens has different pathogenesis processes. Therefore, not every fibrosis model is universally suitable. Which model should be applied in a given study is of great importance. But now, there is still no clear guideline for this.

Over the past 15 years, substantial progress has been made in understanding the role of TIMPs (TIMP-1 and TIMP-2) in the regulation of hepatic fibrosis. Hepatic

fibrosis is a pathological process with the net deposition of ECM proteins[26]. The change of ECM is mainly regulated by MMPs. MMPs are a family of proteolytic enzymes that are capable of degrading the ECM and the activity of MMPs is tightly regulated by the amount of active protein and the concentration of TIMPs[27]. It has been identified that TIMP-1 plays a predominant role in regulating fibrosis by inhibiting the activity of MMP-1, MMP-3, MMP-9, and TIMP-1 is far stronger than TIMP-2[28]. So, TIMP-1 has been considered as an important factor in the progression of liver fibrosis and the expression level could be used as a new index of fibrosis severity.

In our previous studies[13,14], we found that the expression of antigen and mRNA of TIMP-1 in liver tissue of CCL_4-induced fibrosis rat was weaker compared with immune-induced fibrosis. Although higher than normal rat liver, the expression of TIMP-1 of CCL_4-induced liver fibrosis was not consistent with the severity of hepatic fibrosis. In the current study, the fibrosis in CCL_4-induced rat liver fibrosis model developed fast and almost all the histopathological grading of the rats which survived the experiment in this group belonged to grade V, and VI. Fibrous tissue in the fibrosis liver of this model was presented as wide and compact fibrotic septum, and most of the normal architecture of the liver lobules were destroyed and replaced by pseudolobules. But, *in situ* hybridization and immunohistochemical staining showed mRNAs and antigens of TIMP-1 expressed weakly, not proportional to the severity of the fibrosis. While, in immune-induced rat liver fibrosis model, even the fibrotic septum were small and sparse and histopathological grading was lower, the expression of mRNAs and antigens of TIMP-1 was higher compared with CCL_4-induced rat liver fibrosis model. We used Spearman rank-correlation test to analyse the correlation between the serum levels of TIMP-1 and the histopathological stages of corresponding rat, and found that no clear correlation existed between the serum levels of TIMP-1 and the histopathological stages of corresponding CCL_4-induced rat. While, serum levels of TIMP-1 of immune-induced fibrosis liver could reflect the severity of liver fibrosis. In the process of experiment, we failed to detect clear pathologic progression in the inducing process of CCL_4, because the pathological changes developed very fast. We also analyzed the results of *in situ* hybridization of TIMP-1 mRNA in CCL_4-induced fibrosis liver, which indicates that even with same histopathological stage, the TIMP-1 mRNA expression varied greatly, which was distinct from immune-induced rat liver fibrosis.

Currently studies on fibrosis are mostly focused on chronic hepatitis caused by hepatitis virus infection, which is a chronic progressive process. Our study revealed that the fibrosis induced by CCL_4 progressed fast, and autopsies of the fibrosis livers presented hepatocyte vacuole degeneration and necrosis at the early period of CCL_4 induction, indicating the subsequent ECM deposition might be the recovery process, during which connective tissue replaced the damaged architecture. The nosogenesis of CCL_4 induced fibrosis may contribute to this change[29]. The hepatotoxicity of CCL_4 results from its metabolites, the free radicals CCL_3^-, which could damage the hepatocyte by causing lipid peroxidation and by binding covalently to cell structures, leading to flaky hepatocyte vacuolar degeneration and necrosis. This is of obvious difference from the known fibrosis mechanism of viral hepatitis (HBV and HCV), which has been considered as a consequence of immunologic injury caused by the virus infection.

The fibrosis of immune-induced rat model is caused by type III allergy (immune complex type)[30]. The severity of the fibrosis is not so much high as CCL_4-induced rat liver fibrosis, while the progression is similar to human viral hepatitis. Immune complex in serum exerts its hepatotoxicity through activating HSCs that can express TIMP-1, which enhances the deposition of ECM through inhibiting the activity of MMPs[31]. Under TEM, larger numbers of activated HSCs supported the above hypothesis.

In conclusion, the pathological changes of immune-induced rat liver fibrosis model is a gradual process and serum TIMP-1 level can reflect the severity of fibrosis. CCL_4-induced rat liver fibrosis model develops fast in comparison with immune-induced rat liver fibrosis model and no significant correlation exists between the serum TIMP-1 level and the severity of fibrosis, both indicating that the model is unsuitable for experimental observation. Taken together of the difference of the two models, we think immune-induced rat liver fibrosis model is more suitable for the study of human chronic viral hepatitis.

Abstract

AIM: To develop a method to isolate liver stem cells fast and efficiently.

METHODS: Fetal mouse liver cells were characterized by cell surface antigens (c-Kit and CD45/TER119) using flow cytometry. The candidate liver stem cells were sorted by using immuno-magnetic microbeads and identified by clone-forming culture, RT-PCR and immunofluorescence assays.

RESULTS: The c-Kit$^-$(CD45/TER119)$^-$ cell population with 97.9% of purity were purified by immuno-magnetic microbeads at one time. The yield of this separation was about 6% of the total sorting cells and the cell viability was above 98%. When cultured *in vitro* these cells had high clone-forming and self-renewing ability and expressed markers of hepatocytes and bile duct cells. Functionally mature hepatocytes were observed after 21 d of culture.

CONCLUSION: This method offers an excellent tool for the enrichment of liver stem cells with high purity and viability, which could be used for further studies. It is fast, efficient, simple and not expensive.

INTRODUCTION

Stem cell is a very small population of cells in various tissues. It is a self-renewing, typically multipotent progenitor with the broadest developmental potential in a particular tissue at a particular time[1,2]. Studies of stem cell have yielded much exciting insight into the field of life science and medicine including cancer, transplantation and proteomics.

Large-scale proteomic study of stem cell, such as two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) and mass spectrometry analysis, requires relatively large amounts of protein sample extracted from the cells[3]. For the low-abundance samples such as stem cells, the key to such study relies on the successful obtaining of enough amounts of stem cells with high purity. Two most commonly used methods, magnetic activated cell sorting (MACS) and high-speed fluorescence-activated cell sorting (FACS), have been employed to isolate and purify a special population of cells based on the cell surface markers. In the latter method, however, there are some disadvantages. For example, a high fluid pressure might damage the biological activity of the sorting cells; for rare cells such as stem cells, to isolate large amounts of them is also time-consuming[4].

The liver is the central organ of nutrient digestion and processing, where most of a person's metabolism occurs. Although liver regeneration is not dependent on a small group of progenitor or stem cells, which may appear in large numbers when mature hepatocytes are inhibited from proliferation[5], it is believed that in a growing liver both hepatocytes and cholangiocytes differentiate from a common progenitor, or liver stem cell[6]. To date, few liver stem cell-specific markers are available, and some are also shared by hematopoietic progenitors[7,8]. Recently, by using FACS liver stem cells have been isolated based on some non-specific cell surface markers (c-Kit, CD45, TER119, c-Met and Dlk) and identified[6,9-11]. In the study reported here, using immuno-magnetic microbeads, we sorted large amounts of candidate liver stem cells with high purity and identified them with self-renewing capability and multilineage differentiation potential.

MATERIALS AND METHODS

Mice and cells

Animal experiments involving mice were approved by the Institute's Animal Care and Use Committee. BALB/c mice were maintained under pathogen-free conditions. Day 0 of gestation was taken to be detection of a vaginal plug after overnight mating. Embryos were dissected and fetal liver cell suspensions were prepared by mechanical dissociation and then passed through a 30 μm nylon mesh to remove clumps.

FACS analysis and cell sorting

Dissociated liver cells were incubated at 4 ℃ for 10 min with biotinylated anti-CD45.2, TER119 monoclonal antibodies (mAbs) (eBioscience, San Diego, CA). After three washes with staining medium (PBS containing 3% FBS), cells were incubated with FITC-conjugated anti-c-Kit mAb (eBioscience), and streptavidin-labeled phycoerythrin (eBioscience) at 4 ℃ for 10 min. Finally, cells were washed three times and resuspended in staining medium. The labeled cells were analyzed and sorted with FACSAria (Becton Dickinson). The acquisition rate was set at 35 000 events per second. Gating was implemented based on negative control staining profiles.

Immuno-magnetic sorting

Dissociated fetal liver cells were first stained with biotinylated anti-CD45.2, TER119 and/or c-Kit mAbs at 4 ℃ for 10 min. Cells were washed twice with PBS containing 0.5% BSA and 2 mmol/L EDTA. Enrichment of target cells by magnetic microbeads was carried out according to the manufacturer's (Milteny Biotec, Bergisch Gladbach, Germany) protocol. Briefly, cells were resuspended in 80 μL of the same buffer per 10^7 total cells and incubated with anti-biotin microbeads for 15 min at 6-12 ℃. Cells were washed twice and finally resuspended in 500 μL of buffer per 10^7 total cells. A pre-moistened MS column was placed in the magnetic field of a suitable MACS separator. The cell suspension was applied onto the column and then washed three times. Effluents were collected as the negative fraction. Magnetically labeled cells as the positive fraction were collected by flushing the column with buffer after the column was placed outside of the magnetic field. The sorted cells were then incubated at 4 ℃ for 10 min with phycoerythrin-streptavidin and analyzed with FACSCalibur (Becton Dickinson).

Cell culture

Cell culture was performed as described previously with minor modifications[9,10]. Liver cell populations were plated onto 20 μg/mL laminin-coated (Gibco BRL, Gaithersburg, MD) 24-well plates or chamber slides at a density of 1000 cells/cm^2 and maintained at 37 ℃, with 50 mL/L CO_2 for 8-21 d. The medium was DMEM/F12 supplemented with 10% FCS, 2 mmol/L L-glutamine, 50 μmol/L 2-mercaptoethanol, 100 U/mL penicillin-streptomycin, 1 × nonessential amino acids (all from Gibco BRL), 1 μg/mL human insulin and 10^{-7} mol/L dexamethasone (Sigma-Aldrich, St. Louis, MO) renewed every 4 d. Mouse recombinant hepatocyte growth factor (40 ng/mL) and OSM (10 ng/mL) (R&D system, Minneapolis, MN) were added 24 h after culture initiation.

RT-PCR

Detection of hepatocyte or cholangiocyte marker gene expression by RT-PCR was conducted as described[12]. After treated with DNase I (Promega, Madison, WI), equal amounts of RNAs were reverse-transcribed and the cDNAs were amplified by the PCR with gene-specific primers at 94 ℃ for denaturing, 54 ℃ for annealing, and 72 ℃ for extension. β-actin mRNA was used as an internal control. Previous experiments determined 28 cycles to be optimal. The gene-specific intron-spanning primers used are as follows: α-fetoprotein (AFP, amplification of 821 bp), sense 5'-TCACACCCGCTTCCCTCATCCT-3', antisense 5'-CATCCTGCAGACACTCCAG-3'; albumin (ALB, amplification of 705 bp), sense 5'-AGAAGACACCCTGATTACTCT-3', antisense 5'-TCGAGAAGCAGGTGTCCTTGT-3'; cytokeratin 19 (CK19, amplification of 566 bp), sense 5'-GTCCTACAGATTGACAATGCTCG-3', antisense 5'-CTGATCACGCTCTGGATCTGTG-3'; β-actin, (amplification of 390 bp), sense 5'-GTCATCACTATTGGCAACGAGCG-3', antisense 5'-CTAGAAGCACTTGCGGTGCACG-3'. The amplified products were analyzed by electrophoresis on 1% agarose gels and stained with ethidium bromide.

Immunofluorescence assays

Cultured cells were washed with PBS and fixed and permeabilized with methanol/acetone (95:5) for 20 min at –20 ℃. They were then incubated with the primary Ab goat anti-mouse ALB (Bethyl, Montgomery, TX) and mouse anti-CK19 (DakoCytomation, Denmark) in a moist chamber for 16 h at 4 ℃. After washing in PBS, cells were incubated with Cy3-conjugated rabbit anti-goat IgG (Sigma) and FITC-conjugated bovine anti-mouse IgG (Santa Cruz Biotechnology, Santa Cruz, CA) for 3 h at 4 ℃. Nuclei were counterstained with 300 nmol/L DAPI in PBS for 5 min. After final washing, cells were observed using a laser scanning microscope.

Periodic acid-Schiff staining

Cultured cells were fixed in 4% phosphate-buffered paraformaldehyde and then oxidized in 1% periodic acid for 5 min, rinsed in dH_2O three times, treated with Schiff's reagent for 15 min, rinsed again in dH_2O, stained with Mayer's hematoxylin for 1 min, and finally rinsed in dH_2O.

RESULTS

Flow cytometric fractionation and sorting of fetal mouse liver cells

Embryo fetal liver contains lymphohematopoietic progenitors characterized by the CD45 and TER119 antigens. Double staining of embryonic day (ED) 12 fetal mouse liver cells with anti-(TER119 + CD45) mAb and anti-c-Kit (also CD117) mAb revealed four cell populations (Figure 1A). The Q3 c-Kit^-(CD45/TER119)$^-$ cell population, which had no obvious boundary but

Cells were stained as described in Figure 1A. **B**: Histograms for the immuno-magnetically sorted $(CD45/TER119)^-$ cells labeled with phycoerythrin-streptavidin (blue) and the total cell populations before sorting (white). **C**: FACS analysis of ED 13 mouse fetal liver cells stained with the biotinylated anti-c-Kit mAb. **D**: Analysis of the immuno-magnetically sorted $c\text{-}Kit^-$ cells labeled with phycoerythrin-streptavidin (blue). The histogram of Figure 2B is also shown (white).

continuous fluorescence distribution with the Q4 cell population, was considered to be liver stem cell or contain liver stem cell[9,10]. Flow cytometric sorting for Q3 cells revealed the purity of the sorted cells was 83.3% (Figure 1B). We observed that most of the non-$c\text{-}Kit^-$ $(CD45/TER119)^-$ cells were from Q4 cells near Q3 cell population.

Immuno-magnetic sorting of liver stem cells

ED 13 fetal mouse liver cells were analyzed in FACSCalibur (Figure 2A) and similar result was obtained to that shown in Figure 1A. The fraction of $(CD45/TER119)^-$ and $c\text{-}Kit^-$ cell population was 20% and 76.8%, respectively. Immuno-magnetic microbeads were used to separate these two cell populations. After double labeled with the biotinylated primary anti-mAb TER119 and CD45.2, which was then recognized by a monoclonal anti-biotin antibody coupled to microbeads, total fetal liver cells were applied onto the separation column in a magnetic field and only the unlabeled cells (negative fraction, both $TER119^-$ and $CD45^-$) were passed through. FACS analysis of the negative fraction revealed that more than 99% of the cells were $(TER119/CD45.2)^-$ (Figure 2B), indicating that the purity of the sorted cells was above 99%. To separate $c\text{-}Kit^-$ cell population from the liver cells, a biotinylated anti-c-Kit mAb was used. Total fetal liver cells stained with this mAb were first analyzed by FACS (Figure 2C) and the result was similar to that from FITC-labeled

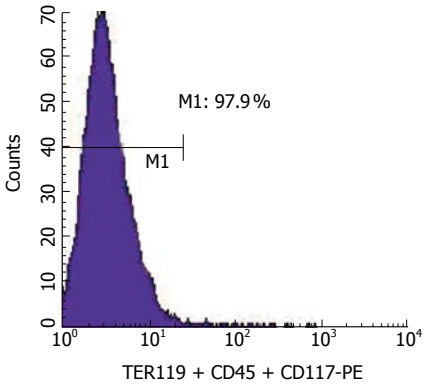

Figure 3 Analysis of the immuno-magnetically sorted c-Kit$^-$(CD45/TER119)$^-$ cells. After sorted, the negative fraction was stained with phycoerythrin-streptavidin and analyzed by FACS.

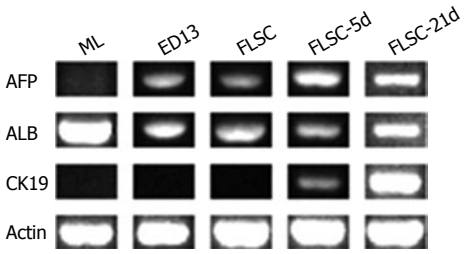

Figure 5 Hepato- and cholangiocyte- specific gene expressions of liver cells. The mRNA was prepared and RT-PCRs were performed for the genes displayed in the figure in each cell subset. β-actin (Actin) gene expression was used as controls for mRNA content per sample. A representative experiment for all the gene expressions of a total of three independent ones is shown. ML, mature mouse liver cells; ED13, ED 13 mouse fetal liver cells; FLSC, fetal liver stem cells [c-Kit$^-$(CD45/TER119)$^-$ cells]; FLSC-5d, FLSC cultured for 5 d; FLSC-21d, FLSC cultured for 21 d.

anti-c-Kit mAb (Figure 1A). Similar procedure using anti-biotin antibody coupled microbeads as described above was performed to sort c-Kit$^-$ cell population. Figure 2D shows the FACS analytical result of the negative fraction and it was revealed that more than 98% of the cells were c-Kit$^-$ cells.

Then we wondered whether these two separation procedures could be combined together and performed once to obtain the c-Kit$^-$(CD45/TER119)$^-$ cell population. Theoretically any unwanted cell that expressed either c-Kit or CD45/TER119 could be magnetically labeled and retained as a positive fraction on the separation column in a magnetic field and only the unlabeled cells, the c-Kit$^-$(CD45/TER119)$^-$ cells, could pass through. Our experiments indicated that this is feasible. After labeled with a cocktail of biotinylated antibodies (c-Kit, TER119 and CD45.2) and recognized by the anti-biotin microbeads, fetal liver cells were applied onto the separation column and the negative fraction was obtained. The purity of the c-Kit$^-$(CD45/TER119)$^-$ cells was 97.9% (Figure 3). The yield of this separation was about 6% of the total sorting cells. The cell viability was above 98% as measured by trypan blue dye exclusion.

Culture and identification of liver stem cells

To identify whether the immuno-magnetically separated c-Kit$^-$(CD45/TER119)$^-$ cells were liver stem cells, their capacity of colony-forming and multilineage differentiation was tested. After cultured *in vitro* for 4 d, obvious colonies (> 50 cells) were generated. Sorting for c-Kit$^-$(CD45/TER119)$^-$ cells (negative fraction) achieved more than 15-fold enrichment of colony-forming cells compared with total fetal liver cells, while the positive fraction of liver cell populations did not generate any colony (only three clones in 96 wells, probably due to c-Kit$^-$(CD45/TER119)$^-$ cell contaminants; data not shown). When we replated the cells from the formed clone onto new culture plates, several of these subcultured cells again formed colonies in 5 d (Figure 4).

Figure 4 *In vitro* subcolony formation from the sorted c-Kit$^-$(CD45/TER119)$^-$ cell. Culture of c-Kit$^-$(CD45/TER119)$^-$ cells was performed on laminin-coated 24-well plates for 4 d. Colonies were then digested and the cells from the formed clone were plated onto new culture plates and cultured for another 5 d. The picture shows a representative subcolony.

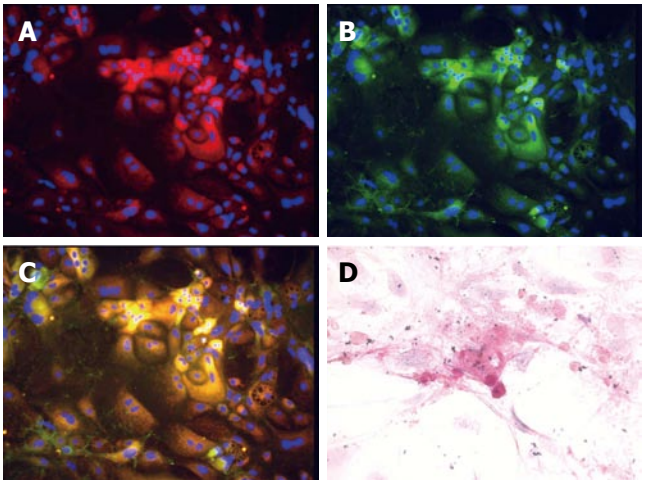

Figure 6 *In vitro* multilineage differentiation of ED 13 c-Kit$^-$(CD45/TER119)$^-$ fetal liver cells. The immunofluorescence pictures were obtained in 12-day cultures(**A** - **C**). Cells gave rise to albumin-positive hepatocytes (**A**, red) or cytokeratin 19-positive cholangiocytes (**B**, green). Also they gave rise to albumin and cytokeratin 19 double positive cells (yellow) and to double negative cells (**C**). The blue dots are DAPI nuclear signals. The original magnification was × 100. Intracellular glycogen was detected by periodic acid-Schiff staining(**D**). ED 13 c-Kit$^-$(CD45/TER119)$^-$ fetal liver cells gave rise to functionally mature hepatocytes, containing abundant glycogen stores, after 21 d of culture. The original magnification was × 400.

The hepatic differentiation of the cultured cells at d 5 and 21 was tested by their gene expression in RT-PCRs (*afp, alb* and *ck19* genes, Figure 5). AFP was expressed throughout the culture process. The expression of lineage markers *ALB* (for hepatocyte) and *CK19* (for cholangiocyte) was also detected. To verify the RT-PCR results, we stained colony-constituent cells at d 12 with

antibodies against albumin or cytokeratin 19. As shown in Figure 6, immunofluorescence revealed that most of cells expressed either albumin or cytokeratin 19 (Figures 6A and B). Two-color ALB/CK19 analysis revealed that ALB^+CK19^+ cells frequently accumulated in clusters, with hepatocytes and bile duct cells in peripheral segregated areas (Figure 6C). Periodic acid-Schiff staining showed that some cells had abundant glycogen stores at d 21 (Figure 6D), indicating functionally mature hepatocytes were generated. Taken together, these results suggest that the sorted $c\text{-}Kit^-(CD45/TER119)^-$ cells were capable of colony-forming and self-renewing and multilineage differentiation.

DISCUSSION

Separation of stem cells is typically done based on surface-marker expression. Previous studies showed that liver stem cells were enriched in the $c\text{-}Kit^-CD49f^+CD29^+CD45^-TER119^-$ fraction of mouse fetal liver cells by using flow cytometry and single cell-based assays[9] and were further enriched in the $c\text{-}Met^+CD49f^{+/low}c\text{-}Kit^-CD45^-TER119^-$ fraction[6]. Whereas oval cells, found in adult liver and marked for $c\text{-}Kit^+CD34^+Thy\text{-}1^+$, have been considered to be close descendants of these stem cells[6]. Similarly, about 10% of total ED 11 mouse fetal liver cells, marked for $c\text{-}Kit^{low}(CD45/TER119)^-$, showed in another study, was purified by FACS and considered to contain the earliest-described hepatic progenitors, also displaying features of liver stem cells[10]. Furthermore, a population of hepatoblasts in ED 14.5 fetal liver was isolated based on the expression of Dlk/Pref-1, a type I membrane protein. However, such Dlk^+ hepatoblasts represent more mature cells than $c\text{-}Met^+CD49f^{+/low}c\text{-}Kit^-CD45^-TER119^-$ cells[11]. Taken together the results of these studies, we concluded that liver stem cells could be enriched in the $c\text{-}Kit^-CD45^-TER119^-$ population. Our results presented in this report indicate that the $c\text{-}Kit^-CD45^-TER119^-$ population, purified by immuno-magnetic microbeads from ED 13 mouse fetal liver, was liver stem cells or enriched the liver stem cells significantly. As the markers for this population (c-kit and TER119/CD45) are all negative, it is easy to use magnetic microbeads to separate these cells at once.

As c-Met was considered to be the positive marker for liver stem cells, as described previously[6], it is also feasible to further separate the $c\text{-}Met^+$ population from the sorted $c\text{-}Kit^-(CD45/TER119)^-$ cells by positive selection using immuno-magnetic microbeads. Also since the liver stem cells have been pre-enriched in $c\text{-}Kit^-(CD45/TER119)^-$, using FACS to separate $c\text{-}Met^+$ cells could also be efficient.

There are several advantages of sorting liver stem cells using immuno-magnetic microbeads. First, this method is simple and inexpensive. Second, using this method, we can sort a total of 5×10^7 labeled fetal liver cells and obtain target cells with a high purity in 5 min, as compared with about 5 h by using an FACSAria cell sorter. As for proteomic analysis such as 2D-PAGE, 10^6-10^7 of cells with a high purity are needed, according to the dimension of the gel and staining method. Third, magnetically enriched populations help to reduce the prolonged exposure of liver stem cells to the high-pressure fluid environment in the flow cytometry, which might damage the biological activity of such a sensitive cell population. For biochemical and functional studies of stem cells, the total process relies on the viability of isolated cells which requires special attention during the cell isolation and purification procedures. In our experiments, the viability of the sorted liver stem cells by FACS was usually about 85%, as compared to above 98% by using immuno-magnetic microbeads. Fast and efficient acquisition of a large number of liver stem cells with high purity and viability is the basis for proteomic studies of liver stem cells.

In conclusion, the present study shows the application of immuno-magnetic microbeads for sorting and enrichment of liver stem cells from mouse fetal liver, by which the biological activity of the cells is kept. This method is fast, efficient, simple and not expensive.

Abstract

AIM: To explore the effect of recombinant human interleukin-11 (rhIL-11) on the expressions of interleukin-11 receptor α-chain (IL-11Rα) and an additional signal transducer glycoprotein 130 (gp130) in intestinal epithelium cell line-6 (IEC-6) after neutron irradiation.

METHODS: Cultured IEC-6 cells were exposed to 4.0Gy neutron and treated with 100 ng/mL rhIL-11 12 h prior to or immediately after irradiation. The apoptosis and necrosis rates and expressions of IL-11Rα and gp130 were observed by flow cytometry, immunohistochemistry, Western blot and image analysis.

RESULTS: The apoptosis rate of IEC-6 cells was increased by irradiation at 6 h ($P < 0.01$), IL-11 stimulation resulted in a decreased apoptosis rate in irradiated IEC-6 cells ($P < 0.05$). In normal control IEC-6 cells, intense immunoreactivity of IL-11Rα was located within the cell membrane and cytoplasm. The level of IL-11Rα expression significantly decreased at 6 h after irradiation ($P < 0.01$) and restored at 24 h after irradiation. In IEC-6 cells treated with both radiation and rhIL-11, the level of IL-11Rα expression was higher than that of irradiated cells ($P < 0.05$). When it came to gp130 protein, it was located in the cytoplasm of IEC-6 cells. After irradiation, we found a progressive decrease in the expression of gp130 protein ($P < 0.05$) in 48 h post-radiation, while in rhIL-11-stimulated cells, it came back to normal level at 24 h after irradiation and decreased at 48 h, but was still higher than that of only irradiated cells ($P < 0.05$).

CONCLUSION: rhIL-11 can protect IEC-6 cells from neutron irradiation. The protective effect of rhIL-11 might be connected with its ability to up-regulate the expressions of specific ligand-binding subunit IL-11Rα and signal-transducing subunit gp130.

INTRODUCTION

Intestine is highly sensitive to neutron irradiation. Once exposed to a given neutron irradiation dose, intestine is damaged severely and has become a severe limitation for patients on frequent radiotherapy for abdominal and pelvic malignancies.

Interleukin-11 (IL-11) is a member of a family of cytokines, including interleukin-6 (IL-6), leukemia inhibitory factor, oncostatin M, and ciliary neurotropic factor. IL-11-induced signaling is mediated by the formation of a hexameric receptor complex, composed of two molecules each of IL-11, IL-11Rα, and gp130[1]. Much attention has been paid to its actions on hematopoietic system[2,3]. Recently, IL-11 has been found to reduce intestinal epithelial injury due to a wide variety of causative incidents, including radiation and chemotherapy[4-11]. Yet the mechanisms of its irradiation protection are scarcely reported and no data on the action and mechanisms of IL-11 in the field of neutron irradiation are available.

In the present study, a model of normal rat intestinal epithelium cell line-6 (IEC-6) was established to observe the effect of recombinant interleukin-11 (rhIL-11) on the expressions of interleukin-11 receptor α-chain and gp130 in IEC-6 cells after neutron irradiation, which would be a base for further research of its effects on intestinal damage induced by irradiation and its mechanisms.

MATERIALS AND METHODS

Cell culture and rhIL-11 stimulation

IEC-6 cell line was kindly presented by Luo QL (Institute of Radiation Medicine, Academy of Military Medical Sciences, Beijing) and cultured in Dulbecco's modified Eagle' s medium (Sigma) supplemented with 10% fetal calf serum (FCS), 0.5% ciprofloxacin under standard tissue culture conditions (50 mL/L CO_2 at 37 ℃). The medium was changed every other day. Before treatment with rhIL-11 (Jiuyuan Genetics Co., Hangzhou), cells were incubated in medium containing 2.5% FCS for 24 h, and subsequently, 100 ng/mL rhIL-11 was administered 12 h prior to or immediately after irradiation. Thus cells in exponential growth period were randomly assigned to four groups: normal control cells, neutron irradiated cells, cells treated with rhIL-11 prior to irradiation (rhIL-11 pretreatment) and cells treated with rhIL-11 after irradiation (rhIL-11 post-treatment).

Neutron irradiation

Culture flasks containing IEC-6 cells were fixed on a tailor-made round plastic plate so that cells could rotate following the plate and absorb rays homogeneously when irradiated. The fission neutron reactor was provided by Institute of Nuclear and New Energy Technology, Tsinghua University. Cells were irradiated at a rate of 39.69cGy/min with a dose of 4.0Gy neutron ray absorbed.

Flow cytometry

Detection of apoptosis and necrosis was carried out according to the manufacturer's instructions (Biosea Biotechnology Co., Beijing). IEC-6 cells were detached from culture flasks with 2.5% trypsin (Sigma) to get monocyte suspension with a cell concentration of 5×10^5-1×10^6/mL, washed with ice-cold phosphate-buffered saline (PBS), centrifuged twice at 4000 r/min, and resuspended in 200 μL binding buffer. Then 10 μL Annexin-V-FITC and 5 μL propidium iodide (PI) were added for 15 min in the dark, and finally 300 μL binding buffer was added. The apoptosis and necrosis rates of the samples were analyzed by a FACS Calibr flow cytometer (BD Company, American).

Immunohistochemistry for IL-11Rα

IEC-6 cells were seeded onto glass tissue slides. Before staining, slides were fixed in a mixer with methanol and acetone (1:1) for 15 min at 4 ℃. After antigen repair with 0.25% trypsin, slides were incubated with rabbit anti- IL-11Rα mAb (1:80, Santa Cruz) for 1h at 37 ℃, then at 4 ℃ overnight, rinsed with PBS and incubated with biotinylated goat anti-rabbit IgG (1:200, Zhongshan Biotechnology Co., Beijing) for 50 min at 37 ℃. After rinsed three times with PBS, slides were treated with streptavidin-conjugated peroxidase (1:200, Zhongshan Biotechnology Co., Beijing) for 50 min at 37 ℃, incubated for 10-15 min in 3,3'-diaminobenzidine solution (Zhongshan Biotechnology Co., Beijing) at room temperature to allow color development and rinsed with distilled water to quench the reaction. Hematoxylin was used as a counterstain. PBS was used in stead of primary antibody as blank control.

Western blot for IL-11, IL-11Rα and gp130

Cells were washed sequentially twice with 1mL ice-cold PBS, centrifuged and resuspended in lysis buffer (1%SDS, 10 mmol/L EDTA, 50 mmol/L Tris-HCL, pH8.1, 1 mmol/L phenylmethylsulfonyl fluoride), sonicated on ice and centrifuged at 12 000 r/min for 15 min at 4 ℃. Protein concentration of the supernatant (protein fraction) was determined using a BCA protein assay reagent kit (Pierce). An aliquot of 25 μg of protein was mixed with an equivalent volume of 2× protein loading buffer containing 2-β-mercaptoethanol and boiled for 10 min before it was loaded onto SDS-polyacrylamide gel. After electrophoresis, proteins were transferred onto nitrocellulose membranes and blocked in PBS-T (0.1% Tween 20) containing 10% nonfat dry milk powder. Protein immunoblots were performed using specific antibodies to IL-11 (1:1000, Santa Cruz), IL-11Rα (1:800), gp130 (1:1000, Santa Cruz) and β-actin (1:1000, Santa Cruz). The membranes were further incubated with peroxidase-conjugated secondary antibodies (Zhongshan Biotechnology Co., Beijing), and protein bands were visualized using a commercial chemiluminescence detection kit (ECL Plus, Pierce) as described by the manufacturer. The prestained protein marker was from New England Biolabs Ltd, UK.

Image analysis and quantitation

The results of immunohistochemistry and Western blot were quantitated using a computer image analysis system (Beijing Aeronautic and Aerospace University) to assess the mean optical density (MOD) and the integral optical density (IOD) of the samples.

Statistical analysis

Data were expressed as mean ± SD. Results were analyzed by one-way ANOVA using SPSS 11.0 software. $P < 0.05$ was considered statistically significant.

RESULTS

Apoptosis and necrosis rates of IEC-6 cells

The apoptosis and necrosis rates of IEC-6 cells were increased significantly 6h after 4.0Gy neutron irradiation, while the apoptosis rate of IEC-6 cells treated with rhIL-11 pre- or post-radiation was much lower than that of only irradiated cells, but the necrosis rate remained unchanged (Figure 1).

Expression of IL-11 in IEC-6 cells

IL-11 expression was found in the cytoplasm of normal IEC-6 cells. The expression of IL-11 was significantly reduced 6 h after 4.0Gy neutron irradiation and returned to normal level 24 h after 4.0Gy neutron irradiation (Figure 2). The quantitative results are shown in Table 1.

Expression of IL-11Rα in IEC-6 cells

Immunohistochemical staining analysis of IL-11Rα expression: In normal control IEC-6 cells, intense immunoreactivity of IL-11Rα was located within the cellular membrane and cytoplasm. Six hours after 4.0Gy neutron irradiation, only a very slight immunoreactivity was found

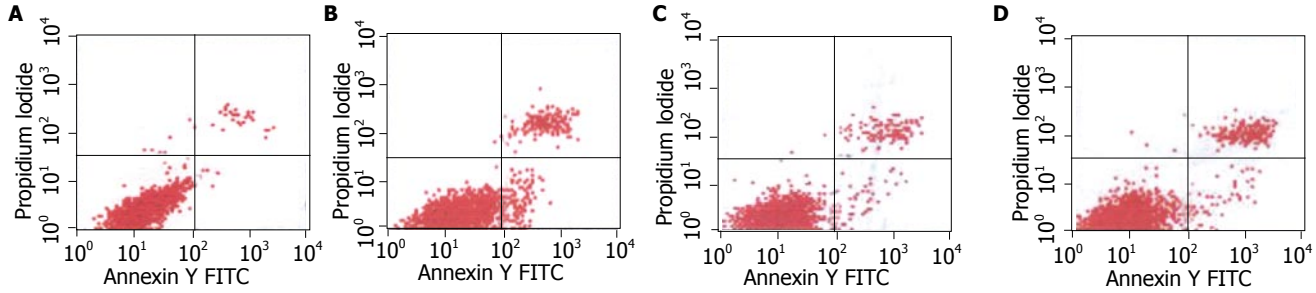

Figure 1 Effects of rhIL-11 treatment on apoptosis and necrosis rates of IEC-6 cells 6 h after 4.0Gy neutron irradiation. **A:** The apoptosis and necrosis rates of normal IEC-6 cells were 0.79% and 1.99%, respectively; **B:** In 4.0Gy neutron-irradiated IEC-6 cells, the apoptosis and necrosis rates were 5.58% and 9.04%, respectively; **C:** In IEC-6 cells treated with rhIL-11 before neutron irradiation, the apoptosis rate was 1.91%, lower than that without rhIL-11 stimulation; **D:** In IL-11 post-treatment IEC-6 cells, the apoptosis rate was 1.86%, lower than that without rhIL-11 stimulation. But in both rhIL-11-treated IEC-6 cells, the necrosis rate was not decreased obviously.

Table 1 Quantitative results of IL-11 expression in IEC-6 cells after 4.0Gy neutron irradiation (mean ± SD)

Time after irradiation (h)	MOD ($\times 10^{-2}$)	IOD ($\times 10^{-1}$)
0	17.33 ± 1.16	17.30 ± 1.04
6	6.33 ± 0. 58 [a]	1.30 ± 0.17 [a]
24	24.67 ± 3.22	27.30 ± 2.59
48	14.33 ± 0. 58	13.33 ± 0.50

n = 3. [a]$P < 0.05$ *vs* normal control group.

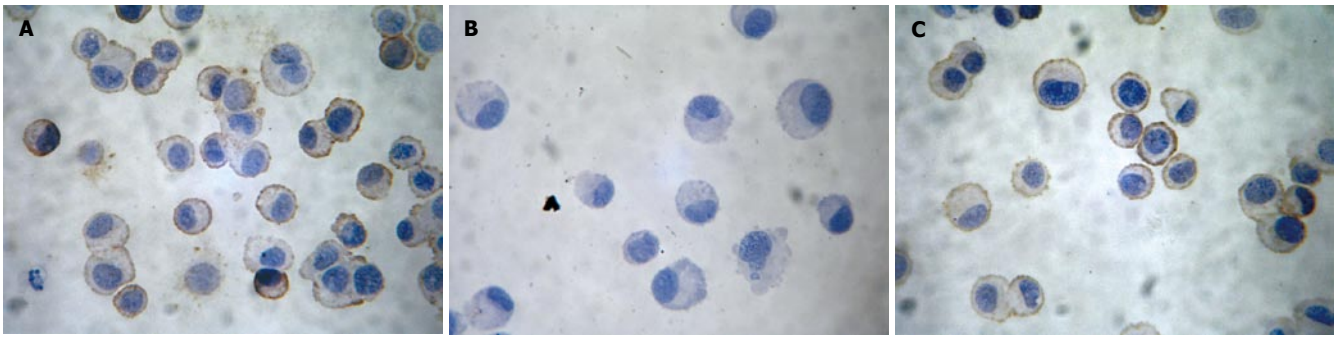

Figure 3 Immunohistochemichal staining of IL-11Rα (400×) located in cytomembrane and cytoplasm of IEC-6 cells. **A:** IL-11Rα was strongly positive in normal IEC-6 cells; **B:** Six hours after 4.0Gy neutron irradiation, dramatic decline was found in IL-11Rα expression; **C:** No obvious decline was observed in IEC-6 cells treated with 100 ng/mL rhIL-11 after 4.0Gy neutron irradiation.

but became normal 24 h after irradiation. In IEC-6 cells treated with both radiation and rhIL-11, there was no decrease in the expression of IL-11Rα (Figure 3). The quantitative results are listed in Table 2.

Western blot analysis of IL-11Rα expression: The results were mainly in accord with those of immunohistochemistry (Figure 4). The quantitative results are listed in Table 3.

Expression of gp130 in IEC-6 cells

gp130 protein was observed in normal IEC-6 cells. After irradiation, gp130 expression was progressively decreased in within 48 h. In rhIL-11-pretreated cells, despite a decrease 6 h post-irradiation, gp130 expression became normal at 24 h and decreased a little at 48 h. Besides, in IEC-6 cells treated with rhIL-11administration after irradiation, gp expression was decreased slightly 48 h after irradiation and no obvious changes were found 6 and 24 h after irradiation. gp130 protein expression in rhIL-11-stimulated cells 24 h and 48 h after irradiation was higher than that of the irradiated cells (Figure 5). The quantitative results are shown in Table 4.

DISCUSSION

IL-11 is a functionally pleiotropic cytokine originated from the primate PU34 bone marrow fibroblast cell line[12]. Though initially known as a hematopoietic growth factor, IL-11 is an important mediator in systems other than the hematopoietic system. Studies revealed that IL-11 plays an important role in intestinal epithelial injury and repair[4-11], immunomodulation[13-14], neurogenesis[15-16], osteoclasto-

genesis[17], general homeostasis of the skin, *etc*[18-19]. Present researches involving intestinal injury and repair on instance intestinal damage induced by chemotherapy and radiation[6, 8-11], inflammatory bowel disease[20], bowel ischemical reperfusion injury[4], short bowel syndrome[7], etc, have proved that IL-11 can prevent injury and accelerate recovery.

Previous studies indicated that IL-11 could exert a potent effect on the recovery of the small intestinal mucosa injury in mice treated with radiation and/or chemotherapy by its combined effects on proliferation and apoptosis of crypt cells[9]. However, the effects of IL-11 are not exclusively stimulatory. *In vitro* studies showed that IL-11 directly interacts with intestinal epithelial cells and reversibly inhibits proliferation of the intestinal crypt stem cell lines (IEC-6 and IEC-18)[21]. It seems contradictory that IL-11 can not only stimulate but inhibit proliferation. Possibly it is because that IL-11 exerts different effects on damaged and undamaged cell clusters. In respect to the undamaged cells, it inhibits proliferation (as reduction of cellular proliferation can be cytoprotective, pretreatment with IL-11 may reduce radiation sensitivity before exposed to rays) and promotes proliferation of damaged cells (enhancing recovery after radiation). Other studies also found that IL-11 pretreatment induces intestinal epithelial cell growth arrest through effects on retinoblastoma protein phosphorylation and delays entry into S phase of the cell cycle[22]. Transient cell cycle arrest is a possible mechanism by which rhIL-11 may protect intestinal epithelial cells from damage induced by chemotherapy or radiation therapy. In this study, pretreatment with rhIL-11 prior to neutron irradiation led to a decrease in apoptosis rate, which may be due to its direct interaction with IEC-6 cells and prolongation of G_1-S phase consequently reducing the radiosensitivity of IEC-6 cells. Data also have shown that

IL-11 is able to protect intestinal crypt stem cells from impairment of their reproductive capacity by radiation[10]. IL-11-administeration after radiation can cause a greater number of crypt cells to survive a given radiation dose[10]. In this study, a decrease in apoptosis rate was found in cells post-treated with IL-11 after irradiation, which may be due to the fact that rhIL-11 stimulation promotes the survived IEC-6 cells to reproduce, leading to the decrease of apoptosis rate. In addition, 4.0Gy neutron irradiation resulted in a significant reduction of IL-11 expression in IEC-6 cells 6 h after irradiation. Simultaneously, flow cytometry assay showed an increased apoptosis rate, indicating that IL-11 can protect IEC-6 cells from neutron irradiation.

It was reported that IL-11 responsiveness is restricted to cells expressing both the IL-11Rα subunit and the transmembrane signaling receptor gp130 on their surface[23]. The Janus kinase-signal transducer and activator of transcription (JAK-STAT) pathway is an important signaling system activated by the IL-11Rα. It was reported that IL-11 stimulation results in decreased activation of caspase-9 and reduced induction of apoptosis in cultured colonic epithelial cells (CEC)[23]. In this study both IL-11Rα and gp130 expressions were decreased in irradiated cells without rhIL-11 treatment 6 h after irradiation (the course of injury). However, in rhIL-11-treated cells, receptor expression level was higher and apoptosis rate was lower than those in irradiated cells without rhIL-11 treatment, indicating that increased IL-11 receptor complex expression induced by rhIL-11 stimulation is involved in the injury and repair of IEC-6 cells caused by neutron irradiation. In irradiated cells, the decreased IL-11 receptor expression is unbeneficial for IL-11 to exert radioprotection effect, thus increasing the apoptosis rate. However in rhIL-11-treated cells, rhIL-11 treatment not only upregulates the expression of IL-11 receptor but also is beneficial to exert its actions, thus reducing the apoptosis rate induced by irradiation. Alterations of receptor expression reflect changes in activation of corresponding signaling pathway. The alteration of IL-11 downstream signal pathway in IEC-6 cells treated with neutron irradiation and rhIL-11 is now under investigation.

Abstract

AIM: To observe the therapeutic effect of early administration of exogenous Basic fibroblast growth factor (bFGF) on acute edematous pancreatitis (AEP) in rats.

METHODS: Thirty male Sprague-Dawley rats were randomly divided into three (n = 10): normal control group (group I), AEP group (group II) and AEP with bFGF treatment group (group III). AEP was induced by subcutaneous injection of cerulein (5.5 μg/kg and 7.5 μg/kg) at 1 h interval into rats of groups II and III. Three hours after induction of AEP, 100 μg/kg bFGF was administrated intraperitoneally for 1h to group III rats. For test of DNA synthesis in acinar cells, *5-bromo-2'-deoxyuridine* (*BrdU*) labeling solution was intraperitoneally injected into the rats of groups II and III 24 h after bFGF treatment. The changes in serum amylase, lipase, pancreatic tissue wet/dry ratio were detected.

RESULTS: In bFGF treatment group, there was a significant decrease in the volume of serum amylase, lipase and the pancreatic wet/dry weight ratio(1383.0 ± 94.6 U/L, 194.0 ± 43.6 U/L, 4.32 ± 0.32) compared to AEP group (3464 ± 223.7 U/L, 456 ±68.7 U/L, 6.89 ± 0.47) (P < 0.01), and no significant difference was found between bFGF treatment and control group (1289 ± 94.0 U/L, 171 ± 23.4 U/L, 4.12 ± 0.26, P > 0.05). The inflammatory changes such as interstitial edema, polymorphonuclear neutrophils (PMNs) and vacuolization were significantly ameliorated compared to AEP group (P < 0.01). A small number of BrdU-labeled nuclei were observed in acinar cells of AEP rats (1.8 ± 0.3 nuclei/microscopic field, n = 10) while diffuse BrdU-labeled nuclei were found in bFGF-treated rats (18.9 ± 1.4 nuclei/microscopic field, n = 10) (P < 0.01). Immunohistochemical study showed increased DNA synthesis in pancreatic acinar cells.

CONCLUSION: Early administration of exogenous bFGF has significant therapeutic effect on cerulein-induced acute edematous pancreatitis in rats. Its mechanism is related to the amelioration of inflammation and facilitation of pancreatic regeneration.

INTRODUCTION

Basic fibroblast growth factor (bFGF) is one of the mitogens that facilitate cellular proliferation, maturation and regeneration[1]. Hoshi *et al*[2] reported that bFGF exerts direct trophic effects on rat pancreatic acinar cells *in vitro*. Some studies[3-6] showed that FGF is involved in the process of acute pancreatic exocrine regeneration during recovery of acute pancreatitis. Acute edematous pancreatitis (AEP) rats were selected as the animal model to investige the therapeutic effect of exogenous bFGF on the early acute pancreatitis (AP) and its mechanism.

MATERIALS AND METHODS

Animal model

Thirty male healthy Sprague-Dawley rats weighing 400-450 g were purchased from the Animal Center, Academy of Zhejiang Medical Sciences. All rats were randomly divided into three groups (n = 10), with 10 rats each group. Group I (normal control group), group II (AEP group), and group III (AEP with bFGF treatment group). AEP was induced in rats of goups II and III by injection of 5.5 μg/kg and 7.5 μg/kg of caerulein (Sigma Chemical Co., USA) subcutaneously at 0 and 1 h after the beginning of experiment respectively[7, 8], while the rats of the control group were subcutaneously injected with normal saline solution.

bFGF treatment and 5-bromo-2'-deoxyuridine (BrdU) label

All animals were anesthetized with 3% thiopental sodium

(0.3 μL/g). In group III bFGF (100 μg/kg) was administered by contiunuous intraperitoneal infusion of 10 μg/mL bFGF solution (Essex Co., China) for 1 h, while normal saline solution was administered to all other rats in groups I and II as the contrast. Twenty-four hours after treatment, 200 μg/mL BrdU-labeling solution (10 mL/kg) was intraperitoneally injected into the rats of groups II and III.

Blood and tissue sample collection

Two hours after BrdU-labeling solution injection, venous blood was taken from all rats in each experimental group to obtain blood samples. Then all rats were killed and pancreatic tissue was divided into 3 portions from each rat and quickly removed.

Histological examination

A portion of the pancreas was fixed overnight in 10% neutral formaldehyde solution and embedded in paraffin. Tissue slices were subjected to hematoxylin and eosin staining and histologic study under light microscope. Slides were coded and examined blindly by the pathologist for the grading of histologic alterations. Histological changes were evaluated according to Kyogoku *et al*[9]. Interstitial edema was scored as 0 = absent, 1 = expanded interlobular septa, 2 = expanded intralobular septa, 3= separated individual acini. Polymorphonuclear neutrophil (PMN) infiltration was scored as 0 = absent, 1=less than 20 PMNs per IPF, 2 =20 PMNs-50 PMNs per IPF and 3 = more than 50 PMNs per IPF. The grading of vacuolization was based on the percentage of acinar cells with cytoplasmic vacuoles per IPF: 0 = absent, 1 = less than 20%, 2 = 20%-50%, 3 = more than 50%. Hemorrhagic and parenchymal necrosis changes were absent and therefore not scored.

Immunohistochemistry examination (S-P method)

DNA synthesis of pancreatic acinar cells was determined as the uptake of Brdu in the cells. Another portion of the pancreas was fixed in 10% formalin, embedded in paraffin, and sectioned at 3 mm. After dewaxing, the tissue was then incubated with the monoclonal antibodies against BrdU for 1 h at room temperature in a humidified chamber. The tissue was washed three times with 0.01 mol/L phosphate-buffered saline (PBS) and incubated in peroxidase-conjugated anti-mouse immunoglobulin G (IgG) for 30 min at room temperature. The tissue was again washed three times with 0.01 mol/L PBS, and immunoreactivity of BrdU was detected using 3, 3'-diaminobenzidine tetrahydrochloride (DAB) with nickel chloride as a chromogen. DAB (10 mg) was dissolved in 0.05 mol/L phosphate buffer (30 mL), and three drops of nickel chloride (3%) and hydrogen peroxide (3%) solution were also added. The DAB solution was applied to the tissue for 5 min at room temperature. The BrdU-labeled nuclei were stained purplish blue.

Statistical analysis

All data were expressed as mean ± SD. Histologic scores were compared using the Mann-Whitney test, while statistical differences of serum amylase were performed using paired Student's *t* test. $P < 0.05$ was considered statistically significant.

Table 1 Changes in serum amylase, lipase and pancreatic wet/dry weight ratio (n = 10) (mean ± SD)

Groups	Serum amylase (U/L)	Serum lipase (U/L)	Pancreatic wet/dry weight ratio
Group I	1289 ± 94.0	171 ± 23.4	4.12 ± 0.26
Group II	3464 ± 223.7[b]	456 ± 68.7[b]	6.89 ± 0.47[b]
Group III	1383 ± 94.6[ad]	194 ± 43.6[ad]	4.32 ± 0.32[ad]

[a]$P > 0.05$, [b]$P < 0.01$ *vs* group I; [d]$P < 0.01$ *vs* group II.

Table 2 Pathological lesion score for pancreas of each group (n = 10) (mean ± SD)

Groups	Edema	PMN infiltration	Vacuolization
Group I	0	0	0
Group II	2.40 ± 1.07[b]	2.50 ± 1.08[b]	2.40 ± 0.96[b]
Group III	0.70 ± 0.67[ad]	0.60 ± 0.59[ad]	0.70 ± 0.62[ad]

[b]$P < 0.01$, [a]$P < 0.05$ *vs* group I; [d]$P < 0.01$ *vs* group II.

RESULTS

Serum amylase, lipase and pancreatic tissue wet/dry weight ratio

When SEP model was established and bFGF treatment was taken after 24 h, serum amylase and lipase activity as well as pancreatic tissue wet/dry weight ratio of group III (bFGF treatment group) (1383.0 ± 94.6 U/L, 194.0 ± 43.6 U/L, 4.32 ± 0.32) were significantly lower than those of group II (AEP group) (3464 ± 223.7 U/L、456 ± 68.7 U/L and 6.89 ± 0.47) ($P < 0.01$), with no significant difference compared with group I (normal control group) (1289 ± 94.0 U/L、171 ±23.4 U/L and 4.12 ± 0.26)($P > 0.05$). There was a significant difference between group I and II ($P < 0.01$) (Table 1).

Histological staining

In the histological examination of pancreatic tissue stained with HE, pancreatitis changes such as angioectasia and inflammatory cell infiltration, tissue edema and vacuolization of acinar cells in bFGF treatment group(group III) were remarkably reduced compared with AEP group (group II) (Table 2 and Figures 1-3).

Immunohistochemical analysis

A small number of BrdU-labeled nuclei were observed in acinar cells of AEP rats (group II) (1.8 ± 0.3 nuclei/microscopic field, n = 10) (Figure 4A). The BrdU-labeled nuclei were diffusely distributed in bFGF treated rats (group III) (18.9 ± 1.4 nuclei/microscopic field, n = 10) ($P < 0.01$) (Figures 4B).

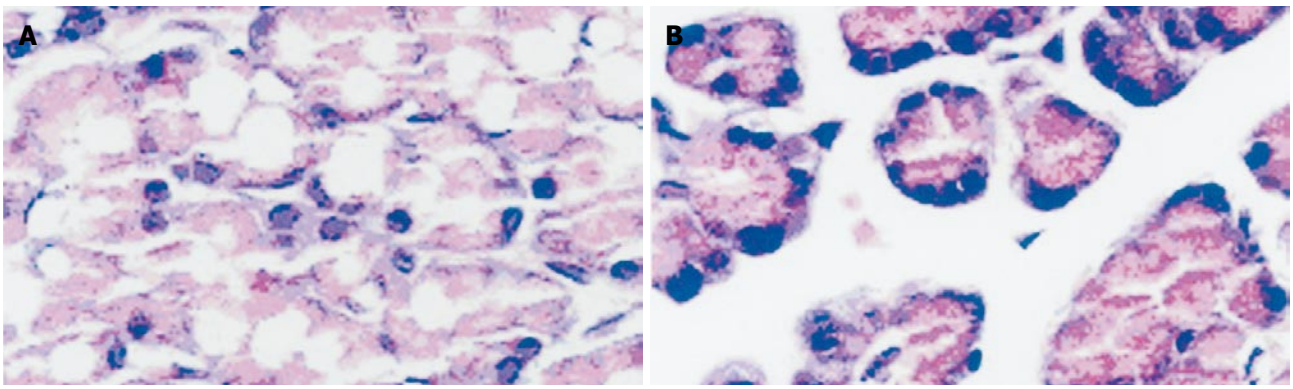

Figure 3 Marked tissue edema and vacuolization of acinar cells group II (**A**) compared to group III (**B**) after bFGF treatment under light microscope (×400).

DISCUSSION

Some factors can repair the injured tissues or cells[10-14] and can be used to treat acute pancreatitis. Recent studies indicate that various growth factors such as bFGF[15-17], TGF-β1[18,19], HGF[6, 20], EGF[18, 21-24] and CTGF[25] are involved in pancreatic repair and tissue remolding in humans and rats with AP. It was reported that ischemia/reperfusion (I/R) injury of intestine and other internal organs reduces the expression of endogenous basic fibroblast growth factor (bFGF) [26-29], and intravenous administration of exogenous bFGF could induce the expression of endogenous bFGF and improve the physiological function of some internal organs after I/R injury[30-33]. So there may be a bright future to accelerate the "positive repair" of internal organs' I/R injuries by using growth factors based on all these results.

The present study used acute edematous pancreatitis rats as a model to observe the therapeutic effect of exogenous bFGF on acute edematous pancreatitis in rats. Early treatment with exogenous bFGF drastically ameliorated all the pathological changes both in histology and in serum enzymes, and showed significant therapeutic effect on ce-

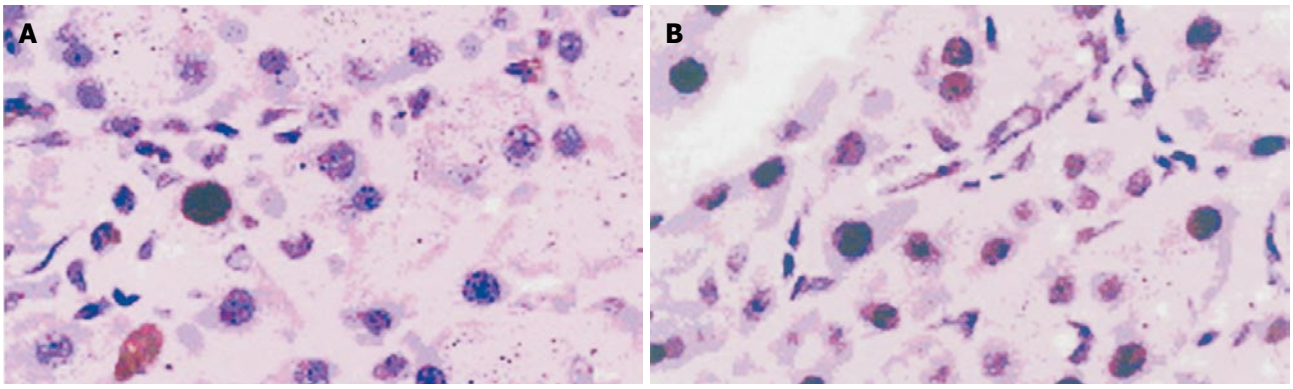

Figure 4 BrdU labeled nuclei of acinar cells in group II (**A**) and group III (**B**) after bFGF treatment (S-P method, ×400).

rulein-induced acute edematous pancreatitis in rats. Immunohistochemical examination showed that DNA synthesis was increased in pancreatic acinar cells of bFGF-treated rats, suggesting that bFGF treatment can promote pancreatic cell regeneration and accelerate rebuilding the integration of injured pancreatic tissue. The beneficial effects of bFGF appear to depend, at least in part, on amelioration of pancreatic inflammation and increase of pancreatic cell growth. Results of the present study have proved that early usage of exogenous bFGF can prevent the development of acute pancreatitis, and may play an important role in limiting its progression to sever pancreatitis.

Abstract

AIM: To assess the combinative role of aflatoxin B_1 (AFB_1), cyanobacterial toxins (cyanotoxins), and hepatitis B virus (HBV) x gene in hepatotumorigenicity.

METHODS: One-week-old animals carrying HBV x gene and their wild-type littermates were intraperitoneally (ip) injected with either single-dose AFB_1 [6 mg/kg body weight (bw)], repeated-dose cyanotoxins (microcystin-LR or nodularin, 10 μg/kg bw once a week for 15 wk), DMSO (vehicle control) alone, or AFB_1 followed by cyanotoxins a week later, and were sacrificed at 24 and 52 wk post-treatment.

RESULTS: AFB_1 induced liver tumors in 13 of 29 (44.8%) transgenic mice at 52 wk post-treatment, significantly more frequent than in wild-type mice (13.3%). This significant difference was not shown in the 24-wk study. Compared with AFB_1 exposure alone, MC-LR and nodularin yielded approximately 3-fold and 6-fold increases in the incidence of AFB_1-induced liver tumors in wild-type animals at 24 wk, respectively. HBV x gene did not further elevate the risk associated with co-exposure to AFB_1 and cyanotoxins. With the exception of an MC-LR-dosed wild-type mouse, no liver tumor was observed in mice treated with cyanotoxins alone at 24 wk. Neither DMSO-treated transgenic mice nor their wild-type littermates had pathologic alterations relevant to hepatotumorigenesis in even up to 52 wk.

CONCLUSION: HBV x gene and nodularin promote the development of AFB_1-induced liver tumors. Co-exposure to AFB_1 and MC-LR tends to elevate the risk of liver tumors at 24 wk relative to exposure to one of them. The combinative effect of AFB_1, cyanotoxins and HBVx on hepatotumorigenesis is weak at 24 wk.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the sixth most common cancer and the third leading cause of cancer mortality worldwide[1]. In the People's Republic of China, HCC is the second leading cause of cancer mortality with 28 463 deaths in 1999[2]. Epidemiological studies revealed that multiple environmental factors were associated with HCC in some high-risk areas. Chronic hepatitis B virus (HBV) infection and dietary aflatoxin exposure are two major etiological risk factors for HCC, which has been studied in the past two decades[3]. For individuals chronically infected with HBV, concurrent exposure to dietary aflatoxins increases the risk of HCC by at least three-fold[4]. Continuous hepatocyte death and regeneration caused by host immune response to viral antigens contributes to the pathogenesis of chronic HBV infection[5]. The HBV x (HBVx) gene, one of the four genes in the HBV genome, encodes a polypeptide of 154 amino acids and is highly conserved among all mammalian hepadnaviruses. Interestingly, in the absence of HBV x gene, duck hepatitis B virus (DHBV) infection did not yield HCC, but the frequent occurrence of HCC was caused by infections of woodchuck hepatitis virus (WHV) and ground squirrel hepatitis virus (GSHV) with the presence of HBV x gene[6]. Compared to other regions of the genome, the viral DNA sequences encoding HBV X and/or truncated envelope PreS2/S proteins were more frequently detected in the primary tumors and tumor-derived cell lines. Although HBVx does not bind to DNA directly, it is capable of trans-activating cellular

genes and is considered to be a tumor promoter during liver carcinogenesis[7]. Some HBV x gene transgenic animals showed an increased susceptibility to chemical hepatocarcinogens[8,9]. Studies using transgenic mouse lines lend further support for the epidemiological finding that chronic HBV infection acts synergistically with aflatoxins in hepatocelluar carcinogenesis[10,11].

However, other risk factors, such as chronic exposure to cyanobacterial toxins (cyanotoxins) through drinking water, were relatively less studied or even overlooked. The mortality rate of HCC was closely associated with the source of drinking water in southern China at high risk of HCC[12]. Wide contamination of cyanotoxins in drinking water sources in these endemic areas suggests that the high incidence of HCC may be associated, in part, with chronic exposure to cyanotoxins via drinking water[13]. Cyanobacteria produce a wide range of secondary metabolites that are hazardous to humans, livestock, and wildlife[14]. Several bloom-forming cyanobacterial genera, including *Microcystis*, *Anabaena*, *Planktothrix* and *Nostoc*, are capable of producing the cyclic heptapeptide toxins, microcystins and *Nodularia*, the latter further metabolized to the cyclic pentapeptide nodularin. These toxins have a number of common structural features, in particular, the unique β-C20 amino acid 3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid. The most widely studied microcystins is microcystin-LR (MC-LR) with an LD_{50} between 32.5 μg/kg body weight (bw) and 10.9 mg/kg bw in rodents by intraperitoneal (ip) injection, oral, and aerosol inhalation routes[15-17]. The direct cause of death in toxin-treated rodents was hemorrhagic shock and liver necrosis. MC-LR is a potent tumor promoter as well[18]. A two-stage carcinogenesis test showed that MC-LR modulated aflatoxin B_1-induced hepatocarcinogenicity. In rats given AFB_1 as an initiator, the subsequent treatment with MC-LR resulted in a synergistic increase in the development of glutathione S-transferase placental form (GST-P)-positive liver cell foci[19]. The hepatotoxicity of MC-LR is, at least in part, explained by its ability to inhibit protein phosphatases 1 and 2A and consequently induces hyperphosphorylation of various proteins, including tumor suppressor gene products, retinoblastoma (Rb) and p53[20]. Nodularin injures mammalian and fish livers in the same manner as microcystins; it also inhibits protein phosphatases and acts as a tumor promoter[21]. The result of a two-stage carcinogenesis experiment indicated that nodularin has the potential to stimulate growth of the initiated liver cells more strongly than does microcystin-LR and, additionally, an initiating capacity similar to diethylnitrosamine (DEN)[22].

Although epidemiological studies conducted in high-risk areas in China have implicated the synergistic effect of chronic HBV infection, dietary AFB_1 exposure and chronic exposure to cyanotoxin-contaminated drinking water on the development of HCC, no experimental design has been made so far to study comprehensively the combinative effect of these three environmental risk factors on the development of liver tumors in animals. In this study, we attempted to use the established HBV x gene transgenic mouse model to assess the combinative role of chemical and viral infection in hepatotumorigenicity.

MATERIALS AND METHODS

Reagents

Aflatoxin B_1 (AFB_1) was purchased from Sigma Chemical Co. (St. Louis, MO). MC-LR (> 90% purity in HPLC), generously provided by Dr. Li-Rong Song, Department of Phycology, Institute of Hydrobiology, Chinese Academy of Sciences, was dissolved in saline to a concentration of 0.5 mg/mL. Nodularin (> 95.0% purity in HPLC), kindly provided by Dr. Wayne W. Carmichael, Wright State University, was dissolved in dimethylsulfoxide (DMSO, Burdick & Jackson, Muskegon, MI) to a concentration of 5 mg/mL. All stock solutions were kept at -20 ℃ until use.

Hepatitis B virus x gene transgenic mice

The development of the HBV x gene transgenic mice used in this study has been reported elsewhere[23]. Briefly, a recombinant retroviral expression vector plasmid pSHDX42 containing a 0.59 kilobase (kb) HBV subtype *adr* DNA fragment which spans nucleotide position 1 248 to 1 841 in the viral genome was constructed. A retroviral enhancer LTR, SV40 polyadenylation sequence, and a universal terminator from the expression vector pLXSHD were also inserted into pSHDX42 to initiate and terminate the transcription of the x gene. The DNA segment in the vector pSHDX42 contained the entire coding region of the x gene (map positions 1376 to 1840) and was released from pSHDX42 by *Bam*H Π/*Sph* I digestion. The purified DNA was microinjected into the pronuclei of fertilized eggs of C57BL/6J mice purchased from the Shanghai Laboratory Animal Center of Chinese Academy of Sciences. The DNA-injected eggs were transferred into the oviduct of pseudopregnant female ICR mice purchased from the Shanghai Laboratory Animal Center of Chinese Academy of Sciences. Genomic DNA and total RNA were extracted from F1 generation tail and liver tissues. Transgenic mice were identified by the methods of nested-primer PCR and Southern blotting of tail genomic DNA as well as RT-PCR of liver mRNA and immunohistochemical staining of HBV X protein in the liver. Six identified transgenic males were mated with wild-type C57BL/6J females to create a male transgenic colony for the following carcinogen treatments. Age- and litter-matched male offsprings were divided into six groups of transgenic and six groups of wild-type mice. All individual mice were identified according to the digit code and were arbitrarily assigned to treatment groups. All mice were maintained and cared for in accordance with the guidelines established by the National Institute of Health.

Nested-primer PCR

In a previous study, the nested-primer PCR of HBV x gene fragment from mouse tail genomic DNA was demonstrated to be compatible with RT-PCR of mRNA from liver samples in identifying transgenic animals[23]. In this study, only nested-primer PCR was used to screen the transgenic mice from the colony. The PCR primers were designed on human HBV subtype *adr* x gene sequence. The pair of outer primers included the forward,

GTACCGACGATCCCACACGA, and the reverse, ATTAGGCAGACGTGAAAAAG, complementary to position 1375 to 1394 and 1841 to 1822 of the x gene sequence, respectively. The inner primer set consisted of the forward, GAAACAAATGCAGGGCAGCCG CGACTTAG, and the reverse, CAGTCTTTGAAG TATGCCTCAAGGTCGGT, which were complementary to the nucleotide positions 1421 to 1449 and 1719 to 1691 of the sequence, respectively. They generated a DNA product of 439 bp.

The reaction mixture of the first PCR consisted of 2 μL of DNA extract in a total volume of 20 μL, with final concentrations of 10 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl, 1.5 mmol/L $MgCl_2$ (10 × PCR buffer, Promega, Madison, WI), a 10 pmol/L concentration of each outer primer, 0.8 U of AmpliTaq DNA polymerase (Sangon, Shanghai, China), and a 10 mmol/L concentration of each dNTP (Promega, Madison, WI). The reaction mixture of the second PCR was identical with the exception of 3 μL of the first reaction products, 10 pmol/L of inner primers and 2.5 U of AmpliTaq DNA polymerase. Reactions with the outer primer set were thermal cycled once at 95℃ for 5 min, 30 times at 94℃for 50 s, 55℃ for 1 min, and then once at 72℃ for 1 min. For the nested PCR product, reactions were thermal cycled once at 94℃ for 5 min, 30 times at 94℃ for 50 s, 60℃ for 50 s, and 72℃ for 1 min, and then once at 72℃ for 10 min. The PCR products were analyzed by electrophoresis on 20 g/L agarose gels, stained with ethidium bromide, and visualized on an UV transilluminator.

Administration of toxins

Both one-week-old male transgenic mice and their wild-type littermates were used for the studies. All dosing was administered by ip injection based on body weight (bw) at the time of treatment. Animals treated with solvent vehicle (DMSO) were used as the controls. In the tumorigenic study with AFB_1, animals were treated with a single dose of AFB_1 at 6 mg/kg bw and were then euthanized either at 24 wk or 52 wk post-treatment. In the tumorigenic studies with cyanotoxins, either nodularin or MC-LR was ip administered to animals at 10 μg/kg bw once a week for 15 wk, and all animals were sacrificed at 24 wk post-treatment. In the co-tumorigenic studies with AFB_1 and cyanotoxins, the animals were initially given a single dose of AFB_1 at 6 mg/kg bw and then, a week later, were treated with 10 μg/kg bw of MC-LR/nodularin once a week for 15 wk. This experiment was terminated at 24 wk after the treatment with AFB_1.

Histopathology

Animals were sacrificed under ethyl ether anesthesia at 24 wk or 52 wk after the initial treatment. The skin, musculature, and internal organs were examined for visible abnormalities, and tissues with tumors and lesions were preserved in 100 mL/L neutral-buffered formalin and embedded in paraffin. Sections were stained with hematoxylin-eosin for histopathological alterations and with periodic acid Schiff's reagent for glycogen accumulation in the hepatocyte. All sections were evaluated by two senior pathologists who were blind to the dosing regimen, and focal hepatic lesions were histologically classified into three morphologic entities: hepatocellular foci, hepatocelluar adenomas or hepatocellular carcinomas.

Statistical analysis

Data were expressed as the incidence of hepatic tumors including carcinoma and adenoma. For animals with both liver adenoma and carcinoma, the statistical analysis of liver tumors was based on the worst level of pathology, carcinoma. The incidences of liver tumors induced by different treatments were statistically evaluated by χ^2 test of a 2 × 2 contingency table or Fisher exact test. One-sided P values less than 0.05 were considered statistically significant.

RESULTS

Synergistic hepatotumorigenesis of AFB_1 and HBVx

During the observation period (24 wk or 52 wk), there was no difference with respect to general fitness between DMSO-treated transgenic and wild-type mice. Macroscopic examination at autopsy revealed no visible tumors in these two control groups of animals. In some AFB_1-treated animals, however, liver tumors were usually multifocal and formed large masses (Figure 1-A1). Upon microscopic inspection, neither neoplastic nor dysplastic alterations were recognized in the livers of DMSO-treated transgenic mice at both 24 and 52 wk post-treatment, but a few inflammatory cells were observed at 52 wk. Some animals treated with AFB_1 developed foci of altered hepatocytes, concentrated mainly in centrilobular areas in which foci consisted of relatively large hepatocytes with vacuolations poorly stained with hematoxylin-eosin staining in the cytoplasm (Figure 1-A2). These vacuolations contained glycogen, as shown in periodic acid Schiff's staining (Figure 1-A3). Clusters of small basophilic cells were observed in some AFB_1-treated animals as well. These phenotypic changes were found in both AFB_1-treated transgenic and wild-type animals. Histologically, tumors displayed extensive pleomorphism and a significantly higher mitotic rate than the adjacent normal liver tissue (Figure 1-A4). They generally were composed of enlarged cells with lipid or glycogen in the cytoplasm.

During the 52-wk observation period, 6 of 29 (20.7%) AFB_1-treated transgenic animals developed HCC, whereas only 1 of 15 (6.7%) AFB_1-treated wild-type mice was found to have HCC. In addition, small neoplastic nodules (adenoma) were identified in 7 of 29 (24.1%) AFB_1-treated transgenic animals and 1 of 15 (6.7%) AFB_1-treated wild-type animals at the 52-wk interval. Overall, the incidence of liver tumors reached 44.8% (13/29) in AFB_1-treated transgenic animals during the observation period of 52 wk, which was significantly higher than that in AFB_1-treated wild-type littermates (13.3%) at the same interval ($\chi^2 = 4.36$, $P < 0.05$). In the short-term tumorigenic study (Table 1), no HCC was recognized in any of AFB_1-treated animals at 24 wk post-treatment; basophilic adenoma was identified in 1 of 11 (9.1%) AFB_1-treated transgenic

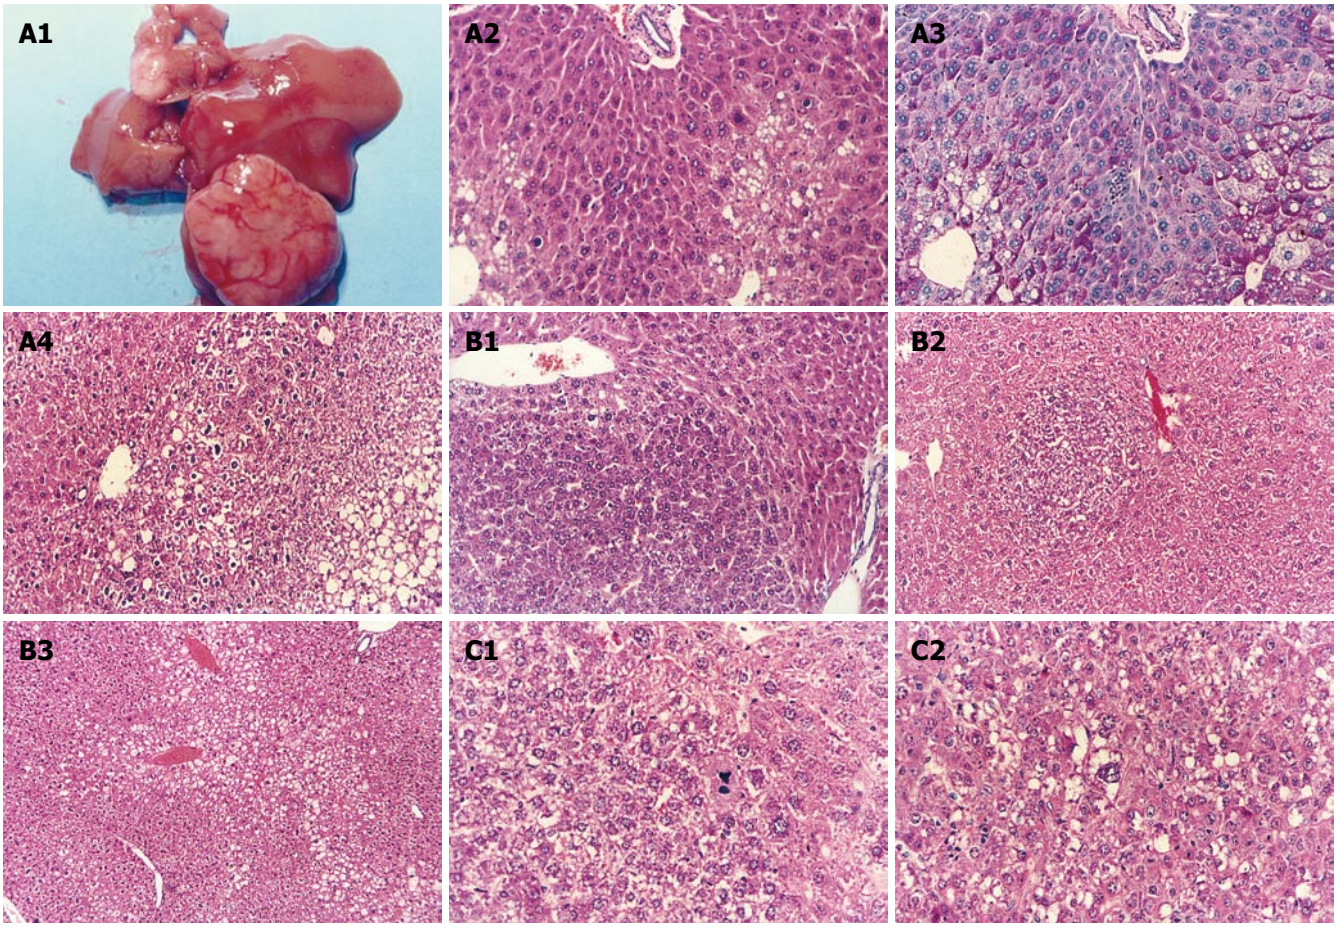

Figure 1 Histopathological alterations identified in liver tissues of mice treated with either AFB_1 (**A**) and cyanobacterial toxins alone (**B**) or in combination (**C**). **A1**: Grossly identified hepatocelluar carcinoma (HCC) in an HBVx gene transgenic mouse at 52 wk post-treatment; **A2**: altered hepatocyte foci in an HBVx gene transgenic mouse (HE × 100); **A3**: periodic acid Schiff's stain for glycogen (× 100) in the continuous liver tissue section of **A2**; **A4**: hepatocellular carcinoma in a wild-type mouse at 52 wk post-treatment (HE × 40). The border appears to be disrupted by neoplastic cells penetrating into the adjacent parenchyma; **B1**: basophilic adenoma in a microcystin-LR-treated wild-type mouse (HE × 40); **B2**: basophilic hepatocyte foci in microcystin-LR-treated transgenic mice (HE × 10); **B3**: clear hepatocyte foci in nodularin-treated wild-type mice (HE × 10); **C1**: HCC in a wild-type mouse treated with both AFB_1 and microcystin-LR (HE × 100). Tumor cells had a great variability in cell and nuclear size, and large cells with large hyperchromatic nuclei were present; **C2**: HCC in a wild-type mouse treated with both AFB_1 and nodularin (HE × 100).

mice and 1 of 20 (5.0%) AFB_1-treated wild-type mice. No statistically significant difference in the incidence of liver tumors was found between these two groups at 24 wk post-treatment. Compared with transgenic animals treated with AFB_1 and sacrificed at 24 wk post-treatment, AFB_1-treated transgenic mice were more likely to develop liver tumors 52 wk after the treatment ($P < 0.05$). In wild-type animals, the AFB_1 treatment did not significantly elevate the risk of developing liver tumors over time.

Contribution of cyanotoxins to the occurrence of AFB_1-induced liver tumors during the short period

To determine if AFB_1 interacts with cyanotoxins to promote the development of liver tumors, wild-type mice were treated with a single injection of AFB_1, followed by repeated injections of either MC-LR or nodularin a week later. Of 21 wild-type mice treated with AFB_1, followed by MC-LR, liver tumors were observed in 4 (19.0%) animals at 24 wk post-treatment (Table 1). Mitotic figures were observed in some tumors. The hepatocytic nuclei were variable in size and chromatin content (dense nuclear chromatin pattern) (Figure 1-C1). By contrast, the incidence of liver tumors in wild-type mice treated with AFB_1 or MC-LR alone was 5.0% (1/20) and 3.9% (1/26) at the same interval, respectively (Table 1). Although the difference in short-term risk of liver tumors was not statistically significant, co-exposure to AFB_1 and MC-LR tended to elevate the risk during the 24-wk period. Alternatively, the incidence of liver tumors in wild-type animals treated with both AFB_1 and nodularin was 33.3% (3/9), which was significantly higher than those in wild-type mice treated with nodularin alone (0%, $P < 0.05$) and slightly higher than those in wild-type mice treated with AFB_1 alone (5.0%, $P = 0.07$) (Table 1). The tumor cells were enlarged and pleomorphic in shape. The nuclei were hyperchromic and exhibited irregular nuclear contour with prominent nucleoli and increased mitotic figures. Small vacuoles found in the dysplastic cells were also observed in the cytoplasm of the neoplastic hepatocytes (Figure 1-C2). This finding suggests a synergistic interaction of AFB_1 and nodularin in the pathogenesis of liver tumors.

In addition to liver tumors, other pathological changes included small eosinophilic, basophilic and clear hepatocellular foci in these groups of animals.

Contribution of cyanotoxins and HBV x gene to the development of liver tumors during the short period

Although a wild-type mouse treated with MC-LR was

Table 1 Incidences of liver tumors caused by exposure to aflatoxin B_1 (AFB_1) and cyanobacterial toxins (CT) alone or in combination in HBV x (HBVx) gene transgenic mice and their wild-type littermates at 24 wk post-treatment

MC-LR: Microcystin-LR; NOD: nodularin. [a]$P < 0.05$ *vs* group 1, [b]$P < 0.01$ *vs* group 1, [c]$P < 0.05$ *vs* group 9, [d]$P < 0.01$ *vs* group 1, [e]$P < 0.05$ *vs* group 3, [f]$P < 0.01$ *vs* group 9.

found to have a basophilic adenoma (Figure 1-B1), no hepatic tumors were observed in all transgenic and other wild-type animals treated with either MC-LR or nodularin. None of DMSO-treated transgenic animals was found to have pathological alterations relevant to tumorigenesis during the 24-wk period. A few small clusters of basophilic and clear hepatocytes were identified in cyanotoxin-treated animals (Figure 1-B2, B3). This finding reveals that cyanotoxins and HBV x gene may play a critical role in the pathogenesis of liver tumors as a tumor promoter rather than an initiator.

Contribution of co-exposure to AFB_1 and cyanotoxins to the pathogenesis of liver tumors in HBV x gene transgenic mice during the short period

As shown in Table 1, transgenic mice treated with AFB_1, followed by MC-LR have a similar risk of liver tumors to their wild-type littermates with the same treatment at 24 wk (20.0% *versus* 19.0%). Consistently, the HBV x gene did not significantly enhance the risk of liver tumors induced by both AFB_1 and nodularin compared to wild-type mice with the same dosing regimen (36.4% *versus* 33.3%). These findings suggest no appreciably combinative hepatotumorgenecity of AFB_1, cyanotoxins and HBV x gene during the 24-wk observation.

DISCUSSION

The nature of coexistence of many types of biotoxins in complex environmental samples, such as food and water, has been reported worldwide. Clear evidence has shown that human populations, particularly HBV carriers in high-risk areas of HCC, are exposed to multiple potent biotoxins, such as aflatoxins and cyanotoxins, through their daily diet and drinking water[24]. To test the epidemiological finding of a combinative risk of HCC associated with co-exposures to AFB_1, cyanotoxins and HBV, we performed a series of tumorigenic studies in HBV x gene transgenic mice treated with AFB_1 and/or cyanotoxins. Although a little inflammation was observed at 52 wk, there was no obvious cell death or regeneration process in DMSO-treated transgenic mice. Even no tumors developed in them during the observation up to 52 wk. Expression of HBV x gene in the liver of AFB_1-treated mice was associated with a greater than 2-fold increase in the incidence of liver tumors at 52 wk post-treatment as compared with AFB_1-treated wild-type littermates. This finding indicates that the HBV X protein functions as a cofactor during AFB_1-mediated hepatocarcinogenesis. The cofactor role of HBV x antigen in the development of hepatocellular carcinoma was also found in the studies of mice carrying HBV x gene exposed to hepatocarcinogen DEN[8,9]. Alternatively, studies of co-tumorgenicity of HBV and AFB_1 using other HBV transgenic mouse models have established that the fragment of HBV genome encoding the entire HBV surface antigen confers a 4- to 20-fold increase in the incidence of liver tumors[11,25].

The underlying mechanism by which the HBV X protein predisposes hepatocytes to the carcinogenic effect of chemical agents has not been fully understood. One possible explanation is the HBVx-induced modulation of specific phase I and II metabolizing enzymes that are involved in bioactivation and elimination of AFB_1. Over-expression of HBV surface antigen and x gene was associated with up-regulated expression of specific cytochrome P450 (CYP) isoforms[10] and responsible for bioactivation of AFB_1 to the ultimate carcinogenic form, exo-AFB_1-8,9-oxide[26]. Additionally, hepatocellular HepG2 cells transfected with HBV demonstrated significant decreases in total GST activity and the level of GST α class[27]. This class of GST is well known to catalyze the reaction in which the AFB_1-8,9-epoxide is detoxified in

the form of glutathionyl-AFB_1 conjugate. Expression of HBV x gene alone, however, was insufficient to induce transactivation of CYP and GST genes or to alter the antioxidant system[28]. Therefore, this possible explanation of the synergistic carcinogenic effect of AFB_1 and HBV x gene remains controversial. A second possible mechanism is the ability of the x gene to inhibit DNA repair, leading to accumulation of DNA mutations induced by chemical carcinogens[29]. HBV X protein has been shown to interact with protein or protein complexes that are directly involved in DNA repair. HBV X protein interferes with the nucleotide excision repair pathway through altering activities of helicases[30,31] or interacting with X-associated protein1 to affect the recognition of bulky lesions in DNA[32]. Another possible mechanism is HBVx transactivation of a wide variety of cellular and viral genes as well as the induction of signaling pathways[7,33]. HBV X protein can induce cell proliferation and deregulate cell-cycle checkpoints, which promotes the survival and proliferation of altered hepatocytes after exposure to a mutagenic agent. HBV X protein transactivates the proto-oncogenes like c jun/fos, c myc and cytokine-encoding genes such as tumor necrosis factor α and transforming growth factor β. On the other hand, HBV X protein can inactivate the cellular tumor suppressor gene product, p53[34]. These findings indicate HBV X protein acts as a tumor promoter in hepatocarcinogenesis. For the virus itself, HBV X protein was reported to enhance the virus replication by activating viral gene expression[35]. Although HBV X protein alone was reported to induce liver tumors in HBVx transgenic mice[36-38], our study showed that HBV X protein alone was insufficient to induce pathologic changes relevant to carcinogenesis, which was consistent with the studies by Lee *et al*[39] and Reifenberg *et al*[40]. The discrepancy may be a result of different genetic backgrounds of transgenic models. In studies showing liver tumors in HBVx transgenic mice, a mouse strain with a very high incidence of spontaneous liver tumors was used[36]. Since our transgenic mice were derived from C57BL/6J mice, the expected incidence of spontaneous liver tumors was less than 4%[38]. In addition, the factor responsible for the difference may include the DNA fragment of HBV genome which was subcloned to the vector. The segment of DNA used in our study contained only the entire coding region of the HBV x gene; by contrast, Yu *et al*[38] used the DNA fragment containing the sequences of HBV x gene, the pre C, and the transcriptional enhancer. Another possibility is the integration site of target gene to the host genome and the copy number of transgene. Our result indicated that the expression of x protein alone predisposes hepatocytes to AFB_1-induced carcinogenesis, although x protein itself does not induce liver tumors.

In the short-term study of the contribution of cyanotoxins alone and in combination with two other factors to the risk of liver tumors, a few altered hepatocellular foci were identified in transgenic and wild-type mice exposed to cyanotoxins alone. With the exception of an MC-LR-treated wild-type mouse with basophilic adenoma, however, no hepatic tumor was found in animals treated with cyanotoxins alone. HBV x gene was not shown to promote the hepatotumorigenicity of cyanotoxins. An important finding in this study, however, was derived from wild-type animals receiving both AFB_1 and cyanotoxins (MC-LR or nodularin). For wild-type animals, the treatment with both AFB_1 and MC-LR was more likely to induce liver tumors than the treatment with one of them during the short-term observation, although the increase in risk was non-significant. Additionally, wild-type mice with the treatment of both AFB_1 and nodularin have a higher risk of liver tumors 24 wk post-exposure than wild-type animals treated with one of them. The difference in risk reached the statistically significant or marginally significant level. These findings suggest that MC-LR and nodularin possess an ability to modulate the development of liver tumors in the AFB_1-initiated animal model. Also, these data proved the previous finding that cyanotoxins are poor initiators and are strong tumor promoters[18,19,22]. Moreover, nodularin was indicated to be a more potent tumor promoter than MC-LR, which is consistent with two-stage carcinogenesis study of modulations of DEN-initiated GST-P-positive foci by cyanotoxins[18,22]. As opposed to what we expected, HBV x gene was not found to further enhance the tumor incidence caused by both AFB_1 and cyanotoxins. These results indicate that tumor promotion of cyanobacterial toxins is stronger than HBV X protein alone during 24-wk period. The tumor promoting activity of cyanotoxins may be attributable to inhibition of protein phosphotase 1 and 2A and subsequent hyperphosphorylation of proteins[41]. The possibility of combinative hepatocarcinogenesis of AFB_1, cyanotoxins and HBV x gene could not been ruled out based on our finding. In this study, the tumorigenic effect of these factors was observed during the short period. Generally, the *in vivo* study of carcinogenesis was carried out in a period of more than a year. Actually, our preliminary study found that two out of four HBV x gene transgenic animals developed liver tumors 52 wk after the treatment with AFB_1, followed by cyanotoxins. The incidences of AFB_1-induced liver tumors were 5.0% and 9.1% in wild-type and transgenic animals, respectively, at 24 wk after the treatment. The same treatment, however, caused a greater than two-fold increase in the incidence in wild-type mice and approximately five-fold increase in transgenic mice at 52 wk post-treatment. Therefore, observation duration is a critical factor in studies of tumorigenicity of potential carcinogens. If the observation period is prolonged, the difference in tumor risk, which was not found significant in the short-term study, may be discernible.

Another limitation of this study was the route of administration of toxins. Repeated injections of cyanotoxins may result in tumor occurrence, although no tumor was observed in almost all animals treated with cyanotoxins. It would be ideal to conduct future studies where the animals are fed AFB_1-contaminated food and cyanotoxin-contaminated drinking water to best fit a model relevant to human exposure.

In conclusion, our study shows that AFB_1 is a strong tumor initiator, and that HBV x gene and nodularin

significantly promote the development of AFB_1-induced liver tumors. Although the significance of the contribution of MC-LR to AFB_1-initiated hepatotumorigenesis is weak, co-exposure to AFB_1 and MC-LR tended to elevate the risk of liver tumors at 24 wk relative to exposure to one of them. HBV x gene could not further increase the contribution of cyanotoxins to AFB_1-initiated liver tumors during the short period. Accordingly, a long-term study of interactive hepatocarcinogenesis of these three factors is needed to confirm the present finding.

ACKNOWLEDGEMENTS

The authors sincerely thank Yan Jin, Shuang-Yuan Kuang and Yi-Qian Wu in Shanghai Cancer Institute for their assistance with screening of HBV x gene transgenic mice, and also thank Professors Shi-Ya Zhu and Yuan-Ding Xu in Fudan University for their work in pathological examinations of all sections.

Abstract

AIM: To evaluate the possible influences of HCV infection and relative antiviral treatment on seminal parameters and reproductive hormonal serum levels.

METHODS: Ten male patients with HCV-related chronic hepatitis and 16 healthy male volunteers were studied. In all subjects seminal parameters (nemaspermic concentration, progressive motility, morphology) and hormonal levels were determined. Seminal parameters and inhibin B, follicle-stimulating hormone, luteinizing hormone, total and free testosterone, estradiol, prolactine in patients were measured after six and twelve months of antiviral combined (interferon + ribavirin) treatment.

RESULTS: Patients before treatment showed a significantly lower nemaspermic motility and morphology as well as lower inhibin B and free testosterone levels than controls. Inhibin B levels in cases were improved six and 12 mo after treatment in five responders (161.9 ± 52.8 pg/mL versus 101.7 ± 47.0 pg/mL and 143.4 ± 46.1 pg/mL versus 95.4 ± 55.6 pg/mL, respectively). Hormonal pattern of patients did not significantly change after treatment, with the exception of estradiol levels with an initial reduction and an overall subsequent increment (19.7 ± 6.4 pg/mL versus 13.6 ± 5.0 pg/mL versus 17.3 ± 5.7 pg/mL). However in 1-year responders a significant increment of free testosterone (14.2 ± 2.54 pg/mL versus 17.1 ± 2.58 pg/mL) occurred. An impairment of nemaspermic morphology occurred, while other seminal parameters did not change significantly during antiviral treatment.

CONCLUSION: Patients with HCV infection show worse spermatic parameters than controls, suggesting a possible negative influence of virus on spermatogenesis, with further mild impairment during antiviral treatment. However therapy could improve the spermatic function, as suggested by the increased inhibin B levels and improved hormonal pattern in responders. Further studies are needed to confirm these preliminary intriguing results.

INTRODUCTION

Hepatitis C virus (HCV) chronic infection is widespread in the world with about 150-180 millions of carriers[1]. Chronic HCV-related hepatitis is a frequent condition with a significant clinical impact due to the rare spontaneous virus disappearance in carriers. Virus transmission occurs predominantly *via* parenteral routes, but is often unclear. Sexual and maternal transmissions are rare (about 5%)[2]. Combined administration of peghilated α-interferon (PEG-IFN) plus ribavirin is the treatment of choice for HCV infection (from 45% to 80% of virus eradication)[3].

HCV is involved in many extrahepatic conditions and at least one of these manifestations is present in 74% of cases (the term "HCV disease" has been used to underline its systemic aspects)[4,5]. The association between extrahepatic diseases and HCV infection has not been definitely proven. Moreover, no organ-specific antibodies (ANA, SMA, anti-LKM) are present in 20%-40% of cases with uncertain role, which might be the results of lymphocyte B stimulation by HCV or the HCV-induced anti-LKM1 recognition of specific antigens[6, 7].

Mixed cryoglobulinemia is the most frequent extrahepatic HCV manifestation (43%-90% of cases)[8, 9]. Other associated diseases include crioglobulinaemic nephropaty and glomerulonephritis[10,11], thyroid diseases (during or after interferon treatment)[12, 13], autoimmune gastritis and

less frequently Sjögren or Sjögren-like syndromes[14], idiopathic pulmonary fibrosis[15], porphyria cutanea tarda[16], lichen planus[17], type 2 diabetes mellitus[18]. Moreover interferon frequently seems to precipitate latent autoimmune gastritis, particularly in females, which is often associated with antityroid antibodies[19].

Very few studies have been performed to evaluate the presence of HCV-RNA in seminal fluid and spermatozoa, particularly in candidates for assisted reproduction techniques, whose seminal parameters and fertility are very poor.

The presence of the virus in the cervico-vaginal secretions has been already demonstrated, while data about its presence in semen are controversial[2]. Indeed polymerase chain reaction (PCR) inhibitors in seminal fluid, especially *Taq* polimerase inhibitors, could interfere with results obtained by this methodology. Levy *et al*[20] suggested that HCV-RNA could be found in males' semen when *Taq* inhibitors have been suppressed by diluitions, thus explaining the previous contradictory results. The authors demonstrated that 30% of the studied males show semen abnormalities (two oligozoospermias and ten oligoasthenoteratozoospermias), confirming the presence of HCV-RNA in the seminal fluid before antiviral treatment for high serum viral load carriers[21]. On the contrary, Debono and co-workers[22] showed that HCV-RNA could not be detected in semen (seminal fluid and spermatozoa) either by PCR or by branched DNA or *in situ* hybridisation[22]. Moreover, these studies have confirmed the low prevalence of HCV sexual transmission.

The aim of this study was to evaluate the seminal parameters (volume, pH, nemaspermic concentration, motility and morphology) and reproductive hormone serum levels including follicle-stimulating hormone (FSH), luteinizing hormone (LH), prolactine (PRL), 17-β-estradiol (17-βE), total and free testosterone, inhibin B, in subjects with chronic HCV-related hepatitis before and after six and twelve months of standard antiviral combined therapy (peg-interferon plus ribavirin), in order to verify the possible influences of the virus and/or antiviral treatment on seminal and hormonal variables.

MATERIALS AND METHODS

Patients

Ten consecutive male patients (age range 33-39 years) affected by HCV-related chronic hepatitis, followed at our department, with viral replication (17 240-5 176 100 copies/mL, branched DNA vers.3.0) and increased aminotransferase levels (1.4-4 X) were enrolled in March-April 2003. They showed normal hepatic function (values of bilirubin, albumin and coagulative parameters within ranges) and no ultrasonographic features of portal hypertension. Viral genotypes were 1 (60%), 2 (20%), and 3 (20%). Causes of viral transmission were unknown in all patients. Two subjects (monitored as blood donors) were infected in the last few months, the mean duration of infection was 11.0 ± 2.7 years. Nobody showed either history of cryptorchidism, varicocele or other conditions at risk for infertility, or other causes of liver disease (HBV, alcohol, autoimmunity, hemochromatosis, *etc*) and previous treatment for hepatitis C.

Sixteen male healthy volunteers aged 18-52 years, without history or features of liver disease, were enrolled in the same period and served as the control group.

Table 1 Characteristics of controls and patients before antiviral treatment (mean ± SD)

Parameters	Cases	Controls
Number	10	16
Age (yr)	36.3 ± 2.4	29.7 ± 7.3
Sperm concentration (n/mL)	85.5 ± 63.5	103.6 ± 54.1
Normal motility (%)	45.7 ± 8.8	60.4 ± 6.9
Normal morphology (%)	28.1 ± 9.6	42.0 ± 6.7
Inhibin B (pg/mL)	101.7 ± 47.0	192.8 ± 78.6
Free testosterone (pg/mL)	15.2 ± 2.2	21.4 ± 3.1
Total testosterone (μg/L)	6.72 ± 2.1	6.7 ± 1.3
Prolactine (μg/L)	8.19 ± 5.1	4.6 ± 1.9
LH (mU/mL)	4.02 ± 2.2	2.5 ± 0.7
FSH (mU/mL)	4.81 ± 1.8	3.6 ± 1.4
17-βE (pg/mL)	19.7 ± 6.4	14.9 ± 2.9

A trained blinded operator investigated chemical-physical characteristics of seminal fluid (volume, pH, sperm concentration, motility and morphology) in patients and controls, according to the WHO criteria and recommendations (1992/1999)[23]. The following hormones were measured in HCV patients and controls: FSH, LH, PRL, estradiol, total and free testosterone, inhibin B. FSH, LH and PRL were determined by immunoradiometric assay (IRMA) (FSH: normal values [nv] 1.2-10 mU/mL; intra- and inter-assay coefficients of variation [CV] 7.5%-8.3%; sensitivity 0.18 mU/mL; LH: nv 1.5-7 mU/mL, CV 5.8%-13.8%, sensitivity 0.20 mU/mL; PRL: nv 2-12 ng/mL, CV 2.7%-8.9%, sensitivity 0.5 ng/mL). 17-βE and total/free testosterone levels were determined by radioimmunoassay (RIA) (17-βE: nv 10-40 pg/mL, CV 10.5%-9.1%, sensitivity 1.4 pg/mL; total testosterone: nv 3-10 ng/mL, CV 8.7%-13.7%, sensitivity 0.05 ng/mL; free testosterone: nv 16-41 pg/mL between 20-50 years of age and 9-31 pg/mL > 50 years of age, CV 10.6%-9.9%, sensitivity 0.15 pg/mL). Serum inhibin B was measured by enzyme linked immunosorbent assay (ELISA) (nv 97-330 pg/mL, CV <7%, sensitivity < 15 pg/mL).

The same seminal parameters and hormone levels were determined in cases at 6 and 12 mo after starting antiviral combined treatment with 1.5 μg/kg peg-interferon α2b a week plus ribavirin 800-1200 mg a day (according to weight). The duration of treatment was twelve months.

Statistical analyses were performed using Student's *t*-test and when appropriate, using matched pair t-test. Age-adjustments were performed by a multiple regression model.

RESULTS

The sperm concentration was not significantly different between controls and cases (before antiviral therapy), while nemaspermic motility and morphology were lower in the latter (after age adjustment: $P = 0.0002$ and $P = 0.0003$ respectively). The two patients with more recent HCV infection presented the worse seminal parameters: progressive motility < 40%, normal morphology < 20%. Inhibin B and free testosterone were significantly lower in patients than in controls (after age-adjustment: $P = 0.004$ and $P < 0.001$ respectively) (Table 1).

After six months of combined antiviral treatment, sperm concentration and motility did not significantly

Table 2 Seminal and hormonal parameters in responders and non responders before, during and after treatment (mean ± SD)

	Month 0	Month 6	Month 12	Month 0	Month 6	Month 12
	Non responders			Responders		
Sperm concentration (*n*/mL)	84.2 ± 56.6	69.0 ± 35.5	66.6 ± 36.1	86.9 ± 76.6	35.2 ± 25.8	76.8 ± 75.3
Normal motility (%)	45.2 ± 7.0	51.4 ± 13.9	46.0 ± 7.4	46.2 ± 10.7	37.0 ± 17.8	43.8 ± 24.3
Normal morphology (%)	34.8 ± 7.6	24.6 ± 11.3	26.0 ± 6.8	21.4 ± 6.0	14.4 ± 9.2	21.6 ± 12.8
Inhibin B (pg/mL)	98.0 ± 49.2	166.4 ± 30.3[b]	95.4 ± 55.6	105.3 ± 50.1[a]	157.4 ± 72.7	143.4 ± 46.1
Free Testosterone (pg/mL)	16.2 ± 1.6	16.4 ± 2.0	16.9 ± 3.4	14.2 ± 2.5	14.6 ± 2.8	17.1 ± 2.6[c]
Total testosterone (μg/L)	7.4 ± 2.0	7.9 ± 0.9[d]	6.6 ± 1.0	6.0 ± 2.0	7.3 ± 2.1	6.9 ± 1.0
PRL (μg/L)	7.0 ± 3.8	7.9 ± 1.8	8.9 ± 3.3	9.4 ± 6.3	7.4 ± 3.9	6.5 ± 2.8
LH (mU/mL)	4.2 ± 2.1	3.6 ± 1.8	3.0 ± 1.2	3.8 ± 2.6	4.5 ± 2.5	3.6 ± 0.7
FSH (mU/mL)	4.8 ± 1.7	4.9 ± 1.0	5.7 ± 1.6	4.8 ± 2.1	5.2 ± 0.8	5.1 ± 0.9
17-βE (pg/mL)	19.4 ± 5.3[e]	14.6 ± 5.1	20.2 ± 6.8	20.0 ± 7.9	12.7 ± 5.2	14.5 ± 2.8

[a]$P = 0.039$ (0 *vs* 12 mo); [b]$P < 0.01$ (6 *vs* 12 mo); [c]$P < 0.05$ (0 *vs* 12 mo); [d]$P < 0.05$ (6 *vs* 12 mo); [e]$P < 0.01$ (0 *vs* 6 mo).

change in HCV patients, while further alterations in morphology appeared ($P = 0.01$). At the same time inhibin B levels significantly increased ($P = 0.004$) (Table 2).

Viraemias at the sixth month were negative in seven patients and there were not any significant differences in seminal and hormonal parameters between the former and the three patients with persistent viraemia. Two responders had virological breakthrough at 12 mo and a total of five patients (50%) showed a full response to combined antiviral therapy.

At 12 mo sperm concentration and motility did not significantly change with respect to basal values and 6 mo parameters, and nemaspermic morphology improved slightly in responders. Inhibin B levels increased after six months of therapy both in responders and in non responders. However after twelve months inhibin B values significantly decreased only in non responders (Table 2). Hormone levels were within normal range in all the patients, even if estradiol values significantly decreased at six months with respect to basal values in non responders, but at twelve months its values were raised in non responders and reduced only in responders (Table 2).

A significant increment in free testosterone levels from baseline to the 1 year evaluation occurred (respectively 14.2 ± 2.54 pg/mL versus 17.1 ± 2.58 pg/mL, $P = 0.04$). Furthermore 1-year hormonal pattern was generally better in responders than the corresponding basal levels, even if the values did not reach the statistical significance probably owing to the small number of subjects.

DISCUSSION

Some reports have linked HCV infection to many extrahepatic manifestations, but not all associations have been definitely demonstrated[4]. These data suggest that HCV chronic infection could alter seminal parameters, particularly reduce the percentage of spermatozoa with normal progressive motility and morphology. Patients showed significantly lower levels of free testosterone and inhibin B, a glycoproteic hormone produced by Sertoli cells which is considered a sensible marker of good spermatogenesis[24]. This reduction could be one of the consequences of the altered gametogenesis found in HCV patients.

The combined antiviral therapy could cause a further alteration in spermatic morphology. On the other hand, its antiviral activity could improve spermatogenesis, as demonstrated by the increased inhibin B levels after six and twelve months of therapy in responders. Moreover, after one year of therapy, the responders showed an overall better hormonal pattern than non-responders. Therefore both HCV chronic infection and related antiviral treatment could act on spermatogenesis.

HCV sexual transmission is quite rare and not all authors have identified viral RNA in sperm[20-22]. Previous studies were performed in the context of assisted reproductive techniques, in order to investigate the risk of infection transmission during performing such techniques. The possible interference of HCV with spermatogenesis has not been previously assessed, thus any comparisons with literature are quite difficult.

It has been shown that HCV can stimulate production of reactive oxygen species (ROS) through expression of core protein with resulting *in vitro* and *in vivo* mitochondrial injury, which might explain its hepatic damage, at least in part[25]. Furthermore, oxidative stress could injure genomic integrity in male germinal cells and cause infertility[26]. Thus, oxidative stress induced by HCV-RNA presence in seminal fluid, could directly or indirectly impair spermatogenesis.

These preliminary data show the negative influence of HCV infection on spermatogenesis and the possible beneficial effect of antiviral therapy. A further follow-up of this cohort is therefore necessary. In the present study, some patients did not eliminate HCV after treated for six months, but interferon could act on HCV sufficiently to eliminate adverse seminal effects. This has been demonstrated for HCV-related membranoproliferative glomerulonephritis[11]. In interferon responders, proteinuria decreased from 6.1 g to 1.3 g, while in non-responders a lower decrement was observed.

This is the first report about hormonal and seminal changes in patients with HCV-related chronic hepatitis

during antiviral treatment. Further studies are necessary to confirm these associations and to determine the exact action on seminal and hormonal pattern in order to establish if semen cryoconservation is useful before the therapy in these patients.

Abstract

AIM: To evaluate the production of reactive oxygen species (ROS) and the expression of inducible nitric oxide synthase (iNOS) in rat isolated Kupffer cells (KCs) stimulated by *Leptospira interrogans* and *Borrelia burgdorferi*.

METHODS: Rat Kupffer cells were separated by perfusion of the liver with 0.05% collagenase, and purified by Percoll gradients. Purified Kupffer cells were tested *in vitro* with alive *L.interogans* and *B. burgdorferi* preparations. The production of ROS was determined by chemiluminescence, whereas iNOS protein expression was evaluated by Western blot assay using anti-iNOS antibodies.

RESULTS: *B. burgdorferi* and to a less extent *L. interrogans* induced ROS production with a peak 35 min after infection. The chemiluminescence signal progressively diminished and was undetectable by 180 min of incubation. *Leptospirae* and borreliae induced an increased iNOS expression in Kupffer cells that peaked at 6 hours and was still evident 22 h after infection.

CONCLUSION: Both genera of spirochetes induced ROS and iNOS production in rat Kupffer cells. Since the cause of liver damage both in leptospiral as well as in borrelial infections are still unknown, we suggest that leptospira and borrelia damage of the liver can be initially mediated by oxygen radicals, and is then maintained at least in part by nitric oxide.

INTRODUCTION

The spirochete *Leptospira interrogans* and *Borrelia burgdorferi* are the etiological agents of leptospirosis and Lyme disease, respectively. All spirochetoses share a bacteriemic phase during the early stage of infection. During this phase, *leptospires* can cause hepatitis in humans, resulting in microscopic alterations in the liver, including enlargement of Kupffer cells (KCs)[1]. In Lyme disease, liver function test abnormalities are common but mild, most often not associated with symptoms[2], rarely with hepatitis. The causes of hepatitis and abnormal liver function tests in leptospiral and borrelial infections are not known. Circulating levels of tumor necrosis factor α (TNF-α) have been detected in patients with leptospirosis and are associated with the severity of the disease[3]. Although borrelial invasion may cause direct hepatocyte damage, the acute "viral-like" illness associated with early *B.burgdorferi* dissemination raises the possibility that systemic or local cytokine release as well as other as yet unknown factors may be responsible for hepatic enzyme elevations[2].

The use of *in vitro* and animal models has shown that spirochetes are phagocytized by KCs, the resident macrophages of the liver[4]. Kupffer cells play an important role in host defense due to their ability to phagocyte bacteria and to detoxify endotoxins[5]. Furthermore, activated KCs play a major role in the initiation and maintenance of liver

damage in the above experimental models via production of inflammatory cytokines[6], and trigger a process called the respiratory burst, which involves an increase in cellular oxygen consumption, the production of reactive oxygen species (ROS)[7-10] and nitric oxide (NO) [11]. ROS is cytotoxic for a variety of microorganisms[12], sometimes, however the target of ROS is not limited to the invading pathogens, but can also be extended to host tissues[13], and in the case of the liver, it has been shown that inactivation of KCs prevents liver injury[14]. In this case ROS may cause oxidative damage by peroxidation of membrane phospholipids and alteration in DNA or mithocondrial functions.

Nitric oxide (NO), a gaseous free radical, is a potent biological mediator in a myriad of physiological and pathological events[11]. Abnormalities of NO production have been hypothesized to mediate macrophage cytotoxicity in host defence reactions and to inhibit smooth muscle contraction, hepatocyte metabolism and protein synthesis[15] and to be of central importance in the pathogenesis of many disease processes[16]. Moreover, increased NO production can function as an adaptive response to acute hepatic inflammation and early sepsis[17, 18]. NO production is mediated by members of the nitric oxide synthase (NOS) family[19]. The iNOS isoform is usually activated from inflammatory cytokines and bacterial products, and is responsible for generating high levels of NO[11].

In this study we analyzed the interaction of live *L. interrogans* and *B. burgdorferi* with isolated rat KCs *in vitro*, as far as the production of ROS and iNOS expression is concerned.

MATERIALS AND METHODS

The following spirochete strains were used: *B. burgdorferi* IRS (ATCC 35211) and *L. interrogans* serovar icterohaemorrhagiae (a gift of M. Fabbi, Istituto Zooprofilattico Sperimentale, Pavia, Italy). Borreliae were cultured in Barbour-Stoenner-Kelly (BSK) II medium at 34 ℃, as previously reported[20], whereas leptospirae were grown in liquid Ellinghausen-McCullough-Johnson-Harris (EMJH) medium at 30 ℃ under aerobic conditions to a density of about 10^8 bacteria per mL and counted in a Petroff-Hausser counting chamber.

When indicated, opsonized bacteria were prepared as follows: spirochetes were centrifuged and resuspended in RPMI 1640 at a concentration of 4×10^7 bacteria/mL. Bacterial suspensions were incubated for 30 min with pooled sera obtained from Lyme disease and leptospirosis patients, at a concentration of 10%. After incubation, spirochetes were washed twice in RPMI 1640 to remove nonhaderent antibodies.

Kupffer cells (KC) were harvested and separated following the procedure of Smedsrød and Pertoft[21] with some modifications, as previously reported[4]. Male Sprague-Dawley rats (180 g to 200 g body weight) were used as liver donors. The animals were anesthetized with pentobarbital sodium (50 mg/kg, intraperitoneally), and the livers were perfused through the portal vein, with 500 mL of calcium- and magnesium-free Hanks' balanced salt solution, which was pre-warmed to 37 ℃ and buffered at pH 7.3 with 10 mol/L HEPES (Sigma Chemicals, St. Louis, MO, USA). The effluent from the liver was collected from the inferior vena cava immediately above the sovrahepatic veins. The liver was then perfused with complete Hanks' balanced salt solution containing 0.05% collagenase (type IV; Sigma), pre-warmed to 42 ℃, and subsequentely excised and placed in a Petri dish. The liver capsule was peeled off and the cells were gently dispersed in calcium- and magnesium-free Hanks' balanced salt solution. The cells were then centrifuged at 50 r/min at 4 ℃ for 2 min in a Beckman J6B centrifuge (Beckman Instruments, Palo Alto, CA, USA). The non-parenchymal cell-enriched supernatant was centrifuged at 800 r/min for 10 min, the pellet was resuspended in 40 mL of phosphate-buffered saline (PBS), and portions of 10 mL were layered on top of a preformed two-step Percoll gradient, and centrifuged at 400 r/min for 15 min at 4 ℃. Purified non-parenchymal cells enriched in KCs extended throughout the lower Percoll cushion. The KC-enriched fraction was diluted in PBS and centrifuged at 800 r/min for 10 min. The resulting pellet was resuspended in culture medium (RPMI 1640 with 10% fetal calf serum) at a concentration of 1.0×10^6 cells/mL. A 0.5 mL portion of cell suspension was added to an 8-well culture plate (LAB-TEK, Nalge-Nunc International, Naperville, Ill). Macrophages were selected by allowing them to adhere for 2 h at 37 ℃, in an atmosphere with 50 mL/L. After non-adherent cells were removed by gentle washing, adherent cells were incubated with RPMI 1640 for 24 h before performing further experiments. As a control, immunofluorescence staining was performed with mouse anti-rat CD11b antibody (Research Diagnostics Inc, Flanders, NJ, USA), more than 95% of adherent cells were positive for CD11b macrophage marker.

Reactive oxygen species produced by KCs was determined by chemiluminescence (CL). The determination of ROS was performed as previously reported[6, 10]. Briefly, 0.25 mL of a suspension of purified KCs was added (2×10^6 cells/mL) to selected wells (see below) of a transparent 96-well microtiter plate (Nunclon, Nunc, Denmark). Macrophages were selected by allowing them to adhere for 2 h at 37 ℃, in an atmosphere with 50 mL/L CO_2. After non-adherent cells were removed by gentle washing, adherent cells were incubated with RPMI 1640 overnight before performing the assays. The culture medium was replaced with 200 μL of a fresh one, and 50 μL of a 3 mmol/L luminol solution (5-amino-2,3-dihydro-1,4-phthalazinedione sodium salt, Sigma) in TRIS buffer (0.1 mol/L, pH 7.4) was added to each well followed by 50 μL of a spirochete suspension in culture medium (final ratio 200-2000 bacteria/cell). All reagents were pre-warmed at 37 ℃ before addition. The final luminol concentration was 0.6 mmol/L. Each experiment was performed in triplicate. In order to normalize the CL signal for variables as the number of KCs and cell viability, Kupffer cells stimulated by a fixed concentration (0.8 μmol/L) of phorbol myristate acetate (Sigma) were used as positive control in each run. For each experiment, the background signal of the CL cocktail was evaluated by measuring blank samples constituted by Kupffer cells in growth medium.

The microtiter plate was placed in a luminometer (Luminoskan Ascent, Labsystems, Wallac Oy, Finland) at 37 ℃, and the CL emissions expressed as relative light units were

acquired at 2 min intervals for 3 h, using an integration time of 10 s. Quantitative evaluation of the signals was performed by evaluating the integrated CL signal over the whole measurement period. Then, the CL response of the system was expressed as the ratio between the integrated CL signal of the sample and that of the control. Additional control experiments, in which no luminol was added, were performed. Use of a microtiter plate format allowed to simultaneously follow the kinetics of the chemiluminescent emission for different samples in a simple way. Due to the possible cross-talk between adjacent wells, no more than 12 samples were measured in the same analytical session. Separate experiments carried out with a conventional chemiluminescent system (horseradish peroxidase, luminol, hydrogen peroxide) confirmed that for the emission intensities found in our experiments the cross-talk between different wells was negligible (less than 0.1%) if the wells were separated by at least two empty ones. Mean values of ROS production by KCs were compared using Student's *t*-test. $P < 0.01$ was considered statistically significant.

The determination of iNOS expression by SDS-polyacrylamide gel electrophoresis (PAGE) and Western blotting was performed as follows. KCs isolated as reported above, were incubated with 200 spirochetes/cell, re-suspended in RPMI 1640, opsonized and unopsonized up to 22 h. As positive controls LPS (10 μg/mL) and INF-γ (100 UI/mL) were used, whereas as negative control any stimuli were omitted. Three different time points were evaluated: 2, 6 and 22 h. At the end of each time point, KCs were scraped, diluted with sample buffer (20% vol/vol Tris 0.5 mol/L, pH 6.8, 2% w/vol SDS, 20% vol/vol glycerol, 10% vol/vol 2-mercaptoethanol, and 0.02% w/vol bromophenol blue) and sonicated. Protein concentration was determined by the Bradford assay. Separation of KC proteins (5 μg/each lane) was performed with a Laemmli buffer system by using a 12% acrylamide gel, as previously described[22]. The Western blot procedure was performed as previously described[23]. Briefly, after electrophoretic transfer, the blots were incubated overnight at room temperature with polyclonal rabbit anti-iNOS antibodies (Affinity Bioreagents, Golden, CO, USA) diluted 1:100 in PBS containing 0.05% (vol/vol) Tween 20. Antigen-antibody complexes were detected using peroxidase-labeled porcine antibodies to rabbit immunoglobulins (DAKO, Copenhagen, Denmark) diluted 1:100 in PBS-Tween. The apparent molecular weight of each band was determined by plotting the positions of rainbow low molecular weight standards (Amersham Biosciences, Little Chalfont, UK). Blots were scanned and the intensity of iNOS bands was determined capturing the images with a Kodak 120 Zoom Digital Camera (Eastman Kodak Company, Rochester, New York, USA) and image processing was performed with Kodak Digital Science 1D 3.0.2 (Eastman Kodak Company, Rochester, New York, USA).

RESULTS

To study ROS production by KCs following incubation with spirochetes, the liver macrophages were incubated alone or with different numbers of spirochetes, and the production of ROS was determined by chemiluminescence. Spirochetes induced ROS production in KCs in a dose-dependent manner (Figure 1). Opsonization of spirochetes increased ROS production, but the increase was not statistically significant (Figure 2), in addition the ROS production induced by borreliae was about twice the generation of oxygen radicals induced by leptospirae ($P < 0.01$) (Figure 2). The time course study of oxygen radical generation showed that ROS was detectable as early as 20 min after the beginning of infection. Leptospirae and borreliae both induced ROS production with a peak 35 min after the addition of spirochetes. The chemiluminescence signal progressively diminished following incubation time and was undetectable for all spirochete preparations at 180 min of incubation (Figure 3). Further time point determinations (4, 6 and 8 h) did not show any ROS production (data not reported).

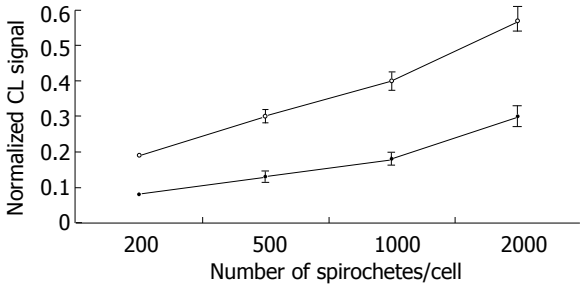

Figure 1 Chemiluminescence (CL) detection of reactive oxygen species generation by Kupffer cells stimulated by L.interrogans and B.burgdorferi. Kupffer cells were incubated in triplicate with borrelia (white circles) and leptospira (black circles) preparations at various bacteria/KC ratio, for 3 h in the presence of 0.6 mM luminol. The chemiluminescence emissions were acquired at 2 min intervals for 3 h. The experiments were repeated three times, and data points represent the mean ± SD of the integrated chemiluminescence signal, normalized to that of the control.

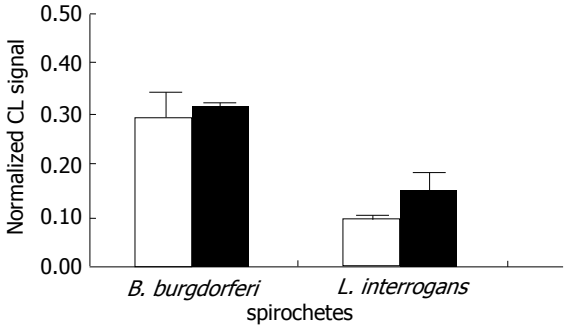

Figure 2 Effect of spirochete opsonization on the chemiluminescence (CL) signal. Each value represents the mean ± SD of three independent experiments carried out at a ratio of 500 spirochetes/KCs using unopsonized (white bars) and opsonized (grey bars) bacteria. Note that the ROS production induced by borreliae was about twice the ROS generation of leptospirae.

To determine whether spirochetes could modify iNOS expression in KCs, iNOS protein was looked for by Western blot assay using polyclonal anti-iNOS antibodies that specifically detect a band of molecular weight of 130 Ku[24]. Kupffer cells were collected 2, 6 and 22 h after bacterial stimulation at the ratio of 200 bacteria/cell. Untreated Kupffer cells as well as LPS- and interferon-γ-stimulated Kupffer cells were also studied. The protein content of each sample was determined and samples of 5

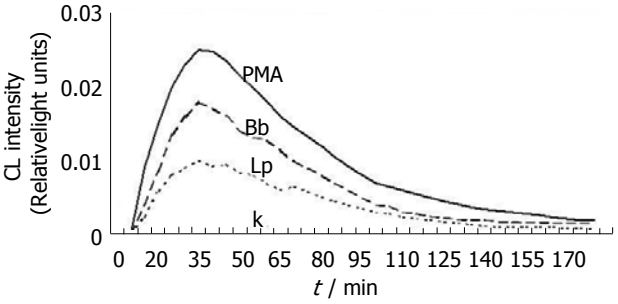

Figure 3 Chemiluminescence kinetic profiles of reactive oxygen radical generation in Kupffer cells treated with L.interrogans and B.burgdorferi. Bacteria were used at a ratio of 2000/KCs. Lp and Bb stand for leptospirae and borreliae, respectively. PMA represents Kupffer cells treated with phorbol myristate acetate, whereas K represents untreated control Kupffer cells.

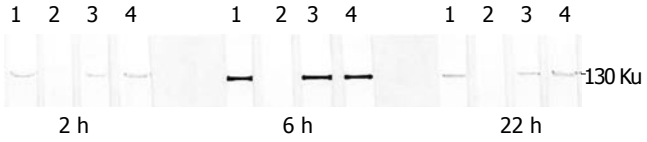

Figure 4 iNOS determination by SDS-polyacrylamide gel electrophoresis and by Western blotting in Kupffer cells stimulated by L. interogans and B. burgdorferi. The 130 ku iNOS protein band was detected by specific polyclonal rabbit anti-iNOS antibodies. The iNOS protein band was evident 2 h after infection. The band peaked 6 h after infection and was still evident 22 h after infection. Lane 1: Kupffer cells stimulated by LPS and interferon-γ (positive control); lane 2: Kupffer cells not stimulated (negative control); lane 3: Kupffer cells stimulated by L.interrogans; lane 4: Kupffer cells stimulated by B.burgdorferi.

μg of protein content were run in each lane and separated by SDS-PAGE. The proteins were then blotted and tested with specific anti-iNOS antibodies. The blots were then scanned and the intensity of iNOS bands was determined capturing the images. The iNOS protein band was evident 2 h after infection. The band peaked 6 h after infection and was still evident 22 h after infection. Six hours after infection, the iNOS band was 5 and 2.5 times more intense than that 2 h and 22 h after infection, respectively. The iNOS protein band was also induced by LPS plus INF-γ (positive controls), whereas the iNOS was not detectable in the absence of stimulating agents (Figure 4). No evident differences in the expression of iNOS protein were seen between KCs stimulated with *B. burgdorferi* and *L. interrogans*, both of which were opsonized and unopsonized.

DISCUSSION

The macrophages of the liver, referred to as Kupffer cells are the most abundant mononuclear phagocytes in the body. The major function of KCs is to clear particulate and foreign materials and micro-organisms from the blood. When activated by antigens or inflammatory stimuli, KCs release superoxide anions, hydrogen peroxide, nitric oxide and hydrolytic enzymes. Kupffer cells also release a number of different immunoregulatory and inflammatory cytokines, including interleukin (IL-1), IL-6, tumor necrosis factor α, interferon-γ[25, 26].

Leptospirae and borreliae are phagocytosed by the Kupffer cells in the absence of opsonizing antibodies (Marangoni *et al* personal Communication VIII International Conference on Lyme borreliosis, Munich, 20-22 June, 1999). The pro-inflammatory cytokine TNF-α is produced by Kupffer cells treated with spirochetes and leptospirae have about twice the stimulatory effect of borreliae[6]. Leptospiral lipo-oligo-saccharide plays a pivotal role in the TNF-α release[6].

The generation of ROS by macrophages and the expression of iNOS occur during the phagocytosis of bacteria, fungi and protozoa[27-29]. In the present work, we comparatively studied the ability of KCs to generate ROS and to express iNOS when stimulated by *L. interrogans* and *B. burgdorferi*. Our findings showed that both the genera of spirochetes induced ROS production in KCs. The use of such a very sensitive method as CL allowed us to demonstrate that when the same amount of bacteria was employed ROS production induced by borreliae was about twice the generation of oxygen radicals induced by leptospirae. This could be partly due to the different size of the bacteria, *B. burgdorferi* being longer and wider than *L. interrogans*. The production of ROS had a maximum 35 min after infection and was undetectable 180 min after infection. The transient feature of the oxidative burst is well documented in monocytes and macrophages, in particular, a similar short-lived and self-limiting oxidative response has also previously been observed during phagocytosis of *Salmonella* by mouse peritoneal macrophages[30, 31] and during the phagocytosis of *T. pallidum* by Kupffer cells[9]. In this study, opsonized leptospirae as well as opsonized borreliae did not enhance ROS production by Kupffer cells in comparison with non-opsonized bacteria. In general, opsonization enhances phagocytosis of bacteria and consequently the production of ROS. However, it has been previously demonstrated (Marangoni *et al* personal Communication VIII International Conference on Lyme borreliosis, Munich, 20-22 June, 1999) that opsonization of leptospirae and borreliae does not enhance phagocytosis by Kupffer cells. Kupffer cells phagocytose leptospirae and borreliae at the same rate in the presence and in the absence of opsonizing antibodies. This probably comes from a constitutional attitude of these bacteria that are not able to escape phagocytosis, differently from *T. pallidum*, a spirochete able to evade phagocytosis by macrophages to a certain extent.

Regarding iNOS, we established that both borreliae and leptospirae induced iNOS expression by Kupffer cells and observed no substantial differences between the two genera of spirochetes in inducing iNOS production.

iNOS is regulated at the transcriptional level of the gene and once induced, iNOS production is maintained for several hours or days[24]. Kupffer cells produce nitrite and nitrate, the end stable products of NO pathway and the overproduction of NO by hepatic cells play a major role in hepatic injury and necrosis[32] associated with endotoxic shock. Kupffer cells also synthetize several cytokines in response to LPS which in turn stimulate the hepatocytes to produce NO[33].

The present *in vitro* investigation demonstrated that

both borreliae and leptospirae could induce iNOS in rat Kupffer cells and that iNOS production was delayed with respect to ROS production. The *in vivo* exposure of KCs to these bacteria, as in the case of leptospirosis and Lyme disease, could lead to a maintained production of NO. In fact, iNOS produces NO from hours to days and overproduction of NO can stimulate neighbouring hepatocytes to generate NO[28] in the liver, resulting in the production of NO over a long period of time after exposure of KCs to leptospirae and borreliae.

In conclusion, our data suggest that a factor responsible for hepatic enzyme elevations in leptospirosis as well as in Lyme disease might be a sequential mechanism of damage initiated by oxygen radicals produced in KCs and maintained by NO production in KCs and likely in hepatocytes.

Abstract

AIM: To investigate the correlation of depressed-type (0-IIc) colorectal neoplasm and family history of first-degree relatives (FDR) with colorectal cancer (CRC).

METHODS: This cross-sectional study was conducted from June 2000 to October 2002 at National Cancer Center Hospital East. Eligible patients undergoing initial total colonoscopy were surveyed regarding family history of CRC among FDR by a questionnaire prior to colonoscopic examinations. All endoscopic findings during colonoscopy were recorded and the macroscopic classification of the early stage neoplasm/cancer was classified into two types (0-IIc *vs* non 0-IIc). Odds ratios (OR) and 95% confidence intervals (CI) were calculated by univariate and multivariate logistic regression to estimate the association between macroscopic features and clinicopathological data including gender, age, and family history of FDR with CRC.

RESULTS: The OR of an association between family history of FDR with CRC and overall early stage neoplasm adjusted by gender and age was 1.85 (95% CI: 1.31-2.61, P = 0.0004), that for non 0-IIc neoplasm was 1.71 (95% CI: 1.22-2.41, P = 0.0017) and for 0-IIc colorectal neoplasm was 2.78 (95% CI: 1.49-5.16, P = 0.0031).

CONCLUSION: Our study shows a significant association between a family history of FDR with CRC and 0-IIc colorectal neoplasm. When patients with a family history of FDR with CRC undergo colonoscopy, colonoscopists should check carefully for not only polypoid, but also depressed-type (0-IIc) lesions.

INTRODUCTION

In Japan, colorectal cancer (CRC) is the third most important cause of cancer mortality and the incidence of CRC is increasing gradually[1]. The prognosis for patients with CRC is strictly dependent on early detection of premalignant and malignant lesions. Familial risk management is one of the important strategies for CRC prevention. There is evidence from cohort and case-control studies that people with close relatives with CRC have an increased risk of CRC and develop the disease at a younger age than those without a family history of CRC[2-4]. In clinical guidelines and rationale for CRC screening and surveillance in USA, approximate lifetime risk of CRC, when a first-degree relative (FDR) was affected with large bowel malignancy, was found to increase by 2-3 fold[5]. In addition, there is a report that a family history of CRC is a strong risk factor for adenoma growth[6,7].

However, previous studies concerning familial risk for CRC did not investigate the data from the perspective of macroscopic classifications of colorectal neoplasm. As the Paris endoscopic classification of superficial neoplastic lesions in the colon proposed, special attention is attached to depressed-type (0-IIc) lesions. Even when the diameter is small, 0-IIc lesions are often at a more advanced stage of neoplasia, with deeper invasion than other types of lesion[8,9]. However, to our knowledge, whether the risk of 0-IIc colorectal neoplasm is correlated with family history of FDR with CRC has not been investigated previously.

In this study, we therefore investigated the correlation of 0-IIc colorectal neoplasm and family history of FDR with CRC.

MATERIALS AND METHODS

Eligibility and exclusion criteria

Between June 2000 and October 2002, all patients undergoing initial total colonoscopy at National Cancer Center Hospital East were screened for eligibility for this study. The exclusion criteria were age < 50 years old, past history of surgical resection for CRC, past history of endoscopic treatment for colorectal neoplasm, family history of familial adenomatous polyposis or hereditary non-polyposis colorectal cancer, past history of inflammatory bowel disease and presence of either submucosal tumor, metastatic colorectal tumor or ischemic colitis. Informed consent was obtained from all patients.

Questionnaire of family history and past history

All patients had been asked for family history of CRC among FDR of patients by a questionnaire prior to colonoscopic examinations. Colonoscopists were kept unaware of this information until the end of the examinations.

Total colonoscopy

A preparatory solution of electrolytes and polyethylene glycol was administered orally to each patient. An anti-cholinergic agent was administered intramuscularly before each examination to prevent persistent colonic spasms, if there was no contraindication to its use. Total colonoscopies were performed using magnifying colonoscopes (CF200Z, CF240Z; Olympus Optical Co. Ltd, Tokyo, Japan). All detected lesions were diagnosed by magnifying colonoscopy using a non-biopsy technique to differentiate between hyperplastic polyps and adenomas[10,11]. When any neoplasm was suspected, 0.2% indigo carmine dye was sprayed on the area to highlight the lesions. All detected lesions were finally diagnosed by magnification with chromoendoscopy, and the lesions diagnosed as neoplasm were removed or biopsied to evaluate the histological findings. Lesions, diagnosed as hyperplastic polyps macroscopically or histologically, were excluded from this analysis.

Histological and macroscopic evaluation

Histological diagnoses were based on the classification of the World Health Organization (WHO)[12]. Intramucosal neoplasms, including intramucosal carcinoma and submucosal cancer that had spread through the muscularis mucosa into the submucosa, were defined as early stage neoplasm/cancer. Malignant lesions involving the muscularis propria or beyond on histological examination were classified as advanced cancer.

All endoscopic findings during colonoscopy were recorded at each examination. The macroscopic classification of early stage neoplasm/cancer was classified into two types (0-IIc *vs* non 0-IIc) using the system proposed by the Japanese Society for Cancer of the Colon and Rectum[13], which is nearly similar to the Paris endoscopic classification proposed in 2003[8]. In this study, type 0-IIc lesions included the combined type (0-IIc+IIa, 0-IIa+IIc, 0-Is+IIc)[9] and laterally spreading flat-type tumor[14,15]; so called "LST non-granular type" as described by Kudo in 1993[16]. Other macroscopic type lesions were classified as the non 0-IIc type.

Table 1 Initial colonoscopic findings of the patients

Patients without neoplasm	579 (36.5%)
Patients with neoplasm	1007 (63.5%)
Patients with only early stage neoplasm/cancer	651 (41.0%)
Patients with only advanced cancer	206 (13.0%)
Patients with both early stage neoplasm/cancer and advanced cancer	150 (9.5%)

Statistical analysis

Odds ratios (OR) and 95% confidence intervals (CI) were calculated by univariate and multivariate logistic regression to estimate the association between macroscopic features (early stage neoplasm/cancer, 0-IIc or non 0-IIc) and clinicopathological data including gender, age, family history of FDR with CRC. Two-sided *P* values less than 0.05 were considered statistically significant. Analyses were performed with Stata software (Version 9.0 for Windows, StataCorp LP. TX, USA).

RESULTS

A total of 2079 patients who underwent initial colonoscopy were screened; 1586 were enrolled in this study. Of 493 excluded patients, 297 were less than 50 years old, 84 had a past history of surgical resection for CRC, 62 had a past history of endoscopic treatment for colorectal neoplasm, 7 had a family history of familial adenomatous polyposis or hereditary non-polyposis colorectal cancer, 4 had inflammatory bowel disease; and the rest were excluded because of the presence of either submucosal tumor, metastatic colorectal tumor or ischemic colitis.

Patient characteristics

The study consisted of 1586 patients, including 1002 (63.2%) men and 584 (36.8%) women, with median age 63 (range, 50-96) years. There were 159 (10.0%) patients with a family history of FDR with CRC.

Detected neoplasm during colonoscopy

In 579 patients (36.5%), there were no neoplastic lesions detected on the initial colonoscopy. Colorectal neoplasm was found in 1 007 (63.5%) patients, among whom 651 (41.0%) patients had only early stage neoplasm/cancer, 206 (13.0%) patients had only advanced cancer, and 150 (9.5%) patients had both (Table 1). Furthermore, 775 (48.9%) patients had at least one non 0-IIc lesion and 63 (4.0%) patients had at least one 0-IIc lesion. The prevalence of 0-IIc colorectal neoplasm was 4.6% (95% CI: 3.3-5.9) in men and 2.9% (95% CI: 1.5-4.3) in women.

In terms of age, the prevalence was 4.1% (95%CI: 2.9-5.3) in men and 3.7% (95% CI: 2.1-5.3) in women. These data showed that there was no statistical difference in frequency of 0-IIc colorectal neoplasm among gender and age. In addition, there were 14 (8.8%) patients with 0-IIc lesions and a family history of FDR with CRC.

Association between early stage, non 0-IIc, 0-IIc colorectal neoplasm and variables

Univariate analysis demonstrated that gender, age, and the family history of FDR with CRC were significantly associated with the prevalence of early stage and non 0-IIc colorectal neoplasm. On multivariate analysis, gender and the family history of FDR with CRC were significantly correlated with early stage and non 0-IIc colorectal neoplasm, although there was no significant association between non 0-IIc colorectal neoplasm and age (Tables 2 and 3). Univariate and multivariate analyses demonstrated that only a family history of FDR with CRC was significantly correlated with 0-IIc colorectal neoplasm, whereas gender and age were not found to be significant (Table 4). The OR of association between 0-IIc colorectal neoplasm and family history of FDR with CRC adjusted by gender and age was higher than that of non 0-IIc

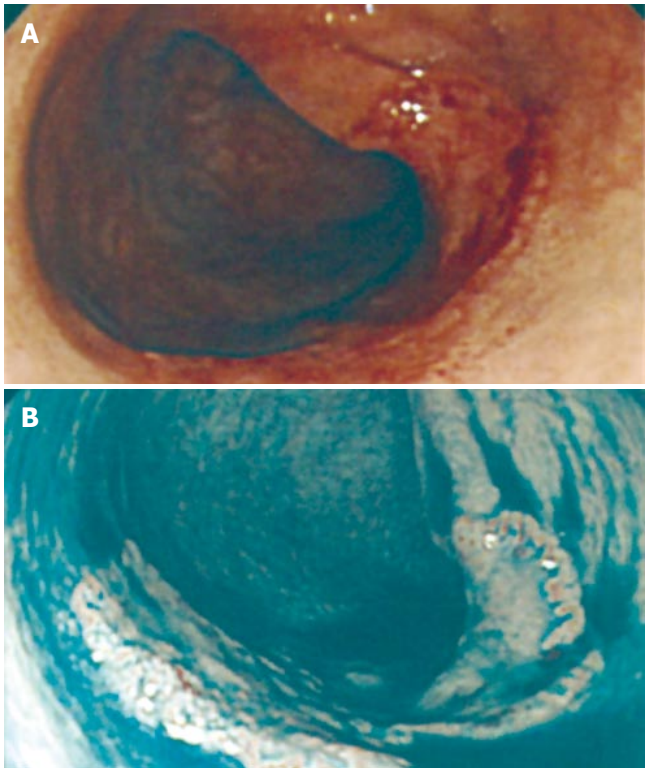

Figure 1 Superficial depressed lesion (0-IIc). **A**: A superficial depressed lesion (0-IIc) of the transverse colon, 27 mm in diameter. Initially it was recognized as a broad patch of erythema and deformity of the haustrum. The patient demonstrated a family history of CRC. His mother had a past history of sigmoid colon cancer at age of 65 years. **B**: After dye spraying, an absolutely depressed area could be clearly identified, with a slightly elevated margin.

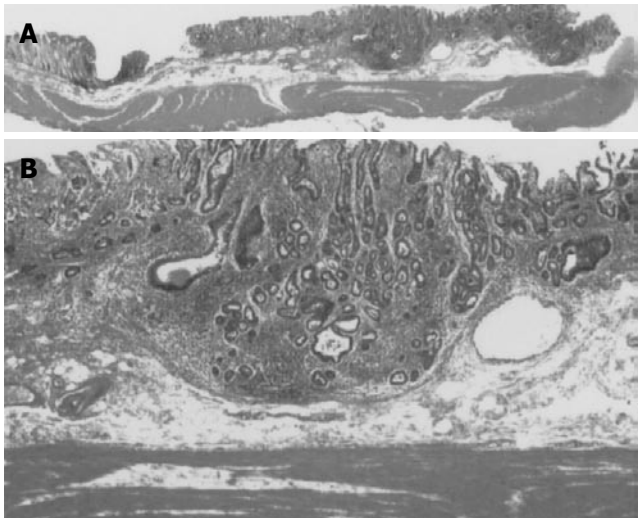

Figure 2 Histological findings. **A**: Low-power histological view of a cut section of the resected specimen confirmed Dukes' A (T1 stage) carcinoma with invasion to the submucosa. **B**: High-power histological view confirmed a well differentiated adenocarcinoma invading 1000 μm below the muscularis mucosa.

colorectal neoplasm (OR = 2.78, 95% CI: 1.49-5.16, P = 0.0031 *vs* OR = 1.71, 95% CI: 1.22-2.41, P = 0.0017).

DISCUSSION

Colorectal neoplasm with superficial morphology is broadly classified into two types, such as polypoid type and non-polypoid type[8,13]. In terms of polypoid type neoplasm, the adenoma-carcinoma sequence has formed the rationale for CRC screening and prevention in Western countries[5,17]. In addition, it is also known that familial risk management is one of the important strategies for CRC prevention due to its associations with bowel malignancy[5] and adenoma growth[6,7]. Almendingen *et al*[7] reported a significant association between family history of FDR with CRC and adenoma growth (adjusted OR = 3.9, 95% CI: 1.2-13.4). In the present study, family history of FDR with CRC was significantly correlated with non 0-IIc colorectal neoplasm (OR = 1.71, 95% CI: 1.22-2.41, P = 0.0017), which tends to show a result similar to previous reports. However, these data are mainly based on the polypoid type colorectal neoplasm.

As the Paris endoscopic classification of superficial neoplastic lesions in the colon proposed, special attention should be focused on depressed-type 0-IIc lesions[8], which are now widely recognized in Western countries as well as in Japan. This recognition has important implication, as the proportion of CRC is likely to be higher in these lesions than in other types, and these lesions tend to be more advanced at the time of diagnosis, despite being smaller[18-23]. Furthermore, it is certainly more difficult to detect 0-IIc colorectal neoplasm than polypoid type lesions during colonoscopy. They usually appear only as patches of erythema or irregularity of the mucosal fold (Figures 1 and 2), so colonoscopists should develop an understanding of the 0-IIc lesion[9]. At the same time, it is very important to identify risk factors for 0-IIc colorectal neoplasm, so if patients with some risk factors for these lesions undergo colonoscopy, we could be more alert to recognizing the lesions. However, it has not been reported whether the risk of 0-IIc colorectal neoplasm is correlated with any patient characteristics, including family history of FDR with CRC.

In the present study, 0-IIc colorectal neoplasm was detected in 63 patients (4.0%), which is nearly similar to data (1.94%-5%) reported by other institutes in Japan[8,9]. More importantly, our study showed a significant correlation with family history of FDR with CRC and 0-IIc colorectal neoplasm (OR = 2.78, 95% CI: 1.49-5.16, P =0.0031), suggesting the possibility of a genetic contribution to the occurrence of 0-IIc colorectal neoplasm. Recently, two major pathways for colorectal neoplasm are highly suspected. Compared to the polypoid lesions arisen in the pathway of adenoma-carcinoma sequence, depressed-type (0-IIc) lesions are proposed to arise in *de novo* pathway and show rapid growth. Molecular biology also suggests that depressed-type lesions are likely to have early *P53* and delayed K-*ras* mutations distinct from the former pathway[24,25]. Moreover, there tends to be high microsatellite instability occurrence in *de novo* cancers compared to early cancers with adenoma[25]. It is also noteworthy that Ricciardiello *et al*[26] have reported there is higher degree of microsatellite instability among patients with family history of FDR with CRC. These results may support our positive association between depressed-type colorectal neoplasm and family history of FDR with CRC.

In addition, the pathway of depressed-type lesions evolving rapidly into a small flat invasive carcinoma is hypothesized to be a major route in hereditary non-polyposis colon cancer (HNPCC)[8], for which the genes hMSH2, hMLH1, and others have been identified as being responsible. In our study, multivariate analysis stratified by age showed higher OR of association between 0-IIc colorectal neoplasm and family history of FDR with CRC in patients before age of 60 years than those after age of 60 years (OR = 4.06, 95% CI: 1.48-11.14, $P = 0.006$ *vs* OR = 2.28, 95% CI: 1.02-5.06, $P = 0.04$), whereas our colleagues previously reported that depressed-type lesions were predominant in the right colon[27]. These characteristics are similar to HNPCC, and further molecular genetic research for depressed-type 0-IIc lesions and HNPCC is required. However, to our knowledge, the association between a family history of FDR with CRC and 0-IIc colorectal neoplasm has not been investigated previously even on NPS (National Polyp Study in USA). The limitation of this study is that the prevalence of patients with neoplasm in this study was higher (63.5%) than that in the general population because of a characteristic of our cancer center hospital, because even we selected the patients who undergo initial total colonoscopy at our hospital, many patients are introduced from general hospital for further examination because of suspicion of colorectal cancer. Although the statistical analysis in this study could avoid these biases, this association should be confirmed in a prospective multicenter study.

In conclusion, the present study demonstrates a significant association between the family history of FDR with CRC and 0-IIc colorectal neoplasm. When patients with a family history of FDR with CRC undergo colonoscopy, colonoscopists should pay attention to not only polypoid, but also depressed-type (0-IIc) lesions.

Abstract

AIM: To investigate the incidence of bacterial overgrowth in the stomach by using a new endoscopic method in which intragastric hydrogen and methane gases are collected and analyzed.

METHODS: Studies were performed in 490 consecutive patients undergoing esophagogastroscopy. At endoscopy, we intubated the stomach without inflation by air, and 20 mL of intragastric gas was collected through the biopsy channel using a 30 mL syringe. Intragastric hydrogen and methane concentrations were immediately measured by gaschromatography. *H pylori* infection was also determined by serology.

RESULTS: Most of intragastric hydrogen and methane levels were less than 15 ppm (parts per million). The median hydrogen and methane values (interquartile range) were 3 (1-8) ppm and 2 (1-5) ppm, respectively. The high hydrogen and methane levels for indication of fermentation were decided if the patient had the values more than 90 percentile range in each sample. When a patient had a high level of hydrogen or methane in one or more samples, the patient was considered to have fermentation. The overall incidence of intragastric fermentation was 15.4% (73/473). Intragastric methane levels were higher in the postoperative group than in other groups. None of the mean hydrogen or methane values was related to *H pylori* infection.

CONCLUSION: Hydrogen and methane gases are more frequently detected in the stomach than expected, regardless of the presence of abdominal symptoms. Previous gastric surgery influences on the growth of methane-producing bacteria in the fasting stomach.

INTRODUCTION

Hydrogen breath tests have been used to evaluate intestinal transit, bacterial overgrowth, and disaccharidase deficiency[1-8]. As hydrogen production increases when a small amount of carbohydrate is supplied to colonic bacteria, the measurement of breath hydrogen concentration has been proposed as an indicator of carbohydrate malabsorption[2]. Similarly, breath methane excretion, which reflects an indirect measurement of the metabolism of the anaerobic colonic flora, has been measured[9,10]. Methanogenic bacteria utilize hydrogen, carbon dioxide, and then synthesize methane[11]. All methane absorbed from the colon reaches the lung and excretes into the breath[12]. If the fermentation occurs in the stomach, we can detect intragastric hydrogen and/or methane gas. We therefore attempted to collect intragastric gas endoscopically and measure the intragastric hydrogen and methane levels in order to determine the bacterial overgrowth in the stomach.

MATERIALS AND METHODS

Patients

Studies were performed in 490 consecutive patients (160 men and 315 women, 19-85 years old) undergoing upper endoscopy. None of the patients had a history of use of proton pump inhibitor (PPI), H_2-receptor antagonist (H_2-RA), antibiotics, steroids, or nonsteroidal anti-inflammatory drugs for a period of at least six month before the investigation. Twelve patients had a previous Billroth I

partial gastrectomy.

Collection of intragastric gas samples

Endoscopy was performed after a topical anesthesia gargle. At the time of endoscopic examination, we intubated the stomach without inflation by air, and 20 mL of intragastric gas was collected through the biopsy channel using a 30-mL syringe. The first 5 mL was discarded for reduction of dead-space error. Intragastric hydrogen and methane concentrations were immediately measured by gaschromatography using Breath Analyzer TGA-2000 (TERAMECS Co. Ltd. Kyoto) and expressed in parts per million (ppm). Linear accuracy response range was 2 to 150 ppm. After collecting an intragastric gas sample, the endoscopist inflated the stomach by air and observed the gastric mucosa.

Determination of H pylori status

At endoscopy, serum *H pylori* IgG antibody titers were measured with an ELISA method (HM-CAP). A value of >2.2 was considered seropositive and a value of <1.9 was considered seronegative. Patients with a value of neither less than 1.9 nor more than 2.2 were excluded from this study.

Statistical analysis

Data of intragastric hydrogen and methane were presented as medians, with interquartile ranges because they were not normally distributed. Comparisons of groups were made using the Mann-Whitney *U* test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Incidence of high hydrogen and methane value in the stomach

Seventeen patients were dropped from this study because their serum *H pylori* IgG antibody titers were indeterminate. Figures 1 and 2 show the distribution of intragastric hydrogen and methane levels in the remaining 473 subjects, respectively. Most of the levels were less than 15 ppm. Overall, the median hydrogen and methane values (interquartile range) were 3 (1-8) ppm and 2 (1-5) ppm, respectively. The high hydrogen and methane levels for indication of fermentation were decided if the patient had the values more than 90 percentile range in each sample. Based on this definition, high hydrogen levels were defined as ⩾21 ppm and high methane values as ⩾8 ppm. In this study, when a patient had a high level of hydrogen or methane in one or more samples, the patient was considered to have fermentation. The overall incidence of intragastric fermentation was 15.4% (73/473). The incidence of intragastric fermentation determined by the intragastric hydrogen level was 11.0% (52/473), whereas those determined by the intragastric methane level was 10.8% (51/473). Of 73 patients with intragastric fermentation, gastric cancer was found in 2 (2/4, 50%), gastric ulcer in 4 (4/38, 11%), duodenal ulcer in 3 (3/15, 20%), previous gastric surgery in 3 (3/12, 25%), and others in 61 patients (61/404, 15%).

Peptic ulcer and intragastric gas concentrations

Intragastric hydrogen and methane values in relation to endoscopic diagnosis are summarized in Table 1. Intragastric methane levels were significantly higher in the postoperative group than in the gastric ulcer group and in the other groups. Intragastric hydrogen levels were lower in the gastric ulcer group than in other groups but this did not reach statistical significance.

H pylori infection and intragastric gas concentrations

Figure 3 shows the means of intragastric hydrogen and methane concentrations by *H pylori* status. None of the mean values were related to *H pylori* infection.

DISCUSSION

Before the discovery of *H pylori* infection in 1983[13], it was demonstrated by many investigators that an increased number of bacteria had been found in the stomach in patients with achlorhydria or hypochlorhydria[14]. The type and numbers of microbial flora present in the stomach are affected by gastric pH[15-17], and a rise in intragastric pH has often been associated with an increased number of bacteria in gastric juice[18-20]. Atrophic gastritis is the most common cause of reduced gastric acid secretion, and it often results in bacterial overgrowth[21-23]. It is presently possible to reduce gastric acid secretion with H_2-RA or PPI. Treatment with PPI[24-26] or H_2-RA[27] induces a clinical state similar to atrophic gastritis with hypochlorhydria and frequently associated with bacterial overgrowth. Recently, there is considerable information on the efficacy of maintenance treatment with reflux esophagitis for up to 1 year[28-30]. As gastric acid plays an important part in the prevention of bacterial colonization of the stomach and the small intestine, reduction of gastric acid secretion by PPI or H_2-RA results in gastric and intestinal bacterial overgrowth[24-27,31,32]. In fact, it has been reported a marked increase in bacterial titers in fasting gastric aspirates from patients receiving H_2-RA[31,33,34]. On the other hand, the results of identification and quantification of microbes in samples from the gastrointestinal tract are significantly influenced by the culture technique[35].

The most direct method for diagnosing bacterial overgrowth is to perform microbiological cultures after obtaining gastric aspirates. Actually, the microbial flora, which is dominated by *Viridans streptococci*, *coaglase negative Staphylococci*, *Haemophilus sp.*[36], *Neisseria spp.*, *Lactobacillus spp.*, *Candida spp.*, and *Aspergillus spp.*[31], has been demonstrated. However, the study of gastrointestinal flora by direct methods is cumbersome, primary due to its inaccessible location. In addition, the results of identification and quantification of microbes in samples from the gastrointestinal tract are significantly influenced by difficulties in accurate tube placement, contamination during insertion, delay between sampling and inoculation of culture media, and inadequate anaerobic isolation techniques. In addition, intubation methods are time-consuming, and uncomfortable. Therefore, breath tests were devised as simple alternatives to these invasive tests.

Breath hydrogen measurement is now used in clinical practice to investigate several disorders, including small intestinal disaccharidase deficiencies, intestinal bacterial overgrowth, and orocecal transit time[1-8]. It is based on the ability of the anaerobic microflora of the colon to ferment carbohydrate that has traveled unabsorbed through the small intestine, and to produce hydrogen. This hydrogen is transported to the lungs and exhaled in the expired breath. Although breath tests, such as measuring fasting or postprandial hydrogen concentrations, are a noninvasive method, avoiding the risk of sampling error, it is unable to identify the site of overgrowth. Then, we attempted to measure intragastric hydrogen and methane concentrations so as to determine the site of bacterial overgrowth and the incidence of fermentation in the stomach.

We previously reported the endoscopic ^{13}C-urea breath test (e-UBT)[37] in which intragastric gas was collected and analyzed. Using the same sample collection method as e-UBT, hydrogen and methane gases, which are produced by hydrogen-producing bacteria, could be detected in the stomach. These values were considered to reflect directly the intragastric fermentation.

To the best of our knowledge, our study is the first investigation to measure directly intragastric hydrogen and methane concentrations. The values of intragastric hydrogen concentrations above 21 ppm and methane above 8 ppm were considered abnormal in this study. When a patient had a high level of hydrogen or methane in one or more samples, the patient was considered to have fermentation. The overall incidence of intragastric fermentation was 15.4% (73/473). There was no difference in the incidence of intragastric fermentation determined by hydrogen or methane concentrations. These results reveal that intragastric fermentation is found in more than 15% of patients without medication even after overnight fasting.

In this study, intragastric methane levels were higher in the postoperative group than in other groups, whereas there was a negligible difference of intragastric hydrogen levels between the postoperative stomach group and other groups, thereby suggesting that previous gastric surgery is more closely correlated to methane-producing bacterial overgrowth in the stomach, compared to hydrogen-producing bacterial overgrowth although the exact mechanism is unknown.

On the other hand, Fried *et al*[26] reported that most of the bacteria identified from the duodenal aspirates belonged to species colonizing the oral cavity and pharynx, suggesting a descending route of colonization. Also, Thompson *et al*[38] indicated that fermentation of ingested carbohydrate by oropharyngeal bacteria could contribute to measure breath hydrogen values soon after meal ingestion. In addition, many investigators have reported that treatment with PPI[23-25] or H_2-RA[26] induces a clinical state similar to atrophic gastritis with hypochlorhydria and a marked increase in bacterial titers in fasting gastric aspirates from patients receiving H_2-RA[18,20,21]. Although Husebye *et al*[36] have reported that fasting hypochlorhydria associated with gastric colonization of microbes belonging to the oro- and nasopharyngeal flora is highly prevalent in healthy old people, atrophic gastritis is the most common cause of reduced gastric acid secretion, and it often results in bacterial overgrowth[21,22]. We previously reported that intestinal metaplasia was detected in 65.4% (358/547) patients with serum IgG antibody to *H pylori*. Therefore, we expected that a discriminative value might be detected between *H pylori*-positive and *H pylori*-negative patients. As shown in Figure 3, none of the mean values were related to *H pylori* infection.

In summary, we measured directly intragastric hydrogen and methane concentrations using endoscopy and found the incidences of hydrogen and methane production in the stomach. In this new method, the intragastric

gas can be easily collected endoscopically and it does not take much time. Hydrogen and methane gases are more frequently detected in the stomach than expected, regardless of the presence of abdominal symptoms. Moreover, previous gastric surgery influences on the production of methane in the fasting stomach and probably the growth of methane-producing bacteria in the upper digestive tract.

Abstract

AIM: To investigate non-invasively the incidence of absorption of carbohydrates in diabetic patients during an oral glucose tolerance test (OGTT) and to determine whether malabsorption may be associated with insulin secretion and insulin resistance.

METHODS: A standard 75-g OGTT was performed in 82 diabetic patients. The patients received 75 g of anhydrous glucose in 225 mL of water after an overnight fasting and breath samples were collected at baseline and up to 120 min after ingestion. Breath hydrogen and methane concentrations were measured. Blood glucose and serum insulin concentrations were measured before ingestion and at 30, 60, 90, 120 min post-ingestion.

RESULTS: When carbohydrate malabsorption was defined as subjects with an increase of at least 10 ppm (parts per million) in hydrogen or methane excretion within a 2-h period, 28 (34%) had carbohydrate malabsorption. According to the result of increased breath test, 21 (75%) patients were classified as small bowel bacterial overgrowth and 7 (25%) as glucose malabsorption. Patients with carbohydrate malabsorption were older and had poor glycemic control as compared with those without carbohydrate malabsorption. The HOMA value, the sum of serum insulin during the test and the Δinsulin/Δglucose ratio were greater in patients with carbohydrate malabsorption.

CONCLUSION: Insulin resistance may be overestimated by using these markers if the patient has carbohydrate malabsorption, or that carbohydrate malabsorption may be present prior to the development of insulin resistance. Hence carbohydrate malabsorption should be taken into account for estimating insulin resistance and β-cell function.

INTRODUCTION

The oral glucose tolerance test (OGTT) is a widely used procedure in the diagnoses of diabetes and intermediate stages of hyperglycemia. Plasma glucose and insulin responses during this test reflect the ability of pancreatic β-cells to secrete insulin and the sensitivity of tissues to insulin[1]. However, it was reported that 2%-20% of carbohydrates escape small intestinal absorption[2]. Based on this fact, digestion and absorption of carbohydrates may affect the results of OGTT. If the patient had carbohydrate malabsorption, plasma glucose and insulin responses during OGTT should be lower. Furthermore, an interesting observation was the outcome of OGTT yielding a remarkable intra-individual variability[3] and this was explained by the hypothesis that the velocity of the initial phase of glucose emptying from the stomach may depend on the grade of interdigestive antral motor activity at the time of glucose ingestion[4]. Although a many investigators have reported a close association between gastric emptying and insulin secretion, the prevalence of absorption of carbohydrates in diabetic patients has been unknown.

H_2 breath tests have been used to evaluate intestinal transit, bacterial overgrowth, and disaccharidase

deficiency[5-12]. Because bacteria represent the sole source of gut H_2 and CH_4, fasting breath H_2 and CH_4 gases have been used as markers of colonic fermentation[13,14]. As H_2 production increases when a small amount of carbohydrate is supplied to colonic bacteria, the measurement of breath H_2 concentration has been proposed as an indicator of carbohydrate malabsorption[6]. Similarly, breath CH_4 excretion, which reflects an indirect measurement of the metabolism of the anaerobic colonic flora, has been measured[15,16]. Methanogenic bacteria utilize H_2, carbon dioxide (CO_2), and then synthesize CH_4[17]. CH_4 absorbed from the colon reaches the lung and excretes into the breath[18].

The aim of the present study was to investigate non-invasively the incidence of malabsorption of carbohydrates in diabetic patients during OGTT and to determine whether malabsorption may be associated with insulin secretion and insulin resistance.

MATERIALS AND METHODS

Patients

A standard 75-g OGTT was performed in 82 diet-controlled diabetic patients (42 women and 40 men; age range 30-84 years, average 62 years) without abdominal symptoms. Patients treated with alpha-glucosidase inhibitors were excluded from this study. None of the patients had a history of use of PPI, H_2-receptor antagonist, antibiotics, steroids, or nonsteroidal anti-inflammatory drugs for a period of at least six month before the investigation. Patients who had a previous history of partial gastrectomy were also excluded from the study. The study was approved by our Local Ethical Committee.

Procedures

The patients received 75 g of anhydrous glucose in 225 mL of water in the sitting position after an overnight fasting. Breath samples were collected at baseline and at 5, 10, 15, 20, 30, 40, 50, 60, 70, 80, 90, 100, 110, and 120 min after ingestion. Breath H_2 and CH_4 concentrations were measured with breath analyzer TGA-2000 (TERAMECS, Kyoto) and expressed in parts per million (ppm). Linear accuracy response range was 2 to 150 ppm. An increase of at least 10 ppm within a 2-h period is indicative of bacterial overgrowth or glucose malabsorption[19]. Venous blood samples were obtained before ingestion and at 30, 60, 90, and 120 min after ingestion and blood glucose and serum insulin concentrations were measured.

Calculations

The homeostasis model assessment (HOMA), fasting serum insulin, the sum of serum insulin during the test, and the Δinsulin/Δglucose ratio were used as indexes of insulin resistance. The HOMA value was calculated as follows: HOMA = fasting plasma glucose (mg/dL) × fasting insulin (pmol/L)/405. The Δinsulin/Δglucose ratio was calculated as follows: (insulin at 30 min - insulin at baseline)/(glucose at 30 min - glucose at baseline).

Statistical analysis

All values were expressed as means ± SD. Comparisons of groups were made using the Mann-Whitney *U* test. A *P* value less than 0.05 was considered statistically significant.

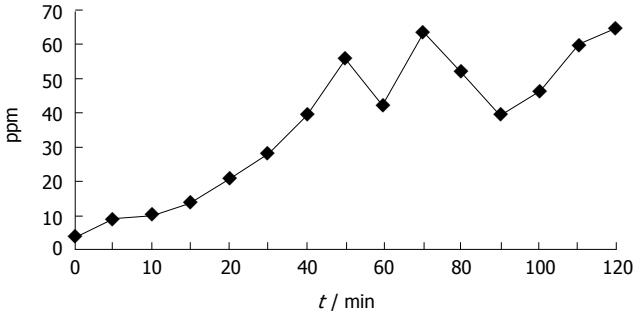

Figure 1 Changes in breath hydrogen concentration during OGTT in the patient with suspicious of small bowel bacterial overgrowth. An increase of H_2 greater than 10 ppm above the baseline was found at 15 min.

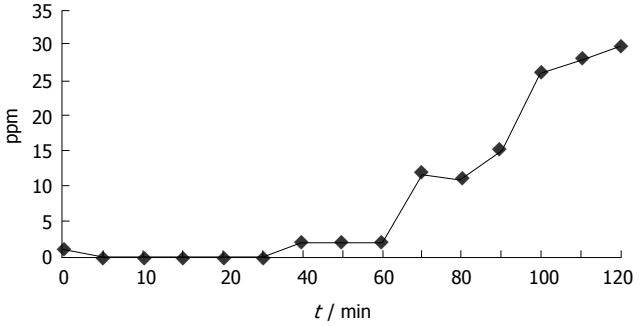

Figure 2 Changes in breath hydrogen concentration during OGTT in the patient with suspicious of carbohydrate malabsorption. Breath H_2 concentration increased gradually from the beginning and reached 10 ppm over the baseline at 70 min and later.

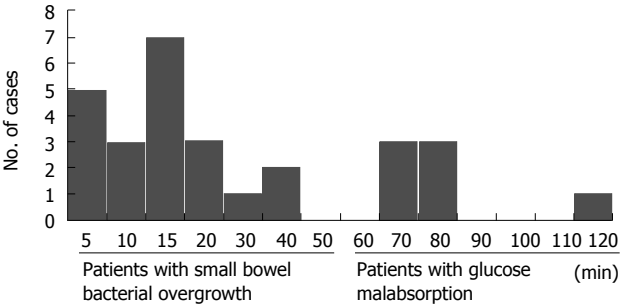

Figure 3 Distribution of time when breath hydrogen and/or methane levels increased more than 10 ppm over baseline.

RESULTS

Incidence of carbohydrate malabsorption

When carbohydrate malabsorption was defined as subjects with an increase of at least 10 ppm within a 2-h period, 34% (28/82) patients had carbohydrate malabsorption. As shown in Figures 1 and 2, small bowel bacterial overgrowth was defined as an increase of H_2 and/or CH_4 greater than 10 ppm above the baseline before the first 40 min, whereas carbohydrate malabsorption without small bowel bacterial overgrowth was defined as an increase of H_2 and/or CH_4 greater than 10 ppm above the baseline at 70 min and later. Of 28 patients with an increase of H_2 and/or CH_4, 21 (75%) patients were classified as small bowel bacterial overgrowth and 7 (25%) as carbohydrate malabsorption (Figure 3). All

Table 1 Characteristics of 82 patients with diabetes mellitus classified according to carbohydrate malabsorption status

	Carbohydrate malabsorption (+)	Carbohydrate malabsorption (-)	*P* value
n	28	54	
Age	63.3 ± 10.3	59.2 ± 9.7	0.34
HbA1c	7.1 ± 1.7	6.4 ± 1.5	0.17
HOMA	2.0 ± 2.1	1.9 ± 1.9	0.22
ΣIR	107.0 ± 95.3	117.0 ± 76.2	0.08
ΔIR/ΔBG	0.18 ± 0.27	0.14 ± 0.21	0.06

28 patients had no abdominal symptom during OGTT.

As shown in Table 1, the values of HbA1c were 7.11% ± 1.70% and 6.43% ± 1.46% in patients with and without carbohydrate malabsorption (including small bowel bacterial overgrowth), respectively. Patients with carbohydrate malabsorption were older and had poor glycemic control when compared with those without carbohydrate malabsorption.

Carbohydrate malabsorption and insulin resistance

The HOMA values in the patients with carbohydrate malabsorption (2.0 ± 2.1) were greater than those without carbohydrate malabsorption (1.94 ± 1.86), but did not reach statistical significance ($P = 0.22$). Similarly, the sum of serum insulin during the test and the Δinsulin/Δglucose ratio were also greater in patients with carbohydrate malabsorption than those without carbohydrate malabsorption (Table 1), but the difference was not significant.

DISCUSSION

Impaired intestinal and gastric motility are frequent findings in diabetic patients[19,20]. However, there is a wide range of symptoms in gastrointestinal motility disorders, and the degree of motility disorders correlate poorly with severity of symptoms. Intestinal peristalsis as well as gastric acid secretion are the most important factors protecting against the small bowel bacterial overgrowth[21]. Although delayed gastrointestinal transit potentially causes bacterial overgrowth, in contrast, a rapid transit may also cause diarrhea due to an increase in intraluminal contents that reach the cecum. It is, therefore, possible that both rapid and delayed gastrointestinal transit cause diarrhea because of bacterial overgrowth or carbohydrate malabsorption. However, patients with bacterial overgrowth may also be asymptomatic[22]. Although gastrointestinal symptoms are present in 50%-70% of diabetic patients, the association between symptoms and bacterial overgrowth in diabetic patients has been unknown.

In the present study, 34% (28/82) patients without abdominal symptoms, including diarrhea, had carbohydrate malabsorption, including 7 patients classified as small bowel bacterial overgrowth. It has been unclear how much of small bowel bacterial overgrowth is opposed to carbohydrate malabsorption. The results of the present study suggest that carbohydrate malabsorption occurs more often in diabetic patients than small bowel bacterial overgrowth.

There is increasing evidence that postprandial hyperglycemia has a major role in the pathogenesis of diabetic macrovascular complications[23,24]. It is widely recognized that postprandial glycemia is potentially dependent on a number of factors, including the rate of carbohydrate entry into the small intestine, small intestinal digestion and absorption, insulin secretion, peripheral insulin sensitivity, and hepatic and muscle glucose metabolism[25]. In addition, postprandial secretion of insulin is prompted as much by the incretin hormones as by entry of glucose into the blood, and the release of incretins is dependent on rates of nutrient entry into the small intestine[26,27]. Our observations confirmed that one third of patients with diet-controlled type 2 diabetes and without abdominal symptoms had carbohydrates malabsorption, which might contribute to postprandial hyperglycemia[25]. Some previous studies also described approximately 35% of the variance in initial postprandial blood glucose concentrations after a 75-g oral glucose load[28,29]. Since patients with carbohydrate malabsorption tended to be older and to have poor glycemic control as compared with those without carbohydrate malabsorption, it is possible that patients with long-standing or poor-controlled diabetes may more often have carbohydrate malabsorption. Conversely, the result and its interpretation of 75-g OGTT might be influenced by carbohydrate malabsorption.

A standard 75-g OGTT has also been used to assess insulin resistance and insulin release. For example, fasting plasma insulin concentrations have been used as an index of insulin resistance, and the 30-min ratio of changes in plasma insulin and glucose has been used as an index of β-cell function[30,31]. Insulin resistance, evaluated by the HOMA value, the sum of serum insulin during the test, and the Δinsulin/Δglucose ratio were greater in patients with carbohydrate malabsorption than those without carbohydrate malabsorption. However, these differences were not significant. This suggests that insulin resistance might be overestimated by using these markers if the patient has carbohydrate malabsorption, or that carbohydrate malabsorption might be present prior to the development of insulin resistance. In conclusion, it is more desirable that carbohydrate malabsorption should be taken into account for estimating insulin resistance and β-cell function.

Abstract

AIM: To explore the role of ghrelin in gallstone disease.

METHODS: We carried out a cross-sectional study in 150 subjects, 38 with gallstones (cases) and 112 controls. We also did a real-time PCR-RT study in twenty gallbladder samples each. Body mass index (BMI), serum insulin, ghrelin, and serum lipids were measured. Logistic regression analyses (univariate and multivariate) were conducted to estimate the probability of gallstone disease associated with serum ghrelin concentrations.

RESULTS: Cases were statistically different from controls in gender distribution (P = 0.01), age (53 *vs* 44 yr, P = 0.002), BMI (28 *vs* 25; P = 0.004), and glucose (5.26 *vs* 4.98 mmol/L; P = 0.05). The prevalence of ghrelin serum levels above the third tercile was lower in subjects without metabolic syndrome (P < 0.05). In a multivariate model, we found a protective effect, when ghrelin values were higher than the median value (OR = 0.27, 95%CI 0.09-0.82, P = 0.02). Twenty (20%) gallbladder specimens expressed ghrelin mRNA.

CONCLUSION: Serum ghrelin concentrations are associated with a protective effect of GD.

INTRODUCTION

Human obesity is associated with many significant comorbidities, including cardiovascular disease, diabetes mellitus, hypertension, stroke, osteoarthritis, and some cancers, gallstone disease (GD), *etc*[1]. GD is exceptionally common in Western populations and is a major source of morbidity in the United States[2] and Latin American countries[3]. A relation between obesity and cholesterol gallstones is well recognized. Obese women are more likely to develop gallstones than are obese men[4]. The bile in obese persons is more lithogenic than is that in nonobese persons, ie, the bile of obese persons has a high ratio of cholesterol to solubilizing lipids (bile acids and phospholipids). This high ratio predisposes to crystallization of cholesterol and gallstone formation. The primary reason for lithogenic bile in obese persons is an increase in total body synthesis of cholesterol[5,6].

Ghrelin is an endogenous ligand of the growth hormone secretagogue receptor and a potent stimulator of growth hormone release in humans[7] Ghrelin is synthesized primarily by the stomach, and in substantially lower amounts by the bowel, pituitary, kidney, placenta, and hypothalamus[8]. In both rats and humans, the ghrelin gene is made up of 4 exons and 3 introns and the precursors contain 117 amino acids (preproghrelin). Ghrelin processing results in different splicing and/or posttranslational mechanisms[9]. Two endogenous growth hormones-releasing peptides have been identified, ghrelin and growth hormone-releasing hormone (GHRH) acts on the GHRH receptor to activate adenylate cyclase and

increase intracellular cAMP, which serves as a second messenger to activate protein kinase A. This indicates that the GHRH receptor is coupled to a G_s subunit. On the other hand, ghrelin acts on the GHS-R and activates phospholipase C to generate IP_3 and diacylglycerol, resulting in an increase of intracellular Ca^{2+}, indicating that the ghrelin receptor is coupled to a G_q subunit[7]

Accumulating evidence suggests that ghrelin contributes to the short- and long-term regulation of body weight as a key element of a complex central signaling network that regulates food intake and energy expenditure[10]; its concentrations increase preprandially and decrease after meals, suggesting a role in meal initiation. Intravenous administration of ghrelin stimulates food intake in humans[11] Ghrelin induces a positive energy balance and induces adiposity in rodents by decreasing fat utilization[12]. Ghrelin concentrations are reported to be decreased in obesity[13] and increased after diet-induced weight loss[14].

The aim of this study was to explore the role of ghrelin in gallstone disease.

MATERIALS AND METHODS

Study population

We conducted a cross-sectional study, an immunohistochemistry study and a PCR-RT study in the check-up unit of the Diagnostic Clinic at the Medica Sur Clinic and Foundation (university hospital with subspecialty care) in Mexico City, Mexico. This hospital provides private care for mainly middle- and high-income individuals from Mexico City and the surrounding metropolitan area. Our sample population was formed from a series of consecutive asymptomatic subjects who were referred to the check-up unit by their companies as an annual requirement, not for symptomatic disease. The study included 150 subjects who agreed to participate, 38 subjects found to have GD (25 women, 13 men) and 112 controls (46 women and 66 men without GD). The study was approved by the Human Subjects Committee at The Medica Sur Clinic and Foundation as conforming to the ethical guidelines of the 1975 Declaration of Helsinki, and written informed consent was obtained from all subjects before commencement of the study. All subjects were asked to complete a questionnaire that included demographic and medical variables. The primary demographic and medical variables were gender, age, date of birth, tobacco and alcohol consumption, family history of cardiovascular disease, previous medical conditions, and previous surgery.

Medical exams included an abdominal ultrasonographic study on all subjects as part of the check-up evaluation. Cases were defined as subjects with an ultrasonographic diagnosis of GD (see below), and controls were defined as patients with no such evidence (sensitivity and specificity > 95%)[15].

Gallstone disease

Abdominal ultrasound was performed using a Sonoline Elegra instrument (Siemens Medical System, Germany) with a 3.5 MHz transducer. Ultrasound diagnosis of GD was assessed by the presence of strong intraluminal echoes that were gravity-dependent or that attenuated ultrasound transmission (acoustic shadowing). All ultrasonographic studies were evaluated, by the same radiologist on two different occasions. Subjects with previous cholecystectomies were not included in the study.

Diet history questionnaire

Participants completed a food frequency questionnaire with commonly used portion measures specified. The questionnaire included questions on the frequency and brand of multivitamin and individual vitamin supplements. The answers were subsequently electronically scanned and the daily intake of various nutrients was determined using SNUT software, a program developed by the Instituto Nacional de Salud Pública, Mexico City[16], and appropriate to the Mexican population, in order to estimate dietary energy, protein, carbohydrate, total, saturated, polyunsaturated and monounsaturated fat, vitamin, mineral, and antioxidant intake.

Physical examination

Body weight was measured, in light clothing and without shoes, to the nearest 0.10 kg. Height was measured to the nearest 0.5 cm. Body mass index (BMI) was calculated as weight in kilograms divided by height in meters squared. Overweight was defined as a BMI ranging from 25 to 29.9 kg/m^2 and obesity when BMI was $\geqslant$ 30 kg/m^2 Waist circumference (to the nearest 0.1 cm) was measured at the midpoint between the lower border of the rib cage and the iliac crest, and hip circumference was similarly obtained at the widest point between hip and buttock.

Analytical procedures

Insulin concentrations were measured using an immunoenzymometric assay (MEIA; Abbott Diagnostics), with inter- and intra-assay coefficients of variation less than 3%.

Serum glucose in the fasting state was measured in duplicate with an automated analyzer. The coefficient of variation for a single determination was 1.5%. Total cholesterol, high-density lipoprotein cholesterol (HDL-C), and triacylglycerol concentrations were measured by enzymatic colorimetric methods, using CHOL, HDL-C plus (second generation) and TG assays (Roche Diagnostics Co., Indianapolis, IN, USA), respectively. Low-density lipoprotein cholesterol (LDL-C) concentrations were calculated using the Friedewald formula[17].

Assessment of insulin resistance (IR) was made using the Homeostasis Model Assessment (HOMA-IR), as originally described by Matthews *et al*[18]: HOMA-IR = fasting insulin (U/L) × fasting glucose (mmol/L)/22.5.

Total serum homocysteine was measured with the fully automated Abbott IMx® homocysteine assay (Abbott Laboratories, Abbott Park, IL, USA). Homocysteine is quantified by the intensity of the polarized fluorescent light measured by the IMx optical assembly. Run-to-run CVs (n = 22) were 2.9, 0.8, and 1.7% at total homocysteine concentrations of 7, 12.5, and 25 μmol/L, respectively.

Serum ghrelin concentrations were determined by radioimmunoassay using RIA kits (Linco Research, St.

Table 1 Demographic, anthropometric, biochemical and diet variables between cases and controls

Variable	Cases n = 38 (median min–max)	Controls n = 112 (median min–max)	P-value[1] Mann–Whitney U test
Age (yr)	52.5 9-80	43.5 18-76	0.002

Physical activity (yes) [n (%)]	20 (52.6)	65 (58.0)	0.58[1]
Metabolic syndrome [n (%)]	15 (39.5)	18 (16.1)	0.006[1]

[1] Fisher's exact test (two-tailed).

Charles, MO, USA). The intra- and inter-assay coefficients of variation were both less than 5%.

Metabolic syndrome

Participants having three or more of the following criteria were defined as having the metabolic syndrome[9]. The waist to hip ratio > 0.85 and high body fat were defined according to previous definitions[19].

Ghrelin mRNA expression

Twenty products of cholecystectomy due to symptomatic gallbladder disease were collected prospectively and frozen at -70 ℃ until the simple was completed. Then, mRNA was extracted with a one-step technique using guanidine isotiocianate. Complementary DNA was synthesized and processed in real-time PCR using syber green colorant as detector. A qualitative study was performed using β-actin as control.

Statistical analysis

We established a comparison of continuous variables between cases and controls by means of the non-parametric test U of Mann-Whitney due to the non-normality in some variables. Categorical variables compared between cases and controls were evaluated with Fisher's exact test (two-tailed). In order to estimate, as main effect, the probability to be a case (GD) according to serum ghrelin values, we built a multivariate model in a logistic regression analysis, adjusted for potential confounders. The association measure derived from this analysis is the odds ratio (OR) estimate of the exponential of the regression coefficient. The statistical analysis was performed using SPSS/PC v12.0 Software (SPSS, Chicago, IL, USA).

RESULTS

Complete information was obtained in 38 cases and 112 controls. We observed differences between cases and controls in some variables, particularly in age (cases were older), in anthropometric variables (cases were more overweight, had central obesity and a higher percentage of body fat), and cases had a tendency to have more insulin resistance and higher serum homocysteine values than controls. The median of serum ghrelin values did not show a statistic difference between cases and controls (Table 1).

Table 2 Relationship between metabolic syndrome and serum ghrelin levels in subjects with gallstone disease

Ghrelin terciles	Metabolic syndrome criteria 0	1	2	3	4	5
1st	0	1	7	4	1	0
2nd	1	3	3	0	4	2
3rd	1	5	2	4	0	0

In addition, there was a statistic difference in the gender distribution between cases and controls. Cases had more women by proportion than controls (65.8% *vs* 41.1%, $P = 0.01$), more hypertension (42.1% *vs* 11.5%, $P < 0.0001$) and more metabolic syndrome (39.5% *vs* 16.1%, $P = 0.006$) (Table 1).

When analyze the relationship between metabolic syndrome and ghrelin serum levels (in subjects with gallstone disease), we observe that in those subjects with metabolic syndrome (three or more criteria, according ATPIII) the prevalence of ghrelin serum levels above the third tercile was lower than in subjects without metabolic syndrome (26.66% *vs* 34.78%, $P < 0.05$) (Table 2) Similar analysis was applied for subjects without GD, but any significant difference was founded (data not shown).

When we tested the main effect of ghrelin (divided by the median value), a protective association was observed (OR = 0.27, 95%CI 0.09-0.82, $P = 0.02$), indicating a reduction in the probability of being a case subject if

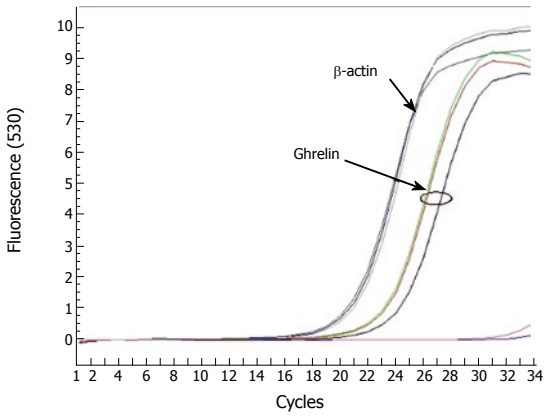

Figure 1 Amplification curves.

the serum ghrelin values are higher than the median, independent of the effect of the control variables: age (yr), gender (males *vs* female), diet lipids (%), homocysteine (μmol/L), BMI (kg/m^2), HOMA-IR, and physical activity (yes *vs* no). All the frozen samples showed ghrelin mRNA (Figure 1).

DISCUSSION

In the present study, we found a statistically significant, negative association of ghrelin serum levels and the prevalence of GD. Obesity is the main risk factor for developing GD and insulin resistance, clinically manifested as the metabolic syndrome. The prevalence of obesity has increased worldwide and is closely associated with an increased morbidity and mortality caused by common diseases of the Western world, such as diabetes, hypertension, coronary heart disease, GD and some cancers[20] Obese individuals are known to have lower ghrelin serum concentrations than healthy controls. In addition, low concentrations of ghrelin are thought to be a consequence of elevated serum levels of insulin and/or leptin, because fasting serum ghrelin concentrations are negatively correlated with fasting serum concentrations of insulin and leptin[13] Recently, ghrelin has been suggested as a regulator of other anorectic cytokines[21] associated with the metabolic syndrome.

Our results could be interpreted as an effect of the negative correlation between ghrelin serum levels and obesity, considering the burden of obesity in GD. However, after controlling for BMI and HOMA-IR, through multivariate analysis, the association remains statistically significant ($P < 0.05$). Even then, the association could arguably be a product of statistical analysis. However, we believed that there are major facts to be considered.

First, ghrelin was originally described both as a "growth hormone-secretagogue" and a "motilin-related peptide". Growth hormone has been associated with gallbladder motility, since hypopituitarism is associated with a form of gallbladder dysmotility that resolves after growth hormone replacement[22] and GD is a frequent complication of long-term octreotide treatment in acromegaly[23].

Second, motilin is a well known small intestine-derived factor in the regulation of gastrointestinal motility in humans involved in receptor-induced gastric motility[24] High motilin concentrations can induce growth hormone releasing effects similar to those of ghrelin and high ghrelin concentrations can induce the gastric prokinetic effect of motilin. Luiking *et al* showed that motilin induces gallbladder emptying in humans[25] and Stolk *et al*[26] observed an impaired motilin-response in fasting cholesterol gallstones patients.

Third, obesity-related insulin resistance could be a determinant factor in the pathophysiology of GD. Scragg *et al*[27] demonstrated higher insulin serum concentration in patients with GD, and an associated increase in the bile cholesterol saturation index[28,29]. In the present study, we observed that cases had lower ghrelin serum levels and higher prevalence of metabolic syndrome, which we have previously reported as a risk factor for GD[30]. Interestingly, Langenberg *et al*[31] reported that lower ghrelin levels were associated with a significantly higher prevalence of the metabolic syndrome, with progressively lower ghrelin levels as the number of metabolic syndrome components increased.

Fourth, We demonstrated the expression of mRNA of ghrelin in frozen tissue, suggesting that the gallbladder is capable of producing ghrelin.

In conclusion, our results suggest that serum ghrelin concentrations are associated with a protective effect of GD. We speculate that this is related with a motilin-like effect of ghrelin on the gallbladder motility. However, further studies are needed to determine the exact role of ghrelin in gallbladder physiology.

Abstract

AIM: To assess the role of retrograde terminal ileoscopy in hematochezia patients with normal colonoscopy.

METHODS: Between January 1997 and March 2005, 39 hematochezia patients (males 36, females 3, mean age 44.7 years) with a reported normal colonoscopy underwent a repeat colonoscopy. After reaching the cecum, attempt was made to localize the ileocecal valve and intubate the terminal ileum. Any abnormality in the mucosa of the terminal ileum was carefully recorded and biopsies were obtained from suspicious-looking lesions.

RESULTS: During the study period there were 39 patients admitted for hematochezia in whom colonoscopy till cecum did not reveal any abnormality. Full-length colonoscopy till the cecum could be performed in all the patients. The terminal ileum could be intubated in 36 patients. No abnormality was noted in 31 patients. Ileal ulcers were noted in two patients. Nodularity along with ulceration of the ileal mucosa, a Dieulafoy's lesion, and an angiomatous malformation were noted in one patient each. Histological examination of the biopsies obtained from the ulcers revealed typical tuberculous lesion in the patient with nodularity and ulceration. One of the patients had typhoid ulcers and another had non-specific ulcers.

CONCLUSION: Retrograde terminal ileoscopy gives limited but valuable information, in patients with hematochezia and should be attempted in all such patients.

INTRODUCTION

Colonoscopy is an established procedure for investigating patients with diseases of the colon and terminal ileum, including patients with prior colonic adenomas or cancer, fecal occult blood loss, a family history of cancer, inflammatory bowel disease, evaluation of iron deficiency anemia and patients with hematochezia[1]. However, although it is expected that endoscopists should be able to intubate the cecum in 90% of attempts[2], in practice this is followed less often than not[3]. On several occasions even a complete colonoscopic examination may not be possible or may not show any abnormality in patients with hematochezia. Moreover, during active bleeding subtle changes in the colon may not be appreciated and sometimes even gross lesions may be missed. Due to this argument and the fact that most of the bleeding will stop by itself, some workers advise that colonoscopy should be performed only after cessation of active bleeding and after proper colonic preparation[4].On the contrary, others prefer to perform colonoscopy as an emergent procedure, so that more lesions are detected early enough for endoscopic therapy to be applied[5, 6].

Terminal ileoscopy is an integral part of complete colonoscopy. Retrograde terminal ileoscopy has been noted to be useful in patients with inflammatory bowel disease, diarrhea, lymphoma, cytomegalovirus-induced ileitis, tuberculosis, portal hypertension and a host of other conditions involving the terminal ileum[7-21]. In a recent study, we have noted that obtaining blind biopsies from even a normal-appearing terminal ileum is useful in patients suspected to have ileocaecal tuberculosis[22]. However, despite being recommended by several authors[7-19, 22], terminal ileoscopy is not routinely performed when colonoscopy is done in all patients undergoing colonoscopy [3]. A more recent study has noted that routine ileoscopy is very useful and easy to perform after proper training has been imparted. However, although stray reports have noted abnormalities in the terminal ileum in hematochezia patients with normal colonoscopy, we are not aware of any study that has dealt with this problem in detail.

MATERIALS AND METHODS

Patients

Between January 1997 and March 2005, colonoscopy with

retrograde ileoscopy was attempted in all patients with hematochezia in whom colonoscopy till the cecum was reported to be normal either during emergency colonoscopy or a routine colonoscopy performed immediately after cessation of bleeding. Upper gastrointestinal (UGI) endoscopy was also performed in these patients but did not reveal any abnormality. Two of these patients had another episode of hematochezia in the past (8 mo and 13 mo before the present hospitalization) and received 4 and 6 units of whole blood transfusion respectively. UGI endoscopy and colonoscopy performed elsewhere did not reveal any abnormality.

Methods

Repeat colonoscopy was performed in our unit. Colonic preparation was performed with either one liter 10% (100 g/L) mannitol solution followed by a WHO oral rehydration solution or a polyethylene glycol-electrolyte-based solution (Peglec, Tablets India, Ltd., Chennai, India). On repeat colonoscopy, a careful search was made for any lesion in the colon. After reaching the cecum, attempt was made to localize the ileocaecal opening and intubate the terminal ileum. Once in the terminal ileum all attempts were made to go as far as possible in the ileum. Any abnormality in the mucosa of the terminal ileum was carefully recorded and biopsies were obtained from suspicious-looking lesions. Biopsies were not obtained from lesions that were likely to be of vascular origin such as ileal varices, spiders, angiomatous malformations and Dieulafoy's lesions.

RESULTS

During the study period there were 39 patients admitted for hematochezia in whom colonoscopy till cecum did not reveal any abnormality. There were 36 males and 3 females. The mean (SD) age of these patients was 44.7 (10.6) years. Of these patients, 34 were admitted to our hospital for hematochezia and the other five were referred from other centers after no lesion could be detected on colonoscopy in these patients. Of the 34 patients admitted to our center, colonoscopy was performed as an emergency procedure in 23 and 11 patients after cessation of the bleeding and bowel preparation. All colonoscopies and ileoscopies were performed by the two senior authors of the paper.

Full-length colonoscopy till the cecum could be performed in all the patients. Colonoscopy did not reveal any abnormality in 38 patients. However, in one of the patients superficial ulcers were seen in the cecum. Despite all efforts, the terminal ileum could not be intubated in three patients. One of the patients had a history of hematochezia 8 months before the present hospitalization.

Of the 36 patients in whom the terminal ileum could be visualized, no abnormality was noted in 31 patients. The other five patients had endoscopic findings on terminal ileoscopy. Nodularity and ulceration of the ileal mucosa were noted in one patient (Figure 1). This patient had superficial ulcers in the cecum too. A Dieulafoy's lesion was noted in one patient (Figure 2). This patient had massive lower gastrointestinal bleeding 13 months prior to the present hospitalization. An UGI endoscopy and colonoscopy at that time did not reveal any abnormality and the patient recovered after conservative management. Another patient had an angiomatous malformation (Figure 3). Ulcers were noted in the terminal ileum in two patients. One of these patients had typhoid fever (Figure 4). In the other patient ulcers were noted only on the ileal side of the ileocecal valve (Figure 5).

Figure 1 Retrograde terminal ileoscopy showing nodularity and ulceration in the ileal mucosa.

Figure 2 Dieulafoy's lesion of the terminal ileum.

Figure 3 Angiomatous malformation seen at ileoscopy.

Figure 4 Ileal ulcers seen at retrograde ileoscopy.

Figure 5 Non-specific ulcers in the terminal ileum.

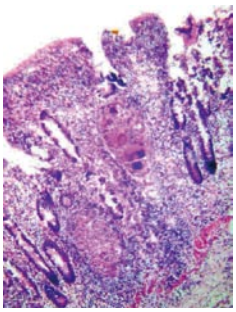

Figure 6 Histological examination of the biopsies obtained from the area of nodularity and ulceration in the terminal ileum showing noncaseating granulomas consisting of Langhans' giant cells and epithelioid cells. Note that a cuff of lymphocytes surrounds the granuloma (HE ×80).

Biopsies obtained from the superficial ulcers in the cecum showed non-specific inflammatory changes. Histological examination of the biopsies obtained from the nodularity and ulcers in the ileum of this patient revealed non-caseating granulomas consisting of Langhans' giant cells and epithelioid cells with a surrounding cuff of lymphocytes (Figure 6), suggestive of tuberculosis. The two other patients with ulcers showed evidence of non-specific inflammation. The patient with typhoid fever was diagnosed to have typhoid ulcer and the other patient to have non-specific ulcer.

DISCUSSION

Colonoscopy remains the procedure of choice for most diseases of the large bowel, including patients with hematochezia[1]. However, the timing of colonoscopy in patients with hematochezia is debatable. While some workers feel that an emergency colonoscopy should be performed in such patients due to the fact that it can detect evanescent findings such as stigmata of recent bleeding or reversible ischemia and can lead to a rapid diagnosis of the cause culminating in its endoscopic management[5, 6], the detractors of urgent colonoscopic examination feel that urgent colonoscopy decreases sensitivity in the presence of active bleeding and that in most cases there is spontaneous cessation of bleeding, even without rendering endoscopic therapy[4]. Others prefer to perform a bleeding scan and angiography in such patients. The advantages of this procedure include the ability to identify the bleeding site whether in the small or in the large bowel, the lack of preparation required for colonoscopy and the ability to perform therapeutic interventions[23]. No matter what the choice of the investigation, an UGI endoscopy must be performed in all such patients, since in about 10% of such patients an UGI source may be responsible for the hematochezia[24]. Although colonoscopy is performed routinely for suspected abnormalities in the colon[1], ileoscopy is not commonly employed in the work-up of patients with ileocolonic abnormalities[3]. This is despite the fact that a number of studies have demonstrated the utility of retrograde ileoscopy during colonoscopic examination of the large bowel[7-22]. A recent study speculated that perceived difficulty of ileal intubation, time constraints, and the expectation of a low diagnostic yield are the likely reasons for the resistance on the part of the endoscopists in attempting retrograde ileoscopy[3].

The results of this study show that a carefully performed colonoscopy that includes retrograde terminal ileoscopy is a very useful tool to diagnose the cause of hematochezia in patients in whom an earlier colonoscopic examination has not revealed any abnormality. Although the yield appeared to be low (13%), the lesions encountered were important in the sense that the diagnosis could be achieved, helping in the treatment of these lesions. In another study, the yield of ileoscopy, performed with an enteroscope in patients with unexplained gastrointestinal bleeding, was noted to be even lower than that noted in the present study. However, in that study the ileal intubation could be achieved in only 39% of patients[25], which is far less than that achieved in most other studies[10, 16, 20-22]. The probable reason for the low ileal intubation rate is the fact that the authors used a more flexible enteroscope instead of a conventional colonoscope for ileoscopy. Moreover, only 10 patients with unexplained gastrointestinal bleeding were enrolled in that study as opposed to those with hematochezia in the present study. It is not clear whether or not these patients had lower gastrointestinal bleeding severe enough to cause hematochezia. The chances of finding a lesion in the terminal ileum was considerably more in our group of patients due to the fact that they had lower gastrointestinal bleeding severe enough to cause hematochezia.

Two of the patients in this series had what is called as obscure GI bleeding[26]. They had an episode of hematochezia in the past and UGI endoscopy as well as colonoscopy did not reveal any abnormality. Unfortunately in one of these patients, despite all attempts, the terminal ileum could not be intubated. However, in the other patient a Dieulafoy's lesion was detected. If ileoscopy was performed with the lesion detected and treated during the previous colonoscopy, the patient would have been spared of a potentially life-threatening episode of hematochezia, suggesting that colonoscopy and ileoscopy should be performed in patients with obscure GI bleeding [26]. We would go a step further and suggest that ileoscopy should be performed while a colonoscopy is performed for all GI bleeding. Waiting for a second episode of bleeding (that might be massive) so as to be labeled as obscure GI bleeding is not warranted. In fact ileoscopy should be an integral part of colonoscopy and all attempts should be made to intubate the terminal ileum during colonoscopy performed for any indication.

Ileoscopy was noted to be useful in one of our patients in diagnosing the cause of the ulcer. In this patient an earlier colonoscopic examination missed superficial ulcers in the cecum. However, histological examination of biopsies obtained from the ulcers in the cecum showed

non-specific changes. If ileoscopy was not performed and biopsies were not obtained from the ileal ulcers, the diagnosis of a curable disease would not have been possible. We have earlier observed such differences in the histological appearance of biopsies obtained from different areas of the colon in patients with colonic tuberculosis[27]. Patients with isolated tuberculous involvement of the terminal ileum have been reported[18].

Except for one patient in whom superficial cecal ulcers were missed on colonoscopy, all the other patients had their disease localized to the terminal ileum. This was because of the design of the study, since patients with lesions found at the first colonoscopy (emergency or elective) were not enrolled. However, in an earlier study, ileoscopy revealed the findings or the diagnosis in 8 of the 57 cases where it was possible and colonoscopic as well as radiological examinations were normal. This group included two patients with lower GI bleeding in whom colonoscopy was normal and ileoscopy revealed typhoid ulcers and NSAID-induced ulcers respectively[16].

The findings noted in this study may not be totally valid in the West, since endoscopists in the developed countries are unlikely to encounter a patient with hematochezia due to typhoid ulcers or tuberculosis. However, with tuberculosis raising its head once again in the developed countries[28-30], such a scenario cannot be totally discounted. The other lesions noted in the present series such as Dieulafoy's lesion, non-specific ulcers and angiomatous malformations are universal diseases and may be seen more commonly.

Abstract

AIM: To compare the efficacies of one-day quadruple therapy and seven-day triple therapy in Chinese patients.

METHODS: Sixty consecutive patients with nonulcer dyspepsia and confirmed *H pylori* infection were randomized to receive either omeprazole 40 mg, amoxycillin 1 g, and furazolidone 100 mg, all twice a day for 7 d or omeprazole 20 mg (at breakfast and dinner), amoxicillin 1 g, furazolidone 200 mg, and colloidal bismuth subcitrate 220 mg four times for only one day. *H pylori* status was determined before and at least 5 weeks after therapy by endoscopy with antral and corpus biopsies for rapid urease test and histology.

RESULTS: *H pylori* eradication was successful in 66.67% (20/30) patients in the 7-d group and in 36.67% (11/30) patients in the 1-day group (P = 0.037). Side effects were induced by the treatment in 13.3% (4/30) patients of each group, but these were all self-limiting, short-lasting, and did not require any specific treatment.

CONCLUSION: The one-day quadruple therapy is less effective than the one-week regimen in curing *H pylori* infection in Chinese patients.

INTRODUCTION

There is clear evidence that *H pylori* is the main etiologic agent of most gastritis, peptic ulcers and gastric cancer[1,2]. Eradication of infection leads to resolution of the gastritis and to spectacular decreases of ulcer relapses and risk of gastric cancer. Treatment of *H pylori* infection is widely accepted for patients with dyspepsia[3,4]. Several regimens for treating *H pylori* infection have been proposed. One-week triple therapies incorporating a proton pump inhibitor (PPI) and two antibiotics are the most frequently recommended treatment for *H pylori* infection in China. Bacterial susceptibility, cost and patient compliance have been shown to be the important factors in determination of anti-*H pylori* therapy regimen. Sometimes, cost has to be taken into account and may be the first important factor in determination for eradication of *H pylori* for patients from poor rural area or countryside. Availability of 1-d quadruple therapies would therefore be of interest, because they will probably reduce cost and side effects and increase tolerance and compliance. A 1-d high-dose quadruple therapy with a combination of amoxycillin (or tetracycline), metronidazole, a bismuth salt and a proton pump inhibitor has led to promising results with eradication rates of 57%-95%[5-8]. However, Wermeille *et al*[9] indicated that a 1-d administration of PPI-based quadruple therapies yielded significantly lower eradication rates (20%) compared to the 7-d regimens (91%). However, experience is limited and the variant results may come from different patient population. In the present study, we therefore aimed to compare the efficacy of a four-drug 1-d treatment with a three-drug 7-d therapy on of *H pylori* infection in Chinese patients with dyspepsia.

MATERIALS AND METHODS

Patients

From November 2004 to April 2005, consecutive dyspeptic *H pylori*-positive patients referred to our hospital for diagnostic upper gastrointestinal tract endoscopy were enrolled in the study. The patients with *H pylori* infection proven by urease test or histology were included in the study. Exclusion criteria were: (1) age under 18 years or

older than 75; (2) allergy to one of the drugs; (3) inability to attend follow-up; (4) previously failed eradication therapy; (5) treatment with antibiotics during the 4 weeks prior to the study; (6) previous ulcer surgery; and (7) liver or kidney disease, severe cardiac or pulmonary disease, alcoholism, drug abuse, or any other conditions associated with poor patient compliance. Eight patients were eventually excluded from the study after randomization. The remaining 60 patients (35 males and 25 female; mean age 54.3 years, range 19-72 years) were included in the study.

Diagnosis of H pylori infection

Four biopsy specimens, two from the antrum and two from the corpus, were obtained using gastroscopy. Biopsy specimens were stained to assess the presence of *H pylori*. Rapid urease test was considered positive if any color change occurred. Patients were considered as *H pylori*-positive when *H pylori* was positive on either histology and/or rapid urease test.

Therapy

Patients were randomized to receive a 7-d course of omeprazole (40 mg), amoxycillin (1 g), and furazolidone (100 mg), all twice daily with meals, or a 1-d course of omeprazole (20 mg, at breakfast and dinner), amoxycillin (1 g), furazolidone (200 mg), and colloidal bismuth subcitrate 220 mg four times a day. During the treatment period, the patients were asked to refer to their study doctor if they had side effects, or the side effects were recorded by means of a structured clinical interview immediately after the end of therapy.

Assessment of H pylori eradication

The efficacy of treatment was evaluated at least 5 weeks after therapy. Endoscopy was performed and a further four biopsy specimens (two from the antrum and two from the corpus) were obtained to assess the *H pylori* eradication status and histology. A patient was considered to be cured if all two tests were negative at the follow-up endoscopy. To evaluate possible recrudescence, a 14C-urea breath test was performed at least 6 mo after eradication therapy. The Medical Ethics Committee of the institution approved the study design. Informed consent was taken from all patients.

Statistical analysis

Proportions were compared using the chi-squared test. Calculations were performed using the SPSS (10.0) for Windows statistical package.

RESULTS

Sixty patients entered the study. Clinical characteristics of the patients are mentioned in Table 1. There were no significant differences between the 1-d quadruple therapy and 7-d triple therapy groups with respect to age, gender, tobacco and alcohol consumption.

Eradication of H pylori

As shown in Table 2, eradication rate in the 1-d group (36.7%) was significantly lower than that in the 7-d group (66.7%). The study was subsequently stopped. The upper gastrointestinal symptoms had improved in 93.3% (21/30) of patients in the 7-d group and in 90% (15/30) of patients in 1-d group.

Table 1 Characteristics of the treated patients

Treatment	*n*	Male/Female	Mean age (range)	smokers *n* (%)	alcohol users *n* (%)
1-d therapy	30	16/14	38.4 (19-71)	6 (20)	7 (23.3)
7-d therapy	30	19/11	43.3 (18-73)	8 (27)	7 (23.3)

Table 2 Evaluation of *H pylori* eradication regimens

	One-day therapy	Seven-day therapy	*P*
H pylori eradication	36.7% (11/30)	66.7% (28/30)	0.037

Table 3 Side effects associated with *H pylori* treatment

Side effects	One-day therapy	Seven-day therapy
Nausea	2	1
Abdominal pain	1	1
Skin rash	0	1
Dizziness	1	1
Side effect (%)	13.30%	13.30%

Side-effects and compliance

As shown in Table 3, there was no difference between the incidences of side-effects in the two groups. Symptoms were almost always mild and not interfering with daily activities. Compliance was 100% in the 1-d therapy as well as in the 7-d therapy group.

DISCUSSION

The optimal anti-*H pylori* treatment should reach high eradication rates with only few and tolerant side-effects, short duration to assure good compliance and lower costs. Three European studies have first stated an effective one-day quadruple therapy for *H pylori* eradication with cure rates being comparable to one-week standard regimen[5-7]. Recently, Lara *et al*[8] showed more optimal eradication rates (95%) for the 1-d therapy group in the United States patients. One-day therapeutic protocols, to our knowledge, have not been studied in Chinese patients. An important consideration is the significantly lower cost of the 1-d regimen compared to the 7-d regimen of the standard regimen. The aim of our study was to investigate the potential advantages of the 1-d quadruple therapy by comparing to a standard 7-d triple therapy.

Unlike the previous reports[5-8], the eradication rate obtained with the 1-d therapy in our study was significantly lower than that obtained with the standard 7-d therapy. Side-effects were minor and did not interfere their daily

activities in the both therapy groups. Compliance and antibiotic resistance are the major factors contributing to the failure of *H pylori* treatment[9-13]. In our study, the compliance was reached 100% in the 1-d therapy group as well as in 7-d therapy group. However, culture was not performed in this study, so we do not know the status of *H pylori* susceptibility to metronidazole and/or furazolidone; therefore, we cannot exclude the possibility of an antibiotic resistance as the reason for our disappointing results. Nevertheless, to date, resistance to amoxycillin and furazolidone are lower as compared with clarithromycin and metronidazole[14,15]. Smoking and drinking do not appear to be the factors in treatment failure with either one-day quadruple therapy or seven-day triple therapy in Chinese patients.

In conclusion, although a 1-d quadruple therapy is less expensive and has fewer side effects, due to the low efficacy obtained in this study, we do not suggest recommending this regimen to be used in Chinese patients for eradication therapy of *H pylori* infection.

Abstract

AIM: To define the optimal injection volume of epinephrine with high efficacy for hemostasis and low complication rate in patients with actively bleeding ulcers.

METHODS: This prospective, randomized, comparative trial was conducted in a medical center. A total of 228 patients with actively bleeding ulcers (spurting or oozing) were randomly assigned to three groups with 20, 30 and 40 mL endoscopic injections of an 1:10 000 solution of epinephrine. The hemostatic effects and clinical outcomes were compared between the three groups.

RESULTS: There were no significant differences in all background variables between the three groups. Initial hemostasis was achieved in 97.4%, 98.7% and 100% of patients respectively in the 20, 30 and 40 mL epinephrine groups. There were no significant differences in the rate of initial hemostasis between the three groups. The rate of peptic ulcer perforation was significantly higher in the 40 mL epinephrine group than in the 20 and 30 mL epinephrine groups ($P < 0.05$). The rate of recurrent bleeding was significantly higher in the 20 mL epinephrine group (20.3%) than in the 30 (5.3%) and 40 mL (2.8 %) epinephrine groups ($P < 0.01$). There were no significant differences in the rates of surgical intervention, the amount of transfusion requirements, the days of hospitalization, the deaths from bleeding and 30 d mortality between the three groups. The number of patients who developed epigastric pain due to endoscopic injection, was significantly higher in the 40 mL epinephrine group (51/76) than in the 20 (2/76) and 30 mL (5/76) epinephrine groups ($P < 0.001$). Significant elevation of systolic blood pressure after endoscopic injection was observed in the 40 mL epinephrine group ($P < 0.01$). Significant decreasing and normalization of pulse rates after endoscopic injections were observed in the 20 mL and 30 mL epinephrine groups ($P < 0.01$).

CONCLUSION: Injection of 30 mL diluted epinephrine (1:10 000) can effectively prevent recurrent bleeding with a low rate of complications. The optimal injection volume of epinephrine for endoscopic treatment of an actively bleeding ulcer (spurting or oozing) is 30 mL.

Liou TC, Lin SC, Wang HY, Chang WH. Optimal injection volume of epinephrine for endoscopic treatment of peptic ulcer bleeding. *World J Gastroenterol* 2006; 12(19): 3108-3113

http://www.wjgnet.com/1007-9327/12/3108.asp

INTRODUCTION

Endoscopic injection of epinephrine is considered a highly effective and simple hemostatic technique for non-variceal upper gastrointestinal (GI) bleeding[1-3]. Although the rate of initial hemostasis is high, rebleeding occurs in 6% - 36% of patients[4-7]. Rebleeding after initial endoscopic hemostasis remains an important determinant of poor prognosis in patients with hemorrhaging ulcers[8, 9]. The wide variation in rates of recurrent bleeding may result from the different volumes (2-30 mL) of epinephrine injected to achieve hemostasis in various studies[4-7]. Clinical trials in patients with bleeding ulcers disclosed that injection of normal saline solution[10] or distilled water[11] is as effective as absolute alcohol[10] or an epinephrine[11] solution for endoscopic therapy. These findings suggest that tamponade plays a primary role in hemostasis with endoscopic injection therapy, and that injection of larger volumes of epinephrine may be beneficial for preventing recurrent bleeding by prolonging the hemostatic effect of local compression. Lin *et al*[12] found that injection of a large volume (13-20 mL) of 1:1 0000 solution of epinephrine can reduce the rate of recurrent bleeding in patients with high-risk peptic ulcers and is superior to an injection of lesser volumes (5-10 mL) of epinephrine (15.4% *vs* 30.8%). Park *et al*[13] also reported that injection of 35-45 mL of an 1:10 000 solution of epinephrine is more effective in preventing recurrent bleeding from ulcers in the gastric body than injection of 15-25 mL of the same solution (0% *vs* 17.1%). However,

what is the "optimal injection volume" of epinephrine for the prevention of recurrent bleeding is not clear. The aim of our study was to define the optimal injection volume of epinephrine with high efficacy for hemostasis and low complication rate in patients with actively bleeding ulcers.

MATERIALS AND METHODS

Patients

This prospective, randomized, comparative trial was conducted in a medical center. Patients with active bleeding ulcers between January 2003 and June 2005 were admitted to our hospital. Emergency endoscopies were performed in the first day of admission, patients were enrolled in this study if the endoscopy revealed an ulcer with active bleeding defined by the Forrest classification[14] as stage Ia (spurting bleeding) or stage Ib (oozing). Patients were excluded if they were under 18 years of age, pregnant, unable or unwilling to give written informed consent, on anticoagulation therapy, or had a bleeding tendency (platelet count < 20 000/mm^3, prothrombin time >2.0 by international normalized ratio [INR], and activated partial thromboplastin time > 60 s), bleeding gastric malignancy and multiple potential sources of bleeding. Possible complications of endoscopic treatment were discussed with patients and their relatives, and written informed consent was obtained before entry into the trial. The protocol was approved by the Clinical Research Committee of our hospital. Clinical characteristics, including age, gender, use of non-steroidal anti-inflammatory drugs (NSAID), blood pressure, pulse rate, comorbid diseases, coagulopathy (platelet count 20 000/mm^3-50 000/mm^3, prothrombin time 1.3-2.0 by INR), and Hb level were recorded. Shock was defined as systolic pressure less than 100 mmHg and pulse rate greater than 100 beats/min accompanying cold skin, sweating, pallor, and oliguria. Endoscopic characteristics, including type of stigma, ulcer size and location were recorded. One biopsy was obtained from the gastric antrum and one from the gastric body after cessation of bleeding. The presence of *helicobacter pylori* infection was assessed with a rapid urease test.

Methods

Patients were randomly assigned to three groups with 20, 30 and 40 mL endoscopic injections of an 1:10 000 solution of epinephrine. Randomization was performed by using a computer-generated randomization list and sealed envelopes. A single experienced senior gastroenterologist performed all endoscopic hemostatic treatments. The post-procedure care of the patients was conducted by other physicians. A commercially available endoscope (GIF-XQ240, Olympus Optical Co., Ltd., Tokyo, Japan) and a 4 mm, 23 G injector needle (NM-8L, Olympus) were used. An 1:10 000 solution of epinephrine was injected around the bleeding site (2 mL/injection at 2 mm-3 mm from the point of bleeding) until a total volume of 20, 30 and 40 mL respectively in three groups. Initial hemostasis was defined as endoscopically verified cessation of bleeding for at least 5 min. Pain in the epigastric area that developed during endoscopic injection and lasted for more than one hour after the injection was considered to be induced by the epinephrine injection. Patients who complained of epigastric pain due to endoscopic injection were recorded. Throughout the period of endoscopic injection, electrocardiographic monitoring and pulse oximeter monitoring were used to detect arrhythmia and signs of ischemia or hypoxemia. Patients who continued bleeding, despite an injection of the total volume of epinephrine, underwent additional endoscopic treatment with heater probe thermocoagulation, and were then given emergent surgery if they failed to achieve successful hemostasis. After initial endoscopic hemostasis, all patients received acid suppressive therapy with 40 mg omeprazole, intravenously every 12 h for 3 d, then orally (20 mg/d) for 2 mo. If *Helicobacter pylori* infection was confirmed by the rapid urease test, the patient was treated for 1 wk with a triple drug regimen (omeprazole, amoxicillin and clarithromycin) as soon as possible. Recurrent bleeding was defined as a subsequent ulcer bleeding that occurred after the initial bleeding stopped. "Rebleeding" was suspected if one or more signs of ongoing bleeding were found, including fresh hematemesis, melena or bloody stools, aspiration of fresh blood via nasogastric tube, unstable vital signs, and a reduction of Hb by more than 20 g/L within 24 h after initial hemostasis. Patients with rebleeding were confirmed by endoscopy and treated with a second therapeutic endoscopy (epinephrine injection plus heater probe thermocoagulation), and then underwent surgery if they failed to achieve successful hemostasis. The end points of this study were (a) endoscopic therapy failure, i.e., a combination of persistent bleeding and recurrent bleeding during follow-up or (b) death of the patient.

Statistical analysis

Unless otherwise indicated, values were expressed as mean ± SD. The Student *t* test was used to compare the mean values of continuous variables. The chi-square test with Yates correction for continuity and the Fisher's exact test were used when appropriate to compare the categorical variables. Clinical, laboratory and endoscopic parameters were analysed. All statistical analyses were performed using SPSS statistical package (version 11.0) on a personal computer. A p value less than 0.05 was considered statistically significant. Any frequency of death was considered as an adverse outcome. Therefore, if a death occurred, the cause was determined. If death was due to recurrent bleeding, a decision of whether to stop the study early was made. Clinical outcomes compared between the three groups were initial hemostatic rate, recurrent bleeding rate, perforated peptic ulcer, need for emergency operation, transfusion requirements, bleeding-related deaths, 30-day mortality, and admission duration.

RESULTS

A total of 284 patients with actively bleeding ulcers (spurting or oozing) were enrolled in the study. Of these, 56 were excluded because of the absence of informed consent, bleeding tendency, gastric malignancy, or multiple potential bleeding sources at endoscopy. There were 228 patients who were included in the study, 76 in each group. Clinical and endoscopic data obtained for patients at study

Table 1 Clinical and endoscopic variables of patients at study entry (n = 76, mean ± SD)

entry are outlined in Table 1. There were no significant differences in age, gender, NSAID ingestion, shock, comorbid diseases, Hb level, coagulopathy, positive H pylori status, bleeding stigma, ulcer size or ulcer location between the three groups. The 3 groups were well matched for factors that could potentially affect outcomes (Table 1).

Initial hemostasis was achieved in 74 of 76 patients (97.4%) in the 20 mL epinephrine group, 75 of 76 patients (98.7%) in the 30 mL epinephrine group and 76 of 76 patients (100%) in the 40 mL epinephrine group. There were no significant differences in the rate of initial hemostasis between the three groups (Table 2). Three patients with spurting bleeding from gastric ulcers, two in the 20 mL epinephrine group and one in the 30 mL epinephrine group, failed to achieve initial hemostasis after injection of 20 mL or 30 mL of the 1:10 000 solution of epinephrine. Bleeding was controlled in all patients by additional heater probe thermocoagulation. Four patients in the 40 mL epinephrine group developed perforation of peptic ulcers and underwent emergent operations within 24 h after endoscopic injection. The rate of peptic ulcer perforation was significantly higher in the 40 mL epinephrine group than in the 20 mL and 30 mL epinephrine groups ($P < 0.05$, Table 2). The rate of recurrent bleeding was 20.3% (15/74) in the 20 mL epinephrine group, 5.3% (4/75) in the 30 mL epinephrine group and 2.8 % (2/72) in the 40 mL epinephrine group. The rate of recurrent bleeding was significantly higher in the 20 mL epinephrine group than in the 30 and 40 mL epinephrine groups ($P < 0.01$, Table 2). Fifteen patients in the 20 mL epinephrine group had recurrent bleeding. Bleeding was controlled in 11 patients by epinephrine injection plus heater probe thermocoagulation, and in 4 by surgical intervention. Four patients in the 30 mL epinephrine group had recurrent bleeding. Bleeding was controlled in 2 patients by epinephrine injection plus heater probe thermocoagulation, and in 2 by surgical intervention. Two patients in the 40 mL epinephrine group had recurrent bleeding. Bleeding was controlled in one patient by epinephrine injection plus heater probe thermocoagulation, and in the other by surgical intervention. The rate of 30-d mortality was 3.9% (3/76), 2.6% (2/76) and 5.3% (4/76) in the 20, 30 and 40 mL epinephrine groups respectively. The causes of death included severe pneumonia with respiration failure in 3 patients, terminal lung cancer in 1 patient, advanced hepatoma with hepatic failure in 3 patients, advanced colon cancer with sepsis in 1 patient and uremia in 1 patient. There was no death due to peptic ulcer bleeding in the three groups. There were no significant differences in the rates of surgical intervention, the amount of transfusion requirements, the days of hospitalization, the deaths due to bleeding and 30-d mortality between the three groups (Table 2). The number of patients who complained of epigastric pain during the procedure of endoscopic injection, was significantly higher in the 40 mL epinephrine group (51/76) than in the 20 mL (2/76) and 30 mL (5/76) epinephrine groups ($P < 0.001$, Table 2).

There was no procedure-related cardiovascular or respiratory complication in three groups. Electrocardiographic monitoring did not record any cardiac arrhythmia, and no abrupt change occurred in oxygen saturation. However, significant elevation of systolic blood pressure after endoscopic injection was observed in the 40 mL epinephrine group ($P < 0.01$), while there were no significant changes in systolic blood pressure after endoscopic injection in the 20 and 30 mL epinephrine groups (Table 3). Significant decreasing and normalization of pulse rates after endoscopic injections were also observed in the 20 and

Table 3 Changes in systolic blood pressure and pulse before and after endoscopic injection therapy (n = 76, mean ± SD)

	Epinephrine (20 mL) n (%)	Epinephrine (30 mL) n (%)	Epinephrine (40 mL) n (%)
Pressure (mmHg)			
Before treatment	108.2 ± 31.8	109.3 ± 29.3	106.2 ± 30.7[b]
After treatment	110.3 ± 21.9	112.7 ± 22.5	129.3 ± 25.8[b]
Pulse (/min)			
Before treatment	96.5 ± 14.7[d]	98.2 ± 15.3[d]	96.7 ± 14.3
After treatment	84.8 ± 12.8[d]	86.3 ± 12.5[d]	101.4 ± 15.2

[b]$P < 0.01$ (paired t-test) in the 40 mL epinephrine group; [d]$P < 0.01$ (paired t-test) in the 20 mL and 30 mL epinephrine groups.

30 mL epinephrine groups ($P < 0.01$) as compared to the 40 mL epinephrine group (Table 3).

DISCUSSION

Peptic ulcer bleeding remains a disease with a considerable morbidity and mortality. The mortality rate is high especially for patients with spurting or oozing bleeding[2, 3, 15]. Endoscopic injection of epinephrine, which is the most widely used method, can significantly reduce rates of further bleeding in non-variceal upper GI[1-3]. Although high rates of initial hemostasis have been obtained, rebleeding occurs in 6% to 36% of patients[4-7]. The wide variation in rates of recurrent bleeding may result from the different clinical features and endoscopic findings between enrolled patients and also the different volumes (2-30 mL) of epinephrine injected to achieve hemostasis in various studies[4-7]. Some factors may be associated with the rate of recurrent bleeding in actively bleeding ulcers after endoscopic injection, including age, shock, comorbid illness, ulcer size, ulcer location and stigmata of hemorrhage[2, 9, 16], which were similar between the 3 groups in the present study, suggesting that the outcomes of endoscopic therapy are unlikely influenced by these factors.

A number of agents have been used to achieve hemostasis in endoscopic therapy. However, what is the best solution for the prevention of recurrent bleeding remains unclear. Lai *et al*[11] demonstrated that a local tamponade with distilled water is as effective as epinephrine solution (11.3 ± 4.7 mL) in endoscopic injection therapy. Lin *et al*[10] have also disclosed similar hemostatic effects of injection with normal saline solution, 3% NaCl solution, 50% glucose water, and pure alcohol. These studies suggested local tamponade is the major effect on sustained hemostasis. Although the mechanisms of hemostasis are different among various agents, clinical studies comparing various agents have demonstrated that no single solution is superior to the others[2, 10, 11]. Laine and Estrada[17] found that local tamponade with normal saline (30 ± 3 mL) solution is less effective than thermal therapy. However, Chung *et al* [18] found that epinephrine injection (1.5 to 19.5 mL) and thermocoagulation have comparable rebleeding rates, indicating that epinephrine injection is technically easier to perform and has a higher initial hemostatic rate. Although the most important mechanism underlying hemostasis in response to epinephrine solution is local tamponade, which is similar to normal saline solution, epinephrine solution offers additional hemostatic effects, including vasoconstriction and platelet aggregation[19]. In a patient with massive active bleeding, it is often difficult to achieve hemostasis with the application of contact devices or laser emergently when visualization of the bleeding site is unsatisfactory. In addition, these methods may not be available in rural hospitals. In our study, the initial hemostatic rate in the 20 mL epinephrine group (97.4%) was as high as that in the 30 mL (98.7%) and 40 mL (100%) epinephrine groups, suggesting that epinephrine solution can be used as a first-line injection solution and hemostatic method for the initial arrest of active bleeding.

Because epinephrine produces vessel compression, vasoconstriction, and platelet aggregation, but not induce vessel thrombosis, the addition of sclerosing agents such as ethanol, ethalonamie or polidocanol would be advantageous in theory. However, clinical trials have not definitively demonstrated a benefit for this combination therapy[6, 20-22]. Likewise, the addition of thrombin or fibrin sealant also dose not reduce the risk of rebleeding[23, 24]. Lin *et al* [12] found that injection of a large volume (13-20 mL) of epinephrine can reduce the rate of recurrent bleeding in patients with high-risk peptic ulcer and is superior to injection of lesser volumes (5-10 mL) of epinephrine (15.4% *vs* 30.8%). Park *et al* [13] also reported that injection of 35-45 mL of an 1:10 000 solution of epinephrine is more effective in preventing recurrent bleeding from ulcers in the gastric body than an injection of 15-25 mL of the same solution (0% *vs* 17.1%). These findings suggest that a continuous injection of larger volumes of epinephrine even after the bleeding stopped is beneficial for preventing recurrent bleeding by prolonging the hemostatic effect of local tamponade, vasoconstriction, and platelet aggregation. However, what is the optimal volume of epinephrine that can achieve permanent hemostasis still remains unknown. In our study, the rate of recurrent bleeding was significantly higher in the 20 mL epinephrine group than in the 30 mL and 40 mL epinephrine groups ($P < 0.01$), while there was no significant difference in the rate of recurrent bleeding between these two groups. The studies of Lin *et al*[12] and Park *et al*[13] enrolled peptic ulcers with spurting, oozing or non-bleeding visible vessels, and found that only 48.7% (38/78) and 52.8% (19/36) of ulcers are active bleeders (spurting or oozing) in the larger-volume injection group respectively. Because our study only enrolled patients with active bleeding (spurting or oozing), the rates of recurrent bleeding in the 30 and 40 mL epinephrine groups were higher than those reported by Park *et al*[13]. However, with a larger injection volume, the rebleeding rate in our study was lower than that reported by Lin *et al*[12] Our study disclosed that an injection of 30 mL epinephrine was an optimal volume for sustained hemostasis and equally beneficial for preventing recurrent bleeding as a 40 mL epinephrine injection.

Sung *et al*[25] found that immediately after the endoscopic injection of a small volume (3-11 mL) of 1:10 000 epinephrine solution, the plasma epinephrine level is increased by 4-5 times above the basal level. In addition, hypertensive emergency and ventricular tachycardia after epinephrine injection have been reported[26]. In our study,

significant elevation of systolic blood pressure after endoscopic injection was observed in the 40 mL epinephrine group ($P < 0.01$), while there were no significant changes in systolic blood pressure after endoscopic injection in the 20 and 30 mL epinephrine groups. Significant decreasing and normalization of pulse rates after endoscopic injections were also observed in the 20 and 30 mL epinephrine groups ($P < 0.01$) as compared to the 40 mL epinephrine group. Therefore, the potential risk of inducing a hypertensive crisis and arrhythmia in patients with underlying cardiovascular diseases by using 40 mL of epinephrine as a hemostatic solution should not be overlooked. Although it has been confirmed that endoscopic injection of epinephrine is safe [6, 20, 23], the injection volume of epinephrine should not be unlimited, because the systemic absorption of epinephrine does occur during endoscopic injection. For large-volume epinephrine injection, electrocardiographic and pulse oximeter monitoring should be used to detect arrhythmias and signs of ischemia or hypoxemia. Our study demonstrated that injection of 30 mL epinephrine was safer than injection of 40 mL epinephrine concerning the potential risk of inducing a cardiovascular event.

The epigastric pain induced by large-volume epinephrine injection is rarely reported in literature. In our study, the number of patients who developed epigastric pain due to endoscopic injection, was significantly higher in the 40 mL epinephrine group (51/76) than in the 20 (2/76) and 30 mL (5/76) epinephrine groups ($P < 0.001$). The epigastric pain induced by large-volume epinephrine injection may be due to tissue ischemia as well as swelling of the ulcer. In addition, injection with a large volume of epinephrine may result in severe tissue necrosis[4, 22, 27] or GI perforation[21, 24, 28]. Perforation of duodenal ulcer in a patient injected a large-volume (35 mL) epinephrine has been reported by Park *et al*[13]. In our study, the rate of peptic ulcer perforation was significantly higher in the 40 mL epinephrine group than in the 20 and 30 mL epinephrine groups ($P < 0.05$). Among the four patients who developed perforation of peptic ulcers, three had deep duodenal ulcers (two with spurting bleeding and one with oozing), the other one had spurting bleeding from a deep and big ulcer (4 cm) in the antrum of the stomach. The size of all the perforated ulcers is greater than 2 cm before endoscopic injection. The cause of perforation may be due to severe tissue necrosis and prolonged inflation in the limited space of the duodenal bulb during the endoscopic procedure. Our study revealed that injection with 30 mL epinephrine was safer than 40 mL epinephrine concerning the potential risk of inducing severe tissue necrosis or peptic ulcer perforation.

In conclusion, diluted epinephrine (1:10 000) solution is good as a first-line injection solution for arrest of active bleeding with a high initial hemostatic rate. Injection of 30 mL epinephrine is optimal for sustained hemostasis with a low rebleeding rate. A 30 mL epinephrine injection is safer than a 40 mL epinephrine injection concerning the potential risk of inducing cardiovascular event and severe tissue necrosis or peptic ulcer perforation. Injection of 30 mL diluted epinephrine (1:10 000) can effectively prevent recurrent bleeding with a low rate of complications. The optimal injection volume of epinephrine for endoscopic treatment of an actively bleeding ulcer (spurting or oozing) is 30 mL.

Abstract

AIM: To report a retrospective analysis of preliminary results of 36 patients who received sirolimus (SRL, Rapamune®, rapamycin) in a consecutive cohort of 248 liver allograft recipients.

METHODS: Thirty-six liver transplant patients with hepatocellular carcinoma (HCC) who were switched to SRL-based immunosuppression therapy from tacrolimus were enrolled in this study. The patients who were diagnosed as advanced HCC before orthotopic liver transplantation (OLT) were divided into group A (n = 11), those who were found to have HCC recurrence and/or metastasis after OLT were assigned to group B (n = 18), and those who developed renal insufficiency caused by calcineurin inhibitor (CNI) were assigned to group C (n = 7) after OLT.

RESULTS: The patients were followed up for a median of 10.4 mo (range, 3.8-19.1 mo) after conversion to SRL therapy and 12.3 mo (range, 5.1-34.4 mo) after OLT. Three patients developed mild acute cellular rejection 2 wk after initiating SRL therapy, which was fully reversed after prednisolone pulse therapy. In group A, only 1 patient was found to have HCC recurrence and metastasis 12 mo after OLT. In group B, 66.7% (12/18) patients (2 with progressive tumor, 7 with stable tumor and 3 without tumor) were still alive due to conversing to SRL and/or resection for HCC recurrence at the end of a median follow-up of 6.8 mo post conversion and 10.7 mo post-transplant. In group C, no HCC recurrence was demonstrated in 7 patients, and renal function became normal after SRL therapy. Thrombocytopenia (n = 2), anemia (n = 8), and oral aphthous ulcers (n = 7) found in our cohort were easily manageable.

CONCLUSION: The conversion to SRL-based immunosuppression may inhibit the recurrence and metastasis of HCC and improve CNI-induced renal insufficiency in OLT patients with HCC.

INTRODUCTION

Sirolimus (SRL, Rapamune®, rapamycin) is a macrocyclic triene antibiotic that was initially found to have antifungal properties, and may act as a primary immune suppressant or antitumor agent. Unlike tacrolimus and cyclosporine, SRL itself does not reduce glomerular filtration rate (GFR) or nephrotoxicity[1]. Liver transplant patients suffering from calcineurin inhibitor (CNI)-related renal insufficiency could be converted to SRL-based monotherapy or combination therapy[2]. SRL has potent antitumor activity *in vitro* and *in vivo*[3-5]. This property may offer a new approach to inhibiting the recurrence and metastasis of hepatocellular carcinoma (HCC) after orthotopic liver transplantation (OLT). Considering these two favorable effects of SRL, we added SRL to our immunosuppressive regimens in November 2003. We here report a retrospective analysis of preliminary results of 36 patients who received SRL in a consecutive cohort of 248 liver allograft recipients. The indications for conversion to SRL-based immunosuppressive regimen with reduction of CNIs included: patients with

advanced HCC before OLT, HCC recurrence or metastasis after OLT, and CNI- induced nephrotoxicity.

MATERIALS AND METHODS

Patients

Between April 2001 and January 2004, a total of 248 patients underwent OLT in our hospital. Among them, 36 (28 men, 8 women) received treatment with SRL. The indication for OLT was HCC combined with hepatitis B-related cirrhosis. These 36 patients were divided into 3 groups: group A: patients with preoperative advanced HCC (n = 11), group B: patients with HCC recurrence and metastasis after OLT (n = 18), group C: patients with CNI-induced renal insufficiency (n = 7). Advanced HCC was defined as stage III-IV according to the pathological TNM classification[6]. Patients were eligible for SRL treatment if the serum creatinine level was ⩾120 μmol/L (normal range, 40-120 μmol/L) on three occasions after exclusion of other causes of nephrotoxicity and after minimization of CNI levels without graft rejection[2]. The study protocol was approved by the Research Ethics Committee of Zhongshan Hospital, and informed consent was obtained from all participants. Patients were followed up for a median of 10.4 mo (range, 3.8-19.1 mo) after conversion to SRL therapy and 12.3 mo (range, 5.1-34.4 mo) after OLT. Chest radiography, abdominal ultrasonography, computed tomographic (CT) scanning and serum alpha-fetoprotein (AFP) measurement were performed once a month during the follow-up period. Liver angiography, chest CT scanning and bone scintigraphy were performed when tumor recurrence or metastasis was suspected.

Immunosuppression

Immunosuppression was started during surgery with 1000 mg methylprednisolone, followed by taper, 240 mg to 40 mg a day for over 6 d. Maintenance prednisone at 5-20 mg daily was then used based on the perceived degree of patient debilitation. Tacrolimus, the routine CNI used in our hospital, was orally administered 12 h after OLT at 0.05-0.1 mg/kg every 12 h. The dose was adjusted to reach target levels of 10-15 ng/mL during the first 14 d. Then the levels were maintained within the range of 6-10 ng/mL during the second 14 d, and 5-8 ng/mL thereafter. Mycophenolate mofetil (MMF) (0.25-0.5 mg, *po*, bid) was used for 12 patients when tacrolimus did not reach the target level after addition of tacrolimus.

Tacrolimus dose was reduced to half, and its concentration was maintained at 2-5 ng/mL. MMF was stopped once SRL therapy was initiated. SRL could impair wound healing in transplant recipients[7]. We started to use SRL in our study at least 1 mo after OLT to avoid affecting the wound healing. All the 36 patients were given SRL at the initial loading dose of 3 mg/m^2. SRL doses were then adjusted to achieve steady-state whole-blood level of approximately 5-8 ng/mL thereafter. SRL oral solution (Wyeth-Ayerst Research, Philadelphia, PA, USA) was administered once daily in the morning, following dilution with water or orange juice. The dose was reduced or increased to 0.5 mg/d if the level was higher than 8 ng/mL or lower than 5 ng/mL.

Table 1 Demographic Data of the patients

	Group A (n = 11)	Group B (n = 18)	Group C (n = 7)
Age (mean±SD yr)	46.6 ± 10.6	47.1 ± 7.8	53.6 ± 5.7
Gender (women/men)	4/7	3/15	1/6
Immunosuppression regimen before switch			
Tacrolimus+steroids+MMF	7	4	1
Tacrolimus+steroids	4	14	6
Immunosuppression regimen after switch			
Sirolimus+tacrolimus	8	13	5
Sirolimus+steroids+tacrolimus	3	5	2

MMF: mycophenolate mofetil.

The patients who were suspected to have rejection underwent liver transplant biopsy. Anti-rejection measures included prednisolone pulse therapy for mild rejection or antibody therapy with thymoglobulin for more severe rejection.

Anti-viral drugs

Lamivudine was started at least 1 wk before OLT (100 mg orally, daily) and continued thereafter. Hepatic B immunoglobulin (800 IU/d) was given intramuscularly for 1 wk, followed by 400 IU twice a week and then once a month according to the anti-HBs titer.

Statistical analysis

Overall survival rate was analyzed using the Kaplan-Meier product limit method. The differences in white blood cell count and serum creatinine levels between the two different groups were evaluated by Mann-Whitney U test. All data were analyzed by SPSS 10.0 (SPSS Inc, Chicago, IL), and $P < 0.05$ was considered statistically significant.

RESULTS

Patient demographics are summarized in Table 1. Tumor extension and histopathological evaluation are summarized in Table 2.

In group A, 11 advanced HCC patients (6 with tumor thrombus in the first right branch of portal vein) were switched to SRL in the early stage (range, 1.0-6.0 mo) after OLT. Only 1 patient was found to have tumor recurrence in liver graft and metastasis in bone and lung 12 mo after OLT, and died at 14 mo posttransplant. The other 10 patients survived without tumor during a follow-up period of 3.9-11.5 mo after conversion to SRL therapy and 5.1- 3.5 mo after OLT.

In group B, 18 patients had tumor recurrence and metastasis within 8 mo after OLT, and were conversed to SRL-based immunosuppression. The overall 1-year survival rate was 68.2%, and 66.7% (12/18) patients were still alive after a median follow-up of 6.8 mo (range, 3.8-14.2 mo) post conversion and 10.7 mo (range, 5.6-20.1 mo)

posttransplant. Four patients who had a single nodule of lung metastasis after transplantation underwent local lung resection. After resection, 2 patients were found to have multiple metastases in the lung again and received bronchial arteriographic embolization, and survived for 5 mo and 9 mo with tumor progression. The other 2 patients remained tumor free at 3 mo and 10 mo after resection for lung metastasis. Another patient who was found to have bone (transverse process of the twelfth thoracic vertebra) metastasis 1 mo after OLT underwent metastasis resection and local radiotherapy. She survived without tumor for 11 mo after conversion and 12 mo after OLT. The other 13 patients had multiple organ (liver and lung) recurrence and metastasis posttransplant, and could not undergo surgical ablation. While no additional therapy beyond SRL was given, 53.8% patients (7/13) were still alive, their tumors remained stable in size after SRL, and 46.2% patients (6 /13) died due to the progression of tumor.

In group C, the conversing SRL time for patients with CNI-induced renal insufficiency CNI was different (range, 1.5-17 mo). No tumor recurrence was demonstrated in the 7 cases. Improvement in renal function was found in 7 patients with their serum creatinine levels returned to normal within 60 d after SRL (154.0 ± 36.2 μmol/L *vs* 83.6 ± 11.4 μmol/L, $P < 0.05$). The most significant improvement was achieved during the first 30 d.

In all the 36 patients, only 3 patients developed biopsy-proven mild acute cellular rejection (Banff criteria rejection activity index of 3-4) 2 wk after initiating SRL therapy, which was fully reversed with prednisolone pulse therapy. All the patients were HBsAg negative and HBsAb positive after OLT after receiving lamivudine and hepatic B immunoglobulin treatment. There was no significant decrease in white blood cell count (6137 ± 1974 c/μL *vs* 5725 ± 1642 c/μL, $P > 0.05$). Eight patients developed anemia (hemoglobin < 10 g/L), and 5 received with red blood cell transfusion, 3 had percutaneous injection of recombinant erythropoietin. Platelet count decreased significantly as compared with baseline in 2 patients (from 125.1×10^9/L to 43.3×10^9/L and from 103.6×10^9/L to 51.2×10^9/L, respectively). The other side effect observed was oral aphthous ulcer (7/36). The symptoms of oral aphthous ulcer improved with a dose reduction of SRL in 2 patients. Relief therapies included antiviral and topical anesthetics in monotherapy or combined therapy in 5 patients. No incidence of hepatic artery thrombosis, delay in wound healing or other allograft dysfunction was found. No other serious hematologic or biochemical changes were observed in this study.

DISCUSSION

The use of SRL in chemotherapy or prevention of tumor proliferation is intriguing[8, 9]. The immunosuppressive and antitumor effects of SRL share a common mechanism of action. SRL inhibits the mammalian target of SRL (mTOR), which prevents acute graft rejection mediated by interleukin-2 and blocks other cytokine signal transduction, thus directly inhibiting tumor cell proliferation[9]. The effects are supported by clinical results with SRL in organ transplantation. Kneteman *et al*[5] followed up 21 patients with HCC beyond Milan criteria who underwent OLT and were treated with a SRL-based immunosuppressive protocol. The 1- and 4-year survival rate was 90.5% and 82.9%, respectively. Only 4 patients were found to have tumor recurrences at a median time of 17 mo postplantation, and the median postrecurrence survival time was 15.5 mo. Compared with the survival rate reported by Yao *et al*[10], our initial experience also suggests that SRL therapy has beneficial effects on HCC patient survival. In group A, only 1 patient died at month 14 posttransplant. The other 10 patients acquired tumor-free survival during a follow-up period of 3.9-11.5 mo after conversion and 5.1-13.5 mo after OLT. In group B, the 1-year survival rate was 68.2% and 66.7% (12/18) patients were still alive (2 with progressive tumor, 7 with stable tumor, and 3 without tumor) after SRL therapy (5 patients had resection for HCC recurrence) after a median follow-up of 6.8 mo (range, 3.8-14.2 mo) post conversion and 10.7 mo (range, 5.6-20.1 mo) posttransplant.

Suppression of the immune system by antirejection therapy has long been linked to increased rates of cancer in transplant recipients. Advances in basic medical sciences have strengthened the association with CNI and increased risk of malignant disease recurrence[11, 12]. Hojo *et al*[12] reported that cyclosporine transforms a noninvasive lung cancer cell line into an invasive phenotype. Vivarelli *et al*[13] reported that patients with HCC receiving a high dosage of cyclosporine during post-liver transplant 3 mo to 12 mo experience a significantly lower recurrence-free survival. These results indicate that cyclosporine can exacerbate tumor growth in patients with malignant tumor[14]. Schumacher *et al*[15] recently reported that *in vitro* suppression of human hepatoma cells by SRL, in contrast to tacrolimus, inhibits hepatoma growth. Our immunosuppressive protocol was planned to minimize the potential impact of steroids and CNIs on HCC recurrence, and to allow for benefits of the previously-reported antitumor

activity of SRL[16]. In group A, only 1 patient who had a tumor (14 cm in diameter) with tumor thrombus in the main branch of portal vein in the explant liver, was found to have recurrence and metastasis 12 mo after OLT. The other 10 advanced HCC patients including 5 with tumor thrombus in the main branch of portal vein have survived without tumor recurrence and metastasis till now (range, 5.1-13.5 mo after OLT). While in group B, 18 advanced HCC patients were found to have intrahepatic recurrence or extrahepatic metastases (mainly in lung) within 8 mo after OLT on maintenance immunosuppression with tacrolimus and steroids. We have also made a retrospective analysis of 40 patients with advanced HCC, including pTNM stage III in 21 patients, and pTNM stage IV in 19 patients, and 9 patients with tumor thrombus in the main branch of portal vein, who underwent OLT before adding SRL to our immunosuppressive regimens. HCC recurrence and metastasis were observed in 11 patients after OLT (11/40, recurrence rate 27.5%), which occurred within 8 mo[17]. As such, recurrence time seemed to be later (≤8 mo *vs* 12 mo) in patients with SRL-based immunosuppression. The difference may be most probably ascribed to the antitumor effect of SRL. However, our study is limited in terms of the number of patients and time of follow-up to properly define the effect of antitumor. Nonetheless, SRL offers a new and promising approach to the prevention or management of posttransplant recurrence and metastasis of HCC. The immunosuppressive efficacy and antitumor activity of SRL may confer a unique for the long-term management of OLT for HCC.

In many open-label studies on liver transplant recipients using SRL as part of a primary immunosuppressive regimen, the occurrence of acute cellular rejection is relatively low. Watson *et al*[18] reported the none of their patients on triple-therapy experiences rejection. Similarly, McAlister *et al*[19] reported that rejection is observed in only 14% patients, which is approximately 50% lower than that in historic patients with conventional immunosuppression. During the median follow-up period of 10.4 mo after conversion to SRL therapy in our cohort, only 3 of 36 patients (8.3%) presented with acute rejection episode, no patient had steroid resistant rejection, and no grafts were lost. These results suggest that SRL-based immunosuppressive protocol is effective in preventing acute cellular rejection.

Renal dysfunction after OLT continues to plague the improvements in patients and graft survival among transplant recipients, and occurs in any different period after OLT. The incidence of chronic renal insufficiency in liver transplant recipients is 0.8% per year, ultimately leading to hemodialysis in 10% of cases and a mortality of 44%[20]. The nephrotoxicity following OLT is likely due to many factors, including hypotension during operation, infection, concomitant use of other nephrotoxic agents. However, the use of CNI such as tacrolimus is a major cause[21]. SRL appears to be devoid of nephrotoxic effects, while demonstrating comparable immunosuppression with CNI[22]. In group C, only after exclusion of other causes of nephrotoxicity and minimization of tacrolimus levels without graft rejection, could the patients be converted to SRL-based immunosuppression, suggesting that the improvement of renal function can not be derived simply from the tacrolimus dose reduction without graft rejection. Our results showed that serum creatinine level in nephrotoxicity group improved significantly after SRL therapy. All the 7 patients had complete normalization within 60 d after SRL treatment, suggesting that the observed improvement of renal function derives from both SRL conversion and tacrolimus dose reduction without graft rejection. Besides, in groups A and B, 29 patients who did not develop renal insufficiency during the SRL therapy further confirmed the non-nephrotoxicity of SRL.

The side-effect profile of SRL differs from that of CNIs. In our study, thrombocytopenia was easily reversible. Anemia could be controlled with blood cell transfusions, and recombinant erythropoietin. Oral aphthous ulcers were treated successfully with a reduced SRL dose and relief therapies. These adverse effects did not require discontinuation of SRL therapy and could be manageable. Hepatic artery thrombosis (HAT) is a dreaded complication, because it is often associated with allograft loss, patient death, or both. However, a single-center report with SRL and tacrolimus in University of Edmonton showed a low incidence of HAT (2%)[18]. In University of Colorado, Dunkelberg *et al*[23] noted that 170 patients with SRL treatment (5.3%) develop HAT compared with 8.3% of historical control patients. In both the Edmonton and the Colorado experience, the dose of SRL is modest (maintenance of 2 mg/d) and SRL levels are generally low (7 ng/mL). Considering that the adverse effects related to the administration of SRL are dependent on dose and concentration, we established the low target level of SRL in our group (5-8 ng/mL). With this approach, no episode of HAT was seen in our study. However, further investigation is necessary for elucidating the relationship between HAT and SRL.

In conclusion, SRL-based immunosuppression may improve CNI-induced renal insufficiency, inhibit the recurrence and metastasis of HCC, and prolong the patients' survival with good tolerability. However, further prospective studies with a large number of HCC patients with long-term SRL therapy are needed to confirm these findings.

Abstract

AIM: To study the expression of trefoil factor 1 (TFF1) and TFF2 in precancerous condition and gastric cancer and to explore the relationship between TFFs and tumorigenesis, precancerous condition and gastric cancer.

METHODS: The expression of TFF1 and TFF2 was immunohistochemically analyzed in paraffin-embedded samples from 140 patients including 35 cases of chronic superficial gastritis (CSG), 35 cases of gastric ulcer (GU), 35 cases of chronic atrophic gastritis (CAG) and 35 cases of gastric cancer (GC).

RESULTS: TFF1 and TFF2 were located in cytoplasm of gastric mucous cells. In CSG, GU, CAG and GC, the level of TFF1 expression had a decreased tendency ($P < 0.05$). The expression of TFF2 was higher in GU than in CSG, but the difference was not significant. The expression of TFF2 also had a decreased tendency in GU, CAG, and GC ($P < 0.05$).

CONCLUSION: The reduced expression of TFF1 and TFF2 in precancerous conditions and gastric cancer may be associated with the proliferation and malignant transformation of gastric mucosa. More investigations are needed to explore the mechanism of TFFs and the relationship between TFFs and gastric cancer.

INTRODUCTION

Trefoil factor (TFF) is a newly discovered protective factor of gastrointestinal mucous, which has attracted more and more attention. This protein family consists of three members: TFF1 known as breast cancer-associated peptide (PS2), TFF2 as spasmolytic polypeptides (SP), and TFF3 as intestine trefoil factor (ITF). Human TFF1 and TFF2 contain only one trefoil structure domain, while human TFF3 contains two Trefoil structure domains[1]. pS2 (mpS2) gene is inactivated in the mouse, the antral and pyloric gastric mucosae of mpS2-null mice are dysfunctional and exhibit severe hyperplasia and dysplasia, while all homozygous mutant mice develop antropyloric adenoma, and 30% of them develop multifocal intraepithelial or intramucosal carcinomas[2]. Welter *et al*[3] found that TFF2 does not express in the pancreas but in pancreatic tumor of humans. Moreover, patients with pancreatic tumor expressing TFF2 have better prognosis. All these findings indicate that TFF is not only the repairing factor for inflammatory mucous and gastrointestinal ulcer, but also correlates with tumor development in digestive system. So far the functions and mechanism of TFF in gastrointestinal tract are unclear. The relationship between TFF and gastrointestinal tumors is still unclear. The aim of this study was to observe the features of the expression of TFF1 and TFF2 in four kinds of gastric mucosal lesion by immunohistochemistry and to explore the relationship between TFF1, TFF2 and tumorigenesis, progression of precancerous condition and gastric cancer.

MATERIALS AND METHODS

Materials

Thirty-five specimens of chronic superficial gastritis (CSG), chronic atrophic gastritis (CAG), gastric ulcer (GU) and gastric cancer (GC) were randomly taken from 150 patients in 1999-2000 (98 males and 42 females, the median age was 52.5 years). All the specimens were paraffin-embedded.

Immunohistochemistry staining

The streptavidin-peroxidase method was applied to immunohistochemistry. The anti-TFF1 protein antibody and the immunohistochemistry test kit (Kit-9710) were the products of Fuzhou Maixin Biotechnology Development

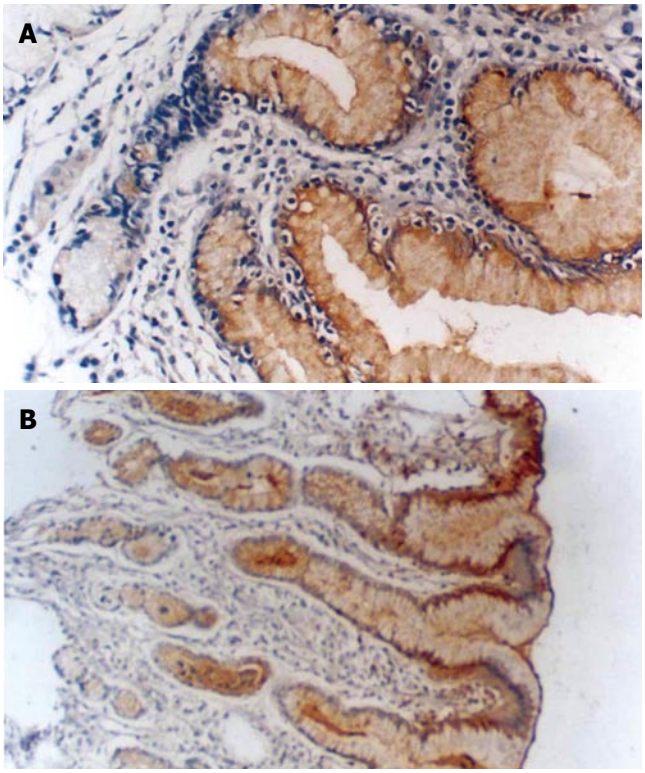

Figure 1 Strong yellow staining of TFF1 in superficial (**A**) and deeper (**B**) glands (SP100).

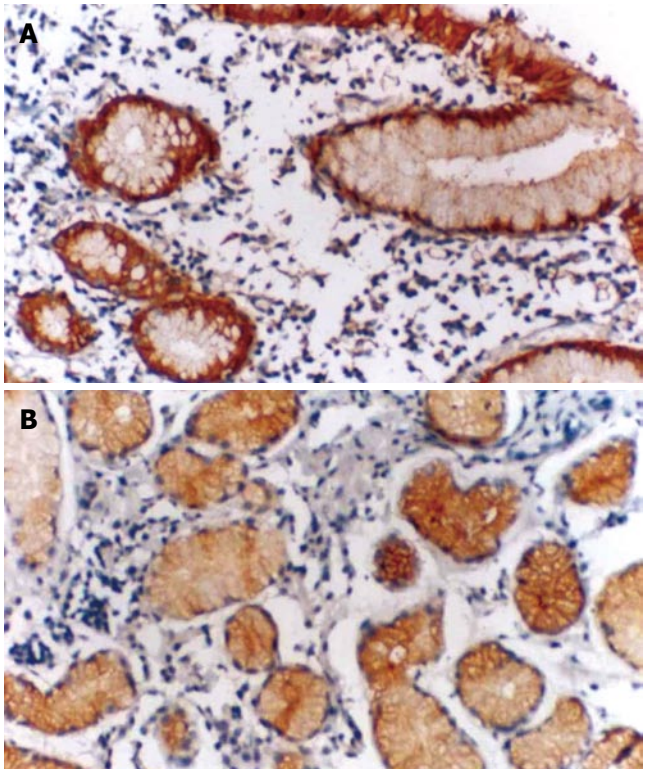

Figure 2 Strong brown-yellow staining of TFF2 in superficial (**A**) and deeper (**B**) glands (SP200).

Company. Anti-TFF2 protein antibody was provided by professor A.Giraud (Western Hospital, Australia). TBS (0.01 mol/L, pH7.4) was used as first antibody for contrast. The immunohistochemistry staining was performed according to the instructions of Fuzhou Maixin Biotechnology Development Company. DAB displayed the color. Yellow or brown-yellow pigmentation could be seen in cytoplasm and cell mucosa. According to the intensity of pigmentation and the range of positive reaction , we made the following scores: 0 = no staining or the staining intensity similar to the background; 1 = weakly positive or little deeper than the background, 2 = moderately positive or significantly deeper than the background, 3 = densely stained or deeply brown stained; According to the positive range, 0 = <10%, 1 = 10%-25%, 2 = 25%-50%, 3 = 50%-75%, 4 = >75%. Four classifications were made: 0-1 as (-), 2 as (+), 3-4 as (++) and above 5 as (+++).

Statistical analysis

All statistical analyses were carried out by SAS 8.0. Wilcox test was used according to the data. $P < 0.05$ was considered statistically significant.

RESULTS

Expression pattern of TFF1 in four kinds of gastric lesion

The expression of TFF1 could be detected in gastric mucosa. TFF1 was yellow or brown-yellow in positive regions and mainly located in cytoplasm. The expression of TFF1 could also be detected in most epithelia, glands and mucus around epithelial cell mucosa. Yellow staining in gastric foveola and superficial glands was relatively strong (Figure 1A). Yellow staining was stronger in superficial glands than in deeper ones and in basal gastric glands (Figure 1B). The level of TFF1 expression had a decreased tendency in different lesions of CSG, GU, CAG and GC ($P < 0.05$) and there was a significant difference between them ($P < 0.05$) (Table 1).

Expression pattern of TFF2 in four kinds of gastric lesion

Brown-yellow TFF2 was mainly located in cytoplasm. The expression of TFF2 could be detected in the mucus around epithelia, superficial and deep glands. However, the expression level was not significantly different between superficial and deep glands (Figure 2A). Yellow pigmentation was stronger in basal gastric glands (Figure 2B). The expression level of TFF2 in different gastric lesions was significantly different (Table 2). In different lesions, the expression level was GU > CSG > CAG > GC. There is no significant difference between CSG and GU. However, both of them were higher than CAG and GC ($P < 0.05$).

Relation between TFF1 and TFF2 expression and clinicopathological characteristics of GC

The level of TFF1 and TFF2 expression was lower in poorly-differentiated carcinoma than in moderately-and well-differentiated carcinoma ($P < 0.0001$, Table 3).

DISCUSSION

TFF is a small molecular protein with rich cysteine, and

Table 1 Expression of TFF1 protein by immunohistochmistry staining

Group	*n*	TFF1 expression				Mean score
		-	+	+ +	+ + +	
CSG	35	0	2	24	9	83.2
GU	35	1	6	20	8	73.7
CAG	35	2	3	27	3	68.1
GC	35	7	5	19	4	57

Table 2 Expression of TFF2 protein by immunohistochmistry staining

Group	*n*	TFF1 expression				Mean score
		-	+	+ +	+ + +	
CSG	35	0	0	22	13	80
GU	35	2	0	18	15	80.7
CAG	35	3	3	21	8	61.2
GC	35	2	5	21	7	60.2

Table 3 Expression of TFF1 and TFF2 in different GC

Type	*n*	TFF1 expression				Positive rate (%)	TFF2 expression				Positive rate(%)
		-	+	+ +	+ + +		-	+	+ +	+ + +	
Moderately-and well-differentiated carcinoma	21	0	2	15	4	81	0	0	14	7	100
poorly- differentiated carcinoma	14	7	3	4	0	50	2	5	7	0	85.7

is characterized by its sub-grade structures containing the trefoil like structure domain. This structure domain consists of 6 cysteine residues linked with 3 intramolecular disulfide chains. TFF is widely expressed in mucosa of endoblasts, especially in the gastrointestinal tract. In the normal gastrointestinal tract, TFF1 expresses mainly in gastric mucosa, TFF2 expresses mainly in gastric and intestinal mucosa, while TFF3 expresses mainly in intestinal mucosa. While the mucosa is acutely injured, this distinctive distribution disappears. TFF can protect against such injuries induced by stress[4], aspirin[5], indomethacin[6], frozen probe[7], *etc*. Alison *et al*[7] showed that when gastrointestinal mucosa is acutely injured, the expression of TFF increases around the injured mucosa. These findings suggest that TFF is a factor for acutely injured gastrointestinal mucosa. However, in this study, the level of TFF1 expression in chronic ulcer tissue was lower than that in chronic superficial gastritis ($P = 0.2587$), while the level of TFF2 expression in GU was slightly higher than that in CSG, but neither of which had any statistical significance, indicating that TFF can recover acute lesion of the mucosa but not chronic injury. The high expression of TFF1 and TFF2 in normal mucosa indicates that TFF1 and TFF2 are related with the physiological renewal of normal gastric mucosa cells.

TFF1 is first extracted from breast cancer cells. In breast cancer, the expression of TFF1 is estrogen-dependent. Recently, it was reported that the estrogen receptor is expressed in normal gastric membrane[8], gastric cancer[9] and pancreatic cancer[10,1]. However, Luqmani *et al*[12] found that the expression of TFF1 in normal gastric membrane and gastric cancer is non-estrogen dependent. The function of TFF1 in gastrointestinal tract and its relationship with estrogen are unclear. The decreased expression of TFF1 in gastric cancer and precancerous status indicates that TFF1 may be one of the inhibitory factors of gastric tumor and the decreased expression of TFF1 may be a sign of the deterioration of gastric membrane.

Human TFF2 contains two "trefoil" structure domains and does not express in breast cancer[13]. Pia Azarschab *et al*[14] found that aspirin (1-2mM) can significantly increase the expression of TFF2. However it is unclear whether this increasing can prevent gastric cancer. In this study, the expressive level of TFF2 in GU was higher than that in CSG, suggesting that TFF2 may play a more important role than TFF1 in the recovery of the gastric membrane. The expressive level of TFF2 in CAG and GC was lower than that in CSG ($P < 0.05$), suggesting that the expressive level of TFF2 decreases in gastric cancer and precancerous status. In this study, the common expression of TFF1 and TFF2 in mucous cells and epithelial mucous indicated that TFF interacts with mucous. TFF2 forms homodimers through cysteine in mucous gel layer[15,16], while TFF1 forms heterodimers in the same area[17,18]. Therefore, the viscosity of mucous is increased and the mucosa defensive barrier is stabilized. Because EGF, TFF1, and TFF2 are expressed in normal mucosa around the small intestinal ulcer, Wright *et al*[19] suggested that the expression of TFF1 is probably controlled by EGF. Yu *et al*[20] found that hydrotalcite increases expression of TFF2 mRNA, suggesting that hydrotalcite regulates TFF2 mRNA expression through the increase of epidermal growth factor

The expressive level of TFF1 and TFF2 was higher in gastric cancer but lower in poorly-differentiated carcinoma than in well-differentiated carcinoma, indicating that decreased expression of TFF1 and TFF2 not only has a close relationship with the occurrence of gastric cancer, but also relates to the malignancy of gastric cancer. So far the specific mechanism of these two proteins in normal gastric mucosa and in the process of malignancy is unclear. Decreased expression of TFF1 and TFF2 may be associated with the proliferation and malignant transformation of gastric mucosa. The results of this study may bring some enlightenments to the prophylaxis and treatment of gastric cancer.

Abstract

AIM: To describe the pattern of inheritance and confirm the diagnostic criteria of primary shunt hyperbilirubinaemia (PSH).

METHODS: Forty members of a family pedigree across four generations were included in this study. All family members were interviewed and investigated by physical examination, hematology and liver function test and the pattern of inheritance was analyzed.

RESULTS: Nine of the forty family members suffered primary shunt hyperbilirubinaemia. The mature erythrocytes of the propositus were irregular in shape and size. The pedigree showed transmission of the trait through four generations with equal distribution in male and female. No individual with a primary shunt hyperbilirubinaemia was born to unaffected parents. The penetrance was complete in adult.

CONCLUSION: The pattern of inheritance is autosomal dominant. The abnormality of erythrocytes and decrease in white blood cell could be supplemented in the diagnosis of PSH. The PSH is a genetic disorder and could by renamed as hereditary shunt hyperbilirubinaemia.

INTRODUCTION

Primary shunt hyperbilirubinaemia (PSH) is a rare clinical jaundice characterized by an elevated unconjugated serum bilirubin, hyperplastic/ineffective erythropoiesis with a normal peripheral red blood cell survival[1]. From the first case described by Israels in 1959, less than 30 PSH cases have been reported in world literature. Most of them were sporadic reports with only 2 small familial analysis[2,3,4]. We present herein a large family pedigree in which the propositus characterized some different from the previous reports and the inheritance pattern was determined to be autosomal dominant, and in which PSH could probably be renamed as hereditary shunt hyperbilirubinaemia.

MATERIALS AND METHODS

Case report

The propositus is a 28-year-old Chinese man who was admitted to our hospital because of asymptomatic fluctuating jaundice observed over the previous five years. At age 23, the patient first presented with elevated serum unconjugated bilirubin, splenomegaly and anemia. The serum bilirubin fluctuated between 50-90 μmol/L. There was no history of infectious hepatitis, malaria, Schistosomiasis or other significant childhood illness. He denied any alcohol intake and was taking no medications at the time of admission to our hospital and worked in a normal fashion as a farmer.

Physical examination revealed a well-developed man of normal stature and growth. Moderate skin icterus was present with mild pallor sclera. The spleen was palpable 4.0 cm below the left costal margin. The liver was impalpable and of normal size on ultrasonography. Murphy's sign was negative. There was no ascites or peripheral edema, and the neurologic examination was normal (Figure 1A and B).

Initial hematology showed the hemoglobin to be 78 g/L, red blood cell count 3.67×10^{12}/L, MCV 97.5 fl, MCH 34.0 pg, white blood cell count 2.7×10^{9}/L and platelets 226×10^{9}/L. The reticulocyte count was 3.0%. The differential white cell count was normal. The peripheral smear showed irregular erythrocytes in shape and size with mild macrocytosis and target-, rod-, tear-drop cells (Figure 1C). Total serum protein and albumin were 71.0 g/L and 46.7 g/L, respectively. Alanine aminotransferase (ALT) and serum lactic dehydrogenase (LDH) were normal. Total and conjugated serum bilirubin were 74.2 and 8.8 μmol/L, respectively. Alkaline phosphatase (ALP) and γ-glutamyl transpeptidase (GGT) were normal. Urine urobilinogen

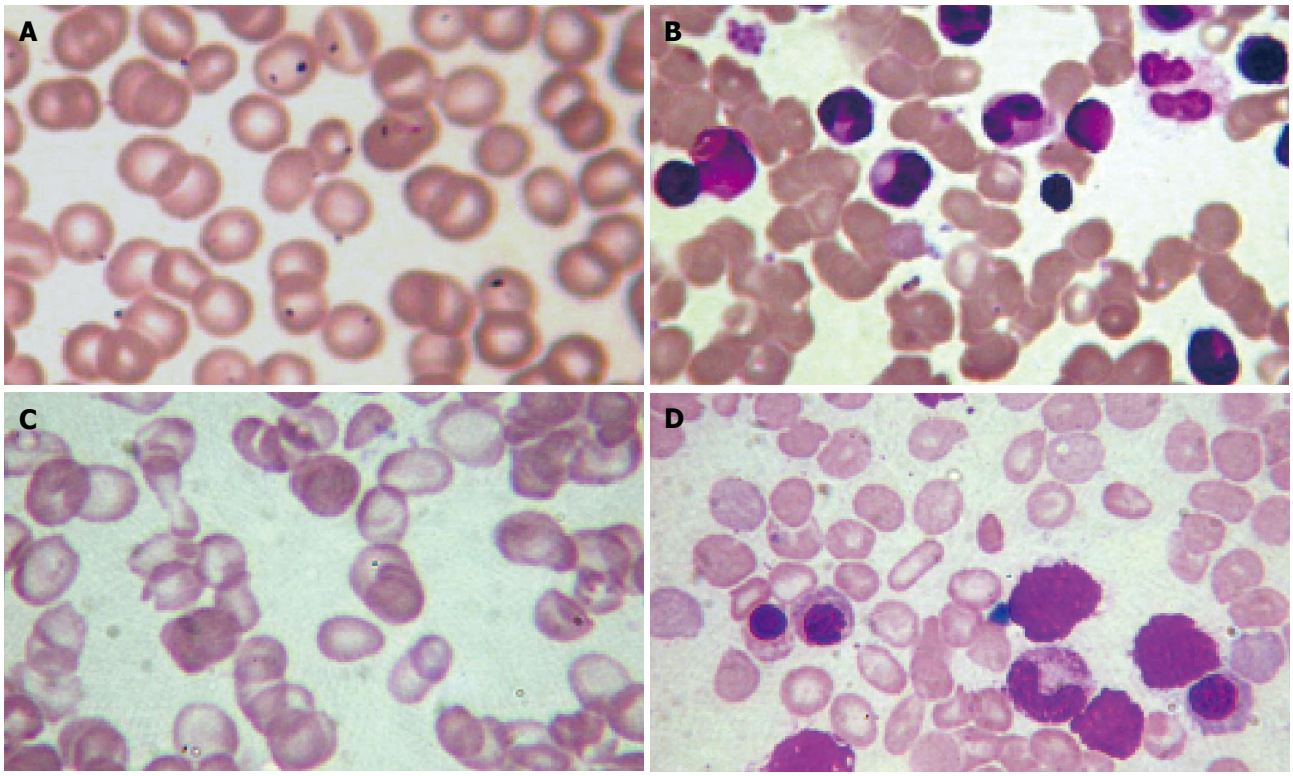

Figure 1 Peripheral smear and bone marrow aspirate. **A** and **B**: Peripheral smear and bone marrow aspirate of a healthy volunteer, respectively (400×, Giemsa); **C**: Peripheral smear of the propositus, showing irregular erythrocytes in shape and size with mild macrocytosis and target-, rod-, tear-drop cells; **D**: Bone marrow aspirate of the propositus which revealed a erythroid hyperplasia and some target-, rod-, tear-drop erythrocytes.

was positive. The serum haptoglobin was 0.06 g/L. Serum iron and total iron binding capacity were normal. Glucose-6-phosphate dehydrogenase, pyruvated kinase was normal, as were the Ham's test and Coombs' test. The hemoglobin electrophoresis, serum protein electrophoresis, autohemolysis, osmotic fragility (before and after incubation) were all normal. The urine for hemosiderin was negative. Administration of phenobarbital (60 mg/24 h) for one week did not reduce plasma bilirubin to the baseline level (total bilirubin 68.3-64.6 μmol/L).

The bone marrow aspirate revealed a hypercellular marrow due to an erythroid hyperplasia. Of particular interest is in which there were some target-, rod-, tear-drop cells erythrocytes consistent with the peripheral smear (Figure 1D).

Pedigree analysis

The symptoms and signs of the all members through four generations were thoroughly inspected by two gastroenterologists respectively. Four to six milliliter blood samples of each member were collected using potassium citrate as coagulating agent. The peripheral blood cell count and ALT, total serum bilirubin, serum unconjugated bilirubin, serum albumin, blood urea nitrogen, creatinine were detected.

RESULTS

In our patient's pedigree, the grandfather, mother and maternal aunt showed recessive jaundice (Figure 2). Nine of them suffered from splenomegaly and had elevated unconjugated bilirubin. Among these suffered persons, 5 showed decreased white blood cell counts and 4 showed decreased hemoglobin simultaneously. The patient's grandfather (Ⅰ-1), mother (Ⅱ-2), maternal aunt (Ⅱ-4), three elder brothers (Ⅲ-5, Ⅲ-7, Ⅲ-9), one cousin (Ⅲ-14), two nieces (Ⅳ-7, Ⅳ-15) had clinical features practically identical to that of the propositus. The patient's immediate family had definitive laboratory corroboration and the same clinical entity distributed equally in male and female.

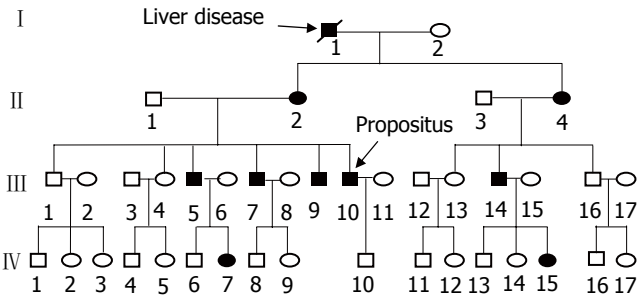

Figure 2 The four-generation family pedigree affected by PSH. The propositus is indicated with an arrow. Symbols are indicated as follows: Circles for females; squares for males; blank for unaffected; full shadowed for affected by PSH.

DISCUSSION

Shunt hyperbilirubinaemia is a subtype of unconjugated hyperbilirubinaemia and it describes the increase in bilirubin production associated with ineffective erythropoiesis. It has been proposed that ineffective erythropoiesis is related to progenitor inhibition, abnormality on erythro-

poietin (Epo)/Epo receptor signaling, *etc*. Secondary shunt hyperbilirubinaemia due to ineffective erythropoiesis can be seen in a number of common clinical disorders, such as thalassemia, myelodysplastic syndrome (MDS) and congenital refractory anemia[5-8]. PSH is a rare disorder with laboratory findings of elevated unconjugated serum bilirubin, mild reticulocytosis, erythroid hyperplasia of bone marrow, splenomegaly and normal peripheral red blood cell survival in the young people[1]. Although some sporadic cases were reported since 1959, the molecular genetic basis has not been previously described because of little pedigree information.

In our case, the clinical findings of the propositus were consistent with the diagnosis of PSH. It is of extreme interest that our patient is unusual in that some abnormal erythrocytes appeared in peripheral smear and bone marrow aspirate, whereas most other reported cases were characterized by normal erythrocytes. It can be proposed that PSH is related to abnormal development of erythrocyte and intramedullary ineffective erythropoiesis. Moreover, the finding of decreased white cell count with normal reticulocyte count indicated the coexistence of splenomegaly and hypersplenism. The abnormal erythrocytes and hypersplenism can be presented as additional clinical findings in PSH diagnosis.

The family pedigree we reported covered four generations. In our patient's pedigree, the grandfather, mother and maternal aunt showed recessive jaundice. Five of eight (60%) adults in the third generation suffered from this defect. The patient's immediate family had definitive laboratory corroboration and it appears that they were suffering from the same clinical entity which distributed equally in male and female. It is speculated that the transmission of defect in our patient's pedigree is an autosomal dominant with equal distribution in male and female. No individual with a PSH was born to unaffected parents. That is, the penetrance was complete in adult. But the severity of clinical features of the disorder was not the same among these affected individuals. Although Bird *et al*[4] reported that the pattern of inheritance of HSP was X-linked transmission[4], the family pedigree was too small to determine the pattern of inheritance. Here we have provided the first evidence that PSH can be inherited as an autosomal dominant Mendelian trait at least in some cases. Nevertheless, we failed to show male to male transmission of definitely affected individuals which would increase the possibility of chance association. Probably it is associated with the incomplete penetrance in the 4th generation. It remains to be determined whether that refers to all cases of PSH or whether there is a spectrum of different diseases.

Up to now, the precise defect of PSH at the cellular and molecular level remains obscure, although the pathogenesis of PSH centers on markedly ineffective erythropoiesis. Our patient's pedigree consists of 4 generations, 29 members, and 9 patients. As the largest pedigree of PSH, this family would be suitable for genome-wide scanning to allow linkage or mapping of suitable PSH genes.

ACKNOWLEDGEMENTS

We thank all the family pedigree members for the co-operation, especially the propositus Mr. Yue-Neng Wen and Miss Xiao-Yun Qi in collecting the blood samples.

TO THE EDITOR

Peptic ulcer disease is a major health care concern in the society today, in view of personal suffering as well as economical health care costs.

Before *Helicobacter pylori* (*H pylori*)

During the last century peptic ulcer research was much focused on the understanding of the relationship of peptic ulcers to acid secretion. The dictum of Karl Schwarz: "No acid - no ulcer" provided the framework for ulcer research.

Surgery aiming at reducing gastric acid secretion is a common treatment of choice, as drugs such as anticholinergics and antacids are not good enough in achieving a reliable treatment response. The surgery involves selective and proximal vagotomy of the parietal cell mass, removal of the gastrin-producing antrum, or combinations of the two. The most extensive operations carried out are the Billroth I and Billroth II operations which regularly remove the antrum, alone or in combination with vagotomy and gastroenteroanastomosis. Both operations involve major surgery and often postoperative complications.

Since the invention of the histamine H_2-receptor antagonists in 1974, the peptic ulcer research field has been even more emphasized and the drug industry has converged on its power on the inhibition of gastric acid secretion as a cure for peptic ulcer disease. This was further encouraged by the 1988 Nobel Prize in physiology or medicine for important principles in drug treatment. The principles that were awarded have resulted in the development of drugs with antagonist action, the acid-inhibitory H_2-receptor antagonist cimetidine is among them.

Along this line even more efficient acid inhibitors that block the H^+,K^+-ATPase, the proton pump, have been developed. To mention one, omeprazole was the first to surface on the arena at the World Congresses of Gastroenterology in 1982, yet some years before taken to the clinic. This compound was later shown to be able to bring down acid secretion to nil and heal ulcers more rapidly than H_2-receptor antagonists. To conclude, the "no acid, no ulcer" concept is consolidated among gastroenterologists as the problem of peptic ulcer appears to be resolved with chronic administration of antisecretory drugs. However, when treatment is withdrawn the ulcers recur. Since then, the recurrence has been considered an effect of receptor up-regulation after long-standing H_2-receptor blockade or persistent hypergastrinemia after treatment with a proton pump inhibitor[1].

Infectious etiology of peptic ulcer disease

An association between gastritis and peptic ulcer disease has been known since the 1940s. Efforts to culture these bacteria however have failed. The Australian histopathologist Robin Warren, in Perth, being unaware of the earlier findings has made similar observations but also the observation that the appearance of these bacteria is similar to the *Campylobacter* genus and preliminary named the bacterium *Campylobacter pylori*[2].

Barry Marshall, being a trainee in internal medicine working in Stewart Goodwin´s Laboratory in Perth, Australia, was with serendipity successful in culturing the bacteria. Over the Easter holiday the Petri dishes with bacterial cultures were inadvertently left in the incubator in five, instead of two days, as recommended for *Campylobacter*. When the dishes were examined after the holidays, small colonies with a shiny appearance were detected. This is the first successful culture and isolation of a bacterium from the stomach of a patient with gastritis. The findings were presented at a Campylobacter meeting 1983[3]. Initially the reports of an association between the bacterium and gastritis were met with great scepticism from the established scientific community. The findings were later published in the Lancet[3].

One major question is whether the bacterium is the cause of gastritis or simply an innocent bystander that happens to colonise a damaged mucosa. In order to rule this out, Barry Marshall and Arthur Morris decided to inoculate themselves by drinking a solution containing vast amounts (10^9) of the bacterium under acid suppression with cimetidine. Both developed signs of an acute gastric "flu"-like illness, with gastric distension, nausea and vomiting. After 10 days endoscopy revealed contraction of *H pylori* and chronic gastritis[4], which gradually subsided over the next

two weeks. Renewed endoscopy could not disclose the organism and the gastritis was healing. In the case of Morris the symptoms remained as a common gastritis. These cases are the ones to confirm the Koch´s postulate that the bacterium itself indeed is the cause of disease[5].

Clinical trials in order to eliminate the bacterium from the stomach showed that treatment with antibiotics could reduce the symptoms and severity of gastritis. Studies also showed that eradication of *Helicobacter* could prevent the relapse of peptic ulcer disease[6]. This has generated a continuing flow of research from the scientific community, which emanated in the acceptance of gastritis and peptic ulcers as basically infectious diseases. The cause of ulcer disease has previously been hidden by a dual false premise that the stomach is sterile and ulcers are caused by stress. This dogma is so deep in scientific thinking that it has taken more than a decade of research and repeat replication of results by scientists to have this fact accepted.

H pylori causes life-long infection

H pylori is a spiral-shaped Gram-negative bacterium that colonizes the stomach. In countries with high socioeconomic standards infection is considerably less common than in developing countries where virtually everyone may be infected.

Infection is typically contracted in early childhood, frequently by transmission from mother to child, and the bacteria may remain in the stomach for the rest of the person's life. This chronic infection is initiated in the antrum of the stomach. As first reported by Robin Warren, the presence of *H pylori* is always associated with an inflammation of the underlying gastric mucosa as evidenced by an infiltration of inflammatory cells[2].

The infection is usually asymptomatic but can cause peptic ulcer

The severity of this inflammation and its location in the stomach are of crucial importance for diseases that can result from *H pylori* infection. In most individuals *H pylori* infection is asymptomatic. However, about 15% of infected individuals will some time develop peptic ulcer disease. The current view is that the chronic inflammation in the distal part of the stomach caused by *H pylori* infection results in an increased acid production from the non-infected upper corpus region of the stomach. This will predispose for ulcer development in the more vulnerable duodenum. After the discovery of *Helicobacter* as the pathogen, a 7-day course of antibiotics in conjunction with acid suppression may heal a previously chronic disabling disease.

Malignancies associated with H pylori infection

H pylori can also infect the corpus of the stomach. This results in a more widespread inflammation that predisposes not only to gastric ulcers in the corpus, but also to stomach cancer. Globally, this cancer has decreased in incidence in many countries during the last 50 years but is still ranked as number two in the world in terms of cancer deaths after lung cancer. Mucosa associated lymphoid tissue (MALT) lymphoma is a specific type of lymphatic neoplasm in the stomach that has been associated with *H pylori*. Curiously, MALT lymphomas regress when *H pylori* is eradicated by antibiotics, why the bacterium seems to play an important role in the development of this tumour.

Microbial origin of chronic inflammatory conditions in general?

The discovery that one of the most common diseases of mankind, peptic ulcer disease has a microbial cause, has stimulated the search for microbes as possible causes of other chronic inflammatory conditions. Even though no definite answers are at hand, recent data clearly suggest that a dysfunction in the recognition of microbial products by the human immune system can result in disease development. The discovery of *H pylori* opens the possibility of an increased understanding of the connection between chronic infection, inflammation and cancer.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B)= 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *Helicobacter pylori, H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of change.

36	Ten mL	Ten milliliters	At the beginning of a sentence
37	umol	μmol	
38	30 sec	30 s	
39	1 g/dl	10 g/L	10-fold conversion
40	OD_{260}	A_{260}	"OD" has been abandoned
41	One g/L	One microgram per liter	At the beginning of a sentence
42	*A*260 nm	A_{260} nm	*A* should be in italic
43	^bP<0.05	^aP < 0.05	In Table, no note is needed if there is no significance instatistics: ^aP<0.05, ^bP<0.01 (no note if P>0.05). If there is a second set of P value in the same table, ^cP<0.05 and ^dP<0.01 are used for a third set: ^eP<0.05, ^fP<0.01.
44	**F*=9.87, $^§F$=25.9, $^\#F$=67.4	^1F = 9.87, ^2F = 25.9 ^3F = 67.4	Notices in or under a table
45	KM	km	kilometer
46	CM	cm	centimeter
47	MM	mm	millimeter
48	Kg, KG	kg	kilogram
49	Gm, gr	g	gram
50	nt	N	newton
51	l	L	liter
52	db	dB	decibel
53	rpm	r/min	rotation per minute
54	bq	Bq	becquerel, a unit symbol
55	amp	A	ampere
56	coul	C	coulomb
57	HZ	Hz	
58	w	W	watt
59	kPa	mmHg	
60	p	Pa	pascal
61	ev	EV	volt (electronic unit)
62	Jonle	J	joule
63	J/mmol	kJ/mol	kilojoule per mole
64	$10\times10\times10cm^3$	10 cm×10 cm×10 cm	
65	N·km	KN·m	moment
66	$x\pm s$	mean ± SD	In figures, tables or text narration
67	Mean±SEM	mean ± SE	In figures, tables or text narration
68	*im*	im	intramuscular injection
69	*iv*	iv	intravenous injection
70	Wang et al	Wang *et al*	
71	EcoRI	*Eco*RI	*Eco* in italic and RI in positive. Restriction endonuclease has its prescript form of writing
72	Ecoli	*E coli*	Bacteria and other biologic terms have their specific expression
73	Hp, *Helicobacter pylori*	*H pylori*	
74	Iga	*Iga*	writing form of genes
75	*igA*	IgA	writing form of proteins
76	5 mg/kg/h	5 mg/kg per hour	
77	0-29%	0%-29%	
78	Number, No, No. cases, number of mice, number of cases	*n*	In figures and tables

READING GUIDE

In the following 20 articles we have attempted to give an update and overview of different aspects of gastrointestinal disease that are treated via a surgical intervention. In addition we have included topics related to advances and innovations in surgical instrumentation and training that are useful in treating gastrointestinal disease. Additional topics covered deal with the ethics of abdominal organ transplantation, inflammatory bowel disease in adolescents and children, and discussions of the quality of life following gastrointestinal cancer. We have also included a discussion of recent discoveries involving the calcium sensing receptor and how this receptor may be employed as both an alternative therapy as well as a possible preventative measure for a variety of gastrointestinal disease issues. As we hope becomes apparent from this collection of articles that the surgeon has and will remain an integral part of the identification and treatment of gastrointestinal disease. We have also included a topic on the surgical scientist and how the surgeon of the 21st century has become an active player in the bench side investigations of causality for gastrointestinal disease.

It is our hope that this collection of articles will give the reader an in depth understanding of the role of the surgeon in all aspects of patient management; from identification of disease related factors, to the removal or repair of the effected tissue, to the postoperative counseling and management of the patient.

Abstract

Management of surgically placed ostomies is an important aspect of any general surgical or colon and rectal surgery practice. Complications with surgically placed ostomies are common and their causes are multifactorial. Parastomal ulceration, although rare, is a particularly difficult management problem. We conducted a literature search using MD Consult, Science Direct, OVID, Medline, and Cochrane Databases to review the causes and management options of parastomal ulceration. Both the etiology and treatments are varied. Different physicians and ostomy specialists have used a large array of methods to manage parastomal ulcers; these including local wound care; steroid creams; systemic steroids; and, when conservative measures fail, surgery. Most patients with parastomal ulcers who do not have associated IBD or peristomal pyoderma gangrenosum (PPG) often respond quickly to local wound care and conservative management. Patients with PPG, IBD, or other systemic causes of their ulceration need both systemic and local care and are more likely to need long term treatment and possibly surgical revision of the ostomy. The treatment is complicated, but improved with the help of ostomy specialists.

INTRODUCTION

Creating and managing enteral stomas is an integral part of many surgical practices. Ostomy outcomes depend on initial optimization of placement and wound care and the circumstances under which the stoma is created (emergent *vs* elective). Unfortunately, even with appropriate technique in the placement of an ostomy, complications are fairly common. Parastomal ulceration, although a rare complication, can prove particularly troublesome. A review of the literature shows many management options but little in the way of definitive care.

An ostomy is a surgically placed opening in the bowel that is brought to the surface of the abdominal wall. The term stoma refers to the actual end of the portion of bowel that comes through to the surface of the abdominal wall, based on the Greek word for mouth or opening. Ostomies themselves may be temporary or permanent, loop or end, and made from small bowel or colon. They can be used as definitive treatment or as a temporary diversion to permit inflammation to resolve or allow an anastomosis to heal. They are used for the management of a variety of pathological conditions, including congenital malformations, cancer, trauma, inflammatory conditions, and ulcerative colitis. They may be exteriorized on the neck, chest, or abdomen. The abdomen is the most common site utilized. Esophagostomy, gastrostomy, jejunostomy, and cecostomy are usually only used temporarily. Colostomy, ileostomy, and ileal conduits are used for more extended periods of time. While each type of ostomy has different characteristics and maintenance needs, they all have complications, many of which can be managed in a similar manner.

TYPES OF OSTOMIES

Colostomy

A colostomy is performed when it is necessary to bypass or remove the distal colon and or rectum. A sigmoid colostomy may be used to divert the fecal stream for anorectal disease or after proctectomy in cases in which the colon is spared of disease. Other indications for either a permanent or temporary colostomy include diverticulitis, congenital anomalies, colorectal trauma, and Crohn's disease.

The most common indication for performing a permanent sigmoid colostomy or end colostomy is carcinoma of the rectum. If the distal rectum and anorectal sphincter mechanism are removed, the colostomy is permanent. Endoanal stapling devices have reduced incidence of this type of ostomy because they permit a low anastomosis in a setting where a hand-sewn anastomosis would not have been possible.

A proximal or transverse colostomy is often used as a temporary basis for obstructing or perforating lesions of the colon, trauma, anastomotic leak, segmental colonic resection to protect an anastomosis when residual disease or sepsis is present, or more rarely for congenital anomalies. Decompressing colostomies are constructed by bringing the loop of bowel to the abdominal surface and creating an opening through the anterior abdominal wall. This provides a mechanism for evacuating fecal contents and also permits access to the obstructed bowel for subsequent resection.

A diverting colostomy may also be performed in order to divert the fecal stream proximal from an area of pathology. In this setting, a fecal diversion promotes healing of the involved site. There are several approaches to the construction of a temporary diverting colostomy. Both ends of the transected bowel can be brought to the abdominal wall as stomas; the proximal end can be brought to the abdominal wall as an end colostomy and the distal end may be over-sewn and left the abdomen (Hartmann's procedure). Alternatively, a primary anastomosis can be performed and a proximal loop can be brought to the abdominal wall for protection of the anastomosis.

Cecostomy

Historically, cecostomy has been advocated to protect a left sided anastomosis, used as a treatment for large bowel obstruction, cecal perforation, volvulus or Ogilvie's syndrome. However, its use nowadays is extremely limited[1]. Cecal volvulus must be treated surgically and is usually treated with ileocolonic resection with ileostomy and mucus fistula. However, if the patient's condition is such that resection is not advisable due to comorbidities, such as if the patient is in frail condition, immunosuppressed, or critically ill, then the best option is to place a cecostomy tube. The purposes of a cecostomy are two-fold. First, it effectively decompresses the cecum, whose distention was a contributing factor in the development of the volvulus. Second, it anchors the cecum to the anterior abdominal wall, which prevents recurrence of the volvulus. This second effect is also known as "pexing" of the cecum[2]. A cecostomy is a temporizing decompressive procedure and does not divert the fecal stream.

Enterostomy

Ileostomy is most often performed after total proctocolectomy for Crohn's disease, familial polyposis, or other conditions requiring the removal or bypass of the entire colon and rectum. If the anorectal sphincter is removed, the ostomy will be permanent, if it is retained it has the potential for reversal. A standard ileostomy may be constructed as either a loop or end stoma. A continent ileostomy is constructed by detubularizing a segment of terminal ileum and reconfiguring it as a reservoir.

An end ileostomy, or Brooke Ileostomy, is the standard of care for patients requiring pan-proctocolectomy. The Brooke technique involves the eversion of bowel to expose the mucosa followed by mucocutaneous suturing to create an end stoma in order to prevent the development of serositis and stricture formation.

A loop ileostomy used to provide temporary fecal diversion following sphincter-saving procedures. Loop ileostomies are typically more difficult to manage because the stoma more frequently empties close to the skin. In addition, a loop ileostomy may be performed more proximally in the ileum and may be associated with higher enzyme and fluid output.

Continent ileostomies are formed after colectomy. A reservoir pouch and valve are created using ileum and a stoma is brought up to the skin; these allow for a storage place for stool and some control of continence. After surgery, patients empty the pouch by using a tube through the ostomy site. This procedure is often used in ulcerative colitis where it is a curative procedure.

OSTOMY PLANNING AND CREATION

Preoperative planning is important in determining ostomy outcomes. Optimal site selection is an important part of stoma construction. Poor stoma placement may cause difficulties with appliance fit. This, in turn, may cause leakage leading to clinically important skin irritation or breakdown around the ostomy[3]. Marking the site must take into account the patient's body habitus and physical limitations as well as any supports or braces utilized by the patient. The patient must be able to visualize and reach the stoma. Skin folds should be avoided.

The location of the stoma is the most important factor contributing to subsequent morbidity and requires marking the site prior to surgery to ensure optimal placement. Marking may be performed by surgeons or trained enterostomal therapists. Proper location of the stoma can reduce or prevent complications.

Enterostomies can be brought through the abdominal wall in laparotomy incisions or through a separate site. Some of the disadvantages of bringing a stoma through a large laparotomy incision include the risk of wound infection, dehiscence, and evisceration. Some stomas are created through the incision, especially when the only goal of surgery is to create a stoma (e.g. PEG placement).

Generally, the stoma should be placed within the triangle formed by lines between the umbilicus and the anterior superior iliac spine, the umbilicus to the pubis, and anterior superior iliac spine to pubis (inguinal ligament), but exceptions exist. For example, the waistline may pose a problem. Typically, in obese patients the stoma should be sited at a higher level, which permits these patients to directly visualize and to care for the stoma optimally. Usually the stoma is placed at the summit of the infraumbilical bulge and within the rectus muscle. The groin, costal margins, waistline, and scars should be avoided because they commonly interfere with appliance management. Consequently, patients should be assessed when standing, sitting, and lying to ensure that the appliance sits properly and the risk for leakage is avoided. In obese patients the stoma should be situated at a higher level of the abdomen so that the patient is able to visualize and access the stoma.

The opposite side of the abdomen should always be

marked, especially in individuals with IBD. As the final amount and area of bowel resection at the time of surgery may be different from originally planned and not allow for creation of the ostomy on the originally planned site. If the terminal ileum has been resected, it is usually easier to bring the stoma out in the left lower quadrant rather than the right. Other locations may be used if appropriate. For example, a jejunostomy may necessitate placement in the upper abdomen.

COMPLICATIONS

Ostomies have a high risk of complications, which are not only related to stoma location or type[4]. Obesity and IBD predispose to complications.

Complications include intestinal obstruction, stenosis, retraction, prolapse, skin irritation, diarrhea, kidney stones, gallstones, ileitis, varices, parastomal abscess or fistula, and parastomal ulceration[5]. Frequency of ostomy complications are in the range of 6%-26%[6,7].

Peristomal skin breakdown/irritation

(Mechanical trauma, effluent contact damage, allergic reactions, fungal infections) Skin irritation is a common problem in patients with stomas. It is more common in ileostomies than colostomies and is seen in 30%-40% of patients[4]. It may be secondary to contact dermatitis, mechanical irritation, trauma, infection, or peristomal hyperplasia. The mainstay of treatment is local wound care and identifying the underlying cause of the problem. Immunosuppressed and diabetic patients are more susceptible to fungal infections.

Parastomal herniation

Parastomal herniation occurs in approximately 10%-30%[8] of all stomas and occurs more often in colostomies than ileostomies. Most of these should be repaired if symptomatic, but because of the incidence of local recurrence, they present a difficult problem. Surgical options include local repair with mesh or relocation. Actual etiological factors include poor wound healing, poor abdominal muscle tone, poor placement of the stoma, poor surgical technique, including too large a fascial opening.

Stomal stenosis

Stomal stenosis usually occurs secondarily to ischemia, infection, or a retracted stoma. The incidence is approximately 10%. Management may require either dilation or revision of the stoma. Dilation itself leads to additional scarring and is only a temporary measure. Dietary modifications may alleviate complications from stomal stenosis.

Stomal retraction

Retraction of a stoma leads to difficulty with appliance placement and as a result leads to skin irritation adjacent to the stoma. The use of a convex appliance often helps outcome and may prevent leakage and skin breakdown.

Stomal prolapse

Stomal prolapse can occur in both end and loop stomas. Both the proximal and distal bowel segments can protrude, although prolapse appears to be more common in the distal segment[9]. The rate of stomal prolapse is 7%-11%[9]. Improvement in surgical techniques and operative placement have reduced the incidence of prolapse. Sizing of the stoma and placement within the rectus muscle are important. Nutritional status of the patient may also affect outcome. In most cases the prolapse is just a cosmetic problem, but may result in strangulation or obstruction if large amounts of bowel herniate. Reduction of an incarcerated stoma may be achieved by the use of an osmotic agent such as sugar or salt, which helps reduce edema. Ice may also be used to reduce swelling. In rare cases, however, surgical revision is indicated for ischemia, obstruction, ulceration or chronic bleeding.

Obstruction

Stomal stricture can occur at the skin and/or fascial level. A stricture may be the result of scarring, inflammation, or technical error. Obstruction can lead to hyperperistalsis and hypersecretion, and subsequent fluid losses resulting in massive dehydration. Most severe stoma strictures require surgical revision.

Peristomal varices/bleeding

Peristomal varices can be seen in patients with stomas and any cause of portal hypertension. Acute management includes direct pressure and injection of sclerosing agents. Recurrence is frequent and usually involves portalcaval shunting in patients who are surgical candidates.

PREVENTION AND OSTOMY CARE

Hughes *et al* found that optimizing the perioperative health status of the patients, particularly the elderly, may reduce morbidity and complication rates. Their results also support specialist surgical care of patients undergoing stomal surgery[5]. Enterostomal nursing can be instrumental in preventing complications and in decreasing the frequency of peristomal complications. Proper fitting of appliances, leakage control, and early local wound care lead to lower morbidity and better quality of life[4].

PERISTOMAL ULCERATION

Symptoms and etiology

Chronic parastomal ulcers in patients with ileostomies or colostomies are unusual and difficult to manage. Many causes have been attributed to parastomal ulceration including infections, fistulas, recurrent inflammatory bowel disease, pyoderma gangrenosum and trauma. Parastomal ulcers occur most commonly in patients with Crohn's disease but have also been observed in patients with mucosal ulcerative colitis. The main symptoms are pain and difficulty with appliance placement. Patients often complain of pain that is quite severe, and may be out of proportion to physical findings. It is usually described as

burning. On examination, erythema and induration with a pink halo are seen. There is often drainage from the mucocutaneous junction, but no overt collection.

Parastomal ulcers that occur within the first few months after stoma construction are more likely to be attributable to operative technique, but may also be due to low grade infection at the site. Those that evolve later are less likely to be associated with the stoma site itself and are more likely caused by recurrence of IBD or chronic infection that only becomes apparent with a weakened host system[10].

Ramanujam *et al* report an unusual case of a squamous cell carcinoma arising at the ileocutaneous stomal site[11]. The patient presented with peristomal ulceration and bleeding and was treated with a wide local excision of the stoma and relocation of the ileostomy. Only two other cases of this have been reported in the literature[11]. Therefore, although rare, one must always consider a malignancy if a peristomal ulcer does not heal after aggressive medical management.

MEDICAL MANAGEMENT

Management of ulceration at the stomacutaneous junction is mostly medical consisting of local wound care, proper appliances, and local and systemic corticosteroids[10]. Wolfsen and colleagues reviewed ten cases over eight years of refractory parastomal ulcers. Eight of the ten patients had ileostomy placement for IBD while the other two had undergone colostomy for colon cancer. Five of the patients were diagnosed as having peristomal pyoderma gangrenosum. Those five patients required a mean of 25 wk of systemic steroid or IBD therapy before resolution of their parastomal ulcers. The other patients had ulcers that were due to contact ulcers from appliances, or dermatoses. These patients received traditional stomal care and topical creams and averaged 4 wk to ulcer healing. They concluded that early dermatologic evaluation should be sought in patients without PPG due to their rapid response to appropriate local therapy[12].

Last *et al* presented their cumulative experience of conservative management in parastomal ulceration in patients with Crohn's disease. They discussed 17 patients with Crohn's disease who developed 28 parastomal ulcers (at least 1.5 cm in diameter), ranging in time from two weeks to seven years after ileostomy construction (the mean time was 45 wk). The methods of management that were utilized included debridement, curettage, unroofing the ulcer complex, pouching of the stoma with Telfa strips in the ulcer base. They reported that most ulcers healed in a mean of 12.7 wk and median of 8 wk. Six patients did not resolve with conservative measures and underwent ileostomy relocation[10]. Last *et al* also suggest that placement of parastomal drains may decrease the rate of infection.

Pyoderma gangrenosum is an idiopathic, inflammatory, ulcerative condition of the skin. A specific type of parastomal ulceration, PPG is unusual and is often misdiagnosed as a stitch abscess, contact dermatitis, irritation from the leaking feces or urine, extension of underlying Crohn's disease, or a wound infection. PPG has been reported in patients with inflammatory bowel disease and occasionally in patients with malignancies. The onset of PPG from the creation of the stoma is extremely variable. Hughes *et al* reported their 7 case experience in a retrospective review in *JAMA*[13]. In these cases, treatment was empiric and the final responses were varied. Histopathology was verified by biopsy. All patients had initially been treated with one or more courses of broad spectrum antibiotics for a presumed skin infection prior to the diagnosis of PPG. Topical clobetasol propionate (a class I topical corticosteroid) used in conjunction with intralesional injection of triamcinolone acetonide was effective in three patients, ineffective in two patients, and used as a possible helpful adjuvant therapy in two others. Three patients required the addition of an immunosuppressive agent (cyclosporine or mycophenolate) due to systemic corticosteroid failure or adverse effects. Oral dapsone also appeared to be helpful in two of the patients. The authors concluded that treatment of patients with PPG is empiric and two fold. The underlying disease process must be treated along with local wound care management (i.e., the addition of a topical corticosteroid)[13].

In children, parastomal excoriation, following chemical irritation can lead to parastomal breakdown and ulceration. Many topical agents have been tried. Hayashi *et al* reported their experience with 15 patients with stomal or perineal skin ulceration treated with topical sucralfate after failure of other common firstline agents. Their results showed complete healing in 13 patents. Their main observations were that noticeable improvement usually took two to three days, healing occurred from the outside in, the sucralfate itself was soothing and improved comfort, when fungal dermatitis was the cause the sucralfate was not effective[14].

The concensus of these studies is that medical management will work for a majority of patients. This includes local wound care, proper appliances, and local and systemic corticosteroids. If systemic disease such as IBD is suspected, the disease should be controlled systemically and the ulcer itself may then resolve. In severe systemic disease, local wound care can be used along with systemic therapy. In many cases it may take weeks for final resolution of the ulcers. The various studies that documented the medical management of parastomal ulcers are summarized in Table 1.

SURGICAL MANAGEMENT

While a last resort, surgical revision of a stoma for parastomal ulceration is a possibility. Reoperation of patients with Crohn's disease is common as a result of stomal complications, including ulceration, and is often associated with recurrence of inflammation both at the ileal site and at the parastomal site[15]. Surgical options include revision of the current stoma or new stoma placement. If the problem is refractory to medical treatment, most surgeons opt to relocate the stoma. The procedure involves takedown of the existing stoma and reformation at a more appropriate site. It is important to optimize systemic disease (IBD) before this is attempted.

Table 1 Medical management of parostomal ulcers

Author	Design	Number of patients	Treatment	Summary
Wolfson *et al*	Retrospective Review	10 patients (8 with IBD), 5 with PPG	Patients with PPG received systemic steroids or IBD therapy. Other patients were treated with conservative measures, corticosteroid creams, wound care.	Patients with IBD should be treated systemically. Patients with other causes for ulceration should be evaluated by dermatology and receive local therapy.
Last *et al*	Retrospective Review	17 patients with Crohn's who developed 28 ulcers	Treatment included debridement, curettage, unroofing the ulcer complex, pouching of the stoma with Telfa strips in the ulcer base.	6 patients did not respond to conservative management, and required relocation.
Hughes *et al*	Retrospective Review	7 patients	Topical clobetasol propionate used with intralesional injection of triamcinolone acetonide in seven patients. Three patients received an immunosuppressive agent (cyclosporine or mycophenolate). Oral dapsone was used in patients.	The underlying disease process must be treated along with local wound care management (i.e. the addition of a topical corticosteroid).
Hayashi *et al*	Retrospective Review	15 children with stomal or perineal skin ulceration	Used topical sucralfate after failure of other common first line agents.	Topical sucralfate can be soothing when other measures fail.

CONCLUSION

Complications with surgically placed ostomies are common and multifactorial. Outcomes can be improved by optimizing the health of the patient, particularly in patients with Crohn's disease or IBD, by careful preoperative planning and placement, thorough surgical training and experience, and by proper wound ostomy nursing care. Unfortunately, despite meticulous preoperative planning, ostomy complications still occur. Parastomal ulceration, although rare, is a particularly difficult management problem. The etiology is varied and treatment possibilities are as well. A review of the literature shows that most patients with parastomal ulcers who do not have associated IBD or PPG respond quickly to local wound care. Patients with PPG, IBD, or other systemic causes of their ulceration need both systemic and local care and are more likely to need long-term treatment, and possibly surgical revision of the ostomy. The treatment is complicated, but improved with the help of ostomy specialists.

Surgical perspectives in gastrointestinal disease: From the editor

In the following 20 articles we have attempted to give an update and overview of different aspects of gastrointestinal disease that are treated via a surgical intervention. In addition we have included topics related to advances and innovations in surgical instrumentation and training that are useful in treating gastrointestinal disease. Additional topics covered deal with the ethics of abdominal organ transplantation, inflammatory bowel disease in adolescents and children, and discussions of the quality of life following gastrointestinal cancer. We have also included a discussion of recent discoveries involving the calcium sensing receptor and how this receptor may be employed as both an alternative therapy as well as a possible preventative measure for a variety of gastrointestinal disease issues. As we hope becomes apparent from this collection of articles that the surgeon has and will remain an integral part of the identification and treatment of gastrointestinal disease. We have also included a topic on the surgical scientist and how the surgeon of the 21st century has become an active player in the bench side investigations of causality for gastrointestinal disease.

It is our hope that this collection of articles will give the reader an in depth understanding of the role of the surgeon in all aspects of patient management; from identification of disease related factors, to the removal or repair of the effected tissue, to the postoperative counseling and management of the patient.

INTRODUCTION

Advances in imaging techniques are changing the way radiologists undertake imaging of the gastrointestinal tract and their ability to answer questions posed by surgeons. Technologic advancements in CT have dramatically improved the detection and characterization of a wide variety of intestinal diseases before and after surgery. In the first part of this paper we review some of the advances in imaging technology. In the second part we discuss how these technical advances improve diagnosis of gastrointestinal disease.

ADVANCES IN IMAGING TECHNOLOGY

Multislice computed tomography

CT is now more commonly performed than fluoroscopic studies in analyzing the gastrointestinal tract. Several generations of CT scanners have become available, starting with 4-slice scanners in 1998 to 64-slice scanners in 2005. With each generational advance more rapid scans are possible with better tailored vascular phase acquisition, and thinner slices. When the resolution of the voxels that make the scanned volume is equal in the longitudinal and transverse (axial) dimensions, the study is considered to be isotropic. In an isotropic resolution scan of the abdomen and pelvis the slice width should typically be less than 1 mm. With such scans the reformats in coronal or sagittal planes will have the same image quality as axial images (Figure 1). Using 64-slice scanners, the entire abdomen and pelvis could be scanned in 5-8 s with isotropic resolution. Modern scanners have software that would almost instantaneously create coronal or sagittal reformats. In our practice every abdominopelvic CT is reconstructed routinely in at least the coronal plane in addition to transverse scans. This plane optimizes assessment of organs such as the mesenteric small bowel which have a tortuous and unpredictable course (Figure 2). Three dimensional image sets such as volume rendering may also be created when deemed helpful prior to surgery[1]. Radiologists are gradually moving away from reading axial slices of CT scans to viewing the abdomen as a three dimensional structure, similar to what the surgeon would see during an operative procedure (Figure 3). Several changes to CT techniques have become accepted in the last few years. In the past positive oral contrast, usually dilute iodinated contrast media or dilute barium, were widely used. These were safe and allowed adequate opacification of the small bowel. The current approach is to favor neutral oral contrast with intravenous contrast when there suspicion of small bowel tumor or inflammatory disease[2]. Advantages of this technique include fewer dilution and admixture artifacts with enteric contents, better visualization of enhancing bowel tumors and inflammation, easier processing of CT angiogram and 3D techniques. One disadvantage of orally administered contrast is the reduced distention of the distal small bowel. This disadvantage could be overcome by either infusion of the enteral contrast under hydrostatic pressure using a nasoenteric tube (CT enteroclysis, see below) or by drinking large volumes of contrast, usually more than 2 liters, in predetermined aliquots over a period of time (CT enterography). Water is the most commonly used neutral enteral contrast; other propriety preparations include (VoLumen, EZ-EM, Westbury, NY) which contains agents to reduce absorption and to add flavor.

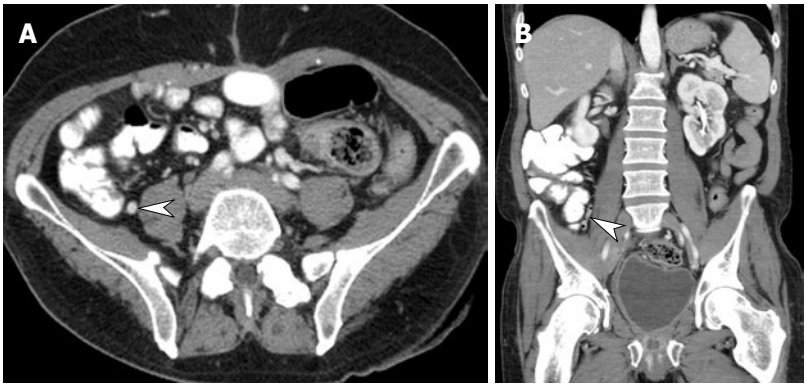

Figure 1 Sixty-three years old man with right lower quadrant abdominal pain. Note the equivalent resolution of the axial image (**A**) and coronal reformat (**B**). In addition it was easier to appreciate the vertically oriented normal appendix (arrowhead) on the coronal reformat.

Figure 2 Abdominal pain and fever in 23 years old female. **A, B**: Coronal reformats with neutral enteral contrast (water) showed dilated proximal loops of small bowel (white solid arrows), and nondistended colon (dashed arrows). A segment of distal ileum (black arrow, image **A**) showed stenosis with mucosal enhancement, consistent with inflammatory stricture causing small bowel obstruction. A second noncontiguous segment of terminal ileum showed intense mucosal enhancement (white arrowhead, image **B**) and comb sign due to mesenteric hypervascularity (black arrowhead, image **B**). The appearances were consistent with acute Crohn's disease. The diagnosis of wall enhancement and thickening is made easier by using water as oral contrast. The coronal perspective also allows easier evaluation of length of involved segments.

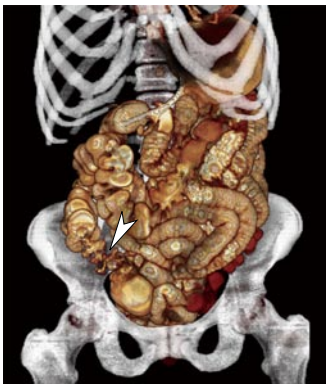

Figure 3 Three dimensional volume rendered image of small and large bowel in 46 years old female with diarrhea. There was no evidence of bowel obstruction. The apparent narrowing of ascending colon (arrowhead) was likely to be due to passage of peristalsis, there was no evidence of mass on two dimensional axial and coronal images. Three dimensional images may be more commonly used in the future to help plan surgery.

CT enteroclysis

CT enteroclysis was first reported in 1992 in an effort to overcome the individual deficiencies of CT and barium enteroclysis and to combine the advantages of both into one technique[3]. In this technique a nasoenteric tube is inserted preferably under conscious sedation and enteric contrast infused under pressure till the entire small bowel is filled. The patient is then taken to a CT scanner to complete the study. As with conventional CT, the choice of enteric contrast is either positive or neutral contrast and depends on the indication[4]. For diagnosing leaks, fistula, peritoneal abscess and low grade small bowel obstruction we prefer positive contrast. For all other indications including assessment of tumors and the inflammatory activity of Crohn's disease we use neutral contrast (Figure 2). CT enteroclysis has several advantages over conventional CT including better assessment of low grade obstruction, enteric fistula, and bowel wall thickening. However this technique has disadvantages of requiring a significant amount of radiologist time, insertion of nasoenteric tube and risks of conscious sedation.

Magnetic resonance enteroclysis

Magnetic resonance enteroclysis is advocated primarily in Europe as a method of interrogating the small bowel without using ionizing radiation. In many ways the technique is similar to CT enteroclysis, except that the nasoenteric tube is inserted in the MRI scanner room prior to the MRI examination. Improvements in magnet technology allow fast scans that could be performed in a reasonable breath-hold. Currently, the poor spatial resolution and motion artifacts impair its value. When compared to CT enteroclysis MR enteroclysis was found to have lower sensitivity and inter-reader agreement in diagnosing a variety of small bowel diseases[5].

CT colonography (virtual colonoscopy)

In this paper we will call CT colonography by its more familiar name, virtual colonoscopy. In this technique very thin slices are obtained in prone and supine positions though the abdomen and pelvis. The resulting images are treated in many ways (Figure 4): (1) Two dimensional reformats in coronal and axial planes; (2) Three dimensional fillet view, where the colon is displayed as if it has been dissected; (3) Endoluminal fly though view. The production of such views requires sophisticated software and appropriate workstation. In our practice, we initially survey the colon on the three dimensional fillet view. Suspected abnormalities are correlated with the axial and coronal two dimensional views, and on the endoluminal view. This approach reduces the time for image interpretation. Measurement of polyp size is made on the endoluminal view, which is considered the most accurate[6]. Subsequently, axial slices are reviewed to diagnose extracolonic abnormalities.

Software programs in routine use include book marking of polyps for correlation with subsequent scans, automatic center line navigation which allows easier fly through, missed patch tool to keep track of surfaces that are not optimally visualized on automatic center line navigation and electronic stool tagging and fluid removal. Currently we prescribe laxatives taken a day prior to the study to reduce the stool burden. However many recent papers have commented on the accuracy of virtual colonoscopy

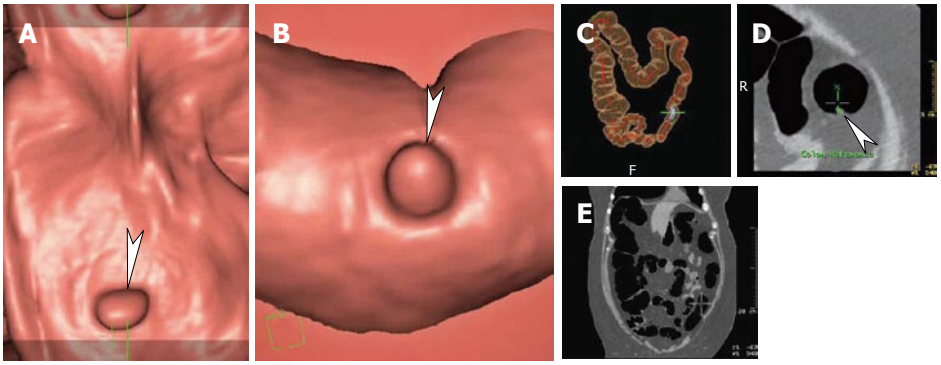

Figure 4 Virtual colonoscopy images in 62 years old female with incomplete optical colonoscopy. **A**: Dissection or fillet view; **B**: Endoluminal fly-through view; **C**: Transparent localizing view; **D**: Two dimensional axial view; **E**: Two dimensional coronal view. At our institution the initial read is the 3 dimensional fillet and endoluminal views in antegrade and retrograde fashion. Sites of concern are correlated with axial or coronal two dimensional views. The entire interpretation including assessment of extracolonic structures takes about 30 min. Note the 6 mm polyp (arrowhead). Its location was confirmed as distal descending colon on image C.

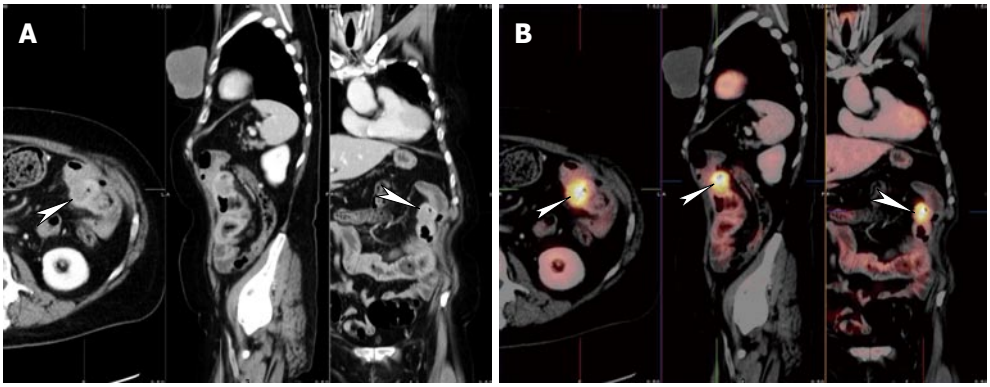

Figure 5 Thirty-nine years old female with prior sigmoid colectomy for cancer, presented with rising CA-125. **A**: Axial, coronal and sagittal images of CT raised concern for possible mass adjacent to the splenic flexure (arrowheads); **B**: Fused images of PET and CT showed hypermetabolic focus (arrowheads) in the mesocolon adjacent to splenic flexure, indicating recurrent tumor. No other sites of tumor were found. While PET is sensitive for recurrent disease it has poor spatial resolution and it would have been difficult to determine if the recurrence was in the colon, mesentery or adjacent spleen. Fusion of PET and CT images allowed accurate anatomical localization.

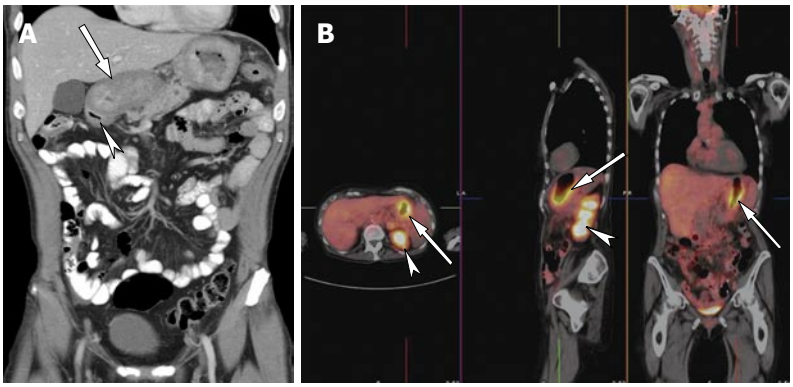

Figure 6 Sixty-nine years old male with dyspepsia. **A**: Coronal reformat showed diffuse thickening of the gastric wall (arrow). The duodenal cap was normal (arrowhead); **B**: Fused PET-CT images showed hypermetabolic activity of the gastric wall indicating cancer. No other foci of abnormal uptake were identified. Note the normal increased activity in the renal collecting systems (arrowheads) due to excretion of radiopharmaceutical.

without using laxatives but instead using low residue diet and tagging feces with dilute contrast[7,8]. The possibility of performing the study without laxative preparation will be a significant advantage of virtual colonoscopy over optical colonoscopy.

Positron emission tomography with CT

Over the past decade positron emission tomography (PET) has changed from a research tool to a full fledged clinical tool excelling in oncological applications. The concept of this technology is based on the fact that tumor cells have a greater avidity for using glucose via glycolysis than most non-cancerous cells[9]. By administering deoxyglucose labeled with a fluorine-18 which is a positron emitting radionuclide (resultant radiopharmaceutical is fluoro-18-deoxyglucose or FDG), it is possible to visualize the location of a tumor. In the first few years of development of PET improvements were made in scanner and detector crystal design. The most significant recent change has been incorporation of PET and CT in the same unit and fusion of the anatomical information from CT and the physiological information from PET (Figure 5)[10]. Both imaging modalities have individual strengths that complement each other. The newer generations of PET-CT scanners utilize multislice CT that allow oral and intravenous contrast information, obviating the need for a separate staging CT scan.

In the gastrointestinal tract PET-CT is used mainly for oncological applications and has been shown to have greater overall accuracy and cost-effectiveness compared to other imaging modalities[11]. PET-CT in the GI tract is commonly used for initial staging, response to therapy and detection of recurrence of esophageal, gastric (Figure 6), colorectal, and gastrointestinal stromal tumors. Additional applications that are showing initial promise include the evaluation of Crohn's disease[12].

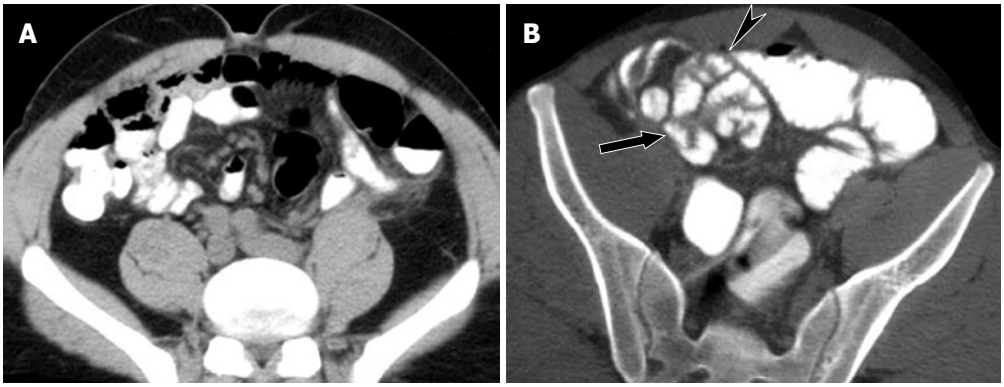

Figure 7 Fifty-four years old with prior hysterectomy presented with abdominal bloating and nausea. **A**: Conventional CT did not show distended bowel or transition point and was interpreted as normal; **B**: CT enteroclysis performed a day later shows distended small bowel loop with beaking (arrowhead) adjacent to anterior parietal peritoneum. Distal small bowel loops were nondistended (arrow). The appearances were of low grade small bowel obstruction due to adhesions.

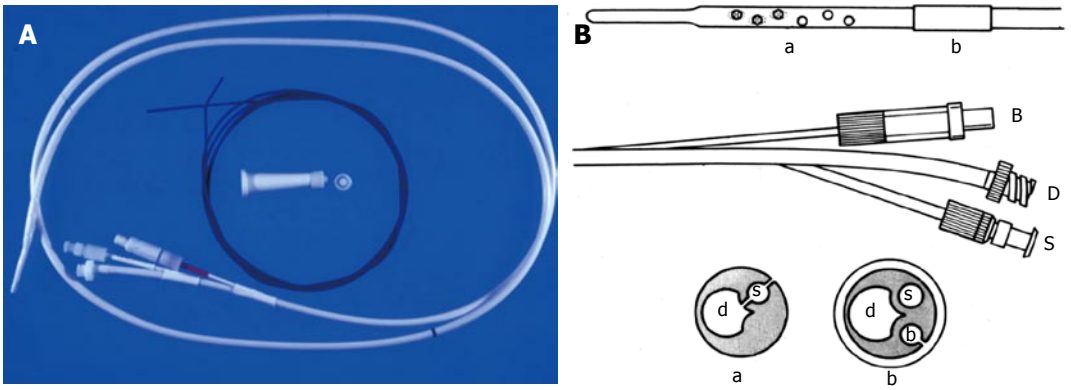

Figure 8 **A**: Image of MDEC decompression and enteroclysis tube with stiffening wire that helps maneuvering the tube into the proximal jejunum; **B**: Line diagram of the tube. B = balloon port, D = drainage port, S = sump port (helps prevent the tube from becoming obstructed by debris). The inset figures show the cross sectional appearances of the tube at positions a and b.

DIAGNOSIS OF MAJOR ALIMENTARY TRACT DISEASE

Gastric tumors

Currently gastric cancer is diagnosed using endoscopic biopsies and locally staged using endoscopic ultrasound. CT is used or more distant staging. Improvements in CT may allow better detection of local invasion of gastric tumor. In a recent study multislice CT had an accuracy of 88.9% in T staging and 70.4% accuracy in N staging, making it comparable to EUS[13]. Virtual gastroscopy, transparency rendering, and 3D mapping of the tumor can help in surgical planning[14]. These techniques however require significant additional time for image creation and interpretation[15].

Small bowel obstruction

Initial studies of conventional CT in small bowel obstruction reported sensitivities of above 90% to 96%, and accuracy of 95%[16,17]. However, these studies were only included patients with high-grade obstruction. In assessing low grade small bowel obstruction, CT enteroclysis is clearly superior to conventional CT (Figure 7)[18]. In addition to identifying the etiology, severity and probable location of small bowel obstruction, CT is useful for determining the presence of closed loop obstruction and strangulation[18]. Recognition of these complications is of great concern to surgeons, particularly those who believe that a trial of conservative nonoperative management is warranted in simple mechanical small bowel obstruction[19]. With the use of multiplanar and 3-dimensional imaging the confidence of accuracy of answering pertinent clinical questions has considerably improved. The development of a multipurpose long tube (MDEC 1400, Cook Inc, Bloomington, IN) has improved the nonsurgical management of uncomplicated partial small bowel obstruction (Figure 8)[20]. Such long tubes have sump ports that are less likely to be occluded and are designed to be used with suction devices currently used in hospitals. Following adequate decompression of the small bowel, a CT enteroclysis may be performed to detect the site and etiology of obstruction.

Crohn's disease

The main groups of Crohn's disease are active inflammatory, fibrostenosing, chronic smoldering and fistulous types[21]. Differentiation of these groups is important in deciding therapy with immunosuppressant, anticytokine drugs and surgery. For instance, inhibitors of the cytokine tumor necrosis factor-alpha have been shown to useful in healing fistulous disease[22] but have no known beneficial effect on, or may exacerbate, fibrostenotic segments. Such drugs are expensive and careful patient selection is required. Multislice CT is quite sensitive in detecting unexpected active Crohn's disease in patients presenting with nonspecific abdominal pain. In determining the severity and extent of known active Crohn's disease neutral oral contrast with intravenous iodinated contrast is the optimal technique. Mucosal hyperenhancement, submucosal edema, wall thickening, and mesenteric hypervascularity ("comb sign") are well demonstrated by this technique (Figure 2). Enteric fistula, fibrostenotic segments and abscess are also diagnosed by this technique. Isotropic imaging with multiplanar reformats is helpful for diagnosis and surgical planning. The important differentiation of small

Figure 9 Neutral enteral contrast CT enteroclysis in 27 years old female presented with chronic diarrhea and anemia. There was a prior history of systemic lupus erythematosis. Coronal reformat showed diffuse smooth small bowel wall (arrow) and fold thickening. Small bowel biopsy showed vasculitis.

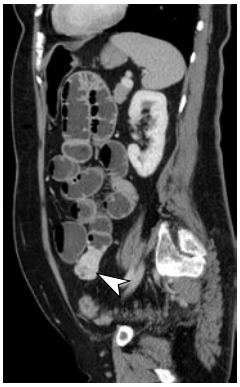

Figure 10 Sagittal reformat of CT enteroclysis in 63 years old female with unexplained gastrointestinal (GI) bleeding showed 3 cm hypervascular submucosal mass (arrow) arising from mid small bowel, proven as a gastrointestinal stromal tumor at surgery. Prior capsule endocsopy had shown no abnormality, other than jejunal angioectasia.

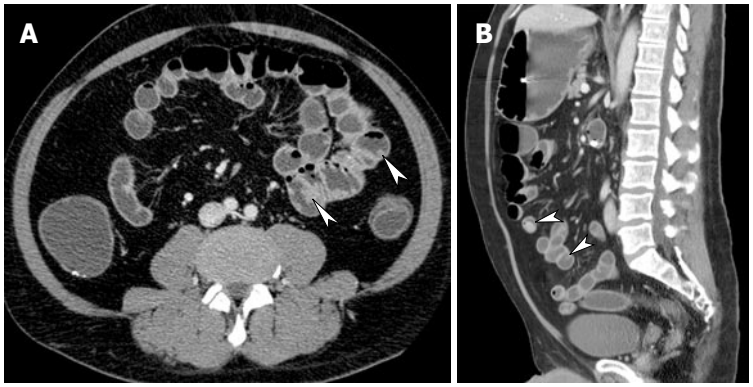

Figure 11 Fifty-two years old male with known Peutz-Jeghers syndrome. Axial (**A**) and sagittal (**B**) images showed multiple polyps of varying sizes in the small bowel (arrowheads). Information regarding the location and sizes of polyps was valuable in performing double balloon endoscopic polypectomy.

Figure 12 Metastatic carcinoid in 59 years old female presenting diarrhea and wheezing. Coronal reformat of isotropic resolution CT enteroclysis performed with neutral enteral contrast showed 3 cm hypervascular mass in distal ileum (arrowhead) and hypervascular liver metastases (arrow).

bowel obstruction due to active inflammation and fibrostenotic disease is accurately performed by CT enteroclysis. Aphthoid lesions of suspected early Crohn's disease, increasingly diagnosed by capsule endoscopy, are usually not visible on CT. If radiological investigation is required in such cases we use barium and carbon dioxide double contrast fluoroscopic enteroclysis. CT is also useful in showing inflammatory small bowel disease other than Crohn's disease (Figure 9).

Small bowel tumors

In the investigation of small bowel mucosal lesions, imaging techniques have had to adapt to the advent of capsule endoscopy. In our institution CT enteroclysis is used to exclude luminal stenosis prior to capsule endoscopy. Where capsule endoscopy is negative despite the high suspicion of tumor, e.g. unexplained gastrointestinal bleeding with positive occult blood, we recommend CT enteroclysis. Capsule endoscopy may miss submucosal lesions (Figure 10). Other reasons for false negative capsule endoscopy include focal lesions at sites where bowel is angulated, where there is rapid or very slow intestinal transit.

The ability to detect polypoid small bowel lesions, as in Peutz-Jeghers, is important when considering double balloon endoscopic polypectomy. In this regard the multiplanar imaging with 16-slice or higher generation CT is useful (Figure 11). In carcinoid tumors the site and number of primary tumors (30% have multiple primary sites) are best diagnosed with CT enteroclysis[23]. Because of its ability to evaluate the small bowel wall and the presence of liver metastases, CT enteroclysis with neutral enteral and intravenous contrast is the preferred technique (Figure 12). Nuclear medicine tests have been used to diagnose and stage carcinoid tumors. Indium-111 or iodine-123 labeled DTPA octreotide, a long acting analogue of somatostatin, has been shown to have a sensitivity of 80%-100% in diagnosing carcinoid[24]. Anatomic localization is improved with the use of single photon emission tomography (SPECT). Fluorine-18 deoxyglucose (FDG) positron emission tomography (PET) may be used for detection of poorly differentiated primary tumors that are not seen with other techniques. However for most small bowel carcinoid tumors, which have slow proliferation, FDG PET is of limited value[24]. PET scanning with fluorine-18 dopa, gallium-68 labeled octreotide or carbon-11 labeled tryptophan has been shown to be very sensitive in localizing tumor extent[24,25]. Small bowel lymphoma is another tumor where FDG PET has been found to be useful. Despite the mild physiologic uptake in the gastrointestinal tract, a positive FDG PET scan after the completion of chemotherapy in patients with small bowel lymphoma is a strong predictor of relapse[26].

Colonic cancer

The application of virtual colonoscopy to colorectal cancer screening caught the attention of the lay and professional communities following a seminal publication[27] which showed that with modern CT technology, virtual colonoscopy compares favorably with optical colonoscopy. Sensitivity of 94% and specificity of 96% for polyps larger than 1 cm were reported[27]. There remain several hurdles before virtual colonoscopy becomes part of the mainstream of colorectal cancer screening methods. These include limited reimbursement by third party payers, size threshold above which suspected colonic polyps will be investigated, ra-

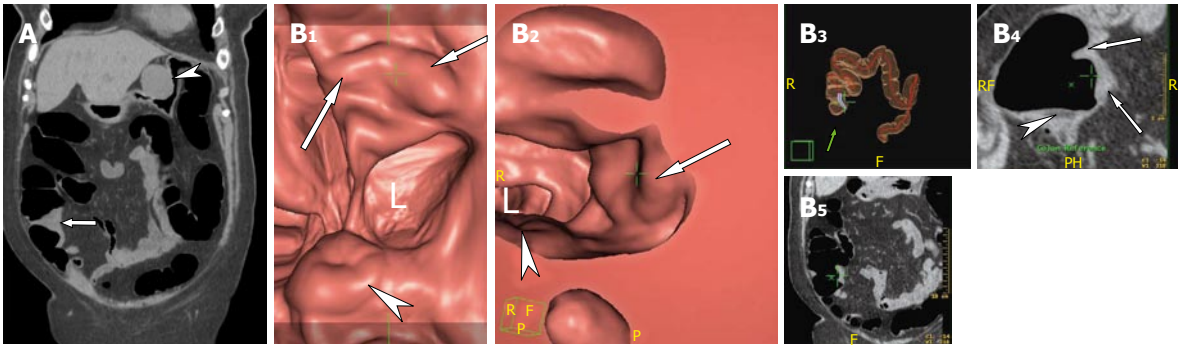

Figure 13 Fifty-eight years old male with incomplete optical colonoscopy. **A**: Coronal reformat showed a mass in the medial right colon (arrow) consistent with colonic cancer. A second mass (arrowhead) showed exophytic growth from the stomach and was subsequently proven to be a gastrointestinal stromal tumor; **B**: Images of virtual colonoscopy showed the mass (arrows) adjacent to the ileocecal valve (arrowheads). L = colonic lumen.

tionale for further work up of incidental findings, such as small low density renal and liver lesions. Currently, virtual colonoscopy is used clinically in patients with incomplete or failed optical colonoscopy (Figure 13) and those with contraindications to sedation. This test has been shown to affect treatment strategy in 7.5 to 19% of patients by identifying additional adenomas and carcinomas[28,29]. The use of virtual colonoscopy in known colon cancer is helpful in evaluating the whole colon for possible missed polyps and stage the cancer at the same time.

In conclusion the practice of alimentary tract imaging will continue to change. Details of the viscera which in the past were only diagnosed by indirect manifestations on barium examination are now demonstrated in exquisite detail by multislice CT. Functional information afforded by PET scanning adds further to the utility of CT in diagnostic imaging. Further developments in 3D imaging for the entire alimentary tube will add to presurgical mapping of many disorders. The modern era of gastrointestinal radiology is here. Active collaboration among surgeons and radiologists will ensure efficient utilization of the various advances discussed in this article.

Abstract

Treating common benign anal diseases has evolved towards more outpatient procedures with better outcome. However, minimizing post-procedure morbidities such as pain and the avoidance incontinence remain the most significant concerns. We introduce some controversies and highlight the developments in current surgical practice for the treatment of common anal problems.

INTRODUCTION

Benign anal conditions are common and may pose troublesome physical, mental and social ailments to patients. There are numerous surgical techniques and non-surgical treatment used to treat this group of disease and most of the modalities are safe and effective. The main concern of treating anal conditions are the after-treatment undesirable pain and sphincter dysfunction which often pose a significant challenges to the attending physicians.

HEMORRHOIDS

Hemorrhoids develop from engorgement and prolapse of the submucosal anal cushion, which composed of an interlacing arteria-venous hemorrhoidal plexus, supported by connective tissue and minute muscle fibres[1]. The bulk of the anal cushion is located above the dentate line, which is devoid of sensation. The classical positions are described as the left lateral, right anterior and right posterior. The division between internal and external hemorrhoids is by their origin pedicles being proximal (overlaid by mucosa) or distal (overlaid by squamous epithelium) to the dentate line. The pressure within the anal cushion contributes to approximately 15 percent of perfect anal continence[2]. It is reported that continence disturbance co-exists in 40 percent of patients with hemorrhoids[3] and disrupting the anal cushion during hemorrhoid treatment may further worsen it.

The true prevalence of symptomatic hemorrhoids is unknown. It was reported to affect up to 10 million of North American and the European population in 1980s[4]. Predisposing factors include hereditary factors, constipation and increased intra-abdominal pressure, which include pregnancy, ascites, coughing and strenuous work. Inadequate fiber intake, prolonged sitting on the toilet and chronic straining at stool are among the risk factors. The symptoms of hemorrhoids are non-specific and the diagnosis is made by direct visualization via anoscopy or proctoscopy examinations. However, further evaluations using sigmoidoscopy or colonoscopy is useful when symptoms are not truly apparent of hemorrhoids especially in the elderly to rule out more serious conditions such as malignancy[5]. Other common symptoms of hemorrhoids include mass protrusion, pruritis ani, itching, mucus discharge and perianal pain[3,5]. Intermittent mass protrusion and occasional painless bleeding often do not require urgent treatment but acute symptoms of pain, bleeding and incarcerated protrusion warrant immediate action. In practice, the classification of hemorrhoids generally follows their prolapsing characteristics and they are staged into 1-1V degrees as outlined by Goligher. This classification serves as a useful guide towards choice of treatment modalities. However, comparison of treatment efficacy is largely focused on symptomatic relief and satisfaction outcome that are mostly measured using pain scores, recurrence rates and disturbance of continence after treatment.

Non-surgical treatments are indeed convenient and can avoid unnecessary complications of surgery. Unfortunately, many of these are lacking in evaluation to confirm their role in hemorrhoid treatment. High fiber intake and laxatives are employed in almost all hemorrhoid stages as an initial choice of treatment with the intention to prevent constipation and straining at defecation and reduces local

inflammation. Similarly, antidiarrhea agents are used when diarrhea or frequent defecation exacerbate hemorrhoid symptoms. These have temporarily reduced hemorrhoids symptoms as shown by several placebo-control studies[6-9]. Relief of symptoms is further enhanced with emphasis on anal hygiene. In general, the symptomatic resolution using conservative measures alone might be temporary and more patients seemed to need further surgical intervention after conservative treatment. Numerous ointments, creams and suppositories are being used as topical agents for hemorrhoids. They are mainly composed of local anesthetics, steroids and several skin irritation preparations to ameliorate symptoms of prurits ani or pain. Their function as remitting agents is indeed very limited.

The most known oral pharmaceutical agent used to treat hemorrhoids is Daflon™, which consists of mainly micronized diosmin and hesperidin. This is a venotropic compound used in various venous disorders. A dose of 500mg taken two to three times daily rapidly diminishes variable degree of hemorrhoid symptoms such as pain, bleeding and swelling within 10 d of treatment[10,11]. In addition, an extended dosage studied by Godeberge[12] using Daflon 1000 mg bid for two months has resulted in 60 percent symptoms severity reduction as compared to 30 percent of the placebo group without much side effects. Nevertheless, rapid symptomatic relief alone might not be satisfying and it is still unclear concerning the ability of this oral pharmaceutical agent in preventing hemorrhoids surgery. Daflon™ is however not readily available in the United States and the use of any pharmaceutical agents for hemorrhoid treatment has yet to achieve wide acceptance among North American physicians.

Asymptomatic external hemorrhoids do not require surgical intervention but these are prone to thrombosis. The treatment for thrombosed external hemorrhoids is rather straightforward. The main aim is to rapidly eliminate pain by means of general conservative measures, clot evacuation or surgical excisions. The choice of treatment depends largely on the severity of pain. It will be wise to embark on surgical procedures at the peak of the pain which is within 24 to 72 h of its initiation. This is because the procedures themselves might be more painful. When the pain is somewhat tolerable, conservative measures is useful because most pain decreases with time. However, surgical excision is more effective with lower relapse rate and longer remission intervals than conservative measures[13]. On the other hand; the treatment for symptomatic internal hemorrhoids had undergone numerous revolutionary modalities. Multiple ablative techniques had been used and these are mainly aimed at fixing of the anal cushion and disrupting the hemorrhoid circulation by means of local office procedures or surgical excision (hemorrhoidectomy). Among the office procedures are injection sclerotherapy, rubber band ligation, diathermy, cryotherapy and infrared photocoagulation. Most of these are simple to perform and capable of producing satisfying short and long-term improvement. Furthermore, repeated attempts can be done until satisfying results achieved. The overall success rates measured by symptomatic improvement and avoidance of further intervention were 80 percent to 90 percent[14-16]. Controversies remain with regard to the best procedure that produce the least complications of pain, bleeding and incontinence. These complications are mainly technical and frequently used as gauge for patients' satisfaction between treatment modalities. Rubber band ligation seemed to have better long term efficacy in terms of lower recurrence and complication rates than other modalities in treating second and third degree hemorrhoids[17-21]. These complications can be substantial and may affect overall treatment success[20-22]. There were many comparison studies between two modalities and the results did not show clear advantage of any procedure over another. Initial results from the use of rubber band ligation for second and third degree hemorrhoids has shown better long term efficacy especially in reducing prolapse but complications such as pain and bleeding remained the same[17-21]. However, in a meta-analysis, Johanson *et al*[22] found that the curative rate was almost similar for all methods of treatment after 12-mo follow-up. The rubber band ligation had the best result at preventing recurrence but complication of post treatment pain was the least after infrared coagulation treatment. Gupta[23] also demonstrated similar result in a randomized study comparing rubber band ligation and infrared coagulation treatments. Combining two modalities has also produced good therapeutic result. Chew *et al* combined injection sclerotherapy with rubber band ligation and achieved 90 percent cure or improvement. The complication rate was 3.1 percent with an overall recurrence rate of 16 percent. Only 7.7 percent of these patients required hemorrhoidectomy[24]. In summary, these studies have shown that most of the office treatments are safe and effective for low grade hemorrhoids but the best among all is yet to be confirmed. Correcting technical issues has lowered the complications rates making office treatment for first to third degree hemorrhoids tolerable and satisfying.

Hemorrhoidectomy is currently the ultimate treatment for advanced or severe hemorrhoids. It has been the standard and eventual treatment for decades before the introduction of stapled hemorrhoidopexy in 1997. There are numerous techniques of hemorrhoidectomy but the two most popularly used are the Milligan-Morgan open procedure and the Ferguson closed procedures. The Milligan-Morgan procedure involves excision of the hemorrhoids with the overlying mucocutaneous tissue. The excision will need to preserve adequate skin bridges in between excised hemorrhoids to prevent stricture. After achievement of hemostasis, the wound is left opened with a classical clover appearance for secondary healing. In the Ferguson procedure instead, the wound is sutured together for healing by primary intention using absorbable materials. Both these techniques had achieved up to 90 percent cure for third and fourth degree hemorrhoids with few wound complications[25-27]. These operations are associated with significant post operative pain and the exact etiology is still unknown. It is thought to be due to anal sphincter spasm and concurrent bacterial infection. The use of local anesthetic injection or peripheral nerve block has shown to benefit patients in terms of immediate pain control[28,29]. These can be combined with oral analgesics and antibiotics such as Metronidazole[30] to alleviate pain. In addition, a con-

comitant lateral internal sphincterotomy was also shown to reduce pain without causing more incontinence[31]. However, routine usage of perioperative antibiotics and lateral internal sphincteromy to diminish postoperative pain are controversial.

Another commonly encountered problem of hemorrhoidectomy is bleeding. There are several modifications of the classical technique have been tried to overcome it. This involved using diathermy, laser, Ligasure™ and Harmonic scalpel™ during hemorrhoid excision. Other complications of hemorrhoidectomy include temporary urinary retention and wound infection, which are usually treated by conservative measures. In 1997, Longo introduced the treatment of prolapse hemorrhoid by means of a stapled mucosectomy. It is indeed the only method that does not require the hemorrhoids to be excised and the term 'stapled hemorrhoidopexy' was hence used[32]. It is otherwise known as the procedure for prolapse hemorrhoids (PPH) and involves excision of rectal mucosa just proximal to the dentate line and fixing the two cut end together using a circular staple device. This results in disruption of hemorrhoidal circulation and produces healing. Stapled hemorrhoidopexy have more peri-operative advantages and seems to fair equal if not better to hemorrhoidectomy in terms of patients' tolerability. However, its effectiveness as an ultimate treatment for prolapse hemorrhoids awaits further evaluations. Comparison with standard excision hemorrhoidectomies in several randomized trials has shown that stapled hemorrhoidopexy produced shorter hospital stay and better tolerated especially during the immediate post-operative period. It also has the advantage of providing earlier return to normal daily activity for patients[33-40]. This may be largely due to the much reduced pain resulted from the procedure. The major short and long-term complications of stapled hemorrhoidopexy were also rare and comparable to the conventional hemorrhoidectomies. Apart from pain, the complications observed include temporary incontinence disturbance. The theoretical anal sphincter trauma or injury caused by instrumentation of this technique did not seem to be real as shown by studies that assessed anal sphincter function and anal manometry at follow up[33,34,39]. Relapse of symptoms occurred in less than 5 percent of cases with an average of 90 percent patients satisfaction can be achieved. This however, did not differ from the hemorrhoidectomy procedures. Most relapse cases in those trials were successfully salvaged using local office treatments or hemorrhoidectomies. In a most recent study by Gravie *et al*, stapled hemorrhoidopexy had produced good long-term outcome of 85 percent cure after 2 years with comparable morbidity to the conventional hemorhoidectomy[41]. This result was shown to be reproducible by any level of operators.

In summary, patients' comfort and avoidance of complications are the prime issues in treating symptomatic hemorrhoids. For optimal outcome, careful symptomatic assessment in determining the degree of disease severity is an important step for the physician to decide which modality suits their patients best.

ANORECTAL ABSCESS

Anorectal abscess is a common condition caused by infection of the anal glands situated in the crypt of the anorectal junction. The spread of the infection into the intersphincteric space resulted in collection of pus into surrounding perianal spaces. It commonly affects young men with the common symptoms include perianal pain, fever, tender lump around the anus and sometimes produces discharge and incontinence[42,43]. In practice, the Park's classification of anorectal abscess into perianal, intersphincteric, ischio-rectal and supralevator is widely used. Perianal and intersphinteric abscesses occurred more commonly then the deeper ischiorectal and supralevator abscesses[42-44]. Apart from the cryptoglandular origin; causes of anorectal abscesses include Crohn's disease, tuberculosis, malignancies and trauma. Patients who are diabetic and immunosuppressed are also prone to ano-rectal abscesses.

Small and simple perianal and intersphincteric abscesses are usually cured by adequate drainage, which is done through a skin incision or transrectally. Clinical examination under anesthesia frequently provides accurate assessment. For the more obscured abscesses, radiological guidance such as CT scan may help in delineating severity.

A perianal eliptical radial incision over fluctuant area of the abscess and breaking of all locules are sufficient to eliminate infection. The incision is preferred to be as close possible to the anus so that any concomitant fistula can easily be treated later. Specimen for culture and sensitivity is not necessary because antibiotic is not needed for treatment. The use of antibiotics is only for extensive cellulitis, necrotizing lesions or in immunocompromised patients or those with valvular heart disease or implants. However, culture result differentiating gut from skin flora is rather sensitive in determining the presence of fistula[42-47] although this is no better than the surgeons' careful search[48]. All necrotic tissues are minimally debrided with care not to injure the anal sphincters and often drains are used to facilitate drainage. The wound is left opened for secondary healing along with adequate analgesia and sitz bath. Reported complication and abscess recurrence were low at 3 and 0.6 percent respectively[42] and the reasons for recurrence were mainly inadequate drainage or missing a concomitant fistula[49]. The treatment of anorectal abscess is more complex when it is deep, large, multiple or associated with a fistula. These may occur due to the abundant adipose tissue filling the supralevator and ischiorectal spaces. In addition, a horseshoe abscess may develop from deep post anal space abscess connecting to the ischiorectal spaces. In these abscesses, the main concern is the presence of concomitant fistulas. The reported incidence is 35-65 percents[43,50].

Beside draining and debridement, the treatment of the abscesses requires meticulous search of the internal openings and determining the amount of anal sphincters involvement along the fistulous tracks. This can be difficult in the setting of active acute inflammation. Preoperative endoanal ultrasonography and magnetic resonance imaging may facilitate in delineating the complexity of these.

In most instances, the detection of an internal opening is achieved by passage of pus seen at proctoscopy and gentle massaging of surrounding abscess swelling. Once identified, the decision to drain percutaneously or transrectally is much based on the type of abscess that one deals with. This is to avoid the development of high trans-sphincteric or extrasphincetric fistulas, which may develop from drainage of supralevator and ischiorectal abscesses. The drainage of supralevator abscesses need special attention to its aetiology[44]. It may be associated with both pelvic inflammatory process or trans-sphicteric spread of cryptoglandular origin. Drainage through the rectum is preferable when they originated from intersphincteric spread. This is to avoid forming a suprasphincteric fistula which is much more difficult to treat in later dates. Another important consideration is to perform fistulotomy or fistulectomy during abscess drainage or to do staged procedures. Excessive sphincterotomy produces incontinence due to inability to judge precisely the amount sphincter involved. In one prospective study, Schouten *et al*[51] compared patients who underwent concomitant fistulectomy from those who had a staged drainage with secondary fistulectomy. They found that immediate fistulectomy at drainage is associated with 40 percent continence disturbance which tend to worsen overtime. They then recommended for abscesses to be drain adequately first and fistulectomy is reserved for a second stage procedure. In contrast, others have demonstrated that concomitant fistulectomy is safe and effective in eliminating fistula and prevent recurrence[50,52]. Persistent symptomatic fistula occurred in 25 percent of patients who did not undergo primary fistulectomy and incontinence were similar whether or not a primary fistulectomy is performed. However, in acute setting of abscess, the use of stage procedure using drainage seton will potentially minimize anal sphincter injury with fistulotomy or fistulectomy.

PERIANAL FISTULA

Perianal fistula and ano-rectal abscess are merely two components of a disease encountered at a different time. Typical symptoms of their co-existence are recurrent perianal pain with chronic purulent discharge. Common etiological factors denote similar therapeutic approach and the presence of one component will merit the search for the other for a complete cure. The Park's classification[53] of perianal fistula into intersphincteric, transphincteric, suprasphincteric and extrasphincteric described the anatomical tract route in relation to the anal sphincter complex, which is useful for therapeutic guidance. Division into simple and complex fistulas entails risk of sphincter dysfunction upon treatment. The main goal of treating perianal fistulae is to eradicate sepsis and eliminate epithealized tracks without causing incontinence. Patients' satisfaction after fistula treatment is largely related to recurrence and the effect on continence[54].

For the low and simple fistulas, effective treatment is by cutting open the fistulous track (fistulotomy) for secondary healing to take place. It is easy to perform but meticulous assessment must be emphasized on the amount of external sphincter involvement especially in multiparous women. Excising the entire fistula track (fistulectomy) when minimal anal sphincter is involved is also safe but has to be performed with precision. The overall rate of recurrence by these procedures is low at around 4 percent[55,56]. Despite this, the reported incontinence rate was up to 45 percent. This mainly occurred after fistulectomy, which also gave a longer healing time due to the larger tissue excision. Risks factors for incontinence include anal deformities from previous surgery, prior diarrhea and internal sphincterotomy[55,57].

The treatment for complex and high fistulas involving multiple tracks and abscesses needs more diligent strategy. Traditionally, if more than half of the sphincters are involved a staged procedure with cutting setons is used. However, identification of tracks in complex fistulas requires a combination of careful clinical and perhaps radiological assessments prior to intervention. Hydrogen peroxide enhanced endorectal ultrasound and magnetic resonance imaging may aid in delineating the tracks and abscesses[58-60]. These examinations will also allow assessment of anal sphincter anatomy and tone prior to surgery and exclude fistulas from Crohn's disease, perianal tuberculosis and malignancy. Guided blunt probing of the tracks will enable drainage seton insertions for abscess and identification of external anal sphincter for later interventions. When the sepsis is eliminated, a cutting seton which is changed or tightened in the office at certain follow up intervals can be applied. The cutting seton will cut through the muscle producing immediate fibrosing effect that prevent sphincter retraction. Using this method, the healing rate is high and recurrence of fistulas occurred at only 4-6 percent of cases[61-63]. However, cutting setons are associated with 19 to 63 percent of incontinence and causes pain and discomfort. The reason for incontinence is multifactor. While it appears obvious that excessive cutting of the external anal sphincter might be the main reason for incontinence, preserving the internal component of the sphincters may be advantages. A technique introduced by Zbar *et al*[64] had shown that by excluding the internal anal sphincter using a modified cutting seton technique gave better continence result by virtue of better post-operative anal pressure measurements. The technique combined a short mucosal flap (not incorporating the IAS musculature) to close the internal opening, and IAS repair and a re-routing of seton (for EAS cutting) through the intersphincteric space. In essence, identification of patients who are prone to develop incontinence after a cutting seton may help. This includes those who had multiple abscess drainage or previous fistula repairs and patients with chronic disease or infection[61]. Avoiding excessive sphincter cut in these patients would certainly be wise. An alternative to overcome cutting seton morbidities is to use a two stage seton fistulotomy. This involved the insertion of a loose seton for abscess drainage followed by a scheduled secondary fistulotomy. The seton could be left for long period of time until sepsis settles or satisfactory healing achieved especially in complicated cases like Crohn's disease[65].

Another option of treating perianal fistulas is using

the advancement flap procedures. This involves elevating flaps composing of rectal mucosa, submucosa and internal sphincter to cover the internal opening without tension. Associated sepsis is initially eradicated and this procedure will require a good bowel preparation to achieve better healing. It is mainly performed when fistulotomy is either dangerous or difficult such in high trans-sphincteric and suprasphincteric fistulas, the anterior fistulas and fistulas associated with Crohn's[66-70] In addition, advancement flap procedures are particularly useful in patients who had failed previous treatment[68,69]. The effective healing rate is between 60-82 percent[68-72]. It is expectedly associated with low continence disturbance of less then 10 percent but the recurrence rate varies from 8 to 40 percent[70-72]. Recurrence and failure are especially observed among patients with Crohn's disease or those who had multiple prior fistula procedures[70-72].

Another method in treating perianal fistula is the use of fibrin glue, which obliterates fistula opening and tracks. This method avoids the extensive dissection of other techniques especially in complex fistulas. The reported success rates for these complex fistulas were moderate and vary from 14 to 60 percents[73-75]. Its use is potentially good in short tract and low-lying fistulas and theoretical continence disturbance from fibrin glue use in these should not be real although reports regarding it are not available. For highlocated internal openings and more proximal fistula, fibrin glue application may be performed using endoscopic assistance[74,75].

PERIANAL CROHN'S DISEASE

In Crohn's disease prevalence of perianal lesions is about 6 to 29.6 percent and it is associated with more colonic and than ileal diseases[76,77]. Severe perianal disease with typical features of multiple non-midline fissures and fistula lesions is rather easy to recognize but it is often difficult to diagnose perianal Crohn's from fistulas of cryptoglandular origin with confidence without active intestinal disease. Furthermore, the yield of histological granuloma for definitive diagnosis is only at 20 to 40 percent of biopsies[78,79]. It is therefore challenging to decide on anti-cytokine therapy or surgical treatment without confirmatory diagnosis. In addition, even when the diagnosis is obvious, healing of perianal lesions from medical treatment is very unpredictable resulting in recurrent attacks and intractable disease. Infliximab, which is an anti tumor necrosis factor antibodies, provides a 60-70 percent response rate in fistulizing Crohn's disease patients who were refractory to immunosuppresant therapy[80,81] and the best response was achieved among the patients with perianal disease[81,82]. It has thus prevent a significant proportion of patients from surgery because excessive radical surgery to treat perianal Crohn's disease may worsen the existing condition. Traditionally, proctectomy and ileostomy is used to treat severe perianal Crohn's disease. Current efforts are now focused on interventions that will alleviate symptoms and avoid proctectomy. More sphincter sparing and conservative measures such as long duration setons were used effectively[83,84]. Fistulotomy is reserved for superficial fistulas and endorectal advancement flap surgery may be appropriate for more complex fistulas after sepsis eradication in patients with permissible rectal disease, competent sphincters and absence of strictures[85,86].

ANAL FISSURE

Comprehensive systematic reviews with regards to the treatment of anal fissures are readily available[87,88] and this chapter is indeed containing a brief overall management summary. Anal fissure is a break in the squamous epithelia of the anal canal. Its true etiology is not completely understood but hypertonic internal anal sphincter is a common finding and this is thought to cause ischaemia and ulceration. However, cases of anal fissure with normal or even lower resting anal pressure is not uncommon. Ninety percent of fissures are found in the midline over the posterior part of the anal canal and it is prevalent in young individuals of the third and fourth decade. Associated anal conditions include Crohn's disease, hemorrhoids and perianal fistula. Typical symptoms of anal fissures are excruciating pain at defecation, which sometimes followed by post defecation bleeding and pruritis ani.

The division of acute and chronic anal fissure is mainly by the length of symptoms existence. Persistent symptoms of 6 wk or more preclude chronic fissures. In addition, an acute anal fissure has sharp margins with signs of acute inflammation and pink granulation tissue overlies the base while the chronic fissures have raised margins and lack of granulation. Often, horizontal fibers of the internal anal sphincter, which is sometimes hypertrophied, can be seen at the base of a chronic anal fissure. The diagnosis of anal fissure requires direct examination of the anal canal usually performed under anesthesia. Anal manometry and continence score are the commonly used tools to accurately assess treatment outcome since the reduction of anal resting and squeeze pressures correlate well with symptoms improvement and healing. Disturbance of continence is indeed the main complication found in every treatment modality. Most acute fissures will resolve after conservative measures of regular fiber diet modification, stool softener and topical and oral analgesia. This will also cure 10% of chronic fissures but the remaining chronic fissures will require further interventions. The use of topical pharmaceutical agents (chemical internal sphincterotomy) is largely aimed at reducing anal sphincter hypertonia which will then reduces ischaemia and hence promote fissure healing. Topical glyceryl trinitrate (GTN) has a symptomatic and healing effect on chronic anal fissures by causing transient relaxation of anal sphincter through exogenous nitrous oxide provision. Healing is usually observed after a period of 8 wk applications. Studies that attempted to determine the optimal dosage for GTN has been eluded by the high improvement rates shown in the placebo arms due to sampling that might include patients with acute fissures[89-91]. In a study by Thornton *et al*[92], rapid reduction in mean anal resting pressure by 20 percent after first application was achieved. For the patients that were compliant, 73 percent of them achieved symptoms relief with 64 percent fissures healed after 8 wk treatment. The clinical improvement was

also found to correlate positively with high pre-treatment maximum anal resting pressure in the mid anal canal and lower fissure score. The main side effect of topical GTN is headaches that occurred in 20-30 percent of treatment and this was independent of the dosage used despite producing 46-50 percent healing[89-91].

Another pharmaceutical group of substance used to treat chronic anal fissures were the calcium antagonist. Topical nifedipine produced up to 90 percent healing and was better in terms of headache complication compared to GTN[93,94] In another study, calcium antagonist diltiazem produced significant pain and bleeding reduction in an additional 48 percent of patients who had either failed GTN treatment or those who could not comply to GTN due to severe headaches with lesser headaches[95].

Botulinum toxin injected around the fissure and the anal sphincters is another substance used in treating chronic anal fissure. It is also believed that the mechanism involved is related local production of nitrous oxide resulting in sphincter relaxation even though the exact mechanism is still obscured. In one double-blind placebo controlled trial of patients who had failed GTN topical treatment, Maria *et al* demonstrated that injection of 20 U of botulinum toxin produced symptoms relief and healing of 86 and 53 percent respectively at one month follow-up as compared to 13 and 27 percent in the placebo group[96].

Furthermore, the healing rate improved after 2 mo follow up and repeat injection can be performed to avoid surgery. It was also not associated with severe local or systemic complication except for transient incontinence, which tends to recover expectantly[96,97]. However, after longer follow up period, it was reported that more than half of patients who received botulinum toxin injection for chronic fissures required lateral internal sphincterotomy due recurrence[98,99].

Currently, the best available treatment for chronic anal fissure is lateral internal sphincterotomy (LIS). It is done by dividing the distal one third of the internal sphincter fibers without extending beyond the dentate line. The sphincter is divided over the lateral aspect to ease healing and management after surgery. Comparison with topical chemical use had repeatedly shown LIS is a better modality with persistent healing rates of 90 percent and provides more rapid symptoms improvement[100,101]. It also produces high patients satisfaction and better quality of life[102]. The reported continence disturbance after LIS is between 10-30 percent and severe incontinence to solid stool occurred in 1 to 3 percent of treated patients[100-103]. Recently**,** efforts are being made to avoid incontinence using a tailored[104] or controlled[105] techniques. These involve precise graduated division of the sphincter tailored to the fissure length rather than the dentate line as the reference points. These techniques had claimed fewer incontinence and stenosis complications. Covering an anal fissure with a skin flap by means of a V-Y flap or a rotational flap is another surgical modality available for chronic anal fissure. This is probably the best method for recurrent fissures after surgical treatment or traumatic sphincters or patients with weak sphincters (low pressure fissures) such that occur in multiparous women or previously irradiated patients. The technique provides the advantage of avoiding further sphincter injury. Unfortunately, reported series comprised small number of patients and it is rather difficult to make conclusions with regards to its effectiveness[106-108]. These techniques seemed to be easy to perform and maybe considered as an alternative methods in treating chronic anal fissures.

Abstract

The immense success of laparoscopic surgery as an effective treatment of gastroesophageal reflux disease (GERD) and achalasia has established minimal invasive surgery as the gold standard for these two conditions with lower morbidity and mortality, shorter hospital stay, faster convalescence, and less postoperative pain. One controversy in the treatment of GERD evolves around laparoscopic antireflux surgery (LARS) as the preferred treatment for Barrett's esophagus and the procedure's potential to reduce the risk of adenocarcinoma of the esophagus. GERD has also been associated with respiratory symptoms, asthma and laryngeal injury, and a second controversy prompts discussions about whether total or partial fundoplication is the more appropriate treatment for GERD. A new and promising alternative in the treatment of GERD is endoluminal therapy. Three types of this new treatment option will be discussed: radiofrequency energy delivered to the lower esophageal sphincter, the creation of a mechanical barrier at the gastroesophageal junction, and the direct endoscopic tightening of the lower esophageal sphincter.

Laparoscopic surgery is discussed not only as a very effective treatment for GERD but also as permanent cure for achalasia. This review analyzes the three most important treatment options for achalasia: medications, pneumatic dilatation, and surgical therapy. Medications as the only true non-invasive option in the treatment of achalasia are not as effective as LARS because of their short half-life and variable absorption due to the poor esophageal emptying. The second treatment option, pneumatic dilatation, involves the stretching of the lower esophagus and is still considered the most effective non-surgical treatment for achalasia. Finally, surgical therapy for achalasia and the two major controversies concerning this laparoscopic treatment are discussed. The first involves the extent to which the myotomy is extended onto the stomach, and the second concerns the necessity and type of antireflux procedure to prevent GERD after myotomy.

LARS and laparoscopic Heller myotomy are the agreed upon as the gold standards for surgical treatment of GERD and achalasia, respectively. In the hands of an experienced laparoscopic surgeon both are safe and effective treatments for patients with excellent subjective and objective long-term results with at least 90% patient satisfaction.

INTRODUCTION

The immense success of laparoscopic surgery as an effective treatment of gastroesophageal reflux disease (GERD) and achalasia has established minimal invasive surgery as the gold standard in the surgical treatment of these two conditions. Compared to open surgery, laparoscopic procedures result in lower morbidity and mortality, shorter hospital stay, faster convalescence and less postoperative pain. The effectiveness of minimally invasive therapy has increased the surgeon's involvement in the diagnosis and treatment of patients suffering from GERD or achalasia and has also resulted in a more profound understanding of the pathophysiology of these diseases.

GERD

In 1956, Nissen[1] was the first surgeon to treat severe GERD by wrapping the gastric fundus around the distal esophagus. The Nissen fundoplication rapidly became the standard for the surgical management of GERD.

Dallemagne *et al*[2] performed the first laparoscopic Nissen fundoplication in Belgium in 1991. After quickly

establishing the safety and efficacy of the procedure, laparoscopic antireflux surgery (LARS) became the state of the art surgical treatment for GERD.

With increased experience and improvements of advanced laparoscopic and esophageal surgical skills, there has been a significant decline in early and long-term complications. In a review of more than 10 000 reported laparoscopic antireflux procedures, morbidity was uncommon (6%), mortality was rare (0.08%), and the reoperation rate was low (4%)[3]. The overall mortality rate is generally low, but does depend on the experience of the surgeon. The rate decreases from 1.3% with an experience of less than 5 cases, to 0.0% with 50 cases or more[4]. The most common side effects of LARS are dysphagia and bloating, but these symptoms are usually self-limited. Dysphagia, for example, is common in the immediate post-operative period, but usually resolves in the first six weeks after surgery; persistent dysphagia occurs in only 2% to 5% of patients[5]. The symptom of bloating also seems overemphasized as a surgical side effect because the prevalence of bloating is quite similar in both surgically and medically treated patients[6].

Although the ultimate goal of both medical and surgical therapy is the alleviation of symptoms, surgical therapy imparts a mechanical solution to GERD whereas medical therapy is aimed at acid suppression. Despite the disparate mechanisms of action, comparisons of medical and surgical therapy of GERD enliven gastroenterologists and surgeons alike. Additional debate concerns the effectiveness of LARS to reverse reflux related injury (e.g., Barrett's esophagus) or alleviate chronic respiratory disease. Finally, technical considerations of LARS, such as the utility of partial or complete fundoplication or the necessity to divide the short gastric vessels, have yet to be completely reconciled.

Medication vs operation

Antireflux surgery has been shown to be very effective at alleviating symptoms in 88% to 95% of patients, with excellent patient satisfaction, in both short and long term studies[7-9]. These excellent results include patients with complicated GERD, such as those with large hiatal hernias, refractory esophagitis and peptic strictures. In addition to symptomatic improvement, the effectiveness of LARS has been objectively confirmed with 24-h pH monitoring, which clearly demonstrates excellent control of esophageal acid exposure more than five years after surgery[8]. When compared to medical therapy, surgical therapy has proven to be superior. A randomized, multicenter trial, with 5-year follow-up, demonstrated that antireflux surgery (open fundoplication) is more effective than proton pump inhibition (PPI) in controlling gastroesophageal reflux disease symptoms[7,10].

Another randomized trial, with 10 year follow-up, evaluating the effectiveness of medical therapy (omeprazole) versus antireflux surgery found that patients who underwent surgery had improved relief of symptoms when compared to the medically treated group[11]. Proponents of medical therapy argue that 60% of patients in the surgical group were taking antacids on a regular basis and should therefore be considered treatment failures. However, the liberal use of antacids in medical practice today makes medication use an unreliable outcome measure of LARS. This is supported by the fact that up to 75% of patients who take such medications after Nissen fundoplication have normal 24-h pH results when tested[12].

Barrett's esophagus

Barrett's esophagus, defined microscopically as intestinal metaplasia of the lower esophageal epithelium, is a result of severe GERD, and carries with it an increased risk of progression to adenocarcinoma of the esophagus. Many patients with Barrett's epithelium have GERD symptoms that are difficult to control with medical therapy, and there is little evidence that the natural history of Barrett's can be affected by proton pump inhibitors (PPIs). Oelschlager *et al*[13] recently reported excellent control of reflux and associated symptoms after LARS in patients with Barrett's esophagus. Complete regression was demonstrated in 34 of 106 (32%) patients with intestinal metaplasia, and in 55% of those with short segments (< 3 cm) of Barrett's esophagus. Hofstetter *et al*[14] observed that low-grade dysplasia regressed to nondysplastic Barrett's in 7 of 16 (44%) patients, and in 9 of 63 (14%) intestinal metaplasia regressed to cardiac mucosa.

Additionally, Bowers *et al*[15] reported a regression rate of 13 of 22 (59%) of patients with short segments of Barrett's. With more and more evidence suggesting that LARS may affect the natural history of Barrett's esophagus, and ultimately the risk of esophageal cancer, surgical therapy should be strongly considered for patients with Barrett' s esophagus, especially for young patients and those with symptomatic Barrett's esophagus.

Respiratory symptoms

GERD has long been associated with respiratory symptoms (chronic cough, sinusitis, and recurrent pneumonia), asthma and laryngeal injury (hoarseness, subglottic stenosis, and laryngeal cancer)[16]. A leading theory suggests that decreased esophageal peristalsis and delayed acid clearance leads to persistent aspiration and subsequently to injury within the respiratory tract. Respiratory complaints in patients with GERD are synonymously referred to as atypical symptoms of GERD, laryngopharyngeal reflux (LPR), or laryngoesophageal reflux disease (LERD). And even though atypical GERD symptoms are much more likely to respond to surgical therapy than medical therapy, the most useful predictor for the relief of reflux-related respiratory symptoms through LARS is a prior positive response to PPI therapy[17].

Johnson *et al*[18] found that patients with typical symptoms of GERD frequently have respiratory symptoms. In their series of patients undergoing Nissen fundoplication for typical symptoms of GERD, 76% of patients who had respiratory symptoms preoperatively, experienced relief of their symptoms postoperatively. Similarly, Farrell *et al*[19] reported on 324 patients who underwent laparoscopic fundoplication for typical and atypical symptoms of GERD. They found that 99% of patients with predominantly typical symptoms experienced symptom relief, whereas 93% of those with primarily atypical symptoms (asthma,

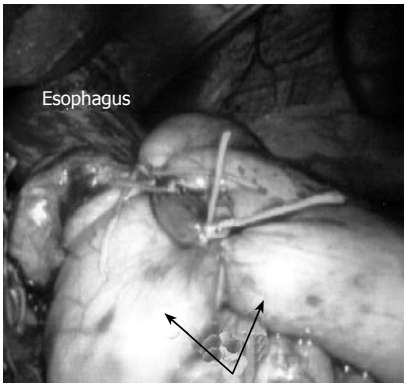

Figure 1 The Nissen fundoplication involves a 360-degree wrap (arrows) of the gastric fundus around the distal esophagus.

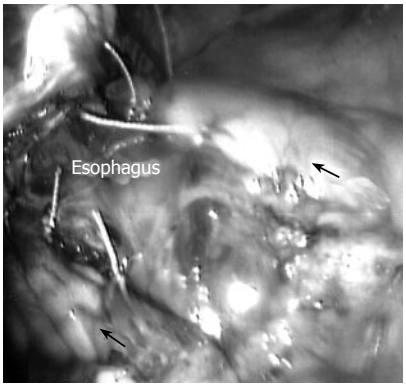

Figure 2 With the Toupet fundoplication, the gastric fundus (arrows) is incompletely wrapped around the posterior, distal esophagus.

cough, and hoarseness) experienced relief. Recently, it has become increasingly evident that GERD can be associated with non-allergic asthma. Spivak *et al*[20] reported significantly improved asthma symptoms for 39 patients who underwent antireflux surgery for the primary indication of asthma associated with GERD.

Total vs partial fundoplication

The total (Nissen) fundoplication involves a 360-degree wrap of the gastric fundus around the esophagus (Figure 1) and is the most commonly performed anti-reflux operation. Further insight into esophageal motility disorders and concerns of postoperative dysphagia has prompted the discussion whether the total or partial fundoplication is more appropriate treatment for GERD. Total wrap supporters acknowledge the fact that the wrap needs to be "floppy" to minimize postoperative dysphagia. It should also be noted that a floppy Nissen fundoplication is safe and effective in patients suffering from a defective esophageal peristalsis. Finally, proponents of the total fundoplication note the decreased the effectiveness of a partial fundoplication in controlling reflux.

Two partial fundoplications are in common practice; they are the Dor and Toupet fundoplications. Of these two partial wraps, the Toupet is the most commonly performed partial fundoplication (Figure 2). Fibbe *et al*[21] compared laparoscopic partial and total fundoplications in 200 patients with esophageal motility disorders and found no difference in postoperative recurrence of reflux and concluded that no tailoring of the surgical management is necessary. Similarly, Laws *et al*[22] found no clear advantage of one wrap over the other in their prospective, randomized study comparing these two groups. Moreover, in a meta-analysis of 9 prospective randomized trials including open and laparoscopic total *vs* partial fundoplications in 793 patients, no statistical difference was found in new-onset dysphagia or recurrence of reflux[23].

Dividing the short gastric vessels

The effect of fundic mobilization has been discussed widely in the surgical community. A meta-analysis of 4 randomized controlled trials found that the operative time is slightly, but not significantly longer when the superior-most short gastric vessels are divided[23]. No significant differences were found regarding the incidence of postoperative dysphagia or complications by dividing the short gastric vessels. The authors of this review favor the complete mobilization of the gastric fundus with division of the short gastric vessels because it is usually necessary for the creation of a "floppy" fundoplication.

Endoluminal therapy

Recent interest in the development in endoluminal therapy has led to new alternatives in the treatment of GERD. These treatment modalities are primarily designed for patients with little or no significant hiatal hernia. These therapies are delivered trans-orally, via upper endoscopy. There are principally three different types of these new treatment options. First, radiofrequency energy delivered to the lower esophageal sphincter (LES) theoretically adds bulk to the LES and changes the sphincter's compliance. Although the mechanism of action has not been fully established, it is presumably due to neurolysis and the abolishment of neuromodulated LES relaxation. With the Stretta Catheter (Curon Medical, Sunnyvale, CA, USA), radiofrequency energy is generated by a four-channel radiofrequency generator, which delivers 465 kHz/2-5 W per channel/80 V through 4 nickel-titanium needle electrodes. The energy is distributed to the LES submucosal/muscular target area at temperatures less than 100 ℃. Multiple prospective non-randomized studies with short-term results, up to 12 mo, showed promising results. Triadafilopoulos *et al*[24] showed improved quality of life scores, decreased esophageal acid exposure, decreased median DeMeester scores (40.0 to 26.4, $P < 0.009$) and 70% of patients off PPI at 12 mo for a group of 118 patients. Additional data on long term follow up, including the incidence and natural history of esophagitis in these patients, are required to establish the utility of this procedure.

A second endoscopic therapy for GERD involves the creation of a mechanical barrier at the gastroesophageal junction (GEJ). Enteryx (Boston Scientific, Natick, Massachusetts) is an ethylene vinyl alcohol copolymer that is endoscopically injected within the submucosa or muscular layers of the esophageal wall 1-2 mm caudal to the Z line. This technique has recently been discontinued by the company due to excessive complications[25]. The Gatekeeper Relux Repair System (Medtronic, Tolochenaz, Switzerland) entails the submucosal placement of a poly-acrylonitrile-based hydrogel prosthesis (1.5 mm × 18 mm) above the GEJ. In a prospective, nonrandomized study of 68 patients with a 6 mo follow up, quality of life was improved,

median LES pressure (8.8 to 13.8 mmHg, $P < 0.01$) was increased and 70.4% of the prostheses were still in place at 6 mo[26]. Concerns remain about the durability of the implants, leaving the long term utility of the procedure in question.

The third category of endoluminal procedures employs direct, endoscopic tightening of the LES. This can be achieved by either sewing or plicating the LES. Currently, three endoscopic suturing devices are available: the EndoCinch (BARD Endoscopic Technologies, Billerica, Massachusetts, USA), the ESD (Wilson-Cook Medical, Winston-Salem, North Carolina, USA), and the Full-Thickness Plicator (NDO Surgical Inc., Mansfield, Massachusetts, USA). The major difference is that the NDO Plicator takes a full thickness suture of gastric fundus whereas the other endoscopic plicators utilize a partial mucosal/submucosal stitch. Partial-thickness sutures have a greater potential to pull through the tissue or migrate over time. The NDO Plicator system appears to have the technical advantages of a single full thickness stitch, with serosa to serosa approximation, leading to direct tightening of the LES, possible lengthening of the LES and favorable altering of the angle of His. Pleskow *et al*[27] showed in a non-randomized, prospective study of 64 patients with follow-up of 12 mo that mental and physical SF-36 scores were significantly improved. Importantly, 80% of patients had improved distal esophageal acid exposure as evidenced by significantly decreased DeMeester scores (44 to 30, $P < 0.001$). Moreover, the majority of patients (68%) were off PPI at 12 mo follow-up.

The NDO Plicator as well as the other endoluminal therapies need to be evaluated very carefully in randomized studies. They will probably not replace the existing LARS but possibly serve as a "bridging therapy" finding its place between the Noninvasive GERD therapy and LARS.

ACHALASIA

Heller[28] was the first surgeon to perform an esophagomyotomy for achalasia in Germany in 1913. Over the next several decades, most of the discussion about myotomy centered on the preferred approach to myotomy, whether via an abdominal incision or using a thoracic technique. This discussion became moot in the 1990s as both approaches were supplanted by the laparascopic technique. The first laparoscopic esophagogastromyotomy was performed by Shimi *et al*[29] in 1991. Current controversies in the treatment of achalasia include the allocation of appropriate therapy, i.e. medical treatment, pneumatic dilation, or surgical treatment, to patients with achalasia. All of these treatments are designed to alleviate the symptoms of achalasia by addressing the failure of the LES to relax upon swallowing. However, in none of these therapies the underlying aperistalsis of the esophagus is addressed.

Pharmacotherapy

Medications are the only true noninvasive option in the treatment of achalasia. However, the medications used to treat achalasia have a short half-life and are variably absorbed due to the poor esophageal emptying experienced by patients with achalasia. As the disease progresses, this treatment modality becomes less and less effective. Calcium channel blockers and nitrates have been widely used, with the sublingual application being preferred[30,31]. Both medications effectively reduce the baseline lower esophageal sphincter tone, but they neither improve LES relaxation nor augment esophageal peristalsis. Persistent dysphagia and adverse effects including headaches, hypotension and peripheral edema make this treatment even more problematic[30,32]. The current recommendations for pharmacotherapy are limited to patients who are early in their disease process, without significant esophageal dilatation, or patients who are high risk for more invasive modalities. Finally, medications should be considered for patients who decline other treatment options.

Botulinum toxin

Direct injection into the lower esophageal sphincter with Botulinum toxin A (Botox, Allergan, Irvine, California) irreversibly inhibits acetylcholine release from cholinergic nerves. This results in decreased constriction of the sphincter and a temporary amelioration of achalasia related symptoms. Following Botox injection, about 60%-85% patients suffering from achalasia will note an improvement in their symptoms[33]. However, in Botox responders, symptoms recur in more than 50% of patients by 6 mo[34,35]. While repeated injections are technically possible, reduced efficacy is seen with each subsequent injection. Repeated esophageal instrumentation with Botox treatment inevitably causes an inflammatory reaction at the gastroesophageal junction. The resulting fibrosis may make subsequent surgical treatment more difficult and/or increase the complication rate. Fortunately, there has been recent evidence that despite Botox therapy, laparoscopic Heller myotomy is as successful as myotomy in Botox-naïve patients. However, prior Botox injection did increase the intraoperative esophageal perforation rate from 2% to 7%[36]. Botulinum toxin therapy is generally recommended for patients who are unwilling to undergo a more invasive treatment.

Pneumatic dilation

Since the original 17th century description by Willis[37], who used a sponge attached to the distal end of a whale bone to dilate a distal esophageal obstruction, the idea of stretching the lower esophagus (today with polyethylene balloons) is still considered the most effective nonsurgical treatment for achalasia. Under direct endoscopic visualization, a balloon is placed across the LES and is inflated up to 300 mmHg (10-12 psi)for 1-3 min. The goal is to produce a controlled tear of the LES muscle to render it incompetent, thereby relieving the obstruction. After pneumatic dilation, good to excellent response rates can be achieved in 60% of patients at one year[38]. Long-term results are less satisfactory. At 5 years, only 40% note symptom relief and at 10-year follow-up, a mere 36% of patients have relief of dysphagia[39,40]. Repeat dilatations are technically possible but show a decreased success rate. The most feared complication of pneumatic dilatation is a perforation of the distal esophagus, which frequently occurs at the left posterior lateral aspect (Boerhaave.s triangle). Risk factors for perforation include a widely dilated

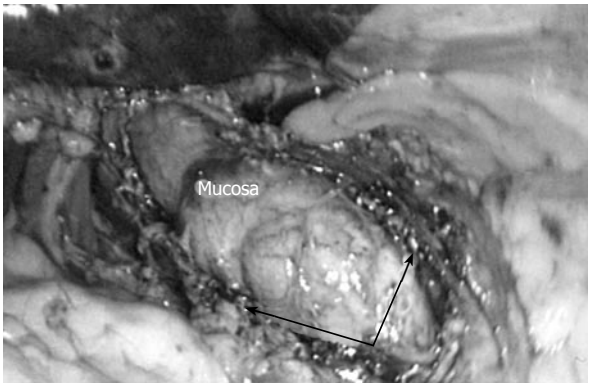

Figure 3 The goal of the Heller myotomy is full-thickness division of the muscular layers (arrows) of the distal esophagus. The myotomy should be long enough to ensure complete obliteration of the lower esophageal sphincter.

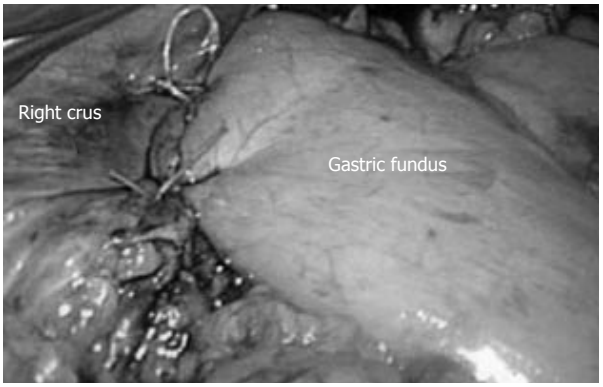

Figure 4 The Dor fundoplication is a 180-degree *anterior* folding of the gastric fundus over the distal esophagus.

esophagus (>7 cm), hiatal hernia, or the presence of an epiphrenic diverticulum. The rate of esophageal perforations during pneumatic dilation is approximately 2%[41]. The current recommendations regarding pneumatic dilation prior to (or instead of) surgical therapy depends upon the referring physician's opinions, the surgeon's expertise, and the patient's preference.

Surgical therapy

Heller first described the surgical destruction of the gastroesophageal sphincter, as therapy for achalasia, in 1913. His original technique used 2 parallel myotomies that extended for at least 8 cm on the distal esophagus and proximal stomach. The conversion to a single anterior myotomy was first proposed by De Brune Groenveldt in 1918. During the 1950s, the thoracic approach to esophagomyotomy was perfected, and in parts of the world, became the preferred technique. Despite the excellent results in improving the dysphagia, open Heller myotomy had a prolonged hospital stay and recovery time. Since the inception of minimally invasive techniques, both the open transabdominal repair and the thoracic approach have fallen out of favor.

First performed by Pellegrini *et al*[42] in 1992, the thoracoscopic approach showed promise, with excellent symptom relief. Unfortunately, technical factors limit the extension of the myotomy well onto the cardia of the stomach and it also makes a concomitant antireflux procedure difficult. Consequently, a higher rate of persistent and recurrent dysphagia (up to 26%) and GERD (35%) occur with this approach. When compared to the laparoscopic technique, this approach results in more postoperative pain and a longer hospital stay.

At this time, the laparoscopic approach is considered superior to the above mentioned surgical therapies. Laparoscopic Heller myotomy (Figure 3) is noted to have a very low morbidity and mortality rate, less postoperative pain, improved cosmesis, and a faster recovery compared to more invasive surgical therapies. Most importantly, excellent symptom relief is noted in 90% of patients[43]. This has established the laparoscopic approach as the premier choice for the treatment of achalasia.

The current indications for laparoscopic surgical treatment of achalasia include patients less than 40 years of age, patients with persistent or recurrent dysphagia after unsuccessful Botox injection or pneumatic dilation, and patients who are high risk for perforation from dilation. This latter group includes patients who have previously undergone surgery at the GE junction, those with esophageal diverticula, and those with distorted lower esophageal anatomy. Patients may prefer surgical therapy for a more durable, long-term result, its superior safety profile, and the decreased likelihood of reintervention.

Currently there are two controversies concerning achalasia discussed within the surgical community. The first involves the extent to which the myotomy is extended onto the stomach. Everyone concurs that a surgical myotomy predisposes patients to postoperative GERD; many surgeons also add an antireflux procedure to address this potential problem. Thus the second controversy involves whether to add an antireflux procedure, and if so, which type of antireflux procedure.

The proximal extent of the myotomy is typically carried 5-6 cm proximal to the lower esophageal sphincter. Whether to carry the distal extent of the traditional 1-2 cm beyond the LES or to be more aggressive and carry the myotomy at least 3 cm onto the stomach is now debated. Oelschlager *et al*[44] found less dysphagia and subsequently fewer interventions to treat the recurrent dysphagia in favor of the at least 3 cm distal myotomy group (3% *vs* 17%).

The necessity and type of antireflux procedure to prevent GERD after myotomy is the second widely discussed topic. Arguments against performing any antireflux procedure include some surgeo's reports of an adequate cardiomyotomy without postoperative reflux. Additionally, performing a fundoplication will obviously prolong the operative time, and there is also a proposed concern about adding a fundoplication in the setting of an aperistaltic esophagus. Proponents supporting the addition of an antireflux procedure mostly favor a partial (Dor, Toupet) over a total (Nissen) fundoplication to avoid a functional obstruction (from the fundoplication) and the persistence of dysphagia.

The anterior, 180-degree, Dor fundoplication (Figure 4) and the posterior, 270-degree Toupet fundoplication are the two most commonly performed antireflux procedures

in combination with the Heller myotomy. Unfortunately, the lack of prospective randomized studies comparing these two procedures leads to no clear advantages of one partial fundoplication over the other. Proponents of the posterior fundoplication believe that it better prevents re-approximation of the myotomy and believe that it is more effective against GERD. Advocates of the anterior fundoplication procedure argue that it is easy to perform, it protects the anterior esophagus following myotomy and it leaves the posterior anatomy intact. Acknowledging these facts, the authors believe the anterior fundoplication is the best technique to alleviate dysphagia and control reflux symptoms.

In conclusion, LARS and laparoscopic Heller myotomy are the agreed upon gold standard for surgical treatment of GERD and achalasia, respectively. Both are safe and effective treatment for patients with lower morbidity and mortality, shorter hospital stay and recovery period and less postoperative pain when compared to traditional open procedures. Additionally, excellent subjective and objective long-term results with at least 90% patient satisfaction have been observed, making LARS and laparoscopic Heller myotomy the treatment of choice in the experienced hands of dedicated minimally invasive surgeons.

Abstract

Cholelithiasis, one of the most common medical conditions leading to surgical intervention, affects approximately 10 % of the adult population in the United States. Choledocholithiasis develops in about 10%-20% of patients with gallbladder stones and the literature suggests that at least 3%-10% of patients undergoing cholecystectomy will have common bile duct (CBD) stones.

CBD stones may be discovered preoperatively, intraoperatively or postoperatively Multiple modalities are available for assessing patients for choledocholithiasis including laboratory tests, ultrasound, computed tomography scans (CT), and magnetic resonance cholangiopancreatography (MRCP). Intraoperative cholangiography during cholecystectomy can be used routinely or selectively to diagnose CBD stones.

The most common intervention for CBD stones is ERCP. Other commonly used interventions include intraoperative bile duct exploration, either laparoscopic or open. Percutaneous, transhepatic stone removal other novel techniques of biliary clearance have been devised. The availability of equipment and skilled practitioners who are facile with these techniques varies among institutions. The timing of the intervention is often dictated by the clinical situation.

INTRODUCTION

Symptomatic gallstone disease is a very common indication for abdominal surgery. It is estimated that around 500 000 cholecystectomies are performed a year in the United States. Gallstones, alone, are rarely an indication for surgery, but 10% of the adult population are believed to carry them. Furthermore, up to one-third of the population over 70 years of age will have gallstones. Gallstone formation is a multifactorial process but is undoubtedly associated with family history, diabetes mellitus, pregnancy, obesity, significant weight loss, and hemolytic diseases. As many as 35% of patients with gallstones will ultimately become symptomatic and require cholecystectomy[1].

Common indications for surgical treatment for cholelithiasis include biliary colic, acute cholecystitis, gallstone pancreatitis, and other presentations of choledocholithiasis including bile duct obstruction and cholangitis. Other relative indications include gallstones in patients undergoing splenectomy for hemolytic anemia, high risk patients in the pretreatment phase for other conditions such as bone marrow transplant. Cholecystectomy is no longer routinely performed for asymptomatic gallstones in those undergoing bariatric surgery or aortic surgery.

Common bile duct (CBD) stones may be discovered preoperatively, intraoperatively or postoperatively. The standard preoperative workup for patients presenting with symptoms attributable to cholelithiasis includes liver function tests, and abdominal ultrasound. These tests, combined with clinical exam and history, constitute the entire workup for most patients. Abnormalities in these tests may suggest the presence of choledocholithiasis. Choledocholithiasis may occur in up to 3%-10% of all cholecystectomy patients[1], or as high as 14.7% in some series[2]. This includes some patients without classic preoperative findings suggestive of choledocholithiasis. Of these asymptomatic patients, it is believed about 15% will eventually become symptomatic[3] and require further interventional treatment.

Since the advent of routine laparoscopic cholecystectomy, the debate has continued about the utility of intraoperative bile duct assessment, primarily with cholangiography or intraoperative ultrasonography. This debate continues to some degree, with most surgeons either selectively or routinely evaluating the bile duct intraoperatively. A smaller subset relies only on preoperative assessment tools, including magnetic resonance cholangiopancreatography (MRCP)

and endoscopic retrograde cholangiopancreatography (ERCP), as a complement to routine laboratory and imaging studies. The most common intervention for common bile duct (CBD) stones is ERCP. Other procedures for CBD stone extraction include percutaneous, transhepatic stone removal and intraoperative CBD exploration, whether laparoscopic or open. The availability of equipment and skilled practitioners who are facile with these techniques varies among institutions. The timing of the intervention is often dictated by the clinical situation.

PREOPERATIVE EVALUATION AND THERAPY

Diagnosis of choledocholithiasis is not always straightforward and clinical evaluation and biochemical tests are often not sufficiently accurate to establish a firm diagnosis. Imaging tests, particularly abdominal ultrasound, are used routinely to confirm the diagnosis. Liver function tests (LFT) can be used to predict CBD stones[4,5]. Elevated serum bilirubin and alkaline phosphatase typically reflect biliary obstruction but these are neither highly sensitive nor specific for CBD stones. Excepting obvious jaundice, a raised GGT level has been suggested to be the most sensitive and specific indicator of CBD stones. A value of greater than 90 U/L has been proposed to indicate a high risk of choledocholithiasis[4]. However, laboratory data may be normal in as many as a third of patients with choledocholithiasis, warranting further evaluation of the CBD by imaging studies to clarify the diagnosis.

In order to help select from the various diagnostic and therapeutic options, patients may be classified preoperatively into high, moderate or low risk groups. The high risk (> 50% risk) group includes those patients with obvious clinical jaundice or cholangitis, choledocholithiasis or a dilated CBD on ultrasonography. Patients with a history of pancreatitis or jaundice, elevated preoperative bilirubin and alkaline phosphatase levels or multiple small gallstones carry a moderate (10%-50%) risk of choledocholithiasis. Patients with large gallstones, without a history of jaundice or pancreatitis and with normal liver function tests are considered unlikely to have CBD stones and therefore at low risk (< 5%)[6-8].

The transabdominal ultrasound examination (US) is the most commonly used screening modality. In patients who present with symptoms attributable to gallstone disease, US may be the only radiologic study ordered. It has the advantages of being widely available, non-invasive, and inexpensive. Ultrasonography, however, is highly operator dependent, but it can provide useful information in experienced hands. For a diagnosis of cholecystitis, in most circumstances, gallbladder stones need to be visualized. The sonographic presence of wall thickening, pericholecystic fluid, and a Murphy's sign, may be helpful but are not required for a diagnosis of acute cholecystitis. The ultrasonographer should routinely report indirect information suggestive of the presence or absence of CBD stones, specifically the CBD diameter or any signs of intrahepatic bile duct dilation. The sensitivity of US for detecting biliary dilatation, as reported in various studies, varies from 55 to 91 percent[9]. A CBD diameter of greater than 6 mm on US is associated with a higher prevalence of choledocholithiasis[10].

Computed tomography (CT) may have some role in diagnosis of gallstone disease and choledocholithiasis. Many patients presenting with acute abdominal pain will undergo a diagnostic CT scan as part of the acute workup. A diagnosis of acute cholecystitis may be evident based on signs of gallbladder inflammation. Cholelithiasis may be detected on CT[11] and often the diameter of the CBD can be measured. In the clinical setting, US may not be necessary for preoperative evaluation if the CT scan provides this information. The role of helical CT cholangiography is still in evolution, particularly in the United States. Intravenously administered contrast agents, combined with high resolution helical scans and three dimensional reconstructions that can be very useful in diagnosing choledocholithiasis[12,13]. The sensitivity of this technique can be as high as 95.5%[12]. This technique is not widely utilized in the U.S. as the available contrast agents often cause significant nausea on administration. The availability of MRCP also limits the need for this modality.

MRCP has emerged as an accurate, non-invasive diagnostic modality for investigating the biliary and pancreatic ducts[14] and has been recommended in some circles as the preoperative procedure of choice for the detection of CBD stones[4,15,16]. MRCP provides excellent anatomic detail of the biliary tract and has a sensitivity of 81%-100% and a specificity of 92%-100% in detecting choledocholithiasis[14]. The accuracy of MRCP in diagnosing CBD stones is comparable with that of ERCP and IOC[14,17]. It thus avoids the need for a potentially high risk, invasive procedure in more than 50% of patients, allowing selective use of ERCP or surgical CBD exploration in those patients who require a therapeutic intervention. These results have led some practitioners to consider MRCP the new gold standard for biliary imaging[14,18]. MRCP may, however, miss stones less than 5 mm in diameter. MRCP is an expensive option that requires significant expertise for interpretation; this modality may not always be readily available.

Endoscopic techniques such as endoscopic ultrasound (EUS) and ERCP can also be useful tools in preoperative diagnosis and, in the case of ERCP, management of choledocholithiasis. Both procedures are more invasive than strictly radiologic techniques, and carry the low, but inherent risks of upper gastrointestinal tract endoscopy. ERCP also carries the risks associated with biliary instrumentation, such as pancreatitis. Endoscopic ultrasound (EUS) can been used to evaluate the CBD and identify calculi. Studies comparing the accuracy of EUS to US, CT and ERCP for detecting choledocholithiasis show a sensitivity of EUS ranging from 88%-97%, with a specificity of 96%-100%[19]. This is comparable to ERCP and avoids the risks of pancreatitis, cholangitis and radiation exposure[19]. The role of EUS, however, is not well established especially when cost and availability of less invasive modalities such as MRCP are considered. EUS may be combined with ERCP at the same endoscopy session if biliary calculi are identified, allowing it to be a bridge to therapeutic intervention.

ERCP has been the gold standard for preoperative diagnosis of CBD calculi. When compared to other tests such

as ultrasonography and MRCP, ERCP has the advantage of providing a therapeutic option when a CBD stone is identified. Stone retrieval and sphincterotomy has supplanted surgical treatment of choledocholithiasis in many institutions[14,20]. Successful cholangiography by an experienced endoscopist is achieved in greater than 90% of patients. Complications associated with ERCP can be as high as 15% and include pancreatitis, cholangitis, perforation of the duodenum or bile duct, and bleeding. These individual complications can occur in 5%-8% of patients. The mortality rate from ERCP is 0.2%-0.5%[21,22]

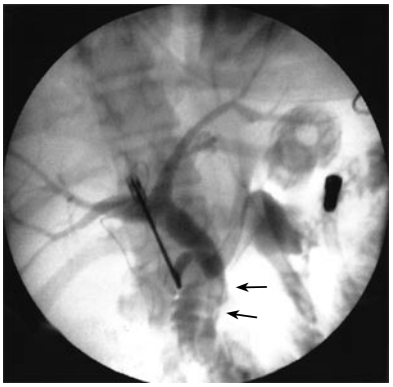

Figure 1 Intraoperative cholangiogram *via* the cystic duct demonstrating proximal biliary dilation and two filling defects in the CBD (Arrows).

INTRAOPERATIVE EVALUATION AND THERAPY

Since laparoscopic cholecystectomy became a routine procedure in the early 1990's, debate has continued about the role of intraoperative bile duct assessment. The interest in intraoperative cholangiography (IOC) came from both the desire to detect CBD stones and to potentially identify any bile duct abnormalities, including iatrogenic injuries at the time of surgery. Routine cholangiography is not generally considered to be the standard of care but still has its proponents[3]. Most surgeons selectively evaluate the bile duct intraoperatively. A smaller subset relies only on preoperative assessment tools including magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) as a complement to routine laboratory and imaging studies.

Intraoperative cholangiography can be a useful tool to identify choledochal calculi but its application remains controversial. Proponents often believe that IOC enables clear definition of the biliary tree anatomy[3,23,24], thus reducing the risk of bile duct injury during cholecystectomy. Most studies on the subject show no significant difference in the rates of ductal injury between routine and selective IOC. Routine IOC has been found to yield little benefit over the selective approach in the detection of symptomatic CBD stones[3] Cholangiography is a relatively straight forward procedure to perform. It does add to the operative time, approximately an additional 15 min[25,26], but surgeon and operative team experience can minimize this. Dynamic fluoroscopic imaging is the technique of choice and can provide a specificity and sensitivity of 94% and 98%, respectively, in experienced hands[27]. This technique may be somewhat less sensitive for patients presenting with biliary pancreatitis[27]. A complete IOC should demonstrate the cannulation of the cystic duct, filling of the left and right hepatic ducts, CBD and common hepatic duct diameter, the presence or absence of filling defects in the biliary tree, and free flow of contrast into the duodenum (Figure 1). Obstruction or other biliary abnormality should be suspected if these findings are not clear.

The overall safety profile of IOC is very good. The incidence of pancreatitis, in contrast to ERCP, is negligible[28]. The reliability, ease to perform, and low complication rate of IOC suggest that, at least in cases where choledocholithiasis is not proven, IOC during a cholecystectomy is a better choice than preoperative ERCP assessment of the bile ducts. More recently intraoperative ultrasonography of the CBD during laparoscopic cholecystectomy has been shown to satisfactorily demonstrate stones and the biliary tree. Use of intraoperative ultrasound requires a significant learning curve, but in experienced hands takes less operative time than traditional IOC[25,26]. Laparoscopic ultrasound compares well with intraoperative cholangiography. With a sensitivity of 96% and a specificity of 100%, and the advantages of saved time and lack of radiation, intraoperative ultrasound may be a superior diagnostic modality when compared to IOC[23]. The use of intraoperative laparoscopic ultrasound is limited by the availability of equipment and surgeon training and experience. Efforts to incorporate ultrasonography training in to surgical residency curricula should aid its acceptance and use.

When CBD stones are detected intraoperatively, a surgeon must make a clinical decision on how to proceed. This decision is often dictated by the availability of equipment, surgeon preference and skill, and the availability of ERCP at a facility. Available options include laparoscopic CBD exploration, intraoperative ERCP, open CBD exploration, or postoperative therapy. Many surgeons are reluctant to proceed with an open procedure when other, less invasive, options are generally available. However, a decision to delay therapy to the postoperative period risks encountering procedural difficulties that preclude endoscopic therapy. Options for intraoperative CBD clearance include variations of laparoscopic exploration. Laparoscopic CBD exploration is most commonly performed with acholedochoscope. The scope, attached to a second video camera and light source, is inserted into the CBD *via* either the cystic duct (Figure 2) or *via* a choledochotomy. Placement of the choledochoscope directly into the CBD *via* a choledochotomy is generally reserved for patients with ducts dilated to greater than 6 mm in diameter on cholangiogram[20]. A continuous saline infusion through the choledochoscope dilates the duct and clears debris. CBD stones can be directly visualized (Figure 3) and instrumented. Between 66 and 82.5% of laparoscopic CBD explorations can be performed via the cystic duct[20,29]. In experienced hands, the CBD clearance rate is as high as 97%[2,29]. In one large series of laparoscopic CBD exploration, the overall morbidity rate of this procedure is approximately 9.5%, with a 2.7% retained stone rate[2]. These data are equivalent to the experience with ERCP.

An alternate technique of laparoscopic CBD clearance involves stone extraction under fluoroscopic guidance.

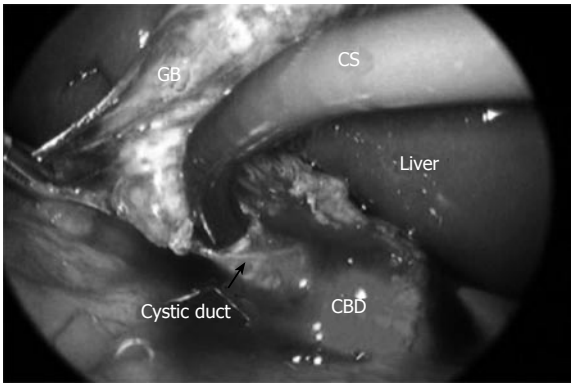

Figure 2 Laparoscopic view of a choledochoscope (CS) entering the CBD *via* the cystic duct. The gallbladder (GB) is retracted to the left of the image.

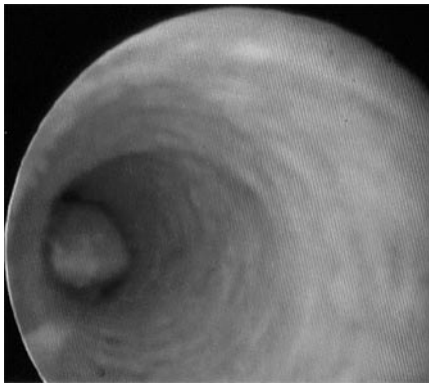

Figure 3 CBD stone as seen through the choledochoscope.

This technique, as described by Traverso *et al*, does not use a choledochoscope, but can be highly effective in CBD clearance for single stones (87%), with an overall 59% success rate[30]. In this technique, instruments, including stone extraction baskets, are passed into the CBD (usually via the cystic duct) under fluoroscopy. The fluoroscopic images facilitate stone capture and removal. This technique simplifies the operating room set up for CBD exploration because additional video equipment is not required. In this series, patients whose ducts were not cleared laparoscopically, underwent ERCP. The authors noted a significantly lower complication rate in patient who did not undergo ERCP[30]. Likewise, the overall associated costs were lower in these patients[31].

Laparoscopic techniques can be very effective at clearing CBD stones, but significant expertise and experience is required to achieve high success rates. Stones impacted at the sphincter of Oddi are often the most difficult to extract by this technique. Long term follow up does not demonstrate a significant risk of CBD stricture or other complications for these procedures[2,29,30]. This technique is also advocated in the pediatric population by some practitioners as a way of avoiding an ERCP[32]. Intraoperative ERCP, although often limited by the immediate availability of a qualified endoscopist, is a technique that can be very useful. This takes advantage of the preexisting anesthetic and does not prolong hospital stay by delaying the procedure[33,34]. In some instances, cooperation between the surgeon and the endoscopist can expedite the procedure[35]. Guidewire placement, throught the sphincter of Oddi, into the duodenum via the IOC catheter can facilitate cannulation, especially for patients with difficult duodenal anatomy[34]. In the case of an unsuccessful extraction, open CBD exploration or drainage of the duct should be considered.

POSTOPERATIVE EVALUATION AND THERAPY

Postoperative ERCP is commonly used modality for CBD clearance when a stone is detected intraoperatively. This technique is highly effective[20], but can be complicated when anatomic variables such as duodenal diverticulae or unusual biliary anatomy, are encountered[36]. On the occasion that ERCP fails, a primary option includes returning to the operating room for a laparoscopic or open exploration. However, other less invasive options may be available.

In selected patients, percutaneous transhepatic (PTH) therapies should be considered for CBD clearance. Access to the biliary system can be obtained percutaneously, under ultrasound guidance. Via this access point, stones can be extracted, a sphincterotomy can be performed, or lithotripsy can be used over a single, or multiple sessions to ensure duct clearance[37,38]. A percutaneous drain can be used to decompress the system between procedures or for temporary stenting after the duct is clear.

Novel approaches have been performed in other anatomic settings which preclude ERCP, such as prior gastric surgery. The most common gastric surgery currently performed is the Roux-Y gastric bypass. In this surgery, a small gastric pouch is created and anastomosed to a limb of jejunum. The majority of the stomach, duodenum, and proximal jejunum are bypassed, making endoscopic access technically difficult. Combined laparoscopic surgical and endoscopic procedures have been described. Endoscopic access can be achieved via a gastrostomy[39] or jejunostomy[40]. The endoscope can be passed under surgical guidance, and an ERCP can be performed in the standard fashion. These procedures are only described in short case reports, but will undoubtedly become more common place with the prevalence of gastric bypass.

In conclusion, given the various diagnostic and therapeutic options available for managing choledocholithiasis, clinical judgment is paramount. The surgeon and the patient are best served by accurate laboratory and radiologic assessment prior to cholecystectomy. In the setting of high preoperative suspicion for choledocholithiasis, preoperative imaging with MRCP may help guide subsequent treatment. If CBD stones are present on MRCP or in the setting of clinical jaundice or cholangitis, preoperative ERCP is the first line option. However, preexisting anatomic abnormalities may influence this decision. Laparoscopic IOC with a CBD exploration is a reliable approach in experienced hands and if an ERCP is unsuccessful.

Cholangiography during cholecystectomy is recommended for patients with a history of gallstone pancreatitis, LFT abnormalities, or an enlarged CBD on preoperative imaging who have not undergone MRCP or ERCP. IOC is also recommended when intraoperative findings suggest anatomic abnormalities or unsuspected CBD calculi.

Intraoperative laparoscopic CBD exploration is the first

option for choledocholithiasis detected in the operating room. Intraoperative or postoperative ERCP are options for incompletely cleared ducts. Percutaneous treatment or combined laparoendoscopic options are available in some centers for patients who cannot undergo ERCP or laparoscopic choledochotomy. Open CBD exploration is a safe option, but usually limited to the setting of concomitant open surgery or as a last resort when other therapeutic modalities fail.

Abstract

Obstructed defecation (OD) and fecal incontinence (FI) are challenging clinical problems, which are commonly encountered in the practice of colorectal surgeons and gastroenterologists. These disorders socially and psychologically distress patients and greatly impair their quality of life. The underlying anatomical and pathophysiological changes are complex, often incompletely understood and cannot always be determined. As a consequence, many medical, surgical, and behavioral approaches have been described, with no panacea. Over the past decade, advances in an understanding of these disorders together with rational and similar methods of evaluation in anorectal physiology laboratories (ARP), radiology studies, and new surgical techniques have led to promising results. In this brief review, we discuss treatment strategies and recent updates on clinical and therapeutic aspects of obstructed defecation and fecal incontinence.

INTRODUCTION

The prevalence of constipation in adults ranges from 2% to 27% in North America, particularly after the age of 65 and with a female predominance[1]. There are two major types of constipation: secondary constipation (due to colorectal cancer, hypothyroidism, hyperparathyroidism, diabetes, use of opiates, antidepressants, and diuretics, stool impaction in the elderly, sexual abuse in women, Parkinson's disease, and other organic pathology and medications) and primary functional constipation, which can be divided into slow transit constipation (colonic inertia), constipation-predominant irritable bowel syndrome, and obstructed defecation[2,3]. Approximately half of constipated patients suffer from obstructed defecation[4]. Obstructed defecation (OD)is a broad term of the pathophysiologic condition describing the inability to evacuate contents from the rectum. This disorder is commonly known by numerous terms, including paradoxical puborectalis contraction (PPC), outlet obstruction, anismus, pelvic floor dyssynergia, nonrelaxing puborectalis syndrome, spastic pelvic floor syndrome, and dyschezia. It may result from functional, metabolic, mechanical, and anatomical derangements involving a rectoanal evacuatory mechanism. Dyssynergia, or uncoordination of the pelvic floor muscles, leads to paradoxical external anal sphincter and puborectalis contraction with no relaxation during defecation[5].

OD may result from rectoanal intussusception, pelvic organ prolapse, rectocele, sigmoidocele, enterocele, solitary rectal ulcer syndrome, PPC and descending perineum syndrome. Other rare causes include rectal hyposensitivity (blunted rectum), idiopathic megarectum, hereditary internal sphincter myopathy and nutcracker anus[4,6].

This condition is usually defined on the basis of symptoms and physiologic and radiologic studies. Symptoms include a feeling of incomplete evacuation and rectal obstruction, passage of hard stools, rectal or vaginal digitation and excessive straining in the constipated patient (stool frequency of fewer than three times per week). Careful perineal and digital rectal examination, colonic transit time study, anorectal manometry, defecography or dynamic magnetic resonance imaging of the pelvic floor usually help assess defecatory dysfunction and establish a correct diagnosis[7,8].

Fecal incontinence (FI) is a second major problem with a devastating effect on patients' quality of life. Its prevalence ranges from 2% to 18% and increases with age especially in institutionalized and psychiatric patients and in women[9]. FI is usually attributable to multiple factors affecting the normal anatomy and physiology of anorectum. Obstetric trauma, anorectal surgery, benign

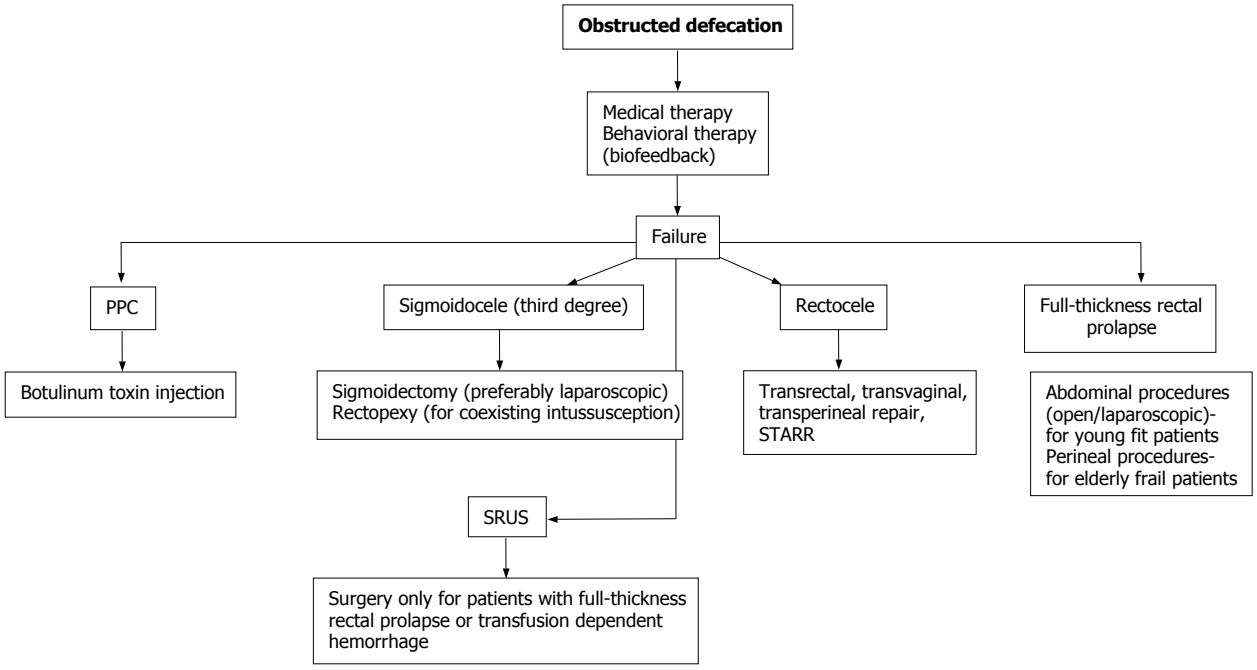

Figure 1 Treatment algorithm for obstructed defecation.

colorectal conditions, cancer, inflammatory bowel and neurologic diseases, aging, drugs, food intolerance, rectal prolapse, congenital abnormalities, and radiation proctitis are all known causes of FI. The most appropriate therapy for FI may be based only on an accurate assessment of anorectal function, including a thorough history, physical examination, anorectal physiology studies (endoanal ultrasound, anorectal manometry with balloon expulsion test, electromyography, and pudendal nerve latency testing) and other imaging tests (defecography, dynamic MR proctography)[10]. The main goal of treatment is to improve continence and the patients' quality of life.

TREATMENT STRATEGY

Obstructed defecation

Once secondary causes for constipation, especially malignancy and slow transit constipation (colonic inertia) are excluded, OD is considered on the basis of clinical examination, normal or prolonged colonic transit time, abnormal anorectal manometry, defecography, or dynamic MRI of the pelvic floor[11] (Figure 1).

Paradoxical puborectalis syndrome

Initial therapy for patients with PPC, as for descending perineum syndrome, solitary rectal ulcer, clinically non-significant rectocele, sigmoidocele, and rectoanal intussusception, is conservative. This includes a high fiber diet of up to 20-30 g/d, adequate hydration, regular physical activity, enemas, and laxatives.

Biofeedback training may be added to the first-line therapy, which teaches patients to relax their pelvic floor muscles[12-14]. There is a paucity of controlled trials showing the true effectiveness of this behavioral treatment. Furthermore, there is no single factor that can predict a favorable outcome with this treatment. In a large retrospective study from Cleveland Clinic Florida, Gilliland *et al* reported a 63% success rate of EMG-based biofeedback for constipation after five or more sessions[12]. They found that age, gender, duration of symptoms, and the coexistence of rectal pain did not influence outcome. In addition, there was no relationship between mean resting or squeeze pressure, length of the high pressure zone, sensory threshold, and maximum rectal capacity and success or failure of biofeedback. Chiarioni *et al* showed improvement in 71% of patients with OD for a period of two years[15]. Various biofeedback techniques (intra-anal and perianal EMG monitoring, manometric anal probe biofeedback, intra-rectal balloon expulsion biofeedback, ultrasound biofeedback) have been done, but none has a superior success rate, which ranges from 30% to over 90%[16-18]. Although the success rate seems to significantly wane with time, the morbidity-free nature of biofeedback makes re-treatment an attractive option.

Despite controversy about the method of biofeedback and the number of sessions needed, it seems reasonable to use this generally safe technique as the initial treatment for OD. After failure of conservative therapy, 50%-75% of patients with PPC may benefit from botulinum toxin type A injection into the puborectalis muscle and external anal sphincter. The short-term effect (3 mo), however, may require repeated injections[19,20]. Surgical division of the puborectalis muscle is usually non-effective and currently not a recommended procedure[21]. Several other treatments exist for this disorder, including progressive anal dilatation and sacral nerve stimulation (SNS). Additional studies are needed to completely evaluate these techniques for this indication.

Solitary rectal ulcer syndrome (SRUS)

This syndrome may be associated with PPC, rectoanal intussusception, rectal prolapse, and descending perineal syndrome. Chronic straining with ischemic ulceration

are components of the pathogenesis, which is still not completely clear. Biopsy from the lesion should be obtained to exclude malignancy. Treatment for this syndrome is conservative and is the same as for PPC, including high fiber and fluid intake, laxatives, suppositories, and biofeedback. Surgery is generally reserved for patients with full thickness rectal prolapse or intractable hemorrhage and should be tailored to the individual patient's operative risk, willingness, and continence and constipation status[22,23]. Regardless of which procedure is selected, it should be safe balancing anticipated morbidity with an acceptable recurrence rate. Unfortunately, a detailed description of the different surgical techniques is beyond the scope of this article.

Descending perineum syndrome

This syndrome is abnormal perineal descent possibly as a result of consistently prolonged straining with defecation, as defined on defecography. Medical therapy with a high fiber diet, laxatives, enemas, and biofeedback is the main treatment for these patients; no viable surgical option exists.

Rectocele

Treatment of rectocele is usually indicated when a herniation of the anterior rectal wall is greater than 3 cm with significant clinical symptoms or non-emptying rectocele on defecography. However, there is no correlation between the severity of symptoms, contrast material retention, the depth of a rectocele and success of the repair[24,25]. Rectocele presents on defecography in 81% of asymptomatic women[26]. The initial treatment is the same as for disorders previously outlined. Surgery may be considered when conservative therapy fails and includes transvaginal posterior colporrhaphy, and transrectal or transperineal repair. Careful patient selection is very important for a successful outcome. Two new techniques include the double stapled Trans-Anal Rectal Resection (STARR) and single stapled Trans-Anal Prolapsectomy with Perineal Levatorplasty (STAPL) for the management of OD associated with rectocele or intussusception. These methods use one or two 33-mm circular staplers (PPH-01 Ethicon-Endosurgery, Inc, Cincinnati, OH) to perform mucosal or full-thickness circumferential transanal resection of the distal rectum. In their randomized study Boccasanta et al reported significant symptomatic improvement after STARR and STAPL in 88% and 76%, respectively, at approximately 2 years[27]. These procedures are considered safe with minimal postoperative pain and high patient satisfaction[28].

Rectal intussusception (internal rectal prolapse)

Approximately half of the patients with rectal intussusception present with clinical symptoms of OD while in 29% it is seen on defecography in asymptomatic patients[29,30]. The mainstay of therapy is dietary management and biofeedback. Surgery is reserved only for patients with combined pathology, usually FI as a result of the external anal sphincter defects or pudendal neuropathy, or if the intussusception progresses to a full thickness rectal prolapse.

Sigmoidocele and enterocele

Deep herniation of the rectovaginal peritoneal cavity containing sigmoid colon or small bowel is usually associated with other manifestations of OD, rectocele, or pelvic organ prolapse. Sigmoidocele is confirmed by defecography. Jorge *et al* from the Cleveland Clinic Florida suggested a sigmoidocele classification based on the degree of descent of the lowest portion of the sigmoid colon[30]. First degree sigmoidocele is located below the sacral promontory but above the pubococcygeal line, second degree is below the pubococcygeal line and above the ischiococcygeal line, and third degree is below the ischiococcygeal line. Staging of sigmoidocele is useful in determining both clinical significance and optimal treatment.

Indications for surgery are symptomatic patients with a third-degree sigmoidocele (below ischiococcygeal line) or during other pelvic surgery, using abdominal or vaginal approaches (hysterectomy, rectal prolapse, rectocele repair). Surgery includes resection of the sigmoid colon (preferably laparoscopic sigmoidectomy), and rectopexy with obliteration of the Douglas pouch; some patients may benefit from dietary and biofeedback therapy. Jorge and colleagues reported symptomatic improvement in 100% of patients who underwent surgery, but in only 33% of patients who have been conservatively treated at a mean follow-up of 23 mo[30].

Fecal incontinence

Fecal incontinence is the result of numerous disorders affecting the anatomy and physiology of the anorectum. Many appropriate medical, behavioral, and surgical treatments exist to correct the underlying pathology and restore continence. Irritable bowel syndrome, inflammatory bowel disease, scleroderma (internal anal sphincter fibrosis), neurological (spinal cord injuries) and psychological problems (dementia, depression, anxiety), diabetes mellitus (autonomic neuropathy), skeletal muscle diseases (myopathy, myasthenia gravis), diarrhea, constipation, and fecal impaction should all be appropriately treated. However, when underlying pathology cannot be identified, the primary goal of the therapy is to relieve symptoms and improve patients' quality of life (Figure 2).

Initial therapy consists of dietary modifications to form stool, control diarrhea or constipation, and treat fecal impaction with overflow incontinence. This treatment includes perianal hygienic measures with barrier cream to prevent skin irritation and dermatitis, increased fiber and fluid uptake, avoidance of dairy products and caffeine, using stool softeners, osmotic laxatives (magnesium salts), and non-absorbable sugars (lactulose). Antidiarrheal agents (loperamide, diphenoxylate/atropine) increase fluid absorbtion, colonic transit time, and anal resting sphincter pressure[31]. Low dose amitriptyline (tricyclic antidepressant) may improve continence due to its anticholinergic and serotoninergic activities[32].

Biofeedback is another first-line therapy for FI. This method of operant conditioning, using visual verbal or auditory signals, improves rectal sensation, rectoanal coordination, and trains external anal sphincter

contractility. Success rates from various series range from 40% to 85%, most probably predicted by patient motivation rather than the duration of FI, manometric or endoanal ultrasound findings, or the biofeedback technique[33,34].

Several other invasive nonoperative techniques exist that may benefit patients with FI. The Procon incontinence device (Incontinence Control Devices, Inc., Kingwood, TX) is a soft catheter with a photosensor and balloon, which may be inserted into the rectum to send a signal warning of coming stool. This device has shown an improvement in the continence of select patients[35]. Submucosal injections of a wide variety of bulking agents have been used to augment the internal anal sphincter (silicon, silicone-based agent [Bioplastique ®], carbon-coated beads [Acyst™ procedure], carbon-coated zirconium oxide beads [Durasphere®], autologous fat, glutaraldehyde cross-linked collagen [GAX], polytetrafluoroethylene [Polytef]) have shown symptomatic improvement in anal resting pressure and incontinence. These office-based procedures are simple, relatively safe, and seemingly efficacious[36].

The Secca® procedure (Curon Medical, Inc., Sunnyvale, CA) uses temperature-controlled radiofrequency energy in the anal canal and distal rectum to create scarring of the internal anal sphincter and tissue fibrosis. In a prospective multicenter study, Efron et al reported improvement in FI and quality of life with resolution of symptoms in 60% of patients[37,38]. Takahashi et al reported similar findings at a two-year follow-up[39].

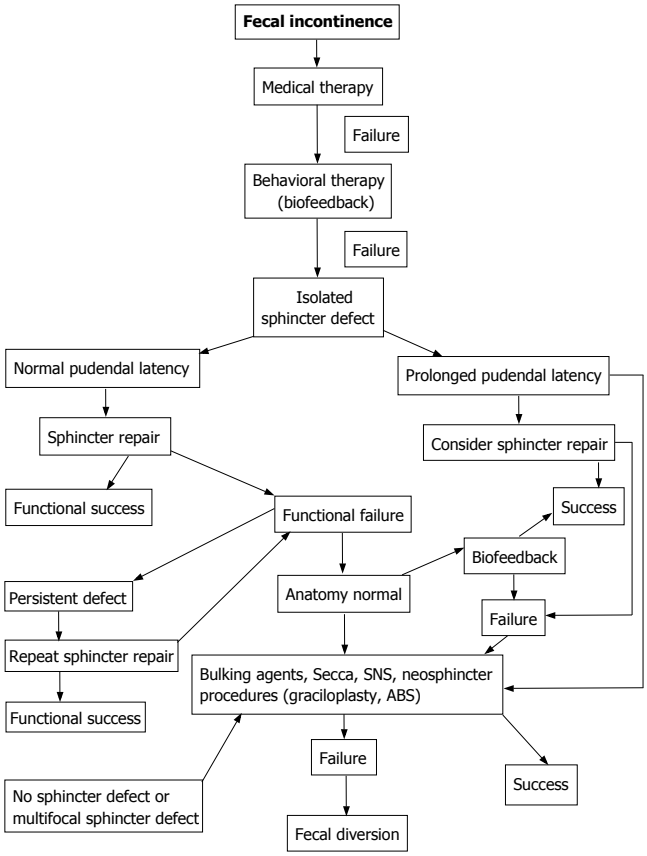

Figure 2 Treatment algorithm for fecal incontinence.

Surgery

Failure of conservative therapy in patients with external sphincter defects but without neurologic injury (intact pudendal nerves) are suited to surgical repair. Anterior defects from obstetric damage is the most common cause of FI in these cases. The surgical procedure is usually anterior overlapping sphincteroplasty, including preservation of all fibrotic scar and overlapping of both sides of the external anal sphincter with non-absorbable sutures[40]. Although approximately 80% of patients benefit from this operation in the short-term period, the rate of incontinence increases after 5-10 years by up to 85%[41-47].

Patients with severe incontinence with significant neurologic injury, multifocal external anal sphincter damage that cannot be primarily restored, or after functional failure of an anatomical successful sphincteroplasty, may be considered for reconstruction with neosphincter procedures using striated muscles (gracilis, gluteus maximus, sartorius, adductor longus). The gracilis muscle transposition is the most commonly used technique. To prevent muscle fatigue and maintain constant contraction, this procedure involves the implantation of an electric pulse stimulator. The dynamic graciloplasty (stimulated gracilis muscle transposition) has yielded significant improvement in FI in 55% to 78% of patients [48-51]. This procedure is complex, associated with substantial morbidity, mostly infective complications, and no longer available in the United States.

The artificial bowel sphincter is an inflatable silicone cuff connected to a pump and a pressure-regulating balloon. The cuff is placed around the anal canal to maintain the basal pressure. The pump is then implanted in the scrotum or labia major. Deflation of the cuff with a shifting of fluid to the balloon, which is located behind the pubis, is controlled by the patient. One multicenter trial showed that the device was functional in 67% of patients during the first year after surgery. Despite a high rate of complications such as cuff erosion, infection in 25%, device failure and removal in 37%, and re-operations in 46%, the overall outcome is successful in more than 50% of patients[52].

Another innovative treatment of FI is sacral nerve stimulation (SNS). It stimulates both somatic and autonomic supply of the pelvic organs and anorectal region through the sacral and pudendal nerves with the neuromodulation of the sensory, motor, and autonomic innervation. However, the exact mechanism of action is unclear. Temporary electrodes are percutaneously implemented for 2-3 wk to stimulate the sacral nerve roots. If patients demonstrate significant improvement in incontinence, the leads are connected to a permanent stimulator in the subcutaneous tissue. Published results of this procedure are encouraging with marked improvement in continence in up to 100% and restored complete continence in 41%-75%[53-55]. Matzel et al published the results of a multicenter, prospective, nonrandomized trial in 37 patients with FI and showed functional improvement (reduction in incontinence episodes per week) in more than 80% of patients[54]. The SNS procedure may also be reliable in some patients with constipation.

Colostomy or ileostomy should be considered in patients with severe FI who have failed multiple procedures, are immobilized, or are considered high-risk. This procedure may be temporary to protect complex reconstructions and improve quality of life until complete distal healing, or permanent; many stomas are amenable to laparoscopic construction[56-58].

In conclusion, the management of OD is primarily medical and behavioral; biofeedback therapy is the preferred method of treatment. Except botulinum toxin injection for PPC, surgery is usually reserved for severe symptomatic patients, who have repairable anatomic defects or combined pathology. The treatment of FI should be based on the appropriate diagnosis, anorectal anatomic and physiologic investigation, and guided by the severity of incontinence. It is important to balance the anticipated improvement in the quality of life with a minimal acceptably low surgical morbidity. The first line of therapy, conservative treatment with biofeedback, is effective in the majority of patients. Well-defined external anal sphincter defects may be best repaired with sphincteroplasty, whereas radiofrequency, bulking agents, and SNS should be offered for suitable patients with more severe FI who have failed noninvasive therapy. Complex procedures such as gracilis muscle transposition and artificial bowel sphincter implantation are reserved for continued profound incontinence after failed previous surgery.

Abstract

The hormonal interactions among the systems throughout the body are not fully understood; many vague clinical symptoms may in fact be manifestations of underlying endocrine diseases. The aim of the following review is to discuss gastrointestinal manifestations of surgically correctable endocrine diseases, focusing on abnormalities of thyroid function, cancer and finally autoimmune diseases. We also review manifestations of pancreatic endocrine tumors, and multiple endocrine neoplasia.

INTRODUCTION

Endocrine disorders are common, and the effects of endocrine disorders present with a wide range of clinical manifestations. This review encompasses the gastrointestinal manifestations of common endocrine diseases and the diagnostic and surgical interventions which may aid in the treatment of neuroendocrine abnormalities.

THYROID DISEASES

Functional thyroid disease

The true incidence of gastrointestinal manifestations of patients with functional abnormalities of the thyroid is not well documented. Gastrointestinal motor dysfunction, manifested by altered intestinal motility and transit time, has widely been accepted as the leading cause of gastrointestinal symptoms of thyroid disease[1]. The reported frequencies of gastrointestinal symptoms in hyperthyroid patients vary between 30% and 50%[2,3]. Patients with hyperthyroidism can experience frequent bowel movements, diarrhea, even malabsorption with steatorrhea[1,3]. Chronic dyspeptic symptoms such as epigastric pain and fullness, as well as eructation, nausea and vomiting are also frequently seen in these patients. Less commonly, hyperthyroidism has been reported to cause persistent and intractable vomiting[4]. The mechanism behind this is not clear; however, direct hormonal effects or stimulatory actions in the central nervous system have been suggested. Treatment of the thyrotoxicosis with beta-blocking agents and anti-thyroid drugs greatly improves these symptoms[4].

Dysphagia is a rare finding in thyrotoxicosis. The dysphagia can have either an acute or insidious onset, and may result from direct mechanical compression from a goiter, or altered neurohumoral regulation[5,6]. Clinically apparent symptoms vary with involvement of either the oropharyngeal or the esophageal phase of swallowing. There tends to be a higher incidence of oropharyngeal dysphagia than esophageal dysmotility. Clinically, these patients demonstrate easy drooling, nasal regurgitation, and weak phonation. They may have a higher incidence of aspiration pneumonia than do those patients with esophageal dysmotility. Dysphagia of thyrotoxicosis usually resolves shortly after resolution of the hyperthyroidism[5,6].

The overall decreased metabolic function seen in patients with hypothyroidism manifests in the GI tract with sluggish intestinal motility, ranging from mild constipation to paralytic ileus and colonic pseudo-obstruction[7]. Insidious symptoms of vague abdominal pain and distension may be present, and can be misdiagnosed as functional bowel disease. The exact biochemical mechanism by which thyroid disorders affect the gastrointestinal system are not fully understood. Changes may be seen on a molecular level with alteration of hormone receptors, dysfunction of the autonomic nervous system and myoelectrical enteric activity, as well as changes on a tissue level in the form of myopathy[3].

Altered gastroenteric myoelectrical activity has been documented by electrogastrography (EGG)[8]. Most studies in the literature detect a lack of correlation between the EGG and gastric emptying in non-euthyroid patients,

with manifestations of smooth muscle dysfunction, dissociation between the electrical signal and muscle response, pylorospasm, and lack of coordination between the antrum and the duodenum[9]. Hormonal effects on the GI tract may be a direct result of thyroid hormone, or as a result of synergistic effects of catecholamines. Tenore et al. investigated the effect of thyroxin (T4) on the intestinal chloride/bicarbonate exchange in hypo- and hyperthyroid rats. They found that alterations in intestinal ion exchange, mainly the flux of chloride, led to mucosal effects and resultant diarrhea. These findings were not seen when T4 was added ex vivo to rat ileum, suggesting that the effect on electrolyte transport likely requires systemic factors[10]. Furthermore, the beta-adrenergic antagonist propranolol inhibits intestinal transit in hyperthyroidism, thereby indicating that some of the dysmotility may be mediated through the adrenergic/catecholamine system[11]. Dysfunction of the autonomic nervous system (ANS) may modify the neuro-hormonal milieu, and result in alterations of myoelectric activity. However, there are no clear data regarding the exact mechanisms involved.

Hypothyroidism characteristically results in accumulation of glycosaminoglycans, mostly hyaluronic acid, in interstitial tissues throughout the body. This leads to interstitial edema that is particularly evident in the skin, heart muscle, and skeletal muscle, but also in the gastric smooth muscle. Edema in the gastric muscle may predispose to abnormalities of gastric myoelectric activity and thus the dysmotility seen in hypothyroid patients[12].

Thyroid malignancy

Patients with familial adenomatous polyposis (FAP), while known to be at high risk for colorectal cancer, also have an increased risk of thyroid malignancy. Papillary thyroid cancer (PTC) was first documented in a patient with FAP in 1949, and in 1968 a relation between FAP and PTC was suggested by Camiel *et al*[13,14]. The relative risk for PTC in FAP patients under 35 years of age has been found to be 160 times that of the general population. Thyroid cancer may be the first finding in patients with FAP, and 30% of thyroid carcinomas are diagnosed 4 to 12 years before the diagnosis of polyposis[15].

It has been suggested that FAP-associated thyroid tumors share unusual histological findings, such as the cribriform morular-variant of PTC (CMPTC)[16-20]. While the overall incidence of CMPTC in FAP patients has yet to be determined, analysis of large FAP registries suggests that it affects about 1%-2% of patients[20,21]. Similar to sporadic PTC, this disease demonstrates female predominance, and multifocality[22-26]. A recent series of seven such patients published by Tomoda et al demonstrated that all patients were female, with a mean age at presentation of 25 years[27]. Despite seemingly aggressive pathology, patients with CMPTC follow a highly favorable long-term course, with 5- and 20-year survivals of FAP-associated CMPTC reported to be 90% and 77%[16]. Patients diagnosed with CMPTC should be screened for FAP[27].

Autoimmune thyroid disease (AITD)

AITD, such as chronic lymphocytic thyroiditis (Hashimoto's thyroiditis) and Graves' disease, has been linked to autoimmune disorders of the gastrointestinal tract, namely celiac disease and atrophic gastritis. This association is not surprising considering that these disease entities share a common haplotype, HLA DR3-DQ2, which is common to many autoimmune diseases[28,29].

Celiac disease, a gluten-induced small bowel mucosal inflammation, demonstrating crypt hyperplasia and villous atrophy, is associated with an increased frequency of AITD. Patients with AITD are affected by celiac disease 5-10 times more than the general population. Also, 4%-10% of patients with celiac disease will also manifest AITD. Positive anti-thyroid antibodies can be seen in 10%-15% of patients with celiac disease. The significance of this discovery of subclinical thyroiditis is uncertain. Patients with AITD who remain hypothyroid despite adequate thyroid hormone supplementation, should undergo screening for celiac disease, as mucosal abnormalities may preclude full absorption of levothyroxine[30].

Atrophic gastritis is a chronic disease characterized by disappearance of oxyntic glands, loss of production of hydrochloric acid and intrinsic factor, as well as demonstration of parietal cell autoantibodies (PCA)[31,32]. Autoimmune gastritis is an early event in juvenile patients with AITD and detectable PCA. The lack of gastric symptoms in this young population often leads to a delay in diagnosis, thus screening for PCA with biochemical markers of gastric damage, such as gastrin levels, is warranted. Abnormal levels help to select patients who may benefit from further investigation with gastroscopy. Segni et al, determined that 30% of juvenile patients with AITD had positive PCA, and demonstrated that 45% of these patients had mild to severe hypergastrinemia[33]. Screening of juvenile patients with AITD is warranted, as atrophic gastritis is associated with a higher risk of gastric cancer and carcinoid tumors[34,35]. Premalignant gastric lesions can be found in up to 26% of these relatively young patients with detectable PCA[36].

ISLET CELL TUMORS OF THE PANCREAS

Islet cell tumors of the pancreas are rare entities which can range in presentation with respect to functionality, malignancy, and pattern of inheritance. The first descriptions of endocrine tissue in the gut came during the late 1800's with the recognition of 'islands' of cells in the pancreas by Langerhans, followed later by the discovery of chromaffin cells in the stomach by Rudolf Heidenhain, and then in the intestinal mucosal crypts of Lieberkuhn by Nikolai Kulchitsky. The recognition and intermittent reporting of islet cell adenomas began in 1902. However it was not until 1921 that the first reported clinical implication of these adenomas became known. Over the next 50 years several different peptides secreted by these tumors were identified, and eventually they were recognized as amine precursor uptake and decarboxylation (APUD) cell lesions, and coined apudomas. Based on functionality, these lesions were classified into clinical syndromes[37].

The clinical presentation of patients with pancreatic endocrine tumors varies from vague complaints of

abdominal pain and nausea to debilitating diarrhea. Due to the variability in clinical symptoms, a biochemical diagnosis is necessary. Once a definitive diagnosis is made based on serum markers, localization often necessitates multiple imaging modalities. Ultrasound is often the first test utilized, but has a low sensitivity, up to 31%[38-40]. Computed tomography (CT) and magnetic resonance imaging (MRI) technologies have improved sensitivity for small lesions, up to 40%-70%[38-41]. In cases where conventional imaging fails to adequately localize the lesion, invasive testing, such as intra-arterial stimulation and venous sampling, provides additional data. While these procedures can be invasive and technically challenging, the results are reliable and specific[42,43].

Labeled octreotide scanning is useful, as many islet cell tumors demonstrate type 2 somatostatin receptors[40]. Positron emission tomography utilizing a serotonin precursor 5-hydroxy-tryptophan has shown excellent results in a preliminary study from Eriksson and colleagues[44]. Endoscopic ultrasound has rapidly come to the forefront in localization studies. While operator dependent, it is highly sensitive in detecting even small tumors. Limitations include tumors in the distal pancreas and those that are pedunculated. In addition, fine needle aspiration can be preformed at the same time for both diagnosis and tattooing of the lesion to allow easy identification at the time of resection[40].

The operative approach varies on the type and extent of tumor. Enucleation is the procedure of choice for benign tumors, while malignant lesions require en bloc resection due to local invasion or presence of metastases. Laparoscopy is appropriate in some cases where enucleation or distal pancreatectomy is required[45].

Insulinoma

Insulinoma is the most common islet cell tumor. It was first described by Wilder and W. J. Mayo in 1927[37]. This tumor is typically solitary, small, and benign. It may be sporadic or associated with MEN I[40]. Hyper-secretion of insulin is often associated with the clinical findings of the "Whipple's triad", which consists of symptoms and signs of hypoglycemia during times of fasting or exertion, a serum glucose level less than 2.5 mmol/L during these symptoms, and resolution of the symptoms with administration of glucose[40,46]. Documenting elevated insulin levels during hypoglycemic periods, levels of endogenous insulin secretion with a C-peptide measurement and calculating the insulin:glucose ratio confirm the diagnosis. Adenomas, islet cell hyperplasia or nesidioblastosis can be the cause of hyperinsulinemia. The adenomatous lesions tend to be small and may be difficult to localize pre-operatively. Localization should be performed with conventional imaging including endoscopic US (EUS), CT, MRI, octreoscan, as well as calcium stimulated arterial-venous sampling (Doppman-Imamura test) for regionalization, if needed. Intraoperative ultrasound is extremely sensitive in localizing small lesions with a sensitivity of 91% in one series[47].

Enucleation is the preferred surgical treatment. In patients with diffuse disease, or tumors too small to localize, a regional resection is warranted after the general location of the tumor is identified by pre-operative arterial stimulation and venous localization[38,43]. Blind resection is not recommended.

Gastrinoma

Zollinger and Ellison described the gastrinoma syndrome (ZES) in 1955[37]. ZES includes a tumor associated with hypergastrinemia, peptic and distal duodenal ulcers. This is the most common islet cell tumor in MEN I, seen in up to 40% of patients. Although considered an islet cell tumor, this lesion is more frequently located in the duodenum, and can arise anywhere within the gastrinoma triangle, which is bounded by the confluence of the cystic and hepatic bile ducts, the junction of the 2nd and 3rd portions of the duodenum, and the neck of the pancreas. The rate of malignancy was noted to be 52% in one of the largest published series by Norton *et al*[48]. Clinically, patients present with recurrent ulcer disease, abdominal pain, diarrhea, and melena; they all demonstrate hypergastrinemia. Symptoms can be controlled with proton pump inhibitors to provide and opportunity to localize the lesion. Imaging with CT and MRI can be diagnostic; EUS has also proven useful as the majority of these tumors are located in the wall of the duodenum. Difficult localization or regionalization can be obtained by visceral arterial stimulatory testing using either secretin or calcium as a secretogogue, with hepatic venous sampling[38,39,42,48,49].

In those lesions that are difficult to localize pre-operatively, a thorough search must be undertaken in the gastrinoma triangle intra-operatively. Intraoperative endoscopy for identification of small intramural duodenal adenomas can be helpful. A duodenotomy is performed to allow clear evaluation of the wall of the duodenum and resection of lesions. If no obvious abnormality can be found, then a pancreaticoduodenectomy may be performed[40]. The role of resection of liver metastases for gastrinoma is not well defined at the present time. Debulking of > 90% of tumor burden may help in overall palliation of symptoms, and may be accomplished surgically or in combination with radiofrequency ablation and/or cryotherapy ablation[40].

VIPoma

These rare tumors, described by Verner and Morrison in 1958, are defined by the oversecretion of vasoactive intestinal peptide (VIP)[37]. The clinical syndrome is one of voluminous secretory watery diarrhea, with hypokalemia and hypochlorhydria. The profound diarrhea leads to significant losses of chloride and potassium, producing symptoms of incapacitating muscle weakness[46,51]. Other symptoms include flushing, due to vasodilatory effects of VIP, hyperglycemia due to glycogenoloytic activities of VIP, and hypercalcemia. The triad of severe secretory diarrhea, elevated fasting levels of VIP, and identification of an islet cell tumor is diagnostic. In a study performed by Koch *et al*[52] the determination of VIP levels can differentiate between patients with chronic diarrhea of other sources, patients with a non-functional islet cell tumor and those due to a functional tumor. VIP levels in patients with a functional tumor were 160-5975 ng/L compared to 80-120 ng/L in those with a non-functional

tumor. Most patients produce diarrhea in excess of 5 L/d, but no less than 0.7 L/d. Localization can be accomplished with conventional imaging, as both CT scan and MRI are sensitive tests for pancreatic and liver lesions. Octreoscan is useful in individuals with equivocal imaging. The most common location for this tumor is the tail of the pancreas, and a majority of these patients will have liver metastases at diagnosis[51].

Octreotide reduces circulating levels of VIP and allows for improvement of the diarrhea. After preoperative optimization, surgical exploration for resection is the most effective treatment. As a significant portion of these patients will have malignant disease at the time of exploration, careful examination of the liver and lymph nodes is necessary. Debulking may have a benefit in improving the symptoms by lowering VIP levels[40,46]. In cases of unresectable disease, adjuvant therapy with octreotide, streptozotocin, 5-fluorouracil and doxorubicin can palliate the symptoms[40]. However, a portion of patients may not respond to octreotide, or may become refractory to the drug due to down-regulation of receptors. Mean survival is 3.6 years, with a possible long-term survival of up to 15 years[51].

Glucagonoma

Glucagonoma was identified by McGarvran *et al*[37] in 1966. While rare, this islet cell tumor may have the most distinctive clinical syndrome. It arises from cells resembling alpha islet cells, is the third most common functioning endocrine tumor, and may be both sporadic or associated with MEN I[40]. Symptoms of excessive glucagon secretion are manifested by a migrating skin rash, diabetes, malnutrition, weight loss, anemia, thrombophlebitis, and glossitis. The necrolytic migratory erythema that is pathognomonic for this condition is felt to be secondary to hypoaminoacidemia associated with elevated levels of glucagons. Restoration of serum amino acids may alleviate this condition. However the data are contradictory. Malignancy is common with these tumors, and the prognosis is worse than with other types of islet cell tumors. The most common age at diagnosis is between 50-60 years. Patients often present with the characteristic pruritic skin rash located on the lower extremities and groins, glucose intolerance or frank diabetes mellitus. Thromboembolic disease is common, and can be the cause of death in some patients[46].

Biochemical diagnosis is based on elevated levels of plasma glucagon. Localization can be accomplished with CT scanning, as these tumors are typically large and located in the distal pancreas. Hepatic metastasis at the time of diagnosis is common[40]. Preoperative preparation involves control of hyperglycemia, treatment of thrombosis, and optimization of nutritional status with total parenteral nutrition. Octreotide has occasionally been used to aide in reduction of plasma glucagons levels, allowing improvement of nutritional status, and alleviation of the rash[46].

An aggressive operative approach is the mainstay of treatment. En bloc resection is required due to the high risk of malignancy, and liver metastases should be resected at the same setting if possible. Hepatic artery embolization, chemotherapy with 5-fluorouracil and streptozotocin, as well as long-term octreotide may be adjunctive. Liver and pancreatic transplantation have been performed in rare instances. The metastatic disease can be indolent, leading to survival for many years[46].

Somatostatinoma

Identification of somatostatinoma was made by Larssen *et al* and Ganda *et al* in 1977[37]. These rare tumors are frequently located in both the duodenum and pancreas, and secrete excess somatostatin. Overproduction of this inhibitory peptide leads to vague symptoms, marked by a decrease in gastrointestinal function. Clinically, it may present with cholelithiasis (70%), mild diabetes (60%), steatorrhea (30%-68%), hypochlorhydria (33%-53%) and weight loss[46]. Many of these tumors are identified incidentally on imaging studies for vague abdominal complaints, or at the time of cholecystectomy. The biochemical diagnosis is made by increased serum levels of somatostatin. Most of these tumors are located in the head of the pancreas or duodenum, and are usually solitary. Pancreaticoduodenectomy is often necessary due to the high risk of malignancy[40].

OTHER FUNCTIONAL AND NON-FUNCTIONAL NEUROENDOCRINE TUMORS

Islet cell tumors of the pancreas can secrete a variety of other hormones, including pancreatic polypeptide, grhelin, corticotropin, neurotensin, and calcitonin[46,51]. The majority of these tumors produce vague symptoms of abdominal discomfort and diarrhea. They can be difficult to diagnose, and should be approached in a similar manner to other functional islet cell tumors[40,46].

Tumors that produce peptides not associated with a clinical syndrome are considered to be non-functional. These lesions often produce symptoms associated with mass effect, such as abdominal discomfort or pain, nausea, emesis, obstruction, cachexia, bleeding, and obstructive jaundice[54]. Due to the lack of functional symptoms, these tumors are typically large when diagnosed, and have been noted to average 10 cm in two published series[54,55]. Conventional imaging with CT will identify these tumors, but they are difficult to distinguish from pancreatic adenocarcinoma. Operative approach to these lesions should be with intent of curative resection by pancreaticoduodenectomy, or distal pancreatectomy. If the lesion cannot be safely resected, an open biopsy should be obtained prior to palliation with gastrointestinal bypass. In a large series published by Liang *et al*, adjuvant chemotherapy and radiation therapy provided a disease-free survival of up to 45 mo, with an overall 5 and 10 year survival of 58% and 29%[54].

Multiple endocrine neoplasia syndromes (MEN)

MEN 1 is characterized by pituitary lesions, islet cell tumors of the pancreas, and hyperparathyroidism. The MEN 1 pancreas can manifest any of the previously mentioned tumors, the most common being gastrinoma. The pancreatic pathology can be in the form of a macroadenoma, microadenoma, islet cell hypertrophy,

hyperplasia, dysplasia, and carcinoma; approximately 50% of MEN 1 patients have tumors which are duodenal in origin. It has been shown that early detection can improve long-term survival, therefore early screening with pancreatic polypeptide and gastrin is advocated for family members of MEN 1 patients[46]. In addition, measurement of insulin, proinsulin, glucagon, and chromogranin A can be utilized. If two of these markers increase over the course of 6 mo, further investigation should be undertaken, and those patients should be referred for surgical exploration[56]. Cure for gastrinoma is difficult due to the size and multiplicity of lesions. The largest series of surgical resection and cure comes from the University of Michigan in which and an 80% pancreatectomy, thorough exploration of the duodenum, and enucleation of smaller pancreatic lesions has been performed[46]. Total pancreatectomy, pancreaticoduodenectomy and pancreas-preserving total duodenectomy have also been reported[46,57].

MEN 2 is subdivided into MEN 2A, characterized by medullary thyroid carcinoma (MTC), pheochromocytoma, and parathyroid hyperplasia; and MEN 2B which includes MTC, tumors of the adrenal medulla (pheochromocytoma, and/or ganglioneuroma), intestinal and mucosal neuromas, and marfanoid habitus. These syndromes can manifest a host of GI symptoms, including diarrhea associated with hypercalcitonemia of MTC, constipation associated with hypercalcemia, and most notably, Hirschsprung's disease associated with MEN 2B[46]. Ganglioneuromas of the intestinal mucosa can lead to manifestations of Hirschsprung's disease with significant symptoms of constipation, pain, distension, and difficulty swallowing. The majority of these patients require surgical intervention for their colonic disease[58].

In summary, endocrine disorders of the thyroid and pancreas often have significant gastrointestinal symptoms. Given the often vague and general quality of these symptoms, diagnosing their endocrine etiology requires a high index of suspicion. Treatment can be achieved both medically, and surgically, if indicated or feasable.

Abstract

Recently, there has been an increased recognition of neoplasms of the pancreas other than ductal adenocarcinoma. Although not as well studied or characterized as pancreatic adenocarcinoma there are many distinct lesions which exhibit diverse biological behaviors and varying degrees of malignancy. These lesions include: endocrine neoplasms, cystic tumors, solid pseudopapillary tumors, acinar cell carcinoma, squamous cell carcinoma, primary lymphoma of the pancreas, and metastatic lesions to the pancreas. These less common neoplasms are being diagnosed more frequently as the number and sensitivity of diagnostic imaging studies increase. This review article discusses the clinical course, diagnosis, and treatment of these less common, but quite relevant, neoplasms of the pancreas.

INTRODUCTION

Ductal adenocarcinoma is the most common of the various tumors that affect the pancreas. There are other distinctive neoplasms of the pancreas, however, which display a wide range of symptoms, biological behaviors, and outcomes. These include endocrine neoplasms, cystic tumors, solid pseudopapillary tumors, acinar cell carcinoma, squamous cell carcinoma, pancreatic lymphoma, and metastatic lesions of the pancreas. These tumors are becoming more frequently documented in the literature and recognized more often, and at earlier stages, due to the increased sensitivity and utilization of diagnostic imaging. Therefore, the correct identification and treatment of these less common neoplasms of the pancreas is becoming increasingly important.

ENDOCRINE NEOPLASMS OF THE PANCREAS

Pancreatic endocrine tumors are far less prevalent than pancreatic adenocarcinomas. They occur in approximately 1 out of 100 000 people annually, and constitute 1%-2% of pancreatic tumors[1]. These tumors frequently manifest as a constellation of symptoms associated with the hormones they produce (Table 1). Classification is based on hormone production and the functional pancreatic endocrine tumors include: insulinomas, gastrinomas, VIPomas, glucagonomas, somatostatinomas, adrenocorticotropic hormone producing tumors, and growth hormone releasing factor secreting tumors. Additionally, there is a subset of non-functional pancreatic tumors which are clinically inert but produce neuroendocrine cell markers such as chromogranin-A and somatostatin receptors[2]. Pancreatic endocrine tumors are also associated with several inherited syndromes, including multiple endocrine neoplasia type I (MEN-1) and von Hipple Lindau disease (vHL).

Insulinomas are the most common functional pancreatic neuroendocrine tumor and are most often associated with fasting hypoglycemia and neuroglycopenic symptoms but may present with cardiovascular symptoms as well. These tumors are frequently small (< 2 cm), predominantly benign, and may occur anywhere throughout the pancreas[3]. The second most common functional pancreatic endocrine tumors are gastrinomas. These tumors produce gastrin and cause Zollinger-Ellison syndrome. Greater than 50% of gastrinomas are malignant at the time of diagnosis and many of these will have liver metastases[4]. These patients commonly have peptic ulcer disease but diarrhea secondary to the increased gastric acid secretion is frequently a presenting symptom[5]. Other less common functional neuroendocrine tumors of the pancreas include VIPomas which are frequently metastatic at the time of diagnosis[6] (> 60%) and cause secretory diarrhea with subsequent electrolyte abnormalities. Glucagonomas are another rare functional pancreatic endocrine tumor. They are usually large (> 4 cm) tumors found almost exclusively within the body and tail of the pancreas and are symptomatically associated with the "4D's" (dermatitis, diabetes, deep venous thrombosis, and depression)[7]. There are additional

Table 1 Classification of pancreatic endorcrine tumous

Tumor	Hormone produced	Percent malignant	Clinical features	5 yr survival	Localization	Treatment
Insulinoma	Insulin proinsulin	10%	Hypoglycemia, neuroglycopenic symptoms	97%	EUS, intraoperative ultrasound	Surgical resection, chemotherapy, dextrose
Gastrinoma	Gastrin	60%-90%	Peptic ulcer disease, diarrhea	60%-70%	SRS, SPECT, EUS	Surgical resection, PPI, somatostatin
Glucagonoma	Glucagon	50%-90%	Necrolytic migratory erythema, diabetes, DVT, depression	50%-60%	CT w/contrast, EUS	Surgical resection, nutritional support, somatostatin, chemotherapy, insulin
VIPoma	Vasoactive intestinal peptide	40%-70%	Secretory diarrhea, hypokalemia, achlorhydria	50%	CT Scan, SRS	Somatostatin, correction of electrolytes, hydration, surgical resection
Somatostatinoma	Somatostatin	70%-80%	DM, cholelithiasis, steatorrhea	40%	CT, EUS, SRS	Surgical resection chemotherapy, somatostatin
Non-functional tumors	Pancreatic polypeptide	60%-80%	Abdominal pain, weight loss, jaundice	50%	CT, MRI	Surgical resection

functional neuroendocrine tumors of the pancreas, each of which present with specific clinical symptoms related to the excess of hormone produced. However, approximately 15%-30% of pancreatic endocrine tumors are termed "nonfunctional", as they may either produce elevated amounts of hormones which do not cause symptoms or may excrete small, clinically insignificant amounts of active hormones[3]. These tumors are generally large, metastatic at the time of diagnosis, and may be distributed throughout the pancreas. Patients generally present with mechanical symptoms associated with the tumor itself, such as abdominal pain, weight loss, and jaundice[8].

The treatment of endocrine tumors of the pancreas includes supportive medical treatment, surgery, both for cure and palliation, and nonsurgical cytoreduction. Frequently, these tumors require a combination of both surgical and medical treatment to best relieve the patients' symptoms and offer the best prognosis. It is important to remember that endocrine neoplasms of the pancreas usually have metabolic derangements which must be corrected prior to further treatment. Patients with insulinomas should have their hypoglycemia controlled, aggressive preoperative nutritional support and anticoagulation is essential for those with glucagonomas, and dehydration and electrolyte abnormalities must be corrected when a VIPoma is diagnosed.

Complete surgical resection of endocrine neoplasms of the pancreas offers the only chance for cure, but patients can sometimes have metastases at the time of diagnosis making complete resection an impossibility. However, some authors have suggested that in patients with metastatic disease, aggressive surgery with debulking and resection of metastases will benefit patients symptomatically and improve survival[9,10]. Combinations of non-surgical cytoreductive modalities and medical treatments are also used to enhance palliation and survival, including cryoablation, hepatic artery embolization, radio frequency ablation, somatostatin analogues, alpha interferon, chemotherapy, and radiotherapy[11].

CYSTIC NEOPLASMS OF THE PANCREAS

The diagnosis of cystic lesions of the pancreas, which constitute less than 10 percent of pancreatic neoplasms[12], has become more commonplace due to the increased frequency and improved accuracy of imaging techniques. This has increased the need for a clear understanding of the diagnosis and management of these cystic lesions. Two of the more common cystic neoplasms are the serous cystadenomas and the mucinous cystic neoplasms. Serous cystadenomas occur predominantly in women, and are typically described as microcystic with a "honeycombed" appearance, although oligo-macrocystic variants do exist. All true serous cystadenomas are benign. However there are a few case reports in the literature of serous cystadenocarcinomas which are classified as malignant due to invasion of cells into surrounding tissues or metastatic spread[13].

Mucinous cystic neoplasms (MCNs) have an epithelial lining made of columnar mucin-producing epithelium that has an ovarian-type stroma and stains positively for estrogen and progesterone receptoms[14]. Unlike the honeycombed appearance of serous neoplasms, most mucinous tumors are unilocular and although uncommon, a finding of peripheral calcification on CT is predictive of a malignant MCN[15]. Series have found that from 8% to 33% of these tumors contain invasive carcinoma[16]. MCNs are generally found in the body and tail of the pancreas and more commonly affect females in the 5th decade of life. With both neoplasms, patients often present with nonspecific complaints such as abdominal pain and weight loss, though they may be asymptomatic[17]. Of note, in a recent review of 106 patients with serous adenomas, 47% of tumors were found in asymptomatic patients as part of the workup of an unrelated problem[18]. It is this type of patient with an incidentally found lesion that presents a challenge in both diagnosis and treatment. Given the risk of invasive cancer the treatment of mucinous cystic neoplasms should be surgical resection. The treatment of serous cystic lesions is more controversial. A recent paper from the Massachusetts General Hospital describing their experience with serous cystadenomas proposes a selective approach towards resection, based on tumor size and the ability to accurately diagnosis the lesion[18]. If radiographic imaging is equivocal, endoscopic ultrasound with fine needle aspiration is performed and markers such as mucin-like antigen and carcinoembryonic antigen (CEA) levels, which are both low in serous tumors and high in

mucinous lesions, are evaluated[16]. If based on this workup the diagnosis of a serous cystadenoma of < 4 cm in an asymptomatic patient is made, expectant management with serial CT scans is recommended[18]. However, due to the difficulty in unequivocally differentiating between benign versus malignant cystic tumors preoperatively, some feel that an aggressive surgical approach should be used for all patients presenting with a cystic pancreatic neoplasm[19,20].

INTRADUCTAL PAPILLARY MUCINOUS TUMORS

Intraductal papillary mucinous neoplasms (IPMNs) of the pancreas are defined as intraductal mucin-producing neoplasms with tall, columnar, mucin-containing epithelium with or without papillary projections. Typically, these tumors involve the main pancreatic duct but recently, a distinction has been made between those tumors which involve the main duct and those which predominantly involve the branches of the ductal system (branch-duct IPMNs). Some have suggested that the branch duct variant of IPMN is more indolent and has a lesser incidence of malignancy than the main duct IPMN[21,22]. IMPNs display a histological range from adenoma, to IMPN with dysplasia, to carcinoma in situ, to invasive carcinoma which seems to mimic the adenoma-carcinoma sequence seen in colorectal cancer. A review of recent reports found that approximately 50% of resected specimens contained invasive carcinoma[23]. Patients generally present in their 60's, but several recent studies have shown that those patients with invasive IPMNs are 5-6 years older than those patients with benign disease[24,25]. Patients are often symptomatic at presentation with complaints of abdominal pain, weight loss, and diarrhea[26]. Thin cut CT scan, which is the radiological test of choice, will often reveal a mass in the head of the pancreas and if diagnostic uncertainty is present, endoscopic ultrasound with fine needle aspiration may be preformed. Treatment of IPMN consists of surgical resection, often a pancreaticoduodenectomy, of all gross disease with an attempt to achieve negative surgical margins. A comparison of recent reports showed a 5 year survival rate from 77%-100% in noninvasive IPMNs compared to 43%-65% in those patients with invasive disease[23-27]. Recurrent disease has been shown to occur both in the pancreatic remnant and at distant sites and therefore close follow-up with frequent imaging has been recommended.

SOLID PSEUDOPAPILLARY TUMORS OF THE PANCREAS

These rare pancreatic neoplasms tend to affect young women and have characteristic histological features, including a combination of solid and cystic components and the presence of pseudopapillae. Interestingly, unlike ductal adenocarcinoma, solid pseudopapillary tumors of the pancreas (SPTs) are not associated with abnormalities in K-*ras*, p53, or DPC4 genes but like colon cancer, do demonstrate genetic abnormalities in the APC/*B*-catenin pathway[28]. Presenting symptoms are frequently non-specific in nature and often include abdominal pain, increased abdominal girth, and the presence of a palpable mass. A review of 718 patients with solid pseudopapillary tumors of the pancreas found a 10:1 ratio of affected women to men, a mean age of 22 years, the presence of metastases in 20% of the patients, and a cure rate greater than 95%[29]. Surgery is the treatment of choice for these tumors, with pancreaticoduodenectomy performed for lesions in the head of the pancreas and distal pancreatectomy for those lesions in the body or tail. Metastatic or locally invasive disease is not necessarily a contraindication to surgery, and improved longterm survival has been demonstrated with aggressive surgical resection[30,31]. There have been reports of some success with radiotherapy or chemotherapy in cases deemed unresectable[29]. Although the majority of these tumors are considered to be of low malignant potential, a recent report of two cases of aggressive SPTs noted death of the patients at 6 and 16 mo after diagnosis. In these cases a high mitotic index and extensive tumor necrosis was noted[32]. These findings might help distinguish a more virulent form of SPT and lead to a more aggressive post-operative treatment course.

ACINAR CELL CARCINOMA

Acinar cell carcinoma of the pancreas accounts for approximately 1% of pancreatic cancers. These tumors exhibit expression of pancreatic enzymes such as trypsin, lipase, chymotrypsin and amylase. Similar tumors with primarily acinar differentiation include mixed acinar-endocrine carcinomas, which exhibit both acinar and endocrine cellular differentiation, and pancreatoblastomas which are usually found in children. Patients most frequently present with abdominal pain and bloating and these tumors may be associated with hypersecretion of lipase which leads to subcutaneous nodules and ectopic fat necrosis[33]. On CT or MRI it presents as an exophytic, hypovascular, and well marginated mass[34]. Unlike typical pancreatic adenocarcinoma the genetic mutations in K-*ras*, *p*53, and S*mad* are uncommonly found but there seem to be alterations in the adenomatous polyposis coli-*b*-catenin pathway which are similar to colorectal cancer[35].

A retrospective review from the Memorial Sloan-Kettering Cancer Center evaluated 39 patients with acinar cell carcinoma[36]. They noted that these lesions were found equally throughout the pancreas, approximately half the patients had metastatic disease at time of presentation, and that the median survival was 19 mo. This median survival (19 mo) falls between that of ductal adenocarcinoma (6 mo) and endocrine neoplasms of the pancreas (40-60 mo). In these patients the stage of disease correlated with survival (14 mo in patients with metastases *vs* 38 mo in patients with localized disease). Patients who were amenable to surgery had a 36 mo median survival as opposed to 14 mo in patients who did not receive surgery. Despite the improved survival in the surgical patients, there was a high recurrence rate (72%) which the authors felt may have been indicative of the presence of micrometastases and may imply the need for adjuvant therapy. Many of these patients who recurred experienced a distant rather than lo-

cal recurrence which suggests the need for better systemic therapy. Case reports have demonstrated some success with concurrent chemotherapy (capecitabine or irinotecan, FU and leucovorin) and radiotherapy which will likely be further elucidated as more data is obtained[36,37].

SQUAMOUS CELL CARCINOMA OF THE PANCREAS

Although not normally present in the pancreas, squamous metaplastic cells may present during periods of inflammation[38]. These cells may then transform to squamous cell carcinoma of the pancreas which is a rare and unusual cancer. The reported incidence is 0.5% to 2% of pancreatic malignancies and a recent case report found 61 cases, including 36 autopsy/registry cases, in the English literature[39]. Their review of these cases found a mean age of 62 years, common presenting symptoms of abdominal/back pain, weight loss, and anorexia, tumor size of 7.8 cm, and equal distribution of the lesion in the head, body, or tail[39]. Given the rarity of this neoplasm, in cases in which squamous cell carcinoma of the pancreas is diagnosed it is important to perform a thorough search for a possible alternate primary location. Patients with squamous cell carcinoma of the pancreas have a poor prognosis, with a median survival of 7 mo for patients undergoing curative resection and 3 mo for those not undergoing a curative resection[39,40]. There are several reports of the use of chemotherapy in unresectable cases, but the prognosis remains poor.

PRIMARY LYMPHOMA OF THE PANCREAS

Primary lymphoma of the pancreas is rare disease and in one study was shown to comprise 1.3% of 1050 pancreatic fine needle aspirations[41] Patients generally range from 58-66 years old and frequently present with abdominal pain, weight loss, and an abdominal mass, while only 25% present with jaundice[42]. The head of the pancreas is the most common location for these tumors but the entire gland may be affected. The majority of primary pancreatic lymphoma displays a B-cell phenotype, although a Japanese report found that 21% of cases were T-cell lymphomas and cases of anaplastic large cell lymphoma and Hodgkin lymphoma of the pancreas have been reported[43-46]. Diagnosis of this rare cancer is critical and requires adequate samples for tissue typing. Fine needle aspiration (FNAs) with flow cytometry has been advocated by some to be an accurate diagnostic tool which then obviates the need for invasive surgery to only those patients with non-diagnostic FNAs[47]. The primary treatment of pancreatic lymphoma consists of chemotherapy and radiotherapy using non-Hodgkin's lymphoma protocols and survival ranges from to 2-6.5 years[42]. For patients undergoing surgery, biliary and gastric bypass may be beneficial to relieve jaundice and prevent obstructive fibrosis in the common bile duct following chemotherapy and radiation. A review of those patients undergoing surgery found that 35% of patients underwent biopsy alone, 27.5% had a biliary bypass, 15% had a gastric bypass, and 7.5% had pancreatic resection[42].

METASTATIC LESIONS OF THE PANCREAS

Although uncommon, the pancreas may serve as a site for distant metastases and when these metastases present as an isolated pancreatic mass, questions regarding diagnosis and treatment may arise. Almost any tumor type may metastasize to the pancreas but in an analysis of a surgical and autopsy database, the majority of tumors found in the surgical database were lymphomas, carcinomas of the stomach, kidney, and lung whereas in the autopsy database metastasis was most commonly from the lung, followed by the GI tract and kidney[48]. A review of resection for metastases to the pancreas found renal cell carcinoma to be the most frequent primary histopathology (62%), followed by non-small cell lung cancer, melanoma, and sarcoma[49]. In this series, postoperative morbidity was 25%, mortality was 6%, and the overall actuarial survival rate for 2 and 5 years was 62% and 25%, which indicates that resection of metastatic disease to the pancreas is safe and may offer some survival benefit in select patients. The prolonged disease free interval between the initial cancer and pancreatic recurrence can be quite prolonged (median 2.6-7.5 years)[48-51]. Hiotis *et al* found that approximately one-third of the metastatic tumors evaluated were clinically suspected to be primary pancreatic neoplasms[49]. These findings demonstrate the difficulty in diagnosing pancreatic metastases and emphasize the need to consider metastatic disease to the pancreas in the workup of any pancreatic tumor and particularly in patients with a history of prior malignancy.

In conclusion, the most common neoplasm affecting the pancreas is ductal adenocarcinoma but there are a host of less common pancreatic neoplasms with distinct clinical and biological behaviors. Although relatively rare, more of these lesions will be seen as diagnostic imaging continues to become more frequent and sensitive. Accurate and timely identification of a pancreatic neoplasm coupled with a knowledge of its biological behavior and therapy will be essential in order to offer patients the optimal therapy.

Abstract

The goal of this review is to outline some of the important surgical issues surrounding the management of patients with early (T1/T2 and N0), as well as locally advanced (T3/T4 and/or N1) rectal cancer. Surgery for rectal cancer continues to develop towards the ultimate goals of improved local control and overall survival, maintaining quality of life, and preserving sphincter, genitourinary, and sexual function. Information concerning the depth of tumor penetration through the rectal wall, lymph node involvement, and presence of distant metastatic disease is of crucial importance when planning a curative rectal cancer resection. Preoperative staging is used to determine the indication for neoadjuvant therapy as well as the indication for local excision versus radical cancer resection. Local excision is likely to be curative in most patients with a primary tumor which is limited to the submucosa (T1N0M0), without high-risk features and in the absence of metastatic disease. In appropriate patients, minimally invasive procedures, such as local excision, TEM, and laparoscopic resection allow for improved patient comfort, shorter hospital stays, and earlier return to preoperative activity level. Once the tumor invades the muscularis propria (T2), radical rectal resection in acceptable operative candidates is recommended. In patients with transmural and/or node positive disease (T3/T4 and/or N1) with no distant metastases, preoperative chemoradiation followed by radical resection according to the principles of TME has become widely accepted. During the planning and conduct of a radical operation for a locally advanced rectal cancer, a number of surgical management issues are considered, including: (1) total mesorectal excision (TME); (2) autonomic nerve preservation (ANP); (3) circumferential resection margin (CRM); (4) distal resection margin; (5) sphincter preservation and options for restoration of bowel continuity; (6) laparoscopic approaches; and (7) postoperative quality of life.

INTRODUCTION

Rectal cancer is a major health concern in the United States, with an estimated 40 340 new cases diagnosed in 2005[1]. There are four major goals in the treatment of a patient with rectal cancer: (1) local control; (2) long-term survival; (3) preservation of anal sphincter, bladder, and sexual function; and (4) maintenance or improvement in quality of life. These goals are best achieved through a multi-modality approach delivered by a multi-disciplinary team. The aim of this review is to outline some of the important surgical issues surrounding the management of patients with early (T1/T2 and N0), as well as locally advanced (T3/T4 and/or N1) rectal cancer.

PREOPERATIVE STAGING

Information concerning the depth of tumor penetration through the rectal wall, lymph node involvement, and presence of distant metastatic disease is of crucial importance when planning a curative rectal cancer resection. Preoperative staging is used to determine the indication for neoadjuvant therapy, as well as to determine whether local excision or radical cancer resection will provide optimal surgical treatment.

The most common imaging modalities currently used in the preoperative staging of rectal cancer are endorectal ultrasound (ERUS), computed tomography (CT) scan, magnetic resonance imaging (MRI), and positron emission tomography (PET) scan.

ERUS

ERUS is an accurate method to preoperatively stage rectal cancers. Although operator-dependent, it can be performed at the time of patient evaluation with minimal preparation or patient discomfort. ERUS is used to clinically determine the tumor (T) and lymph

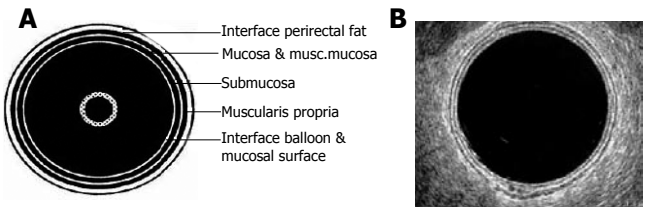

Figure 1 Rectal wall anatomy. **A**: Schematic diagram of ERUS image; **B**: Actual image of normal ERUS[3].

node (N) stage of rectal cancer (Figure 1). According to currently available data, ERUS is 62% to 92 % accurate for T-staging and 64% to 88% accurate for N-staging[2,3]. ERUS is limited by its steep learning curve, operator variability, and limitations for staging near-obstructing tumors and downstaged tumors after chemoradiation therapy. Nevertheless, ERUS is currently considered the most accurate method for local staging of rectal cancer. The performance of ERUS in staging rectal cancer may be overestimated in the literature due to publication bias[4]. A recent analysis of 4118 subjects reported an overall mean T-staging accuracy of 85% (median, 88%) and N-staging accuracy of 75% (median, 76%). Both T-staging and N-staging accuracy rates declined over time with the lowest rates reported in more recent literature[4].

CT

The vast majority of patients with clinically localized rectal cancer have an abdominopelvic CT prior to surgical resection, in an effort to identify intra-abdominal metastatic disease prior to a curative or radical resection. However, the role of CT in the preoperative locoregional staging of rectal cancer is much more limited. In fact, the accuracy of CT for T-stage (53% to 94%) and N-stage (54% to 70%), are substantially lower overall than that of ERUS[2].

MRI

The traditional body-coil MRI is less accurate than ERUS and is rarely used for locoregional staging of rectal cancer. However, newer techniques of endorectal coil MRI and phased-array MRI have been reported to be 66% to 92% accurate in determining T-stage, and can reliably determine extent of tumor mesorectal involvement in up to 100% of cases[2,5,6]. Although promising in the preoperative staging of rectal cancer, MRI is limited by its relatively small field of view (when using the endorectal coil), expense, and patient intolerance. Similar to ERUS, restaging patients treated with preoperative chemoradiation using MRI does not appear to be as accurate. In a study of 50 patients who underwent restaging, MRI had the accuracy of 52% in T stage and 68% in N stage[7]. Most of the inaccuracy in both T and N stages was caused by overstaging, believed to be a result of the inability of MRI to differentiate treatment-induced fibrosis from viable tumors. MRI may play an important role in the future by determining preoperatively whether the mesorectal fascia has been breached by tumor, and thus optimize patient selection for neoadjuvant therapy. The results of an ongoing prospective, multicenter trial should better define the role of MRI in the preoperative staging of patients with rectal cancer.

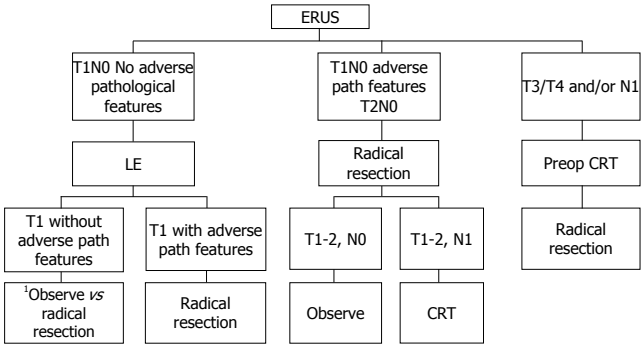

Figure 2 Treatment algorithm for patients with rectal cancer and no evidence of distant metastases. LE: local excision; CRT: chemoradiation therapy. Observation following a LE of a T1 adenocarcinoma, even with good pathological features, may result in 20% local recurrence at 10 years.

PET

PET scanning has been used in the postoperative evaluation of potential recurrences after a curative resection of rectal cancer. This is often initiated by a rising CEA level. However, preliminary data from a prospective trial conducted at our institution suggests that PET may have a role in determining locally advanced rectal cancer response to neoadjuvant chemoradiation[8]. As such, PET can potentially guide changes to the type of neoadjuvant chemoradiation to increase tumor response, as well as guide extent of subsequent surgical therapy. An ongoing, large, prospective study aims to confirm these encouraging results.

SELECTION OF CURATIVE RESECTION

Local excision is likely to be curative in patients with a primary tumor which is limited to the submucosa (T1N0M0), without high-risk features (i.e., poorly differentiated, vascular and neural invasion) and in the absence of metastatic disease. However, recent retrospective series with long-term follow-up suggest that even T1 rectal cancers without high-risk features have higher recurrence rates than expected[9-12]. Therefore, an increasing percentage of these patients are undergoing radical rectal resection. The decision to pursue a radical resection versus a local excision for an early staged rectal cancer is most difficult when the radical resection would require a permanent colostomy. Careful discussion of risks and benefits with the patient is particularly essential in this circumstance.

Once the tumor invades the muscularis propria (T2), radical rectal resection in acceptable operative candidates is recommended. In patients with transmural and/or node positive disease (T3/T4 and/or N1) with no distant metastases, preoperative chemoradiation followed by radical resection according to the principles of TME has become widely accepted (Figure 2). In patients with metastatic disease, complex and interrelated variables such as patient co-morbidities, patient expectations, and

resectability of metastases must be considered when planning surgical therapy. For patients with unresectable distant metastatic disease, surgical excision of the primary rectal cancer may still be considered when palliation of symptoms is anticipated.

CHEMORADIATION THERAPY

The use of perioperative chemoradiation therapy (CRT) for rectal cancer continues to evolve. Based largely on the results of two multicenter trials, the 1990 NIH Consensus Conference on rectal cancer recommended postoperative chemoradiation for patients with transmural and/or node positive rectal cancer[13]. Although postoperative therapy for stage II/III rectal cancer remains a reasonable option, many centers have adopted a treatment strategy of using preoperative chemoradiation therapy. The benefits of neoadjuvant chemoradiation therapy have been well documented, and include tumor regression and downstaging associated with increased tumor resectability and a higher rate of sphincter preservation[14-18]. Moreover, complete pathologic response rates up to 10% to 25% can be achieved[18-25]. The German Rectal Cancer Study Group recently completed a large, prospective, randomized trial that compared preoperative versus postoperative chemoradiation in the treatment of clinical stage II and III rectal cancer[26]. They concluded that, although there was no difference in overall survival between the two groups, there was a significant reduction both in local recurrence rate (6% *vs* 13%, $P = 0.006$) and treatment toxicity in the preoperative group. Although the quality of life for patients treated with preoperative CRT may transiently decrease, this finding is counterbalanced, in large part, by the potential for improved oncologic outcome in properly selected patients[27].

Current studies evaluating treatment outcomes in rectal cancer patients with a complete or near complete response to neoadjuvant chemoradiation have demonstrated improved survival compared to partial responders or non-responders[14,18]. In one report, patients with a complete pathological response had a 5 year disease-free survival of 95.2% compared to 55.4% for those with a partial or no pathological response ($P = 0.03$)[14]. In a recent report from MSKCC, 297 patients with locally advanced (T3-4 and/or N1) rectal cancer were treated with preoperative chemoradiation therapy followed by TME[28]. Patients who achieved > 95% pathological response from preoperative CRT had a significantly improved 10 year OS and RFS rates, when compared to those patients with a < 95% pathological response[28].

In light of the significant response rates that can be achieved with preoperative therapy, some have suggested limiting further surgical therapy to transanal excision alone[29,30]or observation[31,32] for patients with a complete response. This approach is limited by the difficulty in precisely determining tumor response to chemoradiation and assessing residual mesorectal lymph node involvement. Currently, assessment of tumor response is determined postoperatively by objective measurements of tumor volume in the surgical specimen compared to preoperative clinical staging; however, preoperative staging is based on subjective evaluation and, with current methods and technology, remains unreliable following chemoradiation. ERUS is considered the most accurate way to stage rectal cancer. But after radiation therapy, it is difficult to distinguish between residual tumor and radiation fibrosis and accuracy decreases to 47%-58%[33-37].

Similarly, restaging patients treated with preoperative chemoradiation using MRI does not appear to be accurate[7]. As discussed earlier, a preliminary report from MSKCC showed response assessment may be improved with the use of FDG-PET scanning[8]. In a series of 15 patients, FDG-PET scanning was able to more accurately assess treatment responses; confirmation with a large, prospective study is ongoing.

In patients that undergo transanal local excision, there is a risk of leaving residual disease in the mesorectum, even after combined preoperative chemoradiation therapy. Many studies have reported 1.8% to 16% of patients with lymph node involvement despite a complete pathological response in the primary tumor[38-40]. Given the inability of existing imaging modalities to reliably confirm the eradication of mesorectal nodal metastases, patients undergoing TAE alone following preoperative CRT are at risk for local failure due to residual nodal disease. Currently, there are no data to support the routine use of TAE in these patients, and definitive treatment should continue to be rectal resection with TME.

These data strongly support the need for prospective clinical trials designed to optimize the combination and sequencing of multidisciplinary neoadjuvant therapy in order to maximize survival and locoregional control rates in rectal cancer patients. If the response rate can be enhanced, it may permit less radical surgery in patients with complete responses to preoperative therapy and adjust the dose intensity or duration of postoperative chemotherapy. Ultimately, the aim of this approach is to be able to individualize or customize a patient's treatment based upon expression of molecular markers, genetic signatures using gene arrays and response to systemic therapy preoperatively.

In patients treated with preoperative chemoradiation, surgical resection is generally deferred until 6 to 8 weeks following completion of therapy in order to allow maximal tumor response, as well as patient recuperation from the toxicities sometimes associated with chemoradiation. Although the benefit of a prolonged interval from completion of chemoradiation to surgery is unclear, when clinically necessary it does not appear to increase the operative blood loss, operative time, and positive margin rate[41].

EARLY RECTAL CANCER (T1/T2 AND N0)

Local excision

Transanal local excision (LE) for T1 rectal cancer offers minimal morbidity and minimal long-term functional problems compared to radical resection (i.e., APR or LAR). On the other hand, recent evidence suggests that patients treated with LE have higher local recurrent rates than those treated with radical resection[10-12,42]. Preoperative

[1]Patients with T2 cancers on pathology were treated with postoperative chemoradiation.

staging is relatively inaccurate and rates of LR vary widely from 7% to 40% after LE for T1 tumors[10-12,42-45]. Based on more recent, larger studies with longer follow-up, the LR rate appears to be approximately 10% to 25%. In those patients that recur after LE, only 50% or less will ultimately be cured by radical resection for salvage[46]. Because local excision does not remove the lymph node bearing tissue of the rectum (mesorectum), optimal patient selection is imperative in order to diminish the likelihood of offering this procedure to a patient whose rectal cancer might have lymph node metastases.

The risk of lymph node involvement is 0%-12% for T1 cancers, 12%-28% for T2 cancers, and 36%-79% for T3 cancers[47]. Features associated with a significantly increased risk of lymph node metastases include poor differentiation, lymphovascular invasion, and size greater than 3 centimeters[48,49]. It is therefore not surprising that, following local excision, local regional recurrence rates can be as high as 11%-29% for T1 tumors, 25%-62% for T2 tumors, and > 40% for T3 tumors[10,11,47]. Overall survival has been reported from 70% to 89% in recent series of properly selected patients (Table 1)[10-12,43,44]. However, most studies on transanal excision have follow-up data of less than 5 years and a relatively small sample size. This, in addition to the long natural history of the disease, makes conclusions on long term efficacy difficult. In 67 T1 patients treated by LE, a study at Memorial Sloan Kettering Cancer Center reported a 74% 10 year DSS[10].

In patients who develop a locoregional recurrence following local excision of rectal cancer, salvage with a radical resection is possible, with several small series reporting a 50% to 88% disease-free survival (DFS)[44,50]. After final pathology is available from a LE, consideration should be given to immediate radical resection (i.e., within 30 d). Thus, high-risk tumor characteristics and a location or size that does not enable a re-excision with clear margins warrants radical salvage surgery in order to achieve maximum local disease control. In one report of 21 patients at MSKCC, immediate radical surgery in stage I patients with adverse features was superior to those treated initially with LE followed by salvage surgery at the time of local recurrence; 94% DFS was noted in the group treated with immediate radical resection for adverse pathology versus 55% in the cohort treated with radical surgery after LR was documented[51]. A recent report from the Mayo clinic also showed that LE followed by radical surgery within 30 d does not compromise outcome compared with primary radical surgery. In the largest series published to date, 49 patients who underwent successful surgical salvage of local recurrence after LE of T1 rectal cancer, 55% required an extended pelvic dissection with en bloc resection of adjacent pelvic organs[46]. Despite the fact that 47 of 49 patients had complete resection of their pelvic disease, 58% had recurred or died of disease within 33 mo. Five year DSS was 53%[46].

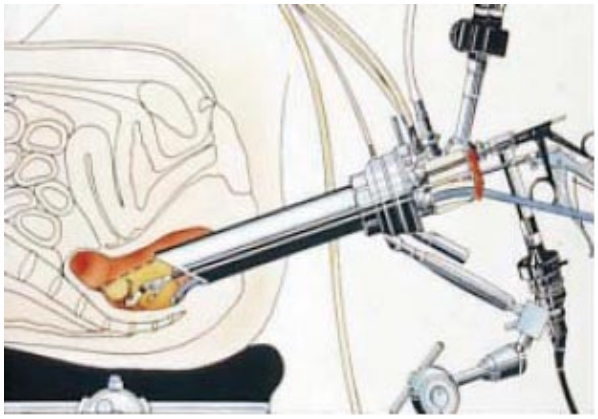

Figure 3 Specialized equipment in use for the performance of TEM[90].

Currently, local excision for cure is recommended only for carefully selected T1 tumors without high-risk features[9,10]. Patients must be followed closely and for a long period, since almost a third of local recurrences after TAE of early stage rectal cancer occur 5 years or more after local excision[10]. The role of adjuvant chemotherapy and radiation after LE is not defined at this time. Local excision is also an option for palliation in patients with locally advanced rectal cancer or stage IV patients unsuitable for radical resection[52].

Transanal endoscopic microsurgery (TEM)

TEM is an option for excising rectal cancers that are otherwise inaccessible by standard transanal excision[53]. Using a specially designed 40 millimeter diameter and 25 centimeter long operating endoscope, tumors located as high as 10 centimeters anteriorly, 15 centimeters laterally, and 20 centimeters posteriorly can be excised under direct vision (Figure 3). TEM provides a technique for full thickness excision of both benign and properly selected malignant lesions (i.e., T1 with no high risk features) that are too high for transanal excision and would otherwise require radical resection[53]. It is imperative to keep in mind that the selection criteria for TEM are the same as those for local excision (described above)[54]. When used on appropriately selected early-stage lesions, TEM can achieve oncologic results similar to those of radical resection,

while limiting morbidity and mortality[54].

LOCALLY ADVANCED RECTAL CANCER (T3/T4 AND/OR N1)

During the planning and conduct of a radical operation for a locally advanced rectal cancer, a number of surgical management issues are considered, including: (1) total mesorectal excision (TME); (2) autonomic nerve preservation (ANP); (3) circumferential resection margin (CRM); (4) distal resection margin; (5) sphincter preservation and options for restoration of bowel continuity; (6) laparoscopic approaches; and (7) postoperative quality of life. The sections that follow examine each of these issues.

Total Mesorectal Excision (TME)

TME is a technique which requires precise dissection in an areolar plane between the visceral fascia that envelops the rectum and mesorectum and the parietal fascia overlying the pelvic wall structures. The end result of this procedure, when performed properly, is an intact mesorectum containing the draining lymph nodes of the rectum. This technique also facilitates pelvic autonomic nerve preservation. TME emphasizes the achievement of negative CRM and distal margins, thus optimizing the oncologic outcome for the patient. TME has been shown to achieve a negative CRM in up to 96% of resected specimens[55]. Most importantly, large series from surgical teams worldwide using TME techniques have reported local failure rates as low as 3% and overall 5-year survival of up to 80% (Table 2)[55-59]. This compares favorably

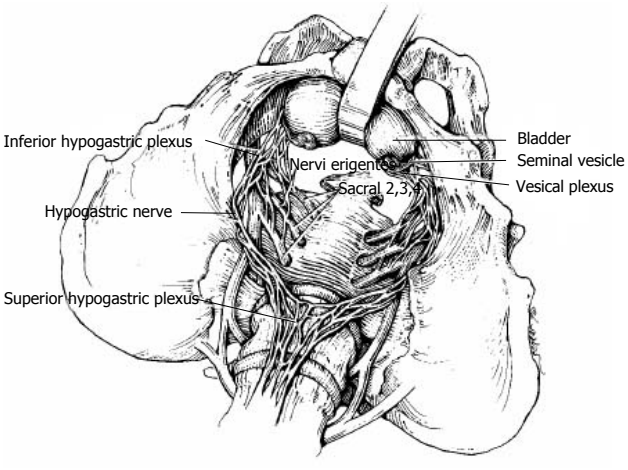

Figure 4 Diagram of pelvic autonomic nerve anatomy[73].

with large reviews of standard surgery that reported local recurrence rates of 15% to 19%, with some studies reporting local failure as high as 48%[60,61]. In fact, in studies comparing rectal resection according to the principles of TME to historical controls of standard, blunt mesorectal dissection, the patients treated with TME consistently have lower local recurrence rates[55,62-64]. Currently, TME should be considered an integral aspect of the optimal surgical management of the patient with locally advanced rectal cancer.

Autonomic nerve preservation

The sympathetic nerves of the pelvis originate from the T12 to L3 ventral nerve roots, ultimately forming the preaortic superior hypogastric plexus (Figure 4)[65]. Distal to the aortic bifurcation, the superior hypogastric plexus forms the hypogastric nerve, which may be intimately associated with the visceral fascia of the mesorectum. Injury to the hypogastric sympathetic nerve trunks results in increased bladder tone with reduced bladder capacity, voiding difficulty, impaired ejaculation in men, and loss of vaginal lubrication and dyspareunia in women. The parasympathetic nerves of the pelvis (nervi erigentes), arising from the S2 to S4 ventral nerve roots, join the hypogastric nerves (sympathetic) on the pelvic sidewall to form the inferior hypogastric plexus (pelvic autonomic nerve plexus) (Figure 4)[65]. Damage to the parasympathetic nerves leads to erectile dysfunction, impaired vaginal lubrication, and voiding difficulty.

Truncal ANP is defined as preservation of the anterior nerve roots of S2, S3, and S4, the superior hypogastric nerves, and the pelvic autonomic nerve plexus[57]. With careful autonomic nerve preservation, postoperative genitourinary and sexual dysfunction can be reduced from 25% to 75% to as low as 10% to 28%[66]. More specifically, neurogenic bladder can be reduced from 9% to 40% with conventional rectal resection to as low as 0% to 11% with TME and ANP[66-68]. The rate of sexual dysfunction may be further reduced by using intraoperative nerve stimulators to help identify and preserve the pelvic autonomic nerves[69]. It must be emphasized, however, that

Figure 5 MRI of rectal cancer with demonstration of circumferential resection margin (CRM)[6]; Black arrows: rectal cancer; White arrows: mesorectal fascia; Dashed line: CRM, which is defined as the shortest distance from rectal cancer to the lateral resection margin of the mesorectum.

factors other than ANP, such as history of chemoradiation, patient co-morbidities (i.e. -atherosclerosis, diabetes mellitus, hypertension), medications (i.e. beta-blockers), and alcohol use may contribute to genitourinary and sexual dysfunction following radical rectal resection.

Circumferential resection margin (CRM)

The importance of the CRM in minimizing local recurrence of rectal cancer was first reported in 1986 (Figure 5). A recent series of 686 patients with rectal cancer treated with TME after a median follow-up of 29 mo documented a 5% local recurrence rate for patients with CRM > 1 millimeter and a 20% local recurrence rate for a CRM $\leqslant$ 1 millimeter[58]. Obtaining a negative CRM is likely to result in decreased rates of local recurrence, distant metastases, and death. In order to provide an optimal oncologic outcome, the surgeon must make all efforts to obtain a negative CRM, including en bloc resection of contiguous structures.

Distal resection margin

Distal spread greater than 1 centimeter beyond the mucosal edge of rectal cancer has been documented in only 10% of cases, all in poorly differentiated, node-positive lesions[70]. Recent data support this finding, suggesting that margins as small as 1 centimeter may provide acceptable oncologic results. In a series from our institution, the recurrence-free survival and local recurrence rates with 3 years of follow-up after preoperative combined modality therapy (CMT) and TME-based resection were not significantly different in patients when margins less than or equal to 1 centimeter were compared to those greater than 1 centimeter. Thus, although we advocate striving for a 2-centimeter distal resection margin when feasible, acceptable oncologic results may be achieved with margins of at least 1 centimeter, especially when resection follows CRT.

Sphincter preservation and restorative options

In patients with acceptable preoperative anorectal function, ideal body habitus and pelvic anatomy, sphincter preservation is usually possible for rectal cancer located greater than one centimeter above the upper portion of the anorectal ring. Generally, slender patients with a wide pelvis are more appropriate for sphincter preserving resection of distal rectal cancer than obese patients with a narrow pelvis[66,73]. Male patients with a long, narrow pelvis and/or enlarged prostate present a technical challenge that may preclude a restorative procedure[73]. Finally, patients with impaired preoperative anorectal function may be better treated with radical resection and permanent colostomy, thus avoiding substantial postoperative perineal morbidity[73]. Hence, it is imperative that the surgeon exercise sound clinical judgment when selecting patients for restorative rectal resection.

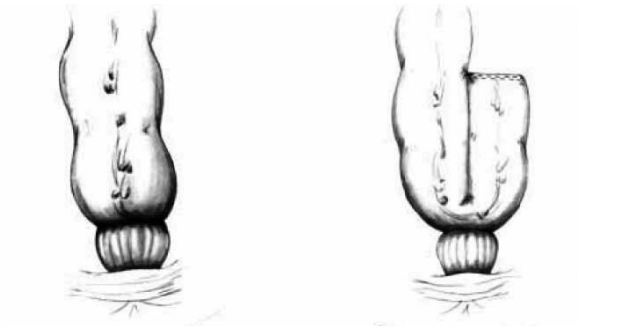

Figure 6 Illustrated comparison of a straight coloanal anastomosis and a coloanal anastomosis with a colonic J-pouch[74].

Classically, bowel continuity following low anterior resection (LAR) was restored with a straight colorectal or coloanal anastomosis. In 1986, J-pouch coloanal anastomosis was developed in order to increase colonic reservoir function and improve quality of life following an LAR that required coloanal anastomosis for restoration of bowel continuity (Figure 6)[74]. A prospective, randomized trial comparing patients with a straight CAA and a coloanal J-pouch anastomosis using the European Organization for Research and Treatment of Cancer (EORTC) QLQ-C30 and QLQ C-38 demonstrated an improved postoperative quality of life in the patients reconstructed with a J-pouch[74]. Randomized studies have demonstrated the superiority of a 6 to 8 cm coloanal J-pouch anastomosis relative to a straight coloanal anastomosis, particularly during the first year following surgery[75]. There is a significant reduction in the postoperative anastomotic leak rate, number of stools per day, and improved quality of life in patients with a J-pouch versus those with a straight coloanal anastomosis after LAR[76].

One disadvantage of the colonic J-pouch is that up to 25% of patients treated with an LAR are not candidates for the procedure, due in large part to the somewhat bulky size of the pouch[77]. In 1997, an alternative procedure, known as the transverse coloplasty, was introduced in an attempt to create a distal colonic reservoir (Figure 7)[78]. A recent randomized trial demonstrated comparable functional results, with improved neorectal sensitivity, when patients undergoing transverse coloplasty-anal anastomoses were compared to those reconstructed with a J-pouch[77]. However, another trial documented

increased leak rates with transverse coloplasty and no differences in bowel function, when compared to a colonic J-pouch[79]. Therefore, colonic J-pouch provides optimal postoperative bowel function with lower morbidity than transverse coloplasty and in most cases should be the primary method of bowel reconstruction when a coloanal anastomosis is required following an LAR[74,79]. However, when reconstruction with a J-pouch is not technically feasible, transverse coloplasty-anal anastomosis provides a reasonable option for bowel reconstruction.

Laparoscopic approaches

Data from small, non-randomized studies evaluating laparoscopic-assisted rectal cancer resection suggest that laparoscopic-assisted TME is feasible when performed by experienced surgeons[80]. From these non-randomized reports, oncologic outcome does not appear to be impaired by laparoscopic rectal cancer resection[81-83]. In addition, short-term morbidity may be reduced in the laparoscopic group, while oncologic outcome is not compromised[81-83]. However, pending prospective, randomized trials focusing on laparoscopic resection of rectal cancer need to be concluded before definitive recommendations can be made concerning the safety and oncologic efficacy of these procedures.

Quality of life following radical resection

Although improved outcome is the ultimate goal for the surgical treatment of rectal cancer, there has recently been increased interest in the quality of life of patients following radical rectal resection. As previously discussed, performing a rectal resection according to the principals of TME with ANP substantially reduces the incidence of postoperative genitourinary and sexual dysfunction. In fact, a recent series reported that even in the face of postoperative fecal incontinence, genitourinary dysfunction, and sexual dysfunction, patients were satisfied with their quality of life following rectal resection[84]. A recent 4-year prospective study of 329 patients with rectal cancer reported the quality of life following radical resection[85]. Using the EORTC QLQ-30 and CR-38 questionnaires, they report that patients undergoing LAR have improved quality of life when compared to patients undergoing APR. In addition, patients who had no stoma, or had their stoma reversed, reported a substantially improved postoperative quality of life compared to patients with a permanent stoma[85].

Another large series with 2 years of follow-up, using the EORTC QLQ-C30 and QLQCR-38 questionnaire, reported opposite results. Patients with a permanent stoma reported significantly better social function ($P = 0.005$), less anxiety ($P = 0.008$), and higher self-esteem ($P = 0.0002$) than patients who underwent restoration of bowel continuity[86]. These findings have been supported by others in the literature[87]. In addition, others have reported that postoperative quality of life improves with time, and should therefore be evaluated in a dynamic fashion[88]. To add further complexity to this issue, patients who are treated with a very low colorectal or coloanal anastomosis may have a decreased postoperative quality of life than patients treated with APR and permanent stoma[89]. It is clear that postoperative quality of life is dependent upon the interaction of patient factors (i.e. co-morbidities and preoperative anorectal function), tumor factors (i.e. extent of local invasion, distance from the anal verge), and surgical factors (i.e. level of the anastomosis). However, the conflicting data in the literature concerning quality of life evaluation for patients with resected rectal cancer underscore the importance of the development of more sensitive, validated instruments.

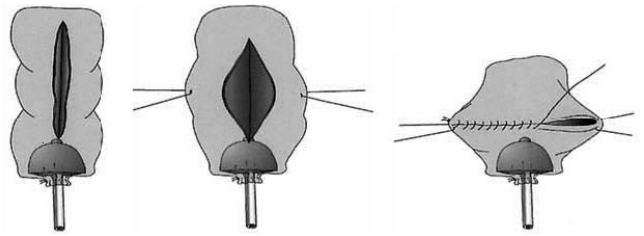

Figure 7 Technique of construction of a stapled coloanal anastomosis with a transverse coloplasty pouch. Alternatively, the pouch may be hand-sewn to the anal canal[77].

In conclusion, surgery for rectal cancer continues to develop towards the ultimate goals of improving local control and overall survival, maintaining quality of life, and preserving sphincter, genitourinary, and sexual function. In appropriate patients, minimally invasive procedures, such as local excision, TEM, and laparoscopic resection allow for improved patient comfort, shorter hospital stays, and earlier return to preoperative activity level. Currently, local excision for cure is recommended only for carefully selected T1 tumors without high-risk features. Recent studies suggest that in patients with resectable rectal cancer, a response to preoperative chemoradiation is predictive of decreased local recurrence and improved survival. As response rates to neoadjuvant therapy continue to improve, it will enable more patients to undergo sphincter-sparing surgery, and will additionally provide a guide to postoperative chemotherapy regimens. However, at this time the existing imaging modalities are limited by their inability to confirm eradication of mesorectal nodal metastases; thus, patients undergoing TAE alone following preoperative chemoradiation therapy are at risk for local failure due to unidentified residual nodal disease. Currently, there are no data to support the routine use of TAE in these patients, and definitive treatment should continue to be rectal resection with TME. By strictly adhering to the principles of TME with autonomic nerve preservation, maintenance of urinary and sexual function can be achieved in the majority of patients undergoing a curative radical rectal cancer resection. The ultimate goal is for physicians to be able to individualize a patient's treatment based upon expression of molecular markers, genetic signatures using gene arrays and response to systemic therapy preoperatively, optimizing the combination and sequencing of multidisciplinary neoadjuvant therapy in order to maximize survival and locoregional control rates.

Abstract

The prevalence of obesity in the United States has reached epidemic proportions. With more than 30 million Americans clinically obese, the younger population has also been affected. Surgical therapy should be offered to the severely obese patient who is refractory to nonsurgical therapy, as established by the 1991 NIH Consensus Conference on Gastrointestinal Surgery for Severe Obesity. Surgery is currently the most effective therapy for weight loss. It is far more effective than any other treatment modality, both in terms of the amount of weight loss and in terms of durability in maintaining weight loss.

INTRODUCTION

The prevalence of obesity in the United States has reached epidemic proportions[1]. With more than 30 million Americans clinically obese, the younger population has also been affected. The number of obese young adults between the ages of 18 and 29 has increased by nearly 50% in the 1990's[2-4], and currently, nearly 25% of children are believed to be obese[5]. Obesity now represents a staggering 5% of the total health care costs in the United States[6]. This, however, is not only an American problem. The prevalence of obesity worldwide is also increasing. In England, the number of obese men and women has tripled over the twenty years between 1980 and 2000[7]. More than 1.5 billion people worldwide are thought to be obese or overweight[8]. Obesity, clinically defined as a body mass index (BMI) greater than 30 kg/m^2, is associated with comorbid conditions affecting nearly every organ system, including the cardiovascular, endocrine, renal, pulmonary, gastrointestinal, and musculoskeletal systems. Type 2 diabetes, hypertension, hyperlipidemia, obstructive sleep apnea, stroke, heart disease, renal disease, degenerative joint disease, venous disease and several forms of cancer have all been associated with obesity[9,10]. In addition, the obese are frequently afflicted by depression, anxiety and low self-esteem[11]. In the United States, obesity leads to a significant decrease in life expectancy and an annual cost of approximately $100 billion, including nearly $4 billion in lost productivity[12,13]. In severely obese individuals (BMI> 35 kg/m^2), the mortality is 12 times higher in men aged 25-34 years and 6 times higher in men aged 35-44 years compared to age-matched nonobese control subjects[14].

In severely obese people, diet, exercise, and pharmacotherapy can produce a modest weight loss in the range of 2%-10% at 1 year. Unfortunately weight regain is common. The worsening obesity crisis, combined with the lack of a durable medical treatment option, has led to an increased interest in surgical approaches for the treatment of obesity. Bariatric surgery may be broadly defined as surgical treatment strategies designed to limit caloric intake, decrease nutrient absorption, or both. Procedures designed to limit caloric intake, termed restrictive procedures, include gastric banding or the placement of intragastric balloons. Surgical procedures that decrease nutrient absorption are termed malabsorptive procedures. Jejunal-ileal bypass, a now historical operation, can be considered a pure malabsorpitve procedure. The most commonly performed bariatric operations, such as gastric bypass and biliopancreatic diversion, introduce elements of caloric restriction and partial nutrient malabsorption[15]. Worldwide, the gastric bypass is the single most frequently performed operation for obesity[16], with more than half being done laparoscopically[17]. Most importantly, patients who undergo gastric bypass have been able to achieve long-term excess weight loss in the range of 49%-62%[18,19,20].

For severely obese adults with weight-related comorbidities, surgery provides the most effective and durable approach for clinically significant weight loss. There is yet no consensus about surgery for severely obese adolescents, but it is nonetheless gaining in popularity, with demonstration of significant and durable weight loss in

individuals 12 to 18 years old[5].

INITIAL APPROACH TO THE OBESE PATIENT

Overweight and obesity are independent risk factors for increased mortality. Dramatic increase in mortality is noted when BMI exceeds 30 kg/m^2. This risk further increases the longer the duration of obesity[23,24]. Disappointingly, only 27% to 42% of obese patients are advised by their healthcare professional to lose weight[21,22]. A variety of non-surgical options are available for the treatment of obesity, including exercise therapy, behavioral and dietary modification, and pharmacotherapy[25]. Successful long-term weight loss may be defined as maintaining a 10% weight-loss over a period of one year, or more strictly as an average weight loss of 30 kg for an average of 5.5 years[26]. For the majority of obese individuals, sufficient weight loss is infrequently obtained by conventional methods.

Dietary modification and nutritional counseling is an essential first step in the treatment of obesity. Unfortunately, no dietary approach has ever demonstrated sustained weight reduction in the severely obese population[6]. Recently, a randomized trial compared common diets for efficacy of weight loss[28]. The Atkins, Ornish, Weight Watchers and Zone diets were compared in patients with a mean BMI of 35 kg/m^2. None of the diets studied produced a mean weight loss of more than 10 kg at one year. Behavioral therapy in combination with dietary modification appears to be more effective than either method alone, but most patients trend towards their pre-treatment weight within 5 years of treatment[29]. Physical activity, as a method for weight reduction, is a necessary component of most weight-loss programs. Consistent exercise has been shown to effect longer lasting weight loss, and the level of physical activity directly correlates with the degree of weight loss[30]. Diet with exercise produces superior results compared to either diet or exercise alone. At one-year follow-up, the addition of exercise to diet alone appears to give more stable weight loss. However, the total weight loss still remains modest, in the range of 6-9 kg after 1 year[31].

Appetite suppressants are also used to effect weight loss. These include serotonin selective re-uptake inhibitors (SSRI's), serotonergic, and noradrenergic agents. Such anorectic agents are usually used in combination with a designed low-calorie diet. With one exception, all studies evaluating their efficacy have shown that a combination of diet and appetite suppressants appear to be effective during the first 6 mo of treatment, but fail to show long-term effectiveness beyond 12 mo[25,32]. Orlistat, a newer agent that induces fat malabsorption, similarly will only lead to an initial excess weight loss of 10%[6]. Long-term studies are less optimistic. After 52 wk of three times per day therapy, when combined with a low calorie diet, orlistat will only lead to a weight loss of 5%[27].

OBESITY SURGERY

Surgical therapy should be offered to the severely obese patient that is refractory to nonsurgical therapy, as established by the 1991 NIH Consesus Conference on Gastrointestinal Surgery for Severe Obesity[33]. The impetus for the introduction of surgical therapy for obesity was borne from the high incidence of long-term weight regain in the severely obese. Patients are eligible for bariatric surgery if they have failed nonsurgical treatments and have a BMI > 40 kg/m^2 or BMI > 35 kg/m^2 with comorbidities.

Preoperative considerations

The obese patient undergoing abdominal surgery warrants special consideration in the preoperative workup. These patients have an overall higher mortality compared with nonobese patients when undergoing gastrointestinal surgery (6.6% *vs* 2.6%)[34]. As they carry higher risks for cardiovascular disease, pulmonary and thromboembolic complications, and wound infections, special care must be taken in preparing these patients for surgery[35]. Operative weight has been shown to directly correlate with an increase in cardiovascular events in both men and women[36]. Risk stratification and appropriate preoperative intervention, therefore, is important in this patient population. Low-risk patients should receive perioperative beta-blockade, while patients that are intermediate and high-risk should undergo noninvasive cardiac testing preoperatively[35].

The risk for deep venous thrombosis and pulmonary embolism is also higher in the obese population compared with the general population. Specific comorbidities in these patients have been identified that increase the risk of deep venous thrombosis (DVT) or pulmonary embolism (PE). These include the presence of venous stasis disease, BMI > 60 kg/m^2, truncal obesity, and obstructive sleep apnea[37]. The presence of clinically severe obesity alone is associated with a high rate of pulmonary embolism in postoperative autopsies[38]. The preoperative use of 5000 units of subcutaneous unfractionated heparin, and every 8 h thereafter during the hospitalization, in conjunction with sequential compression devices, has been shown to provide adequate DVT prophylaxis[39]. Alternatively, low-molecular weight heparin may be used for DVT prophylaxis[40,35]. In patients with a very high risk for postoperative DVT/PE, the preoperative placement of an inferior vena cava (IVC) filter should be considered[41].

Jejunoileal bypass

The field of obesity surgery began in the early 1950's with the jejunoileal bypass, a malabsorptive procedure in the strictest of definitions[42]. As its name implies, this procedure bypasses a large segment of small intestine by connecting the proximal jejunum (roughly 14 inches from the ligament of Treitz) to distal ileum, about 4 inches proximal to the ileocecal valve (Figure 1A). Weight loss is produced by malabsorption of macronutrients, namely carbohydrates, fats, and proteins[17]. Severe diarrhea and nutritional deficiencies frequently result, leading to significant metabolic abnormalities, nephrolithiasis, cholelithiasis, osteopenia, and hepatic cirrhosis. In the past, metabolic bone disease and vitamin deficiencies often necessitated reversal of the procedure[43]. With time, other procedures carried a significantly lower complication

profile and thus supplanted the jejunoileal bypass[44]. This procedure is now of historical significance only.

Biliopancreatic diversion

The vast majority of complications that resulted from jejunoileal bypass resulted from the very long "blind" limb of intestine that neither biliopancreatic juices nor victuals flowed through. Newer malabsorptive procedures have eliminated this "blind" limb[18]. The biliopancreatic diversion (BPD), first described by Scopinaro in 1979[45], involves the creation of a distal gastrectomy with a Roux-Y reconstruction using a 250-cm alimentary tract limb as measured from the ileocecal junction (Figure 1B). The long biliopancreatic limb is anastomosed to the distal ileum, creating a short (50-cm) common channel for nutrient absorption[47]. Weight loss occurs because the ingested food is not entirely digested and absorbed. This is a true malabsorptive procedure. In contrast to purely restrictive procedures, BPD allows patients to continue eating "normally" while achieving significant weight loss[54]. In BPD, nutrient absorption occurs predominantly in the short distal common channel, where both the chyme and biliopancreatic juices mix.

Short-term weight-loss has been reported at almost 15% at 4 mo[47] and more importantly, in a published series of more than 2000 patients[46], a mean long-term weight reduction of 75% of the initial excess weight was achieved. Late complications include anemia, stomal ulcers, bone demineralization and neurologic dysfunction due to vitamin deficiencies. The vitamins most affected are the fat-soluble vitamins A, D, K, and E. Calcium and iron, primarily absorbed in the duodenum, can also be significantly affected. Protein calorie malnutrition has been documented, as well as hepatic failure and polyarthritis[48,49]. Due to the late onset of significant metabolic complications associated with the procedure, it has fallen out of favor in the United States[48].

Duodenal switch

The biliopancreatic diversion with duodenal switch (BPD-DS) adds a sleeve gastrectomy (instead of distal gastrectomy) and duodenoileostomy to the BPD (Figure 1C). The common channel is increased in length from 50 to 100 cm. This procedure was first performed in 1990, with several modifications in the duodenal switch portion to its current form[54]. BPD-DS was first performed laparoscopically by Gagner *et al* in 1999[53]. The duodenal switch modification was made to try to reduce the complication rate, while maintaining reliable weight loss. Although durable weight loss is comparable to the BPD, long-term complications, mostly intractable diarrhea, are still a major concern[50]. Micronutient supplementation is still mandatory to help minimize the risk of vitamin deficiency syndromes and osteoporosis[54]. Nonetheless it remains a very effective treatment for the superobese patients (BMI > 50 kg/m^2). Excess weight loss ranges from nearly 60% to greater than 90% in 10 to 24 mo[51]. At 8 years, excess weight loss may be as high as 70%[52]. In experienced hands, this procedure can be performed safely via the laparoscopic approach[53].

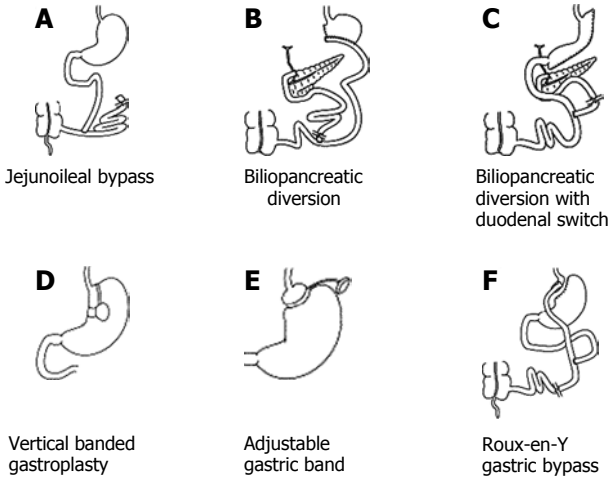

Figure 1 Diagrammatic representation and comparisons of weight loss operations, past and present.

Vertical banded gastroplasty

The vertical banded gastroplasty (VBG) was first described by Mason in 1982[55]. This procedure is a purely restrictive procedure; it leaves the rest of the gastrointestinal tract intact for nutrient absorption. In this procedure, a full thickness hole is made with a circular stapling device in the proximal stomach. Using this hole, the proximal stomach is stapled, parallel to the lesser curve, up to the angle of His. This creates a pouch of approximately 50 mL capacity (Figure 1D). A band of silastic or polypropylene mesh is commonly placed through the hole, circumferentially around the distal portion of the tubularized pouch, thereby limiting the stomal outlet diameter to roughly 1 cm[48,55].

Vertical banded gastroplasty may be performed open or with laparoscopic techniques. Results of VBG vary. Excess weight loss in the first year after surgery is in the range of 60%. Patient satisfaction, meanwhile, ranges from 75% to greater than 90%[56,57]. Five-year follow-up suggests less satisfactory weight loss, with the average excess weight loss being 30%-54%. Frequently, patients cited difficulties in tolerating a regular diet[59-61]. Most disappointingly, a prospective study following patients for more than 10 years after vertical banded gastroplasty found that only 20% of patients maintained the loss of at least 50% of excess body weight[58]. Additionally, a significant portion of patients had persistent vomiting, gastroesophageal reflux, or heartburn. Furthermore, the rate of re-operation may be as high as 29%[62]. When compared to gastric bypass, multiple studies have shown the superior results of gastric bypass over VBG in terms of durable weight loss and long-term outcome. Subsequently, VBG has fallen into disfavor[43,63,64].

Gastric banding

Adjustable gastric banding is a restrictive procedure that does not involve stapling of the gastrointestinal tract. It is considered the least invasive of the operations for severe obesity[65]. The key feature of the current gastric banding devices is the adjustability of the outer diameter of the gastric band. Thus, oral intake can be restricted if the band is tightened, or the band can be loosened in patients that

present with signs or symptoms of obstruction. Dietary compliance is mandatory for the success of the adjustable gastric band. Patients can bypass the effects of the banded gastric pouch by consuming high-calorie liquid diets, thus emphasizing the need for continued cooperation postoperatively between the physician and patient.

Initially described as an open procedure by Kuzmak in 1986, an adjustable silicon band is used to encircle the proximal stomach, creating a small gastric pouch and narrowed outlet[66]. The only device currently approved in the United States is the Lap-Band (Inamed Health, Santa Barbara, California), but is one of several commercially available devices worldwide. The Lap-Band consists of a silicon adjustable elastic band that is placed around the proximal stomach via the pars flaccida, creating a pouch volume of 10-15 mL (Figure 1E). A subcutaneous port enables percutaneous needle access to adjust the volume of the gastric band and consequently the size of the gastric pouch outlet[67]. Although results in Europe have been encouraging[68], the early results in the United States were considered poor relative to other bariatric procedures, with only 36% excess weight loss after three years. Later studies showed improvement with average excess weight loss of 42% at one-year follow-up[69]. A more recent prospective study produced much more impressive results[70] with mean excess weight loss of 50% at one year, 61% at two years, and 65% at three years.

Early complications are uncommon in this laparoscopic procedure and conversion to open operation is infrequent[70,71]. Overall complication rates vary in the literature between 9%-20%[69,70], including band slippage or prolapse, dysphagia, port migration, port-site infection, tube breakage, dilatation of the gastric pouch, gastric perforation, and erosion of the band through the stomach wall[43,70-73]. Some of these complications are treated electively with laparoscopic reposition or replacement of the Lap-Band device, or with repositioning or repair of tubing or the port. Complication rates and frequency of reoperation likely reflect overall experience with the procedure and optimal band positioning. The longer European experience reflects a learning curve with decreasing morbidity and need for reoperation. Total complication rates are 9%-11% in most European studies, but 10%-20% in U.S. studies. Depending on the institution, the reoperation rate varies from 1% to 13%[43,69,70,73-75]. Malnutrition and vitamin deficiencies are uncommon.

The Swedish version of the gastric band, the Swedish Adjustable Gastric Band (AB Obtech, Sweden), was introduced in 1985 by Hallberg *et al*[76]. It consists of an inflatable double-silicon band reinforced by a Dacron net. The silicon balloon on the inner surface can be regulated by a subcutaneous port. Its complication profile is similar to the Lap Band, including band erosion, erosive esophagitis, pouch dilatation, disconnection of tubing, invagination of distal gastric wall, and leakage from the balloon[76,77]. Several studies showed promising results for the Swedish Band. At a five-year follow-up mean excess weight loss was 57%, with approximately 83% of patients obtaining more than 50% excess weight loss[78]. Similar results were obtained by Australian investigators[79] with a mean excess weight loss of 60% at 12 mo, and 69% of patients had a greater than 50% excess weight loss over the same follow-up.

A Swiss prospective, randomized trial compared 90 patients treated with Lap Band and 90 patients treated with the Swedish Adjustable Gastric Band (SAGB)[80]. The SAGB appeared more susceptible to infection and early complication. Although the patients with Lap Band lost more excess weight sooner, the two cohorts trended towards equal excess weight loss by 30 mo post-operatively. At three-year follow-up, only about half of each treatment group lost at least 50% of excess weight. An earlier study with a short follow-up of less than 12 mo showed no difference between the two gastric bands in terms of weight loss and complications[81]. An additional meta-analysis reviewing the two laparoscopic gastric bands revealed similar excess weight loss, although the Lap Band seemed to have a slightly higher long-term complication rate[82]. Overall there appears to be little major difference between the two banding systems.

Intragastric balloon

Another, much less common technique, is the placement of an intragastric balloon. First introduced in the 1980's, preliminary studies in pigs showed ambiguous results when an inflatable balloon was introduced into the stomach in an attempt to reduce stomach capacity and oral intake[15,83]. In humans, the intragastric balloon is inserted orally using a special application sheath. It is placed 10 cm distal to the gastroesophageal junction and inflated with approximately 500 mL of saline, attaining a diameter of 10 cm. The volume can be subsequently adjusted to 400-800 mL. Smaller, 200 mL, air-filled balloons are also available. Large hiatal hernias and peptic ulcer disease usually preclude the use of the intragastric balloon. Immediate complications include nausea, vomiting, and abdominal cramps, suggesting intolerance of the balloon[84]. Other complications include gastroesophageal reflux, belching, and esophageal erosions. As of yet, there are no long-term studies to prove the efficacy of this technique. Relative to other bariatric procedures, weight loss results are modest at best. The greatest reported results are in the range of 10% weight loss sustained at two years[84].

Gastric pacing

Gastric pacing, first introduced in humans in 1996[85], is not widely accepted and still considered experimental. It attempts to provide a non-malabsorptive and non-restrictive method for significant, durable weight loss. The purported mechanism of action is to disrupt normal gastric myoelectrical activity, which subsequently affects both gastric emptying and gastric relaxation. The implantable gastric stimulator (IGS; Transcend, Transneuronix, Inc., New Jersey) includes a battery-operated generator and a bipolar lead. Electrodes are placed into the muscle layer on the lesser curvature of the anterior gastric wall[86]. The electrode delivers a bipolar pulse through its connection to a pacer that sits in a subcutaneous pocket[42]. It is postulated that electrical stimulation disrupts eating behavior by causing a change in parasympathetic activity in the stomach, leading to gastroparesis[42,87]. Weight loss should therefore be induced by consistent and predictable

early satiety. Early human studies in a small cohort showed weight loss in only half the patients[85]. Later studies, also in a small number of patients, were able to demonstrate a modest, but stable weight loss[86]. Thus far, studies on gastric pacing have been plagued by mechanical problems relating to the electrical leads.

The procedure is safely and preferably performed laparoscopically[88]. A large multicenter, randomized, controlled, double-blinded American trial is under way[89]. Early results showed a mean weight loss of 11% at one year. A second round, pilot trial is in progress, employing four electrodes and thus far, a mean excess weight loss of 21% was seen at 7-mo follow-up[89]. Although these results are modest compared to other bariatric procedures, the optimal use of the electrodes, the number of electrodes, and the direction of stimulation has yet to be determined.

Gastric bypass

The Roux-Y gastric bypass, a mixed restrictive and malabsorptive procedure, is considered the gold standard for bariatric surgery[6], and is currently the procedure of choice in the United States[16]. The gastric bypass operation was first introduced by Mason *et al*[90] in 1967. In the initial description of the operation, a loop gastrojejunostomy was created. The Roux-Y gastric bypass (RYGB) was subsequently introduced in 1977[44]. In this procedure, a small gastric pouch of 15-30 mL is created by transecting the proximal stomach. Intestinal continuity is reestablished *via* a Roux-Y gastrojejunostomy (Figure 1F). With the resultant anatomy, dietary foodstuff bypasses the distal stomach, duodenum, and proximal jejunum. Unlike the true malabsorptive procedures, protein calorie malnutrition is rare. The only malabsorption that takes place with RYGB is micronutrient malabsorption, mainly folate, calcium, iron and vitamin B12.

Gastric bypass is effective for many reasons. First, the small proximal gastric pouch restricts the food portions that the patient is able to ingest. It forces the patient into good eating behaviors such as thoroughly chewing one's food and eating slowly. For the first several months after surgery, daily caloric intake ranges from 1674 to 3347 kJ. The second, equally important, contributor to weight loss is that the low level of caloric intake is well tolerated by patients; they do not usually feel hungry. Unlike most other bariatric procedures, gastric bypass results in a decrease in serum ghrelin levels. Ghrelin is a hormone responsible for satiety, and is produced by cells located in the gastric fundus and proximal duodenum in response to an empty stomach. When ghrelin is released into the bloodstream, it stimulates feeding behaviors. The level of ghrelin falls shortly after eating and is clearly one hormone responsible for satiety. After gastric bypass, ghrelin levels are low and remain low for an indefinite period of time, resulting in a prolonged decrease in appetite[91].

When open Roux-Y gastric bypass is compared to open vertical banded gastroplasty (VBG), patients who undergo gastric bypass have superior weight loss as well as long-term weight-loss maintenance[64,92]. Similarly, in a randomized trial of 83 patients, laparoscopic Roux-Y gastric bypass out-performed laparoscopic VBG[63]. Despite the relative simplicity of performing a VBG and, consequently, shorter operative times, weight reduction was significantly greater after laparoscopic gastric bypass at one and two years postoperatively. After gastric bypass, weight loss is significant and durable. Multiple studies support the use of the Roux-Y gastric bypass for the treatment of the severely obese. A mean of greater than 60% excess weight loss is seen at 1-, 2-, 3- and 5-years postoperatively[64,93-95]. Long-term follow-up has been reported at fourteen years, with an excess weight loss of 49%[96]. The best results, obtained by Fobi *et al*, show 80% excess weight loss at two years[97].

The Roux-Y gastric bypass, first described as a laparoscopic procedure in 1994 by Wittgrove *et al*[98], has proven to be safe and effective and has quickly gained popularity[99]. The operation is more challenging than the open gastric bypass, however, and a learning curve of approximately 100 cases should be expected[100,101]. Despite slightly longer operative times in the laparoscopic operation, patients who undergo laparoscopic RYGB have less blood loss, shortened hospitalization time, and a faster return to normal activities when compared to patients who undergo open RYGB. For laparoscopic RYGB, the average length of postoperative stay is 2 d[102-104]. A case series of 400 patients undergoing laparoscopic Roux-Y gastric bypass revealed an average excess weight loss of 69% after one year. This varied by BMI, with slightly diminished results in the heavier patients[99]. The study also showed importantly that operative times decreased steadily with operative experience. This finding is supported by other studies as well[101]. Wittgrove and Clark showed an excess weight loss of 80% after the first year[105]. Schauer *et al*[103] found an excess weight loss of 83% at two years and 77% at 30 mo using the laparoscopic approach.

Laparoscopic gastric bypass is also safe and effective in the super obese (BMI > 60 kg/m^2). For patients with a BMI less than 60 kg/m^2 the excess weight loss is greater than 60% at 1 year in multiple studies whereas in the super-obese, excess weight loss in the range of 50%. The complication profile, however, is similar through a range of BMIs[99,106,107]. Recently, laparoscopic Roux-Y gastric bypass was shown to be safe and effective in patients with a BMI > 70 kg/m^2[108]. Overall, the complication rate following gastric bypass is 10%-15% and mortality is approximately 0.3%[43,101]. Complications include anastomotic leak, thromboembolic events, bleeding, anastomotic stricture, hernia, marginal ulceration, vitamin malnutrition, gallstones, and wound infection. In the laparoscopic approach, complication rates sharply decrease along the surgeon's progress on the operative learning curve[101]. Wound infection and incisional hernia, the most common complication in the open operation, are found at a rate of < 5% and < 1%, respectively, in laparoscopic Roux-Y gastric bypass. Late anastomotic stricture, however, was found more commonly with the laparoscopic approach, nearing 10% in some series[101-103,109]. Nutrient and vitamin deficiencies created by this procedure are easily correctable and, more importantly, preventable with appropriate supplementation. Due to the outstanding weight loss that can be achieved with a relatively low complication profile, laparoscopic Roux-Y gastric bypass has become the bariatric procedure of choice.

COMORBIDITY RESOLUTION

Bariatric procedures in general, and the gastric bypass in particular, produce dramatic improvements of comorbidities associated with severe obesity, with documented resolution of type 2 diabetes and glucose intolerance. Although the exact mechanism is unknown, it appears that the gastrointestinal bypass procedure itself, not just the actual weight loss, plays the major physiologic role in these findings[110]. In addition, improvement or resolution was seen postoperatively in patients with other components of the metabolic syndrome such as hypertension and dyslipidemia. In a comparison of 114 case series, 64%-100% of postoperative patients showed improvement or resolution of their diabetes. A study of 11 reports showed an improvement or resolution of dyslipidemia in 60%-100% of patients. In 19 studies, hypertension showed an improvement or resolution in 25%-100% of patients[17]. Two years after obesity surgery, the incidence of hypertension, diabetes, and lipid abnormalities are reduced relative to medically treated patients. Followed to eight years, the incidence of diabetes showed the most durable reduction, while the reduction in dyslipidemia and hypertension was more modest[112,113]. With appropriate weight reduction, dramatic improvements in sleep apnea are also seen[17,111].

In conclusion, surgery is currently the most effective therapy for weight loss. It is far more effective than any other treatment modality, both in terms of the amount of weight loss and in terms of durability in maintaining weight loss. Additionally, the surgical treatment of obesity produces results that greatly improve or reverse the comorbid conditions often associated with severe obesity. These include diabetes, hypertension, dyslipidemia, and obstructive sleep apnea. This is most apparent in patients who had undergone a Roux-Y gastric bypass. The search for a less invasive, equally effective weight loss modality is still underway. Ideally a non-operative medical therapy will emerge that will produce equal or near-equal results. Until then, surgery will remain the treatment of choice for this population of patients.

Abstract

Inflammatory bowel disease is an important cause of gastrointestinal pathology in children and adolescents. The incidence of pediatric inflammatory bowel disease is increasing; therefore, it is important for the clinician to be aware of the presentation of this disease in the pediatric population. Laboratory tests, radiology studies, and endoscopic procedures are helpful in diagnosing inflammatory bowel disease and differentiating between Crohn's disease and ulcerative colitis. Once diagnosed, the goal of medical management is to induce remission of disease while minimizing the side effects of the medication. Specific attention needs to be paid to achieving normal growth in this susceptible population. Surgical management is usually indicated for failure of medical management, complication, or malignancy. Algorithms for diagnostic evaluation and treatment of pediatric inflammatory bowel disease are presented. The specific psychosocial issues facing these patients are also discussed in this review as are the future goals of research in the complex problem of pediatric inflammatory bowel disease.

INCIDENCE AND ETIOLOGY

The incidence of inflammatory bowel disease (IBD), which is most commonly divided into ulcerative colitis (UC) and Crohn's disease (CD), appears to be more common in countries in the northern hemisphere and in industrialized nations. The true worldwide incidence of pediatric IBD is unknown[1]. The annual incidence rates of 0.2-8.5 per 100 000 for CD and 0.5-4.3 per 100 000 for UC have been reported[2,3]. Some reports indicate that annual incidence of CD is continuing to rise and is approaching or surpassing that of UC[2,4,5]. The overall incidence of IBD increased significantly between 1960 and 1990[2,3]. In patients with IBD, 25%-30% of patients with CD and 20% of patients with UC are younger than 20 years old[4]. Although the incidence in children is lower than that in adults, it is also increasing with most recent estimates reported as 47 per 100 000.

The etiology of IBD is unclear. There are several theories but most agree that IBD is multifactorial. It is believed that a complex interaction of environmental, genetic, and immune factors lead to the development of IBD. The role of each of these components is believed to be different in UC and CD[6]. A combined immunogenetic model that encompasses all three is most likely[7]. Environmental factors including breastfeeding, smoking, diet, occupation, education, climate, and stress have been implicated. The most established association is smoking. Smokers are at a decreased risk for developing UC but at an increased risk for developing CD. The fact that it may be protective in UC has led to investigations of treatment regimens that include transdermal nicotine patches without conclusive results[5,6].

There is a genetic association, but not a clearly defined inheritance pattern. Frequency of IBD in first-degree relatives may be as high as 40%[6]. There is a higher rate of concordance for monozygotic twins with CD > UC compared with dizygotic twins. In UC, there is an increased frequency of HLA-A11 and HLA-A7 and a decreased frequency of HLA-A9 in CD. In Japanese patients with UC there is an increased frequency of HLA-DR2, but this is not seen in other populations[6]. Mutations in the NOD2/CARD15 gene on chromosome 16 have been associated with Crohn's Disease but not UC[7]. This gene is only expressed in monocytes and plays a role in activating nuclear factor-kappa B (NF-κB) which is a critical mediator of inflammatory responses and leads to the production of proinflammatory cytokines[8]. Patients with NOD2/CARD15 genotype have demonstrated fibrostenosing disease, usually in the ileum, and earlier disease onset[9]. It may be negatively associated with UC-like disease or the perforating type of CD[8]. Another gene,

Table 1 Frequency of presenting symptoms in IBD[2,12]

Symptom	CD (%)	UC (%)
Abdominal pain	62-95	33-76
Diarrhea	52-78	67-93
Weight loss	43-92	22-55
Hematochezia	14-60	52-97
Delayed growth	30-33	6
Fever	11-48	4-34
Perianal disease	25	0
Extraintestinal manifestations	15-25	2-16

IBD5, located within the 5q31 cytokine cluster, has been associated with perianal disease in Crohn's patients.

The immune system is also involved, but the inciting event is unclear. An infectious etiology has been considered and essentially all patients with IBD have increased titers against bacteria, viruses, and fungi. Of the many infectious agents that have been considered, including the virus that causes measles, *E.coli*, and M. paratuberculosis, no association of these has been proven[5,6]. Theories that focus on the involvement of the immune system include persistent bacterial infection, defective mucosal barrier, or an imbalance in the regulation of the immune response[7]. One theory of CD is described as an inappropriate immune response triggered by genetic or environmental factors[8]. There is some evidence that interleukin-15 (IL-15) and the IL-15 receptor (IL-15R) system is involved in inflammatory bowel disease. IL-15 is a cytokine with wide cellular distribution in monocytes, epithelium, endothelium, fibroblasts, and muscle cells. It plays a role in T cell proliferation and activation, the production of inflammatory cytokines in natural killer (NK) cells, and the migration of both. It also plays a role in the proliferation and differentiation of B cells. It is implicated in the pathogenesis and maintenance of several chronic inflammatory diseases with immune activation[10].

CLINICAL PRESENTATION

As with adults, the clinical presentation of IBD depends on the site and extent of mucosal inflammation[5,11]. At the time of presentation, 44%-49% of children with UC have rectosigmoid disease, 36%-41% have left-sided disease, and 14%-37% have pancolitis[2]. In terms of severity of illness, 50%-60% present with mild disease, 30% with moderate disease, and 19% with severe disease[4]. In children with CD, 50%-70% of pediatric patients present with disease involving the terminal ileum with more than half also having involvement of the colon, usually the ascending portion. Ten to 20% of children with CD have isolated colonic disease and 10%-15% have diffuse small bowel disease[2]. Gastroduodenal inflammation may be found in 30%-40% of patients with CD, but isolated gastroduodenal disease is rare, less than 5%[4]. The most common presenting symptoms in UC include weight loss, rectal bleeding, diarrhea, and abdominal pain. (Table 1) CD may have an insidious onset with abdominal pain and weight loss which may contribute to a delay in diagnosis.

Table 2 Manifestations of IBD[2,4,5,12,13]

System	Manifestation
Generalized	Fever
	Weight loss
	Malaise
	Anorexia
	Fatigue
	Nausea/vomiting
Ocular	Uveitis
	Episcleritis
	Iritis
	Conjunctivitis
Oral	Cheilitis
	Stomatitis
	Apthae
Pulmonary	Pulmonary vasculitis
	Fibrosing alveolitis
Vascular	Vasculitis
	Thrombosis
Hepatobiliary	Primary Sclerosing Cholangitis
	Hepatitis
	Cholelithiasis
	Jaundice
Pancreatic	Pancreatitis
Gastrointestinal	Abdominal pain
	Nausea/vomiting
	Diarrhea
	Hematochezia
Renal/Urinary	Nephrolithiasis
	Obstructive hydronephrosis
	Enterovesical fistula
	UTI
	Amyloidosis
Hematologic	Iron deficiency anemia
	Anemia of chronic disease
	Thrombocytosis
	Vit B_{12} deficiency
	Autoimmune hemolytic anemia
Endocrine	Decreased growth velocity
	Delayed sexual maturation
Integumentary	Erythema nodosum
	Pyoderma gangrenosum
	Perianal disease
Musculoskeletal	Osteopenia and osteoporosis
	Arthritis/Arthralgias
	Ankylosing spondylitis

If chronic diarrhea or rectal bleeding are present, diagnosis may be more expeditious. Non-specific symptoms of anorexia, fatigue, delayed sexual maturation, and decreased linear growth may be present but not immediately noticed and if noticed may not prompt a workup for IBD because of their nonspecific nature.

Extraintestinal manifestations are common in both adults and children with IBD, affecting 25%-35% of patients (Table 2)[4]. However, in children, these may precede the onset of gastrointestinal symptoms by years, whereas in adults these symptoms are usually concurrent with exacerbation of disease[4,5]. Arthritis is the most common extraintestinal manifestation occurring in 7%-25% of children with IBD[2,4]. Nephrolithiasis occurs in 5% of children with IBD, erythema nodosum occurs in 3%, and pyoderma granulosum in < 1%. Other extraintestinal manifestations include ocular complications, hepatobiliary complications such as primary sclerosing

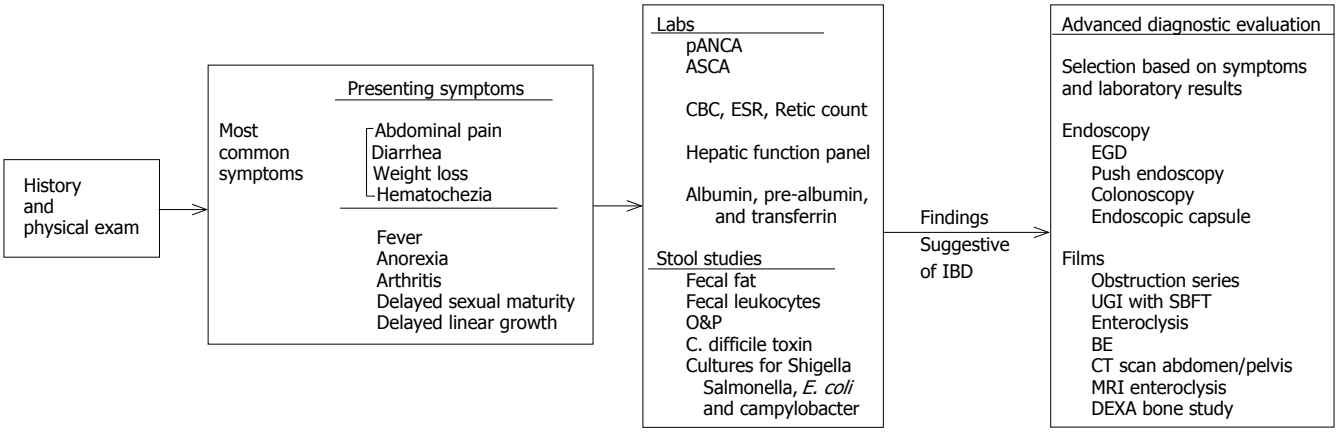

Figure 1 Diagnostic Evaluation for IBD in Pediatric Patients.

cholangitis and choledocholithiasis, and pancreatitis[4]. The differential diagnosis for IBD includes common causes of abdominal pain which includes constipation, gastroesophageal reflux, and peptic ulcer disease. In a population of children who are increasingly overweight, cholelithiasis must also be considered. Gynecologic causes of abdominal pain, such as ovarian cysts and torsion, must be considered in females. Infectious causes of abdominal pain including urinary tract infection, mesenteric adenitis, gastroenteritis, and appendicitis should also be included in the differential. Rectal bleeding can be seen with intussusception, infectious colitis, Meckel's diverticulum, colonic polyposis syndromes, hemorrhoids, and anal fissures. Diarrhea may be seen with gastroenteritis or infectious colitis. It is important to remember, however, that when these symptoms occur together or in the setting of weight loss, anorexia, growth failure, or other extraintestinal manifestations, the diagnosis of IBD must be considered and ruled out.

DIAGNOSTIC WORK-UP

History and physical exam are the initial steps in evaluating the patient with complaints suggestive of IBD (Figure 1). Important historical information includes recent infections, antibiotics, and travel history. Family history with specific attention to IBD diagnosis or related symptoms must be obtained. Without a thorough growth history to determine height velocity, growth failure might not otherwise be detected. Physical exam would include height and weight and calculation of the percentiles for each. Weight loss is present in 85% of children with CD and 65% of children with UC[2,4]. The abdominal exam may be normal or may demonstrate nonspecific tenderness. A mass in the right lower quadrant may be indicative of CD. A rectal exam is important to check for fecal blood, to evaluate for fissures or hemorrhoids, and to evaluate the surrounding area for fistulas or other perianal disease frequently associated with CD.

Laboratory evaluation is important to assess several aspects of patient status. First, serum markers for IBD should be checked[14]. Anti-*Saccharomyces cerevisiae* antibody (ASCA) and perinuclear antineutrophil cytoplasmic antibody (pANCA) assays are highly disease-specific for CD and UC, respectively, and can assist clinicians in diagnosing and categorizing patients with IBD[[11]. ASCA is associated with CD and if IgG ASCA and IgA ASCA are both detected, this is 100% specific for CD[8,11]. Higher ASCA levels are independently associated with onset at an earlier age and with fibrostenosing disease[8]. Positive titers for pANCAs are associated with UC in 60%-80% of cases[11]. Elevated titers can also be seen in left-sided or pan-colitis in children with CD[8,11]. When both tests are considered together, ASCA and pANCA have a specificity of 95% and positive predictive value of 96% for IBD[11]. A complete blood count (CBC), retic count, and sed rate should be checked to look for anemia and signs of acute or chronic inflammation. Albumin, pre-albumin, and transferrin should be checked as an assessment of nutritional status. Finally, stool studies should be performed to evaluate for evidence of malabsorption or infectious etiology. Cultures should evaluate for *C. difficile*, Salmonella, Shigella, *E.coli* (O157:H7), and *Campylobacter*.

Diagnostic imaging can provide valuable information in a patient whose history or physical exam is concerning for IBD. Plain films are important in the acutely ill patient to look for complications such as obstruction, toxic megacolon, or perforation. In the non-acutely ill patient, contrast studies may be more beneficial in making a diagnosis. A barium enema (BE) can identify strictures and abnormal mucosa. It is useful to evaluate the colon and often the terminal ileum if the contrast refluxes back through the ileocecal valve. An upper gastrointestinal (UGI) study with a small bowel follow through (SBFT) can evaluate the proximal gastrointestinal tract including small bowel which in the past has been difficult to assess. This study may show mucosal lesions, strictures, or fistulas. If a bowel obstruction is present, the transition point may be identified. Standard enteroclysis is considered superior to SBFT but is more difficult to perform and may not be tolerated by some patients. A computed tomography (CT) scan is helpful in the diagnosis and management of patients presenting with acute onset of symptoms or an exacerbation of their disease. CT can assess both intestinal abnormality and extraluminal abnormalities such as abscess formation. Ulcerative colitis is associated with mural

Table 3 Medications for IBD[4,12,19]

Class	Generic (Trade)	Use	Side Effects
Aminosalicylates	Mesalamine (Asacol, Pentasa) Sulfasalazine (Azulfadine) Olsalazine (Dipentum) Balsalazide (Colazal)	May be used to induce remission in mild CD or UC May be used to maintain remission in moderate CD or UC	Headache Nausea Anorexia Leukopenia Diarrhea
Corticosteroids	Prednisone Budesonide	Used for induction of remission in CD and UC, not effective in maintenance of remission	Increased risk of infection Hypertension Weight gain Acne Hirsuitism
Immunomodulators	Azathioprine (Imuran, Azasan) 6-mercaptopurine (Purinethol)	Used for maintenance of remission in moderate to severe CD or UC	Nausea/vomiting Diarrhea Pancreatitis Hepatitis Myelosuppression
	Methotrexate (Rheumatrex, Trexall)	May be used to maintain remission in moderate to severe CD or UC that does not respond to azathioprine or 6-mercaptopurine	Myelosuppression Oral ulcers Hepatitis
	Cyclosporine (Neoral, Sandimmune)	Has been used to induce and maintain remission in refractory cases of UC	Renal toxicity Hypertension Gingival hyperplasia Hirsuitism
Biologic Agents	Infliximab (Remicade)	May be used for refractory CD or steroid-dependent patients to induce and maintain remission	Infusion reaction (chest pain, Hyper- or hypotension, And shortness of breath) Nausea Fever/Chills Hives Fatigue

thickening < 1.5 cm, no thickening of the small bowel, increased perirectal and presacral fat, target appearance of the rectum, and lymphadenopathy. Findings consistent with CD include mural thickening > 2 cm, involvement of the small bowel, mesenteric fat-stranding, perianal disease, abscesses, fistulas, and adenopathy[15]. MR enteroclysis is a new technique being evaluated as a method to evaluate the small bowel for CD, and initial reports are promising that it is very sensitive. Thickening of the bowel wall, skipped lesions, stenotic areas, and fistulas have all been diagnosed with more sensitivity when compared to conventional SBFT. It has the added benefit of minimal radiation exposure due to the need for fluoroscopy to place a nasoduodenal tube prior to the study[16].

Finally, bone density studies should be considered either to establish a baseline or, if corticosteroid treatment is prolonged, to evaluate bone mineralization which can be altered in these children. It is important to interpret this study using bone age or height age as opposed to chronological age because using chronological age will lead to an overestimation of the extent of bone disease. Endoscopic evaluation is an essential tool in the workup of IBD. UGI endoscopy looks at the esophagus, stomach, and duodenum. It is useful in identifying other possible sources of fecal blood such as gastritis, duodenitis, or peptic ulcer disease. Using a push endoscopy technique, it may be possible extend visualization to 60-120 cm beyond the ligament of Treitz to evaluate for small bowel CD[17]. Biopsies can be taken to establish or confirm the diagnosis. Colonoscopy is a standard part of the workup for IBD. The advantage of this procedure over contrast studies is the ability to obtain biopsies which can distinguish between UC and CD involving the colon.

Biopsies taken during endoscopic evaluation help distinguish between CD and UC. There are several pathologic features which help distinguish between the two types of inflammatory bowel disease when the colon is the primary site of involvement. UC always involves the rectum and can extend proximally, whereas CD may involve any portion of the colon including isolated right colon involvement or multiple segments with skip areas in between. The microscopic features of UC include diffuse inflammation confined to the mucosa or submucosa. The microscopic features of CD include transmural inflammation with fissuring ulcers, fistulas, granulomas, and vasculitis[18]. The endoscopic capsule has been shown in several studies to have a higher yield than either push endoscopy or enteroclysis when used to evaluate patients with small bowel CD. One such study evaluated two groups of patients, those with the previous diagnosis of CD and those with no prior diagnosis. In both groups, the endoscopy capsule was more sensitive for small bowel pathology than either of the other two techniques[17]. Problems with this technique include difficulty in swallowing the capsule and failure to pass the capsule.

MEDICAL MANAGEMENT

The main goal of medical management for IBD is to achieve clinical and histiologic remission by suppression of inflammation with the least amount side effects from the medications. (Tables 3, 4) Good control of

the inflammatory process will decrease the likelihood of needing surgical intervention. In addition, successful treatment should provide adequate nutritional support to promote normal growth and should attempt to minimize alteration in the physical and social functioning of the child in order to maintain quality of life[1]. For patients with CD, treatment is based on severity of symptoms, which does not necessarily correlate with mucosal healing. CD is classified as mild to moderate, moderate to severe, and severe to fulminant. Mild to moderate disease is treated initially with either 5-aminosalicylic agents (sulfasalazine or mesalamine) or antibiotic therapy with metronidazole and ciprofloxacin[8,12,19]. Both regimens have been reasonably successful in inducing remission in mild disease in adults and children.

For patients with moderate to severe disease, corticosteroids are effective in inducing remission and have been considered the standard for treatment[4,8,12,19]. Prednisone or methylprednisolone remain the first-line therapy in moderately to severely ill children with CD with up to a 90% rate of improvement. The dose is 1-2 mg/kg per day prednisone equivalent (max 4060) for four to six weeks and then taper[4,8,19]. Although corticosteroids act rapidly to alleviate symptoms, they do not heal mucosal lesions and are of no benefit for maintenance therapy[5]. Pitfalls to this treatment include corticosteroid-dependence (1/3-1/2 of patients) and resistance (1/5 of patients) and therefore, weaning as quickly as possible is important to avoid decreased linear growth and minimize potential bone loss[8,19]. Steroids should be avoided in children with profound growth retardation, especially in those who are already Tanner 2 or 3 and who have a limited window of growth remaining[4,8,19]. They should also be avoided in those patients with severe bone loss.

In patients who have achieved remission with corticosteroids, immunomodulators, including azathioprine (AZA) and 6-mercaptopurine (6-MP), a metabolite of AZA, are helpful in maintaining remission[4,8,12,19]. Most pediatric gastroenterologists favor immunomodulators in children with CD as they are better at maintaining remission[8]. They may be initiated at diagnosis, post-op, after a severe attack. They are also used to maintain remission when patients have become steroid-dependent, but they are not effective in inducing remission because of their long onset of action. They have been shown to reduce steroid dependence and resistance from 50% to 20% or less[8]. Adverse effects include hepatotoxicity, myelosuppression, pancreatitis, N/V, and allergic reactions, and these have been associated with an inherited inability to metabolize them. Patients heterozygous or homozygous for an alteration in the gene thiopurine methyltransferase (TPMT) have deficient TPMT activity and are at risk for marked elevations of the active 6-thioguanine nucleotide metabolites and resultant severe leucopenia. Those patients with high TPMT activity can metabolize the drugs to inactive, but potentially hepatotoxic, 6-methylmercaptopurine metabolites. A screening test is available to determine TPMT genotype and activity as well as thiopurine metabolism[8].

Methotrexate (MTX) is another immunomodulator used as an alternative therapy after treatment with the thiopurines (AZA and 6-MP) has proven suboptimal due to inability to maintain remission or patient intolerance to the medication[8]. Methotrexate is also used in patients who do not respond to corticosteroids for induction of remission as it has been shown to induce and maintain remission[4,8,12,19]. Side effects include nausea, vomiting, diarrhea, stomatitis, rash, arthralgias, leucopenia, and hepatotoxicity. The latter is the most treatment- limiting and requires monitoring of serum aminotransferases and biopsy in patients with persistent elevations. There are also concerns of teratogenicity in females of child-bearing age[8].

Table 4 Medical management of IBD[4,12,19]

	CD	UC
Mild	Aminosalicylates Antibiotics	Aminosalicylates
Moderate	Corticosteroids→ Aminosalicylates or AZA or 6-MP or Methotrexate	Corticosteroids→ Aminosalicylates or AZA or 6-MP or Methotrexate
Severe	Corticosteroids→ AZA or 6-MP or Methotrexate or Infliximab	Corticosteroids→ AZA or 6-MP or Methotrexate or Cyclosporine
All cases	Nutritional support Monitor growth closely	Nutritional support Monitor growth closely

Finally, biologic therapy in the form of infliximab, a chimeric monoclonal antibody directed against tumor necrosis factor-α, has been used to treat moderate to severe disease in patients who do not respond to 5-ASA, antibiotics, steroids, or immunomodulators. It can be used as an alternative to prednisone to induce remission or as a first-line therapy in CD with severe, perianal, fistulizing disease or intolerance to corticosteroids[8,19]. Most of the literature is on adults but has been used in children with good results. Approximately 30% of patients do not respond to infliximab[5]. It is possible to develop antibodies to infliximab and thus decrease responsiveness. Concomitant therapy with immunomodulators may help maintain responsiveness[8]. It is generally well-tolerated by adults and children[4,8,19]. Side effects include flushing, rash, dyspnea, and headache and are typically seen at the time of infusion. Other side effects include delayed hypersensitivity reactions, including joint pain/stiffness, muscle pain, fever, general malaise, a lupus-like syndrome, and opportunistic infections, including tuberculosis, histoplasmosis, and sepsis. Leukopenia has been seen as well as lymphoproliferative disorders[5].

Patients with UC may be classified as having mild, moderate, or severe disease. In UC, mucosal healing correlates well with clinical remission[4,19]. The accepted treatment of mild to moderate UC is the 5-aminosalicylic acid agents, sulfasalazine and mesalamine. It is important to treat with appropriate dosing as underdosing is the most common cause of treatment failure. In UC, it is also important to remember that topical treatment with enemas is very effective, often more effective than oral therapy[19]. In patients with moderate to severe disease who are refractory to the aminosalicylates, corticosteroid treatment can induce remission but has no role in

maintaining remission[4,12,18]. The above side effects are still a concern, and the child should be tapered from corticosteroid therapy as soon as possible[4,19]. In patients with severe UC who fail to respond to corticosteroids, cyclosporine is an option for therapy[12,19]. This drug has a serious side effect profile, including renal insufficiency, hypertension, opportunistic infections, seizures, and electrolyte abnormalities[4,19]. Because of the toxicity of cyclosporine, the patient's history should be considered to assess whether surgery is a better option.

The immunomodulators AZA, 6-MP, and MTX have been studied in refractory cases of UC. They are not used to induce remission, but to maintain it[4,12,19]. Their side effects have been discussed above, and monitoring is required. As with the aminosalicylates, underdosing is frequently the cause of failure of therapy.

Aggressive nutritional support can improve growth parameters in pediatric patients with IBD[8]. Special diets have been shown to help alleviate symptoms in CD, but not in UC. However, all children with IBD need appropriate nutritional assessment and support to minimize growth retardation due to malnutrition. During acute exacerbations of IBD, parenteral nutrition may be necessary but has the associated disadvantages of being more invasive and more expensive[3]. In addition, patients receiving parenteral nutrition are at risk of complications from central venous access including infection and bleeding. Enteral nutrition is always preferable if tolerated. Formulas with omega-3 fatty acids may be beneficial[3]. Special attention should be paid to caloric intake and vitamin and mineral supplementation. During active disease, increased metabolic demands may make it difficult to compensate for the added caloric requirements with oral intake alone. IBD patients are also at risk of vitamin and mineral deficiencies, including iron, calcium, vitamin D, vitamin B12, and folic acid. Calcium supplements seem to be the best way to prevent bone disease.

SURGICAL MANAGEMENT

Surgical management of CD is typically required for complications of the disease. Indications include perforation/abscess, obstruction, stricture, fistula, toxic megacolon, or malignancy. Ultimately, greater than 50% of patients will require resection[20-22]. Surgical procedures are based on the location of the disease and the complication. The surgeon must consider the state of health of the patient. Obstruction is the most common cause for surgery in patients with CD. Adhesions are divided carefully, and strictures are either resected or managed with a strictureplasty[21-23]. Given the high rate of recurrence and reoperation, bowel conservation is extremely important to avoid the complications associated with short bowel syndrome and long-term dependence on parenteral nutrition. Strictures less than 10 cm in length can be addressed with a Heineke-Mikulicz strictureplasty. This is performed by incising the bowel lengthwise through the strictured area and closing the defect transversely. Longer strictures, 10-25 cm, may still be managed with strictureplasty using a Finney technique. Again, the bowel is opened in the longitudinal axis through the strictured area and a side-to-side anastamosis is performed. Strictures longer than 25 cm usually require resection. In pediatric patients with severe symptoms despite medical therapy or those with severe growth retardation, surgical resection of the terminal ileum and cecum may be beneficial in providing a disease-free interval of 2-3 years. Primary anastomosis is usually safe in the above mentioned circumstances. However, more severe complications, including perforation, abscess, or toxic megacolon, may require a resection and ostomy formation. Complications after surgery for CD include wound infection, anastomotic leak, anastomotic stricture, fistula, recurrence of disease, small bowel obstruction, and bleeding.

Crohn's disease is characterized by a chronic relapsing course. Recurrence of symptomatic disease after surgery has been reported as 17% at 1 year, 38% at 3 years, and 60% at 5 years. The disease typically recurs at the site of resection[20]. If defined as the presence of endoscopic abnormality, 1 year recurrence has been reported as high as 75%-93% of patients[20]. Growth improved significantly in pediatric patients after surgery[21,24]. Although there is a high rate of recurrence, any disease-free interval with decreased corticosteroid requirements may allow normal growth and sexual development. Risks and benefits must be clearly defined when determining the need for surgery[24]. There is some evidence to indicate that post-op management of CD patients with 6-MP can decrease rate of recurrence (recurrence defined as endoscopically-evident), but there is no standard of therapy[20]. Infliximab has not been investigated in this setting.

Ulcerative colitis may require surgery for emergent or elective indications. The former includes bleeding, toxic megacolon, and perforation. Indications for non-emergent surgery include failure of medical therapy, severe growth retardation, and dysplasia or malignancy. The rate of colectomy is no higher in children than in adults, but children have a higher rate of progression of disease (65% for children *vs* 39% for adults)[4]. Unlike in CD, total proctocolectomy for UC is curative. The procedure used depends on the clinical status of the patient but usually involves a total colectomy with or without a protective ileostomy. Creation of a reservoir in the small bowel with a ileoanal anastomosis is the definitive procedure. Outcome parameters of importance include number of bowel movements per day, consistency of the stool, requirement of stool-regulating medicine, whether patients can discriminate between air and stool, emptying of J-pouch, ability to defer defecation, leakage of stool/soiling, and number of episodes of pouchitis[25]. Complications include wound infection, pouchitis, SBO, pelvic sepsis, bleeding, urinary complications, anastoamotic leak or stricture, soiling, mortality, and permanent stoma, which is reported as high as 30%[25].

Whether to perform proctocolectomies as a one-stage or two-stage operation remains controversial. Many studies show that a total colectomy with J-pouch ileoanal anastomosis can be performed safely as a single-stage operation with the right patient selection and careful attention to signs of complications[21,26,27]. The largest patient series is one of 150 patients with a IPAA without a protective ileostomy compared to 92 patients who

had IPAA with a protective ileostomy[26]. Results were compared, and a significantly lower complication rate was found in the one-stage procedure. However, the exclusion criteria for the one-stage procedure placed the patients with the highest risk of complication in the two-stage procedure group[26].

TYPICAL COURSE OF DISEASE

Crohn's disease is unpredictable and is characterized by recurrent exacerbation of symptoms. The spectrum of disease includes patients that remain in remission, those that have recurrent periods of disease followed by remission, and those that have continuous active disease[5,8]. Serum markers, including ASCA and pANCA, may help stratify patients into subgroups, which help predict natural history[9,28]. ASCA IgG and IgA is found in 100% of CD patients with fibrostenosing disease, whereas pANCA was present in 86% of CD patients with primary colonic involvement. At the time of diagnosis with CD, 40.9% of patients had ileocolonic disease, 28.6% had disease limited to the small bowel and 30.4% had disease involving only the colon and perirectal area[5]. Patients with small bowel disease are more likely to have an obstructive pattern of disease characterized by fibrostenosis. Patients with colonic disease are more likely to have symptoms associated with bleeding and inflammation[5,8]. In general, surgery is for complications of the disease, and three out of four patients will ultimately require surgery. Complications of CD include abscesses, fistulas, strictures, and obstruction from adhesions, and pediatric patients have an even higher risk of developing these complications[5]. They are addressed surgically, with the goal of minimizing loss of length of bowel, since it is not a curative procedure. Removal of the diseased segments is followed by recurrence near the anastomosis. Endoscopic evidence of recurrence is found in up to 93% of patients at 1 year. However, a second operation is only required in 25%-38% of patients at 5 years and 50%-70% of patients at 15 years. Of those requiring a second operation, 37% will require a third one[5].

There is an increased risk of cancer in CD patients, including small bowel adenocarcinoma and colon cancer. The risk is especially high in those patients diagnosed prior to the age of 25 and in patients with a history of pan-colitis. CD patients with small bowel disease are 50-100 times more likely to develop small bowel adenocarcinoma[4]. At the time of diagnosis, most patients with UC have disease distal to the splenic flexure[2,5]. In general, clinical severity at the time of presentation correlates with extent of colonic involvement[2,5,11]. Most patients have a chronic, intermittent course of disease recurrence. Approximately 15%-40% of patients will ultimately require a colectomy, and this correlates with the extent of involvement. Indications for surgery include failure of medical therapy, growth retardation, and complications such as persistent hemorrhage, perforation, toxic megacolon, and the presence of dysplasia or carcinoma[4,5]. Toxic megacolon occurs in 5% of adult patients but is rare in children. It is a surgical emergency associated with risk of perforation, sepsis, electrolyte abnormalities, and hemorrhage. Frank perforation is more common in UC than in CD. It is usually associated with toxic megacolon and serious disease.

The association between UC and colon cancer is well documented[5]. Risk appears to be related to extent of colonic disease, age at diagnosis, and length of time since diagnosis with greater than 10 years being the threshold for identifying an increased risk of cancer[5]. The overall annual incidence of colon cancer in patients with UC of longer than 10 years duration is approximately 1%[5]. Children who develop UC before the age of 14 have a colon cancer incidence rate of 5% at 20 years and 40% at 35 years[4]. It is estimated that the risk of dying from colon cancer is 8% after 10 years from diagnosis[4]. The risk of colon cancer in patients with Crohn's colitis is 4-20 times that of the general population. Overall, patients with UC do not have a significantly increased mortality rate when compared to the general population. However, those patients with CD do have an increased mortality. Their survival rate is 93.7% of that in the general population at 15 years[5].

PROBLEMS SPECIFIC TO PEDIATRIC PATIENTS

Growth retardation was mentioned briefly earlier in this review but warrants further discussion. It may be present at the time of diagnosis or occur as a result of treatment[3]. Inadequate nutrition, chronic corticosteroid use, and decreased physical activity all play a role[3]. It is important obtain a complete growth history and follow growth parameters closely as growth failure may affect a patient' s treatment plan. Height velocity is the most important parameter to diagnose impaired growth, with more than 85% of patients having impaired growth at the time of diagnosis with IBD[4]. Nutritional insufficiency is due primarily to inadequate intake either from anorexia or food fear related to the association of food intake with pain[4]. Undernutrition delays skeletal and sexual maturation, with delays seen in epiphyseal fusion of long bones and in progression through Tanner stages[4]. Corticosteroids may further complicate growth and maturity. Factors contributing to abnormal bone mineralization over-production of inflammatory cytokines with the resultant increase in bone resorption, malnutrition, sedentary life-style, and corticosteroid use. Corticosteroids inhibit osteoblasts, impair intestinal absorption of calcium, and antagonize growth hormone[3]. Diagnosis of bone disease can be made with radiologic studies. A dual energy X-ray absorptiometry (DEXA) study is particularly useful. However, results should be interpreted using bone age or height age, not chronological age which overestimates the extent of bone disease.

In addition to the multitude of medical problems faced by pediatric IBD patients, there are significant psychosocial stressors for these children. Emotional and behavioral issues are common and stem from the chronic nature of the disease. Lifestyle changes can occur unexpectedly due to disease exacerbation. Anxiety, depression, and antisocial and dependent behavior are all common. Anxiety and depression may be related to concerns about

differences from other children and progression of their illness such as relapse of the disease or complications of disease requiring surgery or stoma formation[29]. Difficulty interacting with peers may result from school absenteeism and may be compounded by low self esteem due to delayed growth and development[2,30]. Finally, guilt may be a large psychosocial stressor for the child. The financial strain of a chronic illness, changes in parental work schedules, repeated physician visits, and sibling issues are problems for which a child with IBD may feel responsible. It is also important to remember the educational needs of children with IBD. Due to illness, attendance in school may suffer. If not anticipated and addressed, this can cause the child to fall behind in school. All of the above mentioned problems can be exacerbated if the educational needs of the child with a chronic illness are overlooked[3,29,30].

Assessment of a child's adaptation to his or her disease is a component of long-term care of children with IBD. Several assessment tools exist with most models focused on evaluating social support, coping skills, effects on activities of daily life, and body image[2,3,30,31]. These broad categories are used to assess quality of life and have been shown to be affected by age, education, and gender[30,31]. Finally, the issue of the transition of care is inevitable for children with IBD. After dealing with a chronic illness for, in some cases, years, medical care is transferred to a different provider. The child has built a relationship with the pediatric gastroenterologist and they must change physicians, perhaps at a time when many other changes are taking place. Preparing adolescents with IBD for this transition takes time and planning. This transition can be facilitated by the pediatric gastroenterologist by gradually increasing the patient's participation in, and responsibility for, his or her own care. Older adolescents should know their medications and be able to recognize signs of exacerbation of their disease. In addition, they should know the warning signs of an emergency and be able to take appropriate steps to seek immediate treatment. There are several recommendations for the pediatric gastroenterologist to help make this a smooth transition of care. These include: (1) preparing a detailed, up-to-date medical summary describing the course of the disease, therapy, allergies, *etc*., (2) including copies of relevant test results, and (3) identifying a skilled gastroenterologist who is aware of the special needs of the young adult patient who was diagnosed with IBD as a child[2]. The goal is for everyone involved to view this as a transition of care rather than a transfer of care. Maintaining open communication between the patient and the two physicians is critical for this to be successful.

Future considerations

The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) has identified areas of interest for future research. These include the role of enteric microbial flora; the study of dietary, nutritional, and environmental factors; the evaluation of new therapies and their effects in early onset disease; and the development of a North American Pediatric IBD database[3]. The Working Group of the Second World Congress of Pediatric Gastroenterology, which includes NASPGHAN, has set goals of future research to include establishing the correlation between genotype and phenotype, the determining whether mucosal response in IBD differs between children and adults, understanding the role of previous exposure to infections, and improving the dissemination of knowledge regarding pediatric IBD[1].

Abstract

Outcomes assessment in surgery traditionally has included data regarding peri-operative mortality and morbidity, as well as long-term survival and recurrence in surgical oncology. However, quality of life (QOL) is another important patient-related outcome measure. QOL data can be used to tailor treatment and improve clinical outcomes by detecting physical or psychological problems in patients that otherwise might be overlooked, but which have profound implications for the effective delivery of care. We review several well-validated QOL instruments developed specifically for use in patients with gastrointestinal malignancies, including esophageal, pancreatic and colorectal cancers, and conclude that QOL assessment routinely should be included in clinical trials of novel treatments.

DESCRIPTION OF QUALITY OF LIFE

The assessment of quality of life (QOL) is a relatively new facet of health services research in surgery. Traditionally, surgeons measured success or failure based on perioperative morbidity and mortality. However, as technology has improved surgeons' ability to intervene safely in patients' lives, researchers have been compelled to determine whether improvement in survival translates into improvement in QOL. QOL is a nonspecific term that attempts to define the overall state of a person's life. There are subjective and objective components to the QOL specific to one person. For example, two people with the same health and economic status could perceive their respective qualities of life very differently. Discrepancies in QOL are influenced by the social and psychological status of the individual. Research tools have been developed to quantify both subjective and objective evaluations of quality of life (Q) in order to obtain a healthcare-related value of QOL. Measurement scales are based on social, somatic, psychological, and physical domains to obtain a value (Z). To be validated and used in trials, Z must be shown to equal Q (Figure 1)[1].

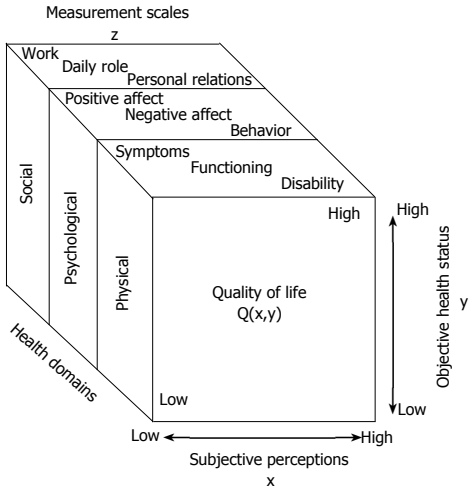

Figure 1 To measure QOL, social, psychological and physical domains of illness are assessed using measurement scales (z). QOL (Q) is dependent on both subjective and objective items. For a questionnaire to be validated, Z must equal Q. (Reprinted with permission from Testa *et al* N Engl J Med 334: 835-840, 1996).

QOL studies have increased rapidly in the medical literature, as demonstrated by the number of citations on Medline. In 2004, a keyword search on "quality of life" identified 5584 articles, whereas 20 years earlier (1984),

only 45 citations were elicited. QOL trials can discriminate between therapies with similar rates of morbidity and mortality, such as diverting ostomy or bowel resection with primary anastomosis in colon cancer, or compare different treatment modalities, such as medicine versus surgery. Assessment of QOL outcomes requires accurate gathering of information, use of pertinent measurement tools, and appropriate follow-up. A structured QOL questionnaire consists of a number of items in the form of questions or statements that draw on various dimensions of QOL . The form used to assess these subjective and objective data must be validated and then filled out either by the patient, a proxy, or by interview (telephone or face-to-face). The telephone interview limits follow-up to people who do not have hearing impairments and who have a telephone. Self-administered questionnaires give patients the opportunity to address problems they might otherwise be reluctant to discuss openly with an interviewer, but there is an increased risk of misinterpretation. Face-to-face interviews decrease misinterpretation but might fail to represent aspects of QOL people are embarrassed to discuss. Survey answers are assigned a score; qualitative information is converted into quantitative data, such that standardized scores are inclusive of all represented dimensions within the instrument[2].

Instruments calculate QOL in a generic or specific manner. Generic questionnaires provide an overall assessment of QOL that is not matched for a certain population or disease state. A popular, validated example of a generic QOL instrument is the Short Form-36 (SF-36). The questionnaire includes 36 items that measure eight dimensions of health on multi-item scales, including physical function, emotional function, physical problems, emotional problems, pain, general health, vitality, and social function. Sample questions include "Does your health now limit you in vigorous activities, moderate activities, lifting or carrying groceries?" and "Have you felt downhearted and blue?" There is also a single-item scale measuring changes in health during the previous year. The scoring scale ranges from 0 to 100, with 0 equal to death and 100 equal to perfect health. On the SF-36 scale, higher scores imply better health[3]. The SF-36 is useful for assessing health in a global manner; for example, the SF-36 has been used around the world to assess QOL in patients with a variety of different chronic diseases[4]. However, the SF-36 is often not sensitive enough to detect small differences in specific treatment groups with unique health care disabilities. Specific health-care instruments are tailored to detect these small differences in QOL when treatment groups are more homogeneous. These questionnaires are specific to a type of disease, population, domain, or symptom[5].

In 1980, the European Organization for Research and Treatment of Cancer (EORTC) started a research program to develop an integrated approach for QOL evaluation in patients with cancer participating in international clinical trials. The goal was to develop a core questionnaire incorporating a wide range of physical, emotional, and social health issues relevant to a broad range of cancer patients, irrespective of specific diagnoses, supplemented with diagnosis-specific (i.e. esophageal, pancreatic, and colorectal cancers) and/or treatment-specific modules. Currently, the EORTC QLQ-C30 is the most widely used disease-specific instrument for the assessment of QOL in cancer patients worldwide. The 30-item questionnaire incorporates five functional scales (i.e. physical, role/daily activities, cognitive, emotional, and social), three symptom scales (i.e. fatigue, pain, nausea and vomiting), and a global health and QOL scale. The single items assess commonly-reported symptoms of cancer patients (i.e. dyspnea, appetite loss, sleep disturbance, constipation, and diarrhea), as well as the perceived financial impact of the disease and treatment[6].

It is important to distinguish between the measurement of direct and indirect costs accrued by patients during the diagnosis, treatment, and surveillance phases of their diseases. Direct health care costs include expenses accrued during visits to physicians, as well as the costs of prescription medications, physical therapy, hospitalization, operative procedures, laboratory, and radiological tests. Indirect costs include the value of production lost to illness-related absence, such as the number of days absent from (paid and unpaid) work and days lost from housekeeping and other daily activities. Currently, large administrative databases compiled by insurance companies, hospitals, and other healthcare institutions are the most reliable source for cost estimation, but they do not include most indirect costs. Estimation of the financial impact of disease on patients is a difficult task. The QLQ-C30 addresses the financial impact of disease by asking "Has your physical condition or medical treatment caused you financial difficulties?" However, other studies have attempted to further quantify the financial impact in a more specific manner. Goossens *et al*[7]. studied the use of a patient cost diary to evaluate all indirect costs in 205 patients with fibromyalgia and low back pain over a two-year period. They found that when the diary was used in conjunction with periodic interviews, there was an accurate estimate of direct and indirect costs, as well as good patient compliance completing the diary. Additional studies have shown that the cost of disease treatment can be collected prospectively to assess for differences in treatment arms using a Collection of Indirect and Nonmedical Direct Costs (COIN) form[8]. In order to fully evaluate the impact of financial strain on QOL, these forms can be used in conjunction with the QLQ-30.

ESOPHAGEAL CANCER

Esophageal cancer is the second most common solid intrathoracic malignancy in the U.S., after lung cancer. The National Cancer Institute (NCI) estimates that 14 520 Americans are diagnosed annually with esophageal cancer, and 13 570 die of their disease.(www.cancer.gov) Management of esophageal cancer depends on the stage of disease at presentation and the general health of the patient; treatment options include surgery, chemotherapy, radiation therapy, multimodality therapy, or palliative care. The esophageal cancer model is a good example of how a generic questionnaire was developed and then refined to obtain a specific QOL instrument that targets patients with esophageal cancer and their disease-specific symptoms. One of the first studies to examine QOL in patients with esophageal cancer used the EORTC QLQ-30 instrument,

in combination with a linear dysphagia scale, to assess for disease-specific complaints. This study by Blazeby in 1995 followed 59 patients (33 post-esophagectomy and 26 post-palliative care) for a median of 16 wk. Overall, patients undergoing palliation had lower QOL scores. However, the palliation group was heterogeneous, in that some patients received esophageal stents and pain medicine, while others received only pain medicine. Symptoms of dysphagia captured on the linear dysphagia scale did not correlate well with global QOL scores acquired on the QLQ-30. The authors concluded that the QLQ-30 is a valid instrument for assessing outcomes after treatment only if an additional disease-specific measure was added to identify dysphagia, an important QOL outcome for patients with esophageal cancer[9].

As a result of this study, esophageal patients and medical experts were consulted to reform and create a new questionnaire. The EORTC QOL Group developed a disease-specific module (QLQ-OES24) for patients with esophageal cancer undergoing surgery, chemotherapy, radiotherapy, and/or endoscopic treatment[10]. Using the EORTC QLQC30 and the dysphagia scale from the EORTC QLQ-OES24, QOL was followed this time in a prospective longitudinal study of patients with esophageal cancer[11]. Blazeby *et al*[12]. followed patients who underwent esophagectomy (n = 55) or palliative treatment with chemotherapy ± stenting (n = 37). QOL scores were obtained before treatment and at regular intervals. Median scores were calculated for patients surviving more than two years after esophagectomy (n = 17), for patients surviving less than two years (n = 38), and for patients undergoing palliative treatment (n = 37). Six weeks after esophagectomy, patients reported worse functional, symptom, and global QOL scores than before treatment. In patients that survived at least two years from the time of treatment, QOL scores returned to pre-operative levels within nine months, but patients who died less than two years after surgery never regained their pre-operative QOL. In both surgery groups, dysphagia improved, and the improvement was maintained until death, or for the duration of the study. Patients undergoing palliative treatment had more advanced disease and were more physically compromised from the beginning of the study. Palliative intervention allowed these patients to maintain their compromised QOL until death. The study demonstrated that esophagectomy had a negative impact on QOL in the short-term. Patients surviving less than two years had an improvement in dysphagia, but not in overall QOL. The authors concluded that if the subset of patients that would not survive two years could be identified pre-operatively, esophagectomy should be avoided and palliation and/or stenting should be recommended instead. In the following years, the QLQ OES24 module was refined to more clearly elicit symptoms of dysphagia and other problems with eating, as they are especially important for patients with esophageal cancer. With further analysis, items with poor convergence were eliminated. Ultimately, the module was refined to four scales and six single items; the QLQ-OES18 is now the prevailing validated disease-specific QOL measure for esophageal cancer (Figure 2). It should be used in combination with the QLQ-C30.

The Rotterdam Symptom Checklist (RSCL), developed in 1990, collects information about physical symptoms after surgery specific to esophageal cancer, including "dysphagia, loss of taste, weight loss, early satiety, blown-up feeling, hoarseness, pain behind the chest bone, food not going down, and nocturnal coughing[13]. A recent study by de Boer *et al*[14]. used the validated RSCL in combination with the Medical Outcomes Study Short Form-20 to assess QOL. Patients were randomized to receive a transhiatal (THE) or transthoracic esophagectomy and were followed for three years. Three months after surgery, patients in the THE esophagectomy group (n = 96) reported fewer physical symptoms (P = 0.01) and better activity levels (P < 0.01) than patients in the transthoracic group (n = 103). However, this difference was not sustained, and at longer follow-up there was no significant difference between the two treatment groups.

Answer question from 1-4 (1: Not at all; 2: A little; 3: Quite a bit; 4: Very much)
Could you eat solid food?
Could you eat liquid or soft food?
Can you drink liquid?
Have you had trouble swallowing your saliva?
Have you choked when swallowing?
Have you had trouble enjoying your meals?
Have you felt full up too quickly?
Have you had trouble eating?
Have you had trouble eating in front of other people?
Have you had a dry mouth?
Have you had problems with sense of taste?
Have you had trouble with coughing?
Have you had trouble with talking?
Have you had acid indigestion or heartburn?
Have you had trouble with acid or bile coming into your mouth?
Have you had pain when you eat?
Have you had pain in your chest?
Have you had pain in your stomach?

Figure 2 The EORTC QLQ-18 is a specific module for esophageal cancer. Patients complete the questionnaire based on QOL symptoms experienced within the last week. (Reprinted with permission from the EORTC.)

Recent trials have shown that clinical outcomes from esphagectomy can be improved by administering neoadjuvant chemotherapy[15]. In 2005, Blazeby examined the effects of neoadjuvant chemo-and radiation therapy on QOL in patients with esophageal cancer. Data were collected using the EORTC QLQ-30 in tandem with the cancer-specific QLQ-OES18. Patients receiving neo-adjuvant chemotherapy (n = 48) or chemoradiotherapy (n = 34) were noted to have a decline in QOL during treatment that was restored by the time of surgery. Patients who received neoadjuvant chemo-radiation had a relative improvement in post-operative nausea, dysphagia, and emesis compared to patients who underwent esophagectomy alone (P < 0.01). The authors concluded that neoadjuvant therapy improves disease-specific survival and potentially improves postoperative QOL[16].

At Yale, we are conducting a prospective cohort study measuring QOL in patients with esophageal adenocarcinoma who undergo THE with or without neoadjuvant chemo-and/or radiation-therapy. The specific aim of the study is to better select patients who will benefit from this type of surgery by identifying demographic and clinical predictors of QOL following

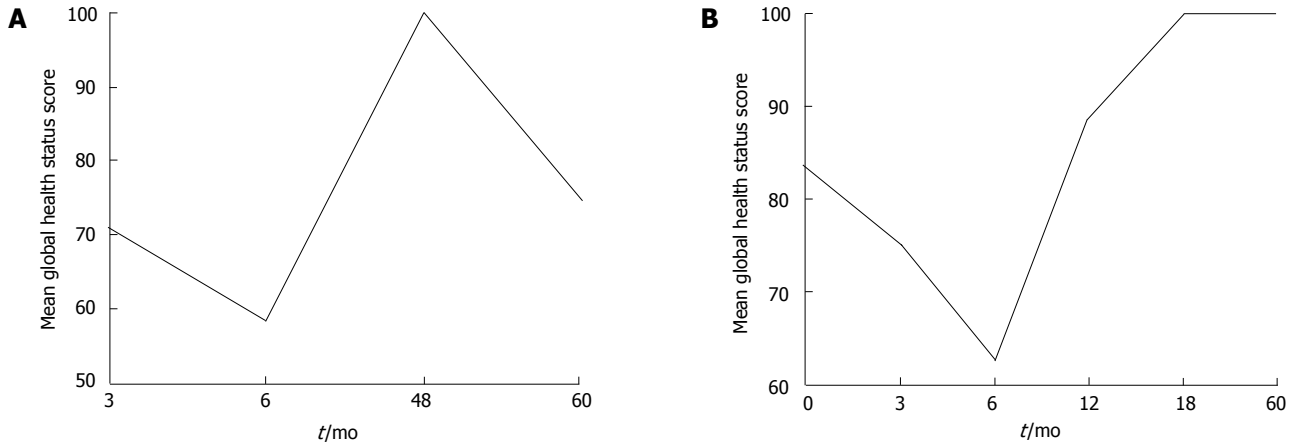

Figure 3 **A:** QOL after THE in patients with esophageal cancer ⩾ 70 years of age. QOL declines sharply for six months and then improves, but the recovery is not durable; **B:** QOL after THE in patients with esophageal cancer ⩽ 55 years of age. QOL declines for six months, but then improves in a more sustained fashion.

THE. The EORTC QLQ-OES18 is administered prior to surgery and then at regular intervals until death or for five years. Preliminary results for the first 21 patients demonstrate a dramatic decrease in global QOL scores in the first six months following surgery, with a gradual improvement in the following year (unpublished results). When comparing age groups following THE, the global QOL score of patients over age 70 years improves after the first six months, and then declines after two years (Figure 3A). In contrast, patients 55 years or younger improve their QOL to pre-operative levels by six months, and these improvements appear to be durable (Figure 3B) The trends in specific symptom scores (i.e. fatigue, nausea and vomiting, pain, and loss of appetite) are variable: they rise and fall during the first year, ultimately declining steadily by the fourth post-operative year. Dysphagia and reflux scores, with a range of 0 (no dysphagia or reflux) to 100 (complete dysphagia or reflux), plateau within the first year; the dysphagia score drops to 0, and the reflux score peaks (mean score, 45) at 18 mo. Functional scores (i.e. physical, emotional, and social functioning) nadir six months following surgery and then rebound to peak at four years; however, scores steadily decline by the fifth year after surgery.

More patients must be enrolled to better characterize the relative influences of such demographic and clinical factors as patient gender, race, tumor stage, comorbidities, and the use of neo-adjuvant and/or adjuvant treatment. Still, from our early data, we would conclude that candidates for THE should be counseled pre-operatively about the effects of surgery on QOL. The association between age and QOL outcomes should be considered when advising patients to undergo THE; that is, patients over age 70 should have a life expectancy of at least six to twelve months post-operatively to warrant the profound effects of THE on QOL.

COLON AND RECTAL CANCER

Colorectal cancer is the third most common cancer in the United States. The American Cancer Society estimates that in 2005, there will be 148 300 new cases of colon and rectal cancer, and 56 290 people will die of their disease (www.cancer.org). Generally, surgery is the initial therapy for patients with colon and rectal cancers. There are two prevailing validated QOL assessment tools for colon and rectal cancer: the Functional Assessment of Cancer Therapy-Colorectal (FACT-C) and the EORTC QLQCR 38, which like the QLQ-OES18 for esophageal cancer, is designed for use with the EORTC QLQ-C30. These instruments have been used in patients undergoing palliative or surgical treatment, regardless of the stage of their malignancy. The EORTC QLQ-CR 38 is a validated, reliable instrument that consists of 38 items inquiring about symptoms specific to colorectal disease and treatment, such as body image, sexuality, urinary problems, defecation or stoma, and future outlook on life[17]. The FACT-C was developed around the same time as the EORTC QLQ-CR 38. It is a shorter questionnaire, composed of 36 items from the core Functional Assessment of Cancer Therapy (FACT-G) merged with the colon and rectal specific items (CCS). These items were developed from interviews with colorectal patients and caregivers. They include two stoma-related questions. In 1999, Ward *et al*[18]. tested the FACT-C in English and Spanish-speaking patients with colorectal disease and found them to be reliable and valid. The authors concluded that the FACT-C had good internal consistency, reliability, and concurrent validity by addressing specific concerns related to colorectal cancer. In addition, in the Spanish population, it elicited subtle differences in QOL based upon extent of disease.

In a recent study by Rauch *et al*[20], 121 patients who received surgery for rectal cancer and who survived at least two years without evidence of disease recurrence were identified. These rectal cancer survivors were mailed three questionnaires: the EORTC QLQ-C30, the QLQ-CR38, and the Duke questionnaire. The Duke health profile is a 17-item validated instrument to assess QOL, but it is not specific for colorectal cancer[18]. The study patients reported less pain when compared to historical controls drawn from the general German and Norwegian populations ($P = 0.002$). Stoma patients reported better social functioning than did non-stoma patients ($P = 0.005$), with less anxiety ($P = 0.008$) and higher self-esteem ($P = 0.0002$). However, this was only detected on the Duke health profile, whereas the QLQ-30 did not demonstrate any difference. It is unclear whether the more generic

Duke profile captured some confounding effect on QOL (i.e. the positive effects of successful medical treatment), or if the EORTC module was too specific and failed to demonstrate real differences in QOL[19].

A recent study by Holloway *et al*[21]. from the University of Texas examined QOL as a predictor of post-operative length of stay (LOS) in 70 patients with colon and rectal cancers using the FACT-C module[20]. Patients completed the FACT-C questionnaire before treatment. LOS for patients scoring in the lowest quartile on the FACT-C in the pre-operative setting was compared with LOS for patients in the remaining quartiles. Patients in the lowest quartile of FACT-C scores had significantly longer LOS. Specifically, lower pre-operative FACT-C scores for physical well-being (9.1 *vs* 7.3 d; $P = 0.04$), functional well-being (9.6 *vs* 7.1 d; $P = 0.006$), and colon cancer concerns (9.5 *vs* 7.1 d; $P = 0.01$) correlated with increased LOS. Advanced patient age and surgical morbidity also predicted longer LOS, but additional factors such as race, nutritional status, stage of disease, and relative training of the operating surgeon did not appear to affect LOS. Courneya *et al*[22]. from Canada utilized the FACT-C on QOL in a prospective randomized-controlled trial to measure the effect of exercise on QOL after any type of colorectal surgery. Patients were assigned in a 2:1 ratio to either an exercise ($n = 69$) or control ($n = 33$) group. Exercise consisted of a home cardiovascular workout lasting 20-30 min, 3-5 times/wk; subjects had to reach at least 65% of their predicted target heart rate. Compliance was not good; therefore, analysis was limited to a comparison between patients who increased physical fitness to patients who had no change or decreased fitness. There was a significant improvement in QOL based on FACT-C scores between patients with increased physical fitness when compared to patients who did not increase physical fitness[21].

In 2005, Jung Yoo *et al*[23]. administered the FACT-C to 98 patients with colorectal cancer at the time of any surgery for rectal cancer. Fifty-two patients completed the survey at one and six months post-operatively; 38% received a stoma as part of the cancer operation. Analysis of variance between FACT-C scores demonstrated that patients' QOL was nadired one month after colectomy and returned to pre-operative levels six months later. This is an example of how QOL analysis can provide useful nformation for the patient regarding the projected post-operative course, which allows them to have some realistic expectations for recovery time and QOL[22].

PANCREATIC CANCER

Pancreatic cancer is the fourth leading cause of cancer-related death in males and the fifth leading cause in females in the Unites States (www.cancer.gov). It is usually diagnosed at an advanced stage, so survival is poor. There has been little change in overall incidence or mortality rates over the last three decades. Fewer than five percent of patients survive five years from the time of diagnosis. Whipple first described the modern pancreaticoduodenectomy (PD) in 1935. It remains the standard surgical treatment for adenocarcinoma of the head of the pancreas. Peri-operative mortality has diminished significantly, with experienced centers reporting rates of less than 5%. However, complications continue to be common and include pancreatic fistula, delayed gastric emptying, intra-abdominal abscess and hemorrhage, and anastomotic leak. Therefore, QOL studies in pancreatic cancer patients could play a significant role in determining appropriate treatment options. The EORTC QLQ-30 module was modified to identify symptoms that are unique to patients with pancreatic cancer. Over a two-year period, the EORTC study group on QOL performed literature searches, interviewed patients and health-care professionals, and identified 26 items related to pancreatic cancer that resulted in the QLQ-PAN-26 instrument[23]. A study by Shaw *et al*[25]. in 2005 examined long-term QOL following PD for benign and malignant disease[24]. The treatment group included 40 patients who underwent PD for benign and malignant disease. The benign group included patients with chronic pancreatitis, neuroendocrine tumors, pseudopapillary tumors and microcyst adenomas. The control group consisted of 58 patients who underwent cholecystectomy by the same surgeon. The two groups were matched for age and gender. Patients were followed for nine years. QOL was assessed using the EORTC QLQ-C30 and the QLQPAN26. While there was no significant difference in global health scores between the two groups, the QLQ-30 identified significant decreases in the post-operative functional scales (physical role, emotional role, and social) amongst the study PD group as compared with the control group. The malignant PD group reported the lowest level of physical and role functioning, greater weakness and concerns for future health, while the benign group had more social/financial difficulties, and upper gastrointestinal symptoms consistent with exocrine insufficiency. Upper gastrointestinal symptoms posed greater difficulties for patients who underwent total pancreatectomy including absolute dependence on pancreatic exocrine supplements and insulin-dependent diabetes. Patients after a PD had more diarrhea ($P < 0.05$) and nausea and vomiting ($P < 0.05$) than the matched patients after cholecystectomy. In part as a result of this study, patients are routinely placed on pancreatic enzyme supplements following PD at this research hospital.

A 2005 prospective longitudinal study by Nieveen van Dijkum *et al*[26]. assessed QOL in 114 patients following PD and a double-bypass procedure (hepaticojejunostomy and gastroenterostomy) for pancreatic and periampullary carcinoma[25]. The study employed the Medical Outcomes Study (MOS) 24 acute-phase questionnaire, the disease specific Gastrointestinal Quality of Life Index (GIQLI), and one question concerning overall QOL derived from the RSCL[13]. The GIQLI is an instrument developed in 1995 that has been validated in many patients with gastrointestinal diseases[26]. The questionnaires were administered over one year, or until death. A transient decline in physical (MOS score) and gastrointestinal (GIQLI score) functioning were observed at two weeks after surgery for both treatment groups. PD patients regained QOL within six weeks of surgery. Double bypass patients did not return to the pre-operative QOL until three months after surgery. There was a more pronounced

decline in all QOL scales after double-bypass procedures as compared with PD. The authors concluded that PD maintains QOL in patients with resectable pancreatic cancer. Palliative double bypass procedures have a beneficial effect on QOL in patients with unresectable pancreatic cancer that are expected to survive at least three months[27].

In conclusion, QOL studies seek to quantify symptoms and perceptions patients have in a generic- or disease-specific manner. Validating subjective and objective data has been labor-intensive; a large body of the work to date has been initiated by the EORTC. The EORTC QLQ-C30 has been used to measure QOL among patients with cancer in a reliable and reproducible fashion. However, it is important to include specific modifiers relevant for different disease processes. For example, dysphagia is measured in esophageal cancer, bowel habits in colorectal cancer, and bile duct obstruction in pancreatic cancer. Historically, post-operative morbidity and mortality have been the barometers used to assess clinical outcomes from different surgical interventions. Interestingly, economic outcomes, such as hospital charges and length of stay have also been reported. QOL is yet another outcome measure that should be collected when gauging the overall appropriateness of a surgical intervention. QOL information should be conveyed to patients in the pre-operative setting, so that they can make more informed decisions regarding their healthcare. We believe future research and clinical trials in surgery options in patients should routinely include analysis of QOL as an outcome measure.

Abstract

Surgical training is changing: one hundred years of tradition is being challenged by legal and ethical concerns for patient safety, work hours restrictions, the cost of operating room time, and complications. Surgical simulation and skills training offers an opportunity to teach and practice advanced skills outside of the operating room environment before attempting them on living patients.

Simulation training can be as straight forward as using real instruments and video equipment to manipulate simulated "tissue" in a box trainer. More advanced, virtual reality simulators are now available and ready for widespread use. Early systems have demonstrated their effectiveness and discriminative ability. Newer systems enable the development of comprehensive curricula and full procedural simulations.

The Accreditation Council of Graduate Medical Education's (ACGME) has mandated the development of novel methods of training and evaluation. Surgical organizations are calling for methods to ensure the maintenance of skills, advance surgical training, and to credential surgeons as technically competent.

Simulators in their current form have been demonstrated to improve the operating room performance of surgical residents. Development of standardized training curricula remains an urgent and important agenda, particularly for minimal invasive surgery. An innovative and progressive approach, borrowing experiences from the field of aviation, can provide the foundation for the next century of surgical training, ensuring the quality of the product. As the technology develops, the way we practice will continue to evolve, to the benefit of physicians and patients.

INTRODUCTION

"See one, do one, teach one" is one way to paraphrase what has been the traditional teaching method of surgical education in the operating rooms of the United States for over a hundred years. This longstanding dogma is being increasingly challenged by legal and ethical concerns for patient safety, 80-h work week training restrictions, the cost of operating room time, and surgical complications. The emerging field of surgical simulation and training offers an opportunity to teach and practice laparoscopic skills outside of the operating room environment. There is enormous potential to address patient safety, risk management concerns, OR management, and work hours requirements with more efficient and effective training methods. The current goal of simulator training is to help trainees acquire the skills needed to perform complex minimally invasive surgical procedures prior to practicing them on living patients. For abdominal surgeons, minimally invasive surgery primarily involves laparoscopic techniques. The concept of minimally invasive surgery also applies to thoracic, gynecologic, head and neck surgery, orthopedics, or any other field where the size of the incisions and the degree of injury to the patient can be minimized with advanced techniques and equipment.

Novel methods of developing these skill sets are necessary because it is becoming increasingly clear that minimally invasive surgery requires a completely different skill set from the one used in traditional, open surgery[1-3]. Here spatial relationships and associated psychomotor skills are necessary to manipulate surgical instruments on a two-dimensional video screen in an actual three-dimensional operative field[4,5]. Developing ambidextrous skills in the small intraabdominal space, handicapped by instruments that have limited degree of freedom[6], while compensating for difficult camera angles and the fulcrum effect[7] often seems to be an overwhelming task for novices in the field of laparoscopic surgery. Unfortunately, even with the restrictions on work hours, we are now teaching residents at least two ways of performing each procedure, essentially doubling the skills that have to be learned over a five year residency.

Over the last few decades laparoscopic procedures have evolved from diagnostic laparoscopy[8] to advanced, more complex procedures. It is now routine for minimally invasive techniques to be used for bariatric, colonic, and advanced foregut procedures. These more advanced procedures require highly developed psychomotor skills. The surgeon's anatomic awareness must be developed in concert with the ability to safely achieve exposure and identify and control important structures. To assist with the critical components of many advanced operations, specialized equipment is available and commonly used. These instruments require a great deal of expertise in order to be used effectively and safely. Anecdotal reports have described significant complications related to the incorrect use of such equipment[9,10]. These developments have not gone unnoticed. The Food and Drug Administration (FDA) has now inserted itself into the training debate by requiring the development of a simulator-based training program (and that physicians demonstrate competence on the device) before approving a novel vascular stenting device. This ruling, in April of 2004, represents the first mandate by the FDA to require simulation training[11] without fully established or accepted data proving the validity of this approach. Similar requirements at the federal level for other advanced devices and skills sets are likely to follow. Payer-mandated and hospital-based credentialing for procedures and equipment is undoubtedly not far behind.

Surgeons who teach and train advanced procedures must now help develop methods of training and evaluation that truly establish procedural based competency. The tools are being developed and it is up to physician-educators to maximize their potential and set the standards for excellence. In a healthcare environment focused on evidence-based medicine and outcomes data, surgeons should set the standards rather than have them imposed by outside interests. The bar has already been set; the Accreditation Council for Graduate Medical Education (ACGME) now requires that program directors provide a statement attesting to the competency of every graduating Chief Surgical resident[12]. Many tools are now available to help with this task. The technology exists to continue to improve the realism and scope of training devices. Standardizing training routines and the effectively integrating systems for evaluation and credentialing is becoming a realistic goal. Below we will review currently available training and evaluation devices for laparoscopic surgery and discuss current future implications for training curricula for surgical residents.

BOX TRAINERS

This type of surgical simulator uses real surgical instruments and equipment including video monitors, cameras, and laparoscopes (Figure 1). It is an opaque box that approximates the size of the adult human abdominal cavity. Slits are prefabricated on the anterior surface of the box, through which trocars (access ports) may be placed. An attached flexible arm acts as a camera holder. Laparoscopic instruments are then inserted through the ports and into the box. Various targets are manipulated inside the box, with visual information relayed through a video source and display comparable to that used in most operating theatres. Tactile feedback is limited, as it is in laparoscopic surgery, by the instruments used. The use of real instruments and equipment is clearly the strength of these systems. However, the drills developed lack the face validity offered by other systems; the instruments may be real, but the "tissues" used clearly are not.

Figure 1 Typical Box trainer with real surgical instruments and equipment including a video monitor, camera, and laparoscope.

Many drills have been developed for use on these trainers. These drills traditionally involve movement and coordination exercises using peg boards or small objects such as beans or sugar cubes. Suturing skills are practiced using standard sutures and needles through plastic drains or other simulated tissue. Cadaveric tissue specimens can be placed inside the box to improve the realism of some tasks, particularly suturing. Practicing skills and tasks in the box trainer that resemble parts of real operations has been shown to stimulate the learning of psychomotor skills[13]. The physical sensory feedback conferred via the instruments in a box trainer is equivalent to that of surgery. The feel of the instruments on the surfaces of tissue, the pressure on closing a handle, and the compliance of compressed structures evokes feedback sensations called haptics[14]. This sensory feedback is one of the important attributes of the box trainer simulator.

Low acquisition cost is another key attribute of these devices. This makes the box trainer the most widely available training system. Its cost and availability have helped establish this type of simulator as one of the most validated systems in surgical training and evaluation. The use of these trainers has been well documented as part of the McGill Inanimate System for Training and Evaluation of Laparoscopic Skills (MISTELS)[15]. This system has been extensive studied and validated and has evolved into the Society of Gastrointestinal and Endoscopic Surgeons (SAGES) Fundamentals of Laparoscopic Surgery (FLS) course and evaluation system[1]. The FLS course combines an interactive CD-ROM educational tool that emphasizes basic principles of laparoscopic surgery with training drills for the box trainer.

The box trainer provides the backbone of the FLS evaluation tool. The FLS exam combines a written exam with a timed and scored laparoscopic skills evaluation in the box trainer. The tasks used for laparoscopic skill evaluation are peg transfer, pattern cutting, placement of a ligating loop, intracorporeal and extracorporeal knot

tying[15,16]. SAGES is currently recommending that all senior residents demonstrate laparoscopic skill competency by taking this exam. An examination fee is charged and, currently, the exam is only offered at six North American testing centers. The exam can also be taken at the yearly American College of Surgeons (ACS) Clinical Congress and the SAGES annual meeting.

The need to take a box trainer-based exam at a specialized test center demonstrates the major disadvantage of this system. The measurement of performance and objective evaluation of skills, or metrics, requires an independent teacher/evaluator[17]. For FLS, objective evaluation is performed with trained test proctors who time performance and apply penalties to the performance based on standardized criteria[18,19]. These criteria have not been published or made widely available, limiting the use of this validated evaluation system to only the approved test centers. As such, the FLS system is not useful as a routine evaluation tool for individual residency programs.

ANIMAL MODELS

These simulators involve the use of a live, anesthetized animal. This is the most realistic, non-patient environment for laparoscopic training. The abdomen in the porcine model is comparable in size to the adult human, with much of the foregut anatomy similar to that of the human[20]. Performing a cholecystectomy in this model provides tactile feedback in an environment where technical errors and complications such as gallbladder perforation or common bile duct injury can occur without consequence to a human patient[21]. Likewise, the canine model is frequently used to practice colon surgery. Animal models also enable trainees to work together as a team on an operation, providing additional insight into setting up an operative case.

As useful as animal labs are, there are many reasons why they are not fully integrated into most surgical curricula. Ethical issues regarding the use of animals for training and studies are not to be discounted, but for most programs the cost issues are prohibitive. There are substantial costs associated with maintaining specialized facilities and providing appropriate staff[22]. In some institutions, including our own, these facilities have been converted into an inanimate skills training lab.

VIRTUAL REALITY SIMULATORS

Virtual reality (VR) surgical simulators are the latest and most promising development in the area of surgical simulation. Sophisticated computer software has been developed in an attempt to replicate critical skills required for laparoscopic surgery and, in some cases, entire procedures. Many of these simulators provide a more believable practice environment than traditional box trainers, hence providing higher face validity. These trainers can be set up to record and save accurate and objective data for individual performance on specific tasks. The metrics of most devices can be customized, setting pass/fail criteria. These features present the opportunity for a trainee to practice independently on their own time as part of a structured curriculum.

The performance records make it possible for the educator to evaluate the performance of a laparoscopic task in an easy accessible format, to track the progress of an individual, and to compare a trainees results to peers and an expert standard[6,23,24]. Virtual reality simulators are also available for technically challenging tasks such as upper and lower endoscopy, endoscopic retrograde cholangiopancreatography (ERCP), hysteroscopy, and cystoscopy[24-28]. Objective measurements such as the time to complete a task, economy of hand motion, dexterity, and instrument path length can be easily used as assessment tools to document the progress of laparoscopic skills. The software of new VR simulators can be adjusted to create more difficult tasks or different levels of difficulty of the same task. Software updates have the potential to provide new drills or procedures which can be simulated using the same hardware. In an attempt to replicate the biggest advantage of box trainers and make the simulations as real as possible, several VR simulators now offer built in haptics, or force feedback, as an option on their systems. These systems, while intriguing, have not yet been shown to significantly contribute to training[29] but do significantly contribute to the cost of the devices.

Currently the following VR simulators are commercially available as training platforms for laparoscopic surgery: Procedicus MIST[30], Haptica ProMIS[31], METI SurgicalSIM, Simbionix Lap-Mentor and Surgical Science LapSim[32]. The two most widely used VR simulators are described in more detail below. The Procedicus MIST (Minimally Invasive Surgical Trainer), the most recent version of the MIST-VR (Mentice AB, Gothenburg, Sweden), uses a desktop computer with an interface similar to two laparoscopic instruments[7]. Twelve different tasks designed to improve hand-eye coordination and to stimulate psychomotor skills constitute the basis of this system. The complexity of these tasks ranges from basic grasping targets to transferring them between instruments to performing these tasks with an increased difficulty level, including the use of diathermy[33]. Recent updates to the system have incorporated suturing and knot tying drills. The MIST system remains the most extensively validated virtual reality training system. Seymour *et al*[34] demonstrated that surgical trainees who practiced a diathermy task to an expected level of performance performed faster and with fewer errors in excising the gallbladder off the liver.

The LapSim system (Surgical Science, Göteborg, Sweden) (Figure 2) also consists of laparoscopic instruments (VLI interface, Immersion Medical, Gaithersburg, MD) connected to a desktop computer (Figure 2). Similar to the MIST, the LapSim focuses on basic laparoscopic skills and suturing. Newer software modules incorporate complex diathermy and bowel manipulation. The LapSim system has different modules mimicking different tasks in the abdominal cavity focusing on camera navigation, instrument navigation, coordination, grasping, cutting, clip applying and more advanced modules like suturing and "running the small bowel." The simulator records data on multiple parameters for each module including "pass/fail," tissue damage and excess instrument motion[35,36]. All of the various data

sets are easily accessible and downloadable with the latest software release. This same software allows a teacher to set up specific drills and tasks as part of a curriculum for each trainee. All the metrics of this system are customizable. Likewise, performance exams can be tailored to skill level or individual requirements. Performance on the LapSim system has been demonstrated to distinguish expert and novice skill levels. This establishes construct validity for this system[36]. Specific skills transfer to the operating room has not yet been demonstrated.

FULL PROCEDURAL SIMULATORS

Full procedural simulators go beyond the basic laparoscopic training of their predecessors and are designed to recreate the specific anatomy allowing the practicing of all skills necessary to perform a particular operation. There are a variety of simulators available for endoscopic sinus surgery, bronchoscopy, endovascular surgery, gastrointestinal endoscopy, and laparoscopic procedures such as cholecystectomy and inguinal hernia repair[37-40]. Many of these simulators are part of a computer-based virtual reality platform. The hernia repair simulator is a physical model simulator[39].

The potential advantage of full procedure simulators over basic skills simulators is obvious. A well designed full procedural simulation should teach skills, anatomy, and the nuances of a complete surgical procedure in an environment where errors can be made without consequence. A full procedure simulator will not replace basic skills drills but will help bridge the gap to the operating room. For instance, in a laparoscopic total extraperitoneal hernia repair (TEP) even an experienced surgeon might encounter difficulties during repair due to the different approach and the unusual view of the inguinal anatomy. A full procedural TEP-simulator in the training of surgical residents resulted not only in improvement of operative performance but with their new understanding the residents were also more willing to recommend this procedure to patients requiring an inguinal hernia repair[39].

TRAINING OF SURGICAL RESIDENTS

In 1999 the Accreditation Council of Graduate Medical Education (ACGME) endorsed the concept of six core competences which every physician should demonstrate: Patient care, medical knowledge, practice-based learning and improvement, interpersonal and communication skills, professionalism, and systems-based practice[41]. These competencies are now the basis of individualized evaluations in most residency training programs. These competencies do not directly address the acquisition of the extensive technical skills required for qualified surgeons or other practitioners of technical specialties. However, these skills are included across most of the competencies and one goal of the ACGME initiative is for training programs to develop novel and accurate measures of these competencies in practice. In 2001, a survey confirmed that the vast majority of program directors in general surgery are in favor of surgical training outside the operating room to augment and complement hands-on experience with

Figure 2 The LapSim virtual reality system: The laparoscopic VLI interface with a PC-based desktop computer.

real patients[42]. The discrepancy between the demand for guidelines for laparoscopic simulator training for surgical residents and the application of these methods is telling. Curriculum development and validation of these methods is now of the utmost priority.

The first nationwide curriculum aiming to address this need is described in the FLS program[1]. This program is available for purchase by individual programs but is primarily designed as an independent evaluation tool. The FLS curriculum does not provide a mechanism for purchasing programs to internally evaluate resident performance or recommend distinct training guidelines. In addition, the FLS was deliberately designed to not include virtual reality computer simulators because of the acquisition costs involved and the lack of standardization and complete validation studies[1]. SAGES intends the FLS to become the standard for evaluation of basic laparoscopic skill acquisition but FLS may have limited long-term appeal if it does not incorporate virtual reality technology as it evolves.

To justify the steep acquisition costs, the validity and reliability of new teaching and evaluation tools must be supported by convincing studies before their widespread acceptance can be expected. Up until now, most skill evaluation for laparoscopic training and, in fact, surgery training in general, has been based on subjective evaluation and recommendation, a system that has been criticized for its lack of validity[43]. More recently simulation systems are being used in some training programs for the objective assessment of individual technical performance and as a supplement to the traditional evaluation[18,44-46]. An important aspect of a valid training system is that novices show an improvement of their skills over time. This has been demonstrated in multiple studies to be correct for the MISTELS, and more recently, for the VR-simulators[32,34,36,47]. Interestingly, some studies seem to support the work hours mandates. VR simulators have been used to demonstrate a decrease in psychomotor skills in residents subjected to sleep deprivation from a night of trauma call. Although the time to complete the tasks was unchanged, the number of errors was increased[48]. Another interesting study shows that alcohol intoxicated medical students perform worse in a VR simulator and regain their capabilities once sober[49]. The conclusions of these studies are quite serious and they rely on the

discriminative validity of the simulator used to assess differing performance.

Despite strong evidence supporting the use of surgical simulators in minimally invasive training of surgical residents, the learning curves to acquire psychomotor skills are relatively unknown within the field of surgical simulation. It is reasonable to think that "distributed practice" or frequent, repeated training provides longer term skill acquisition versus "massed practice", or intense short term training[50]. In a study evaluating the learning curve in laparoscopic skill training, different learning curves existed for surgeons with different laparoscopic backgrounds[24]. Much remains to be learned in determining the most efficient methods of expanding psychomotor skills. Contributing factors need to be identified and evaluated to determine the specific types of exercises that lead to improved performance in the operating room. The optimum practice time and requirements for continued practice need to be delineated.

MAINTENANCE OF SKILLS AND CREDENTIALING OF SURGEONS

As technologies and procedures evolve, newer techniques may require additional specialized skills. How do hospitals, practices, other physicians, and patients ensure that surgeons possess the requisite skills to perform these procedures safely and deal with intraoperative complications? How do we ensure the surgeons retain the skills to maintain a high level of practice? These questions surfaced before the advent of laparoscopic abdominal surgery and persist today with greater urgency because of the requirements and demands of modern practice[51]. The American Board of Surgery (ABS) is considering an objective skills proficiency examination to supplement the current knowledge-based and judgment assessments that comprise the surgery Qualifying and Certification exams. A completely objective, reproducible, and universally accepted evaluation tool is currently lacking, but it is likely that such a system will be developed and implemented in our practice lifetime. Similar to the aviation industry, a surgeon's skills at handling a difficult or emergent problem could be assessed. An exam could incorporate assessment of judgment and anatomic awareness. This exam could be employed for ongoing assessment of skill level at predefined intervals, much like the current recertification exam system. Patients entrust their lives to surgeons who rely on their judgment, visual and psychomotor skills. In this aspect, surgeons share common ground with airline pilots and it seems logical that surgeons, too, should be involved in an established method of acquiring and maintaining their high level technical skills. Surgical simulators will likely become an indispensable tool to these ends. The standards and performance expectations for such a system should be designed and validated by surgeons and surgeon-educators to ensure the exams are fair and reproducible.

The surgery of the future

Surgical simulators have the potential to be much more than tools for training and evaluation. As the technology continues to develop, the high standards required for appraisal and certification should allow future generations of simulators to also be used for operative planning. Complex operations will be planned and practiced in a virtual reality environment based on three dimensional imaging technologies imported into the device. This will be enabled by the same technology that allows us instant access to high-resolution computed tomography (CT) and magnetic resonance imaging (MRI) at our desktops today. After a surgeon has sufficiently practiced the virtual procedure, he would then perform the actual operation in the patient with significantly less operative morbidity, or perhaps with augmented-reality computer guidance[52]. The potential benefits to the patient are enormous.

In conclusion, surgical skills training is undergoing a dramatic transformation. Modern technology and training techniques, combined with external pressures and mandates are forcing surgeon-educators to rethink previously held principles. Simulators in their current form can facilitate the improvement of laparoscopic skills and operating room performance of surgical residents. Development of standardized training curricula for surgical residents remains an urgent and important agenda, particularly for minimal invasive surgery. An innovative and progressive approach, learning from the experiences of the field of aviation, can provide the foundation for the next century of surgical training. As the technology develops, the way we practice will continue to evolve, to the benefit of physicians and patients.

Abstract

Diverticular disease of the colon is primarily a disease of humans living in westernized and industrialized countries. Sixty percent of humans living in industrialized countries will develop colonic diverticula. It is rare before the age of 40, but more prone to complications when it occurs in the young. By age 80, over 65% of humans have colonic diverticula. The cause remains uncertain, but epidemiologic studies attribute it to dietary fiber deficiency. The cause of diverticulitis remains uncertain, but new observations and hypotheses suggest that it is due to chronic inflammation in the bowel wall. Standard medical therapies of bowel rest and antibiotics are still the recommended treatment. However, changing concepts and new therapies indicate that anti-inflammatory agents such as mesalamine and possibly probiotics may be helpful in shortening the course and perhaps preventing recurrences. Standard surgical treatment for perforation for severe acute disease has developed so that two-stage procedures are recommended. In addition, laparoscopic surgery has proven safe and may slowly become the technique of choice.

INTRODUCTION: EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Diverticulosis of the colon is an acquired condition that results from herniation of the mucosa through defects in the muscle layer. Epidemiological and anatomic studies have revealed that diverticular formation of the colon is primarily a disease that occurs in industrialized and westernized countries[1,2]. Approximately 60 percent of humans over age 60 living in westernized countries will develop colonic diverticula[3]. Postmortem studies reveal that it is rare prior to age 40, but increases with age so that one can estimate that by age 80 approximately 65 percent of patients have diverticula of the colon[4,5]. Of major importance is that approximately 25%-30% of these patients will develop a complication: diverticulitis, bleeding, or perforation[5,6]. It is now widely accepted that chronic diverticular formation occurs in westernized societies due to a lack of fiber in the diet[6,7]. The assumption is that decreased dietary fiber intake results in decreased intestinal contents and, hence, decreased size of the lumen, which results in the transmission of muscular contraction pressure to the wall of the colon rather than to the contents of the lumen. The result of increased force (pressure) on the wall is the formation of diverticula at the weakest point in the wall: the sites of penetration by blood vessels.

The cause of acute diverticulitis remains obscure. It has been speculated that obstruction at the mouth of the diverticulum results in diverticulitis, similar to appendicitis, but this is no longer the accepted theory, and some feel that chronic inflammation precedes clinical diverticulitis[6]. Descriptions of diverticular disease may be divided into two stages: (1) diverticular formation; and (2) diverticulitis with either pericolitis (microabcess), pericolic phlegmon, pericolic abscess, pelvic or intraabdominal abscess, and free perforation leading to bowel obstruction, fistulization, or bacteremia and septicemia[8]. In trying to assess the first stage of the disease, our preliminary evaluations identified that there is a microscopic colitis associated with mucosa of the colon adjacent to the diverticula[9]. Others have also identified asymptomatic diverticular inflammation at screening colonoscopy[10].

As illustrated in Figure 1, we hypothesized that diverticular disease is formed in the setting of low fiber

diet. Our studies have revealed that Connecticut diets are low in fiber[11]. Furthermore, our laboratories and others have established that the indigenous bacterial flora in subjects eating a low fiber diet is decreased and altered as compared to subjects eating high fiber[12,13]. Because of this alteration, we postulate a very mild colitis may occur and may progress to a more focal, acute diverticulitis. The sigmoid colon has the smallest diameter of the colon and a different motility pattern. It is the most common site of diverticular formation in western countries. Post mortem studies[4] of 90 colons revealed that 26% had numerous diverticula limited to the sigmoid, but 15% also had an occasional diverticulum of the sigmoid, 30% had sigmoid and descending colon diverticula with 16% scattered throughout and 4% in the sigmoid, descending and transverse. The cecum and ascending colon make up less than 5%. However, right-sided diverticula are definitely more common in humans in Asia and Hawaii[6]. Spastic motility disturbances are associated with the most common forms of the disease in western society. The sigmoid may develop a corrugated appearance. Initial pathology studies suspected an increase in smooth muscle cells, but pathologic studies clearly reveal there is, in fact, an increased deposition of elastin between the myocytes[14].

INFLAMMATORY BOWEL DISEASE AND DIVERTICULAR DISEASE

The simultaneous occurrence of both inflammatory bowel disease and diverticulosis was first discussed by Schmidt and colleagues in 1968[15]. The overlap of Inflammatory bowel disease (IBD) and diverticular disease is being recorded more commonly[16]. Much debate still exists as to whether there is increased prevalence when the two phenomena occur together. However, there clearly is an overlap syndrome in which clinicians must differentiate acute diverticulitis from chronic Crohn's disease[16,17]. Makapugay and colleagues described a picture of chronic colitis associated with diverticular disease. Their work indicated that this may be more prevalent than suspected[18]. Peppercorn described eight patients who were more than 60 years of age and presented with segmental chronic colitis associated with diverticula[19]. Imperiali and associates performed a large perspective study to identify IBD-like lesions[20]. They reviewed 5457 consecutive colonoscopies and found that 733, or 13.5%, had diverticula, but only 20 of these patients (0.36%) met all of the endoscopic criteria for segmental colitis as well. They indicated that the phenomenon was less common than previously suspected.The picture is still not clear, however, since none of the studies did mucosal biopsies to indicate whether there was a low level of inflammation in mucosa adjacent to diverticula that is endoscopically normal, as indicated in some pilot studies[9,20]. Clearly, more studies are needed to fully evaluate the significance of the association of these two phenomena.

THE CLINICAL PICTURE AND DIFFERENTIAL DIAGNOSIS

When colonic diverticula are discovered during an examination such as barium enema, CT scan or colonoscopy which were done for screening or other reasons, they are assumed to be asymptomatic. Since the incidence is so high, most of these patients are not treated. However, as many as 5%-20% of patients with diverticula of the colon are symptomatic and can develop complications[21]. The clinical presentation depends on the degree and extent of the inflammation and the degree of loss of normal bowel function due to sigmoid diverticular formation. The most common presentation is that of left-lower quadrant pain associated with either mild constipation or diarrhea. When the inflammation is severe or there is a micro-abscess or abscess formation, the pain will be more severe and can present as an acute abdomen. Determining the total white blood count is helpful. It is usually elevated when the inflammation is severe. Depending on the severity, there may or may not be elevated temperature. If there is true perforation, the abdomen is much more tender with possible rebound, and a picture of peritonitis with a markedly elevated white blood count and perhaps a toxic-appearing patient. Because of the variable position of the colon and differing anatomy in different individuals, the pain might be located more on the right side or in the pelvis or even in the upper quadrants. When this occurs, a differential diagnosis between gynecologic disease or other diseases attributed to the abdomen must be considered. Radiologic findings are extremely helpful. Because of the possibility of perforation, a barium enema is no longer the preferred procedure. Computerized tomography (CT) scanning is now accepted as the most helpful diagnostic procedure. Areas of inflammation and the associated mesentery soft tissue are identifiable as well as abscesses. It must be kept in mind that it takes time for an abscess to form, and it might be missed on the initial CT examination. A study of 420 patients with left-sided diverticulitis proven at surgery compared CT to contrast enema. The CT was superior, was more sensitive, and was significantly better in grading the severity of inflammation[22]. CT has also proven most helpful in the management of complicated

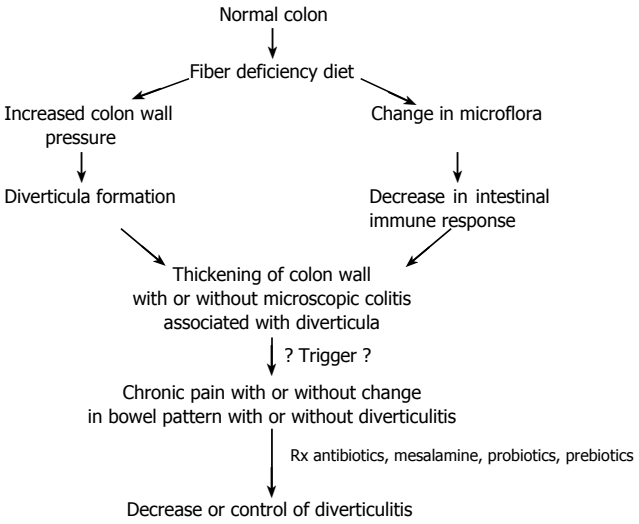

Figure 1 Pathophysiologic development of diverticulitis and proposed therapy.

diverticulitis. It is shown in correlated studies that once an abscess is present, there is a high risk of failure from non-operative management. However, when management is in question, CT is of great help in defining the course of treatment. Furthermore, CT can be very helpful in guiding percutaneous drainage of abscess in order to prevent or delay surgery in selective cases[23].

Colonoscopy is used judiciously when there are any suspicions of very acute inflammation. Once that has subsided, it can be helpful in excluding a suspected malignancy or overlap inflammatory bowel disease picture.

COMPLICATIONS

Perforations and diverticular hemorrhage are the major complications of diverticulosis. Perforation has to be treated acutely. However, when there is perforation into adjacent organs such as the bladder or vagina, appropriate gynecologic and urologic evaluations are necessary. Those patients are treated medically and then surgically if necessary. Diverticular hemorrhage is the most common cause of colonic bleeding in western societies. It is estimated that 3%-5% of patients with diverticula will have severe blood loss at some point. Diagnosis of the site of ongoing diverticular bleeding is important and may be difficult. Radio-isotope studies, colonoscopy, and arteriography, diagnostic and/or therapeutic may be helpful, but barium contrast enemas are of no help[21-24].

MEDICAL THERAPY

Simple, uncomplicated diverticular disease often requires no therapy. Many clinicians advise a high fiber diet, but the evidence that this is helpful in preventing diverticulitis is not yet clear. Once mild symptoms develop, clinicians may prescribe high fiber diets, plus anticholinergic drugs to theoretically relax the bowel. Dicyclomine is used most often. Once there is any sign of infection, such as elevated white blood count or low-grade temperature, antibiotics are indicated. Depending on the institution and the location, broad spectrum antibiotics are used since the colonic flora is a combination of aerobes and anaerobes. If symptoms are severe, combinations of ciprofloxin and gentamicin or metronidazole are recommended, or amoxicillin/clavulanic acid, or sulfamethoxazole/trimethoprim. Treatment is usually anywhere from 1-2 wk with careful monitoring and reevaluation. Diet is always of concern in these patients. When there are acute symptoms, the bowel is rested and low fiber diets are recommended. However, once recovery occurs then high fiber diets are recommended.

Medical treatment is changing. Based on the theory that there is chronic inflammation in the bowel wall, even between bouts of acute diverticulitis, enough interest was created to evaluate the use of anti-inflammatory agents. There are now four groups in Italy that have reported favorable results with the use of mesalamine alone or in combination with antibiotics. Evaluation of these studies[26-31] clearly reveals that mesalamine decreases the length of the course of the diverticulitis, improves management with the use of concomitant antibiotics, has a prolonged effect and also appears to decrease the incidence of recurrent attacks. From these studies, it appears that mesalamine is safe and holds promise as a new therapy in the treatment of acute and chronic diverticulitis.

The theory that inflammation is chronic in the formation of diverticulitis also raises the hypothesis that probiotics would stimulate the immune process and possibly be effective. Only one paper has appeared on this subject[32]. The authors compared the use of an anti-microbial agent plus an absorbent to the same regimen supplemented with non-pathogenic *Escherichia Coli*, Nissle strain. They found that the average remission for the antibiotic regime was 2.43 mo as compared to 14.1 mo for the antibiotic plus probiotic regimen. This is only one study, but the concept is valid and these findings indicate other studies are in order.

SURGICAL TREATMENT

Once medical treatment fails or when the presentation is one of acute abdominal perforation, surgery becomes essential. Standard surgical treatment today may include a longer period of observation, or percutaneous drainage of abscess, but may finally require surgical resection. Three-stage operations are no longer the treatment of choice. The two stage procedure where there is first a colostomy and then later closure of the colostomy after a 4-12 wk period of observation are preferred[21,24,33].

Most guidelines treating elective or non-urgent cases recommend that the resection must remove all thickened diseased colon, but not necessarily all of the proximal diverticulum-bearing colon. It may be acceptable to retain proximal diverticular colon as long as the remaining bowel is not hypertrophied[24]. In almost all cases, all of the sigmoid colon should be removed. In urgent and emergent cases, the resection and diversion are required. In rare cases, it may be attempted in a one-stage procedure.

With the advent of laparoscopic procedures, sigmoid resection may benefit from the approach[34]. Laparoscopic surgery for diverticular disease can be done safely with low conversion and complication rates when performed properly in select patients[34]. When diverticular hemorrhage does not stop, surgery may be indicated. At times it may be emergent. Segmental resection is certainly preferred, but hemicolectomy is often necessary. The operative mortality rates are high, between 9%-11%, and largely depend on co-morbid conditions and the age of the patient. When it is difficult to identify the exact site, morbidity and mortality rates may increase to as high as 35%. Fortunately, most cases of bleeding stop spontaneously, but when surgery is required, the site of bleeding must be identified. On the rare occasion when it cannot, then total colectomy becomes necessary.

Finally, diverticulitis is unusual in young people, especially those under 40. However, when it does occur in this age group, it appears to be virulent and as many as 2/3 of these patients require surgical intervention[21].

Abstract

Calcium is an essential ion in both marine and terrestrial organisms, where it plays a crucial role in processes ranging from the formation and maintenance of the skeleton to the regulation of neuronal function. The Ca^{2+} balance is maintained by three organ systems, including the gastrointestinal tract, bone and kidney.

Since first being cloned in 1993 the Ca^{2+}-sensing receptor has been expressed along the entire gastrointestinal tract, until now the exact function is only partly elucidated. As of this date it still remains to be determined if the Ca^{2+}-sensing receptor is involved in calcium handling by the gastrointestinal tract. However, there are few studies showing physiological effects of the Ca^{2+}-sensing receptor on gastric acid secretion and fluid transport in the colon. In addition, polyamines and amino acids have been shown to activate the Ca^{2+}-sensing receptor and also act as allosteric modifiers to signal nutrient availability to intestinal epithelial cells. Activation of the colonic Ca^{2+}-sensing receptor can abrogate cyclic nucleotide-mediated fluid secretion suggesting a role of the receptor in modifying secretory diarrheas like cholera. For many cell types changes in extracellular Ca^{2+} concentration can switch the cellular behavior from proliferation to terminal differentiation or quiescence. As cancer remains predominantly a disease of disordered balance between proliferation, termination and apoptosis, disruption in the function of the Ca^{2+}-sensing receptor may contribute to the progression of neoplastic disease. Loss of the growth suppressing effects of elevated extracellular Ca^{2+} have been demonstrated in colon carcinoma, and have been correlated with changes in the level of CaSR expression.

INTRODUCTION

The gastrointestinal tract is in charge of handling the complex issues of nutrient, electrolyte and fluid absorption and the secretion of excess electrolytes and fluids. Body calcium homeostasis is regulated by the PTH and vitamin D feedback loop; additionally calcium plays a key role in many other mechanisms like intracellular signaling, cell differentiation, bone metabolism, *etc*. After identifying the calcium sensing receptor in several different tissues many studies were undertaken to characterize the role of extracellular calcium as a first messenger and the receptor as a calcium sensor of the cell. Ca^{2+}-sensing receptor transcripts and/or protein are expressed in the gastrointestinal tracts of fish[1], birds[2], amphibia[3,4] and mammals[5-10] including the human[5,11,12]. Tracings of the expression of the receptor in the gastrointestinal tract shows that the receptor goes back in evolution at least as far as cartilaginous fish (elasmobranchs), e.g., the dogfish shark[1]. In both cartilaginous and bony fish, the Ca^{2+}-sensing receptor has been shown to be expressed on apical surfaces of stomach and intestine[1]. More recent evidence suggests that the Ca^{2+}-sensing receptor may have evolved in the early marine environment in order to support osmo-adaptation. This notion is supported by the more general expression of the Ca^{2+}-sensing receptor in many other tissues outside the gastrointestinal tract that are involved in mono-and divalent ion transport both into and out of fish that live in a seawater environment that is rich in divalent minerals and sodium chloride[1,13]. This theme of the Ca^{2+}-sensing receptor linking divalent and monovalent metabolism is echoed in mammals (e.g., effects of the receptor on fluid transport by the colon; discussed later in this review).

In the amphibian, *Necturus maculosus*, Ca^{2+}-sensing receptor expression was detected on the basal surface of gastric epithelial cells[3]. Wherease in contrast the frog stomach, shows expression of the Ca^{2+}-sensing receptor

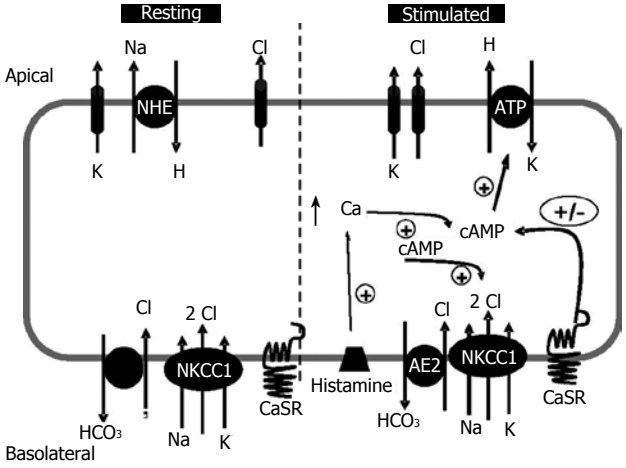

Figure 1 Simplified model of the parietal cell showing the current mechanisms involved in acid secretion in comparison to a resting cell. The Ca^{2+}-sensing receptor (CaSR) and the histamine receptor are located on the basolateral membrane. HCl secretion is mediated by H^+ extrusion *via* the H^+,K^+-ATPase coupled with Cl^- secretion *via* an apical channel. Activation of the CaSR causes acid secretion *via* the H^+, K^+-ATPase.

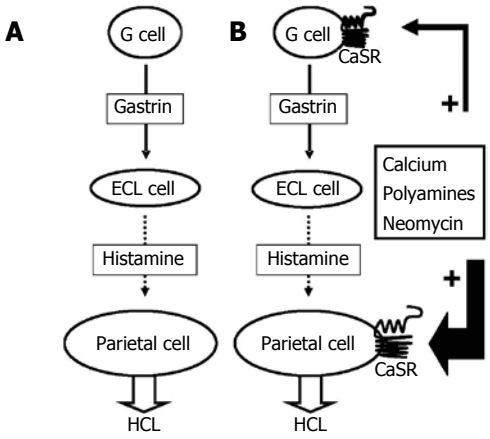

Figure 2 Schematic of acid secretion. **A**: Classically defined pathway of acid secretion: Gastrin released from the G cell binds to receptors on the ECL cell causing histamine release from the ECL cell. The histamine binds to receptors on the parietal cell and stimulates proton efflux; **B**: Modified model of acid secretion involving a functional CaSR on the basolateral membrane of both the G cell and parietal cell. Acid secretion can be activated directly by the CaSR on the parietal cell or *via* the G cell pathway.

on the apical membranes of acid-secreting oxyntic cells[4]. In the chicken, *Gallus domesticus*, the receptor was detected in the duodenum[2]. In mammals, a more complete exploration of Ca^{2+}-sensing receptor expression along the gastrointestinal tract has been performed[5-10,12]. Receptor transcripts and/or protein have been detected in: stomach, small intestinal, and colonic mucosal epithelia, as well as the underlying neural plexuses of Meissner and Auerbach. In addition, Ca^{2+}-sensing receptor expression has also been shown in several human intestinal cell lines (T84, HT-29, Caco-2, FET, SW480, MOSER and CBS;[8,14,15] in addition to primary cultures of human gastric mucosa and human parietal cells[11,16,17].

In mammalian stomach, the Ca^{2+}-sensing receptor has been identified on both apical and basolateral membranes of human G-cells (gastrin secreting cells;[16,17]) and mucous secreting cells[11] and on the basolateral membranes of parietal cells[4,6,18]. In small intestine, both apical and basolateral membranes of villus cells express the Ca^{2+}-sensing receptor[7]. In rat colon the receptor is expressed on both apical and basolateral membranes of surface and crypt epithelial cells[5,7]. A similar pattern of Ca^{2+}-sensing receptor immunostaining in rat was observed in both proximal and distal colon[5]. In the human large intestine, Ca^{2+}-sensing receptor has also been identified on both apical and basolateral membranes of crypts as well as in certain enteroendocrine cells at the base of crypts[7,12].

CALCIUM IN THE STOMACH

Overview

To produce the large quantities of 0.16 mol/L hydrochloric acid required for digestion of ingested food, the mammalian stomach has employed a complex series of neuronal, hormonal and/or paracrine[19]/autocrine feedback regulatory mechanisms[19-22] allowing for the continued production of acid. A model of acid secretion by the parietal cell is shown in Figure 1 summarizing data from many different studies[19,21-24]. Following stimulation, the H^+, K^+-ATPase (proton pump) is trafficked to the apical surface and is responsible for vectorial transport of protons[20-22,25-27]. Once at the membrane protons combine with secreted Cl^- ions to produce the concentrated acid. With the generation of a proton gradient enzymes such as pepsinogen are secreted into the lumen of the gland where they combine with the secreted acid and move from the gland into the interior of the stomach providing an effective solution that is capable of digesting proteins and processing them for amino acid or peptide reabsorption in the intestine.

The common model of acid secretion (Figures 1 and 2) involves stimulation of the gastric glands *via* either neuronal or hormonal pathways which results in the release of gastrin, which in turn acts directly on the endocrine (ECL) cells of the gland. Following stimulation ECL cells secrete histamine causing the parietal cell to insert proton pumps (H^+, K^+-ATPase) into the apical pole of the gland[28] which occurs *via* an active tubular-vesicular insertion mechanism that is used to transport H^+, K^+-ATPases into the apical region of the parietal cell[26]. In conjunction with pump insertion activation of an apical K^+ channel(s) provides K^+ ions that act as the counter ion and exchange with H^+ on the pump[20,21,23,29] (Figure 1) to sustain acid secretion. In addition to cation secretion an additional action of histamine release is to activate and/or insert Cl^- channels into the apical membranes of the parietal cells which mediate Cl^- secretion that accompanies H^+ secretion[20,30,31] (Figure 1). Thus the entire acid secretory process relies on: (1) insertion of H^+, K^+-ATPase into the apical surface for H^+ secretion; (2) concurrent activation of apical Cl^- channels mediating Cl^- secretion which allows for the formation of HCl; and (3) activation of apical K^+ channel(s) for K^+ recycling to the lumen of the gland and thereby providing the counter cation K^+ to maintain H^+, K^+-ATPase activity.

Loss of feedback control of acid (HCl) secretion in the stomach causes symptoms ranging from mild heartburn, to lesions and ulcerations of the gastric mucosa[19,32]. Left

untreated gastric ulcers can lead to abdominal bleeding, hyperplasia of cells, and potentially tumor formation. The complexity of the tissue due to the mixed collection of cell types, as well an additional layer of surface cells (secreting a protective mucous gel layer rich in bicarbonate) has prevented a complete analysis of glandular cell function and the associated feedback loops.

Role of the Ca^{2+}-sensing receptor in acid secretion

Following hormonal or neuronal stimulation there is a transient rise in intracellular Ca^{2+} concurrent with the onset of acid secretion in the gastric gland[19,20,22,33], this process has been associated with activation of pump translocation to the apical pole of the cell , and the associated secretion of acid[34]. Following this stimulatory period intracellular Ca^{2+} levels fall, and acid secretion diminishes to basal levels.

Activation of basolateral CaSR in *Necturus* gastric antrum by elevating extracellular Ca^{2+}, or using other receptor agonists like NPS-467, or neomycin resulted in a rapid hyperpolarization and a decrease in resistance of the basolateral membrane. Circuit analysis of these data suggested that these electrophysiological effects were due to activation of a basolateral K^+ channel(s)[3]. In rat stomach elevating extracellular Ca^{2+} leads to a rapid increase in intracellular Ca^{2+} in parietal cells which can occur in the absence of conventional extracellular secretagogues (e.g. histamine;[6]). To confirm that this rise in Ca^{2+} was associated with activation of the receptor, studies have been conducted using either the potent agonist Gd^{3+}, or addition of an allosteric modifier of the receptor such as the amino acid phenylalanine which both lead to an increase in the rate of acid secretion through the apical H^+, K^+-ATPase in the absence of secretagogues[18,35]. Inactivation of the Ca^{2+}-sensing receptor by reducing extracellular divalent minerals can also down regulate acid secretion even in the presence of potent secretagogues like histamine[18]. From the results of these studies it has now become apparent that the Ca^{2+}-sensing receptor (CaSR) plays an important regulatory role in acid secretion in mammalian gastric glands.

In addition to the animal studies on gastric glands, the CaSR has also been identified in human gastric tissues[11,16,17,36-38]. In the mucous epithelial cells, activation of the receptor results in a rapid rise in intracellular Ca^{2+} as well as a proliferative response when the cells were placed in culture[11]. In G cells, stimulation of the receptor results in gastrin release[16] accompanied by activation of phospholipase C[16] and an increase in intracellular Ca^{2+}[16,17]. The associated histamine release due to CaSR-mediated secretion of gastrin by G cells could account for rebound acid secretion that occurs following exposure to calcium containing antacids. All of these data are consistent with the scheme that the CaSR in the stomach could play an important role in both acid secretion and in mucosal repair. Activation of the receptor may act to modulate the rates of acid secretion in response to total body calcium homeostasis. Should there be a deficiency in calcium receptor activation would increase acid secretion, or prolong acid secretion, thereby allow maximal ionization of calcium from ingested foodstuffs and produce increased calcium delivery to the intestine. Increased intestinal calcium will activate the CaSR on the apical surface of the cells and result in inhibition of fluid secretion and enhanced absorption of the delivered Ca^{2+}. Over time as serum calcium rises, gastric CaSR would either become internalized, or deactivated, leading to a down regulation in acid secretion. In patients with Zollinger-Ellison syndrome (ZES; characterized by ulcer disease of the upper gastrointestinal tract, increased gastrin secretion, and non-β-cell tumors of the pancreas, i.e., gastrinomas), gastrin secretion and serum levels appear to correlate with the activity of the frequently associated hyperparathyroidism. This result would be consistent with gastrin secretion paralleling high PTH-driven elevations in plasma Ca^{2+}. Significant albeit variable, CaSR expression has been detected in human gastrinomas[37,38], suggesting that the receptor could mediate the effect of extracellular Ca^{2+} on gastrin secretion. Consistent with this explanation, activation of CaSR by raising extracellular Ca^{2+} increased rapidly intracellular Ca^{2+} that was not altered by the Ca^{2+} channel blocker, nifedipine[38].

CALCIUM IN THE INTESTINE

Overview

The Ca^{2+}-sensing receptor is expressed in epithelial cells along the entire small and large intestine, but only in colon has the receptor been studied in sufficient detail to permit comment on potential roles in normal intestinal function, in diarrheal states, and the effect of oral Ca^{2+} intake on reducing the risk of colon cancer. The expression of CaSR in nerve plexi involved in smooth muscle function and coordination, however, suggests a potential role in modulating intestinal motility. The latter could be important in coordinating food delivery (Ca^{2+}, amino acids, polyamines) and modulating intestinal motility to maximize nutrient absorption. In addition, an effect of CaSR activation on intestinal motility may be one factor contributing to the constipation that is associated with hypercalcemic states.

Calcium modulates fluid transport in the colon

The primary function of the colon is to both absorb and secrete fluid and thereby maintain normal salt and water homeostasis. The colon is a complex epithelium that consists of both extensive invaginations of the surface which are designated as crypts which make up approximately 90% of the epithelial mass and the remaining 10% being surface cells. Although earlier studies suggested that only surface cells absorb and only crypt cells secrete fluid into the lumen of the colon, recent evidence has established that both surface and crypt cells absorb and secrete fluid (see review for details;[39]). As over 90% of the colonic epithelial surface area is occupied by invaginations or crypts, these structures constitute the major functional unit of the colonic epithelium[40, 41].

The direction of net fluid transport is determined by the relative magnitudes of the absorptive and secretory fluxes. Under basal conditions (absence of hormones, drugs or other factors), net fluid transport by crypts is absorptive[42]. However, colonic crypts alter the direction

of net fluid transport to secretion upon exposure to cell permeable cyclic AMP analogues, (forskolin, or other agents that activate adenylate cyclase), or modulators of cyclic AMP metabolism such as phosphodiesterase (PDE) inhibitors[42]. Addition of cyclic AMP-generating hormones/factors like 5-hydroxytryptophan or prostaglandin E2 to the blood/interstitial surface of the crypt will also increases fluid secretion by colonic crypts[40,41]. Modulation of these fluid transport processes in the colon by cyclic AMP can result in profound fluid and electrolyte losses with associated secretory diarrheas, as is the case during cholera exposure (Figure 3)[40].

Some previous physiological studies in rats, measuring Ca^{2+} fluxes in isolated colonic mucosa suggested that the colon had the capacity to respond to changes in extracellular Ca^{2+}. For example, the colon, as is true for the small intestine, can absorb and secrete Ca^{2+} in response to changes in extracellular Ca^{2+} as well as in levels of 1, 25-dihydroxy vitamin D3[43-45]. These latter observations indicate that colonic mucosal epithelium *per se* is equipped with a Ca^{2+}-sensing mechanism. Recent studies have suggested that this divalent mineral sensing mechanism in colonic epithelia is the CaSR, based on immunolocalization of the receptor in apical and basolateral membranes and receptor function assays[3,8,9,12].

The activation of colonic CaSR by: Ca^{2+}, Gd^{3+} or neomycin, leads to rapid rises in intracellular Ca^{2+} in both surface and crypt cells[5]. The elevation in intracellular Ca^{2+} occurs within a few seconds, consistent with activation of the phosphatidylinositolphospholipase C-inositol 1, 4, 5-trisphosphate (PI-PLC-IP3) pathway by G protein-coupled cell membrane receptors. Ca^{2+}-sensing receptor-mediated increases in intracellular Ca^{2+} can be prevented by pre-treatment with U-73122, a specific inhibitor of phosphatidylinositolphospholipase C. This effect of PLC inhibition demonstrated that intracellular Ca^{2+} transients induced by Ca^{2+}-sensing receptor agonists were not the result of altered entry of extracellular Ca^{2+} into colonic epithelial cells but were rather due to receptor-mediated activation of PI-PLC. The receptor-mediated increase in intracellular Ca^{2+} concentration in colon was shown to be due to the release of Ca^{2+} from thapsigargin-sensitive cell stores[5].

The role of CaSR in modulating colonic fluid movement has been examined in isolated perfused colonic crypts using an in vitro micro-perfusion technique[5,46]. Under basal conditions (i.e., in the absence of forskolin, or other secretagogues), crypts exhibit net fluid absorption[47]. Following exposure to forskolin a net fluid secretion occurs[47]. Activation of either luminal or basolateral CaSR by Ca^{2+} and/or spermine reverses the forskolin-stimulated fluid secretion[5,46]. Further studies will be necessary to fully define the mechanism of CaSR effects on cyclic AMP-mediated fluid secretion. However, based on information recently obtained from the effects of CaSR activation on vasopressin-stimulated increases in cyclic AMP in the kidney thick ascending limb of Henle[48,49], we postulate CaSR-mediated elevation in intracellular Ca^{2+} would activate Ca^{2+}/calmodulin-sensitive phosphodiesterases that would metabolize intracellular cyclic AMP, and thereby abrogate fluid secretion (Figure 3).

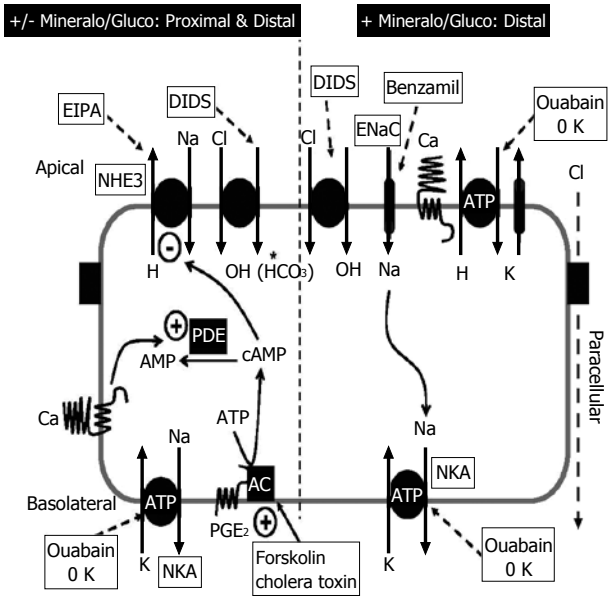

Figure 3 Cell model of proximal and distal colon. Shown are the known transport proteins in absence or presence of mineralocorticoid stimulation and their known inhibitors.

Increasing the levels of calcium on either the apical or basolateral membrane of the intact colon in Ussing chambers or in isolated perfused crypts leads to a decrease in fluid secretion. This decrease remains even in the presence of potent secretagogues such as forskolin; in fact there is enhanced absorption of fluid in the continued presence of potent secretagogues as long as the receptor remains activated[5,6]. In disease states or infectious states, fluid and electrolyte secretion can occur at pronounced levels and can cause dehydration and potentially death. By modulating the CaSR through increased delivery of calcium, or calcimimetic agents to the receptor, it appears possible that secretion could be stopped. This aspect of the CaSR could serve as an important new therapeutic target to modulate secretion and absorption of electrolytes along the intestine and combat secretory disease states.

POTENTIAL ROLES OF THE CaSR IN INTESTINAL EPITHELIAL CELL GROWTH AND DIFFERENTIATION AND NUTRIENT SENSING

Overview

The epithelium of the colon and the small intestine remains in a constant state of renewal. In the colon cells proliferate and become differentiated as they migrate from the base of the crypt towards the surface. Therefore cells at the base of the crypt are highly proliferative but less differentiated, whereas cells along the surface of the colon are highly differentiated and are in a non-proliferative state. Alterations of this tightly regulated process may lead to the development of hyperplastic events (polyps) and/or tumors. A potential role for the Ca^{2+}-sensing receptor in colonic epithelial cell proliferation, differentiation and development is suggested by the observations that receptor

activation reduces proliferation and induces differentiation of a variety of different cell types in addition to the intestinal epithelium. For example, activation of CaSR enhances cell differentiation in both mouse[50,51] and human[52,53] keratinocytes[54]. Moreover, activation of the Ca^{2+}-sensing receptor in other cells modulates proliferation and inhibits apoptosis[55-57].

The Ca^{2+}-sensing receptor responds not only to changes in divalent minerals but also to changes in organic nutrients (such as polyamines)[58] and amino acids[59,60]. Recently this effect was demonstrated in isolated rat gastric glands, whereby stimulation of the Ca^{2+}-sensing receptor by L-amino acids induced acid secretion in vitro[35]. In addition to activation of CaSR, there is evidence that certain amino acids can stimulate gastric acid secretion *via* the system L-amino acid transporter [Kirchhoff] which illustrates an increased layer of complexity in the process of acid secretion. Organic nutrients function primarily by altering the EC_{50} of the CaSR for Ca^{2+}, although direct agonist effects have been demonstrated. These nutrients could potentially alter the conformational structure of the Ca^{2+}-sensing receptor thereby enhancing the affinity for divalent ions and attenuating the cellular effects of receptor stimulation. The potential roles for these nutrients in coordinating protein and divalent mineral metabolism and in providing information on nutrient delivery to intestinal cells will be discussed in the following section.

Role in intestinal cell growth and differentiation

In small rodents such as rats and mice , dietary polyamine intake plays an essential role for normal gastrointestinal tract cell growth and development[61-65]. In humans, the postulated mechanisms for the pro-differentiation and anti-cancer effects of dietary Ca^{2+}/polyamines include: (1) formation of insoluble salts of Ca^{2+} with otherwise tumorigenic fatty acids and bile salts; and (2) modulation of the rates and/or fates of biologically active molecules such as nucleic acids, proteins and phospholipids[66-69]. The presence of CaSR on the plasma membranes of both surface and crypt epithelial cells raises the intriguing possibility that this receptor could mediate some of the dietary effects of Ca^{2+}, polyamines, and other nutrients on tissue modeling of intestinal epithelia.

Increases in polyamines, specifically spermine, results in the generation of IP3, raises intracellular Ca^{2+}, and modulates forskolin-stimulated fluid secretion, all consistent with activation of the colonic epithelial CaSR[46]. Polyamine (spermine > spermidine > putrescine)-mediated augmentation of intracellular IP3 and Ca^{2+} accumulation requires the presence of, and is potentiated by, extracellular Ca^{2+}. The EC_{50} for $Ca^{2+}{}_o$- mediated activation of the CaSR was also reduced by polyamines[46]. These results demonstrate that the colonic epithelial CaSR also positively responds to polyamines.

In cultured intestinal cell lines, CaSR has been shown to increase E-cadherin and reduce β-catenin production which are markers for intestinal differentiation[14,70,71]. In Caco-2 cells expressing the CaSR activation of this receptor by extracellular Ca^{2+} increases thymidine incorporation into DNA as a marker of cell proliferation[72]. Low concentrations of extracellular Ca^{2+} cause a PKC-dependent increase in c-*myc* protooncogene expression in Caco-2 cells and this pro-proliferative effect is abrogated by activation of the CaSR by increasing concentrations of extracellular Ca^{2+}[15]. The CaSR in keratinocytes and certain other cells has been shown to alter proliferation/differentiation and to modulate the activities of MAP and tyrosine kinases associated with cell proliferation[50-52,57,72-77]. All of these data, when taken together, support a potential role for the CaSR as a modulator of cell proliferation and differentiation in intestinal epithelial cells.

Role in colon cancer

Ingestion of high dietary Ca^{2+} promotes colonic mucosal epithelial cell differentiation, decreases cell growth, and reduces the risk for development of colorectal cancer (see recent summaries[78,79] and[14,15,77,80,81] and review by Karen Roland Cell Calcium special issue). Cancer of the colon and rectum is the second most frequently diagnosed malignancy in the United States in addition to being the second most common cause of cancer-related death (>56 000 American deaths this year). Observations that demonstrate that increases in dietary calcium reduce the risk of developing colon adenomas are noteworthy. Specifically, by increasing dietary calcium intake there has been: (1) a reduced risk for colorectal cancer by three-fold in men consuming 1400-1500 mg calcium per day, 19 year prospective study of men working at the Western Electric Co., Chicago[82]; (2) a significant reduction in colonic crypt cell proliferation and enhanced markers of cell differentiation in human subjects at increased risk for colon cancer[81,83,84]; (3) a reduced risk of colorectal adenomas in humans[85] also see[86-89]; (4) decrease in the incidence and number of carcinogen-induced colonic tumors in virtually all studies in rats, see[90] for a review; (5) significantly reduced recurrence of colorectal adenomas in a randomized, double-blind trial of 930 subjects[85]; (6) long term calcium supplements significantly suppressed colonic cell proliferation in adenoma patients[80]. Activation of the CaSR in human carcinoma cell lines by raising extracellular Ca^{2+} promotes E-cadherin expression while suppressing β-catenin activation[14], both markers of cell differentiation[70,71]. In addition, there has also been a correlation between CaSR expression and the stage of differentiation n human colon tumors[14]. These observations provide a significant body of evidence that increases in dietary Ca^{2+} reduce the risk of colon cancer and are mediated by activation of the CaSR.

Role of the receptor as a nutrient sensor

The ability of the CaSR to be activated by l-amino acids has been suggested as a link between protein and calcium metabolism[60]. This was suggested by the direct relationship between dietary protein intake and renal Ca^{2+} excretion[91,92]. A diet high in protein acutely increased urinary Ca^{2+} excretion[91,92] and a low protein intake induces elevated parathyroid hormone levels[93]. The increased urinary Ca^{2+} excretion associated with high protein intake appears due to elevations in intestinal Ca^{2+} absorption[91-93], although this has not been a universal finding[94]. As discussed in previous sections of this review, activation of the CaSR by Ca^{2+} stimulates gastric acid secretion, which

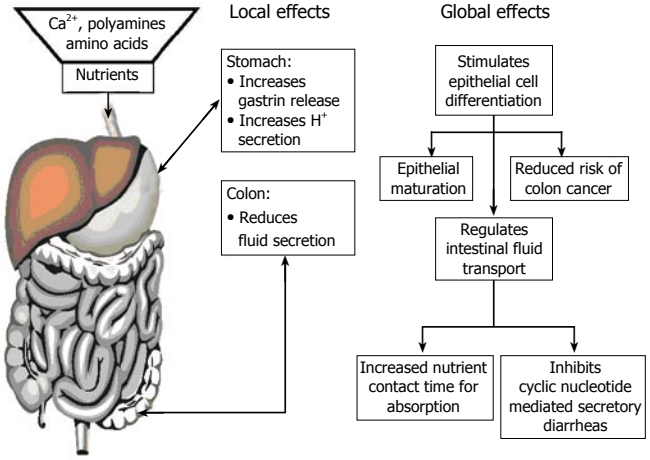

Figure 4 Current theory of roles for the Ca^{2+}-sensing receptor (CaSR) in the gastrointestinal tract.

in turn would promote acid digestion of proteins (together with peptidases). The release of l-amino acids would then promote Ca^{2+} absorption in small and large intestine by their synergistic activation of the Ca^{2+}-sensing receptor.

In summary, Figure 4 presents a current summary of the potential roles of the CaSR in gastrointestinal biology. Because of the unique properties of the CaSR in recognizing and responding to extracellular $Ca^{2+}{}_o$ and nutrients, this receptor presents a potential mechanism linking dietary metabolism (i.e., food digestion and nutrient absorption) to: (1) nutrient availability for epithelial growth and differentiation; and (2) protein and divalent mineral metabolism; (3) dietary Ca^{2+} intake and the associated reduction in risk of colon cancer; and (4) nutrient, salt and fluid homeostasis. In addition, the potential effects of nutrient activation of the CaSR on intestinal motility, coupled to the demonstrated reduction in fluid secretion, would increase nutrient-epithelial contact time and thereby enhance absorption. Finally, the potent ability of CaSR agonists to abrogate cyclic AMP-mediated fluid secretion by the colon has important implications for development of novel oral therapies of cyclic nucleotide dependent diarrheas like cholera.

Abstract

Esophageal and gastric cancers are both common and deadly. Patients present most often after disease progression and survival is therefore poor. Due to demographic variability and recent changes in disease incidence, much emphasis has been placed on studying risk factors for both esophageal and gastric cancers. However, with increasing understanding of these diseases, low survival rates persist and continued intensive studies are necessary to optimize treatment plans. This review article discusses updates in the evolving epidemiology, clinical presentation, risk factors, and diagnostic and treatment modalities of esophageal and gastric cancers.

ESOPHAGEAL CANCER

Epidemiology

Overall, esophageal cancer contributes to 1% of all cancers diagnosed in the United States. Its prevalence in other geographical locations varies and higher incidences are seen in Asia, Africa, and Iran. However, the collective incidence continues to rise[1], and most of this increase is due to the increasing incidence of adenocarcinoma (AC). Today the incidence of SCC and AC are almost equal in the United States, where as of the 1960's, 90% of esophageal cancers were squamous cell (SCC). With this shift in histological type, there is also a shift in demographics. Both AC and SCC are seen more commonly in men, but SCC has a high prevalence in urban populations and in African-Americans, while AC is predominately a disease in Caucasians. Despite the evolving epidemiology of esophageal cancer and the development of new treatments there has been little change in survival. The five year survival for both AC and SCC remains approximately 14%[2].

Risk factors

Due to the demographic variability and the recent rise in AC incidence, much emphasis has been placed on studying risk factors for esophageal cancer. Currently smoking is a known risk factor in both SCC and AC and alcohol consumption is primarily a risk factor for SCC[3-5]. Dietary factors that have been more closely associated with SCC include foods with N-nitroso compounds, betel nut chewing, and hot foods and beverages. The development of SCC is also seen in patients with achalasia of the esophagus, with Plummer-Vinson syndrome, and with the autosomal dominate disease, tylosis. AC, on the other hand, has been closely link with the severe gastroesophageal reflux disease and Barrett's esophagus, the development of a columnar epithelium-lined esophagus[6-8]. Obesity, with a body mass index greater than 30, has also been shown to increase the risk of AC of the esophagus[9].

Clinical presentation

The most common complaints from patients with esophageal cancer are dysphagia and weight loss. Ninety percent of patients have difficulty swallowing solid food and subsequent changes in their diets lead to the loss of weight. Unfortunately the lumen obstruction that causes dysphagia is a sign of advanced disease. Patients with esophageal cancer often point to a specific trouble area in the neck or chest, unlike other dysphagia where there is generalized slowing of esophageal motility. Other less common symptoms include recurrent pneumonias secondary to aspiration, emesis of unprocessed food, hoarseness with recurrent laryngeal nerve invasion, or melena.

The physical exam unfortunately provides minimal additional information. Aside from weight loss, the physical findings are scarce except in metastatic disease where the liver may be enlarged or supraclavicular or

cervical nodes may be palpable. Laboratory values may demonstrate a low hematocrit secondary to bleeding, and most patients have elevated blood urea nitrogen and serum creatinine levels because of dehydration. Markers of nutrition, namely albumin, may also be low. Liver function tests should also be evaluated for metastatic disease.

Diagnostic modalities

Prognosis and treatment planning for esophageal cancer are dependent on the ability to make a diagnosis and establish a clinical stage. A barium swallow study is often done and is an appropriate modality for patient screening, especially in male patients over 50 years of age complaining of dysphagia. It provides cancer suspicion and tumor localization for later endoscopy. Esophagoscopy, however, is necessary for making a diagnosis. It allows for direct visualization and evaluation of Barrett's esophagus and tumors, and can provide a tissue diagnosis with a biopsy. Single biopsies of suspicious lesions in this setting are 93% accurate. The accuracy can improve to 100% with the addition of multiple biopsies (seven) and brushings[10]. An ultrasound probe combined with conventional endoscopy (endoscopic ultrasound) provides the most accurate estimate of disease stage by the tumor-node-metastasis criteria established by the American Joint Committee on Cancer. Ultrasound does so by evaluating the five layers of the esophageal wall with 85% accuracy and by detecting abnormal mediastinal lymph node metastasis with approximately 80% accuracy. EUS guided fine needle aspiration enhance this accuracy. EUS, however, is less accurate in accessing stage following the administration of preoperative chemoradiotherapy[11].

Metastatic disease is evaluated a number of ways. Computed tomography (CT) and positron emission tomography (PET) are both helpful in identifying distant metastasis. Bronchoscopy should also be performed in patients with upper and middle third tumors to exclude invasion into the trachea or bronchi. FNA of palpable supraclavicular or cervical nodes can provide additional valuable information about wide spread disease.

Surgical treatment

There are a number of different surgical approaches for treating early esophageal cancer. For the most part these procedures have similar perioperative mortality rates, approximately 4%[12,13]; however variations are seen in the types of complications that result from each given procedure. Choosing the best treatment strategy for an individual patient is therefore based on a number of different features of a specific lesion and on the preference and discretion of the surgeon. Important things to consider include the tumor location, the extent of lymphadenectomy necessary, and the use of neoadjuvant therapy. Resectable tumors of the middle and distal third of the esophagus are treated with a total esophagectomy. The two most common approaches are the transhiatal esophagectomy and the Ivor Lewis transthoracic esophagectomy. The primary differences between these approaches are the incision sites, the exposure provided by the incision, and the anastomotic site.

The transhiatal esophagectomy uses a midline laparotomy and a left neck incision. The laparotomy allows for blunt dissection of the thoracic esophagus and dissection and mobilization of the often conduit stomach. A cervical anastomosis is carried out through the left neck incision. The Ivor Lewis esophagectomy requires a midline laparotomy with a right thoracotomy. This allows for complete lymph node sampling under direct visualization and a high right sided intrathoracic anastomosis. A variation in this approach is a left thoracoabdominal incision (one incision), but some feel a high anastomosis in the left chest can present additional technical challenges. Another variation is a triincisional esophagectomy using a right posterolateral thoracotomy followed by a laparotomy and a left neck incision. Although the perioperative mortalities and the long term survivals are similar when comparing these different approaches, the anastomotic leak rate has been shown to be higher with the transhiatal approach, while respiratory and cardiovascular complications are more prevalent following the Ivor-Lewis approach[12-14]. However, cervical anastomoses provide a lower incidence of post-operative reflux, and anastomotic leaks are more easily controlled in the neck with lower associated mortalities.

The benefit provided from an extended, or three field, lymphadenectomy (mediastinal, abdominal, and cervical lymph nodes), through a transthoracic approach, remains controversial. A recently published prospective randomized trial from the Netherlands suggested a trend toward improved survival for 220 patients undergoing esophagectomies with extended lymphadenectomy for lower esophageal adenocarcinomas. Patients were randomly selected for either a transhiatal approach or a transthoracic approach with an extended lymphadenectomy. The overall 4.7 year survival rates were 29% and 39%, respectively[15], however, this was not a statistically significant difference. Currently in the United States this three field lymphadenectomy is not standard of care, although adequate lymph node sampling remains necessary for proper staging and prognosis.

Chemotherapy and radiation therapy

A survival advantage with chemoradiotherapy for esophageal cancer is still a matter of controversy. Currently neoadjuvant therapy seems to have a role in managing marginally resectable tumors and tumors with known lymph node involvement. Unpublished data from a trial in London, the MRC Adjuvant Gastric Infusional Chemotherapy Trial (MAGIC), presented at the American Society of Clinical Oncology this year, did show a statistically significant advantage in perioperative chemotherapy versus surgery alone in resectability, progression-free survival and overall survival for lower esophageal cancer[16]. Though this trial grouped esophageal and gastric Ge junction together, it is one of only a handful of studies to demonstate a significant survival advantage for neoadjuvant therapy, even though multiple trials have demonstrated the ability to downstage tumors and achieve a complete resection with clear margins. Though the evidence is sparse, neoadjuvant chemoradiation has

become the norm for patients with T3 or N1 disease on pre-operative evaluation. Definitive chemoradiotherapy is used alone in patients with unresectable tumors and post-operative chemoradiotherapy has shown modest survival benefits in small retrospective trials only[17,18] and is not generally recommended.

GASTRIC CANCER

Epidemiology

Gastric cancer is one of the most common cancers worldwide. In the United States alone, 21 860 patients have been diagnosed with gastric cancer this year, and 11 550 are expected to die as a result of this diagnosis[2]. Interestingly, its prevalence varies significantly with geographic location and in Japan, Korea, and parts of South and Central America, gastric cancer is up to 10 times more common than in the United States. Males are affected more often than females, and African Americans, Hispanics and Native Americans more than Caucasians. As our understanding of gastric cancer evolves, the epidemiology of the disease does as well. Since the 1930's there has been a 75% decrease in the overall incidence of gastric cancer in the United States[2], even without the implementation of routine screening modalities, like in Japan where the high incidence makes screening a cost effective modality. Simultaneous to the decreasing overall incidence is an increasing incidence of proximal gastric cancers and cancers of the gastroesophageal (GE) junction, escalating at a rate higher than that of nearly all other types of cancer. Proximal tumors are known to be more aggressive than distal tumors and have a worse prognosis for stage[20]. This shift to a more aggressive disease pattern and the inability to detect cancer at an early stage has limited our ability to make much progress in gastric cancer survival in the last 2 decades. The 5-year survival rate in the United States remains less than 30%[2].

The majority (95%) of gastric cancers are adenocarcinomas. Other tumors such as gastrointestinal stromal tumors, squamous cell carcinomas, gastric lymphoma, and carcinoid contribute to the other 5% of cancers. However the focus of this article will be on gastric adenocarcinomas.

Risk factors

Because of the geographic distribution and the recent shift in tumor anatomic location, much attention has been focused on determining risk factors associated with gastric cancer. Regional diets in particular have been under scrutiny to help shed light on causes of the disease. Studies comparing different foods have noted that western style breakfasts, diets high in antioxidants, and diets low in salt are shown to be inversely proportional to the incidence of gastric cancer[21]. With the discovery of the bacteria *Helicobacter pylor*i's (*H pylori*) role in ulcer disease, the role of *H pylori* in the development of gastric cancer has been examined as well. *H pylori* infection has now been show to increase the risk of body and antrum gastric cancers up to 6-fold[22,23]. In a prospective randomized control trial from China by Wong *et al*, there was a statistically significant decrease over 7.5 years in the incidence of gastric cancer in patients that received treatment for *H pylori* compared to those that did not receive treatment[24]. The same treatment, however, did not alter the incidence of gastric cancer in patients with premalignant lesions. There has also been an increase in the incidence of gastric cancer in patients with *H pylori* infection when the infection leads to gastric mucosal atrophy and pepsinogen 1 production compared to infected patients without this histological change[25].

A number of medical conditions have also been associated with gastric cancer development. The presence of adenomatous polyps increases the incidence of gastric cancers up to 20%, with greatest risk to patients with multiple polyps and polyps over 2 cm in diameter[26]. The same risk has not been seen in patients with hyperplastic polyps, which account for approximately 80% of diagnosed polyps. Chronic gastritis, pernicious anemia, intestinal metaplasia, acid hypersecretion conditions, Barrett's esophagus, and previous gastric surgeries have also been shown to influence the incidence of gastric cancer. Genetic risk factors for gastric caner include patients with hereditary non-polyposis colon cancer and familial polyposis coli. Cigarette smoking has also been linked with gastric cancer[27].

Clinical presentation

The vague clinical presentation of gastric cancer is the leading reason patients do not get diagnosed until the disease has progressed. Symptoms are nonspecific and are often not present. The most common complaint is epigastric pain, seen in 70% of early gastric cancers[20]. The pain is characterized as constant, nonradiating, and relieved sometimes with food ingestion or antacids. Less than 50% of patients with early cancers will complain of weight loss as a result of dietary changes secondary to the other symptoms. Other less common complaints include dysphagia, in patients with proximal cancers, and nausea and vomiting from gastric outlet obstruction in patients with distal tumors, anorexia, and melena.

The physical exam, unfortunately provides minimal additional information in early disease. Advanced disease may reveal a palpable epigastric mass, an enlarged liver, ascites, a periumbilical nodule or Sister Mary Joseph's node, left supraclavicular adenopathy or Virchow's node. An ovarian enlargement on pelvic exam (Krunkenberg tumor), or mass in the cul-de-sac on rectal exam (Blumer's shelf) may also be present. Elevation of serum alkaline phosphatase and anemia can be seen on laboratory values, but are not specific. Tumor markers are not yet a routinely used. Guaiac positive stools are seen in one third of patients.

Diagnostic modalities

A clear method for diagnosing and screening gastric cancer is important since its presentation often mimics other disease processes and there is a small window of time where the disease is potentially curable. Each different modality has its own strengths and weakness in diagnosing and staging the disease in order to plan the appropriate treatment. Although invasive and costly, endoscopy is

currently the most specific and sensitive method for obtaining a definitive diagnosis besides laparotomy, and has replaced barium contrast radiographs due to its ability to biopsy. It allows for direct visualization of lesions and the opportunity to obtain tissue samples. Endoscopy with seven biopsies of the margin and base of gastric ulcers has a sensitivity of 98% for diagnosing gastric cancers of all stages[10], compared to barium studies with a sensitivity of only 14% in early gastric cancers[28]. Barium continues to have a major role in diagnosing of linitis plastica, a diffuse type gastric cancer which is difficult to appreciate with endoscopy. Brush biopsies are performed in areas at risk of bleeding.

Staging for gastric cancer is based on the evaluation of the tumor (T), regional lymph nodes (N), and metastasis (M), as outlined by the American Joint Committee on Cancer system, and is essential for treatment planning and prognosis. Computed tomography (CT) is heavily relied on as a non-invasive test gathering information regarding metastasis and is performed routinely in patients diagnosed with gastric cancer. Although CT often underestimates nodal involvement and overestimates the depth of invasion, it is useful in assessing for liver metastases and distant spread. Endoscopic ultrasound, on the other hand, is more useful in evaluating the depth of tumor invasion (77% accurate) and regional lymph nodes (69% accurate)[29], but has no role in distant metastatic evaluation. Laparoscopy is the most invasive form of staging, but also 23% more accurate than CT scan in diagnosing peritoneal metastasis, which then precludes curative resection[30]. It is therefore reserved for patients with good performance status and those in which accurate staging is necessary for further treatment planning. New data also suggests that positive cytological washings at the time of laparoscopy are the most predictive preoperative factor of death from gastric cancer[31].

Surgical treatment

Complete surgical resection of gastric cancer provides the only chance for a cure. To obtain this goal, a 6 cm surgical margin with pathologic margins free from microscopic invasion should be attempted in order to offer the lowest possible rate for local recurrence. The type of gastrectomy performed to achieve this goal, however, has changed over time and still remains controversial. It was once thought that a total gastrectomy, with resection of splenic and celiac lymph nodes, splenectomy, and distal pancreatectomy was necessary for all gastric adenocarcinomas. The high morbidity of this operation, without a survival advantage over total gastrectomies with varying levels of lymph node dissections and partial gastrectomies, has led to a change from this practice. By evaluating a number of factors, including the tumor location, stage, and histological type, variation in surgical plans have been entertained and put into practice.

In proximal adenocarcinomas of the stomach, total gastrectomy or esophagogastrectomy remains the operation of choice for most surgeons. When compared to a proximal subtotal gastrectomy, a Roux-en-Y reconstruction has a lower incidence of reflux esophagitis[32]. In addition, the most common site of nodal metastasis for proximal tumors is on the lesser curvature. These nodes may be left behind in a proximal subtotal gastrectomy. However, a proximal gastrectomy, with an adequate node dissection, has an equivalent survival to total gastrectomy, and is still advocated by some surgeons. For distal tumors a subtotal gastrectomy is the procedure of choice. It has been shown that there is no added survival benefit for patients with distal tumors undergoing total gastrectomy and the operative morbidity and mortality is greater for patients who undergo total gastrectomy[33]. In addition, other studies have demonstrated that the quality of life is better for patients following subtotal gastrectomy compared to total gastrectomy[34,35].

Similar to esophageal cancer, the extent of lymph node dissection for curative surgery in gastric cancer remains controversial as well. Retrospective data from Japan has shown a survival benefit for patients with extensive lymph node dissection in stage II or stage III disease. The number of positive lymph nodes also predicts and influences survival when at least 15 lymph nodes, regardless of their position, are surgically biopsied[36,37]. However, extended lymph node dissections in the United States have been linked with increased operative mortality. Therefore numerous studies have looked specifically at this concept; the best way to limit operative mortality without leaving microscopic disease. The draining lymph nodes of the stomach are categorized into 16 stations. These stations are group into clusters referred to as D1, D2, and D3. D1 includes perigastric lymph nodes, D2 includes nodes along the hepatic, left gastric, celiac, and splenic arteries, and the splenic hilum, and D3 includes nodes within the porta hepatic and periaortic region. In the last 20 years, at least five prospective randomized trials have not show a statistically significant survival advantage of a D2 versus D1 lymphadenectomy or a D3 versus D2 lymphadenectomy, including trials from the Medical Research Council[38], the Dutch Gastric Cancer Group[39,40], and the Japan Clinical Oncology Group Study[41] in which 400, 711, and 523 patients were enrolled respectively. Criticism of these studies revolve around the inability of small sample sizes to adequately predict changes in the survival of patients with N2 disease since N2 patients only make up 30% of all the patients studied and only one-forth of these patients are predicted to survive following D2 dissections[42]. In addition, it was shown that surgeons varied in their compliance to dissection guidelines. Recent studies from the United States have demonstrated that in selected high volume centers operative mortality following D2 gastrectomies is no greater than that associated with the D1 resection[43]. Therefore, D2 resections have still been recommended by surgeons in the US who can perform the operation with low mortality. At minimum, a total of 15 lymph nodes must be removed at the time of gastrectomy to adequately stage patients[36] and this requirement has been adopted in the most recent AJCC staging handbook.

The role of laparoscopic surgery for gastric carcinoma is still in evolution. Currently there are a number of centers that successfully perform laparoscopic-assisted distal gastrectomies (LADG) and total gastrectomies, as well as hand-assisted gastrectomies with D1 lymph

node dissections for early gastric cancer treatment. Even more recently laparoscopic techniques have expanded to include treatment of cancers infiltrating deep submucosal layers and treatment of advanced tumors with no known lymph node metastasis with LADG and D2 lymph node dissections[44]. Although in general the operative time for laparoscopic procedures exceeds open procedures, outcomes of the laparoscopic approach suggest a decrease in postoperative pain and operative blood loss, shorter hospital stays, earlier return of bowel function, and fewer cardiac and respiratory complications[44,45]. Authors have not reported a statistically significant difference in the number of nodes dissected or in the adequacy of surgical margins when compared to open procedures. However these studies are limited by a low number of patients enrolled and a lack of long term follow-up regarding patient survival and the recurrence rates of cancer.

Chemotherapy and radiation therapy

Complete surgical resection remains the only chance for cure in patients with gastric cancer, but approximately 80% of patients with adequate negative margins still have recurrences and most patients ultimately die from their disease[46]. Therefore there has been a strong push toward developing effective chemotherapy and radiation regimens to be used with surgical management and many trials have been attempted or are underway. The results from these treatment modalities to date have been modest with little or no effect on overall survival. However in 2001, Macdonald et al looked at the survival benefits of chemoradiotherapy in 556 patients following curative gastric resections[47]. Results showed a 36 mo median overall survival with postoperative chemoradiotherapy compared to a 27 mo median overall survival with surgery alone. This data has established the current standard of care for patients in the United States who have undergone potentially curative gastric resections[47]. The regimen includes a combination of 5-fluorouacil (5-FU) (425 mg/m^2 of body-surface area per day) and leucovorin (20 mg/m^2 per day) for five days, followed one month later with radiation (1.8 Gy/d and 45 Gy total) and modified doses of 5-FU and leucovorin, followed by 2 more 5 d cycles of 5-FU and leucovorin one month later. New data presented from the MAGIC trial in London also demonstrated a significant improvement in resectability, progression-free and overall survival in patients with gastric and gastroesophageal junction tumors given perioperative chemotherapy compared to surgery alone[16]. Other treatment options for unresectable tumors and for patients with distant metastasis are still being investigated in a number of ongoing clinical trials.

In summary, the epidemiology of both esophageal and gastric cancer has changed in the last few decades. Both the surgical management and chemoradiotherapy has evolved as well. Even with our advances in understanding these disease processes and with our improvement in treatment strategies, the overall 5 year survival rate remains exceedingly low and most patients die from their disease. This emphasizes the importance of continued research efforts into both esophageal and gastric cancer in order to continue to improve on what is known.

Abstract

Mesenteric ischemia disorders are precipitated by a circulation insufficiency event that deprives one or several abdominal organs of adequate respiration to meet metabolic demands. Although mesenteric ischemia occurs infrequently, the mortality rate is from 60% to 100%, depending on the source of obstruction. The successful outcome is dependent upon a high index of suspicion and prompt management. We briefly review the pathophysiology and presentation of the various ischemic entities and review the current state of the art in diagnosis and treatment. Despite advances in both diagnosis and treatment, prompt diagnosis and supportive care remain critical for successful outcome. New imaging techniques, endovascular therapy and emerging research may improve our approach to this deadly condition.

INTRODUCTION

Mesenteric ischemia disorders are precipitated by a circulation insufficiency event that deprives one or several abdominal organs of adequate respiration to meet metabolic demands. Although mesenteric ischemia occurs infrequently, the mortality rate is from 60% to 100%, depending on the source of obstruction[1]. Even with recent technological advancement, successful outcome is dependent upon a high index of suspicion and prompt management.

This spectrum of disorders can be roughly categorized by the acuity or chronicity of presentation. Acute mesenteric ischemia is further subdivided based on the etiology of the occlusion; embolic, thrombotic or nonocclusive. It has been estimated that one third of acute cases are caused by arterial embolism, one third caused by acute arterial thrombosis, and the remaining majority of acute cases are caused by a nonocclusive etiology, with a small proportion of cases from venous thrombotic etiology[2,3]. Chronic ischemic symptoms usually stem from longstanding atherosclerotic disease of two or more mesenteric vessels. This article will briefly review the pathophysiology and presentation of the various ischemic entities and review the current state of the art in diagnosis and treatment.

PATHOGENESIS AND PRESENTATION

The classic presentation of patients with embolic disease is of sudden catastrophic abdominal pain out of proportion to physical examination findings. Only one third of patients present with the classic triad of abdominal pain, fever and heme-positive stools. These patients often have a history of cardiac disease which might predispose to embolus formation (atrial fibrillation, ventricular aneurysm, mitral valve disease, *etc.*). If there is a thrombotic component to the acute event, a history of chronic abdominal pain and coexistent atherosclerotic disease can be elicited. Venous thrombosis of the visceral vessels can also precipitate an acute ischemic event. Compromised venous return leads to interstitial swelling in the bowel wall, with subsequent arterial flow impedance and eventual necrosis. Etiologic factors for venous thrombosis include portal hypertension, intrabdominal sepsis, cirrhosis, pancreatitis, malignancy and trauma. Less common causes of acute mesenteric ischemia include arteritis, ergot administration, aortic dissection with concomitant occlusion of visceral vessels, and iatrogenic causes related to cardiopulmonary shunting in cardiac surgery.

Patients who present with nonocclusive mesenteric ischemia do so in a clinical setting of extremely low-flow splanchnic circulation, usually in the presence of vasopressor use. No vascular occlusion is usually demonstrated because pulsatile blood flow is present in larger arteries[4]. Patients with severe cardiac failure are at risk for nonocclusive mesenteric ischemia from vasospasm related to elevated sympathetic activity or hypovolemia.

Catecholamines and medications such as digitalis, by interfering with the autoregulation of mesenteric circulation, can also cause vasospasm.

The etiology of chronic ischemia is also multifactorial and many of the causes are similar to those listed for acute ischemia, but rarely from emboli. The most common cause of chronic intestinal ischemia is atherosclerotic occlusion or severe stenosis of the mesenteric arteries. A stenosis of > 50% is present in 18% of patients older than 65 years, but very few of these patients have symptoms[5]. Slow-growing obstructions are usually the source of this disease. Similar to acute disease, chronic nonatheromatous lesions which probably occur in a higher proportion in the visceral vessels include Takayasu's arteritis, dysplastic lesions, and Buerger's disease[6]. Chronic symptoms are caused by the gradual reduction in blood flow to the intestine. Since total blood flow to the intestine can vary from 20% when fasting to 35% after eating, symptoms occur with the demand for blood flow[7]. The three major gastrointestinal arteries that arise from the abdominal aorta are the celiac axis, the superior mesenteric artery (SMA), and the inferior mesenteric artery (IMA). Since collateral circulation is present at several levels, patients may be asymptomatic even with stenoses in several arteries. When SMA is occluded, the pancreaticoduodenal arteries supply blood via the hepatic and gastroduodenal arteries to the bowel, and when the celiac artery is also occluded, IMA supplies blood to the small bowel via the left colic branch. Frequently angiography will demonstrate a large meandering mesenteric artery, which is an important vessel in the collateral circulation from the inferior mesenteric artery. Symptoms usually occur if two or more vessels are occluded. Chronic mesenteric arterial ischemia typically causes postprandial abdominal pain and weight loss. As the obstructive process progresses, chronic dull pain ensues. Chronic venous occlusion causes vague abdominal pain or distention and usually does not infarct the bowel. Frequently, it is found incidentally on abdominal imaging.

Adequate intestinal perfusion can usually be maintained at near normotensive blood pressures when only one artery is involved, and under these circumstances mesenteric ischemia rarely occurs. When multiple severe occlusions are present, acute intestinal ischemia occurs from the critical reduction in the blood flow. Severe symptoms and possible infarction of the intestines can occur. The bowel becomes ischemic when the intestinal blood pressure falls below 40 mmHg[7].

At the cellular level, ischemia causes mitochondrial dysfunction, loss of ion transfer regulation and intracellular acidosis. Changes in membrane permeability and release of free radicals and degradative enzymes lead to cell death and tissue necrosis. Experimental models in rats have demonstrated mucosal injury and bacterial translocation within 2 h of a 30 min hypovolemic, hypotensive episode[8].

DIAGNOSTIC MODALITIES

Over the last decade, duplex ultrasonography has shown promising results in the diagnosis of chronic mesenteric ischemia. Multiple studies, using angiography as a standard reference, have found that duplex ultrasonography is an accurate screening test for proximal stenosis or occlusion. End diastolic velocity greater than 45 cm/s or peak systolic velocity greater than 275 cm/s portends high specificity for SMA stenosis[9-11]. However, these findings must be correlated with a clinical scenario and angiographic findings. In addition, duplex exams are limited in quality by patient body habitus, overlying bowel gas, patient compliance, and operator dependence[12].

Magnetic resonance angiography, although initially criticized for limitations in resolution and oversensitivity, is being investigated for diagnosis of mesenteric ischemia. Recent studies show a disease specificity of 95%[13]. Li *et al*[14], used magnetic resonance oximetry to evaluate the percentage of oxygenated hemoglobin in the preprandial and postprandial SMA in patients with chronic ischemic symptoms. Compared to asymptomatic atherosclerotic patients, this study showed a statistically significant increase in oxygen extraction and a decrease in oxygenated hemoglobin in the mesenteric ischemia group. Combined with magnetic resonance angiography, oximetry may hold promise as a powerful diagnostic modality. Selective mesenteric angiography is considered to be the gold standard for the diagnosis of acute arterial occlusion. Abrupt cutoff of the SMA with the absence of collateral circulation is diagnostic with virtually 100% sensitivity in acute embolic occlusion[15]. The more important outcome of arterial catheterization in this era however, as discussed below, will be the development of endovascular therapy.

While imaging of the visceral vessels and involved organs are essential to determine severity of disease, physiologic or biochemical means of detection, both for diagnosis and as a predictor of behavior, do not exist. Serum lactate, an established marker of cell hypoxia, has been shown to have a sensitivity of 96% in patients with mesenteric ischemia[16]. However, lactic acidosis is often a late finding in the diagnostic pathway with concomitant shock, bowel necrosis and circulatory collapse. In this regard, several areas of research should be mentioned. Small animal models have shown that tachyarrythmias detected by electrophysiologic sensors of the bowel wall are sensitive indicators of visceral hypoperfusion. Seidel showed that transabdominally placed superconducting quantum interference devices can accurately detect small bowel electrical rhythms *in situ*. Moreover, in this animal model of SMA occlusion, the ischemic intestine exhibited decreased electrical activity which was detected with a sensitivity and specificity of 94% and 100%, respectively. This noninvasive modality stands to be validated with future work[17,18].

Recently, plasma D-dimer has been suggested as an early marker of acute ischemia. In animal studies D-dimer has been shown to correlate with the onset of ischemia and it functions as a time sensitive indicator of disease progression[19,20]. Similarly, the enzyme alcohol dehydrogenase has been identified as a potentially sensitive indicator of bowel ischemia as opposed to generalized systemic hypoperfusion[21]. Glutathione S-transferase, a detoxifying cytosolic enzyme, is also a substance of interest. It is released with cell membrane damage and several isoforms have been correlated with bowel specificity. This enzyme has also been shown to exhibit

a time and duration specific detectable increase with progressive tissue ischemia[22].

Computed tomography (CT) is a fast, widely available noninvasive modality that has improved enormously in recent years. In 2000, the American Gastrointestinal Association concluded that CT was of limited use in the diagnosis of acute mesenteric ischemia, except in patients suspected of having superior mesenteric vein thrombosis[15]. Since then, multidetector row computed tomography has emerged as the gold standard for evaluation of mesenteric ischemia. In one prospective series, the positive and negative predictive values in a series of 291 patients were found to be 90% and 98%, respectively[23]. In another prospective series of 62 patients evaluated for mesenteric ischemia with multidetector CT and mesenteric angiography, the sensitivity and specificity was found to be 96% and 94%, respectively[24].

TREATMENT OPTIONS

Management of mesenteric ischemia clearly depends on the nature, acuity and severity of disease. Early intervention involves resection of nonviable bowel, restoration of blood flow to the ischemic intestine and supportive care. In the acute thromboembolic event, operative embolectomy has been the traditional procedure with reasonable short and long term outcomes. Surgical revascularization for visceral ischemia due to an occluded SMA was first described by Shaw *et al*[25] in 1958, in which they reported two successful cases of mesenteric thromboendarterectomy. For chronic occlusive disease, when revascularization is considered, single-vessel bypass to the superior mesenteric artery has been very successful, even in patients with multiple-vessel occlusions. Cunningham *et al*, reported an 86% symptom-free rate at 5 years after surgical revascularization[26]. In one study, the operative procedure had a perioperative mortality rate of 3%, a 5-year survival rate of 61%, and a 9-year assisted primary graft patency of 79%[27]. Those who advocate multiple vessel revascularization suggest that there is a higher incidence of graft failure and recurrence of symptoms after single-vessel revascularization. At the Mayo Clinic, the 5-year graft patency rates have been 90%, 54%, and 0% with three-vessel, two-vessel, and one-vessel bypasses respectively[28].

Antegrade aortoceliac bypass and transaortic endarterectomy have been successful for poor-risk patients, and are usually adequate for multiple outflows. Antegrade mesenteric bypass grafts from the distal thoracic aorta have also been associated with low mortality and morbidity rates[29]. Antegrade bypass from the supraceliac aorta can reduce kinking, compression, turbulence, and thrombosis, but has been associated with renal ischemia and can be technically challenging. Retrograde bypass from the infrarenal aorta or iliac artery is technically easier and avoids renal ischemia, but has been related to lower inflow and graft kinking. Revascularization of the superior mesenteric artery and celiac axis has been used to minimize the recurrence of symptoms and organ infarction if one graft fails[30]. Graft failure has been reported to be higher in males[31]. While most patients with chronic venous mesenteric ischemia can be treated with anticoagulation therapy, the source of the thrombus must be determined and treated.

Since the first reports of percutaneous transluminal angioplasty of the visceral vessels in 1980, endovascular therapy for atherosclerotic disease has rapidly expanded in both scope and indication in the last ten years. In both the acute and chronic presentation of intestinal ischemia, endoluminal therapy has emerged as a main, if not first-line therapy. Symptom relief with implantation of stents in the proximal celiac artery has been reported[32,33]. In addition, the thrombosis rate of mesenteric prostheses has been reduced from 18% to 1% with the addition of antiplatelet therapy.

Thrombolytic therapy in the management of intestinal ischemia was first reported in 1979 with the successful application of intraarterial streptokinase in the SMA[34]. In those patients with ostial or short segment occlusion of the SMA and celiac artery, recanalization with or without concomitant fibrinolysis (depending on acuity and presence of thrombus) has been shown to have promising initial results[35]. In many centers, intracatheter fibrinolysis with or without embolus retrieval is the initial treatment for SMA thromboembolism[36-38]. With the increase in percutaneous approaches to therapy, concern has arisen regarding the durability of treatment. Hallisey *et al*, reported a 75% primary patency rate at a mean follow up of 2.3 years[39]. Matsumura *et al*, reported a 29% recurrence rate with endovascular treatment within 1 year of treatment[40]. It has been suggested that in selected patients, surgery should be the treatment of choice, because it provides better long-term primary patency[41-43].

When the results of open surgery are compared to those of percutaneous angioplasty and stenting, there is a higher incidence of recurrent symptoms after percutaneous angioplasty[44]. In a recent retrospective review, the Dartmouth group noted an increased rate of restenosis and reintervention in the stent group versus an historical control surgical group. However, despite reintervention, 93% were symptom-free at last follow-up with a significantly smaller periprocedural mortality rate compared to open surgical patients. In addition, the authors pointed out that in one case, stent placement allowed sufficient nutritional optimization as to allow a previously poor risk patient to tolerate a definitive open procedure[45]. Clearly, there may be a role for minimally invasive therapy in high risk patients. With the accumulating experience in high volume endovascular centers, emerging prospective data may be able to more adequately analyze outcome data between the two treatment modalities.

In the subset of patients who suffer from nonocclusive ischemia, intraarterial vasodilator therapy has been largely responsible for the decrease in mortality from 70% in the 1980's to 50%-55% during the last decade[46]. Papaverine, the most common agent in practice today, is a nonaddictive opium derivative extracted from the poppy plant. It functions as a phosphodiesterase inhibitor and is usually infused directly into the SMA at a rate of 30 to 60 mg/h. The resultant accumulation of cyclic adenosine monophosphate acts to relax vascular smooth muscle. Recent work has shown that iloprost, a synthetic carbacyclin derivative of epoprostenol may improve SMA

flow in a hypotensive porcine model. Iloprost, a potent inhibitor of platelet aggregation and powerful fibrinolytic agent, increases flow with no appreciable change in mean arterial pressure and cardiac output. This suggests a possible role for prostacyclin analogues in the treatment of nonocclusive ischemia[47].

Investigational therapy in the treatment of mesenteric ischemia has focused on pharmacologic strategies to treat mesenteric ischemia. These include renin-angiotensin blockers and free radical inhibitors. The renin-angiotensin axis has been shown in a porcine model to play a prominent role in vasoconstriction. In this model, blockade of this signal pathway was able to prevent the ischemic injury from induced splanchnic vasoconstriction[48]. These findings imply that hemodynamic forces of nonocclusive ischemia are mediated, at least in part, by the renin-angiotensin axis.

The dual-hit hypothesis of ischemic injury is comprised of the initial hypoxic episode and then the subsequent reperfusion injury after reestablishment of forward flow. There is significant data to suggest that reactive oxygen metabolites such as superoxide, hydrogen peroxide, and hydroxyl radicals mediate ischemic injury. These substances are thought to activate phospholipase A_2, which leads to chemotaxis and leukocyte-mediated vessel injury[49]. In this regard, inhibition of xanthine oxidase by allopurinol has been shown to attenuate the epithelial cell damage during reperfusion[50]. Similarly, pretreatment with superoxide dismutase and dimethyl sulfoxide attenuates reperfusion injury in animal models[51-53]. However, since most of these therapies require pretreatment to be effective, it is difficult to foresee clinical applicability at this time.

In conclusion, mesenteric ischemia, a spectrum of disorders with multiple etiologies still carries significant morbidity and mortality. Despite advances in both diagnosis and treatment, prompt diagnosis and supportive care remain critical for successful outcome. New imaging techniques, endovascular therapy and emerging research may improve our approach to this deadly condition.

Abstract

For much of the twentieth century, surgery was frequently the solution for peptic ulcer disease. Our understanding of the pathophysiology of ulcers paralleled the development of potent pharmaceutical therapy. As the surgical world developed parietal cell vagotomy which would minimize the complications of surgery, patients failing medical therapy became rare. Emergent surgery for complicated peptic ulcers has not declined however. The development of proton pump inhibitors and the full understanding of the impact of *H pylori* has led to a trend towards minimalism in surgical therapy for complicated peptic ulcer disease. In addition to the changes in patient care, these developments have had an impact on the training of surgeons. This article outlines these trends and developments.

INTRODUCTION

During the twentieth century there were major advances in the understanding of the pathophysiology of what were known as acid-peptic diseases. These advances included the understanding of the role of the vagus nerve, the discovery and eventual peptide sequencing of the hormone gastrin and the landmark discovery of *H pylori*. Advances also occurred in medical therapy. Selective histamine receptor blockers and proton pump inhibitors were developed. Antibiotic therapy was found to eradicate *H pylori*. Thus changes in treatment of acid-peptic disorders have paralleled the changes in the understanding of the pathophysiology. This review will cover current perspectives in surgical treatment and how advances in medical management have impacted surgical practice.

GASTRITIS

Gastritis literally means inflammation of the stomach. This term may refer to acute gastritis or chronic gastritis, two very different disease entities. The Sydney System, used by pathologists and gastroenterologists to classify gastritis, emphasizes the importance of combining topographical, morphological, and etiological information into a schema that helps to generate reproducible and clinically useful diagnoses[1].

Acute gastritis is in many cases synonymous with erosive gastritis. This may be due to toxic damage to the gastric mucosa, commonly from non-steroidal anti-inflammatory drugs (NSAIDs) or alcohol ingestion. Erosive gastritis may also occur in critically ill patients with sepsis, shock or major body burns. On endoscopy, these patients have diffuse superficial gastric erosions and/or petechiae[2]. On histology, there is surface cell damage but a paucity of inflammatory cells. Supportive care with fluid resuscitation and anti-acid therapy results in rapid resolution of this type of gastritis in the vast majority of cases.

Historically, the first line treatment of acute erosive gastritis has been medical therapy. The first step is cessation of the insult, including stopping NSAIDs and resolving hypotension and/or hypoxia with appropriate supportive therapy. Therapy includes anti-acid therapy of any type to bring the gastric juice to a pH > 5 in all patients. In recalcitrant cases, additional treatment such as intravenous pitressin or octreotide may be required. Prior to 1980 there were failures of medical therapy, which required surgery for unremitting hemorrhage. Proposed operative therapy included anti-ulcer operations plus over sewing of bleeding sites, gastric resection and even gastric devascularization. The mortality of these operations ranged up to 40%[2]. Fortunately with modern care the need for surgery in these cases is beyond rare.

Chronic gastritis is most commonly due to *H pylori* infection. Most of these cases are asymptomatic and there

is poor correlation between symptoms and chronic *H pylori* infections with chronic inflammation. Again, surgery plays no role in these cases.

Another type of chronic gastritis is duodenal reflux or bile reflux gastritits. These cases may be spontaneous or secondary to prior gastric surgery. The cases are characterized by abdominal pain and bilious vomiting. On endoscopy, these patients have bile in the stomach, erythematous stripes or patches and sometimes mucosal edema[4]. On histologic examination, there is foveolar hyperplasia, mucosal edema and a paucity of inflammatory cells. Treatment with mucosal protective agents, prokinetic agents, and binders of bile salts has been disappointing. Surgical therapy consists of diversion of bile away from the stomach. In cases of spontaneous bile reflux gastritis, Madura has achieved excellent results with Roux-en-y choledochojejunostomy[5]. In the cases of secondary reflux gastritis (after gastric surgery) diversion of bile and duodenal contents away from the stomach has frequently been accomplished by Roux-en-y gastroenterostomy, with a long Roux limb (> 50 cm).

PEPTIC ULCER SURGERY

The surgical treatment of peptic ulcer disease, the main focus of this review, has changed dramatically over the years. To better understand the evolution of peptic ulcer surgery we must trace its development. We will review some of the highlights in the development of ulcer surgery as we know it today. In 1882 Czerny, a member of Billroth's department, performed local excision of a gastric ulcer, just one year after Billroth's first successful gastric resection for an obstructing carcinoma[6]. The Heinecke-Mikulicz pyloroplasty was first introduced separately by Heinecke in 1886 and by von Mikulicz in 1887. This commonly used pyloroplasty involves a longitudinal incision over the pylorus that is closed transversely. The Jaboulay pyloroplasty, introduced in 1892, is a side-to-side gastroduodenostomy used to bypass the pylorus. Finney later modified the Jaboulay pyloroplasty in 1902 by incising through the pylorus and creating a single lumen. It is important to recall that these operations were developed to treat ulcer induced fibrotic strictures.

Thanks to Pavlov's research, the role of the vagus nerves in gastric secretion was recognized by surgeons fairly early in the twentieth century. In fact, Laterjet *et al* appreciated the need for gastrojejunostomy for the gastric atony induced by vagotomy. Dragstedt popularized truncal vagotomy for the treatment of peptic ulcer disease during the 1940's. He published "Vagotomy for Gastroduodenal Ulcer" in the Annals of Surgery in 1945[7]. Dragstedt rediscovered that vagotomy alone resulted in gastric emptying problems, which again led to the combination of truncal vagotomy with a gastric emptying procedure. In 1937, Graham[8] described the omental patch that we so frequently call the "Graham patch" as a simple technique for treatment of a perforated ulcer.

In 1977, Nyhus *et al*[9] published a large cooperative prospective randomized study at the Veterans Administrations Hospitals showing the best results with vagotomy and antrectomy, making it the most frequently performed operation for duodenal ulcers during the 1970's and 1980's. The truncal vagotomy-antrectomy combination, had an ulcer recurrence rate of 5% or less and a very low post operative mortality rate. Unfortunately, postoperative symptoms including dumping syndromes continued to occur.

A proposed advance in ulcer surgery was selective vagotomy. Selective vagotomy denervated the stomach but spared the hepatic and celiac branches. A drainage procedure was still required. It was hoped that this procedure would result in fewer postoperative digestive sequelae. Unfortunately, trials could demonstrate no advantage of this procedure over traditional anti-ulcer surgery[10]. The progression of physiologic surgery for peptic ulcer disease continued in 1970, when Johnston *et al*[11] in England as well as Amdrup *et al*[12] in Denmark separately successfully performed parietal cell vagotomy also known as highly selective vagotomy. Highly selective or parietal cell vagotomy denervates the parietal cell mass but preserves innervation of the distal stomach (the motor unit). There was a flurry of enthusiasm for this operation. However, the procedure required operative finesse and training which was best acquired in an operating room working with a surgeon who has demonstrated good results with PCV[13].

Great advances in medical management of peptic ulcer disease began in 1977 when histamine H_2 antagonists were introduced to the market. Further improvement in medical treatment of peptic ulcer disease came in 1988 when a proton-pump inhibitor, omeprazole, was introduced to the market. Advances in medical therapy would go on to almost eliminate "failure of medical management" in peptic ulcer disease. Before the advent of H_2 receptor antagonists 50 percent of all duodenal ulcer operations were performed for intractable pain. Today most symptoms are adequately managed by medications. In fact, some believe that intractability may be due to noncompliance with and not resistance to medical therapy[14]. Another dramatic discovery occurred in 1982 (work published in 1984) when the association between *H pylori* infections and peptic ulcer was identified[15,16]. It was astonishing to believe that in the majority of patients, peptic ulcer was an infectious disease. In 1994, at the Consensus Development Conference, the National Institutes of Health panel concluded that infection with *H pylori* plays a significant role in the development of ulcers and that optimal treatment involves combination therapy using histamine H_2 antagonists or proton-pump inhibitors coupled with broad-spectrum antibiotic therapy. The medical literature of the world is replete with studies regarding *H pylori*; and there is now clear evidence, and general acceptance, that treatment with eradication of *H pylori* can cure peptic ulcer.

Today medical therapy cures peptic ulcer in the vast majority of cases. Therefore in many areas of the world elective surgery for peptic ulcer disease has all but disappeared[17]. Surgical management of peptic ulcer disease is still useful in cases of drug failure or for patients unable to obtain the drugs or to comply with medical therapy. In most parts of the world, surgical therapy is now utilized primarily for complications of peptic ulcer.

These are usually emergency operations. Currently up to 90 percent of all ulcer operations are interventions for complications including hemorrhage, perforation, or obstruction[14]. While the numbers of elective ulcer operations have plummeted there is conflicting data on whether the incidence of complications has remained unchanged, decreased, or even increased over the years. Some believe that the need for emergency surgery has not fallen, probably because of the increasing incidence of NSAID-associated complications[17]. A recent review from California indicates that acute surgical emergencies for bleeding or perforated ulcers are on the rise and mortality remains high[14]. Others feel that proton-pump inhibitors and *H pylori* eradication have resulted in fewer emergency operations for peptic ulcer disease[18]. Recent data from Finland from 1987-1999 revealed that elective surgery for peptic ulcer disease has virtually disappeared and that surgical mortality from ulcer surgery has remained unchanged (8%) over the last 15 years[19]. The stable mortality rate probably reflects a balance between an improvement in overall care but in an aging population.

Current surgical options for the management of peptic ulcers and their complications include truncal vagotomy and pyloroplasty, truncal vagotomy and antrectomy, parietal cell vagotomy (PCV), subtotal gastrectomy, patch repair for ulcer perforation, and oversewing of bleeding vessels. Older literature recommended that the choice of operation be based on factors such as patient age, comorbidity and nutritional status[20]. Since 1990, the trend has been towards more minimal operations. This is due to the belief that most patients are either on NSAIDS or will be found to be *H pylori* positive.

Several series have suggested patients with complicated peptic ulcer (bleeding or perforation) are less likely to be *H pylori* positive compared to non-complicated ulcers[21-23]. Others refute this, finding high *H pylori* infection rates in patients with perforated ulcers[24,25]. With bleeding ulcers; a major concern is false negative *H pylori* tests[26]. Thus the rapid urease test is unreliable in the face of bleeding[27]. and even results with the polymerase chain reaction for *H pylori* are controversial[28,29]. Although the role of *H pylori* infection in complicated ulcer disease, however, remains controversial, several clinical trials demonstrate that patients with eradication of *H pylori* infection have a reduction in rebleeding rates and rate of ulcer recurrence[30-33]. Similarly, the rate of recurrent ulcer disease following perforation also has a demonstrable association with persistent *H pylori* infection, and post-operative eradication seems to be a necessary step in the management of these patients[24,25,34]. Further, patients with gastric outlet obstruction have been shown to have better outcomes, with fewer recurrences or complications when *H pylori* eradication is a part of their therapeutic management[35].

With the current understanding of pathophysiology most surgeons feel that it is prudent to pursue a conservative approach in the majority of patients. This includes repair of perforations or oversewing of bleeding vessels without performing a definitive ulcer operation. This approach is supported by modern medical regimens designed to eradicate *H pylori* infection[3]or by the cessation of NSAIDS[37]. It has been demonstrated that *H pylori* eradication may significantly reduce the rate of duodenal ulcer re-bleeding, and that if the infection is cured, the preventive effect may be maintained for at least 48 mo[31].

Recent data available suggests that perforations caused by *H pylori* and NSAIDS may be two distinct entities, and supports a policy of patch repair followed by eradication of *H pylori* in those who are infected[38]. A series of more than one hundred patients with perforated duodenal ulcer treated by simple closure of the perforation and *H pylori* eradication therapy versus simple closure and omeprazole revealed far lower ulcer recurrence rates in the *H pylori* eradication group[34]. Several other series support this approach[39,40]. In addition, a survey of surgeons in the United Kingdom reveals a conservative bent towards ulcer surgery in that nation[41]. However, it is essential to recognize that the recommended approach of patch repair and antibiotics for *H pylori* for peptic ulcer perforation treatment may never be supported by trial data comparing minimal surgery and *H pylori* eradication to an anti-ulcer operation[42]. Reasonable exceptions to the conservative approach in treating complications of peptic ulcer disease may be seen in patients who have failed an anti- *H pylori* regimen, have suffered other ulcer complications, have dependency on chronic NSAID therapy, or are known to be *H pylori* negative[36]. Also, the role (if any) of *H pylori* in ulcer recurrence after peptic ulcer surgery is unclear[43-47]. Virtually all anti-ulcer operations have now been performed laparoscopically. Laparoscopic patch repair of perforated duodenal ulcers has been widely applied with success[48]. Laparoscopic parietal cell vagotomy has been performed using a variety of techniques[49]. Widespread use of this operation is again unlikely for the same reasons that open PCV has dropped from favor. With improvements in instrumentation and robotics, minimally invasive gastric resections will become less formidable. Certainly truncal vagotomy via laparoscope is not difficult for any surgeon versed in laparoscopic anti-reflux surgery. However, while these approaches become readily available, their need is diminishing.

Future trends may be impacted by swings in the HP pendulum. As mentioned, some suggest that the incidences of HP infection in complicated ulcers might be lower than in non complicated ulcers[21-23]. Three recent series suggest that the HP infection rate in complicated ulcers is between 81% and 93%[24,25,34]. In contrast some feel that the rate of HP infection in ulcer patients is decreasing[50]. Widespread eradication of *H pylori*, may result in the emergence of idiopathic (no-*H pylori* and no-NSAIDs) ulcers. Such a trend may reverse the current conservative approach to the surgical treatment of ulcer complications. Finally, one must consider the impact of all trends on surgical training. An examination of trends in American surgical residencies is illustrative. For all gastric-related surgery, the average reported cases per chief resident ranged from 9.8-12.4 with a peak in 1990 and a nadir in 1999; in 2001 the reported case average was 11.3. Over the same interval, vagotomy decreased from 24% in 1990 to 7% in 2001[51]. Graduating chief residents in surgery in the United States have performed (on average) less than 1 parietal cell vagotomy (PCV) during their residency. The

average number of all types of vagotomy for graduating chief residents was 3.5, including 3.2 truncal vagotomies and 0.3 PCV procedures. Because residents may never see a PCV performed during their residency, it is possible that PCV, once in the mainstream of surgery, is obsolete[52].

In conclusion, the understanding of the pathophysiology of peptic ulcer and the development of powerful pharmaceuticals has had a great impact on the practice of surgery in this disorder. The discovery of and treatment for *H pylori* in peptic ulcer disease has affected surgical approaches. Complications of peptic ulcer disease have not gone away although they are being treated non-surgically with increasing frequency. When surgery is required for complicated peptic ulcer disease most surgeons now favor a minimalist approach with closure of perforations or simple over sewing bleeding vessels but without a definitive anti-ulcer operation. When the next generation of surgical residents finish their training will ulcer surgery even exist, or will it simply be a historical topic in surgical textbooks? Will case numbers drop to the point where we won't have surgeons who are trained in performing these operations or will endo-luminal approaches eliminate the need for these operations? Surgery for unremitting hemorrhage from gastritis has disappeared. Considering the advances made in the twentieth century is there reason not to think that with future advances anti-ulcer surgery will go the same route?

Abstract

Metastatic colorectal cancer to the liver is associated with a uniform poor prognosis without treatment. Advances in therapy over the past decades have now allowed surgical resections of the liver to occur with a low morbidity and mortality. Improvements in chemotherapy regimes have paralleled technical improvements and now allow a new group of patients to become eligible for surgical resection. This chapter will review the recent advances in surgical and chemotherapeutic regimes in metastatic colorectal cancer to the liver.

INTRODUCTION

Colorectal cancer is the 3rd leading cause of cancer related deaths in males and females. In 2005 it is estimated to afflict 72 915 males and 71 004 females in the United States. (www.cancer.org) Autopsy studies have shown that the liver is the most common site of distant disease in colorectal cancer (Welch J 1979), and approximately 60% of patients will develop liver metastases at some point during the course of their disease.(Kemeny 2005)

Malignant tumors of the liver were once considered a lethal disease. Untreated metastatic colorectal carcinoma has a median survival of 6 to 9 mo. (Khatri 2005) Today multiple studies have demonstrated the safety and efficacy of hepatic resection. This chapter will review the history and evolution of hepatic resection for metastatic colorectal cancer to the liver.

SURGICAL CONSIDERATIONS

While reports of liver resections extend back from before the 19th century (Keen 1899), there was significant mortality associated with these procedures. Couinaud, Goldsmith and Healey substantially aided our understanding of the segmental anatomy of the liver and this has contributed substantially to the development of safe hepatic surgery. (Healey 1953; Couinaud 1954; Goldsmith 1957; Couinaud 1999) Surgical resection is the primary treatment for metastatic liver lesions, as patients who do not undergo resection do not survive 5 years. (Scheele J 1995) Large studies by experienced hepatobiliary surgeons have demonstrated a mortality of less than 5% for liver resections (Coppa 1985; Fong 1999), with a five year survival of 20%-38% (Gayowski TJ 1994; Fong Y 1997) for lesions confined to the liver. Additional studies have demonstrated that larger tumors and multiple tumors can also be removed safely (Adson 1980; Adson 1984; Fong 1999). An area undergoing evolution is extrahepatic spread, which traditionally was considered a contraindication for surgery. However, colorectal metastases to the lung do warrant resection in patients along with liver metastases (Regnard JF 1998), and more recently, 5-year survival after surgery for hepatic and extrahepatic disease has been reported to be as high as 29% in carefully selected patients (Elias 2004). Future randomized trials will have to be performed to delineate if resection of extrahepatic disease constitutes a sustained survival benefit for patients.

Optimization of surgical techniques has also aided in reducing peri-operative mortality from liver resections. Measurements of functional liver reserve can be evaluated by bilirubin, prothrombin time, and percent indocyanine green retention. (Miyagawa S 1995) If a large resection is planned, or there is concern regarding the function of the remaining liver, pre-operative portal vein embolization (PVE) offers a method to maximize the size of the hepatic remnant. (Makuuchi M 1990) A study of patients with

metastatic colorectal cancer to the liver demonstrated the efficacy of PVE. Preoperative PVE was performed in patients with a CT-scan estimated post-resection volume of 40% or less, all of whom had received pre-operative chemotherapy. The median increase in CT scan estimated liver volume was 42%, and 63% of the patients were able to undergo an extended liver resection (17/19 resections involved 4 or more segments). (Azoulay D 2000)

INFUSION PUMPS

As systemic therapy for colorectal liver metastases was historically ineffective, studies were undertaken to look at direct infusion of higher doses of chemotherapy directly into the hepatic arterial system. Cancers of the liver have been shown to primarily derive their blood supply from the hepatic artery. (Breedis C 1954) Therefore, chemotherapy delivered through the hepatic artery will directly target the cancer cells before the drug has an opportunity to be metabolized. The rationale behind hepatic directed chemotherapy is based on three principles. (1) a five fold increase in the concentration of drug reaching the liver by avoidance of initial systemic dilution (20% of systemic blood flow goes to the liver); (2) the arterial supply to tumors and predominantly portal venous supply to normal liver increases drug delivery to the tumor with relative sparing of normal liver tissue; (3) hepatic metabolization of certain drugs reduces the hepatic venous concentration minimizing systemic toxicity. Confirmation of the benefit of hepatic administration *vs* portal administration of chemotherapy comes from a small randomized trial in which patients received chemotherapy with floxuridine via the hepatic artery or the portal vein. Fifty-percent of patients receiving arterial chemotherapy responded to treatment, but, there were no responders in patients receiving chemotherapy via the portal vein. One third of patients from the portal treatment group who crossed over to arterial chemotherapy subsequently had a response to treatment. (Daly JM 1987)

Systemic (IV) chemotherapy was first compared to hepatic artery infusion (HAI) chemotherapy in patients with unresectable colorectal liver metastases randomized to receive 5-fluorodeoxyuridine (FUDR) IV or by HAI. Fifty percent of patients receiving HAI infusion had a decrease in measured tumor burden, compared with a 20% response rate for systemic IV infusion ($P = 0.001$). Some patients with tumor progression on IV therapy crossed over to HAI therapy and 33% of these patients responded or had stabilization of disease. Patients receiving HAI had a higher incidence of extrahepatic disease compared to the systemic IV treatment (56% *vs* 37%, $P = 0.092$). Complications of HAI treatment included biliary sclerosis (8%) and ulcers (17%). (Kemeny N 1987) A similar randomized trial from the National Cancer Institute also demonstrated the efficacy of HAI chemotherapy. Sixty-two percent of patients receiving HAI had tumor regression, while only 17% of patients receiving IV therapy had a response. HAI patients had significant rates of biliary sclerosis (21%) and ulcer disease (17%), however, HAI therapy improved survival benefit at two-years to patients without hepatic artery nodal disease. (Chang AE 1987) Additional randomized trials have shown an improved tumor regression and preservation of quality of life with HAI infusion in carefully selected patients compared to selected controls. For example, the survival benefit existed only in the subset of HAI patients with less than 30% liver involvement, treated at specialized centers, and only when the comparison group received either systemic chemotherapy or only supportive care. (Rougier P 1992; Allen-Mersh TG 1995) A meta-analysis of all treatment groups at this time did not demonstrate a survival benefit for patients receiving HAI therapy over systemic therapy. (Harmantas A 1996) However, a more recent prospective trial has shown a survival benefit of HAI. In this trial 117 patients were randomized to IV versus systemic 5-FU and leucovorin. Similar to other trials, an increased response rate (47% *vs* 24%, $P = 0.12$), and time to hepatic progression (9.8 *vs* 7.3 mo, $P = 0.034$) was seen in HAI as compared to systemic therapy. Despite an increase in extrahepatic disease progression, overall survival was improved in patients with HAI (24.4 *vs* 20 mo, $P = 0.0034$). Importantly, quality of life assessments also showed an improvement in physical functioning at 3 and 6 mo of follow-up. (Kemeny N 2006)

The technique to place the catheter for drug delivery has been modified over the years such that current treatment involves an open laparotomy to cannulate of the gastroduodenal artery, and cholecystectomy. An analysis of 544 consecutive hepatic artery pumps in patients with unresectable colorectal cancer, revealed increased complications in patients with variant anatomy, pump insertion into an artery other than the GDA, and placement by a surgeon performing < 25 cases. However, the study also showed that only 16% of pumps had failed by two years. (Allen P 2005)

In 1995 Moertel demonstrated the advantage of adjuvant chemotherapy in Stage III colorectal cancer (Moertel C 1995). As hepatic resection became a safer procedure, investigators began to question whether resection followed by adjuvant therapy could offer a survival benefit as well as reduce liver recurrence. The German Cooperative study randomized patients to surgical resection alone versus surgical resection and HAI of 5-FU and folinic acid. Interim analyses did not demonstrate a conclusive survival benefit and the study was terminated. (Lorenz M 1999) However, an additional randomized trial demonstrated a survival benefit for HAI. Patients after liver resection received either HAI with floxuridine, dexamethasone, and, IV fluorouracil and leucovorin, or, systemic therapy alone of fluorouracil and leucovorin. Survival at two years was increased in the group receiving combined HAI and systemic therapy (86 *vs* 72%, $P = 0.03$).(Kemeny N 1999) An intergroup study randomized patients to surgery alone *vs* adjuvant HAI FUDR with IV 5-FU. While 4-year recurrence rate and liver recurrence-free rate were improved with therapy (25% *vs* 46%, $P = 0.04$, and 43% *vs* 67%, $P = 0.03$), the improvement in overall survival did not reach stastical significance. (Kemeny MM 2002) This may have been secondary to the fact that a significant number of patients that were disqualified from the study at the time of surgery, or, that the performance of the study at multiple institutions introduced another

variable.

In summary, HAI can be performed safely in institutions with appropriate experience. In patients with resectable tumors, HAI may offer a survival benefit either alone or when used in conjunction with systemic therapy. The patients with advanced disease that will receive the most benefit from HAI are those without peri-portal nodal disease.

CHEMOTHERAPY

For many years the only chemotherapy option in advanced colorectal cancer was the thymidylate synthase inhibitor 5-FU, given in combination with folinic acid (leucovorin), to potentiate the effect of 5-FU. These drugs had been shown to prolong disease free survival, with a large meta-analysis demonstrating a response rate of 32% and a median survival of 11.5 mo. (Project 1992) The development of newer agents has significantly influenced the management of advanced colorectal cancer.

Oxaliplatin is a third generation platinum drug that forms DNA adducts and results in cell death, with more efficacy and less side effects than previous generation platinums such as cisplatin.(Woynarowski JM 1998) Oxaliplatin used in combination with 5-FU and leucovorin improves disease free survival when used as an adjuvant in stage II or III colorectal cancer.(Andre 2004) In advanced colorectal cancer, the use of oxaliplatin with 5-FU/LV (FOLFOX) improved response rates to 50.7% and increased median survival, although not significant, to 16.2 mo.(de Gramont A 2000)

CPT-11(Irinotecan) and its active metabolite SN38 inhibit topoisomerase I, resulting in single strand DNA breaks and inhibition of DNA synthesis. (Kawato Y 1991) A randomized trial of irinotecan and 5-FU/Leucovorin (FOLFIRI) demonstrated an improved response rate of 39% and improved median survival of 14.8 mo in patients with metastatic colorectal cancer ($P = 0.04$ versus 5-FU/LV). (Salz L 2000) More recent trials have looked at treating patients with FOLFIRI or FOLFOX and with disease progression, transferring the patient from irinotecan to oxaliplatin or vice versa. This trial demonstrated impressive improvement in survival of 21.5 and 20.6 mo, limited only by toxicity profiles.(Tournigand C 2004)

As research in cancer therapy has progressed, more specific targets of cancer cells have been identified. Cancer cells express vascular endothelial growth factor (VEGF) in an effort to promote new vessel growth and tumor survival. Bevacizumab is humanized monoclonal antibody against VEGF. A randomized phase 3 trial of bevacizumab in combination with irinotecan, fluorouracil and leucovorin (IFL) versus IFL alone demonstrated increased disease free progression (10.6 *vs* 6.2 mo respectively) and increased survival (20.3 mo *vs* 15.6 mo). (Hurwitz H 2004) The epidermal growth factor receptor (EGFR) is an integral part of the cell that is the target of many signals regulation cell growth and death. A monoclonal antibody against EGFR, cetuximab, has also been demonstrated to prolong survival in patients with colorectal cancer refractory to irinotecan (8.6 *vs* 6.9 mo). (Cunningham D 2004)

NEOADJUVANT CHEMOTHERAPY

The armamentarium for treatment of metastatic colorectal cancer has improved over the years. While surgical resection offers the best outcome, many patients are not resectable and therefore undergo either HAI or systemic chemotherapy as described above. Bismuth was the first to demonstrate that preoperative chemotherapy could downstage tumors and make surgical resection an option. Patients in this study ($n = 330$) had nonresectable colorectal liver metastases, based upon tumor size, location or number of metastases, and underwent treatment with 5-FU, leucovorin, and oxaliplatin. Fifty-three patients responded to chemotherapy such that they became eligible for hepatic resection. The overall 5-year survival of patients undergoing surgery was 40%, with no peri-operative mortality. While 64% of patients had a hepatic recurrence, almost one-half were able to undergo an additional hepatic resection. (Bismuth 1996) These results have been substantiated in additional trials using the same chemotherapy with five-year survival of 35%-50%.(Giacchetti 1999; Adam R 2001)

Analysis of unresectable patients undergoing HAI infusion has only identified a small number of patients that became amenable to surgical resection. The first study was a retrospective analysis of 5-FU based HAI in patients with colorectal and non-colorectal liver cancer. Surgical resection became an option in 5.8% (14/239) of patients. Of these patients, 9 had metastatic colorectal cancer and underwent surgery. Five patients remained free of disease at a mean follow-up of 36 mo. (Elias D 1995) A similar retrospective study by Meric et al identified 383 patients with metastatic colorectal cancer who received HAI with FUDR. Twenty two patients had a response such that they were able to undergo additional procedures. Ten were able to undergo a resection alone while 6 underwent resection with cryotherapy or radiofrequency ablation. At a median post-operative follow up of 17 mo, the majority had recurrence and only 1 patient was alive without evidence of disease. (Meric f 2000) A phase I trial of the chemotherapy regimen of HAI of FUDR and dexamethasone with systemic oxaliplatin ± irinotecan or 5-FU/LV, demonstrated safety and an improved response rate when compared to systemic chemotherapy alone. Despite the fact that the majority of these patients had progression of disease on previous chemotherapy regimens, and 87%-90% had a partial response, seven of thirty-six patients were able to undergo liver resection and 2 had a complete pathologic response. (Kemeny N 2005) These encouraging results warrant further studies on the role of HAI with systemic chemotherapy in patients that fail to respond to other first line chemotherapy regimens.

The ability to respond to neoadjuvant chemotherapy improves survival and may be a significant harbinger of long-term survival. Allen studied patients presenting with colorectal liver metastases presenting within 1 mo of the primary surgery. All patients were resectable by radiological criteria. One group of patients went directly to surgery while the other group of patients received neoadjuvant chemotherapy consisting of 5-FU in combination with either oxaliplatin or irinotecan. The administration of

chemotherapy did not statistically influence survival, and no patients became radiographically unresectable while on chemotherapy. However, the patients on chemotherapy that had stabilization or regression of disease, had significantly improved survival over those patients that had disease progression on chemotherapy. (87% versus 38% 5-year disease specific survival, respectively, P = 0.03). (Allen P 2003) While this paper demonstrates the predictive value of response to chemotherapy, it also shows that patients who had disease progression also benefited from surgical resection.

CHEMOTHERAPY AND HEPATIC TOXICITY

With the knowledge that pre-operative chemotherapy can be given to downstage patients and possibly select those patients that are going have an improved survival, one must consider the effect of the chemotherapy on the liver. A retrospective analysis of 67 patients after liver resection revealed significant increase in morbidity in the group that received pre-operative chemotherapy consisting of 5-FU combined with either oxaliplatin or irinotecan. While there was no mortality, post-operative complications occurred in 37.8% of patients receiving neoadjuvant therapy and only in 13.6% of patients undergoing resection alone (P = 0.03). Transient hepatic failure occurred in 5 patients in the chemotherapy group. Pathologic examination of liver outside of the tumor revealed significantly increased sinusoidal dilatation in the chemotherapy group (49% *vs* 25% respectively, P = 0.005). There was no difference in steatosis or fibrosis. Multivariate analysis revealed preoperative chemotherapy to be one of the factors associated with increased post-operative morbidity. (Karoui M 2006)

Nodular regenerative hyperplasia (NRH) is the result of hyperplasia of hepatocytes with obliteration of surrounding liver in the absence of fibrosis. (Steiner 1959) The result is an enlarged liver with large nodules and at times, portal hypertension that mimics cirrhosis. The inciting factor of NRH is not known. A large study of 2500 autopsies demonstrated an incidence of only 2.6%. In this study, there was an increased incidence in older patients with collagen vascular diseases, tumors, and with underlying cirrhosis. (Wanless 1990) Pathologic analysis often noted thrombosis or diminutive portal veins, suggesting that alterations in portal flow influenced the development of NRH. Additional support for modifications in blood flow comes from two described cases of congenital absence of the portal vein, where a liver biopsy confirmed NRH, (Grazioli L 2000), however, many additional studies of NRH have not demonstrated vascular abnormalities.

NRH has also been shown to occur after chemotherapy. A consecutive study of hepatectomy specimens identified NRH in 7% of specimens. (Washington K 1993) All these patients had received pre-operative 5-FU regimen for colon cancer metastatic to the liver. However, there remains a disparity between drug administration and development of NRH, as not everyone in this study who received chemotherapy developed NRH. More recent studies have begun to describe cellular mechanisms of NRH. Notch signaling is a highly conserved intracellular signaling pathway that is fundamental in cell differentiation and embryonic development. In mice and humans, there have been four NOTCH receptors described (NOTCH1-4). In mice, loss of notch signaling is a fatal event. However, if one of the receptors of Notch signaling (Notch1) is inactivated early in postnatal development, this leads to NRH in the absence of vascular abnormalities.(Croquelois 2005) In addition, overexpression of IL-6 has also been shown to lead to NRH in mice.(Maione D 1998) These studies demonstrate pathways that could be targets for future understanding and prevention of NRH.

A retrospective study analyzed adjacent liver in resected liver specimens for metastatic colorectal cancer. All patients received 5-FU, leucovorin and either oxaliplatin or irinotecan. NRH was demonstrated in 4% of specimens. Importantly, 51% of specimens had sinusoidal dilatation with one-half having additional venoocclusive fibrosis. This was most common in patients that had received oxaliplatin therapy. (Rubbia-Brandt 2003)

Bevacizumab has anti-angiogenic properties and it is not yet known if livers resected after this therapy will have alterations in post-resection regeneration or function. At Yale, we have performed hepatic resections after 5-FU based therapy with oxaliplatin or irinotecan. In addition, some patients have also received bevacizumab. NRH has been frequently observed in patients receiving oxaliplatin particularly with extensive treatment. To date however this has not impacted negatively on the postoperative course or on hepatic regeneration.

FUTURE DIRECTIONS

With the progression in the understanding of colorectal disease new therapies will evolve. Instead of a surgical intervention to install an infusion pump to direct therapy into the liver, perhaps a therapy will be targeted to a gene. For example, adenoviral vectors are taken up by the liver and processed safely without evidence of inducing tumors (Bell 2005). These vectors can be used to carry cytokines, genes and apoptotic inducing proteins. Microarray technology has identified profiles of colorectal cancers that are likely to metastasize (Croner R 2005) and may help identify patients that need systemic chemotherapy. Gene profiling has identified characteristics that portend a favorable response to chemotherapy. (Matsuyama R 2006) The challenge will be to translate these studies into meaningful data for the patients with colorectal cancer.

In conclusion, the treatment of liver tumors has evolved substantially over the last century. The best chance for survival is surgical resection, and today liver resection can be performed with a low morbidity in correctly selected patients. Improvements in chemotherapy have improved survival in primary and metastatic colorectal cancer. Furthermore, chemotherapy has been able to downstage patients with advanced disease rendering them surgically resectable. Future studies will need to evaluate the hepatic side effects of newer drug regimens.

Abstract

Solid organ transplantation has rapidly developed into the therapy a choice for end-stage organ failure. The expansion of its use has resulted is a large deficiency in organ supply. To address this, the field of organ transplantation has attempted to develop new strategies that would increase the availability of organs for transplant. Some of these strategies include expansion of the donor pool by increasing the number of living donors or using deceased donor organs that may be marginal or "expanded". The intent is to bring life-saving therapy to individuals in need; however, much of this expansion has been brought forward without clear prospective guidelines. This article focuses on the current disparity between organ supply and demand, and how this has impacted the use of living donors and development of the "expanded donor" concept.

INTRODUCTION

The field of solid organ transplantation has made dramatic improvements to the overall health of patients suffering from end-stage organ failure. The ability to provide successful organ replacement is a testament to the progress made in the development of modern immunosuppression and the refinements made in the surgical management of these patients. The subsequent expansion of solid organ transplantation is depicted in Figure 1 which demonstrates that currently more than 90 000 patients are awaiting some form of solid organ transplant in the United States. Unfortunately, this rapid success in organ transplantation has not been matched by a parallel increase in the supply of organs available for transplant. Figure 2 demonstrates this graphically, where the additions to the waiting list continue to increase in a nonlinear fashion while the number of recipients receiving organ transplants has increased little in the last five years. The disparity between individuals awaiting organ transplantation and the supply of transplantable organs is the single largest impediment to application of successful organ transplantation for

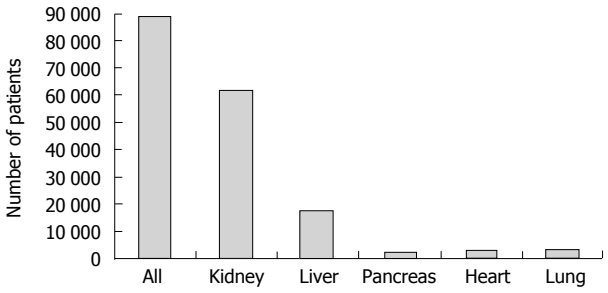

Figure 1 Number of patients on waiting list. May 12 2005 (www.optn.org)

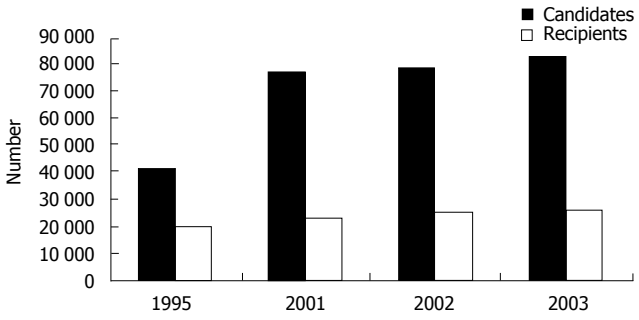

Figure 2 Growth of the number of candidates for transplantation compared to the number of recipients. (www.optn.org)

patients suffering end-stage organ failure.

One of the major ways transplant centers have attempted to increase the number of transplants performed is through increasing the numbers of living donors. Analysis of the types of organs used in organ transplantation shows that the year 2001 marks a significant shift to living donors. Figure 3 demonstrates in the year 2001, living donors were used more often as a source for kidney transplantation than were deceased donors. Analysis within the deceased donor pool reveals that as the median age of the donors has increased and as the severity of illness amongst the donors has increased, the use of marginal donors has played a greater role in supplying organs for transplantation. As the disparity between need and supply continues to widen, there are increasing pressures to seek alternative methods to supply organ donors to meet this crisis. An analysis of this disparity can most readily be divided between those issues that impact recipients directly and those that impact the number, type and quality of donors. With respect to recipients, the disparity between those listed and those transplanted can be regulated by imposing restrictions on the indications for transplantation. This, however, would be socially unacceptable as it is essentially withholding life-saving therapy. Another avenue to narrow the gap between those waiting for transplant and the supply of transplantable organs would be a change in the allocation policy. While allocation strategies continue to be modified within the organ groups (kidney, liver, pancreas, lung, heart) the intent of the new allocation strategies is to supply organs to those patients in the greatest need. The unwillingness to restrict the indications and the allocation of organs, demonstrates that society and the medial community will continue to broaden the inclusion criteria for patients who will benefit from transplantation. Surgical and immunosuppressive advances have markedly improved survival of all types of grafts of the past decade. From 1993 to 2002, the one-year graft survival of deceased donor kidneys improved from 82.1% to 89%, while live donor kidney grafts improved from a 91.4% to 95% 1-yr graft survival[1]. During this same time frame, pancreas grafts demonstrated improvement from 78.0% to 86.2%, while deceased donor liver grafts showed increases in graft survival from 73.9% to 82.4%. This continued growth in including more recipients is no doubt fueled by the success of transplant, both in quality of life and duration of life obtained.

EMERGENCE OF THE EXPANDED DONOR

Within the deceased donor category there are two broad distinctions of donor types. Those donors being designated as brain dead donors and donors designated as donation after cardiac death. The criteria for the diagnosis for brain death was established in 1968 by a NIH sponsored gathering of professionals. Documents coming out of this meeting, designated as the Harvard Brain Death Criteria[2], were instrumental in establishing brain death as medical and legal criteria to allow withdrawal of life support. At the time of this conference, there were many individuals being sustained on life support in intensive care units throughout the United States with no hope of recovery. This allocation of scarce ICU beds was negatively impacting the delivery of health care throughout the country. The establishment and acceptance of brain death criteria provided a legal, ethical and medical basis for the withdrawal of life support from these non-salvageable patients. It is from this pool that the majority of organ donors within the United States have been supplied. Although brain death criteria is accepted in North America, within other hemispheres, (i.e. Asia), brain death criteria has not been accepted due to religious and social beliefs. The efforts in the United States to increase the numbers of deceased donors have been varied and include public service announcements, education and legal mandates administered through regulatory agencies of health care within the United States. Despite these efforts, the conversion rate of deceased donors is below predicted values. However, even if all potential deceased donors were converted for donation, their numbers would be inadequate to supply enough organs for the increasing number of patients awaiting transplant[3]. Consequently, although a tremendous amount of resources have been applied to increasing the conversion rate within potential brain dead donors, the deceased donor pool would fall short of satisfying the disparity between those in need and awaiting solid organ transplantation. As a consequence, increasing the numbers of deceased donors have resulted in expansion of donation after cardiac death. Prior to the establishment of brain death criteria, the only deceased donors used for transplantation came from donation after cardiac death category. Though not formally recognized as such, donors after cardiac death should be considered to be a member of the expanded donor pool. Expanded donors are defined as organs that carry additional risks for transplantation beyond those associated with the standard transplant procedure[4]. This group of patients is typically composed of critically ill patients with no expectation of neurological recovery, in whom the decision to withdraw life support has been made. Within this group, various protocols have been applied to establish usability of the potential grafts[5]. Many organ procurement organizations throughout the United States have undertaken initiatives to increase the number of organs retrieved from this class of donor. Although acceptable within the defined limits for

kidney transplantation[6], this category of donor represents significant risks when applied to liver transplantation, specifically that of biliary complications and hepatic artery stenosis[7]. Despite the medical, legal and ethical justification for this procedure it is still shrouded in an era of suspicion by many members of the lay public and medical community. The suspicions rest with the perception that patients are prematurely withdrawn from life support to supply organs for transplantation. While the use of deceased donors from brain dead patients is considered standard of care within the transplant community, utilization of expanded donors has been evolving.

Within the specialty of kidney transplantation, a formalized definition of the expanded donor has been proposed (UNOS policy 3.5.1)[8]. This category of brain dead donor may carry the potential of increased risk of graft dysfunction and shortened graft survival; however, use of these kidneys would augment the current short supply of kidneys used for transplant and may appropriately serve the needs of recipients who otherwise would not be transplanted. Expanded donor kidneys, as defined by UNOS, are primarily all donors greater than 60 years of age or donors greater than 50 years of age who have co-morbidities of hypertension, cerebral vascular accident as a cause of death or creatinine elevation greater than 1.5. Institution of expanded donor utilization requires: definition of the expanded donor graft, identification of recipients who have given informed consent to be recipients of an expanded donor graft, and expedited placement of these kidney grafts to lessen the deleterious effects of cold storage time. Medical and ethical justifications for use of these expanded donors comes from analysis of SRTR (Scientific Registry of Transplant Recipients) data demonstrating that the relative mortality risk within the population of dialysis patients is lower with the use of an expanded donor kidney compared to remaining on dialysis at approximately 182 d after successful transplant and continues to have a survival advantage as long as the graft continues to work. What defines an expanded donor within the deceased donor liver grafts has been more difficult and currently there is no consensus. Within the deceased donor category, criteria such as age, infection, anatomic anomalies, presence of malignancies and steatosis carry with them added risk of liver transplants. Non-heart beating donor grafts derived from donation after cardiac death and livers that have been acquired through split procedures appear to have similar graft survival rates as standard deceased donor grafts, however, they are associated with more long-term complications[7,9]. Despite the obscurity of a true definition of expanded donor within the liver transplant community, many of these grafts are likely to expose the recipient to increased short term risk, including death, and may also result in more long term risks compared to standard liver grafts[10]. The balance, however, rests in the fact that increased waiting times are associated with increased mortality risks of those patients awaiting liver transplantation. It has been demonstrated by population analysis that the sickest patients awaiting liver transplantation do derive a survival benefit from transplantation with essentially any liver made available for transplantation[11]. Additionally, analysis of deceased donor liver grafts from a mid-west OPO demonstrates that there are few "perfect livers" available for transplant and in fact the number of livers included in the "perfect" category represent less than 3% of the livers used for transplant during the study (unpublished observations). Therefore, due to this spectrum of quality among the livers being utilized for liver transplantation, which extends from perfect livers to expanded donor livers, to livers that are not usable, the majority of deceased donor organs used for transplant are less than optimal.

It is not surprising that expansion of inclusion criteria within the deceased donor pool to include riskier organs for transplant has also stimulated expansion within the living donor category. 1954 marks a historic event in human history. It was at that time, December 24, 1954, when the first successful organ transplant was performed. This was a kidney transplant performed in Boston between identical twins. The necessity for using a living donor at that time was to overcome the immunologic barrier to transplant. Through the use of an identical, living donor the deficiency in immunosuppression therapy did not result in graft loss or patient loss. The ethical dilemma at that time was substantial and continues today. For the first time in medical history a healthy, volunteer donor was subjected to real and significant harm (surgical removal of a kidney) to provide benefit for another individual. Clearly this activity appears to violate the first rule of medicine *primum non nocere*. The justification for exposing the living donor to real and significant risks was balanced by the fact that the recipient who suffered end-stage kidney failure had no acceptable treatment options available. The diagnosis of end-stage kidney failure at that time resulted in the certain death of patients, as dialysis therapy was not available. Additionally, previous kidney transplant attempts resulted in graft loss secondary to rejection, or patient loss secondary to infection. This was, as Francis Moore described, "a desperate case". Additionally, legal intervention at the time justified exposure of the live donor as a trade-off in risks. Specifically, courts ruled that loss of an identical twin sibling would impose far more psychological harm and damage than would exposure to the risks associated with live donation. Since 1954, the inclusion criteria for acceptable, living donors has expanded. It has expanded with respect to organs being donated for transplantation as well as candidates being accepted for donation.

LIVING KIDNEY DONORS

Since 1954, the expansion of candidates deemed appropriate for living donation has moved beyond identical twins. With the development of effective immunosuppressive therapy, genetic identity is no longer required for successful transplant. This expansion began with genetically related donors, siblings or parents to donors that had an emotional relationship with the recipient including spouse and significant others. The increased use of living donors in kidney transplantation (Figure 3) has been further supported by the relative safety of the operation. Published reports demonstrate a

mortality risk of approximately 0.03% and a complication rate less than 3% when performed in high volume centers[12]. Additionally, surgical advances have improved the acceptance and willingness of living donation, as the movement from open nephrectomy to laparoscopic nephrectomy has demonstrated. Patients are more willing to undergo laparoscopic nephrectomy associated with earlier recovery and less pain associated with the donation. Analysis of population studies demonstrates that recipients of living donor grafts have decreased morbidity associated with transplant and an increase in patient and graft survival, as compared to deceased donor grafts. This improvement in survival of both patients and grafts is multifactorial and can be ascribed to earlier transplantation, limitation of cold ischemia time and transplantation with a better functioning graft. The most recent expansion of donor inclusion now includes directed, altruistic donation, non-directed anonymous donation and solicitation for donation. Directed, altruistic donation is usually provided by a donor who has a casual acquaintance relationship with the intended recipient. These donors usually originate from church groups, work organizations or other loose social associations. Because of the obvious benefits to the recipient and well defined and small risk to the donor, these donor-recipient pairs have been medically and ethically accepted by the transplant community. Further modifications of the living donor, recipient relationship include a swap donation between incompatible recipient donor pairs and other incompatible recipient donor pairs[13]. Previously, excluded groups have been the non-directed anonymous donors who now have become more acceptable within the transplant community. These donors are individuals who feel an overwhelming desire to donate a kidney to anyone on a transplant list for the sole purpose of improving their quality of life and longevity. This group was previously excluded on the basis of psychological instability; however, recent studies have demonstrated that although a significant portion of this group is excluded based on medical and psychosocial contraindications, there are individuals who are both psychiatrically and medically appropriate for donation[14]. Some programs have accepted these live donors for donation to patients on their transplant waiting list while others have accepted donation to the waiting list within the region. The most recent and unsettling practice within the living donor category has been outright solicitation for organ donation. This process most notably depicted through internet web sites appears to suffer from ethically questionable motives. In all forms of living donation the following practices exist. First, in directed donation, be it genetically related emotionally or casual acquaintance, there is a clear and definable benefit for which the donor can experience and value in the recipient. It appears that the risk benefit analysis under this relationship favors donation. In non-directed living donation, that being from a stranger or anonymous donor to either a transplant center waiting list or a regional waiting list, the benefit derived by the donor is in terms of a self-motivation and realization of doing a profoundly charitable and noble act for another human being. The benefit received by the recipient is obvious and the same for any recipient of living donor graft. Under this arrangement it appears that the risk benefit analysis would still favor the process of living donation. In both of these circumstances, the recipients participate in a well organized transparent and regulated system of valuation, regulation, allocation and access to the transplant graft. In the context of solicitation for donors, however, the emotional bond between donor and recipient pair is more difficult to define. The genetic bond is non-existent and motivations of pure altruism may take on a different a definition. Potential donors usually survey websites for the most compelling or set of characteristics that would satisfy their desire to donate. Reciepients have access in a non-equal way compared to other registered wait list recipients with UNOS. This injustice between access to secondary sources of organ allocation results in difficulties to delineate motives between donor and recipient pair, and provide the potential for exploitation of either or both participants in this enterprise, thus, making solicitation for living donation difficult to defend on ethical grounds. Donors are not prohibited from donating to the list in an anonymous fashion if altruism is their true motivation; however, recipients who undertake this process jump the queue among other recipients for access to this scarce resource. This unequal distribution of access undermines the trust and confidence of organ allocation within the US system.

LIVING LIVER DONORS

In the practice of liver transplantation, use of the living donor began as a case reports in the late 1989[15]. This was further studied in a prospective, comprehensive, IRB supported protocol at the University of Chicago[16], in which 20 donor-recipient pairs underwent transplantation. This study incorporated key components of the use of living donors, specifically; research ethics consultation, assignment of a donor advocate, demonstration of field strength of the institution and physician team prior to undertaking the study and a cooling off period with multiple steps in the informed consent process[17]. This landmark study in the use of living donors served to establish modifications in the living donor surgical procedure and facilitated incorporation and dissemination of the practice of living donor liver transplants for pediatric recipients world-wide. Justification for exposing donors to a potentially significant harm was offset by the dire circumstance of infants awaiting the liver transplant patient. Prior to institution of the living donor liver transplant procedure for infants, the mortality rates for infants awaiting liver transplantation approached 30%[18]. With the rapid acceptance of this surgical innovation, the mortality in some institutions performing pediatric liver transplantation diminished to less than 1%[19]. Throughout the study, the surgical techniques were modified and living donor liver transplantation for pediatric recipients has become standard of care worldwide. The estimated mortality risk for the donor is approximately 0.1%, with morbidity less than 15%[20]. It is important to note that within the use of living donors for pediatric liver transplantation, the majorities of donors are genetically or emotionally related to the recipient and include parents,

siblings, aunts, uncles and grandparents.

Extension of living donor liver transplantation to adult recipients began in the late 90's, from various institutions conducting independent small series[21,22]. Contrary to the pediatric experience, the introduction of adult-to-adult living donor liver transplantation did not benefit from a prospective, well defined, single center study. In fact, the majority of institutions performing adult-to-adult living donor liver transplant did so without an accepted IRB protocol. Consequently the risks and benefits associated with the procedure were difficult to quantify and not applicable across programs. Donor deaths have occurred and it wasn't until 2001 where the first widely publicized donor death stimulated regulatory intervention in New York State concerning adult to adult living donor liver transplantation[23,24]. Secondary to that well publicized complication, the numbers of adult-to-adult living donor liver transplants rapidly diminished within the United States, having only recently begun to increase[25]. Adult-to-adult living donor liver transplantation is performed in many countries throughout the world and in particular serves as the only source of organs for transplantation in regions where religious opposition to deceased donation occur (i.e. Japan and China)[26]. Unfortunately, the development of the procedure has not clearly delineated indications and contraindications for both recipients and donors. This is a process which continues in evolution and is dependent upon reports from individual centers. There is currently an NIH sponsored multi-institutional trial collecting data which should be very important to help define the appropriate role and complications of adult-to-adult living donor liver transplantation for both recipient and donors alike. Although the majority of donor-recipient pairs have both a genetic or emotional relationships justifying the risk/benefit of such a procedure, there has been increased inclusion of anonymous living donors and solicitation for living donors. In an operation whose mortality has been predicted between 0.6 and 1% and whose morbidity has ranged as high as 67% the donor population[27,28], it is difficult to ethically justify the undertaking of the riskiest live donor operation performed to date without understanding the benefit derived in the risk/benefit analysis. Living donation has also been applied to lung transplantation, although small in number it appears that well selected donors and recipient pairs result in an acceptable outcome justifying the exposure of the donor to this operation[29,30]. The relative safety to this operation is no doubt dependent upon the small number of centers who are engaged in this practice. With respect to living donor intestinal transplantation, it appears that in well controlled circumstances, when performed in experienced centers, this operation may be of benefit to recipients with acceptable risks to donors[31,32]. However, the number of cases remains small and the demonstration of an inadequate deceased donor supply have not fully justified exposure and utilization of the live donor for intestinal transplantation. Therefore, it is difficult at this time, outside of an experimental protocol, to ethically justify placing a donor at unknown risk for undergoing intestinal procurement for a unclear recipient benefit.

In conclusion, it is clear that as transplantation provides a successful treatment for a variety of diseases which result in end-organ failure and that the demand for organs will continue to out strip the supply. This disparity will continue to drive the practice of expanding the criteria for what is defined as an acceptable deceased donor or living donor. With respect to deceased donors, expansion of the inclusion criteria can only be accomplished at the margins currently defined as *expanded donor criteria*. Utilization of these grafts does result in added risks experienced by the recipient. It is imperative that these added risks associated with the use of expanded, deceased donor grafts are appropriately matched to the expected outcomes in the recipients for whom they are used. Specifically, it would not be ethically acceptable to use a 70 year old kidney in a 16 year old recipient unless there were significant and compelling reason to expose such a recipient to the risks and limited survival of such a graft. Additionally, it may not be acceptable to utilize a 21 year old perfect kidney in transplantation of a 75 year old recipient with multiple medical problems who has an expected life expectancy of less than 3 years. These are difficult decisions which have not been codified into practice plans currently. With respect living donor use for kidney transplantation, it appears that our current dilemma rests in the use of living donor grafts procured from solicited donors. The risk/benefit analysis has always favored performance of a relatively safe nephrectomy for the demonstrable benefits in the transplant recipient. This risk/benefit relationship has always been solidified and enriched by a donor-recipient relationship; be it genetic, emotional or acquaintance. In liver transplantation, it appears that until such time when reliable indicators exist to exclude expanded donor grafts, the survival advantage with transplantation continues to be a compelling argument in favor their use. In the field of living donor liver transplantation, adult-to-pediatric transplantation has been incorporated as standard of care in pediatric liver transplantation. Within the adult-to-adult living donor liver transplantation procedure, the extent of the donor operation, inclusion and exclusion of donor candidates, and inclusion and exclusion of recipients continue to require delineation. Under the current practice it appears that more formalized, investigation and study would be required to protect both recipient and donor pairs and to define, clearly, the indications and contraindications of adult-to-adult living donor liver transplantation. With respect to the use of all living donors, informed consent, donor follow up, and protection of donors, should be paramount in institutions undertaking this enterprise.

Abstract

In this article, we have reviewed the hepatic perfusion disorder (HPD), etiopathogenesis of HPD and corresponding diseases. Review of the literature was based on computer searches (PubMed, Index Medicus) and personal experiences. We considered HPD reflects perfusion differences due to redistribution of arterial blood flow among segments, subsegments and lobes of the liver. The plain CT scan findings of HPD manifests as triangular or wedge-shaped areas of low attenuation. On contrast-enhanced CT scan, HPD manifests multiple (or single) transient wedge-shaped, rotundloid or irregular appearance, homogeneous hyperattenuation (in less cases, hypoattenuation) during the hepatic arterial phase (HAP) and isoattenuated or slightly hyperattenuated areas during the portal arterial phase. Dynamic enhanced magnetic resonance (MR) features are similar to enhanced CT scan. Angiographic findings include non-opacification of portal vein on portograms or wedge-shaped segmental staining in arterial and parenchymal phases on hepatic angiograms. The causes of HPD are arterioportal shunts (APS), intrahepatic vascular compressions and portal vein occlusion, steal phenomenon by hypervascular tumors, vascular variations and any other unknown reasons. It is very important for radiologists to be familiar with the various appearances of HPD to avoid false-positive diagnosis of pseudolesions and not to overestimate the extent of the disease.

INTRODUCTION

Definition of HPD

Hepatic perfusion disorder (HPD) refers to perfusion differences among segments, subsegments and lobes of the liver caused by various etiologies. It is usually transient peripheral and triangular, wedge-shaped or rotundloid hepatic parenchymal enhancement during the hepatic arterial phase (HAP) and returns to normal attenuation/intensity on portal venous phase (PVP) on CT and MR dynamic enhancement, and segmental staining or segmental perfusion defect on angiograms. It usually has a straight margin, and contains normal vessels and without mass effect. With the improvement of temporal resolution of CT and MR, detection rate of this phenomenon has increased recently. However, the nomenclature of this phenomenon is different in different imaging modalities, HPD is a good nomenclature for this phenomenon suitable for any other imaging modalities. This article presents the nomenclature and history of hepatic perfusion disorders and their spectrum with etiopathogenesis.

Nomenclature and history

In 1981, Inamoto *et al*[1] and Nishikawa *et al*[2] first described segmental low attenuation areas within the liver not corresponding to mass lesions. This phenomenon was attributed to decreased portal flow. In 1982, Itai *et al*[3] reported transient hepatic attenuation difference (THAD) during the HAP on CT, and explained the pathophysiology and etiology of this phenomenon. In 1984, Matsui *et al*[4] described segmental staining on hepatic angiograms and portal vein occlusion on portograms (a sign of intrahepatic portal vein obstruction) in liver tumor cases. They also found that the areas of segmental staining on hepatic angiograms were the ones of hepatic parenchymal enhancement during the HAP on CT. In 1988, Itai *et al*[5] reported the findings of segmental intensity difference (SID) on MR images. They found that the SID was defined as a zone of homogeneously long T1 and long T2 signal intensity with segmental or subsegmental distribution not corresponding to the areas of the mass. In cases of SID, they studied MR images combined with other images, such as CT scans, ultrasound (US) and angiography, for corresponding abnormalities. The areas of SID were trapezoid hypoechoic areas contacting with the hepatic contour as disclosed on US studies. They also found that many cases with wedge-shaped defects showed by portography and segmental staining on arteriography revealed no areas of low attenuation on plain CT and MR images and no pathologic dif-

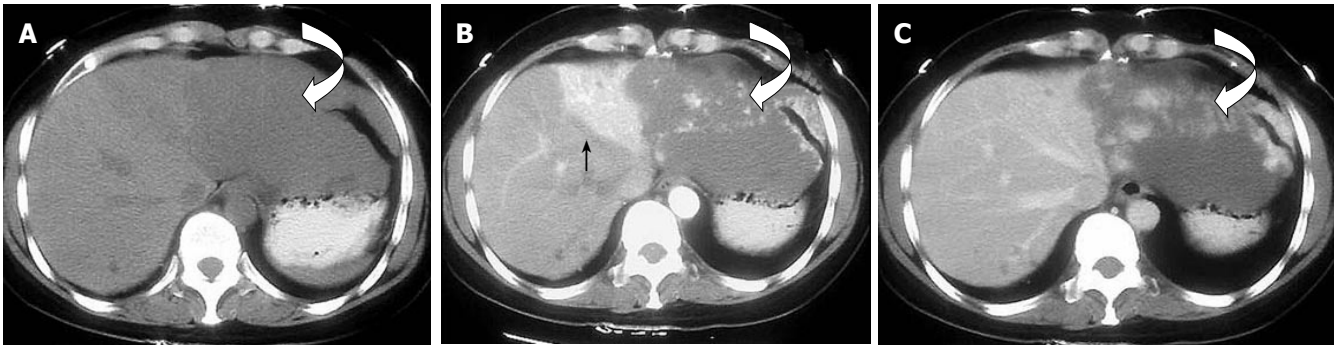

Figure 1 HPD in a 48-year-old woman with cavernous hemangioma. **A:** Pre- contrast administration transverse CT scan shows a large well-defined hypo-attenuating lesion located in segment Ⅱ (curved open arrow); **B:** HAP CT scan shows a nodular enhanced hemangioma (curved open arrow) and wedge-shaped segmental homogeneous hyperattenuating areas (solid arrow) adjacent to the tumor; **C:** PVP CT scan shows the still nodular enhanced hemangioma (curved) and the peripheral area resumed isoattenuating.

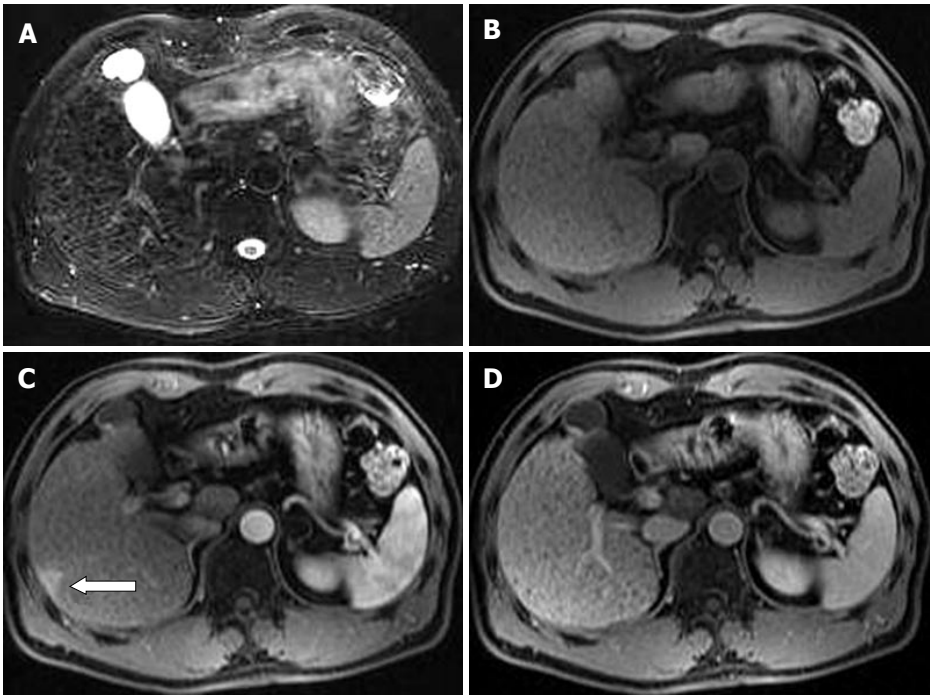

Figure 2 HPD in a 56-year-old man with liver cirrhosis. **A:** Fat-saturated breath-hold turbo FSE T2-weighted transverse MR scan shows multiple punctuate hypointensity cirrhotic nodules and surrounding reticulated fibrotic liver parenchyma, without any obvious hyperintense tumoral lesions; **B:** pre- contrast administration transverse spoiled gradient-echo T1-weighted MR image (118/4.1; flip angle, 80°) shows no obvious hypointense tumoral lesions observed; **C:** transverse contrast-enhanced T1-weighted MR image obtained during HAP shows a subcapsular small patchy hyperintense tumor-like lesion (pseudolesion) (open arrow); **D:** transverse contrast-enhanced T1-weighted MR image obtained during PVP shows no lesion in that area.

ferences at microscpic examination. In 1997, Gryspeerdt *et al*[6] reviewed the phenomenon of hepatic perfusion differences on dual-phase spiral CT scan, and first nominated it as hepatic perfusion disorders (HPDs). They considered that various HPDs are related to portal venous inflow obstruction, hepatic venous outflow obstruction (e.g., Budd-Chiari syndrome, cardiac failure, mediastinal fibrosis), mediastinal or thoracic venous inlet obstruction, focal liver lesions, inflammatory processes, normal anatomic variants in the hepatic blood supply, altered hemodynamics after the placement of a transjugular intrahepatic portosystemic shunt, and uncertain causes. In the same year, Lee *et al*[7] observed the correlation between the arterioportal shunt caused by liver biopsy injury and wedge-shaped early transient enhancement phenomenon of the liver during helical dynamic CT in 21 patients, and nominated it as transient subsegmental parenchymal enhancement (TSPE). After that, many authors reported this phenomenon as THAD and HPD[8-14]. However, THAD reflects an enhanced, redistributing arterial flow to a hepatic segment or lobe on CT; it cannot reflect other imaging modality findings, such as segmental staining on arteriogram, trapezoid hypoechoic areas on US and SID on MR. In our opinion, HPD is a good nomenclature for this phenomenon suitable for any other imaging modalities.

Imaging features

The plain CT scan findings of HPD manifests as triangular or wedge-shaped areas of low attenuation. The metabolic pathophysiology of the phenomenon is decreased glycogen and subsequent increase of fat and/or edema secondary to venous inflow obstruction due to portal branch occlusion. On contrast-enhanced CT scan, HPD manifested multiple (or single) transient triangular, wedge-shaped, rotundloid or irregular appearance, homogeneous hyperattenuation (in less cases, hypoattenuation when the hepatic artery is compressed or occluded) during the hepatic arterial phase (HAP) and isoattenuated or slightly hyperattenuated areas during the portal arterial phase (PVP) (Figures 1 and 2). Plain MR scan is defined as a segmental

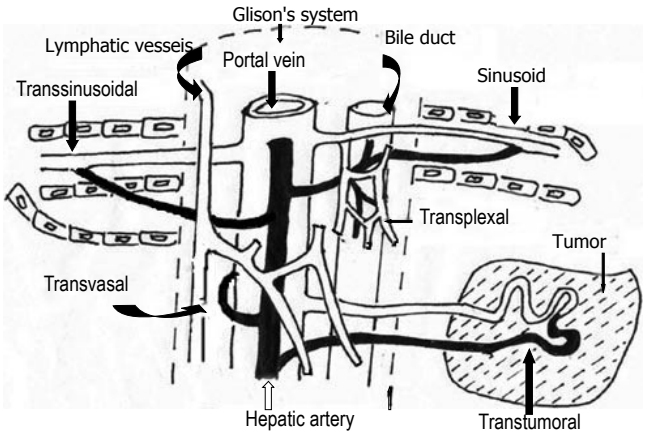

Figure 3 Schematic drawings showing hepatic microvasculature and arterioportal anastomoses or arterioportal shunts, including the transsinusoidal route (between the interlobular arterioles and portal venules or sinusoids) and the transplexal route (peribiliary plexus), transvasal route (perilymphatic vessels) and transtumoral route.

or subsegmental iso-intensity on T1- and T2-weighted images (in less cases, long T1 and long T2 signal intensity). Dynamic enhanced MR features are similar to enhanced CT scan. Angiographic findings included non-opacification of portal vein (a sign of intrahepatic portal vein obstruction) on portograms or wedge-shaped segmental staining in arterial and parenchymal phases on hepatic angiograms, and corresponding features are seen if there is an occlusion of hepatic vein or aberrant blood supply. There lacks special report of US features about HPD yet, trapezoid hypoechoic areas on US were found corresponding to SID on MR or THAD on CT images[6]. There is also no report about real-time contrast-enhanced US features of HPD as yet.

Table 1 The causes of HPD

The causes of HPD

Liver cirrhosis
Congenital APS
Intrahepatic vascular compression and occlusion
Neoplasms
Malignant tumors: HCC, cholangiocarcinoma, metastases
Benign tumors: hemangioma, FNH
Inflammatory changes
Hepatic abscess, acute cholecystitis, cholangitis.
Focal eosinophilic necrosis
Hepatic parenchymal compression
Rib compression
Perihepatic peritoneal tumors
Pseudomyxoma peritonei
Perihepatic fluid collections
Others
Right-sided heart failure
Pericardial disease
Budd-Chiari syndrome
Mediastinal fibrosis
Steal phenomenon by hypervascular tumors
HCC
Hypervascular metastases: islet cell tumors, carcinoids, renal cell carcinoma, and breast cancer
Vascular abnormalities and hereditary hemorrhagic telangiectasia
Vascular variabilities: capsular vein, accessory cystic vein, aberrant right gastric vein
Hereditary hemorrhagic telangiectasia
Unknown causes

PATHOGENESIS OF HPD

HPDs may be noted to accompany tumors; however, they may occur due to non-tumor vascular reasons as well. Among the reasons of HPD are arterioportal shunts, intrahepatic vascular compression and occlusion, steal phenomenon by hypervascular tumors, vascular abnormalities and hereditary hemorrhagic telangiectasia, and any other unknown reasons (Table 1).

Arterioportal shunts

A distinctive feature of the liver is its unique dual blood supply, which comes from the hepatic artery (25%) and the portal vein (75%). There can be several potential communications between the vessels, including transsinusoidal, transvasal and transplexal (peribiliary) routes (Figure 3). In some pathologic cases, an organic or functional communication between a hepatic arterial branch and the portal venous system occurs, resulting in redistribution of arterial flow into a focal region of portal venous flow due to high pressure in hepatic artery and low pressure in portal branch. On dynamic enhanced CT/MR scan or hepatic arteriography, HPD manifests as a transient area of high attenuation/intensity or segmental staining due to passage of contrast material from arterial blood into portal vein branch, thus enhancing/staining a focal area of the liver before the adjacent parenchyma is enhanced/stained through the portal venous system. The areas with APS are enhanced or stained intensively due to hyperperfusion; in contrast, the other areas without APS are enhanced or stained normally due to normal perfusion. The helical CT or MR findings of APS are as follows: (1) Early enhancement of the peripheral portal vein branches during the HAP and before the main portal vein is enhanced; and (2) enhancement of the peripheral portal vein branches and main portal vein without enhancement of the superior mesenteric and splenic veins. Hepatic arteriographic findings of APS are early visualization of small portal branches when hepatic artery is visualized.

The causes of APS include: (1) Trauma: Abdominal trauma sometimes causes an organic communication between the arterial and portal venous systems due to vascular rupture or produces functional APS due to portal or hepatic vein thrombosis; (2) Neoplasms: Hepatic neoplasms include both malignant tumors such as HCC, cholangiocarcinoma and various hypervascular metastases and benign tumors such as hemangioma and focal nodular hyperplasia (FNH)[14]. HCC is either the most common malignancy of the liver or the most common cause of HPD. In cases of peripheral small HCC, APS is induced

via the transtumoral route, and in cases of large HCC, APS is induced via the transvasal route (due to portal vein tumor thrombosis), the transtumoral route (through the tumor itself), or the transsinusoidal route (between microscopic hepatic arterioles and portal venules distal to portal vein compression or thrombosis) and a transplexal (peribiliary) route. Cholangiocarcinoma may cause APS when the portal or hepatic vein is compromised. Hypervascular metastasis may cause APS similar to HCC. It was considered that hepatic hemangioma seldom causes APS; however, recent studies have shown that there is transtumoral route of an arterioportal shunt between the hepatic artery and the portal vein[17-19]. The arterioportal shunt of a hemangioma is somewhat different from that of an HCC because most HCCs accompanying an arterioportal shunt tend to be large tumors with portal vein invasion. In small hepatic lesions < 3 cm, the incidence of arterioportal shunt is significantly higher in a small hemangioma than in a small HCC[20]. Small hemangioma with large arterial flow and flash filling has APS and shows HPD more frequently than a large one[17,18]. FNH is supplied by an anomalous enlarged hepatic artery and is neither supplied nor drained by the portal vein. We found that FNH showed HPD in two cases, although the pathogenesis is unknown. There was neither HPD observed in our practice nor articles reported in hepatic adenoma whether it may show HPD is unknown yet; (3) Interventional procedures: Interventional procedures (e.g., hepatic biopsy, biliary and abscess drainage, various physical treatment of hepatic tumor, percutaneous transhepatic cholangioscopy, and transjugular intrahepatic porto-systemic stent shunt) can produce iatrogenic arterioportal fistulas due to portal vein injury[21,22]; (4) Liver cirrhosis: Liver cirrhosis is caused mainly by parenchymal necrosis, which is followed by deposition of connective tissue, nodular hepatocyte regeneration, and distortion of the lobular and vascular hepatic architecture, and false lobules, producing portal hypertension. Liver cirrhosis is known to alter normal hepatic blood flow dynamics, resulting in increased arterial flow and decreased portal venous flow to the liver. APS is believed to be secondary to occlusion of the small hepatic venules and retrograde filling of the small portal vein branches by way of arterioportal anastomoses (transsinusoidal route)[23]. In addition, hypertrophy of the peribiliary plexus and direct anastomosis in the peripheral area of the liver are another routes of APS. Due to false lobules formation and distortion of the vascular hepatic architecture, HPD may appear as small enhancing nodules during HAP in cirrhotic patients and may be confused with small hepatocellular carcinomas. A correct diagnosis can be made by observing the portal phase (rapid wash out with hypoattenuating lesion in HCC, isoattenuating in case of HPD at CT) and the lack of T2 hyperintensity at MRI. MR with reticuloendothelial contrast agents (supermagnetic iron oxide, SPIO) may also be of help (signal loss in HCC, no signal loss in case of HPD); (5) Congenital APS: Some congenital hepatic diseases, such as infantile hepatic hemangioma, arteriovenous malformations (AVMs) and infradiaphragmatic total anomalous pulmonary venous return (TAPVR), can also be associated with APS.

Intrahepatic vascular compressions and occlusion

Intrahepatic vascular includes hepatic artery, portal and hepatic vein, and may be compressed and occluded by many causes: (1) Compressions and occlusion of hepatic artery: As a result of the compression and occlusion of hepatic artery, the hemodynamic balance between the portal vein and the hepatic artery in the affected lobe or segment may change. Different from common features of HPD, areas of hypoattenuation/intensity may be seen on contrast-enhanced CT or MR images and segmental staining defect may be seen on hepatic arteriograms due to decrease in the blood flow of the affected hepatic artery[16]; (2) Compression and obstruction of portal vein: When the compression and obstruction of portal vein occurs, perfusion alterations are produced by increases in arterial flow through transsinusoidal, transvasal, transtumoral, and especially transplexal (peribiliary) routes to compensate for the diminished portal venous flow (functional APS) and by decreased dilution of the contrast material by the non-enhanced portal venous flow[10,14,16]; (3) Compressions and obstruction of hepatic vein: Occlusion of the hepatic veins results in increased sinusoidal pressure and reverses the pressure gradient between the sinusoidal and portal veins. The portal vein then becomes a draining vein and there is an increase in hepatic arterial flow, resulting in a functional APS, as in liver cirrhosis[16].

The causes of compression and obstruction of intrahepatic vessels include: (1) Neoplasms: Hepatic tumors are either sometimes associated with portal vein compromise and or, less frequently, with hepatic vein and artery compromise. As a result of the invasion of the hepatic artery due to tumoral compression and encasement, the blood flow in the compromised areas decreases. The invasion of the portal and hepatic vein due to tumor may result in obstruction due to tumor thrombosis, blood flow decrease or stasis[10]; (2) Inflammatory changes: Local inflammation can cause hyperemia of the hepatic artery and stoppage of regional portal or hepatic venous flow, as in cases of hepatic abscess, acute cholecystitis, cholangitis. The compromised areas include both the inflamed lesion and the surrounding parenchyma[16]. Recently, there is a report that focal eosinophilic necrosis may cause HPD. Pathologically, focal eosinophilic necrosis is a focal area of hepatocellular necrosis caused by severe eosinophilic infiltration of perivascular space. Therefore, one may assume that eosinophilic infiltration of the perivascular space may be the cause of the stoppage of regional portal venous flow, portal thrombosis and occlusion[14]; (3) Hepatic parenchymal compression: When there is increased pressure on the hepatic parenchyma, blood flow through the portal vein is reduced due to portal venous low pressure system and consequently, increased arterial inflow to the affected hepatic segment due to the high pressure arterial system[11]. The causes of hepatic parenchymal compression include rib compression (in some cases, the medially concave rib may constantly compress the hepatic parenchyma), perihepatic peritoneal tumors, such as pseudomyxoma peritonei, and perihepatic fluid collections. This transient hemodynamic change is reversible when

the compression is removed; (4) Others: Other causes of compressions and obstruction of intrahepatic vessels include right-sided heart failure, pericardial diseases, Budd-Chiari syndrome, or mediastinal fibrosis, which may result in hepatic vein occlusion[10]. In patients with right-sided heart failure, the contrast agent can be seen within the hepatic veins during HAP due to decreased hepatic vein flow, while during PVP stagnation of the contrast agent within the sinusoids may give rise to a mottled appearance of the parenchyma.

Steal phenomenon by hypervascular tumors

Hypervascular tumors usually include HCC and hypervascular metastases, such as islet cell tumors, carcinoids, renal cell carcinoma, and breast cancer. These hypervascular tumors may result in "hypertrophy" of the hepatic arterial blood supply to the lobe or segment of the liver containing the tumor, and can "steal" arterial blood from the surrounding parenchyma due to siphoning effect, which is similar to the phenomenon of stealing blood caused by AVMs. Then the hepatic parenchyma adjacent to the tumor can receive more than usual arterial blood supply and the perfusion of the remainder of the lobe is reduced. The net effect of this stealing depends on the tumor location, degree of tumor vascularity, and ratio of tumor to parenchyma blood supply[10,25,26].

Vascular abnormalities and hereditary hemorrhagic telangiectasia

Vascular variabilities, such as capsular veins drain into adjacent hepatic sinusoids, accessory cystic veins drain into the liver parenchyma of segments IV-V, parabiliary system from the head of the pancreas, duodenum and distal stomach drain into the posterior part of segment IV, veins from the gastric antrum and pancreatic head into segments I and IV, which are third hepatic inflow tracts, may drain the systemic venous circulation into the liver[27-29]. Focal intensively enhanced areas are seen on HAP images of CT or MR, segmental staining is seen on arteriogram because of the early inflow of contrast material compared with the inflow into the surrounding parenchyma, which receives contrast material mainly from the splenic and superior mesenteric veins. Common locations of the HPD caused by vascular variations are adjacent to the gallbladder fossa, anterior to the porta hepatis, adjacent to the falciform ligament, and in the subcapsular area. These HPDs might appear either wedge-shaped and triangular; in less cases, they appear nodular, it makes difficult to differentiate from a true lesion, especially located in subcapsular areas[10]. Sometimes, hepatic arterial supply derived from the cystic artery (hepatic branch artery-ramus profundus) can also produce a hyper-perfusion in a pericystic location during HAP, similar to those produced by the cystic vein.

Hereditary hemorrhagic telangiectasia (HHT, Osler-Weber-Rendu disease) is a vascular disease with autosomal dominant transmission characterized by multiple telangiectases, which are thin-walled, dilated vascular channels with arteriovenous communications. HHT affects mucocutaneous tissue most frequently, but any part of the body can be affected, including the liver. The hepatic changes, including widened and tortuous hepatic arteries, telangiectases, arteriovenous and portovenous fistulas, connective tissue formation with fibrosis and atypical cirrhosis, high cardiac output, secondary congestive heart failure due to a left-to-right intrahepatic shunt, portal hypertension, gastrointestinal hemorrhage, ascites, or encephalopathy[30-32]. APSs are nearly universal in HHT, and HPDs often occur. Contrast-enhanced CT or MR shows heterogeneous perfusion of the hepatic parenchyma with multiple, peripheral, wedge-shaped or irregular areas of intensively enhanced areas during the HAP. Angiography shows diffuse mottled capillary blush with multiple segmental or subsegmental staining.

CONCLUSION

HPDs reflect a hemodynamic change in the normal dual blood supply of the liver in area of surrounding lesion. The nature of HPDs is perfusion differences due to redistribution of arterial blood flow among segments, subsegments and lobes of the liver. Among the reasons of HPD are arterioportal shunts, vascular compression and occlusion, steal phenomenon by hypervascular tumors, vascular variations and any other unknown reasons. It is very important for radiologists to be familiar with the various appearances of HPD to avoid false-positive diagnosis of pseudolesions and not to overestimate the extent of the disease. Because knowing the characteristics of HPDs and differentiating them may prevent the tumor diameter from being measured larger than they actually are in the case of hypervascular tumors such as HCC.

Abstract

AIM: To determine the effects of electrical stimulation of nucleus ambiguus (NA) and dorsal motor nuclei of vagus (DMV) on gastric acid and bicarbonate secretion in rats.

METHODS: NA and DMV in rats were electrically stimulated. Pylorus ligation or esophagus perfusion was used to collect the gastric secretion. The titratable H^+ quantum, H^+ concentration, HCO_3^- secretion quantum were measured.

RESULTS: Electrical stimulation of NA had no effects on the volume of gastric juice, titratable acidity and acid concentration, but elicited a pronounced increase in the total bicarbonate. However, electrical stimulation of DMV significantly increased the titratable acidity, the volume of gastric juice and the acid concentration. Similarly, electrical stimulation of either NA or DMV decreased the respiratory frequency and sinus bradycardia.

CONCLUSION: NA in rats can not control the secretion of gastric acid but the secretion of bicarbonate in gastric juice, while DMV controls the secretion of gastric acid.

INTRODUCTION

The knowledge of brain stem nuclei controlling vagal parasympathetic outflow to the gastrointestinal tract has been derived principally from anatomic and physiological investigations of the dorsal motor nuclei of vagus (DMV). It was reported that electrical stimulation or lesion of DMV results in pronounced alterations in gastric motility and secretory function[1-4]. However, Kerr[2] showed that DMV is not the only origin of the vagal parasympathetic nerve innervating the stomach and vagal parasympathetic neurons might come from the nucleus ambiguus (NA). Studies indicate that the increased gastric motility in cold water-immersion stress rats is significantly inhibited, but there is no change in gastric acid secretion in rats pretreated with narceine or pentobarbital sodium[5,6]. These results suggest that the primary parasympathetic center innervating gastric motility and acid secretion consists of different nuclei. Moreover, recent morphological studies suggest that vagal parasympathetic neurons innervating the stomach are largely located in DMV and partly in NA[7-9]. So far, whether there are differences in the functions of DMV and NA in controlling gastric secretion remains unknown.

A great number of morphologic and physiological studies suggest that parasympathetic preganglionic neurons of the heart are located in DMV, NA and intermediate zone[10-13]. Previous experimental data have established that electrical stimulation of NA induces bradycardic responses, which can be abolished by injection of lidocaine into the rostral ventrolateral medulla[14,15].

It was reported that the medulla is the essential center of respiratory rhythm in mammals[16]. Respiratory neurons can be divided into two groups according to their positions: dorsal respiratory group and ventral respiratory group. NA is a component of ventral respiratory group[17]. A group of respiratory neurons in the rostral NA complex is involved in the generation of inspiratory and expiratory drives which enables spontaneous respiration[18]. The aim of this study was to investigate the effects of electrical stimulation of NA and DMV on gastric acid and bicarbonate secretion as well as respiratory frequency and heart rate.

MATERIALS AND METHODS

Animals

Male Wistar rats weighing 270-310 g were provided by

Experimental Animal Center of Shandong University, China. The animals were individually housed in cages at 22 ± 2 ℃ with free access to food and water in a normal day/night cycle. All experiments were conducted according to the guidelines of the International Association for the Study of Pain[19] and every effort was made to minimize both the animal suffering and the number of animals used.

Experimental methods

The rats were intra-abdominally anesthetized with urethane (1 g/kg) and placed in a Jiangwan type I stereotaxic apparatus (made in China). The dorsal surface of the brain stem was exposed by limited occipital craniotomy. According to the coordination of the NA as defined by the atlas[20], an electrode (40-60 μm in diameter and 10-16 kΩ in resistance) was inserted vertically into the right or left side of the brain stem at a level 12.7 mm caudal to Bregma and 2.0 mm lateral to the midline, and to a depth of 9.6 mm below the dorsal surface. In the study on DMV, the electrode was inserted vertically into the right or left side of the brain stem at a level 13.8 mm caudal to Bregma and 0.7 mm lateral to the midline, and to a depth of 8.3 mm below the dorsal surface. Stimulation came from a BL-410 biological experimental system (Chengdu Taimeng Company, China). Stimulus parameters were 0.1 mA, 0.3 ms, 40 Hz and the stimulus duration was 10 min.

To study the effects of stimulation of NA and DMV on gastric secretion, pylorus ligation was used. A 2-mm tracheal cannula was inserted into the tracheal. The site between pylorus and duodenum was ligated. Three hours later, the site between cardia and esophagus was also ligated. The stomach was removed and gastric secretion was collected. Indices used to study gastric secretion were the volume of gastric juice, titratable H^+ quantum, H^+ concentration, HCO_3^- quantum. Values for titratable H^+ quantum were determined by back titration to pH 7.0 using 0.01 N NaOH. HCO_3^- secretion was determined as previously reported[21].

In the study on NA, we also used the method of esophagus perfusion to collect gastric secretion. A 2.5-mm tracheal cannula was inserted into the tracheal. A polyethylene tube (2 mm in diameter) was inserted into the esophagus to perfuse warm (37 ℃) normal saline at 2.0 mL/min. A 3-mm polyethylene tube was inserted into the stomach from the joint of cardia and duodenum to collect the gastric secretion. Base-line secretion values were determined from three consecutive 20-min values before stimulation. The three consecutive 20-min values were taken from beginning of the stimulation of NA to assess the change of secretion function. The index used to study gastric secretion was titratable H^+ quantum. Values for titratable H^+ quantum were determined by back titration to pH 7.0 using 0.01 N NaOH.

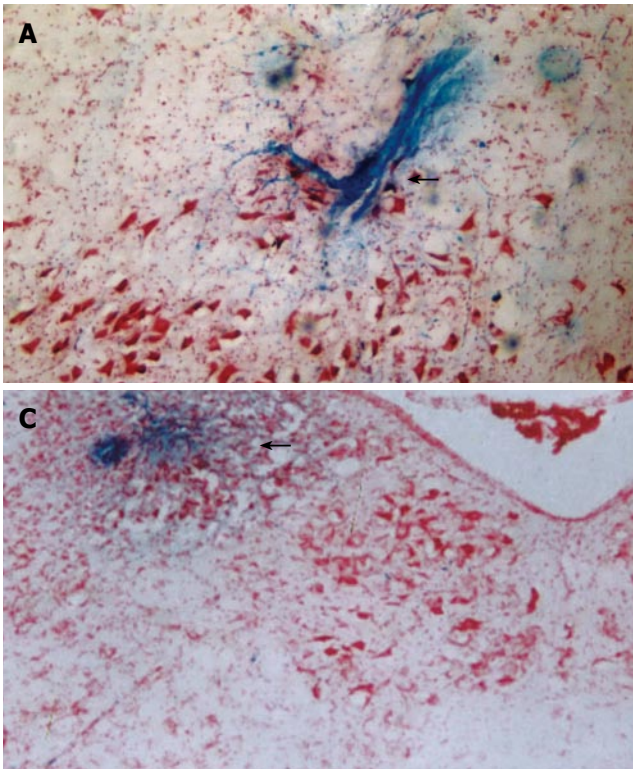
Respiration and electrocardiogram were continuously monitored using the BL-410 biological experimental system. Respiratory frequency and heart rate during stimulation were determined from the first 30 s of the stimulation period. Rectal temperature was monitored and maintained at 37-38 ℃ with a bulb.

Histological identification of stimulated sites

At the end of the experiments, the direct current of 1 mA was given to the stimulated site in the brain stem for 15 s. Then, 0.9% sodium chloride solution and 1% potassium ferrocyanide formalin solution were injected respectively into the aorta and out flowed from the right atrium. The brain was removed and fixed in a 10% formalin solution for 2-3 d. The brains were sectioned at 40 μm with a freezing microtome. Histological sections were stained with neutral red and examined microscopically. Only the results obtained when the tips of the stimulus electrode were just within the NA were used for statistical analysis.

Statistical analysis

Data were expressed as mean ± SD. The difference between two groups was evaluated by Student's *t* test. $P < 0.05$ was considered statistically significant.



RESULTS

Histological identification of stimulated sites

The NA and DMV with their corresponding brain atlas are shown in Figure 1. The stimulated nuclei were identified according to the right atlas.

Effects of stimulation of NA and DMV on gastric H^+ and HCO_3^- secretion

Electrical stimulation of NA had no effects on the volume of gastric juice, titratable acidity and acid concentration, but elicited a pronounced increase in the total bicarbonate ($n = 8$, $P < 0.01$, Table 1). Electrical stimulation of DMV significantly increased the titratable acidity, the volume of gastric juice and acid concentration, with no change in bicarbonate quantum after pylorus ligation (Tables 1 and 2) and in titratable H^+ quantum after oesophagus perfusion (Figure 2).

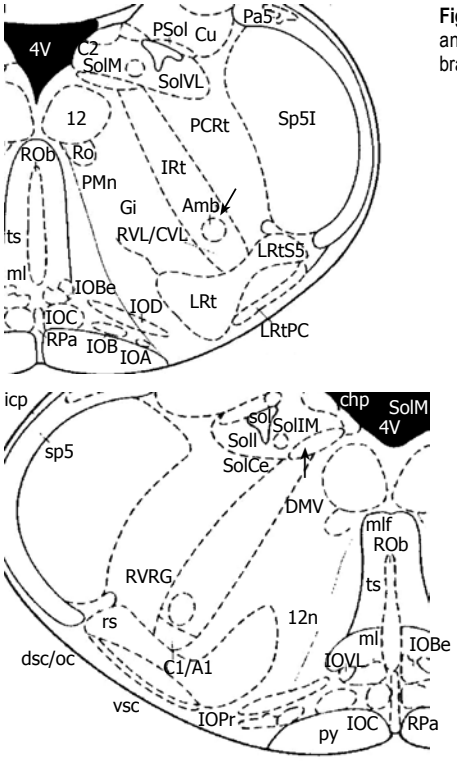


Figure 1 NA (**A**), DMV (**C**) and their corresponding brain atlas (**B**, **D**).

Table 3 Effects of stimulation of NA and DMV on respiratory frequency and heart rate (mean ± SD)

	n = 8	Respiratory frequency (times/min)	Inhibitory rate of respiratory frequency (%)	Heart rate (beats/min)	Inhibitory rate of heart rate (%)
Right NA	Control	91.2 ± 19.4		394.3 ± 70.1	
	Stimulation	34.9 ± 23.0[b]	51.5 ± 17.3	261.7 ± 77.1[b]	29.1 ± 8.9
Left NA	Control	101.8 ± 23.2		385.1 ± 37.6	
	Stimulation	45.6 ± 19.8[b]	64.7 ± 19.7	244.5 ± 44.3[b]	29.4 ± 12.3

[b]$P < 0.01$.

Effects of stimulation of NA and DMV on respiratory frequency and heart rate

Both respiratory frequency and heart rate were inhibited significantly after stimulation of NA and DMV ($n = 8$, $P < 0.01$). There were no significant differences in the inhibitory rate of NA and DMV (Table 3).

DISCUSSION

To our knowledge, the effects of NA and DMV on gastric H^+ and HCO_3^- secretion have not been examined up to now. In the present study, electrical stimulation of NA produced pronounced changes in HCO_3^- secretion but no changes in H^+ secretion. However, electrical stimulation of DMV produced pronounced changes in H^+ secretion but no changes in HCO_3^- secretion. The results of gastric H^+ secretion after stimulation of NA were consistent with those after pylorus ligation and

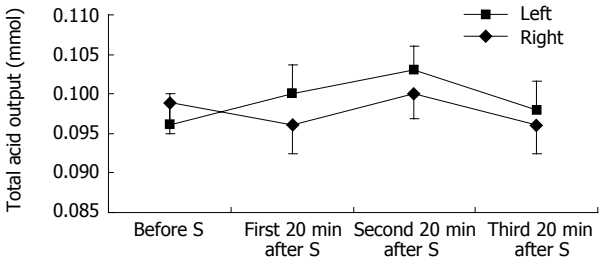

Figure 2 Effect of stimulation of NA on gastric acid secretion after oesophagus perfusion (S: stimulation).

esophagus perfusion. Pagani *et al*[22] found that electrical stimulation of cat NA produces no changes in gastric acid secretion. Morphological studies suggested that vagal parasympathetic neurons innervating the stomach are largely located in DMV and partly in NA[7,11]. These results indicate nervous fibers from NA and DMV innervate different cells of the stomach. NA innervates the nonacid-secreting cells and DMV innervates the acid-secreting cells. Our previous study also showed that gastric motility decreases significantly after stimulation of rat NA. Although this result is not consistent with that of Pagani *et al*[22], the gastric motility changes when NA is stimulated. All the results suggest the nervous fibers from NA mainly innervate gastric smooth muscles while the fibers from DMV innervate both gastric glands and gastric smooth muscles, which is consistent with the report of Kerr[2].

Morphologic and physiological studies suggest that parasympathetic preganglionic neurons of the heart are located in DMV, NA and intermediate zone[12], especially in NA. The NA, DMV, caudal ventrolateral medulla (CVLM) and lateral tegmental field (FTL) are located in the cardio-inhibitory area[23]. Electrical stimulation of NA and DMV

induces bradycardic responses, and the inhibitory rate of NA to the heart rate is not significantly different from that of DMV. Machado and Brody[15] also reported that electrical stimulation of NA induces bradycardic responses, which can be abolished by injection of lidocaine into the rostral ventrolateral medulla. NA efferent fascicles contain more large fibers (presumably B-type), whereas the DMV contains more fine caliber fibers (presumably C-type), and vagal control of the heart involves the convergence and integration of distinct NA and DMV projections within the cardiac plexuses[12]. In our study electrical stimulation of NA and DMV significantly decreased the respiratory frequency, and the inhibitory rate of respiratory frequency in NA was not significantly different from that in DMV. Rentero *et al*[24] investigated the activity pattern of cardiac motoneurons in rat NA using extra-cellular recordings and found that cardiac vagal motoneuron firing is modulated by the central respiratory cycle, showing peak activity during inspiration, which may be the mechanisms of respiratory sinus arrhythmias.

Both NA and DMV are the visceral motonucleus and located in the medullary visceral zone (MVZ), named "life center" which modulates the activities such as circulation, respiration, and digestion[25]. In our study, electrical stimulation of NA significantly increased HCO_3^- secretion, but induced no changes in H^+ secretion. In contrast, electrical stimulation of DMV significantly increased H^+ secretion, but induced no changes in HCO_3^- secretion. Similarly, stimulation of NA and DMV induced respiratory sinus arrhythmias. All these findings indicate that the effects of NA and DMV on gastric secretion, respiration and heart rate are mediated by the vagus.

Abstract

AIM: To analyze the phenotype and function of dendritic cells (DC) from patients with hepatocellular carcinoma (HCC) in order to understand their role in this disease.

METHODS: Myeloid dendritic cells were enumerated in peripheral blood of HCC patients. CD80, CD83, CD86 and HLA-DR expression on naïve and stimulated myeloid dendritic cells from peripheral blood were analyzed. Myeloid dendritic cells were isolated from peripheral blood and their function was tested. Phagocytosis was analyzed using FITC-dextran beads, peptide specific stimulation, the capacity to stimulate allogeneic T cells and secretion of cytokines upon poly dI:dC was tested.

RESULTS: Myeloid dendritic cells were reduced in patients with HCC. No differences in CD80, CD83, CD86 and HLA-DR expression were found on naïve and stimulated myeloid dendritic cells from HCC patients and healthy controls. Normal phagocytosis or stimulation of peptide specific T cells was observed in contrast to an impaired allo-stimulatory capacity and a reduced IL-12 secretion.

CONCLUSION: Impaired IL-12 production of mDCs in patients could lead to an impaired stimulatory capacity of naïve T cells suggesting that IL-12 directed therapies may enhance tumor specific immune responses in HCC patients.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer in the world with a poor prognosis and limited survival in the majority of the patients[1, 2]. A number of different studies suggest that immunotherapeutical approaches will be successful for the treatment of this disease[3, 4]. Lymphocytic infiltration of the tumors is indicative of a better survival after surgical resection of the tumors[5]. Adjuvant treatment with activated lymphocytes has also been shown to increase tumor free survival after removal of the tumor[6]. Others and we identified potential tumor antigens for HCC[7-9], which can be used for vaccination purposes including peptide pulsed dendritic cells (DCs).

DCs are the most potent professional antigen-presenting cells (APC) unique in their ability to efficiently prime both $CD4^+$ and $CD8^+$ cytotoxic T cell responses following encounter with antigen and maturation[10]. Upon antigen uptake, DCs undergo the process of maturation and migration and upregulate adhesion and costimulatory molecules and secrete cytokines[11-13].

Two main subsets of DCs namely myeloid (mDCs) and plasmacytoid DCs have been described. These subsets differ in their origin, expression of phenotypic markers, route of activation and immunological activity[14]. $CD11c^+$ mDCs originate from myeloid bone marrow precursors and produce large amounts of IL-12 upon stimulation, which in turn promotes cell-mediated immune responses that are crucial for the detection and elimination of malignant cells[14, 15]. $CD11c^-$ pDCs, however, are of lymphoid origin, express high levels of IL-3 receptor-α chain and secrete less IL-12. A number of different antibodies have recently been generated, which allow for detection and isolation of these DC subgroups from peripheral blood

and other tissues[16]. The development of new DC specific antibodies[16] allows for direct analysis of DC numbers in peripheral blood and minimizes isolation or culture procedures for the enrichment of DCs that may induce the selection of particular cell subsets and phenotypic or functional modifications of DCs present in the blood[17].

Several studies have suggested that impaired function of DCs might be an important factor in the escape of the tumor from the immune control in cancer patients[18]. At least two mechanisms by which tumors can alter DC maturation and DC function are currently known. The first one affects the ability of hematopoietic progenitor cells to differentiate into functional DCs during the early stages of their maturation[19], whereas the second one affects the *in vitro* maturation of DCs from $CD14^+$ monocytes[20]. An understanding of the mechanisms of defects in DC function in different cancers will shed light on the role of DCs in tumor escape mechanisms[21]. Moreover, correction of DC dysfunction might be one possible option to enhance tumor-specific immune responses in HCC, which can be either used alone or in combination with immunotherapy to treat HCC.

This study investigates the frequency and function of circulating mDCs from patients with HCC directly *ex vivo*. mDCs were analyzed in detail for expression of costimulatory molecules and MHC class II surface expression directly *ex vivo* and after poly dI:dC stimulation. Most importantly, we have directly isolated mDCs from blood of HCC patients to test their function in four different functional assays: stimulation of allo-responses, stimulation of peptide-specific responses, phagocytosis and secretion of IL-10, IL-12 and TNF-α. We could clearly demonstrate that mDCs from patients with HCC displayed a normal phenotype, but were impaired in IL-12 secretion possibly leading to a decreased allostimulatory capacity observed in our study.

MATERIALS AND METHODS

Human subjects

Blood samples were collected from patients in the Department of Gastroenterology, Hepatology and Endocrinology, Hannover Medical School, Germany. Written consent was obtained from all patients before blood and tumor sampling and the Ethics Committee of Hannover Medical School approved the study protocol. HCC was diagnosed according to the diagnostic guidelines of the European Association for the Study of the Liver (EASL)[22]. Serological tests (i.e., HCV RNA, hepatitis B surface antigen) were performed as previously described[7]. Liver cirrhosis and tumor staging were done according to Child-Pugh[23] and CLIP[24].

Quantification and phenotyping of mDCs

Peripheral blood mononuclear cells (PBMCs) were isolated from peripheral blood as previously described[7] and stained using the following antibodies: anti-CD1c-PE, anti-CD14-PE-Cy5, anti-CD19-PE-Cy5, anti-HLA-DR, anti-CD80-FITC, anti-CD83-FITC and anti-CD86-FITC (Pharmingen) or the corresponding isotype controls and analyzed on a fluorescence-activated cell sorter (FACS Calibur, Becton-Dickinson, Heidelberg, Germany). When indicated PBMCs were incubated for 4 h in the presence of poly dI:dC (Amersham Pharmacia). A total of 500 000 to 1×10^6 events were acquired for each sample on an FACS Calibur. 7-amino-actinomycin D (7-AAD) was used to exclude dead cells from analysis. Four-color analysis was performed using Cell Quest Software (Becton Dickinson, Heidelberg, Germany). Absolute numbers of DCs per ml of blood were calculated using the following equation: (% of gated DCs-% of isotype control) × absolute number of leukocytes.

Intracellular cytokine analysis

Intracellular FACS analysis was performed to analyze cytokine secretion by mDCs. PBMCs were isolated from peripheral blood and stimulated with poly dI:dC (Amersham Biosciences) for 48 h. Golgi-Stop (Pharmingen) was added during the last 6 h of stimulation. PBMCs were stained with a panel of antibodies to detect mDCs as described above, fixed, permeabilised and labeled with FITC-labeled antibodies against TNF-α, IL-10 and IL-12 and corresponding isotype controls (Caltag Laboratories). The evaluation of cytokine production was based on the percentage of cytokine expressing $CD1c^+$,$CD19^-$, $CD14^-$ cells.

Isolation of PBMC and CD1c+ DCs

PBMCs were isolated from heparinized blood by standard density gradient separation using Ficoll density gradient (Biochrom AG, Berlin, Germany). $CD1c^+$ cells were positively selected using a two-step immunomagnetic cell sorting procedure (MACS) following the manufacturer's instructions (Miltenyi Biotec GmbH, Bergisch Gladbach, Germany). Briefly, $CD19^+$ cells were depleted from freshly isolated PBMCs followed by positive selection of $CD1c^+$ cells. Purity of $CD1c^+$ DC was controlled by flow cytometry and found to be > 85%.

Quantification of endocytosis by freshly isolated mDCs

Measurement of FITC-dextran uptake was performed as previously described[25]. In brief, freshly isolated mDCs were suspended in culture medium and FITC-dextran (MW 40 000) (Molecular Probes, Leiden, The Netherlands) was added at a final concentration of 1.0 mg/mL and incubated at 37 ℃ for 30 min. The DCs were washed four times with cold PBS containing 1% fetal calf serum and the incorporation of FITC-dextran was analyzed using FACScan. The incorporation of FITC-dextran at 4 ℃ was used as control. The data are shown as fluorescence intensities.

Mixed lymphocyte reactions using freshly isolated CD1c positive DCs

Allogeneic PBMCs (1×10^5) from a healthy donor were resuspended in complete RPMI medium (Gibco BRL, Eggenstein, Germany) supplemented with 2% human AB serum, plated with indicated numbers ($10\text{-}10^4$) of $CD1c^+$ DCs in 96 well plates (Greiner, Frickenhausen, Germany) and incubated at 37 ℃ in a humidified incubator contain-

ing 50 ml/L CO_2. Phytohaemagglutinin 1 μg/mL (Sigma Aldrich, Munich, Germany) was added to PBMC in separate wells as a positive control. After 5 d, 1 μCi/well [3H]-thymidine (Amersham Biosciences, Freiburg, Germany) was added and plates were harvested after 16 h and harvested onto filters using an automated cell harvester (Wallac, Turku, Finland). The amount of [^{3}H]-thymidine incorporated into DNA was measured by a beta-counter (Wallac, Turku, Finland), and the results were expressed as mean counts per minute (cpm). A stimulation index (SI) was calculated for each donor by dividing the mean cpm of the replicates of DC stimulated PBMC by that of the control cultures (PBMC incubated in medium in the absence of DCs).

Analysis of antigen-specific stimulatory potential using a peptide specific T cell line

mDCs (1×10^5) were incubated with the M1 peptide or an irrelevant peptide control for 1 hour. After 1 hour, cells were washed and incubated with 1×10^5 M1 specific T cells. In parallel, T cells were stimulated with T2 cells pulsed with the M1 peptide or a negative control. After 20 hours supernatants were harvested and tested for GM-CSF release by ELISA (Pharmingen).

Statistical analysis

Kruskall-Wallis' analysis of variance and Student's *t* test were used to assess differences between the different study cohorts. Differences with a *P* value of < 0.05 were considered statistically significant.

RESULTS

Detection and quantification of mDCs in peripheral blood

Peripheral blood from a total of 25 patients with HCC was analyzed. Patients' and control group clinical characteristics are shown in Tables 1 and 2. Using a CD1c specific antibody, mDCs were detected in peripheral mononuclear cells and the frequency was determined for every individual subject tested. As shown in Figure 1, the median frequency of mDCs was significantly ($P < 0.001$) decreased for HCC patients (1.5 ± 0.24 mDCs/μL), compared with 23 healthy controls (3.14 ± 0.41 mDCs/μL). In order to exclude that the observations made was only due to chronic liver disease but not due to the presence of HCC, we have also analyzed mDCs from different control groups such as patients with chronic HBV and HCV infection, non-viral liver cirrhosis as well as patients with metastasis from colorectal carcinoma. However, significantly lower mDC frequencies were found in blood from patients with HCC, when compared to patients with chronic HBV infection (2.03 ± 0.52 mDCs/μL), non-viral liver cirrhosis (1.95 ± 1.2 mDCs/μL) and colorectal liver metastasis (1.48 ± 0.61 mDCs/μL) (Figure 1A). In addition, direct comparison of HCC patients with and without chronic viral hepatitis revealed no significant differences as shown in Figure 1B.

Phenotypic analysis of circulating mDCs in peripheral blood before and after in-vitro stimulation

mDCs from patients with HCC and healthy controls were further analyzed for the expression of costimulatory molecules and MHC class II by FACS analysis directly *ex vivo* (Figure 2A). No significant differences were found for the expression of CD80 (HCC patients 0.9 ± 0.05 *vs* healthy 1.0 ± 0.04), CD83 (HCC 1.54 ± 0.38 *vs* healthy 2.2 ± 0.51), CD86 (HCC 36.5 ± 9.54 *vs* healthy 34.7 ± 9.57) and HLA-DR (HCC 83.2 ± 10.1 *vs* healthy 89.5 ± 15.2). Next, mDCs, which are known to express TLR3[26], were stimulated with poly dI: dC and expression of CD83, CD86 and MHC class II was analyzed. As shown in Figure 2B, poly dI:dC stimulation induced a strong up-regulation of CD83 on mDCs. However, there was no difference in CD83 up-regulation between mDCs from HCC patients and healthy controls (6.58 *vs* 8.09). Similar results were found when stimulated mDCs from HCC patients and healthy controls were analyzed for up-regulation of CD86 (HCC 3.53 *vs* healthy 4.09) and HLA-DR (HCC 1.88 *vs* healthy 1.8), indicating no difference in the ability of mDCs to mature after poly dI:dC stimulation.

Table 1 Clinical characteristics of HCC patients analyzed in Figure 1 A and B

Age (yr)	Cause	Sex	Child score	AFP (μg/L)	CLIP score	mDCs (cells/μL)

FITC-dextran uptake by mDCs from HCC patients and healthy controls

Using CD19 depleted cells, we were able to isolate CD1c$^+$ mDCs from peripheral blood and analyze their function directly *ex vivo* and without *in vitro* stimulation or maturation. This procedure resulted in > 85% pure mDC populations (data not shown), avoided *in vitro* artifacts and therefore mimicked closely the *in vivo* situation. First, endocytosis ability of freshly isolated mDCs was measured using FITC dextran beads. FITC dextran uptake was compared between mDCs from HCC patients and healthy controls. As shown in a representative experiment (Figure 3A), phagocytosis could easily be followed over time with an increase of mean fluorescence intensity (MFI) from 6.3 to 14.6, 19.7 and 27.7 at 0, 7, 15 and 30 min respectively. Figure 3B shows the relative increase of MFI for the two groups after 7, 15 and 30 min. No significant difference was seen when endocytosis by mDCs from HCC patients and healthy donors was compared.

mDCs can stimulate antigen-specific T cells

Since mDCs from HCC patients and healthy controls could take up dextran beads equally well, we next analyzed the antigen presenting capacity of these cells. To assess the ability of mDCs to stimulate antigen-specific CD8$^+$ T cells, mDCs from HLA-A2 positive healthy donors and HCC patients were used to stimulate T cells specific for a common recall antigen, the Influenza matrix peptide M1[27]. mDCs were pulsed with M1 peptide and an irrelevant peptide and used to stimulate M1-specific CD8$^+$ T cells. T2 cells pulsed with the same peptides were used as control for every experiment in parallel. Cytokine secretion by M1 specific CD8$^+$ T cells was analyzed in the cell supernatants. Influenza M1 specific T cells secreted 306 pg/mL GM-CSF when mDCs from HLA-A2 positive donors were used (Figure 4) and slightly lower GM-CSF was released when M1 specific T cells were stimulated with mDCs from HCC patients (159 pg/mL). However, this difference was not significant, since the T2 stimulation (as a positive control) was also slightly different between the two experiments (Figure 4). As expected, no peptide specific GM-CSF secretion was found when mDCs were used from an HLA-A2 negative donor (data not shown).

The allo-stimulatory capacity of mDCs from HCC patients is impaired

To test the allostimulatory potential of mDCs from HCC patients, we studied their function in an allogeneic mixed

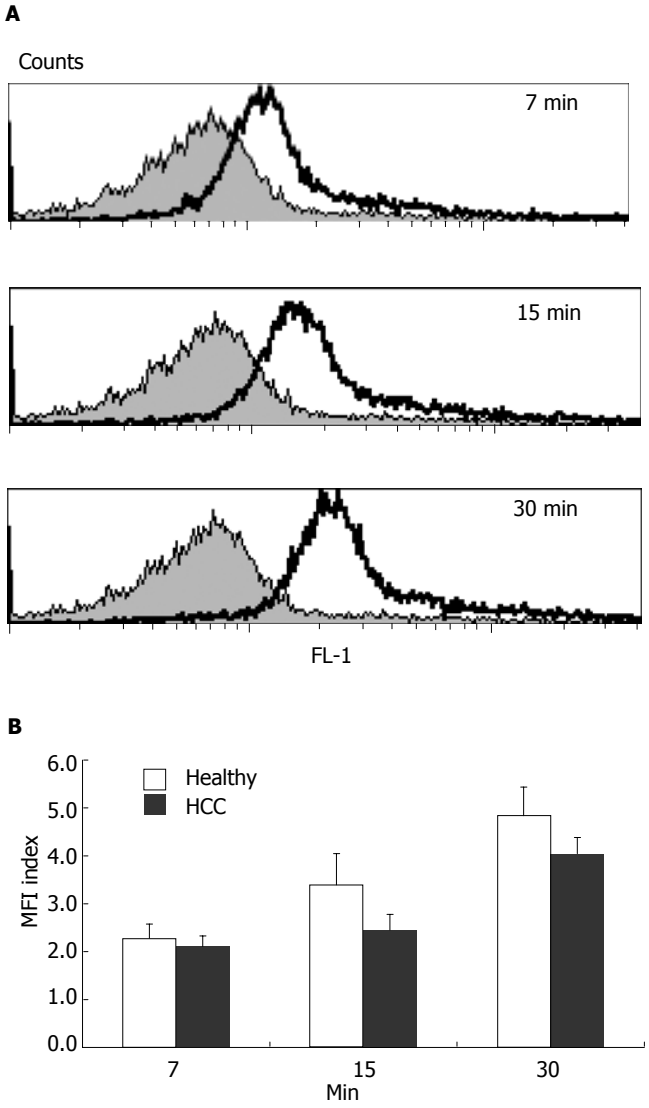

Figure 3 FITC-dextran uptake by mDCs.

lymphocyte reaction (MLR). mDCs were isolated from peripheral blood of HCC patients and healthy controls. PBMCs from a third healthy donor were used as responder cells. Figure 5 summarizes the average of eight HCC patients and six healthy donors. mDCs from HCC patients were clearly less efficient in inducing T cell proliferation than mDCs from healthy donors. For all the stimulator concentrations tested (10-10^4), a significant reduction in allostimulatory capacity of mDCs was seen ($P < 0.05$). Ten thousand mDCs from HCC patients stimulated allogeneic T cells almost 3-fold less than mDCs from healthy donors with a stimulation index of 13 *vs* 35. When 10 fold fewer mDCs were used, still a significant difference in allostimulatory function was seen. It has been shown that patients with chronic HCV infection have impaired function of circulating mDCs[28]. Therefore, we compared the allostimulatory potential of mDCs from patients with and without chronic HCV infection to mDCs from healthy controls. Our analysis clearly demonstrated that not only patients with chronic HCV infection and HCC but also those patients without chronic hepatitis have impaired circulating mDCs in peripheral blood (Figure 5B).

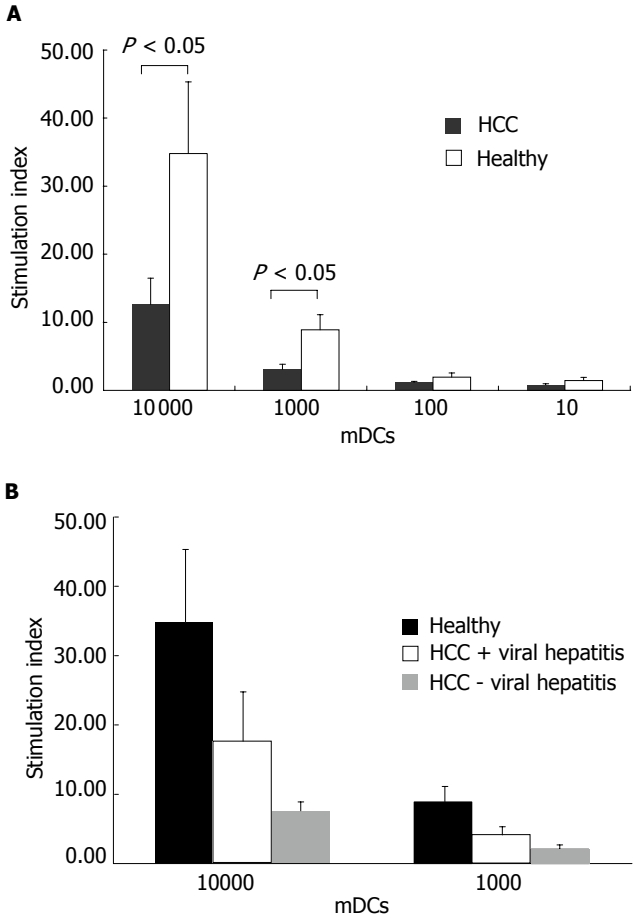

Figure 5 Impaired allogeneic MLR stimulation by mDCs from HCC patients. **A**: Stimulation index of mDCS from HCC patients and healthy controls; **B**: Comparison of stimulation index of mDCs derived from healthy controls and patients with or without chronic viral hepatitis.

Impaired cytokine production by mDC from HCC patients

We next analyzed the expression of cytokines by mDCs, since a perturbation of the cytokine network has been previously reported in patients with neoplasms including HCC[29-32]. Therefore, we analyzed the expression of IL-10, TNF-α and IL-12 by mDCs in HCC patients. PBMCs from healthy donors and HCC patients were stimulated for 48 h with poly dI: dC and analyzed for cytokine secretion by intracellular cytokine staining.

As shown in Figure 6, no significant differences for

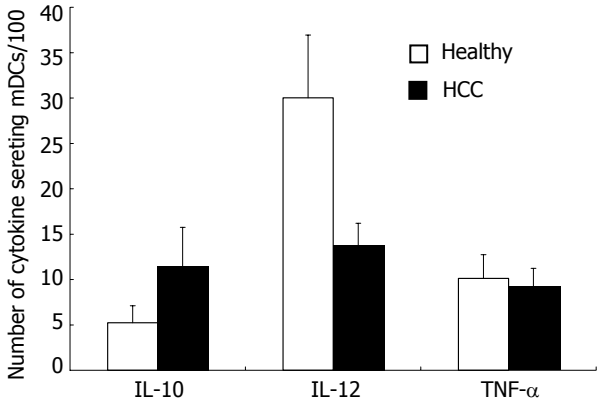

Figure 6 Impaired cytokine production by mDCs from HCC patients.

TNF-α and IL-10 production by mDCs were found. In contrast, the percentage of mDCs expressing IL-12 upon poly dI:dC stimulation was significantly lower in HCC patients (30.2) than in healthy controls (13.76, $P < 0.01$).

DISCUSSION

Until today treatment options for HCC are limited to surgery and local ablative therapy[33, 34]. Therefore, much emphasis has been put on understanding the development of HCC and investigating new therapeutic options, of which one is immunotherapy[3]. Previously, we have shown that more than 50% of HCC patients develop tumor specific immune responses against a well-defined tumor antigen[7]. However, in most patients analyzed, tumors progressed in spite of tumor specific humoral and cellular immune responses. Therefore, we are interested in investigating possible immunological mechanisms, which might lead to suppression of antigen-specific T cells in HCC patients. Recently, we have shown that $CD4^+CD25^+$ regulatory T cells are increased in both peripheral blood and tumor of HCC patients[35]. However, it is highly likely that a combination of regulatory T cells along with other factors is responsible for a defective anti-tumor immune response seen in HCC patients. Impaired function of professional antigen presenting cells has been suggested as a possible mechanism to promote tumor escape from immune control[21].

A number of different studies have analyzed the function of monocyte derived DCs in different liver diseases including HCC[25, 36, 37]. However, recent studies have shown that impaired function of monocyte derived DC might be the result of inefficient culture conditions rather than of patients' diseases[38]. Therefore we have performed our analysis on directly *ex vivo* isolated DCs avoiding *in vitro* manipulations. In order to verify that the findings made are not simply due to underlying liver diseases such as chronic viral hepatitis or liver cirrhosis, which can be found in the majority of patients with HCC[2], different control groups such as patients with HBV and HCV infection, liver cirrhosis and liver metastasis from colorectal cancer were included in the study for comparison. In addition, HCC patients with and without chronic viral hepatitis were compared with each other. Consistent with published data by others, we have observed a decreased number in circulating mDCs[31], which is an unlikely reason for impaired T cell responses seen in patients with different type of tumors including HCC[21]. Therefore, the main focus of our study was to investigate the function of mDCs isolated from patients with HCC. Professional antigen presenting cells pick up antigens, process and present them to T cells and cause potent T cell stimulation by expression of appropriate cytokines and costimulatory molecules[10]. Therefore, we performed a detailed step-by-step functional analysis of *ex vivo* isolated non-manipulated mDCs from patients with HCC and compared them to mDCs from healthy controls.

Interestingly, most functional assays performed showed no differences between mDCs from HCC patients and healthy controls such as expression of costimulatory molecules, most cytokines analyzed, antigen uptake and peptide presentation. However, when mDCs from HCC patients or healthy controls were tested to stimulate allogeneic PBMC, mDCs from HCC patients were clearly less potent stimulators. Similar results have been observed for patients with other tumors[29] and non-malignant liver diseases[39]. In addition, the observations made were not due to underlying chronic viral hepatitis, since mDCs from HCC patients with or without chronic viral hepatitis were less potent stimulators. However, the exact mechanism for this observation has not been elucidated. Because no differences were found for the MHC class II, CD80, CD83 and CD86 expression on mDCs, we extended our analysis for other potential factors leading to reduced stimulatory capacity of DCs.

Cytokines secreted by DC have been shown to have an important regulatory role in activation of the immune response. Therefore, we analyzed the expression of three different cytokines; TNF-α, IL-10 and IL-12 by mDCs upon stimulation. Although, we could not detect differences in the number of TNF-α or IL-10 expressing mDCs, significant differences were found in the numbers of IL-12 producing mDCs between HCC patients and healthy donors. IL-12 has been shown to play an anti-tumor role *in vivo*[32, 40]. An imbalance in the cytokine expression pattern as shown by low levels of IL-12 and normal or higher levels of IL-10 has been seen in other cancer patients[32, 41]. Our data suggests that reduced IL-12 expression of mDCs from HCC patients could lead to an impaired T cell stimulatory effect, which could not only account for a reduced allogeneic T cell response but also further account for an impaired general immune response.

Although, we have not been able to demonstrate this in our study due to limitations in the amount of blood that could be obtained from HCC patients, one could postulate that exogenous IL-12 might reverse impairment of DC function seen in our study. Indeed a number of clinical studies have seen promising results treating HCC patient with thalidomide in selected cases[42, 43]. Moreover, it has been shown that thalidomide might lead to an enhanced IL-12 secretion by DC s *in vitro*[44].

In summary, direct evaluation of DCs from HCC patients without *in vitro* manipulation has allowed us to

clearly demonstrate a decrease in the frequency of mDCs in peripheral blood of HCC patients and more importantly a functional defect of these cells leading to impaired stimulation of allogeneic T cells. Decreased IL-12 production by mDCs might be a possible cause of this impairment, which suggests that IL-12 directed therapies could reverse this phenomenon and should be further investigated in the context of immunotherapeutic approaches to the treatment of HCC.

Abstract

AIM: To investigate both whether the risk of gastric cancer is associated with the Ile/Val single nucleotide polymorphism (SNP) of human epidermal growth factor receptor-2 (*HER-2*) transmembrane domain-coding region at codon 655 and the suggested existence of *HER-2* expression in gastric cancer cases in a Turkish patient group.

METHODS: Polymerase chain reaction (PCR) followed by restriction fragment length polymorphism (RFLP) strategy was used to analyze the presence of *HER-2* SNP at codon 655. c-erbB-2 expression pattern was analyzed by immunohistochemistry. The results were compared between gastric carcinoma group and chronic gastritis group, as well as between clinicopathological parameters and carcinoma.

RESULTS: Results showed that Ile/Val genotype accounted for 20% within the Turkish gastric carcinoma group, and none in chronic gastritis group, and this genotyping was associated with stage IV gastric cancers (P = 0.04). Positive membranous *HER-2* immunoreactivity, on the other hand, accounted for 24% within the Turkish gastric carcinoma group and none from chronic gastritis cases; further, it was correlated with intestinal type carcinomas (P = 0.007), and stage III-IV carcinomas (P = 0.004).

CONCLUSION: These observations imply that the tested *HER-2* SNP may participate in the development and progression of gastric cancer. Thus, after confirming these results with large sample groups, *HER-2* codon 655 SNP and/or c-erbB-2 overexpression may also be used as a poor prognostic indicator for gastric carcinomas.

INTRODUCTION

Gastric adenocarcinoma is the second leading cause of cancer-specific mortality worldwide and efforts intended for prevention and early detection of gastric carcinoma are effective and yet important[1]. Despite various treatments such as gastrectomy with extensive lymphadenectomy and surgery combined with chemotherapy, the control of gastric cancer at advanced stages is still challenging.

Molecular genetic analyses have indicated that transformation of normal epithelial cells into a cancer is a multi-step process associated with the progressive accumulation of abnormalities in DNA repair genes, tumor suppressor genes, oncogenes, cellular growth factors, surface receptors, and cellular adhesion molecules[2]. Structural and functional alterations of human epidermal growth factor receptor-2 (*HER-2*) also known as c-ErbB-2/neu proto-oncogene have been reported in different steps of carcinogenesis including initiation, promotion and progression[3]. *HER-2* is a member of the epidermal growth factor (EGF) receptor family located at chromosome 17q21 that encodes a 185-kDa transmembrane glycoprotein with tyrosine kinase activity[4-6]. It is localized to the cell membrane and binding of extracellular growth factor ligands to HER-2 leads to the formation of dimers with another molecule of HER-2 or with HER-1 (EGFr), HER-3 or HER-4. This dimerization results in phosphorylation of tyrosine residues on the cytoplasmic domain of the receptor and subsequent activation of intracellular signaling pathways that regulate diverse biologic responses, including proliferation,

differentiation, cell motility, and survival[7]. Overexpression of c-erbB-2 has frequently been reported in various cancer types including breast, ovary, lung, salivary gland, colon, prostate and pancreatic and has been suggested to be an indicator of poor prognosis[8,9]. *HER-2* DNA amplification is suggested to be the principal mechanism of *HER-2*/neu protein activation and is nearly always accompanied by its protein overexpression in breast cancer. It has been also reported c-erbB-2 overexpression in 10% to 38% of gastric cancer cases using immunohistochemical, Southern blot, and fluorescent *in situ* hybridization analyses that suggest differences in c-erbB-2 expression among subtypes of gastric cancer[10-13]. However, controversy continues in terms of correlation between the HER-2 protein expression and gastric cancer prognosis. There have been reports correlating the lymph node metastasis and/or liver metastasis with HER-2 expression[14-17], whereas others showed no correlation between clinicopathologic findings and HER-2 expression[18,19]. In addition, it has also been shown that HER-2 expression is fewer than 10% in diffuse adenocarcinomas[16,17]. The use of trastuzumab, a function blocking monoclonal antibody against the extracellular domain of HER-2, as a treatment option in HER-2-overexpressing advanced breast cancer patients underlines once again the importance of this protein and its downstream signaling cascade(s) in the pathogenesis of above-mentioned cancers.

Presence of a single nucleotide polymorphism (SNP) in the transmembrane coding region of the *HER-2* gene at codon 655, encoding either isoleucine (Ile: ATC) or valine (Val: GTC), has been reported in different cancer types[12,13]. Changing the existing isoleucine (Ile: ATC) to valine (Val: GTC) at codon 655, suggests an increased dimerization, autophosphorylation of HER-2 and tyrosine kinase activity, which may cause the transformation of cells[16]. Some of the reports have revealed that the presence of Ile/Val SNP is associated with increased risk of breast cancer development[20]; on the other hand, others have shown that this correlation is controversial[21-24]. One reason for these contradictory results might be the substantial differences in genetic polymorphism in the *HER-2* codon 655 between ethnic groups.

In this study, the frequency of *HER-2* codon 655 polymorphism, resulting in an A to G transition (Ile655Val) and alterations in c-erbB-2 protein expression have been investigated in Turkish gastric cancer patients in association with the clinicopathologic parameters.

MATERIALS AND METHODS

Materials

The specimens at Pamukkale University Department of Pathology archive have been used and paraffin-embedded tissues of 25 gastric carcinomas (8 with diffuse type, 16 with intestinal type, i.e., 5 with well, 4 with moderately, 7 with poorly differentiated adenocarcinoma, classified according to Lauren classification and 1 with adenosquamous type) were selected as the study group in this study (Table 1). All carcinomas were staged according to UICC criteria, graded according to WHO criteria, and histopathologically typed according to Lauren classification. Paraffin-embedded tissues of 18 chronic gastritis cases selected from the same collection served as the control group.

Table 1 Clinicopathological details of gastric carcinoma cases

		Patients (*n*)
Gender	Male	15
	Female	10
Age (yr)(mean ± SD)	35-80, (58.8 ± 12.8)	
Histologic type (Lauren)	Intestinal	16
	Diffuse	8
	Adenosquamous	1
Histologic type (WHO)	Well	7
	Moderatelly	5
	Poorly	4
Serosa invasion	Positive	19
	Negative	1[1]ND
Nodal involvement	Positive	14
	Negative	6[1]ND

[1] Not Determined: 5 cases were endoscopic biopsy samples so cannot be determined.

DNA extraction and mutation analysis

DNA extraction from paraffin-embedded tissues was performed using the QIAamp DNA Mini Kit (Qiagen, Hilden-Germany) according to the manufacturer's protocol. SNP in *HER-2* transmembrane segment involving codon 655 was analyzed by polymerase chain reaction (PCR) followed by restriction fragment length polymorphism (RFLP) strategy[25]. The 148 bp transmembrane segment of *HER-2* was PCR-amplified using the gene specific primers, i.e., forward (*HER-2*/F) 5'-AGAGCGCCAGCCCTCTGACGTCCAT-3', and reverse (*HER-2*/R) 5'-TCCGTTTCCTGCAGCAGTCTCCGCA-3'[25]. All PCR amplifications were performed in a total volume of 50 μL containing 10 μL of extracted DNA, 20 pmol/L of each forward and reverse primer, and 25 μL of HotStarTaq Master Mix [containing 2.5 units of HotStarTaq DNA polymerase, 1 × PCR buffer with 1.5 mmol/L $MgCl_2$, and 200 μmol/L of each dNTP (Qiagen, Hilden-Germany)]. Thermal cycling conditions for the PCR are as follows: initial activation of HotStarTaq DNA polymerase at 95 ℃ for 15 min, followed by 35 cycles of 94 ℃ for 0.5 min, 62 ℃ for 0.5 min, 72 ℃ for 1 min, and a final extension of 72 ℃ for 10 min. PCR products were subjected to electrophoresis on a 2% ethidium bromide (Et-Br) stained agarose gel and visualized under UV for the control of their specificity and integrity.

For RFLP analysis, 5 μL of each PCR product was digested with *Bsm*AI (New England Biolabs, Ipswich, MA-USA) at 55 ℃ for 2 h, and enzyme was heat-inactivated at 80 ℃ for 20 min. *Bsm*AI digestion gave fragments of 116 bp and 32 bp for the Val (GTC) allele and a single 148 bp fragment for the Ile (ATC) allele[11]. Fragments digested with *Bsm*AI were subjected to electrophoresis on a 3% molecular screening grade agarose gel (Roche Diagnostics, GmbH, Mannheim-Germany), stained with Et-Br and visualized under UV light.

Immunohistochemistry

Formalin fixed, paraffin-embedded tumor-rich representative tissues were used for immunohistochemical staining. Reactions were performed with anti-c-erbB-2 polyclonal antibody (DAKO, Glostrup-Denmark) using the streptavidin biotin peroxidase method along with DAB as chromogen by Ventana-NexES IHC automatic immunostainer. Staining patterns were analyzed semiquantitatively and scored in the range of 0 to 3, score 0: Less than 10%; score 1: More than 10% of tumor cells with partial membranous staining; score 2: More than 10% cells with moderate membranous staining; score 3: More than 10% cells with strong membranous staining.

Statistical analysis

The data were analyzed by the Chi-Square test. Differences at $P < 0.05$ were considered to be significant. Statistical analyses were performed with SSPS software, Version 11.0.

RESULTS

HER-2 PCR-RFLP analysis showed that none of the 18 chronic gastritis cases had the SNP in *HER-2* gene at codon 655 (Figure 1A), whereas 4 of 25 gastric carcinoma cases (20%) had the Ile/Val genotype (Figure 1B, Table 2). The difference between these two groups were significant ($P = 0.04$). All 4 mutation positive cases were stage IV in terms of clinicopathologic parameters (Table 2). However, presence of this SNP did not show any correlation with the age, gender, histological type (according to Lauren), serosal invasion, lymph node metastasis, and distant metastasis.

Positive membranous c-erbB-2 immunoreactivity (scores 2-3), on the other hand, was detected in 6 of 25 carcinoma cases (24%), i.e., 4 cases with score 2 (16%) and 2 cases with score 3 (8%) (Figure 2A and B, Table 2), whereas 5 cases showed score 1 staining (20%) and 14 cases showed no staining at all (56%, Table 2). Results from chronic gastritis cases revealed no positive membranous c-erbB-2 immunoreactivity, i.e., 4 cases had score 1 staining (19%) (Figure 2C) and 17 cases had no staining at all (81%). When the results from carcinoma group were compared with clinicopathologic parameters, positive membranous c-erbB-2 immunoreactivity was correlated with intestinal type carcinomas ($P = 0.007$), and stage III-IV carcinomas ($P = 0.004$). However, no correlation with the age, gender, serosal invasion, lymph node metastasis, and distant metastasis was observed.

DISCUSSION

The aim of this study was to investigate both whether the risk of gastric cancer is associated with the Ile/Val SNP of *HER-2* transmembrane domain-coding region at codon 655 and the suggested existence of c-erbB2 expression in gastric cancer cases in a Turkish patient group. Results showed that Ile/Val genotype accounted for 20% of the Turkish gastric carcinoma group ($P = 0.04$), and this genotype was associated with stage IV gastric cancers. However, it did not show any correlation with the age, gender, histological type (according to Lauren classification), serosal invasion, lymph node metastasis, and distant metastasis. Positive membranous c-erbB-2 immunoreactivity, on the other hand, accounted for 24% of the Turkish gastric carcinoma group and it was found to be correlated with intestinal type carcinomas ($P = 0.007$), and stage III-

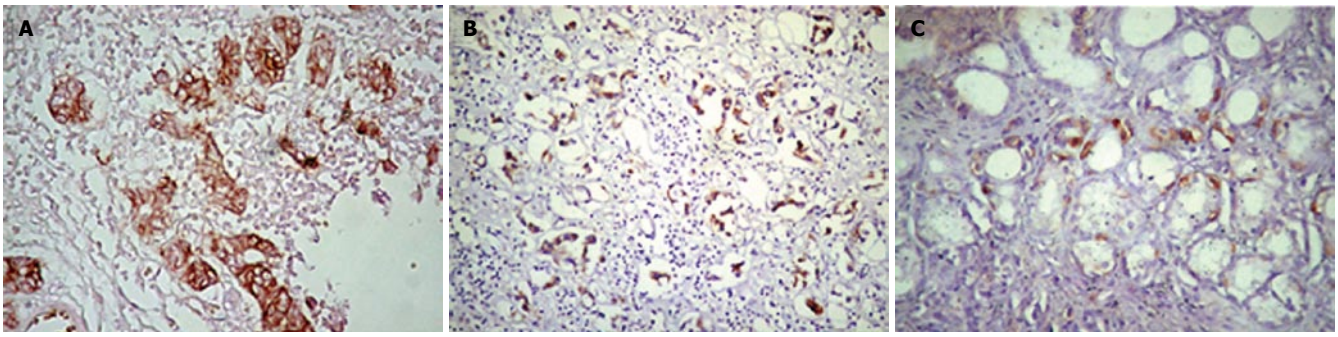

Figure 2 Representative images of HER-2 immunoreactivity in **(A)** moderately differentiated intestinal type adenocarcinoma (score 3), **(B)** poorly differentiated intestinal type adenocarcinoma (score 3), and **(C)** chronic gastritis (score 1).

IV carcinomas ($P = 0.004$). These observations imply that the tested *HER-2* SNP may participate in the development and rapid progression of gastric cancer. However, further larger sample studies particularly containing early stage gastric carcinoma patients, are needed to confirm the presence of SNP and/or c-erbB-2 overexpression may also be used as a poor prognostic indicator for gastric carcinomas.

HER-2 encodes a receptor tyrosine kinase functioning as a growth regulatory protein and a cell motility factor[26]. Alterations of *HER-2* have been implicated in the carcinogenesis and are frequently observed in a variety of tumors[24, 27-29]. The molecular mechanism of the association between the Ile/Val SNP at codon 655 of *HER-2* and cancer has not been fully understood; however, it has been suggested that Ile/Val SNP at codon 655 of *HER-2* results in increased dimerization, autophosphorylation of *HER-2* and tyrosine kinase activity[16], which may cause the transformation of cells. In spite of initial reports on the association of this SNP with the risk of a variety of cancers, there is still an ongoing debate on this topic. To our knowledge, this is the first study in a Turkish gastric carcinoma group investigating the existence of the Ile/Val genotype. Although the study group here is small, the 20% occurrence rate in this Turkish gastric carcinoma patient group is comparable to the reported 21% occurrence rate in a Japanese gastric carcinoma group of 212 patients[25]. It suggests a significantly increased risk of gastric cancer development. The association of this genotyping with stage IV gastric cancers also supports this finding.

Overexpression of c-erbB-2, on the other hand, has been associated with poor prognosis and shorter overall survival[14, 30-32] and may be used as a predictive marker for the response to therapy in some cancers[33]. However, a controversy also continues in terms of correlation between the c-erbB-2 protein expression and gastric cancer prognosis. There have been reports correlating the lymph node metastasis and/or liver metastasis with c-erbB-2 expression[14-17], whereas others showed no correlation between the clinicopathologic findings and c-erbB-2 expression[18,19]. Results of this study also correlate with a previous report by Dursun *et al*[34] in terms of positive membranous c-erbB-2 immunoreactivity within a Turkish gastric carcinoma group. Like suggested previously[34] this study has shown association of positive membranous c-erbB-2 immunoreactivity with intestinal type carcinomas ($P = 0.007$), and stage III-IV carcinomas ($P = 0.004$). However, it has to be taken into consideration that both studies have worked with small patient groups leading to a decreased statistical power to detect a positive association of any kind. Thus, further investigation with a desirable study group size is necessary to assess the importance of c-erbB-2 expression in gastric carcinomas for the Turkish population. Nevertheless, results of this study suggest increased c-erbB-2 expression may be considered as a poor prognostic indicator.

In conclusion, this study suggests that the tested SNP in the transmembrane domain-coding region of *HER-2* could be associated with development of gastric carcinoma and may serve as a predictor of risk of malignant phenotype of gastric cancer for the Turkish population. Although the association of the *HER-2* immunoreactivity with clinicopathologic characteristics, especially with intestinal type carcinomas, is also suggested, this has to be confirmed with a larger sample size.

Abstract

AIM: To detect the therapeutic effects of chemical destruction of celiac ganglion in patients with pancreatic carcinoma with intractable pain.

METHODS: Ninety-seven cases with advanced pancreatic carcinoma received chemical destruction of celiac ganglion-5 mL pure alcohol injection around celiac artery under ultrasonic guidance. The changes of visual analogue scale (VAS), serum substance P (Sub P), β-endopeptide (β-EP) and T-lymphocyte subtypes level were compared between pre- and post-therapy.

RESULTS: Successful rate of puncture was 98.7%, with one failure. No serious complications such as traumatic pancreatitis, pancreatic fistula, abdominal cavity hemorrhage or peritoneal infection occurred. VAS, serum Sub P and β-EP level significantly changed after treatment (8.0 ± 2.3 *vs* 4.6 ± 2.1, 254.1 ± 96.7 *vs* 182.4 ± 77.6, 3.2 ± 0.8 *vs* 8.8 ± 2.1, $P < 0.01$, $P < 0.05$, $P < 0.01$) with complete relief rate 54.2%, partial relief rate 21.9%, ineffective rate 12.5% and recurrent rate 10.7%. The T-lymphocyte subtypes level remarkably increased when compared with that of pre-therapy (46.7 ± 3.7 *vs* 62.5 ± 5.5, $P < 0.01$).

CONCLUSION: Our study suggests that chemical destruction of celiac ganglion under ultrasonic guidance is highly safe, and can evidently relieve cancer pain and improve the cellular immunity in patients with advanced pancreatic carcinoma.

INTRODUCTION

Pancreatic carcinoma (PC) is a hyper-malignant disease. Its onset is insidious but its development is aggressive. The radical excision rate is lower than 25%. About 70% of the patients with PC have obvious symptoms of pain and at the late stage all PC patients suffer from severe and intractable pain. The pain has been the chief complaint of the patients with PC, which has significantly decreased their life quality. Thus, to improve the living quality of patients with PC has become the main task for palliative treatment. In 1998, we began to perform chemical destruction of celiac ganglion by ultrasonic intervention in patients with PC in an effort to reduce cancer pain. The results suggested that this method is effective in alleviating the pain caused by PC and can up-regulate the cellular immune level.

MATERIALS AND METHODS

Patients

Our study included 97 patients, 64 males and 33 females, aged between 38 to 79 years, with body weight ranging from 41 to 78 kg (Table 1). Seventy-two were definitely diagnosed as PC by operation (including 26 by pathological biopsy) and 25 by B-ultrasound, CT or MRI (including 10 combined with the increase of CA19-9 value). All the patients suffered from pain in the abdomen and back, characterized by persistently or intermittently attacking pain. According to visual analogue scale (VAS), 29 had moderate pain, 63 had severe pain, and 5 had mild pain. The duration of pain was between 11 to 67 d. All the patients depended on drugs to alleviate the pain before treatment.

Methods

Instruments and reagents used in the study were color B-ultrasonic diagnostic apparatus Aloka-680EX made in Japan, 3.5 MHz convex probe, puncture shelf Aloka MP-2411B made in Japan, puncture needle CNF2220 made in USA, medical analytical anhydrous alcohol and procaine injection (10 g/L). All the patients were fasted for less

Table 1 General data of 97 PC cases

Location of tumor	Diagnosis					Size of tumor (cm)	Metastasis				
	Patients *n*	Operation	Image+ A19-9	Image			Liver	Lung	Lymph node	Colon	Spinal column
Head of pancrreas	55	46	4	5	4.1 ± 2.3	7	-	15	1	-	
Neck of pancrreas	17	13	-	4	5.5 ± 3.8	2	-	3	1	-	
Body of pancrreas	12	5	3	4	4.7 ± 3.1	-	-	3	-	-	
Tail of pancrreas	7	7	-	-	8.6 ± 3.5	-	-	4	-	-	
Whole pancreas	6	1	3	2	-	-	1	2	-	1	

than 12 h before operation; then they were given procaine skin test and VAS training. They were required to catch how to exactly express the degree of pain with VAS and received the compatibility test of posture and respiration. If the patient felt too nervous, he was given intramuscular injection of 10 mg valium 30 min before operation.

Chemical destruction of celiac ganglion

By B-ultrasonic scanning when the patient was lying, the situation around origin plane of celiac arterial trunk was confirmed as the target region. The point of puncture was accordingly confirmed. Routine sterilization was performed on the abdomen and probe. Puncture was performed after local anesthesia of the insert path of needle. B-ultrasound dynamically supervised the course of puncture until the needle arrived at the target region, which was symbolized with heaving impulse and no blood when the syringe was drawn back. Then the patient was given 10 mL procaine injection (10 g/L). If the patient felt significant alleviation of pain or felt warm on his abdomen, the puncture was considered successful. After that, anhydrous alcohol (15 mL) was given to destroy the ganglion. Post-operational fasting, fluid infusion and anti-infectious treatment were performed. If all procedures were carried out smoothly, the patient could then be given normal diet 24 h after operation.

Criteria of curative effects

We used 5 different terms to describe the curative effects: complete relief (CR), partial relief (PR), mild relief (MR), no relief (NP) and recurrence (RC). Those patients who felt no pain and unnecessary to take pain-killers were described as CR. Those who felt significant alleviation of pain after operation but still needed pain-killers occasionally were described as PR. Those who felt a little alleviation after operation but still needed pain-killers because the pain disturbed their sleep were described as MR. Those who felt no change between before and after operation were described as NR. Those who felt alleviation after operation but the pain recurred soon were described as RC.

Visual analogue scale (VAS)

A direct line of 10 cm in length was used. Its both ends expressed 0 and 10, which stood for no pain and the severest pain, respectively. Patients marked the location of pain by themselves, which was used as the basis of quantification.

Sub P and β-EP

Fasting cubital venous blood (4 mL) was averagely grouped: 2 mL Sub P and 2 mL β-EP blood specimens. Iniprol (1000 U) and heparin (10 g/L, 20 U) were added into the Sub P blood specimen. At the temperature of 4 ℃, centrifugation, at a speed of 3000 r/min was performed for 15 min. The upper plasma was preserved at the temperature of -70 ℃.

The β-EP blood specimen was placed in a plastic tube in which there were EDTA-Na2 (6 mg) and bacitracin (160 μg). Then, low temperature centrifugation was performed and the plasma was preserved at the temperature of -20 ℃. The Sub P and β-EP kits were provided by Neurobiological Department of the 2nd Military Medical University and were assayed with the automatic radioimmunoanalyzer FJ-2008P made in Xi'an The unit of Sub P and β-EP was ng/L and nmol/L, respectively.

Assay of T lymphocyte subtype

Fasting venous blood (5 mL) was sampled. Luminescence immunoassay and flow cytometry were used to determine the level of CD_3^+, CD_4^+, and CD_8^+ (cluster of differentiation) and the results were expressed as the percentage of positive cells. MFITC was used to mark the mcAb rats' anti-human CD_3^+, CD_4^+, and CD_8^+ and FITC was used to mark the IgG of rats. All the reagents were purchased from the American Santa Company. Thirty-eight healthy persons were tested as control group.

Statistical analysis

All data were expressed as mean ± SD. *t* test was used to examine the significance of the difference between before and after the treatment and among the groups. *P* value < 0.05 was taken as significant.

RESULTS

The success rate of puncture was 98.7% (96/97). Puncture failed in one patient, who had PC complicated with portal hypertension and there were many variciform veins along the puncture route. In addition, the patient had poor tolerance to puncture posture. We had to give up puncturing on him because the puncture needle could not safely arrive at the target region. In the other 96 patients with successful puncture, there were no such complications as traumatic PC, abdominal cavity hemorrhage, pancreatic fistula or peritoneal infection. Of them, the pain was

CD_3^+: [a]$P < 0.05$, [b]$P < 0.01$ *vs* Preoperation; CD_4^+: [c]$P < 0.05$, [d]$P < 0.01$ *vs* Preoperation; CD_8^+: [e]$P < 0.05$, [f]$P < 0.01$ *vs* Preoperation; β-EP: [g]$P < 0.05$, [h]$P < 0.01$ *vs* Preoperation.

completely relieved in 52; partially relieved in 21; slightly relieved in 11 and the puncture had no effect in 12. The longest follow-up time was 104 d. The pain recurred in 9 patients on the d 11-51 after puncture, respectively. The recurrence rate was 10.7%. The statistical analysis showed that there were significant changes in VAS, Sub P and β-EP on d 3 after puncture: significant decrease of VAS and Sub P ($P < 0.01$ and $P < 0.05$, respectively) and significant increase of β-EP ($P < 0.01$). By the dynamic follow-up on d 7, 15 and 30, the level of VAS, Sub P and β-EP kept stable, suggesting the stability of our treatment effect (Table 2).

The results showed that the level of CD_3^+, CD_4^+, and CD_8^+ in patients with PC was significantly lower than that in control group ($P < 0.01$). On the 3rd d after chemical destruction of celiac ganglion, the level of subtype T increased slightly compared with that of preoperation but with no significance. On the 7, 15 and 30 d after operation, the level of CD_3^+, CD_4^+, and CD_8^+ increased significantly compared with that of preoperation ($P < 0.01$). The level of β-EP remarkably increased on the 3rd d after operation and there was significant difference compared with before operation ($P < 0.01$). Moreover, the serum β-EP was kept at a high level at 7, 15 and 30 d during follow-up (Table 3).

DISCUSSION

Mechanism of ultrasonic intervention on the pain caused by pancreatic carcinoma

The pain caused by PC mostly comes from the stimulation on the pancreatic sensory nerve fiber, which is conducted through the visceral sympathetic nerve[1-3]. Although the distribution of pancreatic visceral nerves is very complex, they concentrate in the celiac ganglion, project to relevant spinal segments and reach the nerve center of central nervous system, consequently causing pain. In clinic, excision of celiac ganglion or plexus can significantly inhibit the obstinate pancreatogenic pain[1]. Therefore, blocking of the celiac ganglion can theoretically alleviate the pain caused by PC. However, it is difficult by ordinary image technique to show the situation of celiac ganglion. The celiac ganglion is situated on the wall of celiac artery and the anatomical position is fixed. B-ultrasound can clearly show the celiac arterial trunk and its neighboring structure. Therefore, abdominal B-ultrasound can provide indirect guidance for the localization of celiac ganglion. Local injection of anhydrous alcohol, through its demyelinization to destruct the celiac ganglion, can permanently block the transmission passage of the nerves, resulting in alleviation of the pain.

Evaluation of the analgesic effect

As a subjective feeling, pain is affected by various factors. Therefore, in order to objectively reflect the changes of pain after treatment, apart from VAS, Sub P and β-EP were chosen as the evaluation indexes of efficiency. Sub P is an important nerve transmitter of pain. Its concentration in the blood is directly proportional to the injury stimulation[4]. Therefore, Sub P can objectively reflect the degree of pain. β-EP is the main endogenous opiate peptide in human, which has the same analgesic effect as morphine. Millan[5] found that the secretion of β-EP in patients with chronic or carcinoma pain decreased and that the secretion of β-EP increased after the alleviation of pain. In addition, the secretion of β-EP was negatively related to the degree of pain.

The results of our study showed that the overall effective rate of analgesia of chemical destruction of celiac ganglion was 87.5% and the effectual rate was 76.1%. Three days after the treatment, both VAS and Sub P decreased significantly ($P < 0.01$ and $P < 0.05$, respectively) whereas β-EP increased remarkably ($P < 0.01$). Our follow-up of one month showed that the levels of VAS, Sub P and β-EP kept stable. Thus we may conclude that this method is effective against the pain caused by PC. Nerve destruction can decrease the release of the dolorogenic Sub P and up-regulate the level of β-EP, by which the pain is alleviated. However, in 12 patients pain was not significantly alleviated in our study. We suppose that the pain was related to the incomplete obstruction caused by metastatic cancer of colon in 2 cases and hepatic metastasis in 9 and in the remaining one patient, bone destruction of lumbar spine shown by imaging examination, so we suggested that there might be some somatic nerve injured which was associated with the low effectiveness of simple visceral nerve blockade on the pain.

There were no severe complications in the patients. Diarrhea was the common symptom after treatment and the occurrence rate was about 61.5% (59/96). The reason was that after the destruction of celiac ganglion, the inhibitory effect on intestinal wall neuron decreased while its excitability increased, which led to the accentuation

of peristalsis and secretion. Oral activated charcoal was effective on relieving the symptom.

Relationship between analgesia and immune function of T cells

Kelsen *et al*[2] reported that in 77 PC patients, there was significant difference in the survival time between the pain group and no pain group ($P < 0.01$), whether the patient had received operation or not. The survival time of the patients with pain was significantly shorter than those without pain, indicating that the pain caused by PC was closely related to the prognosis. Melzack *et al*[6] observed that the level of Ts, TH and null lymphocyte in patients with pain caused by cancers decreased significantly in 1983. They concluded that pain caused by cancers might induce "dormancy" of T subtypes. The relation between the pain caused by cancers and the immunity of cells has attracted more attention because cellular immunity plays the main role in tumor immunology and it can inhibit the occurrence and progress of cancers. In addition, Ts can identify the neoantigen and TH can kill the carcinogenic cells by cytotoxic reaction. Ma *et al*[7] reported that in 70 patients with tumors at the intermediate or late stage, the level of CD_3^+, CD_4^+ and CD_8^+ in the pain group was significantly lower than that in no pain group ($P < 0.01$) and after the pain was alleviated the level of CD_3^+, CD_4^+ and CD_8^+ increased significantly ($P < 0.05$). Thus it can be concluded that pain caused by tumors can lead to the decrease of human immunity and influence the prognosis and effective control of pain can improve the activity of T subtypes. Morphine is the commonly used pain-killer. It has been proved that perennially taking morphine can lead to addiction and resistance to drugs. Moreover, repeated use of morphine can result in atrophy of pleura and decrease of the expression of CD_3^+, CD_4^+ and CD_8^+[8-10]. Therefore, analgesia should be reasonable in quantity taking into account of its influence on immune function. Our results showed that the expression of T subtypes in patients with pain caused by PC was significantly lower than that in control group, indicating the necessity to protect the immune function. One week after the destruction of celiac ganglion, the expression of CD_3^+, CD_4^+ and CD_8^+ remarkably increased ($P < 0.01$), indicating that analgesia with chemical destruction of celiac ganglion can improve the immune suppression in patients with PC and increase the expression of T subtypes.

Presently it is not clear about the mechanism of pain treatment regulating the immune function. Studies have been focused on the endogenous opiate peptides. On the one hand, β-EP, as an endogenous opiate peptide, has the inhibitory function on pain by the κ and μ receptor pathway; on the other hand, β-EP, as an immune derived product, is the active substance with close relation to the nerve, incretion and immune systems[11]. Maddle *et al*[12] found that β-EP has an important regulatory activity on immunity. Its up-regulation can promote T-lymphocyte multiplication, antibody polymerization and cytotoxic function of NK. Brown *et al*[13] found that there are opiate receptors on the immune cells and β-EP can take part in the regulation of T subtypes and promote their differentiation and growth through opiate receptors. Our study showed that the level of β-EP in pain group was significantly lower than that in control group ($P < 0.01$), which is consistent with the literature. After analgesic therapy, the level of β-EP increased significantly ($P < 0.01$), with a similar trend to that of T subtypes. β-EP level increased significantly ($P < 0.01$) on the 3rd day after treatment, which was ahead of that of CD_3^+, CD_4^+ and CD_8^+. Therefore, we presume that β-EP might take part in the immune regulation of CD_3^+, CD_4^+ and CD_8^+.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381901
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*. in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included.

Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

_____

Author Name in abbreviation (Family names are put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

RESPONSIBLE EDITOR FOR THIS ISSUE: Gary A Abrams, Associate Professor

World Journal of Gastroenterology (*World J Gastroenterol , WJG*), a leading international journal in gastroenterology and hepatology, has an established reputation for publishing first class research on esophageal cancer, gastric cancer, liver cancer, viral hepatitis, colorectal cancer, and *Helicobacter pylori* infection, providing a forum for both clinicians and scientists, and has been indexed and abstracted in *Index Medicus*, MEDLINE, PubMed, Chemical Abstracts, EMBASE, Abstracts Journals, Nature Clinical Practice Gastroenterology and Hepatology, CAB Abstracts and Global Health. *WJG* is a weekly journal published by The *WJG* Press. The publication date is on 7th, 14th, 21st, and 28th every month. The *WJG* is supported by The National Natural Science Foundation of China, No. 30224801 and No.30424812, which was founded with a name of *China National Journal of New Gastroenterology* on October 1,1995, and renamed as *WJG* on January 25, 1998.

Abstract

Receptor tyrosine kinases (RTKs) such as the epidermal growth factor receptor family participate in several steps of tumor formation including proliferation and metastatic spread. Several known RTKs are upregulated in gastric cancer being prime targets of a tailored therapy. Only preliminary data exist, however, on the use of the currently clinically available drugs such as trastuzumab, cetuximab, bevacizumab, gefitinib, erlotinib, and imatinib in the setting of gastric cancer. Preclinical data suggest a potential benefit of their use, especially in combination with "conventional" cytostatic therapy. This review summarizes the current knowledge about their use in cancer therapy as well as new approaches and drugs to optimize treatment success.

INTRODUCTION

Gastric cancer is a common, but difficult to treat disease entity. Apart from potentially curative surgery, chemotherapy as well as radiochemotherapy may be applied, but do not cure the disease[1]. Thus, improvement of gastric cancer therapy will depend on novel therapeutic approaches. Receptor tyrosine kinases (RTKs) are a family of 56 proteins characterized by a transmembrane domain and a tyrosine kinase motif[2]. They function in cell signalling and transmit signals regulating growth, differentiation, adhesion, migration, and apoptosis[3]. Aberrant receptor tyrosine kinase activity was initially described in various epithelial cancers; nowadays, it is well accepted that receptor tyrosine kinases play an important role in almost all types of cancer[4,5]. The mutational activation and/or overexpression of receptor tyrosine kinases transforms cells and often plays a crucial role in the development of cancers.

For this reason, RTKs have become targets of immunological inhibitors, the best known being trastuzumab (Herceptin®, directed against the erb B2 receptor, also known as Her2/Neu oncogene) and cetuximab (Erbitux®, active against the epidermal growth factor receptor [EGFR]). In the case of EGFR, pharmacological inhibitors such as gefitinib (Iresssa®) directed at the kinase domain (EGFR-TKI) of the receptor have been developed; other pharmacological inhibitors of tyrosine kinases include imatinib (Gleevec®) which is licensed for the treatment of leukaemia and gastrointestinal stroma cell tumors (GIST).

As tailored concepts of cancer therapy evolve, RTKs offer prime targets for such an individualized approach to cancer treatment. This review examines the information available on this group of receptors, describes the most relevant subsets that have been found in case of gastric cancer, and summarizes data on the use of their inhibitors in clinical studies. In the end, we present new attempts to optimize the efficacy of already available compounds and promising new drug developments.

Receptor tyrosine kinases

RTKs are membrane bound proteins consisting of a ligand-binding domain at the extracellular surface, a single transmembrane segment, and a cytoplasmic part harboring the protein kinase activity. With the exception of the insulin receptor family of RTKs, all known RTKs form monomers in the cell membrane. Ligand-induced dimerization, resulting in autophosphorylation of their cytoplasmic domains, is the major mode of activation of RTKs.

The known 56 RTKs are divided into 21 families with similar structure and the potential of intrafamilial dimerization; their classification has been reviewed by Robinson *et al*[2]. The best known examples are the epidermal growth factor receptor family (erb B1 to B4), the different vascular endothelial growth factor receptor (VEGFR) subtypes, the

fibroblast growth factor (FGF) receptor family, and the platelet derived growth factor (PDGF) receptor family.

RTKs present in gastric cancer

We have recently analyzed the expression of RTK mRNAs in different human cancers, including 12 samples of gastric cancer[6]. The median of relative gene expression levels of the 56 known RTKs in these cancer specimens are illustrated in Figure 1. Our findings suggest that several RTKs, including those of the EGFR family, the FGFR family, and the different VEGFR subtypes are present in gastric cancer and thus offer potential targets for a selective therapy. In the following, we will summarize findings by others regarding the expression of the RTKs in gastric cancer with emphasis on those for which clinically established modalities of therapeutic intervention exist, namely the EGFR family and VEGF.

EGFR family – EGFR and erb B2

The EGF receptor/ligand system seems to be involved in the regulation of gastric mucosal proliferation and progression of gastric carcinoma. Increased EGFR binding has been observed in gastric carcinomas in comparison to adjacent normal gastric mucosa. Moreover, elevated EGFR levels have been found in gastric carcinoma with worse prognostic factors (T3/4, positive lymph-nodes, G3, diffuse-type). In univariate and multivariate analysis, EGFR levels are an independent indicator of poor prognosis[7,8]. A down-regulation of an inhibitor of EGFR activation, EGFR related protein (ERP) occurs in gastric cancer as well[9]. Changes in the constitutive phosphorylation and activity of tyrosine kinases such as EGFR may contribute to differences in cell adhesion and phenotype of gastric cancer cells[10]. Espinoza *et al* described that gastric adenocarcinomas potentially depend upon the TGFalpha-EGFR autocrine loop for growth and exhibit increased aggressiveness in the presence of aberrant p53[11].

The overexpression of the growth factor receptor oncogene erb B2 in gastric carcinomas was first described by Yonemura *et al* in 1991, who reported a 12% positive rate in 189 gastric cancers[12]. These findings were confirmed by many other studies, which provided further evidence that the highest rate of overexpression was found in patients with advanced disease, and that erb B2 altered expression can be considered as an independent predictor of outcome[13,14]. Ougolkov *et al*[15] found a more frequent overexpression of erb B2 in gastric cancers with concurrent liver metastasis than in those without, and concluded that activated erb B2 may be involved in the process of liver metastasis thus suggesting a role for erb B2 overexpression in identifying gastric cancer patients who are at high risk of developing liver metastasis. In contrast, activating mutations of the erb B2 tyrosine kinase seem to be rare events in gastric cancer[16].

Vascular endothelial growth factor

Vascular endothelial growth factor (VEGF) is expressed in many gastric carcinoma cell lines and may play an important role in cell growth directly. VEGFR is virtually ubiquitous in human tumors and may promote tumor growth and metastasis by participating in both paracrine and autocrine pathways as higher levels of VEGFR have been correlated with more aggressive disease[17]. KDR is the main human receptor responsible for the VEGF activity in both physiological and pathological vascular development, and VEGF-KDR signalling pathway has been validated as a priority target for the development of anti-cancer therapy. A first report on 16 patients with early gastric cancer (pT1-T2, N0) suggested that expression of VEGF may indicate an increased risk of recurrence, making VEGF neutralization an interesting therapeutic target in these subjects[18].

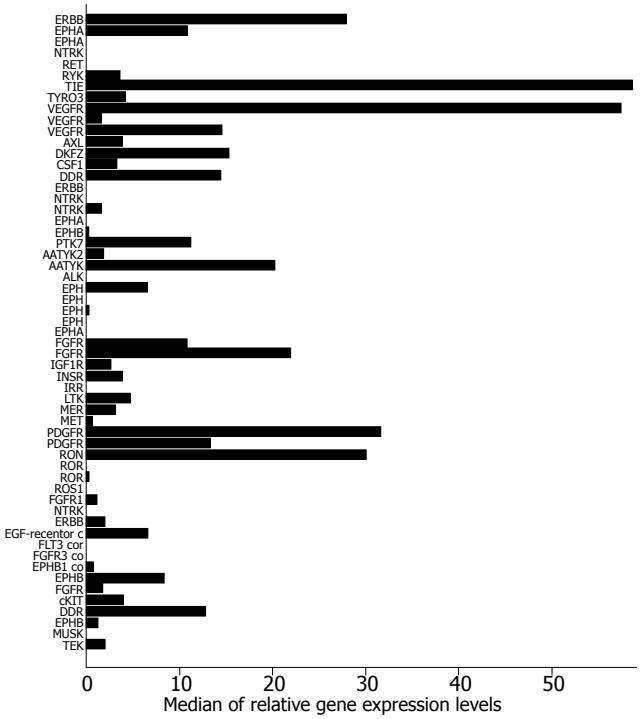

Figure 1 Median gene expression of receptor tyrosine kinases in 12 gastric cancer specimens.

Fibroblast growth factor receptor family

We have previously described an increased expression and autocrine stimulation of fibroblast growth factor (FGF) 2 mRNA in the course of gastric ulcer healing[19]; with respect to gastric cancer, the secretion of growth factors of the FGF family by fibroblasts stimulates proliferation of cancer cells of scirrhous gastric cancer[20]. The expression of FGF2 mRNA (formerly known as basic fibroblast growth factor, bFGF) in gastric cancer specimens is associated with higher microvascular density, tumor progression and a worse prognosis[21]. An orally active inhibitor of FGF-receptor autophosphorylation has been successfully tested in animal models of gastric cancer; further studies are awaited[22].

Platelet derived growth factor receptor

Already more than a decade ago, the expression of platelet derived growth factor (PDGF) and its receptor mRNAs were linked to gastric cancer growth[23]. Later on, the expression of PDGF-A mRNA in biopsy samples of gastric cancer specimens was determined to be a preoperative prognostic marker associated with shorter survival[24]. As

imatinib mesylate as an inhibitor of the PDGFR tyrosine kinase became available, its effectiveness against gastric cancer cells was assessed *in vitro* and *in vivo*. Unfortunately, the agent itself exhibited no cytostatic effect of relevance; yet in combination, imatinib mesylate might serve as an effective chemosensitizer of antitumor drugs, such as 5-FU and paclitaxel for gastric carcinoma, targeting the PDGF/PDGFR-signalling pathway of tumor cells and stromal cells in disease progression and angiogenesis[25].

Leflunomide is a small molecule inhibitor of PDGFR-mediated phosphorylation and inhibits PDGF-mediated cell signalling[26]; it is converted to its main metabolite, SU0020, which interferes with de novo pyrimidine synthesis. At this time, it is not clear whether the mechanism of action of this drug in humans is due to inhibition of PDGF-dependent signalling, inhibition of pyrimidine synthesis, or a combination of both[27-29]. A multi-institutional phase II study in hormone refractory prostate cancer patients with leflunomide found partial responses in 1 of 19 patients, a prostate-specific antigen decline greater than 50% in 3 of 39 patients, and improvement in pain[27].

Hepatocyte growth factor receptor / c-MET

Soman *et al* were able to identify TPR-MET fusion as an event of gastric cancer pathogenesis in certain cases[30]; in addition, c-MET activation seemed to occur[31]. Preliminary data raised in animal models of gastric carcinoma suggest that adenoviral-mediated gene transduction of an HGF antagonist (NK4) results in suppression of tumor growth, invasion, angiogenesis, and metastasis[32,33]. The use of this construct was able to overcome resistance against gefitinib in an animal model of scirrhous gastric cancer[34], yet clinical data is lacking.

USE OF RTK INHIBITORS IN GASTRIC CANCER

Available RTK inhibitors

The inhibitors of tyrosine kinases currently approved by the United States Food and Drug Administration (FDA) for the use in different human malignancies are summarized in Table 1. Substances under development are described in the paragraphs below. If treatment results of RTKIs are to be evaluated, one has to keep in mind that inhibition of a growth factor receptor does not typically aim at killing the cell like "conventional" cytostatics, but stoping proliferation. Therefore, standard assessments of tumor response like complete response, partial response, and stable disease may not reflect the "true" efficacy of such a regime.

Table 1 FDA-licensed tyrosine kinase inhibitors, their targets, modes of action, and clinical use

Agent	Target	Mode of action	Established clinical application
Imatinib mesylate	bcr-abl; PDGFR, c-kit	Kinase inhibitor	CML, GIST, hypereosinophilic syndrome
Gefitinib	erbB1/EGFR	Kinase inhibitor	NSCLC
Erlotinib	erbB1/EGFR	Kinase inhibitor	NSCLC
Cetuximab	erbB1/EGFR	Blocking antibody	Colorectal cancer
Trastuzumab	erbB2/HER	Blocking antibody	Breast cancer
Bevacizumab	VEGF	Neutralizing antibody	Colorectal cancer

Immunological agents

VEGF - Bevacizumab In contrast to the other immunological agents which attach directly to the receptor of the tyrosine kinase, the currently available antibody bevacizumab interrupts the signal cascade by neutralizing the ligand. In a study comprising over 800 patients with metastatic colorectal cancer, the addition of bevacizumab to irinotecan, 5-fluorouracil, and leucovorin as first-line therapy led to a significant increase in survival time[35]. Recent studies concerning the neutralizing antibody bevacizumab, and the small molecule tyrosine kinase inhibitor SU5416, demonstrated that, while unlikely to be effective as monotherapy, incorporation of VEGFR blockade into cytotoxic regimens may increase overall response rates in solid tumors. However, incorporation may also introduce new toxicities, including thromboembolic complications and bleeding[36-38]. Gastrointestinal bleeding, epistaxis and thrombotic events have been seen in 10.3%, 50% and 19.1%, respectively, of the patients receiving bevacizumab alone[39]; these side effects should be taken into consideration when deciding about bevacizumab therapy. There is a phase II trial of bevacizumab, irinotecan, and cisplatin in metastatic or unresectable gastric cancer (National Cancer Institute [NCI] protocol 6447) currently active, of which only the high rate of thromboembolic events in six (25%) of 24 patients (95% CI, 11% to 45%) has recently been reported[40]. However, the incidence of thromboembolic events was not significantly different when compared to a similar irinotecan-based protocol not containing bevacizumab, and there was no difference in the pattern of venous thromboses.

A small molecule inhibitor of VEGFR2 (Vatalanib; PTK787/ZK 222584) has been developed; preliminary data on its use in colorectal cancer exist[41]. With respect to gastric cancer, a Japanese group reported the effects of another VEGFR tyrosine kinase inhibitor (SU6668) in a mouse model of gastric cancer. SU6668 did not directly alter the growth rate of the cancer cells, but inhibited tumor angiogenesis, resulting in the inhibition of tumor dissemination in the peritoneum[42].

Erb B2 / HER-neu – Trastuzumab When considering how EGFR/erb B-targeted therapeutics function, it is important to mention that, in contrast to the small molecule kinase inhibitors, antibodies targeting EGFR and erb B2 have the inherent ability to recruit immune effector cells such as macrophages and monocytes to the tumor through binding of the antibody constant Fc domain to specific receptors on these cells. In xenograft models at least, this mechanism is relevant with the anti-tumor activity of erb B2-targeted trastuzumab[43]. Whether this mechanism has a role in clinical efficacy in cancer patients remains unproven[44]. Trastuzumab (Herceptin) is a humanized monoclonal antibody, which was approved by the United States FDA in 1998 for the treatment of advanced breast cancer. This was the first approval of a monoclonal antibody for use in solid tumor therapy[45]. Recently, it was

investigated whether trastuzumab could affect the growth of HER/neu-overexpressing gastric cancer cells based on the antibody-dependent cell-mediated cytotoxicity (ADCC). It has been demonstrated that these cells could be killed by trastuzumab-mediated ADCC and this correlated with the degree of HER-2/neu expression[46]. However, the trastuzumab-mediated ADCC was significantly impaired when tested in peripheral blood mononuclear cells from patients with advanced disease as compared to those with early disease. Moreover, natural killer cells purified from patients with advanced disease showed less trastuzumab-mediated ADCC in comparison to those from healthy donors. Consequently it has also been postulated that some treatment modalities, such as those involving the use of interleukin 2, could contribute to reverse NK dysfunction, which may be necessary for successful trastuzumab treatment of gastric cancer. Funato *et al*[47] used MKN-7 and KATO-III gastric cancer cells, which express the erb B2 oncogene, to study the mechanism of resistance to cisplatin. They found that erb B2 expression in gastric cancer is related to cisplatin sensitivity, and that anti-erb B2 antisense oligonucleotides could induce increased sensitivity to this drug. Experimental therapy utilizing a different anti-HER mouse-human chimeric monoclonal antibody named CH401 documented efficacy in an *in vivo* model of gastric cancer, yet clinical data are lacking[45].

Epidermal growth factor receptor (EGFR) – Cetuximab

Cetuximab has been approved by the FDA for use in colorectal cancer; cetuximab and other molecules inhibiting the EGFR pathway in colorectal cancer have been recently reviewed[48,49]. One large trial of cetuximab in colorectal cancer comprising 329 patients with irinotecan-refractory metastatic cancer indicated a delayed median time to progression by combining cetuximab with irinotecan[50]. A known adverse characteristic of anti-EGFR therapy is an acne-like skin rash associated with treatment response, which was observed in about three out of four patients[51]. In contrast to gefitinib, the response of cancer cells to cetuximab occurs independent of the mutational status of the EGFR[52,53]. Unfortunately, there are no relevant clinical data available on the use of cetuximab in patients suffering from gastric cancer. As cetuximab is a chimeric antibody which may cause immunological reactions, humanized anti-EGFR antibodies have been developed, one being matuzumab, which currently undergoes phase II trials including studies in patients suffering from gastric cancer[54].

Pharmacological agents – small molecule tyrosine kinase inhibitors

Imatinib: Imatinib is an established and licensed treatment modality in gastrointestinal stroma cell tumors (GIST)[55], but with respect to gastric cancer, only limited data about its use exist. A single study in an animal model of gastric cancer suggested no independent activity of imatinib, but proved an effective chemo- sensitization of antitumor drugs, such as 5-FU and paclitaxel for gastric carcinoma, targeting the PDGF/PDGFR-signalling pathway of tumor cells and stromal cells in disease progression and angiogenesis[25].

EGFR-inhibitors–Erlotinib and Gefitinib

The first representative of this drug class to be approved for cancer therapy was gefitinib (Iressa®) in the third line treatment of non-small-cell lung cancer[56]. A subsequent phase III trial (Iressa Survival Evaluation in Lung cancer, ISEL) failed to demonstrate survival advantage for those patients when compared with placebo[57]. Furthermore, in other malignancies such as gastric carcinoma, preliminary data indicate that treatment efficacy with this regimen is limited as well[58]. A phase II trial to investigate the efficacy, tolerability and pharmacokinetics of gefitinib in pretreated patients with metastatic gastric carcinoma included 75 subjects who were randomised to receive 250 or 500 mg/d gefitinib orally. The authors found that gefitinib monotherapy was generally well tolerated in pretreated patients with gastric metastatic adenocarcinoma, with disease control achieved in 18.3% of cases analyzed. The most common drug-related adverse events were diarrhea, rash and anorexia. The only dose-related adverse events were rash (25.0% at 250 mg/d *vs* 44.7% at 500 mg/d) and anorexia (8.3% at 250 mg/d *vs* 15.8% at 500 mg/d). Rojo *et al*[59]evaluated immunohistochemically the percentage of tumor cells expressing EGFR, pEGFR (the activated phosphorylated form), pMAPK, pAkt (phosphorylated Ser473) and Ki67, before and after treatment with gefinitib. Prior to treatment EGFR expression was found in 62.5% of tumors, whereas pEGFR levels were significantly reduced after the treatment. However, a decreased proliferation was observed only in those tumors with low levels of pAkt, suggesting a role for the PI3k-Akt pathway in gefinitib resistance. Recent studies suggested that clinical response to gefitinib in lung cancer depends on the presence of somatic mutations of the EGF receptor in the tumor which enhance the responsiveness of the receptor to EGF ligand and increase its sensitivity to inhibition by gefitinib[60-62]. In the case of gastric cancer, no such mutations are known. Data on the use of erlotinib (Tarceva®; OSI-744) in gastric cancer is limited to a single study of 70 patients having either gastric cancer (n = 26) or gastroesophageal junction cancer (GEJC) (n = 44). No patient in the gastric cancer cohort presented an objective response, but five patients in the GEJC cohort did so, one being a complete response. An overall response rate was 11%[63]. The best known therapeutics targeting members of the EGFR family which are currently available or under investigation are summarized in Table 2.

Attempts to optimize treatment efficacy of RTKIs

As resistance against single agents may arise and tumor survival may rely on more than one growth factor pathway, several attempts have been made to optimize treatment efficacy, most of them still being in preclinical testing. The following options exist: (1) Combination of inhibitors of the same pathway (e.g. gefitinib and cetuximab) in order to further enhance signal abrogation; (2) To combine inhibitors of different RTK pathways or apply non-selective inhibitors of several pathways in case the cancer cell loses its reliance on one specific pathway; (3) To select cells dependent on growth factor stimulation by use of other cytotoxic drugs or radiation and subsequently eliminate these by an immunological or pharmacological

RTKI.

Enhanced abrogation of one RTK pathway by combining different inhibitors

In 2004, two groups described the use of cetuximab combined with gefitinib and erlotinib as enhanced abrogation of the EGFR signal cascade in *in vitro* as well as *in vivo* models. Matar *et al*[64] utilized an EGFR-dependent human tumor xenograft model and found a synergistic effect on cell proliferation and superior inhibition of EGFR-dependent signalling and induction of apoptosis. Even suboptimal doses of gefitinib and cetuximab given together resulted in a complete and permanent regression of large tumors. In the combination-treated tumors, there was a superior inhibition of EGFR, mitogen-activated protein kinase, and Akt phosphorylation, as well as greater inhibition of cell proliferation and vascularization and enhanced apoptosis. Using cDNA arrays, 59 genes could be identified that were coregulated and 45 genes differentially regulated, including genes related to cell proliferation and differentiation, transcription, DNA synthesis and repair, angiogenesis, signalling molecules, cytoskeleton organization, and tumor invasion and metastasis. Huang *et al*[65] reported similar findings in head and neck tumors and in a model of lung cancer; they observed that gefitinib and erlotinib retained the capacity to inhibit tumor cell growth in case of cetuximab resistance. Again, the combination of antibody and kinase inhibitor resulted in more profound tumor regression and regrowth delay.

Another group applied trastuzumab and an inhibitor of EGFR and erb B2 tyrosine kinases, lapatinib, in erb B2-overexpressing breast cancer cell lines. Only in combination, treatment resulted in a markedly downregulated survivin protein expression and enhanced tumor cell apoptosis thus suggesting a potential improvement in clinical response[66]. But not all findings support the idea of combining inhibitors of the same pathway: in an *in vitro* model using two human epidermoid cell lines the combination of cetuximab and gefitinib demonstrated antagonistic effects. Administration of either drug alone led to a diminution in EGFR levels, while their combination increased the cellular expression of EGFR. These findings suggest that new and tempting treatment strategies on the EGFR target consisting in a double hit with a monoclonal antibody and a TKI must be considered with caution[67]. Data with regard to gastric cancer are currently lacking.

Inhibition of several RTK pathways: combination of different substances, non-selective inhibitors

Cancers possessing complex kinase profiles may respond better to a multimodal therapy tackling several pathways; and such regime may simultaneously reduce the emergence of resistance. Therefore a combination of different agents or a single "unspecific" inhibitor of several pathways may offer advantages over inhibition of a single pathway.

Combinations of different agents: As there is currently no single known inhibitor of all relevant receptor tyrosine kinases, combination of the well evaluated agents offers a straightforward concept of therapy, taking into account that in most cancer therapies different substances are being combined. First data were raised in phase I or II breast cancer trials by combining trastuzumab with small molecule inhibitors of EGFR such as gefitinib or erlotinib indicating that this combination provided a well tolerated targeted therapy with preliminary evidence of antitumor activity[68,69]. As activation of the EGF receptor may induce vessel formation by cellular liberation of VEGF, approaches blocking both pathways possess certain attractiveness. In conditions of limiting VEGF, EGF plays an important role in endothelial cell proliferation, survival, and sprouting of small vessels. Animal data suggest that combined inhibition of EGFR and VEGFR pathways may produce synergistic results and that resistance to EGFR inhibition may be overcome by inhibition of VEGFR tyrosine kinase[70,71]. In an *in vivo* model, the combination of anti-VEGF-R and anti-EGF-R therapies was effective in inhibiting gastric cancer growth whereas the decrease in tumor growth in mice treated with DC101 (an anti-VEGF-R antibody) or cetuximab alone did not reach statistical significance[72]. As mentioned above, the addition of an inhibitor of the hepatocyte growth factor was able to overcome resistance against gefitinib resulting from the interaction of stromal and cancer cells in an animal model of scirrhous gastric cancer[34].

Inhibitors not selective for a single pathway: Agents targeting multiple RTKs are currently undergoing preclinical testing or phase I studies. These include AEE788 (directed against EGFR, erbB2, VEGFR2; Novartis), BAY 43-9006 (Sorafenib; Raf kinase, VEGFR2, PDGF-R beta; Bayer), SU11248 (PDGF-R, VEGFR, c-kit-R, FLT3-R; SUGEN), and ZD6474 (VEGFR and EGFR, AstraZeneca), all designed to inhibit multiple mechanisms of tumor growth in addition to conventional chemotherapy[73-76]. Similar to the combination of anti-EGFR and anti-VEGFR antibodies mentioned above, McCarthy *et al*[77] tested the inhibitor of both tyrosine kinases, ZD6474, in an orthotopic model of gastric cancer. The agent led to marked

Table 2 Therapeutics targeting the EGFR family

Agent	Type	Target	Status
Trastuzumab	Humanized mAb	erbB2	Approved for breast cancer
Pertuzumab	Humanized mAb	erbB2	Phase II trials
Cetuximab	Chimeric mAb	EGFR	Approved for colorectal cancer
Matuzumab	Humanized mAb	EGFR	Phase II trials
Panitumab	Humanized mAb	EGFR	Trials ongoing
Gefitinib	TKI	EGFR	Approved for NSCLC
Erlotinib	TKI	EGFR	Approved for NSCLC
Lapatinib	TKI	EGFR/erbB2	Phase III trial / breast cancer
AEE788	TKI	EGFR/ erbB2/ VEGFR	Phase I trials
CI-1033	Irreversible TKI	EGFR/erbB2	Phase II trials
EKB-569	Irreversible TKI	EGFR/erbB2	Phase II trials
EXEL 7647 /TKI EXEL 0999		EGFR/ erbB2/ VEGFR	Phase I trials

(incomplete list; modified according to ref. 44)

inhibition of tumor growth, tumor cell proliferation, and decrease in microvessel density. The authors concluded that therapies such as ZD6474 that target two distinct aspects of tumor growth, angiogenesis and tumor cell proliferation, warrant further investigation.

Combination of standard chemotherapeutic agents and radiation with inhibition of RTKs

"Conventional" chemotherapy and RTKIs: The combination of antibody based therapies with conventional therapy has become a standard procedure in many cancers. For example, in colorectal cancer, cetuximab or bevacizumab is typically combined with irinotecan-based regimes[35,50]. One of the first reports on the use of an RTKI, trastuzumab, in breast cancer documented the inhibition of DNA repair subsequent to DNA damage by cisplatin by an antibody to Her2/Neu. Therapy with this antibody led to a 35%-40% reduction in repair of cisplatin-DNA adducts after cisplatin exposure and, as a result, promoted drug-induced killing in target cells[78]. Another study using human tumor xenografts found that gefitinib caused growth inhibition of tumors and enhancement of the activity of a number of cytotoxic drugs, but neither was dependent on high levels of EGFR expression[79]. In an animal model of pancreatic cancer, inhibiting phosphorylation of EGFR, VEGFR, and PDGFR by appropriate RTKIs in combination with gemcitabine enhanced the efficacy of gemcitabine alone, resulting in inhibition of experimental human pancreatic cancer growth and significant prolongation of survival[80]. Similar results were obtained in a model of estrogen receptor-positive breast cancer in which successful cooperation of the dual erb B1/B2 inhibitor lapatinib with tamoxifen was evidenced[81]. Yet there are pitfalls of combinatorial therapy: the combination of two substances may not always be beneficial; for example, the combination of tamoxifen and trastuzumab in estrogen-receptor positive breast cancer may be less effective than either substance alone possibly due to an increase in erb B2 signalling pathways that occurs when tamoxifen is added to trastuzumab[82]. In case of gefitinib, addition of this RTKI to platin-based chemotherapy in non-small cell lung cancer (INTACT 2 trial) showed no added benefit in survival, TTP, or RR compared with standard chemotherapy alone. This large, placebo-controlled trial confirmed the favorable gefitinib safety profile observed in phase I and II monotherapy trials[83]. Currently only data from animal or *in vitro* testing exist with respect to gastric cancer; Park *et al*[84] investigated the effect of gefitinib combined with oxaliplatin, 5-fluorouracil, or paclitaxel in a gastric cancer cell line, SNU-1. This study demonstrated the antitumor activity and a significant cell cycle arresting effect induced by gefitinib in SNU-1 human gastric carcinoma cells, and its synergistic interaction with oxaliplatin and paclitaxel. There are preliminary data on a multicenter phase II study of irinotecan, cisplatin, and bevacizumab in gastric or gastroesophageal adenocarcinoma which indicate an excellent disease control rate of 13/15 cases; in a subset of ten patients with measurable disease who had received at least two cycles of therapy, 5 partial responses, 4 minor responses (15%-29% reduction) and 1 stable disease were observed[85]. Other, less toxic substances have been assessed as well. Thus it has previously been documented that gastric tissue exposed to acetylsalicylic acid (ASA) expresses high levels of EGFR[86,87]. A positive loop regulation between COX and erbB2[88] as well as EGFR[89] has been postulated. Since nonsteroidal anti-inflammatory drugs (NSAIDs) might be a tool of carcinoma prevention in the gastrointestinal tract[90] we investigated the mechanisms of a potential synergism of simultaneous cyclooxygenase (COX)- and EGFR-inhibition. It has previously been described that simultaneous administration of COX- and EGFR-inhibitors exerts tumor preventive effects in nude mice[91]. A combination of these two substances with a protein kinase A (PKA) antisense oligonucleotide was able to eliminate tumors in more than half of the animals treated[92]. Preliminary data from our group indicate that acetylsalicylic acid may modulate the expression and activation of EGFR in gastric cancer cells rendering them more susceptible to gefitinib treatment[93].

Radiation therapy and RTKIs: Radiation causes cell death by induction of cellular injury which may rely on subsequent growth factor/receptor tyrosine kinase activation for repair, the combination of radiation and RTKIs seems to be obvious. Currently, however, only data with respect to experimental therapy, especially in animal models, exist. E.g., She *et al*[94] examined the effect of addition of gefitinib to radiation therapy in a nude mouse model of different cancers, including lung and breast cancer. Gefitinib significantly enhanced the antitumor action of radiation therapy against the test tumors without significant adverse effects, increasing the therapeutic selectivity of ionizing radiation in these model systems. In a similar model, PTK787/ZK222584, a specific inhibitor of VEGFR tyrosine kinases, was tested. Tumors vascularized by radiation-damaged vessels responded to PTK787/ZK222584 with longer latency and slower growth rate than controls, and a trend toward further increase in necrosis, indicating that irradiated tumor vessels are more susceptible to VEGFR inhibition than unirradiated vessels[95].

CONCLUSION

Receptor tyrosine kinases participate in several steps of tumor formation including proliferation and metastasis formation. As several of them are upregulated in gastric cancer, they offer potential prime targets for a tailored therapy. Unfortunately, only preliminary data exist on the use of the currently clinically available drugs such as trastuzumab, cetuximab, bevacizumab, gefitinib, erlotinib, and imatinib in the setting of gastric cancer. However, phase II trials are underway to examine the potential of these drugs in adenocarcinoma of the stomach. As RTK inhibitors with a broad range are being developed, the potential usefulness of this drug class is most likely to further increase as preclinical data in models of gastric cancer already indicate their effectiveness. The approach of combining RTKIs with "conventional" means of tumor therapy such as cytostatics and radiation therapy is most likely to find its way into clinical application in near future. RTKIs alone typically only inhibit tumor growth and do not aim at killing the cancer cell, but they might prove to

be an effective chemosensitizer of other antitumor drugs as they are able to block the process of cellular restitution following injury caused by radiation or "conventional" cytostatics. Different trial designs may be necessary given that some RTKIs might only work in small subsets of patients (for example, the fate of gefitinib in non-small cell lung cancer) and often improve patients' condition without leading to an objective response. Genomic or proteomic analysis of aberrations in individual patients may be necessary to decide about a tailored therapy.

Abstract

Many experimental and clinical observations suggest that intestinal microflora plays a potential role in the pathogenesis of inflammatory bowel disease (IBD). Manipulation of the luminal content using antibiotics or probiotics represents a potentially effective therapeutic option. The available studies do not support the use of antibiotics in ulcerative colitis (UC). Antibiotics are effective in treating septic complications of Crohn's disease (CD) but their use as a primary therapy is more controversial, although this approach is frequently and successfully adopted in clinical practice.

There is evidence that probiotic therapy may be effective in the prevention and treatment of mild to moderate UC. In contrast, a lack of successful study data at present precludes the widespread use of probiotics in the treatment of CD.

Both antibiotics and probiotics appear to play a beneficial role in the treatment and prevention of pouchitis and further trials are warranted to fully quantify their clinical efficacy.

INTRODUCTION

The rationale for using antibiotics and probiotics in the treatment of inflammatory bowel disease (IBD) is based on convincing evidence implicating intestinal bacteria in the pathogenesis of the disease[1].

The distal ileum and the colon are the areas with the highest bacterial concentrations and represent the sites of inflammation in IBD. In addition, pouchitis, the non-specific inflammation of the ileal reservoir after ileo-anal anastomosis, appears to be associated with bacterial overgrowth and dysbiosis. Furthermore, pouchitis does not occur prior to closure of the ileostomy.

Patients with Crohn's disease (CD) consistently respond to diversion of faecal stream, with immediate recurrence of inflammation after restoration of intestinal continuity or infusion of luminal content into the bypassed ileum[2,3]. Moreover, the composition of the enteric flora is altered in patients with IBD, and enteric bacteria or their products have been found within the inflamed mucosa of patients with CD[4]. Increased number of aggressive bacteria such as *Bacteroides,* adherent/invasive *Escherichia coli* and enterococci, and decreased number of protective lactobacilli and bifidobacteria have been observed in IBD[5].

However, the most compelling evidence that intestinal bacteria play a role in IBD has been derived from animal models. Although there is a great diversity in genetic defects and immunopathology, a consistent feature of many transgenic and knockout mutant murine models of colitis is that the presence of normal enteric flora is required for full expression of inflammation[6]. Indeed, there is evidence that immunological tolerance to commensal bacteria is lost in patients with IBD[7,8]. These findings have led to the proposal that manipulation of intestinal microbiota flora, either with antibiotics or probiotics, may be therapeutic in IBD. Some suggested mechanisms of action of antibiotics and probiotics are shown in Table 1.

There is a growing body of evidence from animal studies and clinical trials that antibiotics and probiotics have therapeutic effects in ulcerative colitis (UC), CD and pouchitis.

ANTIBIOTICS

Animal model studies

In several rodent models the use of broad-spectrum an-

Table 1 Suggested mechanisms of action of antibiotics and probiotics

Antibiotics	Probiotics
Eradication of bacterial antigenic triggers	Inhibition of pathogenic enteric bacteria by:
Elimination of bacterial overgrowth	decreasing luminal pH
Reduction of pro-inflammatory bacterial toxins	secretion of bacteriocidal proteins
Potential immunosuppressive properties of antibiotics	resisting colonization
	blocking epithelial binding
	Improvement in epithelial and mucosal barrier function by:
	production of short-chain fatty acids
	enhancing mucus production
	increasing barrier integrity
	Alteration of immunoregulation by:
	increasing interleukin-10 and TGFβ, and decreasing TNF levels
	increasing IgA production

tibiotics can both prevent and treat experimental colitis, whereas metronidazole and ciprofloxacin can only prevent experimental colitis but cannot reverse the established disease[9-13]. Broad-spectrum antibiotics are effective in almost all models of acute and chronic colitis[13-16], but they have only a transient efficacy in HLA-B27 transgenic rats[17]. Interestingly, ciprofloxacin and metronidazole have selective efficacy in different colonic regions of interleukin-10 (IL-10) knockout mice, suggesting that different bacteria cause inflammation in different colonic segments[15]. These studies suggest that most clinical forms of IBD may respond to a specific combination of broad-spectrum antibiotics.

Ulcerative colitis

Only a few trials on the use of antibacterial agents have been carried out in UC and the results are controversial. Most clinicians have used antibiotics as an adjuvant therapy for severe UC. Dickinson *et al*[18] carried out a double-blind controlled trial on the use of oral vancomycin as an adjunct for acute exacerbations of idiopathic colitis and found that there is no significant difference between the two treatment groups, with only a trend towards a reduction in the need for surgery in patients treated with vancomycin[18].

Intravenous metronidazole used in conjunction with corticosteroids, is as effective as placebo in inducing remission in patients with severe UC[19]. In a double-blind, placebo-controlled trial in patients with acute relapse of UC, Burke *et al*[20] randomized 84 patients to receive corticosteroids plus oral tobramycin or placebo and found that after 1 wk of treatment, 74% of patients in the tobramycin treatment group and 43% in the placebo group ($P < 0.003$) achieve complete symptomatic remission. However, the combination of tobramycin and metronidazole does not have any beneficial effect when compared with a standard steroid treatment in severely acute UC[21].

Mantzaris *et al*[22] investigated ciprofloxacin in a randomised, placebo-controlled study and randomized 70 patients with mild to moderate active UC to receive either 250 mg ciprofloxacin twice a day or placebo for 14 d and found that 70.5% of patients in the ciprofloxacin group and 72% in the placebo group achieve remission. Moreover, a short course of intravenous ciprofloxacin is not effective as an adjunctive treatment to corticosteroids in severe UC[23]. In contrast, some efficacy of ciprofloxan has been observed in a more recent randomised placebo-controlled trial when ciprofloxacin is administered for 6 mo to patients with active UC poorly responding to conventional therapy with steroids and mesalazine[24]. At the end of the study, the treatment-failure rate was 21% in the ciprofloxacin-treated group and 44% in the placebo group ($P < 0.002$). This difference was detected using clinical criteria; while endoscopic and histological findings showed differences only at 3 mo but not at 6 mo.

The non-absorbable broad-spectrum antibiotic, rifaximin, was investigated in a small controlled study to evaluate its efficacy and systemic absorption in patients with moderate to severe active UC refractory to steroid treatment. Twenty-eight patients were randomised to receive either rifaximin 400 mg twice daily or placebo for 10 d as an adjunct to standard steroid treatment. Although there is no significant difference in the clinical efficacy score between the two treatments, only rifaximin determines a significant improvement in stool frequency, rectal bleeding and sigmoidoscopic score[25].

Whilst rifaximin does not permanently alter the colonic microbiota, resistant *Bifidobacterium* species have been found after 3 intermittent courses in patients with UC[26].

Crohn's disease

Broad-spectrum antibiotics are widely used to treat CD[27], but large controlled trials have not yet been performed (Table 2).

Metronidazole has been the most investigated agent. In 1978, Blichfeldt *et al*[28] found that there is no difference between metronidazole and placebo-treated patients in a placebo-controlled, double-blind, crossover trial. However, a positive trend in favour of metronidazole is observed when only the colon is involved[28]. In the National Cooperative Swedish study, metronidazole has been compared with sulphasalazine as a primary treatment for Crohn's disease. Although no significant difference is found between the two groups, metronidazole is effective in patients who fail to respond to sulphasalazine[29]. In

Table 2 Antibiotics trials in active Crohn's disease

Study	Patients (*n*)	wk	Main outcome	Study design	Treatment schedules
Blichfeldt *et al*[28]	22	8	Improvement (clinical/lab score)	DB crossover study	MZ (+ SASP/CS) Placebo (+ SASP/CS)
Ursing *et al*[29]	22	16	Change in CDAI and orosomucoid	DB crossover study	MZ SASP
Ambrose *et al*[30]	72	4	Improvement (Clinical/lab.score)	DB RCT	MZ CO, MZ/CO, placebo
Sutherland *et al*[31]	99	16	Change in CDAI from baseline	DR RCT	MZ (10/20 mg/kg) Placebo
Prantera *et al*[32]	41	12	Clinical remission (CDAI < 150)	NB RCT	MZ + Cipro Steroids
Colombel *et al*[34]	40	6	Clinical remission (CDAI < 150)	NB RCT	CIPRO 5-ASA
Arnold *et al*[35]	47	24	Change in CDAI	NB RCT	CIPRO (+ conc drugs) Placebo (+ conc drugs)
Steinhart *et al*[33]	134	8	Clinical remission (CDAI < 150)	DB RCT	MZ+CIPRO (+ bud 9 mg) Placebo (+ bud. 9 mg)

CDAI: Crohn's disease activity index.

another study, metronidazole was used either as a single therapy or in combination with cotrimoxazole and compared to cotrimoxazole alone and a double placebo in patients with a symptomatic relapse of CD, which shows that after four weeks of treatment there is no difference in response among the three treatment groups[30]. In a Canadian randomised, placebo-controlled trial, Sutherland *et al*[31] demonstrated that treatment with metronidazole for 16 wk significantly decreases the Crohn's disease activity index (CDAI), but no difference is found in the rates of remission compared with placebo. As in the Swedish study[29], the Canadian study found that metronidazole is effective for colonic and ileocolonic CD, but not for ileitis. Unfortunately, metronidazole has numerous side-effects including nausea, anorexia, dysgeusia, dyspepsia and peripheral neuropathy, which limit its use in approximately 20% of patients.

An antibiotic combination was used in an Italian randomised controlled study[32] in which 250 mg metronidazole four times daily plus 500 mg ciprofloxacin twice daily were compared to a standard steroid treatment for 12 wk. No significant differences were reported in the rates of remission between treatments (46% with ciprofloxacin plus metronidazole and 63% with methylprednisolone), suggesting that this antibiotic combination is a potential alternative to steroid treatment in the acute phase of CD[32]. In another trial[33], this combination of metronidazole and ciprofloxacin was supplemented with budesonide (9 mg/d) for active CD. No difference was registered compared to placebo, but the overall response in the two groups was lower than that in previous studies using budesonide, suggesting that antibiotic treatment is more effective in colonic disease than in isolated small bowel disease.

Ciprofloxacin (1 g/d) was compared to mesalazine (4 g/d) in a controlled study[34] of mild to moderate active CD for 6 wk. The results suggest that ciprofloxacin is as efficacious as mesalazine (remission observed in 56% and 55% of patients treated with ciprofloxacin and mesalazine respectively), thus offering a potential alternative treatment for active CD. Furthermore, ciprofloxacin has been shown to be effective when used in combination with standard treatment in patients with resistant disease [35].

Other antibiotics have also been investigated. Shafran *et al*[36] carried out an open-label study on the efficacy and safety of rifaximin (600 mg/d) for 16 wk in the treatment of mild to moderate active CD, and found that at the end of the study, 59% of patients are in remission (CDAI < 150) with a significant reduction of the mean CDAI score compared to baseline ($P < 0.0001$). Leiper *et al*[37] reported that 64% patients have an impressive positive response to clarithromycin, many of whom are unresponsive to other treatments.

Many studies have tried to evaluate the efficacy of antimycobacterial drugs in patients with CD, pursuing the possibility that a strain of *Mycobacterium* might be an aetiological agent in CD. Borgaonkar *et al*[38] performed a meta-analysis of all randomised controlled trials in which antimycobacterial therapy was compared with placebo and found that antimycobacterial therapy is only efficacious in the maintenance of remission after a combined treatment of corticosteroids and antimycobacterial agents. However, the investigator emphasised that because of the high incidence of side-effects and the small number of studies included in the meta-analysis, the data are inconclusive and should be interpreted with caution.

The same antibiotics used to treat luminal CD have been reported to be beneficial for the treatment of perianal CD, but no controlled trials are available[39]. Metronidazole (20 mg/kg) can close 62%-83% fistulae[40,41]. The combination of metronidazole and ciprofloxacin results in an improvement in 64% of patients with closure of fistulae in 21%[42]. Unfortunately, fistulae tend to recur in most patients following cessation of treatment. Although the results of these uncontrolled studies are inconclusive, metronidazole and ciprofloxacin alone or in combination, are used by most clinicians as first-line treatments for patients with perianal disease in conjunction with surgical drainage of abscesses.

The use of antibiotics in the prevention of post-

operative disease recurrence has also been investigated. Rutgeerts *et al*[43] have assessed the efficacy of metronidazole at 20 mg/kg per day in a placebo-controlled double-blind study. In their study, sixty patients were randomised to receive either metronidazole or placebo for 12 wk and endoscopic relapse was evaluated by Rutgeerts score at the end of the treatment. They found that metronidazole significantly decreases the incidence of severe endoscopic relapse (grade 3 or 4) and the clinical recurrence rate. More recently, ornidazole used continuously for 1 year, has been shown to be significantly more effective than placebo in the prevention of clinical and endoscopic recurrence in the neoterminal ileum[44].

Pouchitis

The awareness of the crucial importance that faecal stasis and bacterial overgrowth may play a role in the pathogenesis of acute pouchitis has led clinicians to treat patients with antibiotics.

Antibiotics have become the mainstay of treatment for pouchitis, although controlled trials are not available. Metronidazole is the first-line treatment, and most patients with acute pouchitis respond quickly to its administration of 1-1.5 g/d[45,46]. A double-blind, randomised, placebo-controlled, crossover trial was carried out by Madden *et al*[47] to assess the efficacy of 400 mg of metronidazole three times daily *per os* for two weeks in 13 patients (11 completed both arms of the study) with chronic, unremitting pouchitis. The found that metronidazole is significantly more effective than placebo in reducing stool frequency (73% and 9%), even without improvement in endoscopic appearance and histological grade of activity. However, a significant proportion of patients (55%) may experience side-effects while using metronidazole, including nausea, vomiting, abdominal discomfort, headache, skin rash and metallic taste. Recently Shen *et al*[48] compared the efficacy and side-effects of ciprofloxacin and metronidazole in treating acute pouchitis in a randomised clinical trial. Seven patients received ciprofloxacin (1 g/d) and nine patients received metronidazole (20 mg/kg per day) for 2 wk. The results of this study have shown that both ciprofloxacin and metronidazole are efficacious in the treatment of acute pouchitis. Both reduce the total pouchitis disease activity index (PDAI) scores and lead to a significant improvement in symptoms as well as endoscopic and histological scores. However, ciprofloxacin leads to a greater reduction in PDAI scores as well as improvement in symptoms and endoscopic scores. Furthermore ciprofloxacin is better tolerated than metronidazole (33% of metronidazole-treated patients reported adverse effects, compared with none in the ciprofloxacin group).

Given the management difficulties posed by chronic refractory pouchitis, the use of combined antibiotic treatment has been explored. In an open trial, 18 patients with active pouchitis not responding to standard therapy (metronidazole or ciprofloxacin) for 4 wk, were treated orally with rifaximin (2 g/d) plus ciprofloxacin (1 g/d) for 15 d. Symptom assessment, endoscopic and histological evaluations were performed at screening and after 15 d using PDAI scores. The results indicate that 16 out of 18 patients (88.8%) improve ($n = 10$) or go into remission ($n = 6$) with the median PDAI score before and after therapy being 11 and 4 respectively ($P < 0.002$)[49].

More recently, 44 patients with refractory pouchitis received metronidazole (800 mg to 1 g/d) and ciprofloxacin (1 g/d) for 28 d. The results reveal that 66 patients (82%) go into remission with the median PDAI score before and after therapy being 12 and 3 respectively ($P < 0.0001$), and the patients' quality of life is significantly improved after the treatment (median IBD Questionnaire score increased from 96.5 to 175)[50].

Table 3 Organisms associated with probiotic activity

Most commonly	Other bacterial strains	Yeast
Lactobacilli	Enterococci	Saccharomyces boulardii
Bifidobacteria	Non-pathogenic *E. coli*	
Streptococci		

PROBIOTICS

The use of probiotics for the purpose of health maintenance and disease prevention is first proposed by Elie Metchnikoff, the Russian Nobel prize winner[51], who at the turn of the last century suggested that a high concentration of lactobacilli in the intestinal flora is important for the health and longevity of humans. Probiotics are defined as "living organisms, which upon ingestion in a certain number exert health benefits beyond inherent basic nutrition"[52].

A number of bacteria are associated with probiotic activity (Table 3). For clinical application, probiotic strains need to be resistant to acid and bile and the ability to be metabolically active within the luminal flora where they should ideally survive but not persist in the long term. They should be antagonistic to pathogenic bacteria and safe for human use while maintain their viability and beneficial properties during the manufacturing processes[53].

Animal model studies

Encouraging results of probiotic therapy have been obtained in experimental colitis. Administration of *Lactobacillus reuteri* can significantly reduce inflammation in acetic acid-and methotrexate-induced colitis in rats[54,55]. More recently *Lactobacillus sp.* has been shown to be able to prevent the development of spontaneous colitis in IL-10 deficient mice[56], and continuous feeding with *Lactobacillus plantarum* improves an established colitis in the same knockout model[57]. A strain of *Lactobacillus salivarius* (subsp. *salivarius*) reduces the rate of progression from inflammation to dysplasia and colonic cancer in IL-10 deficient mice[58], and *Bifidobacterium infantis* and of *Lactobacillus salivarius* are able to attenuate inflammation and reduce the ability to produce Th1-type cytokines in the IL-10 knockout model[59].

VSL#3 is characterised by a very high bacterial concentration (each packet containing 450 billion viable bacteria) and the presence of a cocktail of eight different bacterial species. This product contains viable lyophilised bacteria of four strains of lactobacilli (*L. casei, L. plantarum, L. acidophilus, L. delbrueckii* subsp. *bulgaricus*), three strains of

bifidobacteria (*B. longum, B. breve, B. infantis*) and one strain of *Streptococcus salivarius* subsp. *Thermophilus*. Rachmilewitz and colleagues[60] found that VSL#3 results in a significant attenuation of inflammation with a decrease of myeloperoxidase and nitric oxide synthase activity of the iodoacetamide-induced colitis. Madsen and colleagues[61] have reported a significant improvement in inflammation together with a reduction in mucosal levels of pro-inflammatory cytokines and normalisation of colonic barrier integrity in IL-10 knockout mice.

Ulcerative colitis

Promising results of probiotics have been found in the treatment of UC. In 3 recent trials involving the non-pathogenic strain of *Escherichia coli* Nissle 1917, similar efficacy has been observed to that of mesalazine in the maintenance treatment of UC[62-64].

We carried out a pilot study using the probiotic cocktail, VSL#3, as maintenance treatment for patients with UC in remission, allergic or intolerant to sulphasalazine and mesalazine, to assess its impact on the faecal flora. Twenty patients received 6 g a day of VSL#3 (1800 billion bacteria) for 12 mo and were assessed clinically and endoscopically at baseline, at 6 and 12 mo, and in the event of a relapse. Stool culture and determination of faecal pH were also performed at different intervals[65]. Microbiological determination showed a significant increase in concentration of lactobacilli, bifidobacteria and *Streptococcus thermophilus,* evident after just 20 d, which persisted throughout the treatment period, and returned to basal levels within 15 d after treatment. Faecal concentration of *Bacteroides*, enterococci, coliforms, *Clostridia* and total anaerobes and aerobes was not affected, but faecal pH was significantly reduced by the treatment. Fifteen of the twenty patients (75%) remained in remission throughout the treatment period[65].

Furthermore, VSL#3 at very high dosage (3600 billion bacteria/d) can induce remission in 63%, with a positive response in a further 23% of patients with active mild to moderate disease[66].

In addition, an open uncontrolled 4-wk study found that the yeast *Saccharomyces boulardii* could induce remission in 71% of patients with mild to moderate UC[67]. These studies highlight the wide range of organisms that may be beneficial as probiotic therapy for UC.

Crohn's disease

Campieri *et al*[68] performed a randomised trial to evaluate the efficacy of a combination of rifaximin and the probiotic preparation, VSL#3, in the prevention of post-operative recurrence of CD. Rifaximin (1.8 g/d) for 3 mo, followed by VSL#3 (6 g daily) for 9 mo, was compared with mesalazine (4 g/d) for 12 mo in 40 patients after curative resection for CD. After 3 mo of treatment, the antibiotic-probiotic combination resulted in a significantly lower incidence of severe endoscopic recurrence compared to mesalazine [2/20 (10%) *vs* 8/20 (40%)]. This difference was maintained throughout the study period [4/20 (20%) *vs* 8/20 (40%)][68].

No such clinical effect was seen in a study by Prantera *et al*[69] who reported that the probiotic *Lactobacillus GG* could not prevent post-operative disease recurrence in an 1-year double-blind, placebo-controlled trial. Similar negative results have been recently reported by the GETAID French group. A randomised double-blind, placebo-controlled study showed that *Lactobacillus johnsonii* LA1 ($4x10^9$ cfu/d) is not superior to placebo in preventing endoscopic recurrence of CD[70].

In a small pilot study[71], treatment with capsules containing *E.coli* Nissle 1917 was compared to placebo in the maintenance of steroid-induced remission of colonic CD. Twelve patients were treated with *E.coli* Nissle and 11 with placebo. The results showed that at the end of the 12-wk treatment period, the relapse rate is 33% in the *E.coli* group and 63% in the placebo group. Unfortunately, because of the small number of patients treated, this difference did not reach statistical significance.

However, a small comparative open study[72] showed that the combination of *Saccharomyces boulardii* (1 g/d) and mesalazine (2 g/d) is significantly superior to mesalazine (3 g/d) in maintenance of remission, suggesting that probiotic treatment in CD may be beneficial. More recently, a double-blind trial showed that *Lactobacillus* GG is not superior to placebo in prolonging remission in children with CD when given as an adjunct to standard therapy[73].

Pouchitis

Although probiotics are less widely used in clinical practice than antibiotics, they may be efficacious in the prevention and treatment of pouchitis. We have compared the efficacy of VSL#3 with placebo in the maintenance and treatment of chronic pouchitis[74]. Forty patients who obtained clinical and endoscopic remission after 1 mo of combined antibiotic treatment (rifaximin 2 g/d + ciprofloxacin 1 g/d) were randomised to receive VSL#3, 6 g daily (1800 billion bacteria/d) or a placebo of identical appearance for 9 mo. Clinical assessment was carried out every month, endoscopic and histological assessments were performed at entry and subsequently every two months. Stool samples were cultured before and after antibiotic treatment and subsequently every month during maintenance treatment. Relapse was defined as an increase of at least 2 points in the clinical portion of the PDAI and confirmed endoscopically and histologically. Whilst all 20 patients treated with placebo had a relapse during the 9 mo follow-up period, 17 of the 20 (85%) patients treated with VSL#3 remained in remission at this point. Interestingly, all these 17 patients had a relapse within 4 mo after the active treatment. Faecal concentrations of lactobacilli, bifidobacteria and *Streptococcus salivarius* subsp. *thermophilus* were significantly increased within 1 mo after VSL#3 treatment, and remained stable throughout the study. However, this increase did not affect the concentration of the other bacterial groups, suggesting that the beneficial effect of treatment is not mediated by suppression of endogenous luminal bacteria.

A recent study examining the maintenance of remission in patients with refractory or recurrent pouchitis showed that remission is achieved in 85% of patients treated with VSL#3, 6 g/d (1800 billion bacteria/d) and 6% in

the placebo group after 1 year of treatment[75]. In addition, continuous administration of VSL#3 results in a significant increase in IL-10 tissue levels, a significant decrease in tissue levels of the pro-inflammatory cytokines (TNF alpha, IL-1 and IFN gamma) and a decrease in matrix metalloproteinase activity[76]. This may aid our understanding of the mechanisms of action by which VSL#3 maintains remission in pouchitis. In contrast, *Lactobacillus GG* is ineffective in preventing relapse in patients with chronic pouchitis[77].

We have also carried out a double-blind, placebo-controlled trial to evaluate the efficacy of VSL#3 in preventing pouchitis onset following ileal-anal anastomosis for UC[76]. Forty patients were randomised to receive VSL#3, 3 g per day (900 billion bacteria/d) or an identical placebo for 12 mo. Patients were assessed clinically, endoscopically and histologically at 1, 3, 6, 9 and 12 mo according to the PDAI. The results indicate that patients treated with VSL#3 have a significantly lower incidence of acute pouchitis compared with those treated with placebo during the first year of ileostomy closure (10% *vs* 40%; $P < 0.05$). Moreover, the IBD Questionnaire score is significantly improved in the group treated with VSL#3, and the median stool frequency in patients not developing pouchitis, is significantly less in the VSL#3 group compared with the placebo group[78].

CONCLUSION

There is strong evidence that enteric commensal bacteria are involved in the pathogenesis of IBD. Therefore, modification of the gut bacterial flora by antibiotics and probiotics may be effective in treating UC, CD and pouchitis.

Antibiotics are a well established, efficacious treatment option for various manifestations of IBD. Antibiotics play an essential role in treating the septic complications of CD, including intra-abdominal and perianal abscesses and perianal fistulae, although their use in CD as a primary therapy is poorly documented. There is good evidence that ciprofloxacin, metronidazole or their combination is effective in Crohn's colitis and ileocolitis, though not in isolated ileal disease. Large controlled trials are needed to define optimal antibiotic regimens. In addition, their use in UC is not supported by the available studies and large trials with broad-spectrum agents are required. Although proper controlled trials have not yet been conducted, the use of antibiotics in pouchitis is largely justified.

Probiotics provide an attractive alternative to antibiotics in the treatment of IBD as trials to date have shown that they safe and have no side-effects. Promising results have been obtained from studies using probiotics, in both the prevention of relapse and the treatment of mild to moderate attacks of UC. Studies using probiotics in the treatment of CD are less clear due to conflicting and limited data. There is also considerable evidence that the highly concentrated cocktail of probiotics, VSL#3 is efficacious in preventing pouchitis onset and relapse.

Studies have highlighted the importance of selecting a well characterised probiotic preparation for treatment. In fact, viability and survival of bacteria in many available preparations are unproven. It should be remembered that the beneficial effect of one probiotic preparation does not imply efficacy of other preparations containing different bacterial strains, because each individual probiotic strain has its unique biological properties.

There is a need to improve our understanding of the composition of the enteric flora and the relationship between intestinal physiology and the luminal ecosystem. Only then can we truly optimise the bacteria-modifying treatments now available to effectively treat IBD.

Abstract

The incidence of acute pancreatitis in Japan is increasing and ranges from 187 to 347 cases per million populations. Case fatality was 0.2% for mild to moderate, and 9.0% for severe acute pancreatitis in Japan in 2003. Experts in pancreatitis in Japan made this document focusing on the practical aspects in the early management of patients with acute pancreatitis. The correct diagnosis of acute pancreatitis and severity stratification should be made in all patients using the criteria for the diagnosis of acute pancreatitis and the multifactor scoring system proposed by the Research Committee of Intractable Diseases of the Pancreas as early as possible. All patients diagnosed with acute pancreatitis should be managed in the hospital. Monitoring of blood pressure, pulse and respiratory rate, body temperature, hourly urinary volume, and blood oxygen saturation level is essential in the management of such patients. Early vigorous intravenous hydration is of foremost importance to stabilize circulatory dynamics. Adequate pain relief with opiates is also important. In severe acute pancreatitis, prophylactic intravenous administration of antibiotics at an early stage is recommended. Administration of protease inhibitors should be initiated as soon as the diagnosis of acute pancreatitis is confirmed. A combination of enteral feeding with parenteral nutrition from early stage is recommended if there are no clear signs and symptoms of ileus and gastrointestinal bleeding. Patients with severe acute pancreatitis should be transferred to ICU as early as possible to perform special measures such as continuous regional arterial infusion of protease inhibitors and antibiotics, and continuous hemodiafiltration. The Japanese Government covers medical care expense for severe acute pancreatitis as one of the projects of Research on Measures for Intractable Diseases.

INTRODUCTION

There are several guidelines for the treatment of acute pancreatitis, mostly based on published evidence[1-4]. If, however, there were no published evidence, data would not be adopted in guidelines even if the therapy is employed in clinical practice. There is little evidence for the treatment of acute pancreatitis in critically early stage, and thus it is not mentioned in the guidelines.

In July 2003, the Japanese Society for Abdominal Emergency Medicine, the Japan Pancreas Society and the Research Committee of Intractable Diseases of the Pancreas supported by the Japanese Ministry of Health, Labour, and Welfare published "Evidence-Based Clinical Practice Guidelines for Acute Pancreatitis"[2,5]. The working party of the Research Committee of the Intractable Diseases of the Pancreas made the present document for the management of acute pancreatitis in the early stages after onset[6], which was not mentioned in the guidelines[2,5]. The management of patients with acute pancreatitis is complicated by an unpredictable outcome[7]. Many patients initially identified as having mild disease progress to severe disease indolently over the initial 48 h. This document is the consensus of experts in pancreatitis in Japan and focuses on the practical aspects in the early management of patients with acute pancreatitis and decisions needed within the first 48 h of care, introducing literatures on the treatment of acute pancreatitis published in Japanese.

This consensus guideline on acute pancreatitis is a review of literatures and experts' opinions in Japan intended for general clinicians in primary care and emergency department, and gastroenterologists who do not have expertise in pancreatitis. However, this consensus by experts is only an example of standard practical medical care for patients with acute pancreatitis in Japan. Physicians need not necessarily follow this consensus but have to determine measures depending on hospital and patient specifics.

ESSENTIALS OF PRIMARY CARE OF ACUTE PANCREATITIS

All patients diagnosed with acute pancreatitis should be managed in the hospital. Monitoring of blood pressure, pulse and respiratory rate, body temperature, hourly urinary volume, and blood oxygen saturation level (SpO_2) by pulse oximetry is essential. Early vigorous intravenous hydration is of foremost importance. The correct diagnosis of acute pancreatitis and severity stratification should be made in all patients using the criteria for the diagnosis of acute pancreatitis and the multifactor scoring system proposed by the Research Committee of Intractable Diseases of the Pancreas[8] as early as possible. Following the correct diagnosis of acute pancreatitis, severity stratification should be performed promptly and repeatedly after the onset, in particular for the first 48 h.

It is not possible to distinguish mild from severe acute pancreatitis during the early stages. Serum levels of amylase and lipase do not reflect the severity of acute pancreatitis[9,10]. Even patients who appeared to be mild acute pancreatitis at the first hospital visit (within 48 h after onset) often deteriorate. All patients with severe acute pancreatitis must be monitored closely for the development of organ failure and should be managed in, or referred to, an intensive care unit (ICU) with full monitoring and systems support. The mortality rate of patients with mild acute pancreatitis within the first 24 h who later showed exacerbation during 24-48 h was reported to be 11%[11].

When the diagnosis of severe acute pancreatitis was made, systemic administration of antibiotics and protease inhibitors, and special measures such as continuous regional arterial infusion (CRAI) of protease inhibitors and antibiotics, continuous hemodiafiltration (CHDF), and selective decontamination of the digestive tract (SDD) should be considered.

Patients with severe acute pancreatitis and those requiring interventional radiological, endoscopic, or surgical procedures should be managed in, or referred to, a specialty unit. Principles of management of acute pancreatitis are summarized in Table 1 and Figure 1.

DIAGNOSIS OF ACUTE PANCREATITIS

Acute pancreatitis should be diagnosed according to the diagnostic criteria for acute pancreatitis proposed by the Research Committee of Intractable Diseases of the Pancreas[8]. Clinical criteria for the diagnosis of acute pancreatitis are (1) acute abdominal pain and tenderness in the upper abdomen, (2) elevated pancreatic enzyme levels in blood, urine, or ascitic fluid, and (3) radiologic abnormalities characteristic of acute pancreatitis. Acute pancreatitis can be diagnosed when two or more of the above criteria are fulfilled and other causes of acute abdominal pain are excluded. Acute exacerbation of chronic pancreatitis is included in acute pancreatitis.

The incidence of acute pancreatitis in Japan appears to be increasing[12] and ranges from 187 to 347 cases per million populations. Approximately 4.9% of patients who visited hospitals complaining of acute abdominal pain were found to have acute pancreatitis[13]. Thus, acute pancreatitis should be considered as a differential diagnosis for cases with signs and symptoms of digestive diseases. A history of the present illness and life-style, physical examination, blood tests such as amylase and lipase, and imaging studies such as abdominal plain X-ray, ultrasonography (US) and computed tomography (CT) should be undertaken to assist in the diagnosis of acute pancreatitis. Therefore, every hospital that receives acute admissions should have facilities for acute pancreatitis to be diagnosed at any time. In addition, physicians should be aware of the presence of acute pancreatitis patients but without abdominal pain or

signs and symptoms.

The initial treatment should be started as early as possible following the diagnosis of acute pancreatitis.

PRIMARY CARE OF ACUTE PANCREATITIS (WITHIN 48 H OF DIAGNOSIS)

Severity stratification

Following the correct diagnosis of acute pancreatitis, severity stratification should be performed promptly and repeatedly after the onset, in particular for the first 48 h. Severity of acute pancreatitis should be evaluated and scored by the multifactor scoring system proposed by the Research Committee of Intractable Diseases of the Pancreas (JPN severity scoring system) (Table 2)[8]. We recognize that the Ranson, modified Glasgow, and APACHE II systems for evaluating acute pancreatitis are well established, but they might be outdated and are not used in Japan. Pathology-specific systems such as Ranson's and the modified Glasgow require 48 h of data collection before the severity can be evaluated. JPN severity scoring system contains variables that represent different organ systems and can be consistently recorded at the time of admission to facilitate immediate management decisions.

When the correct diagnosis of acute pancreatitis is made, it should be considered to perform contrast-enhanced CT (CE-CT) and/or CE-magnetic resonance imaging (CE-MRI)[14-17], systemic administration of antibiotics[18] and protease inhibitors[19], and special measures such as CRAI of protease inhibitors and antibiotics[20,21], CHDF[22], and SDD[23]. Patients with severe acute pancreatitis and those requiring interventional radiological, endoscopic, or surgical procedures should be managed in, or referred to, a specialty unit.

There is no simple and reliable index to predict aggravation of acute pancreatitis in the early stages. Despite the importance of recognizing severe disease early in the course, many patients initially identified as having mild disease progress to severe disease indolently over the initial 48 h[11]. Severity stratification should be made repeatedly, particularly within the first 48 h after admission. Early recognition of severe disease and application of

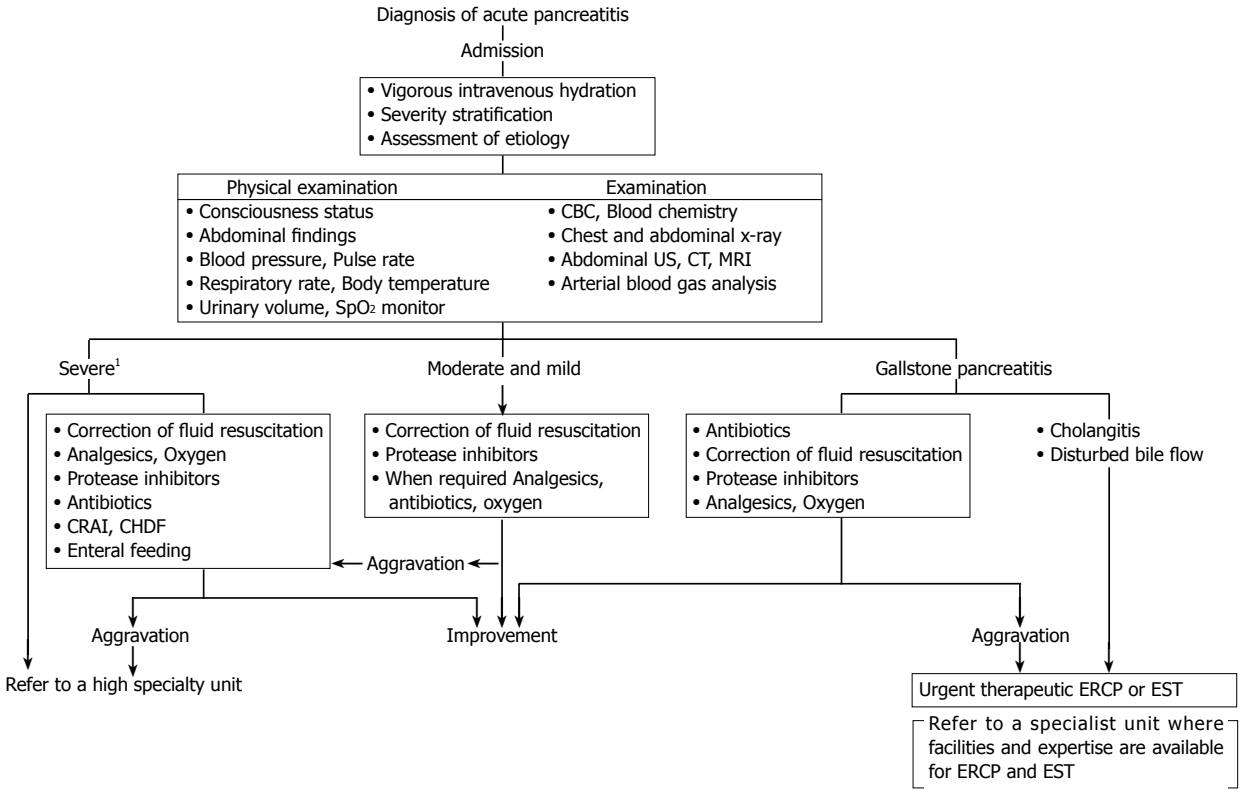

Figure 1 Algorithm of the primary management of acute pancreatitis at an early stage. [1]Hospitals that cannot provide appropriate monitoring and adequate systemic support should transfer all patients with severe acute pancreatitis to a high special unit or intensive therapy unit. SpO_2: Blood oxygen saturation level by pulse oximetry, CBC: Complete blood count, US: Ultrasonography, CT: Computed tomography, MRI: Magnetic resonance imaging, ERCP: Endoscopic retrograde cholangiopancreatography, EST: Endoscopic sphincterotomy, CRAI: Continuous regional arterial contrast infusion of protease inhibitors and antibiotics, CHDF: Continuous hemodiafiltration.

Table 2 Criteria for grading the severity of acute pancreatitis

Prognostic factors	Clinical signs	Laboratory data
Prognostic factor I (2 points for each positive factor)	Shock Respiratory failure Mental disturbance Severe infection Hemorrhagic diathesis	BE ⩽ -3 mEq/L Ht ⩽ 30% (after hydration) BUN ⩾ 40 mg/dL or creatinine ⩾ 2.0 mg/dL
Prognostic factor II (1 point for each positive factor)		PaO_2 ⩽ 60 mmHg (room air) FBS ⩾ 200 mg/dL Total protein ⩽ 60 g/L LDH ⩾ 700 IU/L Ca ⩽ 7.5 mg/dL Prothrombin time ⩾ 15 s Platelet count ⩽ 1×10^5 /mm^3 CT grade IV or V[1]
Prognostic factor III	SIRS score ⩾ 3 (2 points) Age⩾ 70 yr (1 point)	

BE: Base excess, Ht: Hematocrit, BUN: Blood urea nitrogen; FBS: Fasting blood sugar; LDH: Lactate dehydrogenase; SIRS: Systemic inflammatory response syndrome. [1]CT grade IV or V: Presence of diffuse and uneven density in the pancreatic parenchyma or the presence of inflammatory changes extending beyond the border of the pancreas. Severity score: Sum of the points for the positive prognostic factors is defined as the severity score. Standardized criteria: Severe: Presence of more than one prognostic factor I, and/or the presence of more than two prognostic factor II (severity score ⩾ 2 points). Moderate: Presence of one prognostic factor II (severity score = 1 point). Mild: Acute pancreatitis without prognostic factor I or II (severity score = 0 point).

Table 3 Stage classification of acute pancreatitis and mortality rate in nationwide survey in 2003 in Japan

Stage	Severity score	Severity	No of patients (%)[1]	Died[2]	Mortality rate
Stage 0	0 point	Mild	943 (53.3)	1	0.10%
Stage 1	1 point	Moderate	280 (15.8)	2	0.70%
Stage 2	2-8 points	Severe I	455 (25.7)	17	3.70%
Stage 3	9-14 points	Severe II	63 (3.6)	16	25.40%
Stage 4	⩾ 15 points	Most severe	27 (1.5)	16	59.30%
Total			1768 (100)	52	2.90%

[1]In 2004, nationwide survey of patients with acute pancreatitis who visited the hospitals in the year 2003 (from January 1 to December 31) was performed by stratified random sampling method. From the first survey, the total number of patients treated for acute pancreatitis in Japan in the year 2003 was estimated as 35 300 (95% confidence interval, 30 500-40 000). Clinical records of 1768 patients with acute pancreatitis were obtained in the second survey for analysis of etiology and outcome.
[2]Number of patients who died of acute pancreatitis or related complications.

appropriate therapy require vigilance as decisions regarding management need to be made shortly after admission, often within the first 24 h.

Case fatality in acute pancreatitis in Japan in 2003 according to the JPN severity score was 0.2% (3/1223) with 0-1 point (Stage 0, 1), 3.7% (17/455) with 2-8 points (Stage 2), and 35.6% (32/90) more than 9 points (Stage 3, 4) (Table 3)[12].

Assessment of etiology (diagnosis of acute gallstone pancreatitis)

The etiology of acute pancreatitis should be entertained

early, especially in patients with gallstone pancreatitis. Although the vast majority of stones that cause acute pancreatitis rapidly pass out of the common bile duct (CBD)[24], emergency endoscopic retrograde cholangiopancreatography (ERCP) with or without endoscopic sphincterotomy (EST) in selected patients with severe gallstone pancreatitis, who have evidence of biliary obstruction, cholangitis, and an elevated serum bilirubin levels within 24 h of admission, is reported to decrease the incidence of biliary sepsis[25]. Although abdominal US is considered the gold standard for the diagnosis of cholelithiasis, it is not sensitive for the evaluation of choledocholithiasis in the setting of acute pancreatitis. Abdominal US can detect gallstones in the gallbladder in 60%-80% of cases, and in the bile duct in 25%-90% of cases of gallstone pancreatitis in the early stage[26]. Gallstones may be present in the CBD even in the absence of biliary ductal dilatation on abdominal US[27]. Laboratory testing may assist in the early identification of CBD stones. In patients with serum alanine aminotransferase (ALT) (or glutamic-pyruvic transaminase [GPT]) values greater than 150 IU/L at admission and without a history of high quantities of alcohol intake, gallstone pancreatitis cannot be denied even in the absence of bile duct dilatation[27,28]. Increasing serum levels of bilirubin or transaminases within 24-48 h of admission for acute pancreatitis predicts a persistent CBD stone[27]. It is reported that combination of abdominal US and laboratory parameters enables to diagnose gallstone pancreatitis with a sensitivity of 94.9% and a specificity of 100%[24]. When the diagnosis of gallstone pancreatitis is in doubt, repeated imaging studies such as abdominal US, CT, MR cholangiopancreatography (MRCP)[29], or endoscopic ultrasound (EUS)[30], together with serum biochemical tests such as ALT, alkaline phosphatase (ALP), γ-glutamyl transpeptidase (γ-GTP) and total bilirubin may provide good evidence for the presence or absence of gallstone pancreatitis[28].

Urgent therapeutic ERCP or EST should be performed in acute pancreatitis patients with suspected or proven gallstones[24,31,32]. All patients with severe acute gallstone pancreatitis should be managed in, or referred to, a specialist unit where facilities and expertise exist for ERCP at any time for CBD evaluation followed by EST and stone extraction or stenting, as required.

Abdominal CT

Although it is not clear how soon the full extent of the necrotic process occurs and only a quarter of acute pancreatitis patients develop necrosis, it is current practice in Japan to perform CE-CT on admission for severity stratification and correct evaluation of the range of poorly perfused area. A low-density area (poorly perfused area) on CE-CT suggests ischemic change with vasospasm or necrosis in and around the pancreas[33]. The presence of pancreatic necrosis and its range, infiltration of inflammatory changes are closely related with severity and prognosis[15,34]. In addition, CE-CT is required for the decisions on special measures such as CRAI of protease inhibitors and antibiotics, and CHDF. However, since anxieties persist over the potential for extension of necrosis and exacerbation of renal impairment following the use of intravenous contrast media[35,36], vigorous intravenous hydration for the purpose of intravascular resuscitation is important during and after CE-CT.

In severe cases, CT evidence of a low-density area suggesting ischemic change with vasospasm or necrosis in and around the pancreas, free intraperitoneal fluid and extensive peripancreatic fluid collection are observed since an early stage. Since the full extent of the necrotic process occurs at least 4 d after the onset of symptoms[16] and an early CT may therefore underestimate the final severity of the disease, it is desirable to perform CT on admission and repeated CT for reevaluation 2 or 3 d later.

Evaluation and monitoring of circulatory dynamics and fluid resuscitation

Monitoring index: As the inflammatory process progresses early in the course of the disease, there is an extravasation of protein-rich intravascular fluid into the peritoneal cavity resulting in hemoconcentration. The reduced perfusion pressure into the pancreas leads to microcirculatory changes resulting in pancreatic necrosis[37]. At first, for appropriate fluid resuscitation, initial evaluation and monitoring of circulatory dynamics is important.

In all cases, status of consciousness, blood pressure, pulse and respiratory rate, oxygen saturation, body temperature, and hourly urinary volume should be monitored appropriately and chronologically.

The most important aim of fluid resuscitation is to stabilize circulatory dynamics, largely to keep the blood pressure and pulse rate at levels identical to those before onset of acute pancreatitis, and secure reasonable urinary volume. Since the urinary volume is closely related to appropriate circulatory plasma volume and blood pressure, maintenance of urinary volume is easy to monitor; 1 mL/kg body weight is the minimal hourly urinary volume that should be maintained.

In addition to the above-mentioned monitoring, cardiothoracic ratio (CTR) by chest X-ray, blood gas analysis, serum electrolyte, and hematocrit should be determined to perform appropriate fluid resuscitation. Despite sufficient initial fluid resuscitation, aggravation of consciousness status, and the occurrence and progression of metabolic acidosis require re-examinations of other factors such as mesenteric ischemia and reevaluation of circulatory dynamics by determining central venous pressure (CVP) and monitoring pulmonary-artery catheter pressure. In cases of unstable circulatory dynamics, transfer to ICU with full monitoring and systems support should be considered.

Fluid resuscitation: (1) The amount of fluid resuscitation. Extravasation of protein-rich intravascular fluid into the peritoneal cavity early in the course of acute pancreatitis causes hemoconcentration and intravascular hypovolemia leading to impaired microcirculation in the pancreas. The decreased blood flow leads to stasis, thrombosis and subsequent pancreatic necrosis. Vigorous intravenous hydration can prevent the development of pancreatic necrosis. Fluid resuscitation for acute pancreatitis should be started by extracellular fluid such as acetate or lactate Ringer solution from a peripheral vein. Healthy adults require 1500-2000 mL fluid (30-40 mL/kg body weight),

whereas patients with acute pancreatitis require 2-4 times (60-160 mL/kg body weight) the volume administered to healthy adults.

The severity of acute pancreatitis changes at every moment even if it appears to be mild on admission. Although acute pancreatitis typically results in significant intravascular losses, patients with acute pancreatitis are often given suboptimal fluid resuscitation. Since it is rare for the administration of large fluid volumes to be problematic in mild cases, aggravation by insufficient fluid resuscitation must be avoided. In particular, a large amount of fluid resuscitation (about 1/2-1/3 of the amount required for the first 24 h) is necessary in the first 6 h. Approximately 6 h after initiation of treatment, blood pressure, pulse rate, hourly urinary volume and the above-mentioned index must be re-evaluated to make plan for subsequent fluid resuscitation. In a mild case of acute pancreatitis, the amount and rate of fluid resuscitation should be reduced.

If shock or a pre-shock is present on arrival at the hospital, rapid intravenous fluid resuscitation of 500-1000 mL must be performed. Patients of 60 kg body weight with moderate to severe acute pancreatitis require about 1200-4800 mL fluid resuscitation for the first 6 h and 3600-9600 mL for the first 24 h. If the patient does not recover from circulatory failure by fluid resuscitation, administration of catecholamine and transfer to ICU with full monitoring and systems support should be considered.

We have reported that the average amount of fluid resuscitation on the first hospital day in patients who died of acute pancreatitis was 2788 ± 246 mL (n = 52, mean ± standard deviation) and that the amount of fluid resuscitation in 78.9% of these fatal cases for the first 24 h after admission was less than 3500 mL[38]. Indeed, all patients with inadequate fluid resuscitation (rehydration less than 4.0 liters) as evidenced by persistence of hemoconcentration at 24 h developed necrotizing pancreatitis[39].

The amount of fluid resuscitation required on the first and the following hospital day in moderate acute pancreatitis to maintain 120 mmHg or higher systolic blood pressure and hourly urinary volume of more than 1 mL/kg body weight was 4873 ± 2280 mL/d and 2000-2500 mL/d, respectively, while that in severe acute pancreatitis was 7787 ± 4211 mL/d and 4000-5000 mL/d, respectively[40]. Based on abdominal CT findings, Takeda *et al*[41] reported that the amount of fluid resuscitation on the first hospital day in patients with acute pancreatitis with inflammatory changes extending to anterior pararenal space, mesentery of the colon and the retroperitoneum beyond inferior pole of the kidney was approximately 4000 mL, 6000 mL, and 8000 mL, respectively. In some cases, body weight may increase more than 10 kg within a few days after onset of acute pancreatitis. It will take 1-2 wk for diuresis to occur resulting from re-filling to decrease body weight[41].

A large amount of fluid resuscitation is necessary until an adequate urinary volume is attained. Administration of diuretics before achievement of adequate fluid resuscitation may lead to a deterioration of the situation. Restriction of the amount of fluid resuscitation and excessive diuresis by diuretics because of fear of aggravation of pulmonary and systemic edema by a large amount of fluid resuscitation at this time may exacerbate the dysfunction of important organs including the kidney. Fluid resuscitation should be performed to promote prompt recovery from a potential shock state even if respiratory care under intratracheal intubation is required as a result of a large amount of fluid resuscitation. (2) Route of infusion. It is desirable to secure and keep the central venous route to maintain long-term fluid resuscitation and continuous infusion of protease inhibitors in moderate and severe acute pancreatitis, while the central venous route is redundant in mild cases. In severe acute pancreatitis, a central venous route should also be secured to monitor CVP chronologically and to determine the amount and rate of fluid resuscitation.

In the early stages of acute pancreatitis, vascular permeability often increases, and thus circulatory volume decreases resulting in a tendency for collapsed vascular lumen. Since access of the central vein is difficult in such cases, adequate levels of fluid should be given from a peripheral vein as the initial therapy. However, the femoral vein should be avoided if possible to prevent deep venous thrombosis and infection, and to securely obtain the route for CHDF and CRAI therapy. (3) Caution of fluid resuscitation. Since excessive amounts and a high rate of fluid resuscitation may cause pulmonary edema in patients with acute pancreatitis complicating heart, lung and renal dysfunction, and in elderly people, it is important to control the amount and rate of infusion according to the above-mentioned indexes such as blood pressure, pulse rate, urinary volume and CVP. However, it is thought that shock and aggravation of acute pancreatitis at an early stage tend to be due to insufficient amounts of the initial fluid resuscitation. It should be kept in mind to give adequate amount of fluid resuscitation at an early stage.

Serum levels of electrolyte and calcium should be measured and corrected appropriately, especially when tetany occurs due to low serum calcium concentrations.

There is no evidence to support the usefulness of administration of albumin preparation and fresh frozen plasma (FFP) for primary care within 48 h of onset. Administration of colloid fluid at the acute stage may retard improvement of pulmonary edema in the re-filling period.

Analgesics: Since acute pancreatitis often causes extreme abdominal pain, which may disturb cardiopulmonary functions, adequate pain relief is required.

The following drugs should be given; buprenorphine (0.1-0.2 mg intramuscular or intravenous injection, or 0.3 mg/h intravenous drip infusion) or pentazocine (7.5-15 mg intramuscular or intravenous injection, or 15-30 mg intravenous drip infusion). Since there is a possibility that these drugs induce spasms of the sphincter of Oddi and disturb the outflow of bile and pancreatic juice when given frequently, administration of atropine sulphate in combination with analgesics is recommended. In addition, these analgesics must be given with caution, due to the risk of drug dependence when used continuously. However, neither buprenorphine nor pentazocine is approved by health insurance in Japan for pain of acute pancreatitis. Intramuscular or subcutaneous injection of pentazocine and buprenorphine is only approved for pain control

of carcinoma and postoperative state, while intravenous injection of pentazocine is approved for anesthesia and buprenorphine for myocardial infarction and anesthesia.

A mixture of opium alkaloids and atropine (1.0 mL contains 20 mg opium alkaloid hydrochloride and 0.3 mg atropine sulphate, 1.0 mL subcutaneous injection), and a mixture of morphine and atropine (1.0 mL of this solution contains 10 mg morphine hydrochloride and 0.3 mg atropine sulphate, 1.0 mL subcutaneous injection) can also be given. Pain relief by epidural anesthesia is also possible in a high specialty unit. Since both reagents may cause respiratory depression, intensive monitoring of cardiopulmonary function is required after administration.

For mild pain in acute pancreatitis, non-steroidal anti-inflammatory drugs (NSAIDs) such as diclofenac suppository and indomethacin suppository can be used. However, these agents should be used with caution due to associated adverse effects such as pernicious anemia, hemolytic anemia, granulocytopenia, thrombocytopenia, liver damage, acute renal failure, asthma, interstitial pneumonia, and peptic ulcer hemorrhage. These drugs are usually not used in moderate and severe cases of acute pancreatitis. In particular, NSAIDs are contraindicated in patients in pre-shock status.

Antibiotics: In mild and moderate cases of acute pancreatitis, prophylactic administration of antibiotics is unnecessary because the incidence of fatal infection of the pancreas and the exudates around the pancreas is low.

In severe acute pancreatitis, prophylactic intravenous administration of antibiotics at an early stage is recommended[18,42,43]. Antibiotics with a broad antibacterial spectrum and good penetration into the pancreas[44] such as imipenem[18,42] and meropenem[43] are desirable. If infection of the biliary tract is suspected, administration of the second or later generation cephalosporins is also recommended. Clinicians should always take microbial substitution and fungal infection into consideration when using antibiotics.

The maximum dose of antibiotics that is approved by the Japanese Government should be used to attain sufficient concentrations in and around the pancreas. For example, intravenous infusion of 1-3 g/d imipenem or meropenem dividing into 3 times is recommended (1.0 g of imipenem or meropenem can be dissolved in 100 mL physiologic saline or 5% glucose solution, and infuse for more than 30 min). However, special attention has to be paid to the patient's liver and renal function. In particular, in severe cases, it is necessary to re-evaluate the dose of antibiotics every day because liver and renal function changes chronologically day by day. If possible, it is recommended to monitor serum concentrations of antibiotics. Moreover, clinicians should be concerned about the possibility of developing fungal infections.

In cases with advanced inflammation in and around the pancreas, SDD is often undertaken to prevent bacterial translocation[23].

Protease inhibitors: Although the effect of protease inhibitors has some controversy, experts of pancreatitis in Japan recommend to administer protease inhibitors as soon as the diagnosis of acute pancreatitis is confirmed[19,45]. Recent meta-analysis of 10 articles of randomized controlled trials evaluating the effects of protease inhibitors for acute pancreatitis has revealed that treatment with protease inhibitors does not significantly reduce mortality in patients with mild acute pancreatitis, but may reduce mortality in patients with moderate to severe acute pancreatitis[46]. Table 4 shows examples of protease inhibitors used for acute pancreatitis in Japan[47].

Table 4 Recommended doses of protease inhibitors for acute pancreatitis[47]

	Mild and moderate	Severe
Protease inhibitor	FOY FUT UTI	FOY + UTI FUT + UTI
Initial dose[2] (during the first 12 h)	Maximum usual one-day dose[1] by continuous intravenous infusion	Maximum usual one-day dose[1] by continuous intravenous infusion
Until d 3[2]	Above dose for 24 h	Above dose for 24 h
First wk[2]	Gradually reduce the above dose or intermittent administration	Above dose for 24 h
Second wk[2]	Reduce the dose or cease	Maintain or gradually reduce the above dose
Third wk[2]	Reduce the dose or cease	Maintain or gradually reduce the above dose

FOY: Gabexate mesilate, FUT: Nafamostat mesilate, UTI: Ulinastatin. [1]Administer the one-day dose during the initial 12 h. [2]Severity stratification should be made repeatedly, and the doses of protease inhibitors must be increased or decreased depending on the severity. The usual daily dosage for acute pancreatitis of FOY, FUT and UTI approved by the health insurance is 200-600 mg, 10-60 mg and 50 000-150 000 units, respectively. Since, however, severe acute pancreatitis often complicates disseminated intravascular coagulation (DIC) and shock, it is recommended to give these reagents in doses that are approved for these disorders in severe acute pancreatitis (daily dosage for severe acute pancreatitis of FOY, FUT and UTI is 20-39 mg/kg body weight/d, 1.44-4.8 mg/kg body weight per day, and 10 000-300 000 units /d, respectively).

Usual doses of gabexate mesilate (FOY), nafamostat mesilate (FUT) and ulinastatin (UTI) for acute pancreatitis are 200-600 mg/d, 10-60 mg/d and 50 000-150 000 units/d, respectively. However, since severe acute pancreatitis is often complicated by disseminated intravascular coagulation (DIC) and shock, it is recommended that these reagents should be given in doses approved for these disorders in severe acute pancreatitis. The guidelines for acute pancreatitis in 1991 from the Research Committee of Intractable Diseases of the Pancreas recommended combination therapy with FOY or FUT together with UTI when severe pancreatitis is predicted[47].

FOY and FUT have several adverse effects that clinicians must be aware of; FUT increases serum potassium (K) concentration[48,49], and FUT and FOY may cause phlebitis, and inflammation, ulcer and necrosis of the skin with extravasation. In addition, there are reports of anaphylactic shock by repeated administration of FOY and FUT[50,51].

Enteral feeding: Based on the fact that enteral feeding stimulates pancreatic secretions[52], classical management recommends that patients presenting with acute pancreatitis be fasted until symptoms begin to resolve. However, there is no sufficient evidence to support the concept of gut rest (prohibiting enteral intake) in acute pancreatitis. Acute pancreatitis results in hypermetabolic and hyperdynamic situation creating a high catabolic stress state[53]. Failure to achieve a positive nitrogen

balance is associated with increased mortality in patients with severe acute pancreatitis[54]. Traditionally, total parenteral nutrition (TPN) has been advocated in these patients in order to supply adequate nutrients and prevent hypercatabolic states avoiding stimulation of exocrine pancreatic secretions. However, TPN in patients with acute pancreatitis has not been shown to be beneficial[55]. Early enteral nutrition through a nasojejunal tube is associated with a significantly lower incidence of infections, reduced surgical interventions, and a reduced hospitalization period compared with TPN[56]. Enteral nutrition is as safe and efficacious as TPN and may be beneficial during the clinical course of this disease. Even in severe acute pancreatitis, a combination of enteral feeding with parenteral nutrition from early stage is recommended if there are no clear signs and symptoms of ileus and gastrointestinal bleeding[58].

Although the majority of studies have reported enteral feeding via a nasojejunal tube, a recent pilot study of early nasogastric feeding in patients with severe acute pancreatitis proved that this approach might be feasible in up to 80% of cases[59]. However, caution should be used when administering nasogastric feeding to patients with impaired consciousness due to the risk of aspiration of refluxed feed.

Other treatments: Patients with acute pancreatitis often have deficiency of vitamin B1 due to alcohol abuse and malnutrition or abnormal and irregular dietary habits. Exacerbation of lactic acidosis or shock in such patients may suggest a deficiency of vitamin B1 and require corrective measures.

TRANSFER TO ANOTHER HOSPITAL

Transfer time to a high specialty unit

All patients when diagnosed with acute pancreatitis should be managed in a hospital. Patients with suspected acute pancreatitis should be examined at hospitals with facilities for blood examination and imaging studies. Depending on the severity, full monitoring and systemic support in high care unit (HCU) or ICU is necessary. Hospitals that cannot provide appropriate monitoring and adequate systemic support, should transfer all patients with severe acute pancreatitis to ICU as early as possible.

Evidence-based therapeutic guidelines for severe acute pancreatitis[2,5] published by the Japanese Society for Abdominal Emergency Medicine, the Japanese Pancreas Society and the Research Committee of Intractable Diseases of the Pancreas recommends transferring acute pancreatitis patients with the JPN severity score 2 points or above[8]. Severe or aggravating cases should be transferred to ICU as early as possible to perform the CRAI of protease inhibitors and antibiotics or CHDF.

Instructions of transfer

During transfer, cardiopulmonary function such as blood pressure, pulse and respiratory rate, and oxygen saturation must be monitored. In addition, a venous route must be secured by continuing fluid infusion to be able to cope promptly with a sudden change. In severe cases, a doctor and a nurse should accompany the patient during transfer.

Before deciding to transfer a patient, it should be considered about the influence of street transportation for long time on the patient's clinical condition when vigorous fluid resuscitation is necessary at early period of illness.

Local core hospitals require facilities that can deal with severe acute pancreatitis.

SPECIAL MEASURES

Continuous regional arterial infusion of protease inhibitors and antibiotics (CRAI)

To obtain high concentrations of protease inhibitors and antibiotics in the pancreas, these reagents are continuously infused into the artery through a catheter with tip placed at a portion where the bloodstream irrigates the inflamed area of the pancreas. Concentrations of protease inhibitors and antibiotics in pancreatic tissue after CRAI are approximately 5[60] and 5-10 times[61], respectively, higher than those after intravenous infusion. This procedure is therefore expected to directly inhibit inflammatory processes in the pancreas by strongly inhibiting activity of proteases that might aggravate pancreatic damage and inhibit most of the pathogens present in pancreatic infections[8,20,21,62]. Since protease inhibitors used in Japan also have anticoagulant and anticomplement activities [63], it is possible that these reagents inhibit the development of pancreatic necrosis by preventing the formation of microthrombi in pancreatic vessels and evolution of ischemia into pancreatic necrosis.

This procedure is indicated in severe acute pancreatitis cases with a low density area of the pancreas on CE-CT on admission, which corresponds with ischemic change and vasospasm on angiography or necrosis in and around the pancreas[33]. Takeda *et al*[21] have demonstrated that CRAI of protease inhibitors and antibiotics is effective in reducing mortality and preventing the development of pancreatic infection when initiated within 48 h after the onset of severe acute pancreatitis. FUT or FOY is used for this procedure, because these agents are synthetic low-molecular-weight protease inhibitors that inhibit a number of serine-proteases, and C1r and C1s esterases[63]. In addition, FOY and FUT might easily penetrate into the pancreatic acinar cells due to their low molecular weight and inhibit the inflammatory process in the pancreas. With regard to antibiotics, imipenem is used because of its broad spectrum and good penetration into pancreatic tissue[44]. Since CRAI of protease inhibitors and antibiotics for the treatment of acute pancreatitis is still debatable and not covered by health insurance in Japan, informed consent must be obtained from the patient before performing this procedure.

Continuous hemodiafiltration (CHDF)

CHDF is a combination of continuous hemofiltration with hemodialysis developed as a continuous renal replacement therapy for patients with severe conditions. It is usually performed continuously for 24 h, and for 3-14 d. This procedure can be used to control fluid balance in patients with excessive fluid resuscitation but inadequate diuresis. However, in some hospitals this procedure is positively performed even if there is sufficient urinary volume, because CHDF can remove excess humoral mediators

including cytokines during the hypercytokinemic state of systemic inflammatory response syndrome such as severe acute pancreatitis[22,64,65].

When this procedure is started early after onset of acute pancreatitis, reduction of chemical mediators and improvement of respiratory function is obvious, while the incidence of multiple organ failure is low compared to cases in which the procedure is initiated at a late stage[64]. Health insurance in Japan has approved CHDF as one of insurance-applicable treatment modalities for severe acute pancreatitis.

Abstract

AIM: To investigate the expression of the four secreted gel-forming mucins (MUC2, MUC5AC, MUC5B and MUC6) in a series of gastric carcinomas, classified according Laurén's, Mulligan's, WHO and Goseki's classifications, with special attention to all the different components (major and minor) present in tumors and to follow up clinical data.

METHODS: Expression of MUC2, MUC5AC, MUC5B and MUC6 was investigated using immunohistochemistry and *in situ* hybridization.

RESULTS: Expression of secreted gel-forming mucins in gastric carcinoma was particularly complex, each mucin being not restricted to any histopathological type even considering all components (major and minor) present in a given tumor. There was a worst survival in patients with a higher content of mucus (Goseki II or IV) and high positive MUC2 expression.

CONCLUSION: Complexity of mucin gene expression patterns in gastric cancer may reflect a precise state of differentiation at the cell level not recognized in used morphologic classification systems. High expression of MUC2 was nevertheless associated with mucinous subtype of the WHO classification and with group II of Goseki's classification identified by the major component of a particular tumor. The quantity and quality of mucus were related to survival.

INTRODUCTION

Gastric cancers constitute a highly heterogeneous group of tumors with respect to epidemiology, genetics, histopathology and biological behavior. Numerous histopathological classifications have been proposed to identify the morphological variability in a reproductible manner and to correlate to prognosis. These different classifications include Laurén's, Mulligan's, World Health Organization (WHO), and Goseki's classifications, which all are based at least in part on the quantity of mucus present in an individual tumor[1-3]. The Goseki's classification combines two distinct criteria, e.g. the tubular differentiation and the intra-cellular mucin content[3]. It was shown to be the only classification with prognostic value additional to TNM staging[4]. All histopathological classifications are based on the identification of the major component of the tumor, neglecting the various minor components. However, in pathological practice, assessment of a histopathological type of gastric carcinoma is difficult due to the considerable variation frequently present within an individual tumor.

Epithelial mucins consist of at least thirteen different types that are usually subdivided into secreted gel-forming mucins and membrane-bound mucins[5-7]. The first class includes the four large mucins MUC2, MU-

C5AC, MUC5B and MUC6 whose genes are clustered on chromosome 11p15.5 and which are involved in the mucus gel formation. MUC5AC and MUC6 are the major mucin components in normal gastric mucosa. MUC5AC is highly expressed in mucous cells of the superficial and foveolar epithelium, whereas MUC6 is present in mucous neck cells and in mucous glands of cardia and antrum[8-11]. MUC5AC and MUC6 are also expressed in some gastric carcinomas[12-15]. Moreover, MUC2 and MUC5B which are absent or barely detectable in normal gastric tissues have been reported in gastric carcinoma[12-16]. MUC2 expression has been related more specifically to the mucinous carcinomas of WHO classification and to group II of Goseki' s classication (high tubular differentiation and high mucin content) whereas MUC5AC has been associated with the group IV of Goseki's classification (poor tubular differentiation and high mucin content)[14,15,17]. However, coexpression of multiple mucins is frequently observed in gastric carcinomas[9,13,15]. Such a complex pattern of mucin expression may reflect the variety frequently observed in gastric carcinomas.

In an effort to bring additional information in understanding the histopathological diversity of gastric carcinomas, we investigated the expression of the secreted gel-forming mucins (MUC2, MUC5AC, MUC5B and MUC6) in a series of gastric carcinomas with special attention to all the different components (major and minor) present in tumors and to follow up clinical data.

MATERIALS AND METHODS

Tissue samples and histopathological study

A series of 31 gastric adenocarcinomas was obtained from institutional files. Cases included 7 women and 24 men with a mean age of 65 years-old, from 39 to 89 years. The surgical specimens were quickly immersed in fresh 4 g/L neutral formaldehyde solution (pH 7.4) in phosphate buffer and then were processed for paraffin embedding. Each gastric carcinoma was classified according to each of the following histopathological classifications; i.e. Laurén's classification, Mulligan's classification, WHO classification and Goseki's classification. These classifications are based on the identification and classification of the major component of the tumor on hematoxylin-eosin-saffron (HES) coloration. The Goseki's classification was realized on an adjacent tumor slide with Periodic Acid Schiff and Alcian Blue combined coloration. The Goseki's classification combines two distinct criteria, e.g. the tubular differentiation and the intracellular mucin content[3]. Four group are defined: group I, high tubular differentiation and poor mucin content; group II, high tubular differentiation and high mucin content; group III, poor tubular differentiation and poor mucin content; group IV, poor tubular differentiation and high mucin content[3]. The classification proposed by Mulligan recognizes three forms of gastric carcinoma: the intestinal cell type, the mucous cell type and the pylorocardiac gland cell type. In this classification the intestinal and mucous cell types are similar to the intestinal and diffuse types defined by Lauren. The pylorocardiac gland cell type carcinoma is a distinct group of gastric carcinoma characterized by large cells with clear cytoplasm [2]. The differentiation of each tumor was assessed on the basis of the degree of gland formation as well, moderate, poorly differentiated or undifferentiated. When the tumor presented with a major and one or more minor components, a sample where the different components were present was chosen to further perform the immunohistochemical and *in situ* hybridization studies on serials sections (4-μm thick).

Immunohistochemistry

Immunohistochemistry was performed using an automated immunostainer (ES; Ventana medical systems, Strasbourg, France). Primary antibodies were directed against MUC2 (polyclonal, LUM2-3, 1/1000)[18], MUC5AC (monoclonal, 1/2) (Novocastra, New Castle, UK), MUC5B (polyclonal, Lum5B-2, 1/1000)[19], MUC6 (monoclonal, 1/5) (Novocastra). The pretreatment was realized by a steamer for MUC2 (for 1 min 30) or by a microwave for MUC5AC, MUC5B and MUC6 (for 20 min), in citrate buffer (pH 6.0). For polyclonal antibodies, the sections were incubated for 32 min with normal goat serum to block the non-specific antibody-binding sites and endogenous peroxidase activity was suppressed by first incubating the specimen in 30 mL/L hydrogen peroxide. The immunohistochemistry method used a 3-step indirect process based on the biotin-avidin complex. Slides were counterstained with hematoxylin. Negative controls were run by omission of the primary antibody and positive controls with the appropriate tissue (normal colonic mucosa for MUC2, normal gastric mucosa for MUC5AC and MUC6, normal respiratory submucosal glands for MUC5B). The immunohistochemical results were estimated on the whole tumor and on the different components. The immunostaining was scored semiquantitatively as: 0, no immunostained cells; 1, less than 30% of immunostained cells; 2, more than 30% and less than 60% of immunostained cells; 3, strictly more than 60% of immunostained cells.

In situ hybridization

In situ hybridization was performed as described previously using four ^{35}S-labeled antisense oligonucleotide probes corresponding to each tandem repeat domain of *MUC2*, *MUC5AC*, *MUC5B*, and *MUC6*[20]. Briefly, tissue sections were deparaffinised, rehydrated, incubated with 2 mg/L proteinase K (Roche Diagnostics, Meylan, France) for 15 min and fixed again in 40 g/L paraformaldehyde in PBS for 15 min. Sections were then immersed in 0.1 mol/L triethanolamine (Sigma, L'Isle d'Abeau Chesnes, France) containing 2.5 ml/L acetic anhydride for 10 min. Sections were prehybridized in 4 × SSPE, 1×Denhardt' s buffer for 45 min, and hybridized overnight at 42 ℃ in 20-100 μL of a 4 × SSPE solution containing 500 mL/L formamide, 1 g/L *N*-lauroylsarcosine, 1.2 mol/L sodium phosphate (pH 7.2), 1 × Denhardt's buffer, 3 g/L yeast tRNA, 20 mmol/L dithiothreitol, and 125 MBq/L of ^{35}S-labeled oligonucleotide. After post-hybridization washes, slides were dipped in LM-1 emulsion (Amersham, Les Ulis, France), developed 1-3 wk after exposure, and counterstained with methyl green pyronin (Sigma). The following controls were performed: (1) competition studies by treatment of tissue sections with

a large excess of unlabeled oligonucleotide identical to or distinct from the ^{35}S-labeled-probe; (2) verification of the absence of background by careful examination of non-epithelial structures (vessels, muscle, and connective tissue). The intensity of the hybridization signal was scored semiquantitatively as: 0, absent; 1, weak (visible at magnification ×200); 2, moderate (visible at magnification × 100); 3, strong (visible at magnification ×40).

Statistical analysis

Comparisons of the percentages in the different classifications were performed using chi-square and Fischer's exact tests. Survival was determined from the date of surgery to the time of death using the Kaplan–Meier method. Statistical significant of differences in survival curves was evaluated using the log-rank test. All statistical analyses were carried out by the SPSS 10.0 (SPSS, Chicago, IL, USA) software system. $P < 0.05$ were considered to indicate significant differences.

RESULTS

Histopathological results

Among the 31 gastric carcinomas, 2 were well differentiated, 11 moderately differentiated, 16 poorly differentiated and 2 undifferentiated. 14 carcinomas were classified as intestinal type in the Laurén's classification, these tumors being mainly classified as intestinal cell type in the Mulligan's classification, as tubular in WHO classification and as group I or II in the Goseki's classification. 12 tumors were classified as diffuse type in the Laurén's classification, being classified as mucous cell type in the Mulligan's classification, as signet-ring cell in the World Health Organization (WHO) classification and as group III or IV in the Goseki's classification. 3 carcinomas, not individualized in the Laurén's and Mulligan's classifications, corresponded to the mucinous type of the WHO classification and were classified in group II of Goseki's classification (Table 1).

Relationship between histopathological classifications and MUC expression

All MUCs were observed in each subtype of gastric carcinomas classified either in Laurén's classification, Mulligan's classification, WHO classification or Goseki's classification (Table 1, Figure 1). MUC2 was the major secreted gel-forming mucin detected in our series of gastric carcinomas. It was detected in 81% of the cases by immunohistochemistry and in 74% of the cases by *in situ* hybridization. MUC2 immunoreactivity was observed in the cytoplasm, in intracellular mucus vacuoles of tumoral cells, and also in extracellular mucus (Figure 1). Detection of MUC2 was not associated with a particular subtype of gastric carcinoma whatever the classification. However, high MUC2 immunostaining (in more than 30% of the tumoral cells), was significantly associated with the mucinous subtype of WHO classification ($P=0.015$) and with the group II of the Goseki's classification ($P=0.01$, Table 1). Although less significant, the absence of *in situ* hybridization signal for MUC2 was more frequent in the signet-ring subtype of the WHO classification ($P=0.04$) and in the diffuse subtype of Laurén's classification ($P=0.04$, Table 1). MUC5AC was detected in 65% of the cases by immunohistochemistry and in 52% of the cases by *in situ* hybridization. MUC5AC immunoreactivity was localized in the cytoplasm of tumoral cells, without staining of intracellular mucus vacuoles (Figure 1). MUC5AC detection either by immunohistochemistry or *in situ* hybridization was not associated with a particular subtype of gastric carcinoma classified by Laurén's, Mulligan's, WHO or Goseki's classifications (Table 1). MUC5B was

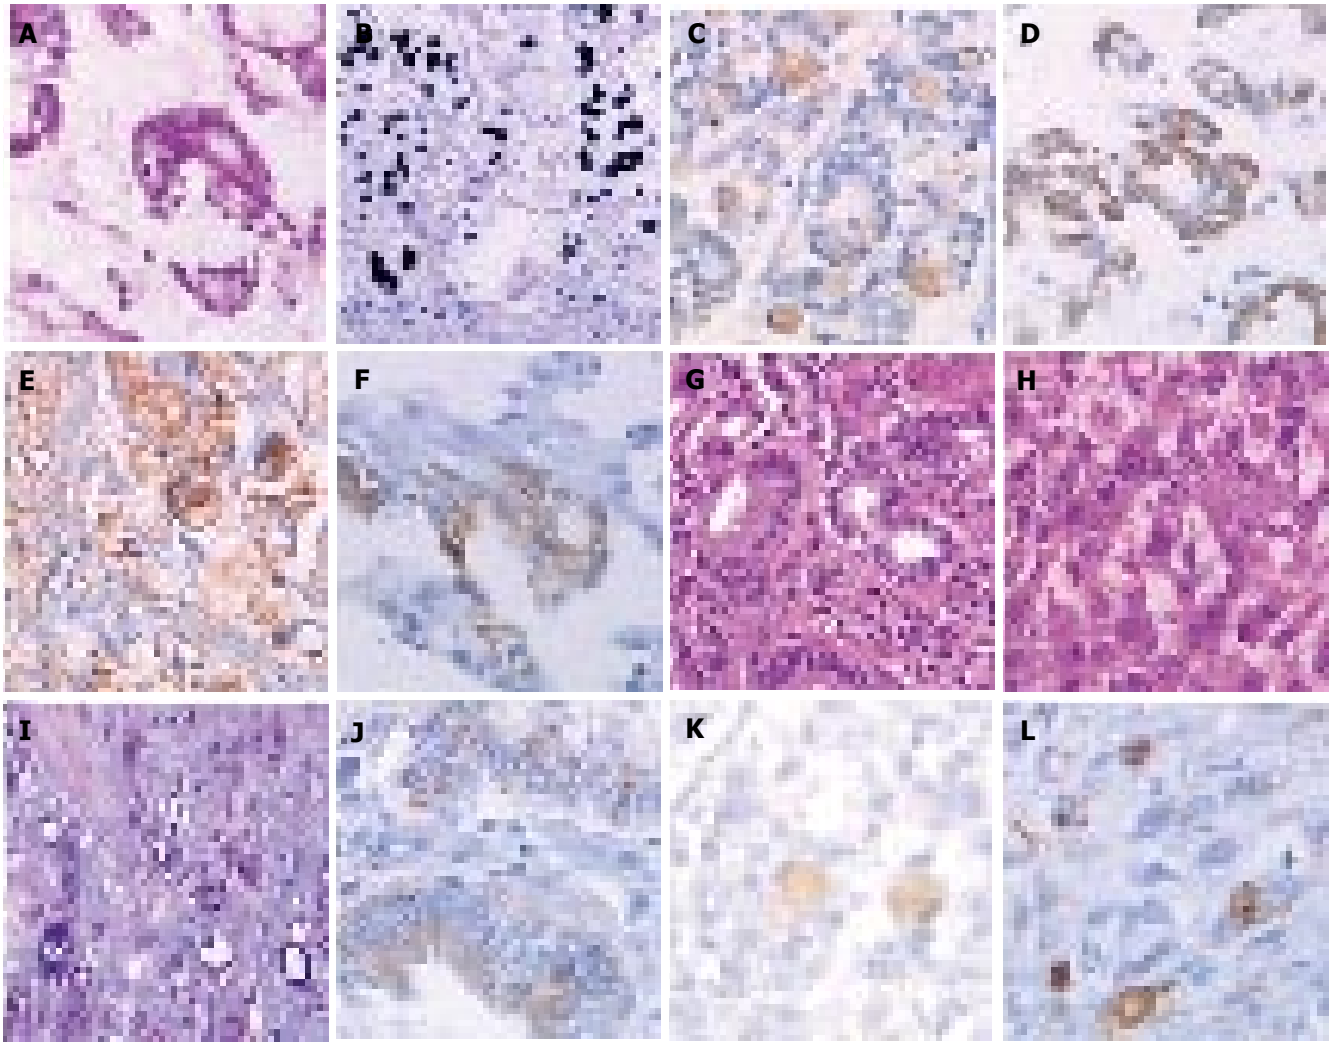

Figure 1 Expression of the secreted gel-forming mucins in gastric cancers. **A**: Mucinous subtype in WHO classification, group II in Goseki's classification (HE-safron × 125); **B:** Strong MUC2 in mucinous subtype (*in situ* hybridization × 40); **C**: MUC2 in intracellular mucus vacuoles in mucinous subtype (SABC × 125); **D:** MUC5AC in the cytoplasm of tumoral cells in mucinous subtype (SABC × 125); **E:** MUC5B in the cytoplasm, within intracellular mucus vacuoles and in extracellular mucus in mucinous subtype (SABC × 125); **F**: MUC6 in the cytoplasm of tumoral cells in mucinous subtype (SABC × 200); **G:** Gastric cancer classified group I in Goseki's classification (HE-safron × 125); **H:** Gastric cancer classified group III in Goseki's classification (HE-safron, × 200); **I:** Gastric cancer classified group IV in Goseki's classification (PAS and Alcian blue × 200); **J:** MUC2 in the cytoplasm of tumoral cells in group I gastric cancer Goseki's classification (SABC × 200); **K:** MUC2 in intracellular mucus vacuoles in group III gastric cancer in Goseki's classification (SABC × 200); **L:** MUC2 in intracellular mucus vacuoles in group IV gastric cancer in Goseki's classification (SABC × 200).

detected in 77% of the cases by immunohistochemistry and in 29% of the cases by *in situ* hybridization. MUC5B immunoreactivity was observed in the cytoplasm, in intracellular mucus vacuoles of tumoral cells and in extracellular mucus (Figure 1). MUC5B detection either by immunohistochemistry or *in situ* hybridization was not associated with a particular subtype of gastric carcinoma whatever the classification (Table 1). The discrepancies between the immunohistochemical and *in situ* hybridization results for MUC5B and at a lesser extent for MUC5AC corresponded mostly to cases which presented less than 30% of positive cells by immunohistochemistry and were negative by *in situ* hybridization. MUC6 was detected in 39% of the cases by immunohistochemistry and in 35% of the cases by *in situ* hybridization. The detection was observed in the cytoplasm of the tumoral cells, without staining of intracellular mucus vacuoles (Figure 1). Its expression was not associated with a particular subtype of gastric carcinoma whatever the classification (Table 1). No significant difference was observed for immunohistochemical or *in situ* hybridization detection of MUC2, MUC5AC, MUC5B or MUC6 between well/moderate differentiated carcinomas and poorly/undifferentiated carcinomas. The coexpression of at least two MUCs in the same tumor was frequent either identified by immunohistochemistry (83% of the gastric carcinomas) or *in situ* hybridization (54%). The coexpression of three MUCs in the same tumor was also remarkable either by immunohistochemistry (64%) or *in situ* hybridization (38%). In the series, 22% of the cases presented with the four MUCs detected by immunohistochemistry and 13% by *in situ* hybridization. The coexpression of at least two MUCs in the same tumor was not associated with a particular subtype of the

Goseki's classification.

Relationship between the different components and MUC expression

Among this series of 31 gastric carcinomas, we observed an histopathological heterogeneity in the majority of individual tumors. Indeed, 61% of the series presented with more than one component (one major component and one or more minor components). Given the difficulty to demonstrate a constant correlation between MUC expression and histopathological classifications, we further evaluated the expression of the four secreted gel-forming mucins independently in all the different components, major or minor, classified according to the Goseki's classification, frequently present in a same gastric carcinoma.

When the immunohistochemical labeling was studied separately in each component of each gastric carcinoma classified on the basis of the Goseki's classification, MUC2, MUC5AC, MUC5B and MUC6 were observed in all the different groups (group I to IV, Table 2). In particular, MUC2 was not restricted to the components classified as group II of Goseki (83% of histopathological components of group II were positive for the immunohistochemical detection of MUC2), but was also detected in components classified as group I (67%), group III (20%) or group IV (69%). Similarly, MUC5AC, MUC5B and MUC6 were detected in components classified as group I, group II, group III or group IV. The comparison between the tumors which presented with a component of Goseki group II (major or minor) and the tumors which presented without this component was not statistically different.

Relationship between TNM and MUC expression

Among this series of 31 gastric carcinomas, 5 were T1, 20 were T2, 4 were T3 and 2 were T4, 2 were Nx, 6 were N0, 15 were N1, 5 were N2 and 3 were N3. The immunohistochemical and *in situ* hybridization detection of MUC2, MUC5AC, MUC5B or MUC 6 was not associated with T1-T2 tumors when compared to T3-T4 tumors, and was not different between N0-N1 tumors in comparison to N2-N3 tumors. Moreover, the detection of two or three MUCs in the same tumor, either by immunohistochemistry or *in situ* hybridization, was not significantly associated with T1-T2 or T3-T4 tumors, nor with N0-N1 or N2-N3 tumors.

Relationships between TNM, Goseki classification, MUC2 expression and survival

Follow up data showed that there was a significant difference in mean survival time decreasing between the carcinoma patients with T1, patients with T2, patients with T3 and those with T4 tumors (Log rank 9.63, $P=0.022$). There was also a significant difference in mean survival time decreasing between the carcinoma patients without lymph node metastasis (N0) and those with lymph node metastasis (N+) (Log rank 9.29, $P=0.0023$). Patients with Goseki II or IV classes had worst survival (mean 24 mo) than those with Goseki I or III classes (mean 51 mo) $P=0.0036$, Figure 2. Patients with positive immunohistochemical MUC2 expression more than 30% had a worst survival (mean 20 mo) than those with positive MUC2 expression less than 30% (mean 39 mo) $P=0.0434$ and those without MUC2 expression 0% (mean 72 mo) $P=0.0391$. Patients with positive immunohistochemical expression of MUC2 less than 30% had worst but not statistically significant, survival than those without MUC2 expression ($P=0.0951$, Figure 3).

DISCUSSION

In the present study, we looked for a correlation between the expression of the secreted gel-forming mucins MUC2, MUC5AC, MUC5B, MUC6 and histopathological classifications (WHO, Laurén, Mulligan and Goseki) in a series of 31 gastric carcinomas with a special attention to all components (major or minor) present in an individual tumor. Expression of MUC2 was frequently observed in all subtypes of gastric carcinoma whatever the classification. However, the high expression of MUC2 was significantly associated with the mucinous subtype of the WHO classification and with the group II of Goseki's classification (high tubular differentiation and high mucin content). A relationship between gastric mucinous carcinomas and group II of their classification has been previously reported by Goseki *et al*[3]. The WHO and the Goseki's classifications are more precise than the Laurén's and the Mulligan's classifications to classify gastric carcinoma, individualizing the mucinous subtype and group II respectively. Moreover, the Goseki's classification, that combine two distinct criteria, e.g. the tubular differentiation and the intra-cellular mucin content was shown to be the only classification with prognostic value additional to TNM staging[3,4]. The asso-

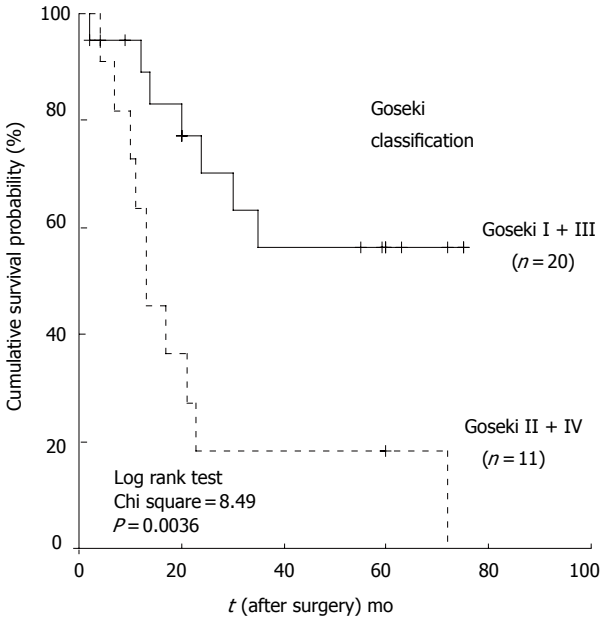

Figure 2 Survival curves for patients divided according to their Goseki classification.

ciation between expression of MUC2 and mucinous carcinoma has been previously reported in stomach, as well as in other organs, e.g. colon, breast, pancreas, ovary and pseudomyxoma peritonei[14-15,21-23]. Surprisingly, expression of MUC2 was not significantly associated with the intestinal subtypes of Laurén's or Mulligan's classifications ($P \geq 0.07$), although it is abundantly expressed in small intestine and colon as well as in intestinal metaplasia[8,24].

MUC2 is not the only secreted gel-forming mucin expressed in gastric carcinoma. Some gastric carcinomas expressed MUC5AC and/or MUC6, which are present in normal gastric mucosa[8,11]. Moreover, some gastric carcinomas expressed MUC5B, which was shown previously to be expressed during the stomach embryogenesis[25]. A significative association between the tumoral expression of MUC5AC and diffuse gastric carcinoma as defined in Laurén classification has been observed by some authors in comparison to unclassified carcinomas[14,26]. However, this association was controversed by others using the same MUC5AC antibody but comparing the diffuse subtype to the intestinal and unclassified carcinomas of the Laurén's classification[12,15]. MUC5AC has been also found more frequently expressed in group IV of Goseki's classification, which corresponds in part to the diffuse type of the Laurén's classification[3,15]. In our series, the expression of MUC5AC was frequent in the diffuse subtype of the Laurén's classification (75% of the cases in this subtype), in the group IV of Goseki' s classification (83%) and in the signet-ring subtype of the WHO classification (75%) but the comparison with the other subtypes did not reach the significant level. Moreover, the expression of MUC6 in our series was not associated with any histological type of the gastric carcinomas, whatever the classification, in accordance with previous studies [12-15]. In addition, expression of MUC5B, which before this study had never been extensively studied in gastric carcinoma using a morphological approach, was not found to be associated with particular subtypes of the Laurén's, Mulligan's, WHO or Goseki's classifications.

Given the difficulty to demonstrate a constant correlation between MUC expression and histopathological classifications, we further evaluated the expression of the four secreted gel-forming mucins independently in all the different components, major or minor, frequently present in a same gastric carcinoma. In our series, 39% of the tumors presented one component, whereas 61% presented at least two different components further classified according to the Goseki's classification. With this approach, none of the gel-forming mucin was restricted to any group of Goseki. In particular, MUC2 was not restricted to the components classified as group II but was also expressed in components classified as group I, III or IV. Furthermore, the comparison between the tumors which presented with a component of Goseki II (major or minor) and the tumors which presented without this component was not statistically different. Thus the association between MUC2 and the group II of Goseki was not reinforced by the study of each component. The best correlation between MUC expression and histopathological classifications was achieved for MUC2 and mucinous carcinomas of WHO classification and group II of Goseki's classification, these classifications being based on the identification of the major component of the carcinoma.

In this study, we also looked for a correlation between TNM and MUC expression. We did not found any association between expression of MUC (individual MUC or several MUCs) and T or N stade. More particularly, although increased mucin gene heterogeneity has been described in advanced gastric carcinomas[9], this was not confirmed in our series. A correlation between the

expression of gastric mucins, i.e. MUC5AC and MUC6 and a poorer prognosis has been reported by some authors[27]. Nevertheless, these results were not confirmed by others[17,28]. As expected, we observed a significant difference in mean survival time between the carcinoma patients according to the TNM stage. We observed a shorter mean survival time for patients with gastric carcinoma classified as Goseki II or IV in comparison to patients with Goseki I or III tumors. Interestingly, we also observed a shorter mean survival time for patients with positive MUC2 expression (in more than 30% of the cells) in comparison to patients without MUC2 immunohistochemical detection. Thus the quantity and quality of mucus present in gastric carcinoma were related to survival. This association between MUC2 expression and poorer outcome was controversed in the literature[17,29,30].

In conclusion, expression of secreted gel-forming mucins in gastric carcinoma is particularly complex. Complexity of mucin gene expression patterns in gastric cancer may reflect a precise state of differentiation at the cell level not recognized in the used morphologic classification systems. Nevertheless, this study showed a correlation between a high expression of MUC2 and mucinous subtype of gastric carcinoma that is achieved by considering the major component of the tumor. We also observed a shorter mean survival time in patients with a higher content of mucus (Goseki II or IV) and high positive MUC2 expression.

Abstract

AIM: To reverse the multidrug resistance (MDR) by RNA interference (RNAi)-mediated MDR1 suppression in hepatoma cells.

METHODS: For reversing MDR by RNAi technology, two different short hairpin RNAs (shRNAs) were designed and constructed into pGenSil-1 plasmid, respectively. They were then transfected into a highly adriamycin-resistant HepG2 hepatoma cell line (HepG2/ADM). The RNAi effect on MDR was evaluated by real-time PCR, cell cytotoxicity assay and rhodamine 123 (Rh123) efflux assy.

RESULTS: The stably-transfected clones showed various degrees of reversal of MDR phenotype. Surprisingly, the MDR phenotype was completely reversed in two transfected clones.

CONCLUSION: MDR can be reversed by the shRNA-mediated MDRI suppression in HepG2/ADM cells, which provides a valuable clue to make multidrug-resistant hepatoma cells sensitive to anti-cancer drugs.

INTRODUCTION

Human hepatocellular carcinoma (HCC) is one of the most prevalent malignancies worldwide, especially in Asia and Africa, with an estimated 0.5 million new cases and around 1 million deaths annually[1]. MDR is the most common impediment to successful chemotherapy for a variety of cancers[2], especially HCC. Classic MDR characterized by cross resistance to antineoplastic drugs, is caused by over-expression of MDR1 gene encoding P-glycoprotein (P-gp), a member of the ATP-binding cassette (ABC) transporter superfamily. In liver, the expression of P-gp on the apical side of various cell membranes enhances the secretion of drugs into bile[3]. A disruption of P-gp-mediated drug extrusion results in a resensitization of tumor cells to treatment with antineoplastic agents, and may allow a successful drug treatment of the multidrug resistant cancer cells.

Most efforts at reversing MDR during the past two decades have been focused on compounds that modulate p-gp activity. In clinical trails, the efficiency of these drugs are difficult to access, mainly because of inherent adverse pharmacokinetic side effects[2], such as hypotension, heart failure, hyperbilirubinemia, and immunosuppression by cyclosporin A. Moreover, tumor cells can acquire resistance to the applied chemosensitizers, a so-called tertiary resistance. Consequently, it is necessary to develop alternative, less toxic and more efficient strategies to overcome MDR. It may, therefore, be more appropriate to target MDR1 gene expression. Indeed, MDR1 transcription has been targeted with ecteinascidin 743 in pre-clinical studies[4] and more recently by modulation of the orphan nuclear receptor SXR[5]. Strategies involving antisense and transcriptional decoy[6] and the use of anti-MDR1 mRNA hammerhead ribozymes have also been suggested [7].

RNAi is a conserved cellular mechanism by which double-stranded RNA (dsRNA) silences the corresponding homologous gene[8]. These 21-25 nucleotides with long, double-stranded small interfering RNA (siRNA) molecules can direct degradation of eukaryotic mRNAs in a sequence-specific manner. Two major discoveries have highlighted the potential of RNAi application in gene therapy. The introduction of synthetic siRNA of 21 nucleotides into mammalian cells can result in efficient gene silencing[9], and shRNAs expressed from RNA promoters within expression vectors also trigger RNAi[10, 11]. Recently, modulation of MDR by transfection of synthetic siRNAs has been reported [12, 13]. However, complete reversal to the drug-sensitive phenotype of parental cells has not been

obtained in any study. This is probably due to two reasons. Firstly, the transfection of synthetic siRNAs causes only transient suppression of target genes, which is often limited to the cell lines that are easy to be transfected. Secondly, the P-gp has a long half life time[14]. Thus, for achieving stable long-term RNAi effects, shRNA is developed[10].

In this study, we constructed two shRNAs targeting different coding regions of human MDR1 gene, because not all siRNA target sequences are equally potent[15]. After two shRNAs were respectively introduced into a multidrug resistant cell line HepG2/ADM derived from HepG2, efficiency of MDR1 gene suppression and whether MDR was reversed were evaluated.

Table 1 Sequences of shRNA oligonucloetides

Oligonucloetides	Sense + loop + antisense DNA template
MDR-A	5′-GATCCGCTTTGGCTGCCATCATCCAttcaagacgTGGATGATGG CAGCCAAAGTTTTTTGTCGACA-3′; 3′-GCGAAACCGACGGTAGTAGGTaagttctgcACCTACTACCGT CGGTTTCAAAAAACAGCTGTTCGA-5′
MDR-B	5′-GATCCGGCCTAATGCCGAACACATttcaagacgATGTGTTCGGCATTAGG CCTTTTTTGTCGACA-3′; 3′-GCCGGATTACGGCTTGTGTAaagttctgcTACACAAGCCGTAATCCGGAA AAAACAGCTGTTCGA-5′

The underlined parts are loops of shRNA oligonucleotides.

MATERIALS AND METHODS

Cell lines and cell culture

The HepG2 cells (Chinese Center for Type Culture Collection) were cultured in DMEM (Gibco BRL, Gaithersburg, MD, USA) contianing 10% of heat-inactivated FCS (Gibco BRL, Gaithersburg, Md. USA). Cells were incubated at 37 ℃ in a 50 mL/L CO_2 air incubator with saturated humidity. The establishment of a multidrug-resistant cell line HepG2/ADM was described previously[16]. The HepG2/ADM cells could survive a 24 h-treatment with adriamycin at a concentration of 5.0 mg/L, and are able to keep growing in the medium containing 1.0 mg/L adriamycin. To maintain MDR phenotype, HepG2/ADM cells were cultured with DMEM supplemented with adriamycin at 1.0 mg/L (Pharmacia, Uppsala, Sweden).

Design of siRNAs and cloning of siRNA hairpin loops

Two different siRNAs targeting different parts of the MDR1 gene (accession number: M14758) were designed: MDR-A (5'-AACTTTGGCTGCCATCATCCA-3', targeting nucleotide 586-606 of MDR1 mRNA sequence) was described previously [17]; MDR-B (5'- AAGGCCTA-ATGCCGAACACAT-3', targeting nucleotide 3494-3514 of MDR1 mRNA sequence) was designed according to the recommendation from the website http://sirna.qiagen.com. The two sequences were individually incorporated into a pair of oligonucleotides (produced by Wuhan GenSil Biotechnology, China. Table 1) where the target sequence appears as antisense followed by sense orientations separated by a 9-nucloetide spacer sequence and flanked at either end by Hind III or BamH1 restriction enzyme sites. The annealed oligonucleotides were cloned into pGenSil-l (Wuhan GenSil Biotechnology, China) according to the manufacturer's recommendations. The transcribed shRNA of MDR-A was 5'ATCCAttcaagacgTG-GATGATGGCAGCCAAAGU- -U-3', and the transcribed shRNA of MDR-B was 5'-GGCCTAATGCCGAACA-CATttcaagacgAT- -GTGTTCGGCATTAGGCCUU-3'. The underlined parts were loops of the two shRNAs.

Transfection and selection of stably transfected cell clones

The HepG2/ADM cells were transfected with 2μg of pGenSil-1/MDR-A, pGenSil-1/MDR-B, or empty vector pGenSil-1. Transfection was performed in 50%-60% confluent cells in 6-well plates using 9 μL of Lipofectamine 2000™ (Invitrogen, USA). Forty-eight hours after transfection, cells were grown in 10 cm cell plates with medium containing G418 (400 μg/mL) but without adriamycin. After 3 wk of culture, visible colonies were picked up and expanded. The stably transfected clone cells were observed to show green fluorescence under microscope and the clones without expression of the transfected gene did not show green fluorescence (Figure 1).

Detection of P-gp Function

Rh123 accumulation is sensitive and specific for indicating the transport function of P-gp[18, 19]. To observe the RNAi efficiency in the transfected cells, Rh123 (Sigma, MO, USA) was chosen to detect P-gp functions. The assay was performed as described by Broxterman *et al* [18]. Briefly, cells were cultured in 6-well plates. When the cells reached 70%-80% confluence, Rh123 was added to cells at a final concentration of 0.25 μg/mL and incubated at 37 ℃ for 1 h. The cells were washed 3 times with 4 ℃ PBS and resuspended at $5\text{-}10 \times 10^5$ cells/mL in 4 ℃ PBS. Rh123 fluorescence was analyzed with a FACStar flow cytometer (Becton Dickinson Immune Cytometry Systems) equipped with an argon laser. The blast population was gated by forward- and side-scatter characteristics. Rh123 fluorescence of 10 000 cells was measured logarithmically through a 530 nm bandpass filter at an excitation wavelength of 488 nm. HepG2 cells without incubation with Rh123 served as a negative control. Rh123 efflux was measured by counting cells in the M1 region of the plot and calculated as percentages of cells in the M1 region of the plot. The bigger percentage of cells in M1 region indicated the greater cellular Rh123 efflux and also a higher P-gp function. All 146 clones were checked.

Real-time reverse transcription chain reaction

Human MDR1 real-time PCR primers used in experiments are 5R-TGGTTCAGG TGGCTCTGGAT-3R and 5R-CTGTAGACAAACGATGAGCTATCA -CA-3R. Human GAPDH primers for real-time PCR used have been previously described[20]. Total RNA was isolated from the cells by TRIzol (Invitrogen, USA) 60-70 d after cell transfection. All RNA samples were stored at -80 ℃ until use. RNAs were reversely transcribed into cDNAs using RevertAid-TM first strand cDNA synthesis kit (Fermentas, Inc.) according to the manufacturer's instructions. Real-time PCR and data collection and result analysis were performed on

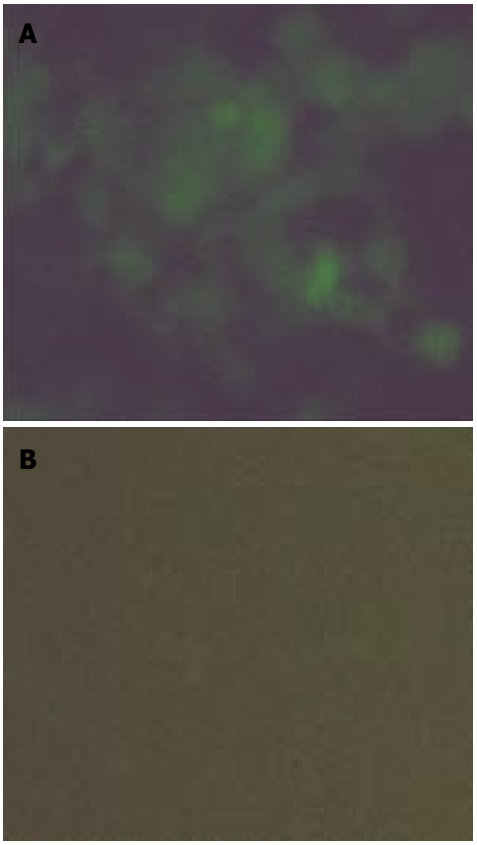

Figure 1 Stably transfected cells showing green fluorescence under a fluorescence microscope (**A**) and cells without stable expression of the transfected gene (**B**).

ABI PRISM®7000 sequence detection system (Applied Biosystem, USA). All quantitations were normalized to an endogenous control GAPDH. The relative quantitation value of each target gene was analyzed using a comparative C_T method. The following formula was used to calculate the relative amount of the transcript in the sample and normalized to an endogenous reference (GAPDH): $2^{-\triangle\triangle CT}$, where $\triangle C_T$ is the difference in C_T between the gene of interest and GAPDH, and $\triangle\triangle C_T$ for the sample = $\triangle C_T$ of the actual sample -$\triangle C_T$ of the lowest expressing sample (used as calibrator). The MDR1/GAPDH ratio in drug sensitive HepG2 cells was set at 1, and $L0g_{10}1 = 0.00$.

Cell cytotoxicity assay

The cytotoxicity assay and ID50 determination of anticancer drugs on the different clone cells were analyzed by the microculture methyl tetrazolium (MTT) method as described previously [21]. Briefly, in each experiment 10 000 cells per well were seeded in 96-well plates and cultured with DMEM or DMEM complemented with adriamycin in dilution series for 48h. Four repeated wells were used for each concentration. The total medium volume of each well was 200 μL. After 48 h of culture, 50 μL of (3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT; Sigma, MO, USA) at 2 mg/mL was added to each well and incubated for 4 h at 37 ℃. Plates were centrifuged at 800r/min for 6 min, the medium was aspirated from plates, leaving about 30 μL of medium in each well. One hundred and fifty μL of dimethyl sulfoxide (DMSO) (Merck KGaA, Darmstadt, Germany) was added to each well and the plates were shaken for 10 min to solubilize the formazan crystals. The plates were read immediately at 540 nm on a scanning multi-well spectrophotometer (Titertek, Alabama, USA). Absorbance from the cells treated with adriamycin was corrected against the absorbance from the untreated control cells. The ID50 value was defined as the dosage of drugs at which 50% of cells died after 48 h of treatment, which was calculated from 3 independent experiments for each clone. Since the basal growth rates of the cell lines had no significant difference in the first 2 d (data not shown), the errors caused by that were ignored.

Statistical analysis

For statistical analysis of P-gp function and cell cytotoxicity assay, the unpaired *t*-test was performed on SPSS 11.0 software. The real-time PCR data were analyzed using the SDS software on the ABI PRISM®7000 sequence detection system, the confidence limit was set at 95%.

RESULTS

ShRNAs decreased P-gp function

The RNAi efficiency was evaluated by measuring specific P-gp activity. P-gp-mediated transport indicated by intracellular decrease of Rh123 fluorescence was studied using flow cytometry. The P-gp activities of 58 pGenSil-1/MDR-A-transfected clones and 78 pGenSil-1/MDR-B-transfected clones were analyzed. Meanwhile, 10 HepG2/ADM control clones transfected with an empty pGenSil-1 vector were also analyzed. Two of the pGenSil-1/MDR-B-transfected clones showed a complete suppression of the P-gp function. More than 60% of the pGenSil-1/MDR-B-transfected clones (49 of 78 clones) showed an intermediate decrease of the P-gp function, whereas 8 clones did not show any significant changes of P-gp function. None of the pGenSil-1/MDR-A-transfected clones showed a complete suppression of P-gp activity, although different suppressions of P-gp function were detected. None of the control clones exhibited any significant alterations of P-gp function. Compared with HepG2 cells, the P-gp functions of HepG2/ADM/pGenSil-l/MDR-B clone 1 and clone 2 cells were at a low level near to that of the HepG2 cells, the P-gp functions of the HepG2/ADM cells and control HepG2/ADM/vec clone cells were much higher (Figure 2).

ShRNAs decreased MDR1 mRNA level

To further confirm the data from P-gp function study with Rh123 fluorescence, real-time RT-PCR was performed to quantify the RNAi-mediated suppression of MDR1 mRNA. The MDR1 mRNA expressions of parental cells, HepG2/ADM cells, HepG2/ADM/pGenSil-l/MDR-B clone 1 and clone 2 cells and the HepG2/ADM/vec control clone cells were measured. Expression of MDR-B shRNA in HepG2/ADM/pGenSil-l/MDR-B clone 1 and clone 2 reduced MDR1 mRNA expressions by 93% and 92%, respectively. MDR1 mRNA expression was reduced by 40% in the HepG2/ADM/vec control clone (Figure 3).

ShRNAs reversed multidurg-resistant phenotype

The reversal of MDR-mediated by shRNA was measured

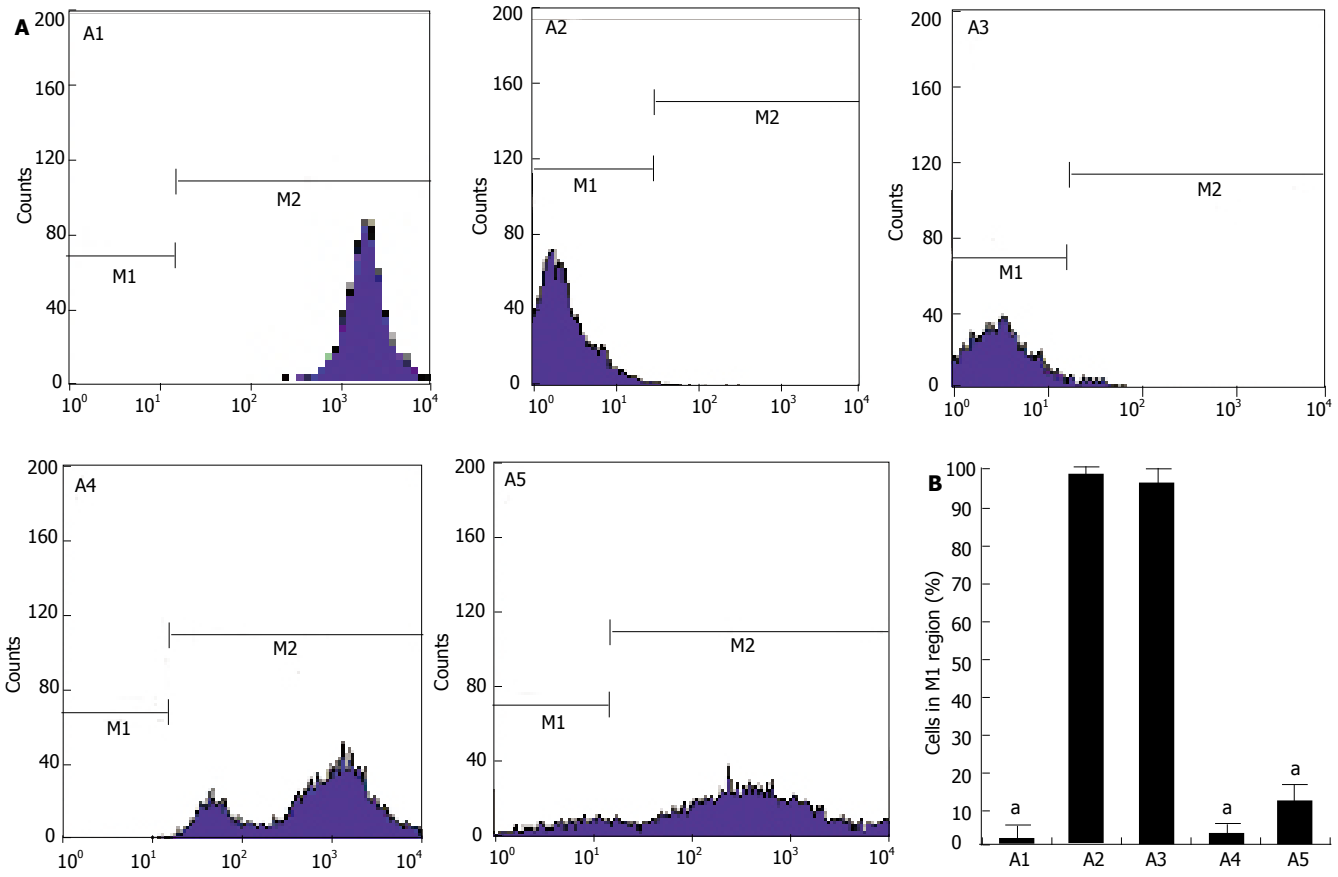

Figure 2 P-gp activity in HepG2 cells (A1), HepG2/ADM cells (A2), HepG2/ADM/vec control clone cells (A3); HepG2/ADM/pGenSil-l/MDR-B clone 1 cells (A4); HepG2/ADM/pGenSil-l /MDR-B clone 2 cells (A5) Rhodamine123 efflux was measured by counting cells in the M1 region of the plot. The marker bar M1 was set to indicate the cells with high Rhodamine123 efflux; the marker bar M2 was set to indicate the cells with low rhodamine123 efflux. Data were presented as mean ± SD. $^aP < 0.05$ *vs* untreated multidrug-resistant cell line HepG2/ADM.

sh 2	0.467 ± 0.617[a]	3.312

$^aP < 0.05$ *vs* ID50 value of HepG2. The data are presented as mean ± SD. Sh1, sh2 and con represent HepG2/ADM/pGenSil-l/MDR-B clone 1, clone 2, and the control HepG2/ADM/vec clone, respectively.

of HepG2/ADM/pGenSil-l/MDR-B clone 1 and clone 2 cells was decreased to a very low level near to that of the drug-sensitive HepG2 cells.

DISCUSSION

To improve the effect of RNAi-mediated gene silencing, some vector plasmids have been developed to express siRNAs as inverted repeats showing similar potency to initial RNAi. These siRNA-like molecules are commonly designated as shRNAs. For generating shRNAs, these vectors have been designed to be able to obtain the stable expression of shRNAs using strong RNA polymerase-II-depen-

dent promoters like CMV or EF1a, or RNA polymerse-III promoters like U6 or H1[10, 22-27]. Since experiences with antisense and ribozyme technology indicate that RNA polymerase-III expression systems can offer a great potency for maintaining stable expression of short RNA molecules *in vitro* as well as *in vivo*[28], the U6-driven expression vector pGenSil-1 was applied in this study. The size of the loop structure of shRNA has a considerable influence on the gene suppression activity. Brummelkamp *et al* [10] reported that a 9- nucleotide loop shows more effects than a 7-nucleotide loop, whereas a 5-nucleotide loop structure shows only moderate effects. Therefore, the two shRNAs were designed with a 9-nucleotide loop in our study.

The two shRNAs in this study showed different RNAi efficiencies. PGenSil-1/MDR-A was selected as previously described by Yague *et al* [17]. In his report, MDR-A shRNA constructed in pSUPER plasmid had an excellent RNAi effect on KD30 cell line, a multidrug resistant cell line derived from K562 leukemia cells. On the contrary, MDR-A shRNA did not show any significant RNAi effect on HepG2/ADM cells. One reason may be that the KD30 cell line is generated by a single-step selection in a low concentration of adriamycin (0.0174 mg/L)[17], while the HepG2/ADM cells are resistant to a high concentration of adriamycin. Another reason may be that the same siRNA sequence may have different RNAi efficiency in different tumor cells[12]. The different vector and loop structure of shRNA may also affect RNAi effects. Our study indicated that the pGenSil-1/MDR-B had a significant RNAi effect on HepG2/ADM cells. The MDR1 mRNAs were reduced by 93% and 92% respectively in HepG2/ADM/pGenSil-l/MDR-B clone 1 and clone 2 by expressions of MDR-B shRNA. The remaining MDR1 mRNA in the two clones was probably due to transgenic deletion, incomplete or inappropriate integration effects. The two clones showed a complete reversal of multidrug-resistant phenotype, indicating that the MDR-B siRNA might be very useful in designing new strategies for treatment of hepatoma in the future.

The empty pGenSil-l vector-transfected clone showed a slight decrease of MDR1 gene expression, which was suggested by real-time RT-PCR, Rh123 efflux test and cell cytotoxicity assay. That may be due to the withdrawal of adriamycin from the cell culture medium for a relatively long time[29].

The general obstacle to cancer gene therapy is the delivery of a therapeutic gene. Additional problems of clinical P-gp inhibition by anti-MDR1 siRNAs may arise from the physiological expression of this ABC transporter in several epithelial and endothelial cells. For example, P-gp is strongly expressed in the luminal membranes of the endothelium of blood vessels in the brain[30], suggesting that this efflux pump plays an important role in the blood-brain barrier and is crucial for limiting the potential neuro-toxicity of many anticancer drugs. Thus, in clinical practice the application of P-gp-inhibiting shRNA expression vectors should be restricted to P-gp expressing cancer cells. One promising strategy for cancer cell-specific delivery of siRNAs targeting MDR1 is to develop vector systems delivering siRNA in a cell-type specific manner. Lentiviral vectors could offer some advantages in upcoming preclinical studies[31]. A "replication-defective" E1A-mutant adenoviral vector that efficiently and selectively replicates in "classic" multidrug-resistant cells has been reported[32]. These viral vectors may contribute to developing more useful vectors for the MDR reversal gene therapy in multidrug-resistant cancers.

In conclusion, the highly adriamycin-resistant HepG2/ADM cells can be completely reversed to an adriamycin-sensitive phenotype by the shRNA-mediated RNAi. The target sequence can be integrated into gene therapy vectors for the potential application in clinic.

Abstract

AIM: To evaluate prospectively 4 selected serum fibrosis markers (tenascin, hyaluronan, collagen VI, TIMP-1) before, during and 12 mo after IFN treatment of children with chronic hepatitis B.

METHODS: Forty-seven consecutive patients with chronic hepatitis B (range 4-16 years, mean 8 years) underwent IFN treatment (3 MU tiw for 20 wk). Fibrosis stage and inflammation grade were assessed in a blinded fashion before and 12 mo after end of treatment. Serum fibrosis markers were determined using automated assays.

RESULTS: IFN treatment improved histological inflammation but did not change fibrosis in the whole group or in subgroups. Only hyaluronan correlated significantly with histological fibrosis(r = 0.3383, P = 0.021). Basal fibrosis markers did not differ between responders (42.5%) and nonresponders(57.5%). During IFN treatment only serum tenascin decreased significantly in the whole group and in nonresponders. When pretreatment values were compared to values 12 mo after therapy, TIMP-1 increased in all patients and in nonresponders, and hyaluronan decreased in all patients and in responders.

CONCLUSION: Tenascin reflects hepatic fibrogenesis and inflammation which decreases during IFN treatment of children with chronic hepatitis B. TIMP-1 correlates with nonresponse and hyaluronan with histological fibrosis.

INTRODUCTION

The potential of interferon α (IFNα) to normalize aminotransferase activity, eliminate serum HBV DNA and HBeAg and reduce liver necroinflammation in patients with chronic hepatitis B is widely acknowledged[1-3]. In children with chronic hepatitis B treatment with IFN leads to long-term serological and biochemical remission in less than 50%[4-6]. Nonetheless, several reports suggested that IFN treatment for hepatitic C can halt or even reverse liver fibrosis[7-10], while its antifibrogenic potential in chronic hepatitis B needs to be confirmed[11]. Histological staging of liver fibrosis plays a central role in the liver pathological assessment since progressive fibrosis may lead to cirrhosis, the most important predictor of decompensated liver diseases and death[3, 12].

Liver biopsy is the standard method to assess fibrosis stage which allows to semiquantify the extent of fibrosis, yielding a static view[13]. However, biopsy has significant disadvantages for the assessment of fibrosis and fibrosis progression. Thus despite minor histological fibrosis, progression might be fast, since the accumulated extracellular matrix is the result of a dynamic process characterized by changes in matrix synthesis (fibrogenesis) and removal (fibrolysis)[14]. Furthermore, liver biopsy is invasive and histological scoring systems are not sensitive enough to detect small changes in fibrosis stage. Finally, bioptical sampling error can reach 25%-33% for a difference in one stage, when using the METAVIR system which ranges from 0 (no fibrosis) to 4 (cirrhosis)[15,16]. Therefore, noninvasive markers that may reflect overall hepatic fibrogenesis and fibrolysis in chronic hepatitis would be of great clinical benefit,

allowing repeated assessment of progression or therapeutic interventions, especially in children with chronic hepatitis B or C who are treated with IFN or other antiviral or potential antifibrotic agents[17-19].

The aim of this study was to investigate the clinical usefulness of selected matrix-derived serum markers (tenascin, hyaluronan, collagen VI, tissue inhibitor of metalloproteinase 1 or TIMP-1) in a long-term follow-up of children with chronic hepatitis B treated with IFN α.

MATERIALS AND METHODS

Patients

The study was carried out prospectively in 47 children (mean age 8 years, range 4-16, 31 boys and 16 girls) with serologically and biopsy-verified chronic hepatitis B. The children were positive for HBs and HBe antigens and had increased serum activity of HBV DNA polymerase for at least 1 year. Patients with autoimmune hepatitis or HCV coinfection were excluded from the study. None of the children was treated with antiviral and immunomodulating drugs during the 12-month period before inclusion into the study. Informed consent was obtained from all patients' parents and the protocol was approved by the local ethical committee of the Medical University of Bialystok. Serum samples were evaluated at three time points: at the start and the end (5 mo) of IFN α treatment, and 12 mo after end of treatment. Serum samples were stored at -70 ℃ until use. Standard liver tests were measured by validated automated methods and included total bilirubin, albumin, alanine transaminase (ALT), aspartate aminotransferase (AST), gamma-glutamyltransferase (gamma-GT). HBsAg and HBeAg were determined by MEIA (IMx, Abbott).

IFN treatment and definition of response

IFN (IFN α 2a: 30 children or IFN α 2b: 17 children) was applied at the dose of 3 MU tiw subcutaneously for 20 wk according to the schedule approved by the Polish Interferon Study Group[20]. HBeAg/antiHBe seroconversion and lack of HBV DNA polymerase activity 1 year after end of treatment was considered as the criterion of treatment response.

Measurement of serum fibrosis markers

Monoclonal antibodies were used to detect tenascin, collagen VI and TIMP-1 in sandwich immunoassays performed in an automated analyzer employing fluoresceine-labelled capture antibodies and alkaline phosphatase labeled detection antibodies. Hyaluronan was determined using biotinylated cartilage link protein. The immune complexes were separated from serum using magnetic particles covered with monoclonal anti-fluoresceine (anti-biotin in case of hyaluronan). The assays were developed for the BAYER IMMUNO 1 immunoassay system and validated in several cohorts of liver patients and healthy individuals[21-23].

Histological analysis

Percutaneous liver biopsies were obtained before treatment and 12 mo after IFN α discontinuation. The liver specimens were fixed in buffered formalin and embedded in paraffin. Histological sections were stained using hematoxylin-eosin, Masson-Goldner, Masson's trichrome and reticulin stains. Fibrosis stage and inflammation grade were assessed in a blinded fashion by a single pathologist according to the method of Batts and Ludwig[24].

Table 1 Baseline characteristics of the group of children with chronic hepatitis B

Data of the patients	Mean	SD	Minimum	Maximum
Age (yr)	8	3.51	4	16
HBV infection (mo)	44	30	10	144
ALT (nkat/L)	1600	1567	350	9902
AST (nkat/L)	1367	1117	567	7718
GGT (nkat/L)	250	150	50	1150
Bilirubin (μmol/L)	8.5	4.3	3.4	23.9
Albumin (g/L)	65.6	4.2	57.2	74.3
Hyaluronan (μg/L)	34.3	21.5	14.6	113.5
Tenascin (μg/L)	748.8	265.9	295.6	1480.2
TIMP-1(μg/L)	558.1	121.2	342.2	852.3
Collagen VI (μg/L)	5.8	2.2	2.3	14.2
Staging	2.0	0.6	1	3
Grading	1.6	0.7	1	3

Normal ranges: AST: 167-667 nkat/L; ALT: 167-667 nkat/L; GGT: 150-583 nkat/L; Bilirubin: 1.7-18.8 μmol/L; Albumin: 58.8-69.6 g/L.

Statistical analysis

Results were expressed as means ± SD. Statistical analysis was performed with the Wilcoxon rank-sum test for independent samples and Wilcoxon signed rank test for paired samples. The relationship between the serum fibrosis markers and liver histology scores was analysed by the Spearman rank-correlation test for nonparametric data and by the Pearson method for parametric data. Tests were considered statistically significant at $P < 0.05$.

RESULTS

Patient characteristics

The baseline characteristics of the 47 children are presented in Table 1. They were classified into responders (n = 20; 42.5%) and nonresponders (n = 27; 57.5%). There were no significant differences between the groups regarding age, gender, body mass, duration of HBV infection, the levels of bilirubin and albumin, the activity of GGT, levels of baseline liver fibrosis markers (tenascin, hyaluronan, collagen VI, TIMP-1) and grade of inflammation. However, treatment responders displayed a significantly higher activity of ALT (2184 ± 2217 *vs* 1150 ± 550 nkat/L) and AST (1717 ± 1567 *vs* 1100 ± 500 nkat/L) (P = 0.0453 for both) and a higher fibrosis score according to Batts and Ludwig (2.3 ± 0.5 *vs* 1.8 ± 0.6; P = 0.004).

Basal levels of serum fibrosis markers

We arbitrarily defined mild/moderate fibrosis as stage ⩽ 2 (n = 39) and advanced fibrosis as stage = 3 (n = 8) accor-

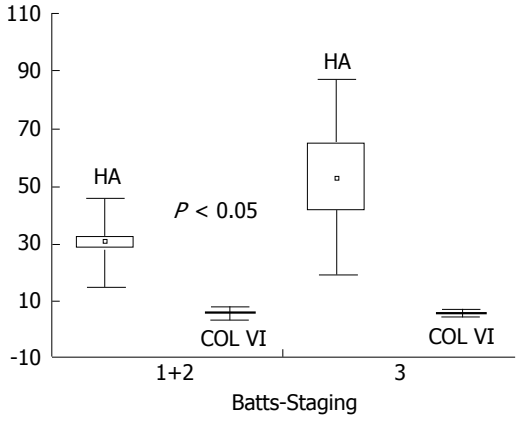

Figure 1 Correlation of serum fibrosis markers with histological staging (mean ± SD).

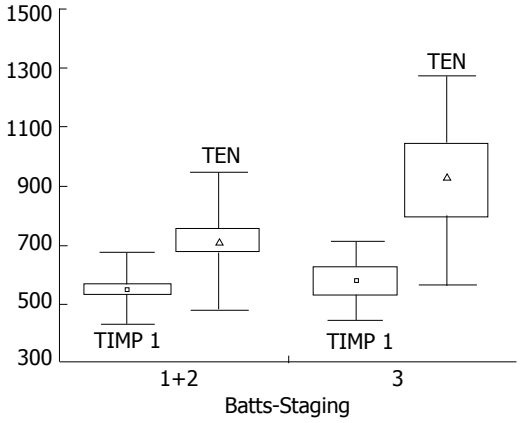

Figure 2 Correlation of serum fibrosis markers with histological staging (mean ± SD).

ding to Batts and Ludwig. There were no significant differences in mean serum levels of tenascin, collagen VI and TIMP-1 between children with mild and advanced liver fibrosis, while levels of hyaluronan were higher in the latter group (30.3±15.8 *vs* 53.1±34.3 μg/L; $P = 0.0266$). There was a trend for increased tenascin and TIMP-1 in children with advanced fibrosis (Figure 1, Figure 2). We also arbitrarily defined mild inflammation as grade 1 ($n = 20$) and severe inflammation as grade ⩾2 ($n = 27$) according to Batts and Ludwig. There were no significant differences in mean concentrations of all serum fibrosis markers between children with mild and severe hepatic inflammation.

Effect of IFN on serum fibrosis markers

At end of treatment there were no significant changes in serum fibrosis markers in responders, while in nonresponders only tenascin decreased significantly ($P = 0.0074$). Twelve months after end of treatment serum hyaluronan was significantly lower than before treatment ($P = 0.0076$), while serum TIMP-1 was increased ($P = 0.0072$). In responders only hyaluronan decreased significantly ($P = 0.0304$), while in nonresponders the level of TIMP-1 increased ($P = 0.0064$, Table 2). Tenascin reached pretreatment levels in both responders and nonresponders.

Effect of IFN on liver histology

There were no significant changes in fibrosis stage after IFN therapy in the whole cohort, 2.0 ± 0.6 *vs* 2.1 ± 0.6, according to Batts and Ludwig and in subgroups, responders: 2.3 ± 0.5 *vs* 2.2 ± 0.7; nonresponders: 1.8 ± 0.6 *vs* 2.0 ± 0.6. Histological inflammation improved significantly in the whole group, 1.6 ± 0.7 *vs* 1.2 ± 0.7, $P = 0.0373$.

Correlation between serum fibrosis markers, histology and biochemical parameters

There were no significant correlations between baseline levels of the 4 serum fibrosis markers with liver fibrosis or inflammation according to Batts and Ludwig, or with AST, ALT, GGT, albumin or bilirubin. Only hyaluronan correlated significantly with histological fibrosis ($r = 0.3383$, $P = 0.021$).

DISCUSSION

Liver biopsy has been considered the gold standard for the assessment of hepatic fibrosis. Current recommen-

dations suggest that this procedure precede antiviral treatment in most patients with chronic hepatitits B or C[25]. However, liver biopsy is invasive with the potential for complications, such as bleeding which occurrence ranges from 0.3% to 0.5%[26,27], and mortality up to 0.1%[26,28]. In addition, since the biopsy core only represents 1/20 000 to 1/50 000 of the liver, biopsy is prone to sampling error, and variations in fibrosis staging may be high among different pathologists[15,16,21,29]. For these reasons, especially in children, non-invasive detection of histological liver damage, paticularly of fibrosis, is needed. Ideally serum markers of fibrosis should be applicable to patients with chronic hepatitis to either diagnose the stage of liver fibrosis, potentially replacing liver biopsy for this purpose, or to monitor progression of fibrosis or fibrogenesis, particulary during treatment [17,30]. Markers of the dynamics of fibrogenesis and fibrolysis are urgently needed, e.g. for short-term assessment of antifibrotic drug effects, but difficult to validate.

In this study we evaluated the changes of 4 serum fibrosis markers derived from the extracellular matrix (tenascin, hyaluronan, collagen VI and TIMP-1) before, at the end of and 12 mo after treatment of children with chronic hepatitis B with IFN. Our results showed a significant decrease of hyaluronan in responders and increased TIMP-1 in nonresponders, when levels before and 12 mo after interferon α treatment were compared. While falling during treatment, serum tenascin reached pretreatment levels in both responders and nonresponders. There were no significant changes in histological liver fibrosis 12 mo after the 5-mo course of IFN in all patients or in the subgroups of responders and nonresponders. This was expected, since the rate of fibrosis progression or regression in patients with chronic hepatitis B or C was usually slow. Assuming that IFN has at least some antifibrotic activity, as suggested before in large retrospective analyses of patients with chronic hepatitis C[31, 32], the histological scoring systems are obviously not sensitive enough to detect small changes in liver fibrosis and (modest) antifibrotic treatment effects. Nonetheless, the course of serum fibrosis (fibrogenesis) markers in our small but well defined group of children suggests that IFN indeed has antifibrogenic activity, especially in responders. This antifibrotic effect seems to be transient, as exemplified by serum tenascin which was depressed only during IFN treatment.

Prior to our study there had been no longitudinal, prospective studies of serum fibrosis markers in children with chronic hepatitis B, and only few studies analysed the effect of IFN therapy on the stage of liver fibrosis in children. Our findings are consistent with our previous study[33] and with those of others, who did not observe improvement of liver fibrosis by antiviral treatment in children, when biopsy was performed before and immediately after[34] or 9-12 mo after end of treatment[35, 36], while Gregorio *et al*[37] found significant improvement in staging in responders. However, these reports included small numbers of patients (≤24). It has been demonstrated that fibrosis stage changes more slowly than inflammation grade[7, 38]. This explains why we did not observe a significant improvement in fibrosis, while inflammation was clearly suppressed by IFN treatment.

We found that hyaluronan was the best serum marker to predict advanced liver fibrosis, since its level correlated significantly with histological fibrosis and was significantly higher in children with advanced *vs* mild/moderate liver fibrosis. These data are in keeping with previous results in patients with chronic viral hepatitis[39-43]. Thus the ability of this test to differentiate patients with extensive liver fibrosis from those with mild liver fibrosis was stronger than that of other markers, i.e., PIIINP, collagen IV, MMP-1, MMP-2 and TIMP-1[44] and laminin, collagen IV, PIIINP and TGF β1[45].

In children, up to now serum hyaluronan had only been studied in biliary atresia and cystic fibrosis[46-48], and there had been no data on collagen VI in chronic viral hepatitis or on TIMP-1 or tenascin in childhood liver diseases in general. Previous studies indicated that most serum fibrosis markers are influenced by body growth, especially PIIINP[49,50]. Thus healthy children have higher PIIINP levels than adults, excluding its use as reliable fibrosis marker for pediatric patients. Hyaluronan appears to be a useful marker of fibrosis stage also in children due to its short biological half life of only a few minutes and a prominent uptake by sinusoidal endothelial cells[51]. Similarly, tenascin and TIMP-1 are applicable to children with chronic hepatitis B as markers of fibrogenesis/inflammation and of fibrogenesis, respectively.

Our data suggest that serum hyaluronan, tenascin and TIMP-1 could be useful fibrosis markers in future studies of children with chronic viral hepatitis.

Abstract

AIM: To compare gene expression profiles of pancreatic adenocarcinoma tissue specimens, human pancreatic and colon adenocarcinoma and leukemia cell lines and normal pancreas samples in order to distinguish differentially expressed genes and to validate the differential expression of a subset of genes by quantitative real-time RT-PCR (RT-QPCR) in endoscopic ultrasound-guided fine needle aspiration (EUS-guided FNA) specimens.

METHODS: Commercially dedicated cancer cDNA macroarrays (Atlas Human Cancer 1.2) containing 1176 genes were used. Different statistical approaches (hierarchical clustering, principal component analysis (PCA) and SAM) were used to analyze the expression data. RT-QPCR and immunohistochemical studies were used for validation of results.

RESULTS: RT-QPCR validated the increased expression of *LCN2* (lipocalin 2) and for the first time *PLAT* (tissue-type plasminogen activator or *tPA*) in malignant pancreas as compared with normal pancreas. Immunohistochemical analysis confirmed the increased expression of *LCN2* protein localized in epithelial cells of ducts invaded by carcinoma. The analysis of *PLAT* and *LCN2* transcripts in 12 samples obtained through EUS-guided FNA from patients with pancreatic adenocarcinoma showed significantly increased expression levels in comparison with those found in normal tissues, indicating that a sufficient amount of high quality RNA can be obtained with this technique.

CONCLUSION: Expression profiling is a useful method to identify biomarkers and potential target genes. Molecular analysis of EUS-guided FNA samples in pancreatic cancer appears as a valuable strategy for the diagnosis of pancreatic adenocarcinomas.

INTRODUCTION

Pancreatic cancer remains one of the most deadly tumor types. The 5-year survival rate after diagnosis is less than 3.5%[1]. So far, the difficulties persist to diagnose pancreatic cancer early. Indeed, the molecular mechanisms underlying pancreatic oncogenesis remain partially understood.

Several fundamental studies suggest the implication of a number of molecules involved in cell cycling, apoptosis or signal transduction. Unfortunately, the clinical relevance of these molecules is still pending. For example, the screening of the activating mutations of the proto-oncogene *K-ras*, which are the most frequent alterations observed to date in pancreatic cancer, is not thought to be sufficiently robust as a diagnostic or prognostic marker[2]. The combination of several genetic alterations such as those found in tumor suppressor genes *p16, DPC4, p53* did not improve the sensitivity and specificity of K-*ras* mutation test for the diagnosis[3]. The development of new diagnostic tools is hence crucial for the detection of pancreatic cancer at an early stage.

Large-scale analysis of gene expression has been widely proposed as a powerful method for malignancy diagnosis, predicting invasion and metastasis through the identification of biomarkers. Pancreatic cancer has previously been the focus for such studies[4-8]. However, a rather low concordance between different studies was found in a meta-analysis of several of these studies[9]. There are several possible explanations; one of them being differences in probe design (oligonucleotides or cDNA), support (nylon membranes or glass slides) or the underlying detection technology (fluorescence or radioactivity). No matter what the reason is, there are controversies about the need of multiple well-defined and validated approaches to find a transcriptional "consensus" for a given tissue or cell type.

In this study, we used commercially dedicated macroarrays containing 1176 genes, selected on their functional implication in cancer biology, to study the expression profiles in pancreatic adenocarcinomas (surgical specimens and cell lines). We compared these profiles with those of normal pancreas, other adenocarcinoma cell lines of colon origin as well as with a non-adenocarcinoma leukemia cancer cell line. This array has never been used in expression profiling studies of pancreatic adenocarcinomas.

An important issue is the limited access to pancreatic tissue specimens. Being a minimally invasive technique for patient exploration, endoscopic ultrasound-guided fine needle aspiration (EUS-guided FNA) is now largely used for pancreatic tumor diagnosis[10]. Therefore, to support the clinical relevance of these studies, we determined whether quantification of these markers would be feasible in EUS-guided FNA specimens for prognostic or molecular diagnosis procedures.

MATERIALS AND METHODS

Cell and tissue samples

All cell lines were of human origin and were grown at 37℃, 50 mL/L CO_2 in the presence of 10 mL/L fetal calf serum, penicillin/streptomycin (Invitrogen Inc. Carlsbad, CA, USA) and 2 mmol/L L-glutamine (Invitrogen). ASPC-1 (ATCC: CRL-1682), Capan-1 (ATCC: HTB-79), Capan-2 (ATCC: HTB-80), NP29 (kindly provided by Dr. Gabriel Capellá, Barcelona, Spain), HCT 116 (ATCC: CCL-247) and K562 (ATCC: CLL-243) cells were grown in RPMI 1640 medium (Invitrogen). PANC-1 (ATCC: CRL-1469), B × PC-3 (ATCC: CRL-1687), SW480 (ATCC: CLL-228), SW620 (ATCC: CLL-227) and MIAPaCa-2 (ATCC: CRL-1420) cells were grown in Dulbecco's modified Eagle medium (DMEM), 1.0 g/L glucose. HT-29 cells (ATCC: HTB-38) were maintained in DMEM with 4.5 g/L glucose. Caco-2 cells (ATCC: HTB-37) were grown in RPMI 1640 in the presence of 10 g/L non-essential amino acids. Pancreatic ductal adenocarcinoma specimens were obtained from patients undergoing pancreaticoduodenectomy, after written consent and in accordance with French ethical guidelines. Pancreatic cancer samples were obtained through EUS-guided FNA in patients who have given their written consent. The protocol was approved by the Ethical Committee from Midi-Pyrénées CPPRB-1. Briefly, FNA was performed using GF-UC 30p ultrasound endoscope (Olympus, Rungis, France). Samples of pancreatic cancer tissue were obtained from each patient. The core biopsies were then transferred in Dubosq-Brazil medium and the cellular material remaining in the needle was immediately put in RNA later (Ambion, Woodward Austin, TX, USA). All cases of pancreatic cancer were diagnosed based on histological features. One of the normal pancreatic specimens was obtained from an organ donor. The other two normal pancreatic RNA samples were from Clontech (Palo Alto, CA, USA), each a pool from two individuals.

RNA extraction, cDNA labeling and membrane hybridization

Cells were rinsed in PBS and total RNA was extracted with the RNeasy mini-kit (QIAGEN, Valencia CA, USA). Adenocarcinoma tissues were first grinded mechanically in liquid nitrogen with a pestle in a mortar. Cellular samples obtained by EUS-guided FNA were temporarily stored at -25℃ in RNA later (Ambion), and total RNA purified using the RNeasy micro-kit (QIAGEN). The quality and the quantity of the RNA were systematically determined with an Agilent Bioanalyzer 2100. Atlas Pure Total RNA Labeling System (Clontech) and α^{33}P-dATP (-92.5 TBq/mmol) (GE-Amersham, Saclay, France) were used for cDNA target synthesis of 25-40 μg of total RNA. Only targets with a total activity superior to 1 million cpm were used. The membranes (Atlas Human Cancer 1.2, Clontech) were hybridized overnight, washed according to the manufacturer's recommendations and exposed on phosphor storage screens for generally three days. The screens were then scanned in a phosphorimager. All cell lines were analyzed at least twice, i.e. independent RNA extraction, labeling and hybridization procedures.

Expression data analysis

The scanned images were analyzed with the ImaGene software (V.4.0) (Biodiscovery Inc. Los Angeles, CA). Spots having an intensity inferior to the negative spots (foreign DNA) on the membrane (mean + 2SD) in more than 50% of the experiments in each category were eliminated. By this procedure, 871 genes were retained and used for further analysis. The gene names used are respecting the nomenclature proposed by HUGO. Functions and tissue expression distribution came from the database SOURCE available at http://source.stanford.edu or from

Table 1 Sense (S) and antisense (AS) primers used in quantitative RT-PCR analyses

the relevant references as indicated. The Genesis software (V1.5.0)[11] was used for clustering analysis. For principal component analysis (PCA) with biplot representation [12] the R software (V.1.9) was used (http://www.r-project.org/). FDR analysis was performed with the Significance Analysis of Microarrays (SAM) software (V1.21): http://www-stat.stanford.edu/~tibs/SAM/.

Real-time RT-QPCR

For quantitative real-time RT-PCR (RT-QPCR) analysis, 3 μg (tumor samples, cell lines, and normal pancreas) or 5-10 ng (cell aspiration) of total RNA were reversely transcribed using Superscript II RNase H$^-$ reverse transcriptase (Invitrogen) and random hexamers using standard conditions. Generally, 5% of the RT reaction was used as template for the subsequent RT-QPCR reactions using the SYBR Green technology (Applied Biosystems Foster City, CA, USA) in a GeneAmp 5700 sequence detector system (Applied Biosystems). The expression levels were normalized to 18S ribosomal RNA levels. The sequence, orientation and corresponding exon localization of the primers used are shown in Table 1 as well as the length of the amplicon.

Immunohistochemical analysis

Paraffin-embedded tissue sections were dewaxed and permeabilized with citrate buffer, pH 6, for 3 min ×5 min in a microwave oven. The slides were rinsed 3 min× 5 min in PBS at room temperature and treated for 10 min with Dako protein block solution (Dako, Glostrup, Denmark). The sections were then incubated with a monoclonal mouse anti-human lipocalin 2 antibody (clone 211-01) (The Antibody Shop, Denmark), (1:100 in PBS, 10 g/L BSA) over night at 4℃. After rinsing (3 min × 5 min in PBS), the sections were treated with 30 mL/L H_2O_2, 100 mL/L methanol in PBS for 15 min followed by two rinses (2 min × 5 min) in PBS, 10 g/L BSA, and the incubation with an HRP-coupled rabbit anti-mouse IgG antibody (P0161; Dako) (1:50 in PBS, 10 g/L BSA) for 1 h at 20℃. The slides were then rinsed 3 min × 5 min in PBS + 10 g/L BSA and incubated 1 h (20℃) with an HRP-coupled goat anti-rabbit IgG antibody (P0448; Dako) (1:50 in PBS, 10 g/L BSA) and finally rinsed 2 min × 5 min in PBS + 1% BSA prior to development with one drop of AEC + substrate chromogen solution (Dako) for 15 min. The slides were washed in running cold water for 10 min and counterstained with Mayer's hemalun solution (Merck, Darmstadt, Germany) and mounted with Dako glycerol mounting medium. Pictures were taken with the Visiolab 2000 software using a Nikon eclipse E400 microscope.

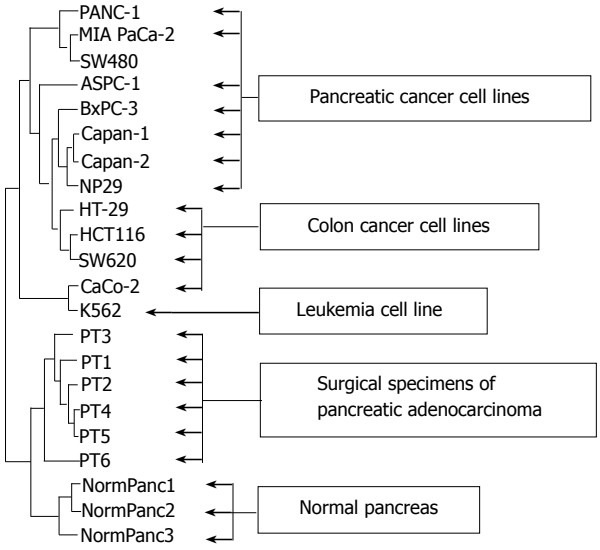

Figure 1 Hierarchical clustering analysis of sample expression profiles. Dendrogram of centered mean expression data using euclidian distance with average linkage clustering, showing relationships in gene expression profiles of samples. Closely related samples are found in the same branch of the tree and a reduced branch height represents a closer relationship between groups.

RESULTS

Expression profiling

Using Clontech's Human Cancer 1.2 macroarrays, the expression profile of 1176 genes associated with cancer was studied in 7 human pancreatic adenocarcinoma cell lines (PCL), PANC-1, MIA Paca-2, ASPC-1, BxPC-3, Capan-1, Capan-2, NP29, and 6 tumor samples, PT1-PT6, obtained through surgical resection of pancreatic adenocarcinomas. In order to assess the specificity of the expression of pancreatic tumor cells, 5 human colon cancer cell lines (CCL), SW480, HT-29, HCT116, SW620, Caco-2, 1 leukemia cell line (LCL), K562 and 3 normal human pancreatic tissue samples, NormPanc1-3, were included in the study. After screening of the expression data as described in the material and methods section, 871 genes were retained for further analysis. The expression data are available at the following URL: http://ifr31w3.toulouse.inserm.fr/microArrayPancreas/DataSummary.xls. In a hierarchical cluster analysis of samples based on centered mean expression data, two main clusters could be identified, corresponding to cell lines (up) and tissue samples (down), respectively (Figure 1). Among the clusters identified within the cell lines, one was purely pancreatic (BxPC-3, Capan-1, Capan-2 and NP29) and one comprised only colon cancer cell lines (HT-29, HCT116 and SW620). At the top of the dendrogram, a colon cancer cell line SW480 clustered with two pancreatic cancer cell lines, PANC-1 and MIA PaCa-2. In a hierarchical clustering analysis of the 871

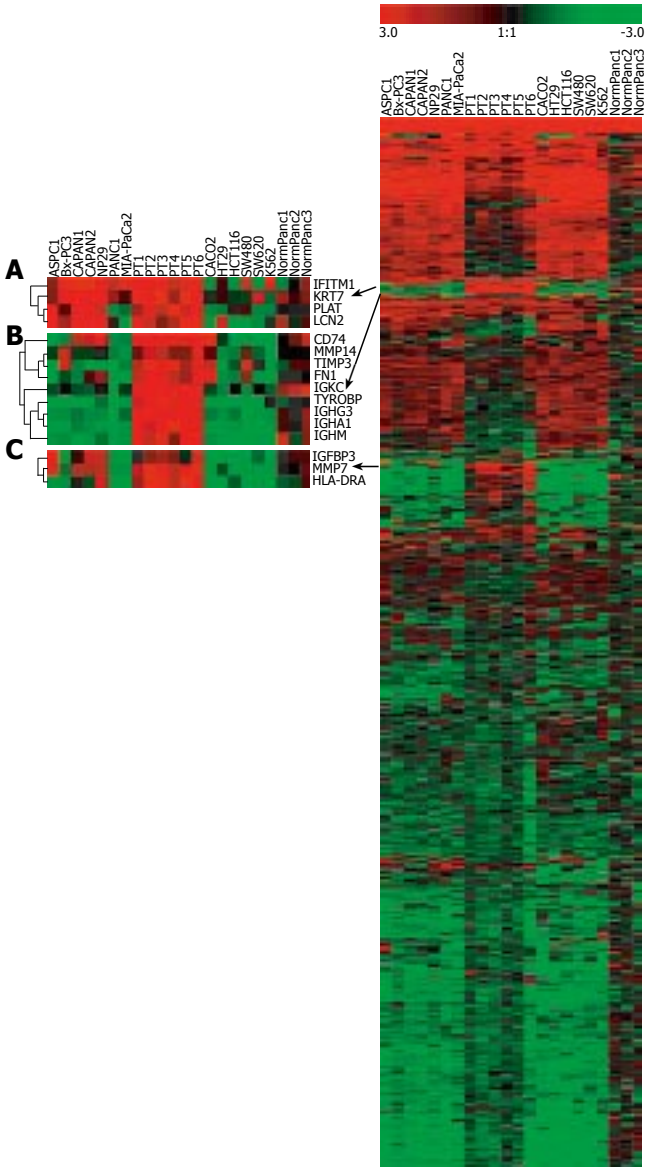

Figure 2 Hierarchical clustering analysis of gene expression profiles. Right: Expression profile of the 871 genes retained after data-filtering. Left: Three magnified subclusters (**A**-**C**) showing the genes overexpressed in most of pancreatic tumors. Red color indicates high expression levels; green color indicates low expression levels.

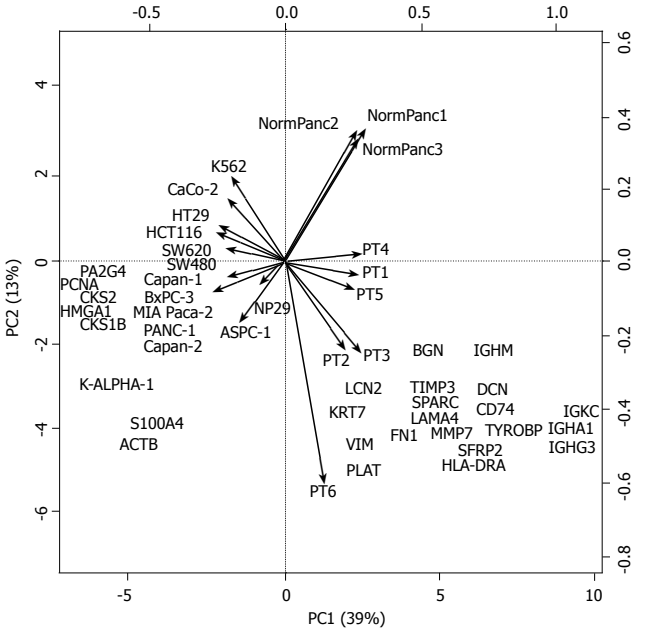

Figure 3 Principal component analysis (PCA) of gene expression data. Biplot resulting from a PCA of the line and column centered data containing 871 genes (individuals) in lines and 22 samples in columns (variables). The 28 genes contributing the most to the total variability are shown. The two principal components (PC1 and PC2) contribute to more than 50% (39% and 13%) of the total variability and resolve four biological sample categories: PC1 on the horizontal x-axis distinguish between cell lines (left) and tissue samples (right) whereas PC2 on the vertical y-axis distinguish between malignant pancreas samples (bottom) and other sample categories (top).

genes retained after filtering, three subclusters (A, B and C) contained genes with an elevated expression in pancreatic tumor samples (PT) and a lower expression in normal pancreas and non-pancreatic cancer cell lines (NormPanc, CCL and LCL) (Figure 2). Subcluster A containing four genes, *IFITM1*, *KRT7*, *PLAT* and *LCN2*, exhibited an expression profile particularly specific for neoplastic pancreas. These four genes were overexpressed in the majority of PCL and in PT1 to 6, but not in non-pancreatic cell lines and in normal pancreas. Subclusters B and C showed genes overexpressed in all PT, in some pancreatic cancer cell lines but not in normal pancreas.

In order to estimate the variability of the experimental procedures, several biological and technical replicates were performed. In a hierarchical clustering analysis, these replicates either clustered directly together or regrouped within clusters of the respective cell line validating our experimental protocols and data acquisition procedures (data not shown). We used the SAM software to detect the genes that were significantly over-expressed in malignant pancreas, referring to the mean expression in pancreatic tumors (PT) and pancreatic cancer cell lines (PCL) as compared with the other groups normal pancreas (NormPanc), colon cancer cell lines (CCL) and leukemia cell line (LCL). Among the genes selected by SAM (FDR < 2%), the ones with an at least 2-fold higher expression level in malignant pancreas are shown in Table 2. In the same table are also represented other expression fold ratios, i.e. the comparison between pancreatic and colon cancer cell lines (column PCL/CCL) as well as the fold ratio between pancreatic tumors and normal pancreas (column PT/NormPanc). The five genes with the highest expression ratios were *PLAT*, *KRT7*, *CD74*, *MMP7*, and *LCN2*. The ratio of mean expression level of these genes in PT as compared with that in NormPanc, was found to be equal to or above 3.36, indicating that they discriminate well between adenocarcinoma and normal tissues. The ratio of the gene mean expression level in PCL as compared with that in CCL discriminates between pancreatic and colon cancer cells, which is important to differential diagnosis.

Although clustering methods are the most widely used technique to group genes based on expression patterns, PCA is rapidly gaining acceptance in the field of transcriptome analysis. PCA permits data visualization of complex multidimensional datasets by projecting data into a sub-space with 2 or 3 dimensions. Moreover, a biplot representation of PCA results (Figure 3) provides

Table 2 Significantly overexpressed genes (over 2-fold) in malignant pancreas

Gene symbol	Gene description	Mean fold expression ratios		
		Malignant Panc/others	PCL/ CCL	PT/ NormPanc
PLAT	Plasminogen activator, tissue-type	6.22	4.36	6.74
KRT7	Keratin 7	5.72	4.92	3.97

CYR61	Cysteine-rich, angiogenic inducer, 61	2.03	2.41	1.22
PTGES	Prostaglandin E synthase	2.03	2.84	1.11
HIF1A	Hypoxia-inducible factor 1, alpha subunit (basic helix-loop-helix transcription factor)	2.01	1.24	2.87

a powerful visual overview of the relationships between genes and samples. The sub-space determined by PCA captures the highest amount of the total variability. In our line and column centered data matrix, the first (PC1) and second (PC2) principal components captured 39% and 13% of the total variability, respectively (Figure 3). In the biplot, samples are shown as arrows, and the genes are shown by their HUGO ID symbols. Arrows of similar length, pointing in the same direction display a higher degree of correlation. As observed in the hierarchical clustering analysis (Figure 1), SW480 was more associated to pancreatic cell lines than to other colon cell lines. Also in agreement with figure 1, the leukemia cell line K562 was correlated with the colon cell line Caco-2. An analysis of the PC1 (horizontal x-axis) revealed a clear distinction between tissue samples and cell lines, with a positive x-coordinate value for all tissue samples and negative for all cell lines. More interestingly, the same analysis of PC2 (vertical y-axis) discriminated malignant pancreas (pancreatic tumors and pancreatic cell lines) from the other samples categories studied, with the exception of SW480.

To improve the interpretation, only the 28 genes contributing most to the total variability of the data set are shown in the biplot. The co-localization between a gene and a sample type signifies an overexpression in the given sample type. Accordingly, genes such as *PCNA*, *HMGA1*, *PA2G4*, *CKS2* and *CKS1B* were specifically overexpressed in cell line samples, whereas *IGHM*, *IGKC*, *IGHA1* and *IGHG3*, all immunoglobulins, were highly associated with tumor samples. The extreme position of these genes on the horizontal axis in the biplot indicates they are involved in the distinction between cells and tissue samples. The overexpression of genes of the immune response is a characteristic of cancer tissue samples versus cell lines. Furthermore, a set of genes, including *PLAT*, *VIM*, *HLA-DRA*, *IGHG3*, *ACTB*, *S100A4*, and others located in the lower half of the biplot, was involved in the discrimination between malignant pancreas and all other samples. Among them, *LCN2*, *KRT7*, *VIM* and *PLAT*, appeared to be highly correlated with both pancreatic tumors and pancreatic cell lines. However, in the third principal component (PC3), *VIM* was positioned far from the three other genes (data not shown). Interestingly, *CTRL* (chymotrypsin-like), was found to be specifically expressed in normal pancreas and absent in PT or PCL. CTRL is a poorly characterized serine protease with chymotrypsin- and elastase-2-like activities, which is expressed as a pro-protease in normal pancreatic tissue[13]. The absence of *CTRL* expression in adenocarcinoma samples is in agreement with the absence of other serine

Table 3 Relative mRNA levels presented as $2^{[Ct(18S)-Ct(gene\ of\ interest)]}$ (mean x 10^{-2} ± SEM)

protease digestive enzyme, such as chymotrypsin and trypsin, present in normal pancreatic tissue and known to be down-regulated in pancreatic cancer.

Differentially expressed genes in neoplastic pancreas

Taken together, the three statistical methods used in our study (hierarchical clustering, Figure 2, the SAM method, Table 2, and PCA, Figure 3) retained seven genes as differentially overexpressed in malignant pancreas. Among these genes, 3 are involved in the immune response: *CD74*, *HLADRA*, and *IGHG3*, and 4 genes previously suggested as key proteins in pancreatic cell biology or oncogenesis**:** *KRT7*, *MMP7*, and *PLAT* and *LCN2*. Among them, three genes *LCN2*, *KRT7* and *PLAT* were selected for further validation by real-time RT-QPCR. This choice was based on the highly specific expression profile in malignant pancreas (Figure 2; subcluster A) and elevated mRNA levels in the corresponding samples (Table 2) as well as on their specific positioning in the PCA analysis, that is in the interface between the pancreatic tumors and pancreatic cancer cell lines. These studies confirmed significantly elevated levels of *LCN2* and *PLAT* mRNA in malignant pancreas samples, tumors and cancer cell lines (Mann-Whitney test: $^{a}P < 0.05$) (Table 3). However, they were unable to confirm the macroarray results concerning *KRT7* expression levels.

The PLAT protein is known to be overexpressed in pancreatic cancer tissues[14]. However, even though several studies have reported elevated *LCN2* mRNA levels in pancreatic cancer[15], and LCN2 protein in human pancreatic juice in patients with pancreatic cancer[16], the presence of the LCN2 protein in pancreatic adenocarcinoma is less well characterized. Therefore, in order to evaluate the expression of the lipocalin 2 protein in pancreatic tumors, we performed immunohistochemical analysis using a monoclonal anti-lipocalin 2 antibody. As shown in Figure 4A, little or no labeling was observed in normal pancreas ($n = 3$). However, in sections of pancreatic adenocarcinomas ($n = 5$), a strong apical labeling was detected in ducts invaded by carcinoma (Figure 4B and C).

LCN2, KRT7 and PLAT transcripts in EUS-guided FNA samples

We investigated the possibility to use EUS-guided FNA as a source of pancreatic sample to study the expression of *KRT7*, *LCN2* and *PLAT* genes as diagnostic biomarkers. The presence of these mRNAs was therefore examined by RT-QPCR analysis in 12 samples, originating from different individuals, obtained through EUS-guided FNA from patients with pancreatic adenocarcinoma. Compared with normal pancreas, the expression level of the *KRT7*, *LCN2* and *PLAT* transcripts were 26.7 ± 18.16, 20.6 ± 7.6 and 70.8 ± 35.4 (mean ± SE), respectively. In each case, 18S ribosomal RNA was used for normalization. Even though 10 out of 12 patients presented elevated levels of expression for *KRT7* and *LCN2* and 11 for *PLAT,* only the levels of *PLAT* and *LCN2* expression were significantly different from normal pancreas (unilateral Student *t* test: $P < 0.05$). These results were thus perfectly concordant with those obtained from pancreatic cancer cell lines and tumors.

DISCUSSION

Large scale analysis of gene expression has been widely proposed as a powerful method for identification of molecular markers of neoplasia and for the generation of novel taxonomies for cancer. Accordingly, several studies, have been conducted to characterize the expression profiles in human pancreatic adenocarcinomas[15, 17]. However, to the best of our knowledge, none of these studies report the comparison between pancreatic and colon cancer cell lines. Moreover, this study reports, for the first time, about the use of the dedicated Atlas Human Cancer 1.2 cDNA macroarray containing 1176 cancer-associated genes to study expression profile in pancreatic carcinoma. We report the expression profiles of pancreatic adenocarcinoma cell lines and tumors and compared with that of normal pancreas specimens, colon cancer cell lines and one hematopoietic cell line K562. This was done to differentiate pancreatic and non-pancreatic cancer gene profile in view of differential diagnosis. The fact that several groups have previously reported elevated expression levels of *LCN2* mRNA in pancreatic cancer[18-21], was reassuring for the validation of our study design. However, reports validating this overexpression at the protein level are very scarce[22]. Lipocalins are small extracellular proteins with important role in cell proliferation and differentiation, possessing protease inhibitory properties and/or carrying lipophilic ligands such as retinoids and fatty acids into the cells[23]. The localization of LCN2 protein at the apical side of cells from ducts invaded by the tumoral process might be of pathophysiological importance and supports further analysis for a better understanding of the role of this protein in cancer.

Interestingly, the overexpression of *PLAT* in pancreatic adenocarcinoma has not been reported in previous expression profiling studies. PLAT was recently shown to play a critical role in tumor angiogenesis and in the devel-

opment of exocrine pancreatic cancer[24], contributing to an invasive phenotype[14,25]. The vast majority of pancreatic adenocarcinomas express KRT7[26,27] and it has previously been indicated as overexpressed in pancreatic cancer by gene expression profiling studies[28]. However, the KRT7 protein is suggested as a marker of normal pancreatic duct epithelial cells playing a role in cell differentiation[29]. The reported expression of KRT7 in both normal and malignant pancreas could, at least in part, explain why we were unable to observe a significant difference in expression levels between both sample types. Among the seven genes retained on our study, three are highly implicated in the immune response: *CD74*, *HLADRA, IGHG3*. *IGHG3* was only overexpressed in tumor samples suggesting an immune cell origin. In contrast, elevated levels of *CD74* and *HLADRA* were found in tumor samples and also in some pancreatic cancer cell lines. Elevated levels of *CD74*, and *HLADRA* were observed in several types of cancers, including gastric cancer and renal epithelial neoplasms[30,31].

The quantitative RT-PCR on EUS-guided FNA samples of *PLAT* and *LCN2*, validated the overexpression found by the macroarray analysis. Thus, the quality and the amount of cellular sampling using pancreatic EUS-guided FNA allow the extraction of sufficient quantities of RNA to perform RT-QPCR analysis as a new tool for early diagnosis, as described recently for lymph node metastasis[32]. Furthermore, when performed directly on resected tumor pieces, fine needle aspiration has been shown to produce a relative enrichment of cancer cells, in comparison to tumor samples. This enrichment has been attributed to the capability of epithelial cancer cells to be aspirated more easily than stromal cells[33]. To the best of our knowledge, no gene expression had been evaluated with EUS-guided FNA biopsies from patients with pancreatic adenocarcinoma. EUS-guided FNA is a safe method for patient exploration. Morbidity rate ranges from 1% to 3% when performed by experienced endosonographers[34]. Therefore, identification and quantification of potential molecular markers for pancreatic cancer on cellular samples obtained by EUS-guided FNA could be a promising approach for the diagnosis of solid pancreatic masses. Future studies are needed to prospectively evaluate new molecular biomarkers using this procedure, in order to increase the accuracy of current standard histological and cytological analyses, that was only 80 to 85% in pilot studies[35,36].

Abstract

AIM: To examine the effects of adiponectin on the functions of Kupffer cells, key modulators of lipopolysaccharide (LPS) -induced liver injury.

METHODS: D-galactosamine (GalN) and LPS were injected intraperitoneally into adiponectin-/- mice and wild type mice. Kupffer cells, isolated from Sprague-Dawley rats, were preincubated with or without adiponectin, and then treated with LPS.

RESULTS: In knockout mice, GalN/LPS injection significantly lowered the survival rate, significantly raised the plasma levels of alanine transaminase and tumor necrosis factor-α (TNF-α) and significantly reduced IL-10 levels compared with wild type mice. TNF-α gene expression in the liver was which higher and those of IL-10 were lower in knockout mice than in wild type mice. In cultured adiponectin-pre-treated Kupffer cells, LPS significantly lowered TNF-α levels and raised IL-10 levels in the culture media and their respective gene expression levels, compared with Kupffer cells without adiponectin-pre-treatment.

CONCLUSION: Adiponectin supresses TNF-α production and induces IL-10 production by Kupffer cells in response to LPS stimulation, and a lack of adiponectin enhances LPS-induced liver injury.

INTRODUCTION

Obesity is currently a serious medical problem world wide. It is an independent risk factor of non-alcoholic steatohepatitis (NASH) and alcoholic liver injury[1,2]. The pathogenesis of these diseases involves lipopolysaccharide (LPS)[3-5]. The complex of LPS and LPS-binding protein (LBP) activates Kupffer cells to secrete tumor necrosis factor (TNF)-α, which plays an important role in liver injury[6,7]. The control of the response of Kupffer cells to LPS is thought to be critical in the prevention of LPS-induced liver injury. Indeed, the selective inhibition of Kupffer cells by the administration of either gadolinium chloride or methyl palminate results in the abrogation of liver injury with an inhibition in TNF-α secretion[8]. Interleukin (IL)-10, which is secreted by Kupffer cells in the liver after LPS stimulation[9], has strong anti-inflammatory effects in the liver, and prevents liver fibrosis[10,11]. Interferon (IFN)-γ activates the signal transducer and activator of transcription (STAT-1) in hepatocytes and promotes apoptosis in hepatocytes after administration of D-Galactosamine (GalN)/LPS[12]. In GalN/LPS induced liver injury, the modulation of the production of these cytokines from Kupffer cells is important.

Adiponectin, a 30 ku adipocyte complement-related protein (Acrp30), is an adipocyte-specific plasma protein (normal level, 5-30 mg/L), and is paradoxically decreased in obesity and in cases of alcoholic fatty liver[13,14]. Adiponectin contains two types of receptors, AdipoR1 and AdipoR2. Whereas AdipoR1 is expressed ubiquitously and abundantly in skeletal muscle, AdipoR2 is most abundantly expressed in the liver and is an intermediate-affinity receptor for full-length and globular adiponectin[15]. Adiponectin improves the insulin sensitivity, and has anti-

atherogenic and anti-inflammatory effects. In the liver, it has anti-fibrogenic effects and regulates hepatic stellate cells[16].

We recently reported that adiponectin inhibits the phagocytosis of human macrophages and LPS-induced TNF-α release[17], and induces IL-10 gene expression in human macrophages[18]. We hypothesized that adiponectin has anti-inflammatory effects on Kupffer cells, key modulators of LPS induced liver injury, by regulating the release of cytokines. However, the effects of adiponectin on LPS-induced liver injury and Kupffer cells remained poorly understood. In the present study, to clarify the effects of adiponectin on LPS-induced liver injury, we investigated the effects of adiponectin on GalN/LPS-induced liver injury using adiponectin knockout mice. We also examined the effects of adiponectin on cytokine production from Kupffer cells in primary cultures.

MATERIALS AND METHODS

All experimental protocols described in this study were approved by the Ethics Review Committee for Animal Experimentation of Osaka University School of Medicine. Recombinant mouse full-length adiponectin was prepared as described previously[16]. The method of disruption of the mouse adiponectin gene was described previously[19].

Murine model of acute hepatitis

To clarify the role of adiponectin in LPS-induced liver injury, experiments were conducted using adiponectin-/- mice and wild-type (WT) control C57B6 mice (28-32 g body mass; 10-12 wk old)[19]. Each mouse was simultaneously injected intraperitoneally with 700 mg/kg of GalN and 10 μg/kg of LPS. The doses of GalN and LPS were determined in previous studies and our preliminary study[12]. LPS from *E. coli* O55:B5 and D-galactosamine (GalN) were purchased from Sigma (St. Louis, MO). Groups of 10 mice were treated to determine the survival curve. Groups of 6 mice were treated to measure the plasma levels of alanine aminotransferase (ALT), TNF-α, IL-10, and IFN-γ. Groups of 6 mice were sacrificed as follows: before, 0.5, 1, and 4 h after the administration to measure the gene expressions of TNF-α IL-10, IFN-γ in the whole liver and IFN-γ in the spleen, assessed by means of real-time polymerase chain reaction (PCR).

LPS stimulation on Kupffer cells

Male Sprague-Dawley (SD) rats (10 wk old, $n = 6$) were anesthetized with pentobarbital sodium, and the portal vein was cannulated. The liver was perfused with a ethylene glycol bis (beta-aminoethyl ether)-N, N, N', N' -tetraacetic acid (EGTA) solution, and digested with a 0.5 g/L collagenase solution. Differential centrifugation on Nycodenz (Pharma, Oslo, Norway) density gradients was performed as described before[20]. We evaluated the purity of the isolated Kupffer cell population by counting CD68 positive cells, ranging from 88.5% to 93.0%. Kupffer cells from each rat were maintained and treated separately. The Kupffer cells were maintained at 37°C under 50 mL/L CO_2 in Dulbecco's modified Eagle medium containing 100 mL/L fetal calf serum with or without adiponectin (10 mg/L) for 24 h. After a 24 h pretreatment with and without adiponectin, LPS was added to the culture medium at a concentration of 10 mg/L. The doses of adiponectin and LPS were determined in previous studies and our preliminary study[6,17]. TNF-α, IL-10, IFN-γ concentrations in the culture medium were measured 0 and 4 h after the commencement of LPS stimulation. Total RNA of Kupffer cells was isolated at 0, 0.5, 1, and 4 h after the commencement of LPS stimulation.

Measurement of plasma concentrations of ALT and cytokines

Plasma ALT concentrations were measured by using a transaminase CII-test kit according to the protocol provided by the manufacturer (Wako Pure Medical, Osaka, Japan). Circulating levels of TNF-α, IL-10, and IFN-γ were assessed using commercial enzyme-linked immunosorbent assay (ELISA) kits for mice (Biosource Int., Camarillo, CA). Their concentrations in the culture media of Kupffer cells were quantified using ELISA kits for the rat (Biosource Int.).

Quantification of gene expression levels

Total RNA from whole liver, spleen and Kupffer cells were extracted using a Qiagen (Hilden, Germany) QIAshredder and an RNA-easy Mini kit according to the instructions provided by the manufacturer. The reverse-transcription polymerase chain reaction (RT-PCR) was performed as described previously[21]. The Quantitect PCR probe kit and Quantitect gene assay kit for mice TNF-α, IL-10, and IFN-γ were purchased from Qiagen and used in a real-time PCR analysis of the mouse samples. Primers for rat glyceraldehydes-3-phosphate dehydrogenase (GAPDH), TNF-α, IL-10, IFN-γ, and mice GAPDH were designed using the computer program Primer Express (Applied Biosystems, Foster city, CA). Dynamo SYBR Green qPCR kit (Finzymes, Espoo, Finland) was used for the real-time PCR analysis of rat TNF-α, IL-10, IFN-γ, GAPDH and mice GAPDH. Real-time PCR was performed using a DNA Engine Opticon 2 real-time PCR Detection System (MJ Research, Waltham, MA). Relative gene expression was quantified using GAPDH as an internal control. The expressions of adiponectin receptors, AdipoR1 and AdipoR2 were assessed with RT-PCR as previously published[22].

TUNEL assay

Quantification of apoptotic hepatocytes in liver sections was performed by counting the number of TUNEL-positive cells. The data were expressed as the average number of TUNEL-positive cells per five high power fields (HPF) (×100). The TUNEL assay was performed based on the instructions provided by the manufacturer (In Situ Apoptosis Detection Kit; TaKaRa, Shiga, Japan, and Liquid DAB Substrate kit; Zymed Lab. Inc., South San Francisco, CA).

Statistical analysis

The results are presented as the mean ± SE. Analysis of variance (ANOVA) for the groups was performed by the

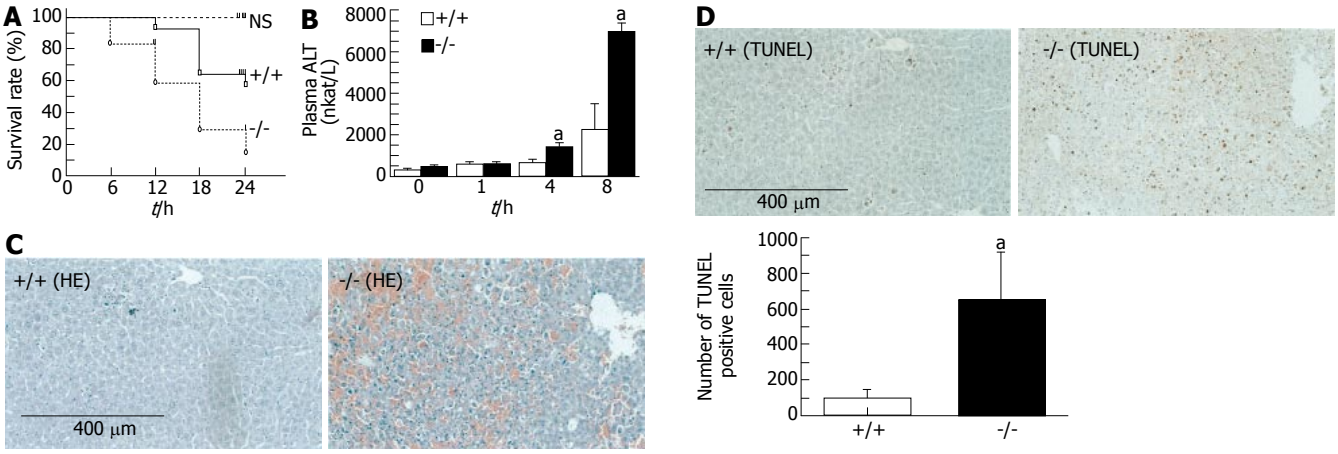

Figure 1 GalN/LPS induced changes in mice. **A:** Survival rate (n = 10); **B:** Plasma ALT (mean ± SE, n = 6). $^aP < 0.05$, $^bP < 0.01$, *vs* WT; **C:** Histology of the liver. Massive liver injury in adiponectin-/- mice. (Hematoxylin-eosin × 100); **D:** Large numbers of apoptotic hepatocytes in adiponectin-/- mice (TUNEL × 100). Scale bar = 400 μm. $^aP < 0.05$, *vs* WT mice.

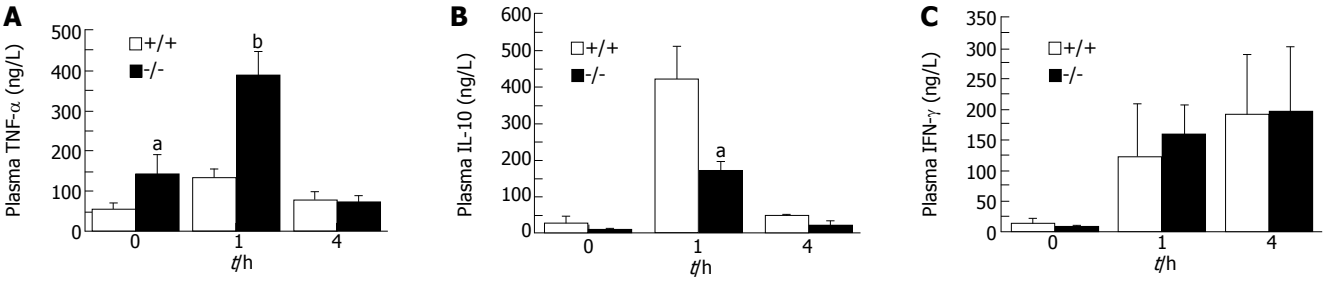

Figure 2 Plasma concentrations of TNF-α, IL-10 and IFN-γ in mice after GalN/LPS administration. (mean ± SE, n = 6). $^aP < 0.05$, $^bP < 0.01$, *vs* WT.

Mann Whitney test, followed by Scheffé's test for multiple comparisons to allow pairwise test for significant differences between groups. The statistical significance of the lethality rates was determined by a Log-rank test. Statistical significance was defined as $P < 0.05$.

RESULTS

GalN/LPS induces severe liver injury in KO mice

The survival rate of adiponectin-/- mice after GalN/LPS administration was significantly lower than that of WT mice 24 h after the administration ($P = 0.041$; log-lank test; Figure 1A). GalN/LPS administration resulted in an elevation of plasma ALT concentrations in both WT and adiponectin-/- mice, although increases at 4 and 8 h after administration were significantly higher in adiponectin-/- mice than in WT mouse (at 4 h; WT, 693.5 ± 472.8 *vs* adiponectin-/-, 1458.6 ± 541.8 nkat/L; $P < 0.01$, at 8 h; WT, 2255.5±3242.3 *vs* adiponectin-/-, 6988.1 ± 978.5; $P < 0.05$; Figure 1B). A histological examination revealed that GalN/LPS administration induced massive liver injury in adiponectin-/- mice mice (Figure 1C). The number of TUNEL-positive hepatocytes in adiponectin-/- mice livers was significantly higher than that in WT mouse livers 8 h after GalN/LPS administration (WT, 95 ± 118 *vs* adiponectin-/- mice, 683 ± 729 apoptotic cells/HPF; $P < 0.05$; Figure 1D).

Effects of GalN/LPS on plasma TNF-α, IL-10 and IFN-γ

Prior to GalN/LPS administration, plasma TNF-α concentrations were significantly higher in adiponectin-/- mice than in WT mice ($P < 0.05$; Figure 2A). Plasma TNF-α concentrations increased reaching peak levels 1 h after the administration, and were significantly higher in adiponectin-/- mice mice than in WT mice at their peak ($P < 0.01$; Figure 2A). Plasma IL-10 concentrations also increased, reaching peak levels 1 h after the administration of GalN/LPS. In adiponectin-/- mice, IL-10 plasma concentrations were significantly lower than those of WT mice at their peak ($P < 0.05$; Figure 2B). Plasma IFN-γ concentrations increased continuously up to 4 h after GalN/LPS administration, and no significant difference between adiponectin-/- mice and WT mice was found (Figure 2C).

Effects of GalN/LPS on liver TNF-α, IL-10, IFN-γ and splenic IFN-γ mRNA expression

The TNF-α mRNA expression level in the liver increased, reaching a peak level 1 h after GalN/LPS administration, and this level was significantly higher in adiponectin-/- mice than in WT mice 1 h after the administration ($P < 0.01$; Figure 3A). The IL-10 mRNA expression level in the liver also increased, reaching a peak level 4 h after GalN/LPS administration, and the levels at 1 and 4 h were significantly higher in WT mice than in adiponectin-/- mice (at 1 h;

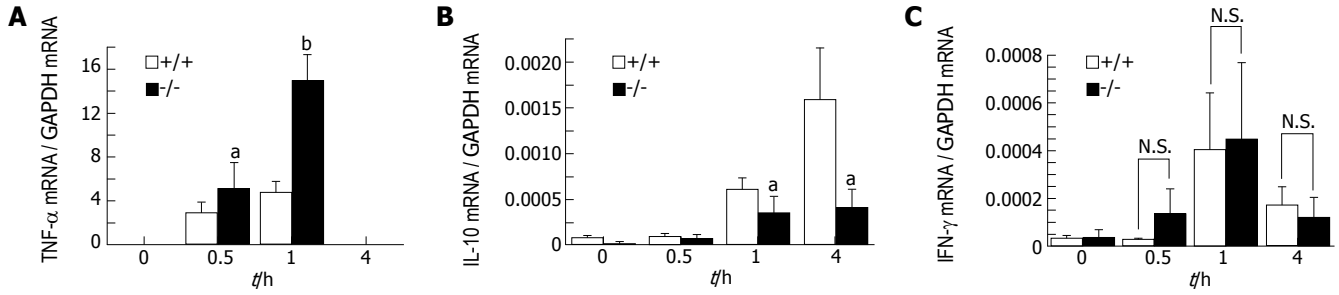

Figure 3 TNF-α, IL-10 and IFN-γ in the liver (**A-C**) of mice following GalN/LPS administration. (mean ± SE, $n = 6$). [a]$P < 0.05$, [b]$P < 0.01$, *vs* WT (Scheffé's test).

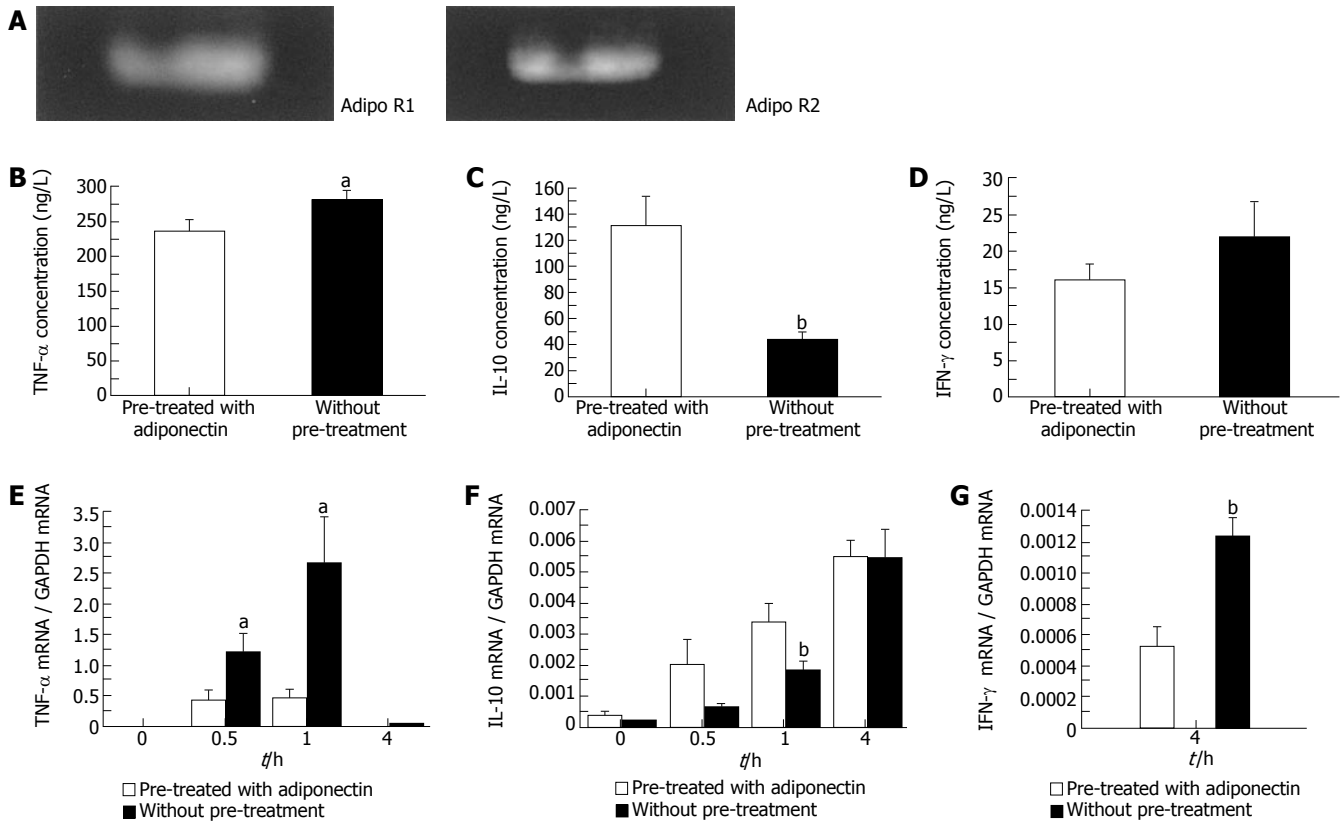

Figure 4 The expressions of adipoR1 and AdipoR2 in Kupffer cells (**A**). Effect of adiponectin on TNF-α, IL-10 and IFN-γ production by LPS-stimulated Kupffer cells *in vitro* (**B-D**). Pre-treated with or without adiponectin (10 mg/L) for 24 h followed by the stimulation with LPS (10 mg/L). TNF-α, IL-10 and IFN-γ mRNA expression in Kupffer cells after LPS stimulation (**E-G**). (mean ± SE, $n = 6$). [a]$P < 0.05$, [b]$P < 0.01$ (Scheffé's test).

$P < 0.05$; Figure 3B). The IFN-γ mRNA expression level in the liver increased, reaching peak levels 1 h after GalN/LPS administration, but no significant difference between adiponectin-/- mice and WT mice was found (Figure 3C). In the spleen, the IFN-γ mRNA expression levels also reached peak levels at 1 h after the administration, but there was no significant difference between adiponectin-/- mice and WT mice (data not shown).

Adiponectin receptors expression in Kupffer cell

We comfirmed the expressions of AdipoR1 and AdipoR2 in rat Kupffer cells using RT-PCR (Figure 4A).

Adiponectin inhibits LPS-induced TNF-α production in Kupffer cells

Pretreatment of Kupffer cells with adiponectin led to a reduction in the levels of TNF-α released in response to LPS stimulation. TNF-α levels in the culture media of adiponectin-pretreated Kupffer cells were significantly lower than those for untreated cells 4 h after LPS stimulation ($P < 0.05$; Figure 4B). The LPS-induced TNF-α mRNA expression level in Kupffer cells was markedly suppressed by adiponectin pre-treatment. The expression level of TNF-α mRNA in Kupffer cells increased, reaching peak levels 1 h after LPS stimulation, but the levels at 0.5 and 1 h after the commencement of LPS stimulation in culture media of adiponectin-pretreated Kupffer cells was significantly lower than in those of untreated cells (at 0.5 h; $P < 0.05$, at 1 h; $P < 0.05$; Figure 4E).

Adiponectin increases LPS-induced IL-10 production in Kupffer cells

Pretreatment of Kupffer cells with adiponectin increased the release of IL-10 in response to LPS stimulation.

IL-10 concentrations in the culture media of adiponectin-pretreated Kupffer cells were significantly higher at 4 h after LPS stimulation than those without adiponectin pre-treatment ($P < 0.01$; Figure 4C). The expression level of LPS-induced IL-10 mRNA in Kupffer cells was markedly increased as a result of adiponectin pre-treatment. The expression level of IL-10 mRNA in Kupffer cells was significantly higher in adiponectin-pretreated Kupffer cells 1 h after LPS stimulation than in untreated cells ($P < 0.05$; Figure 4F).

Lack of effect of adiponectin on LPS-induced IFN-γ production in Kupffer cells

Pretreatment of Kupffer cells with adiponectin had no significant effect on IFN-γ concentrations in the culture media (Figure 4D). But the expression level of LPS-induced IFN-γ mRNA in Kupffer cells was significantly higher in adiponectin-pretreated Kupffer cells 4 h after LPS stimulation than in untreated cells. IFN-γ gene expression in Kupffer cells at 0 and 1h after LPS stimulation could not be determined quantitatively by RT-PCR ($P < 0.01$; Figure 4G).

DISCUSSION

The major findings of the present study were that a lack of adiponectin accelerates LPS-induced liver injury, and that adiponectin has an anti-inflammatory effect on Kupffer cells. Our results demonstrate that adiponectin-pretreated Kupffer cells produced less TNF-α and more IL-10 as a result of LPS treatment. These results suggest that adiponectin has an anti-inflammatory effect on LPS-treated Kupffer cells. An intraperitoneal injection of GalN/LPS in mice resulted in a more serious liver injury that was associated with a significantly higher mortality in adiponectin-/- mice than in WT mice. The plasma levels of TNF-α were significantly increased and those of IL-10 were significantly decreased in adiponectin-/- mice compared to WT mice, and TNF-α gene expression in the liver was significantly higher and those for IL-10 were lower in adiponectin-/- mice than in WT mice. These results indicate that a lack of adiponectin enhances LPS-induced liver injury and that the altered production of cytokines in Kupffer cells caused by a lack of adiponectin affect the severity of LPS-induced liver injury.

TNF-α causes liver cell apoptosis in GalN-sensitized mice[7,23]. Mice that are deficient in TNF-α receptors are protected against GalN/LPS-induced liver damage[24]. In our study, plasma TNF-α levels increased significantly in adiponectin-/- mice after GalN/LPS administration compared with WT mice, suggesting that a lack of adiponectin causes an over response of TNF-α production. Indeed, TNF-α gene expression in the liver increased significantly in adiponectin-/- mice after GalN/LPS administration compared with WT mice. Sennello *et al.* recently reported that adiponectin protects hepatocytes from TNF-α induced cell death[25]. Our results are in agreement with this conclusion. We previously reported that, in peripheral macrophages, adiponectin inhibits LPS-induced TNF-α production possibly through the suppression of TNF-α-induced IκB-α-NF-κB activation via the cAMP-dependent pathway[17,26]. In the present study, adiponectin pre-treated Kupffer cells showed a lower response to LPS than the controls. The TNF-α concentration in the culture media of adiponectin pre-treated Kupffer cells showed a significantly lower elevation than those of untreated cells, and TNF-α gene expression levels after the LPS stimulation of adiponectin pre-treated Kupffer cells were significantly lower than those of untreated cells. The TLR4 receptor system plays an important role in innate immunity[27]. Kupffer cells of mice express TLR4 mRNA and respond to LPS. The LPS-binding protein (LBP) complex associates with the CD14, and via TLR4, activates Kupffer cells to secrete TNF-α[7]. Adiponectin may inhibit this receptor system directly by suppressing IκB-α-NF-κB activation, although further studies will be needed to confirm this conclusion.

IL-10 exhibits a hepatoprotective role in GalN/LPS-induced liver injury by inhibiting the release of TNF-α[10,11,28]. In our study, plasma IL-10 levels were significantly diminished in adiponectin-/- mice after the administration of GalN/LPS compared with WT mice. GalN/LPS treatment of adiponectin-/- mice significantly reduced IL-10 gene expression in the liver compared with WT mice. Kupffer cells are known to release substantial amounts of IL-10 following LPS stimulation[9]. In our study, IL-10 concentrations in the culture medium of adiponectin pre-treated Kupffer cells showed a significantly higher response to LPS stimulation than the control cells. We recently reported that adiponectin increases IL-10 gene expression in human macrophages[18]. IL-10 gene expression in adiponectin pre-treated Kupffer cells was also significantly higher than in untreated cells. These data show that physiological concentrations of adiponectin are sufficient to induce IL-10 production in Kupffer cells in response to LPS stimulation, and that a lack of adiponectin resulted in a lower IL-10 response to LPS stimulation in Kupffer cells. These results suggest that adiponectin inhibits TNF-α production directly as well as indirectly through the induction of IL-10. Further studies will be required to elucidate the precise mechanism of this cross-talk.

IFN-γ is also involved in the toxic effects of LPS on the liver[29], and IFN-γ monoclonal antibodies reduce LPS-induced mortality in mice[30]. The overexpression of IFN-γ activates STAT-1 in the liver and promotes hepatocyte apoptosis following GalN/LPS administration[12]. IL-10 is reported to inhibit IFN-γ[31]. However, Sennelo *et al.* recently reported that, in a model of Concavaline A induced hepatitis, there was no significant difference in serum IFN-γ levels between lipodystrophic aP2-nSREBP-1c transgenic mice, with higher serum adiponectin, and *ob/ob* mice, with lower serum adiponectin levels[25]. Our study found no significant differences in plasma levels of IFN-γ between adiponectin-/- mice and WT mice, or IFN-γ gene expression levels in the liver and splenic lymphocytes between adiponectin-/- mice and WT mice. We found no significant difference in IFN-γ concentration in the culture media of adiponectin pre-treated Kupffer cells and untreated Kupffer cells. However, 4 h after the LPS stimulation, IFN-γ gene expression levels of adiponectin pre-treated Kupffer cells were significantly lower than

those of untreated cells. Further studies will be required to elucidate the effect of adiponectin on IFN-γ production in Kupffer cells.

Obesity is an independent risk factor for the development of chronic liver diseases such as NASH and alcoholic liver disease[1,2]. Serum adiponectin levels are decreased in obesity, and alcohol decreases the expression of adiponectin[13,14]. Adiponectin has been reported to confer protective effects against alcoholic liver injury, and hypoadiponectinemia is involved in the progression of non-alcoholic fatty liver disease (NAFLD) to steatohepatitis[32,33]. Our results suggest that the hypoadiponectinemia in obesity induces an altered response of Kupffer cells to LPS, and is possibly involved in the development of alcoholic liver disease and NASH. Adiponectin receptors 1 and 2 (AdipoR1 and AdipoR2) have been cloned by expression cloning[15]. AdipoR1 is expressed abundantly in skeletal muscle, and is also expressed in the liver. AdipoR2 is predominantly expressed in the liver. Thakur V *et al* showed the expressions of adipoR1 and R2 in Kupffer cells and we also found these expressions in Kupffer cells[34]. Recently Wolf AM *et al* reported the up-regulation of adiponectin in liver in ConA mediated acute liver failure[35]. In GalN/LPS induced acute liver injury, the expressions of adiponectin in the liver could not be determined quantitatively by RT-PCR (data not shown). To elucidate the effect of adiponectin produced in the liver in this model, further studies will be needed. Masaki *et al* reported that adiponectin prevents LPS-induced hepatic injury in a KK-Ay obese mice model[36]. KK-Ay obese mice show not only hypoadiponectinemia but also hyperglycemia and insulin resistance. Hyperglycemia and hyperinsulinemia should have an effect on the response of inflammatory cytokines to endotoxemia[37]. We used adiponectin-/- mice to rule out the effects of such other factors. In this model, we were able to clarify the direct effect of adiponectin deficiency on LPS-induced liver injury *in vivo*.

In conclusion, a deficiency of adiponectin could enhance LPS-induced liver injury possibly through modulation of cytokine production by Kupffer cells. The development of adiponectin receptor agonists or molecules that can induce adiponectin secretion might be helpful in controlling LPS-related liver diseases such as NASH and alcoholic liver injury.
